To accomplish the various objectives of this chapter, it is organized as follows. First, the basic concepts involved in transport phenomena such as the integral and differential forms of species conservation equations are explained. This is followed by detailed models of flow and species transport in porous media. Both direct simulation models that contain no approximation to the governing equations and averaged equations based on various upscaling theorems are included. For the latter, although the averaging procedure is presented here in a succinct manner, the reader is referred to Whitaker,[27] Wood *et al.*,[28] and Lasseux *et al.*[29] for details. This is followed by a discussion on mass transfer models in the context of direct numerical simulations. Finally, detailed mass transfer equations for important species such as oxygen, glucose, and lactate coupled with models for cell growth kinetics are presented.

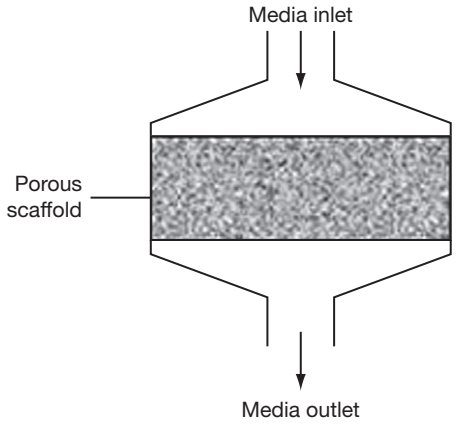

Figure 1 Schematic of a perfusion culture system.

3.309.2. Transport Phenomena: Diffusive, Convective, and Reactive Transport Mechanisms

Some of the important concepts of transport phenomena are first reviewed. In this section, for brevity purposes, we consider only the mass transport mechanisms of a representative species such as oxygen, glucose, or lactate. For full details on the derivation of fluid mass and momentum conservation equations (also referred to as the Navier–Stokes equations), readers are referred to Deen[30] and Batchelor.[31] The discussions that follow in this paper assume that the fluid is of constant density which is generally valid for cell culture media.

The fundamental transport mechanisms governing the mass transport of a representative species both in the bulk medium and within the scaffolds are convection, diffusion, and reaction. In general, the pore-scale fluid flow within the 3D scaffolds may be assumed to be laminar. Assuming an idealized cylindrical pore structure, the laminar flow is characterized by a low to moderate Reynolds number (typically less than 2300), where the Reynolds number Re is defined as

$$Re = \frac{\rho |\mathbf{u}| d_{\text{pore}}}{\mu} \qquad [1]$$

Here, ρ is the density of the fluid (culture medium) permeating the pores in the scaffold, $|\mathbf{u}|$ is a characteristic speed of the fluid inside the scaffold which is usually obtained from the macroscopic bulk motion prevailing outside the scaffold or the specified boundary condition, and d_{pore} is a characteristic pore diameter.

Diffusion of species occurs due to the migration of molecules from regions of higher concentration to regions of lower concentration resulting in a nonzero flux. The diffusive flux, $\mathbf{J}_{\text{diff}}$, depends on the local gradient of the concentration of a given species (e.g., oxygen or nutrients) and is mathematically represented by Fick's law of diffusion.

$$\mathbf{J}_{\text{diff}} = -\mathbf{D}_i \cdot \nabla C_i \qquad [2]$$

where C_i refers to the local concentration of the species, and $\mathbf{D}_i$ is the diffusivity tensor. A negative sign indicates that the flux is positive when there is movement of molecules down the gradient (negative sign cancels the negative gradient along the direction of positive flux). For isotropic scaffolds (i.e., the arrangement of pores are statistically the same across all directions), the diffusivity tensor can be replaced by a single scalar, namely, the diffusion coefficient D_i.

Convection occurs due to bulk motion of the fluid within the porous channels of a scaffold. The convective or advective flux, $\mathbf{J}_{\text{conv}}$, depends on the local concentration, C_i, and the mass-averaged velocity, $\mathbf{u}$. It may be noted that in modeling most transport processes, the preferred mixture velocity is the mass-averaged velocity which is also the fluid velocity $\mathbf{u}$.

$$\mathbf{J}_{\text{conv}} = \mathbf{u} C_i \qquad [3]$$

The details of evaluating this local fluid velocity $\mathbf{u}$ within the porous scaffold are deferred to **Section 3.309.3**. The total flux is given by the sum of eqns [2] and [3] as follows:

$$\mathbf{J}_{\text{total}} = \mathbf{J}_{\text{diff}} + \mathbf{J}_{\text{conv}} = -\mathbf{D}_i \cdot \nabla C_i + \mathbf{u} C_i \qquad [4]$$

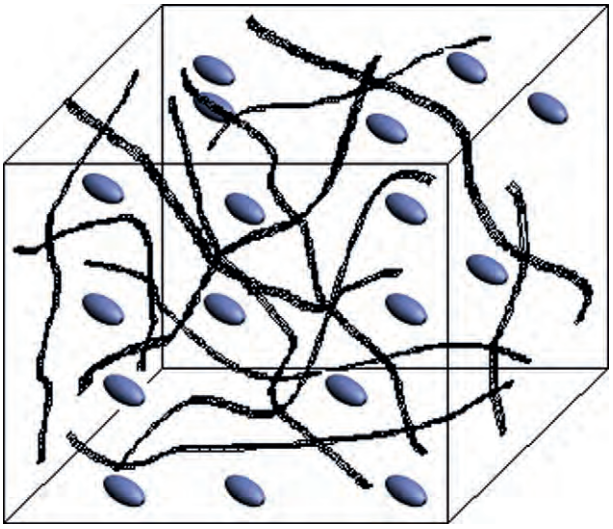

Figure 2 A schematic of a control volume (CV) for a porous fibrous scaffold seeded with cells (represented as ellipsoids). Transport into and out of this CV occurs due to diffusive and convective fluxes while the cells contribute to species production or consumption within the CV.

The conservation equation for C_i can then be written in terms of eqn [4] as given below.

Now consider a fixed control volume (CV) for a porous scaffold seeded with cells as shown in **Figure 2**.

Applying the standard integral form of conservation equation[30] for species C_i within this CV yields

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_V C_i \,\mathrm{d}V = -\int_S \mathbf{J}_{\text{total}} \cdot \mathbf{n} \,\mathrm{d}S + \int_V \rho_{\text{cd}} \dot{R} \,\mathrm{d}V \qquad [5]$$

This equation states that the rate of change of the concentration of species i within the CV is equal to the net balance of the convective and diffusive fluxes occurring across the surface of the CV and the rate of consumption or production of the species by the cells that reside within the CV. In the above, V is the CV, S is the CV surface, $\mathbf{n}$ is the unit normal vector on the surface of the CV (pointed outward), and $\dot{R}$ is the reactive flux which is the rate of consumption (reaction) or production of species C_i within the CV per unit cell density and ρ_{cd} is the cell density within the scaffold. For species that are consumed such as oxygen and nutrients, $\dot{R}$ is negative, while for the metabolic waste products that are produced, $\dot{R}$ is positive. For a fixed CV applying Leibniz's theorem for eqn [5] and using eqn [4] for $\mathbf{J}_{\text{total}}$, yields the following:

$$\int_V \frac{\partial C_i}{\partial t} \,\mathrm{d}V = -\int_S [-\mathbf{D}_i \cdot \nabla C_i + \mathbf{u} C_i] \cdot \mathbf{n} \,\mathrm{d}S + \int_V \rho_{\text{cd}} \dot{R} \,\mathrm{d}V \qquad [6]$$

If the concentration field is smooth and if the size of the CV is chosen to be very small compared to the linear dimensions of the scaffold, Gauss' divergence theorem can be applied to eqn [6]. This yields the differential form of the above integral conservation law for the species C_i given by the following equation.

$$\frac{\partial C_i}{\partial t} + \mathbf{u} \cdot \nabla C_i = \nabla \cdot (\mathbf{D}_i \cdot \nabla C_i) + \rho_{\text{cd}} \dot{R} \qquad [7]$$

For constant isotropic diffusivities, the above equation simplifies to

$$\frac{\partial C_i}{\partial t} + \mathbf{u} \cdot \nabla C_i = D_i \nabla^2 C_i + \rho_{cd} \dot{R} \quad [8]$$

Equations [7] and [8] are the fundamental forms of differential equations that are usually employed in most of the transport studies of oxygen and nutrients within biomaterials. The consumption rate of species such as oxygen or nutrients by the cells usually follows a Michaelis–Menten type kinetics[32–34] and is described by

$$\dot{R} = -\frac{V_{max} C_i}{K_m + C_i} \quad [9]$$

where V_{max} is the half-maximal rate of species consumption and K_m is the Michaelis–Menten constant. Other kinetics such as Monod kinetics can also be used to describe the consumption rates of species such as oxygen.[35] Following Croll *et al.*,[35] the Monod kinetics for oxygen consumption by cells is given by

$$\dot{R} = -\left(\frac{\mu_{max}}{Y_{XS}} + m_s\right) \frac{C_i}{K_m + C_i} \quad [10]$$

where μ_{max} is the maximal cell specific growth rate, Y_{XS} is the yield of cells per unit oxygen, and m_s is the maintenance coefficient, the minimum oxygen consumption required to keep the cells alive. Still other kinetics such as zeroth-order kinetics have also been described for species consumption.[36]

In the following sections, the details of computing the flow field within a porous scaffold and subsequently evaluating the mass transport equations described in this section are presented.

3.309.3. Analysis of Transport Models in Porous Media

In many of the biotechnological applications involving bioreactors and porous scaffolds, the flow field usually does not directly depend on the concentration fields of the species. However, this may not be the case if the presence of the cells and consideration of cell growth within the scaffold are taken into account. In the latter case, the fluid velocity depends on the cell volume fraction which in turn depends on the concentration of species. The discussion of this situation is deferred until Section 3.309.3.2. In any case, first the fluid velocity field is obtained for a given geometry which is subsequently used to solve for the transport of species. Therefore, we first consider the problem of evaluating the flow field within a porous scaffold in Section 3.309.3.1. This is followed by Section 3.309.3.2 where the mass transfer models for important species such as glucose, oxygen, and lactate are reviewed in greater detail.

3.309.3.1. Flow Field Evaluation

A number of earlier studies have presented analytical solutions of the flow field in porous media for idealized configurations where the elements in the media are arranged in a very regular and defined way. In this regard, some of the salient works and their references are provided in the review by Jackson and James[37] on fibrous porous media. While these analytical results are limited in their applicability, they are nevertheless useful for obtaining an estimate of the flow field under limit conditions. Due to the necessity for finding accurate solutions to more complex scaffold configurations and for a wide range of Reynolds numbers where obtaining analytical solutions are difficult or impossible, numerical and computational tools are employed.

The different computational approaches used for solving the flow problem within a porous scaffold can be broadly classified into the following two modeling categories depending on the level of approximations involved in obtaining the solution: (i) direct numerical simulations and (ii) macroscopic averaged equations. A review of these two approaches is presented below.

3.309.3.1.1. Direct numerical simulations: mathematical formulation

Direct numerical simulation aims at resolving the fluid flow structure in its entirety without any underlying approximations of the governing equations. Any locally discontinuous and inhomogeneous flow fields due to the presence of fibers and other pore-scale structures may be predicted accurately without any averaging assumptions on the microstructure of the porous matrix.

The flow of an incompressible Newtonian fluid is governed by the equations of continuity and momentum (Navier–Stokes) which are expressed as follows:

$$\nabla \cdot \mathbf{u} = 0 \quad [11]$$

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u}\right) = -\nabla p + \nabla \cdot \mu\left[\frac{\nabla \mathbf{u} + (\nabla \mathbf{u})^T}{2}\right] + \mathbf{F}_b \quad [12]$$

Here, ρ is the density and μ is the Newtonian viscosity of the culture medium which are assumed constants, $\mathbf{u}$ is the local velocity vector of the fluid, p is the fluid pressure, and $\mathbf{F}_b$ is the body force vector. The first term on the left hand side of eqn [12] denotes the local fluid acceleration, and the second term represents fluid inertia. On the right hand side, the first term represents the pressure gradient force, the second term represents the viscous forces, and the last term represents the body forces. Usually, body force due to gravity is absorbed into the pressure as a hydrostatic head contribution giving rise to a modified pressure. With the pressure so modified, in the absence of any other body forces, $\mathbf{F}_b$ is set to zero. If the Reynolds number of the medium is such that *Re* given by eqn [1] is $\ll 1$, the inertia of the fluid can be neglected and eqn [12] simplifies to an unsteady Stokes equation:

$$\rho \frac{\partial \mathbf{u}}{\partial t} = -\nabla p + \mu \nabla \cdot \left[\frac{\nabla \mathbf{u} + (\nabla \mathbf{u})^T}{2}\right] \quad [13]$$

Furthermore, if the flow is steady, eqn [13] takes the form of the steady Stokes flow equation commonly employed in many fluid flow analysis through a porous scaffold used in biological applications:

$$\mu \nabla \cdot \left[\frac{\nabla \mathbf{u} + (\nabla \mathbf{u})^T}{2}\right] - \nabla p = 0 \quad [14]$$

The assumption of low Reynolds number is justified only for very small pore diameters (of the order of few microns) and low flow perfusion rates. For medium and large pore

diameters, and for nominal to high flow rates, eqn [12] or its steady state version needs to be employed in order to get accurate solutions.

3.309.3.1.1.1. Initial and boundary conditions

Two commonly employed boundary conditions consists of (i) periodic boundary conditions for velocities and pressure at all the boundaries and (ii) a prescribed inlet flow rate (velocity) boundary condition specified at one of the boundaries. With the latter, a traction free boundary condition is usually prescribed at the outlet of the computational domain. The flow rate prescribed at the inlet is often determined from the experiments and is a prescribed quantity. At all other boundaries, a periodic boundary condition is imposed. For unsteady problems, a zero flow initial condition is specified in the interior of the computational domain.

3.309.3.1.2. Numerical methods

The main computational methods for solving the equations of the continuum models can be broadly classified in four types, namely: (i) finite difference method, (ii) finite element, (iii) finite volume methods, and (iv) Lattice Boltzmann method. A brief discussion on each of these methods is provided below.

3.309.3.1.2.1. Finite difference method

The basis of the finite difference method is the construction of a discrete grid, the replacement of continuous derivatives in the governing equation (eqn [12]) by equivalent finite difference expressions using Taylor series expansion techniques, and solving the resultant algebraic equations. Consider a discrete point in the grid uniquely specified by the spatial indices (i, j, k) such that the coordinates are given by $(i\,\Delta x, j\,\Delta y, k\,\Delta z)$, where Δx, Δy, and Δz are the mesh discretization sizes. Let the time level be denoted by n such that $t^n = n\,\Delta t$, where Δt is the discrete time step size. For a generic variable ψ which can denote either the velocity components or pressure, the Taylor series expansions in space along ith direction and time are given by

$$\text{Space}: \psi_{i+1}^n = \sum_{m=0}^{\infty} \frac{\Delta x^m}{m!} \left[\frac{\partial^m \psi_i}{\partial x^m}\right]^n$$

$$\text{Space}: \psi_i^{n+1} = \sum_{m=0}^{\infty} \frac{\Delta t^m}{m!} \left[\frac{\partial^m \psi_i}{\partial t^m}\right]^n \qquad [15]$$

Based on eqn [15], some of the most often used difference expressions are given below:

$$\text{Central difference}:$$

$$\frac{\partial \psi_i}{\partial x} = \frac{\psi_{i+1} - \psi_{i-1}}{2\Delta x} + O(\Delta x^2)$$

$$\frac{\partial^2 \psi_i}{\partial x^2} = \frac{\psi_{i+1} - 2\psi_i + \psi_{i-1}}{\Delta x^2} + O(\Delta x^2) \qquad [16]$$

$$\text{Forward difference}: \frac{\partial \psi_i}{\partial x} = \frac{\psi_{i+1} - \psi_i}{\Delta x} + O(\Delta x) \qquad [17]$$

$$\text{Backward difference}: \frac{\partial \psi_i}{\partial x} = \frac{\psi_i - \psi_{i-1}}{\Delta x} + O(\Delta x) \qquad [18]$$

It can be noted that the central difference formulae given by eqn [16] are second-order accurate while the forward and backward difference formulae given by eqns [17] and [18] are first-order accurate. Application of a second-order spatial discretization to eqn [12] (neglecting the body forces) yields the following time-dependent linear system of equations:

$$\mathbf{M}\dot{\mathbf{u}} = -\mathbf{A}(\mathbf{u})\mathbf{u} - \mathbf{B}_G p + \mathbf{K}_{visc}\mathbf{u} \qquad [19]$$

where $\mathbf{M}$ is the discretized mass matrix (first term of LHS in eqn [12]), $\mathbf{A}(\mathbf{u})$ is the discretized convective operator (second term of LHS in eqn [12]), $\mathbf{B}$ is the discretized gradient operator (first term of RHS in eqn [12]), and $\mathbf{K}_{visc}$ is the discretized viscous operator (second term of RHS in eqn [12]). It should be noted the term $\mathbf{A}(\mathbf{u})\mathbf{u}$ is nonlinear and the degree of nonlinearity scales with Re. The time derivative $\dot{\mathbf{u}}$ can be discretized using a Taylor series expansion such as the one given for spatial terms in eqn [15]. Depending on the time level at which the spatial operators (RHS of eqn [19]) are evaluated, the finite difference method can be classified as explicit or implicit. If the current time level n is used, the scheme is implicit and if the previous level $(n-1)$ is used, the scheme is explicit. Following Peyret and Taylor,[38] a θ method may be employed to discretize eqn [19] and this results in the following linear algebraic system:

$$\frac{\mathbf{M}\mathbf{u}^n - \mathbf{M}\mathbf{u}^{n-1}}{\Delta t} = \theta\left[-\mathbf{A}(\mathbf{u})\mathbf{u} + \mathbf{B}_G p + \mathbf{K}_{visc}\mathbf{u}\right]^n + (1-\theta)\left[-\mathbf{A}(\mathbf{u})\mathbf{u} + \mathbf{B}_G p + \mathbf{K}_{visc}\mathbf{u}\right]^{n-1} \qquad [20]$$

It should be noted that $\theta = 1$ results in a fully implicit scheme and $\theta = 0$ results in a fully explicit scheme. Both the implicit and explicit schemes are only first-order accurate in time. A value of $\theta = \frac{1}{2}$ results in a Crank–Nicolson type discretization which is second-order accurate both in space and time. A fully explicit scheme has both viscous and convective (also called the CFL) time step restrictions because of numerical stability issues (see, Peyret and Taylor[38]). A fully implicit scheme has no time step restrictions but requires highly sophisticated iterative techniques to solve the above linear algebraic system. Such solution techniques used in implicit schemes are the most time-consuming part of any DNS simulations. The discrete form of the continuity eqn [11] is given as

$$\mathbf{B}_G^T u = 0 \qquad [21]$$

where $\mathbf{B}^T$ is the divergence operator and is equal to the transpose of the gradient operator given in eqn [19]. In general, eqns [20] and [21] need to be solved instantaneously to advance both the velocity and pressure fields in time. Several other methods of discretization can be employed to treat the individual terms in eqn [19] depending on the nature of the problem. In many numerical schemes and commercial codes, it is usual to treat the convective terms explicitly and viscous terms implicitly. This is mainly done to avoid severe nonlinearities introduced in the linear algebraic systems associated with high Re and implicit treatment of convective terms. However, such a treatment of convective terms especially for high Re flows needs to be done with care. For example, an explicit treatment of convective terms with a second-order spatial differencing of the velocity derivatives results in numerical instabilities. Usually, upwinding techniques in which the spatial derivatives of velocities are biased

along the flow direction are used to alleviate such problems.[38] A detailed discussion of many upwinding schemes, treatment of various boundary conditions, and other sophisticated forms of finite difference discretizations, such as projection methods, fractional step methods, and compact finite difference schemes, can be found in the works of Peyret and Taylor,[38] Ferziger *et al.*,[39] Brown *et al.*,[40] Mahesh,[41] and the references mentioned therein. In any case, the discretization of eqns [11] and [12] always results in a linear algebraic system similar to the one given by eqn [19] whose solution yields the velocity and pressure field.

The matrices that arise in eqn [20] are generally sparse (few nonzero elements) due to the compact nature of the finite difference stencil used in the discretization procedure. The solution of such sparse linear systems is a computational bottleneck for many large-scale numerical simulations involving millions of elements. Direct solution methods for solving such linear systems based on Gaussian elimination are usually not practical due to excessive memory requirements and intensive use of computational (CPU) resources. In such cases, iterative methods are the most preferred solution techniques because of their lesser memory requirements even for fully 3D problems and also due to the ease of implementation for parallel computations. A review of many sparse linear iterative methods including the popular Krylov-family of solvers such as GMRES methods and advanced multigrid solution acceleration techniques are provided by Saad.[42]

3.309.3.1.2.2. Finite element method

The finite element method (FEM) is another popular numerical technique that employs an integral or variational formulation for solving the governing equations. The most commonly used integral approach is the method of weighted residuals. This technique forms an integral equation by multiplying the governing eqns [11] and [12] by weighting or test functions $\hat{\mathbf{u}}$ and $\hat{p}$, followed by integrating them over the domain of interest (computational domain). Assuming $\mathbf{F}_b = 0$, the weighted integral formulations are given by

$$\int_V \hat{\mathbf{u}}\cdot\left[\rho\left(\frac{\partial \mathbf{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}\right)\right]\mathrm{d}V = \int_V \hat{\mathbf{u}}\cdot\left[-\nabla p+\nabla\cdot u\left(\frac{\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathrm{T}}}{2}\right)\right]\mathrm{d}V \quad [22]$$

$$\int_V \hat{p}\nabla\cdot\mathbf{u}\,\mathrm{d}V = 0. \quad [23]$$

The test functions $\hat{\mathbf{u}}$ and $\hat{p}$ essentially denote the variations of velocity and pressure. The domain of interest is then discretized using nonoverlapping elements such as triangles or quadrilaterals in 2D and hexahedrons and tetrahedrons in 3D. Both the variations and the independent variables are then expanded using known complete function spaces such as polynomials, Legendre functions, Chebyshev functions etc., with unknown coefficients which are then substituted into the integral equations. If the variations $\hat{\mathbf{u}}$, $\hat{p}$, and the independent variables $\mathbf{u}$ and p are expanded using the same function space, then the methods is known Galerkin FEM which is one of the most popular method used in many commercial CFD softwares. The next step involves the weak formulation of which is obtained by integrating the first two terms in the RHS of eqn [22] by parts and is given by

$$\int_V \hat{\mathbf{u}}\cdot\left[\rho\left(\frac{\partial \mathbf{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}\right)\right] = \int_S \hat{\mathbf{u}}\cdot\left[-p\mathbf{I}+\mu\left(\frac{\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathrm{T}}}{2}\right)\right]\cdot\mathbf{n}\,\mathrm{d}S - \int_V \nabla\hat{\mathbf{u}}:\left[-p\mathbf{I}+\mu\left(\frac{\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathrm{T}}}{2}\right)\right]\mathrm{d}V \quad [24]$$

where $\mathbf{I}$ is the identity tensor and $\mathbf{n}$ is the unit normal vector on the domain boundary (pointed outward). Equation [23] remains unaltered and is usually not integrated into its weak form. The first term in the RHS of this equation is a boundary integral term where S denotes the boundaries of the computational domain. For those boundaries where an inlet velocity or mass flux is specified, the variation $\tilde{\mathbf{u}}$ vanishes and for those boundaries where a traction $\mathbf{T}$ is specified, the term $\left[-p\mathbf{I}+\mu\left(\frac{\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathrm{T}}}{2}\right)\right]\cdot\mathbf{n}$ is substituted with $\mathbf{T}$.

Details of the matrix formulation for the Galerkin FEM, the stabilized treatment of convective terms for high *Re* flows, and other forms of FEMs such as penalty FEM, least-squares FEM can be found in Reddy and Gartling[43] and are not discussed here for brevity. The discretization procedure in all these cases once again leads to a sparse linear system of equations similar to the one given by eqn [19]. The time marching procedure and the solution methodologies are similar to the ones discussed earlier and hence will not be repeated.

3.309.3.1.2.3. Finite volume method

The basis of finite volume method is that, an integral form of the conservation equation [12] is used to derive the discretized approximations. The integral form of the fluid momentum equation (neglecting $\mathbf{F}_b$) is obtained as follows

$$\int_V\cdot\left[\rho\left(\frac{\partial \mathbf{u}}{\partial t}+\mathbf{u}\cdot\nabla\mathbf{u}\right)\right]\mathrm{d}V = \int_V\left[-\nabla_p+\nabla\cdot\mu\left(\frac{\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathrm{T}}}{2}\right)\right]\mathrm{d}V \quad [25]$$

Applying Gauss' divergence theorem yields the integral conservation law for fluid momentum

$$\int_V \rho\frac{\partial \mathbf{u}}{\partial t}\,\mathrm{d}V+\rho\int_S \mathbf{u}(\mathbf{u}\cdot\mathbf{n})\mathrm{d}S = \int_S\left[-p\mathbf{I}+\mu\left(\frac{\nabla\mathbf{u}+\nabla\mathbf{u}^{\mathrm{T}}}{2}\right)\right]\cdot\mathbf{n}\,\mathrm{d}S \quad [26]$$

The first step in the finite volume method is to divide the physical domain into a number of nonoverlapping CVs such that there is one CV surrounding each grid point. In the second step, the governing equation [26] for the unknown velocity is integrated over each CV. Finally, the integrals are evaluated by assuming a piecewise profile for the variation of each velocity component and this results in a linear system of algebraic equations for the grid point and its neighbors under consideration. The linear system is once again similar to eqn [19] and the solution procedure for this system follows the same procedure as explained earlier. The important aspect of the finite volume formulation is that the resulting solution satisfies an integral conservation property on the whole domain. The details of the discretization procedure, differences between cell-centered versus vertex-centered CV procedures, and the evaluation of the advective and diffusive fluxes given in eqn [26] are provided in Ferziger *et al.*[39]

3.309.3.1.2.4. Lattice-Boltzmann method

Another efficient direct numerical method to solve for the flow field inside realistic scaffold geometries is the Lattice-Boltzmann (LB) method.[44,45] LB method breaks physical space into discrete nodes, and each node is associated with a particle distribution function. In each timestep, these distributions translate between neighboring nodes and these translations are governed by an LB equation. Such translations results in collisions whose dynamics is governed by the Boltzmann theory that conserves physical properties such as mass and momentum. Application of the Chapman–Enskog multiscale expansion on the LB equation approximates the Navier–Stokes equations to the second order.[44] Thus, LB methods are used to simulate flow physics governed by the continuity and Navier–Stokes equations.

The methods described in this section constitute the DNS techniques used for obtaining the velocity and pressure fields. The only approximations involved are those introduced by the discretization procedures. In order to avoid under resolution of the flow structures, the discretization procedure in a DNS method usually involves a large number of elements in order to accurately represent the complex microarchitecture of the porous scaffold. Direct numerical simulations of the flow through a full porous scaffold are prohibitive in terms of computational costs because of the demand on accuracy to resolve widely disparate length scales. While the pore diameter is usually of the order of few microns, the typical dimension of the scaffold may be of the order of millimeters or even centimeters. However, a reasonable yet meaningful description of the flow field can be achieved by using simplified geometries or by reducing the size of the computational domains or both. A review of the computational models that have employed both detailed pore-scale resolutions of biomaterial scaffolds and simplifications of the size of the computational domains is provided in the following.

3.309.3.1.3. Pore-scale geometry description

The most common simplification is to consider a representative unit cell (a smaller portion of the complete scaffold) consisting of a regular lattice made of cylinders or spheres, or a random arrangement of rigid cylindrical fibers. For example, Vossenberg *et al.*[46] have considered a regular cylindrical lattice of cylinders arranged both parallel and perpendicular to the flow direction and solved for the velocity field using the commercial software COMSOL Multiphysics 3.3 which is based on FEM. Singh *et al.*[47] have calculated the flow field within the entire scaffold structure (5 mm × 5 mm × 5 mm) consisting of cylindrical fibers arranged to form a 90° (parallel and perpendicular) lay-down pattern using the commercial finite volume solver Fluent (ANSYS).[48] Cantini *et al.*,[36] Boschetti *et al.*,[49] and Raimondi *et al.*[50] have considered a periodic lattice of spheres for describing their porous scaffold. The latter study has also considered the presence of the biological cell clusters (approximated as spheres) embedded within the porous scaffold structure. Olivares *et al.*[51] have employed regular scaffold structures such as gyroid and hexagonal scaffolds in their computational study to determine the mechanical stimuli at the cellular level where the cells are cultured in a perfusion bioreactor. Such regular geometry of the scaffold structures provides for a greater control of the transport mechanisms.[5]

Many scaffolds used in tissue engineering do not possess a regular geometrical structure and simplifications using standard lattice structures may provide incorrect estimates of the local shear stress and fluid velocities. Recently, many state-of-the-art imaging techniques together with computer aided design tools have emerged that attempt to closely approximate the real structure of scaffolds in three dimensions (3D). With the advent of powerful computers and the development of efficient computational codes, calculation of 3D flow fields inside such complex and realistic scaffold microarchitectures with or without cells seeded in them has become more feasible. One of the most widely used imaging technique for generating an accurate 3D description of a porous scaffold is the microcomputed tomography (microCT or μCT).[52] μCT is a nondestructive imaging technique to quantify the internal structure of an object in three dimensions. It provides hierarchical biological imaging capabilities with isotropic resolutions ranging from the millimeter down to nanometer length scales.[53] The **Figure 3** shows a typical image obtained from a μCT scan of a porous β-tricalcium phosphate scaffold.[53]

These images can then be converted to computational meshes which can then be used to evaluate the fluid flow and shear stresses by solving eqns [11], [12], and [14] with appropriate boundary and initial conditions. Some of the very recent studies that have utilized the μCT images for computing the fluid flow include the contribution by Anderson *et al.*,[54] Raimondi *et al.*,[55] Cioffi *et al.*,[56] Maes *et al.*,[57] Jungreuthmayer *et al.*,[58] and Sandino *et al.*[59] Jungreuthmayer *et al.*[58] have additionally considered a linear elastostatics model to calculate the deformation of the cells within the scaffold. Their model employs numerically seeded cells of two common morphologies where cells are either attached flatly on the scaffold wall or bridging two struts of the scaffold. In Sandino *et al.*,[59] finite element models have been used to analyze the behavior of the mechanical stimuli within some calcium phosphate-based porous scaffolds in terms of stress and strain distributions in the solid material phase and fluid velocity, pressure and fluid shear stress distributions in the pores. For modeling purposes, two porous materials, namely, calcium phosphate-based cement and biodegradable glass have been used. The microstructural details have been obtained by means of micro-computed tomography. Steady state version of the Navier–Stokes equation [12] has been used to simulate the-flow with an inlet velocity of 10 $\mu m\,s^{-1}$. The fluid pressure p is set to zero at the oulet and all other boundaries are considered as no-slip walls. In **Figure 4**, a representative plot of the fluid velocity, pressure, and shear stress distributions within a porous scaffold has been shown.[53]

Porter *et al.*[60] have used the LB method to simulate the 3D flow field inside a porous scaffold whose geometry was obtained from μCT images.

Other state-of-the-art imaging techniques such as X-ray tomography,[61] magnetic resonance microscopy (MRM) to generate tomographic mappings of a porous medium at micron-scale resolution,[62] high-resolution magnetic resonance imaging (MRI) images,[63] and 3D digital volumetric imaging (DVI)[64] have also been used to characterize the porous scaffold architecture. In Jaganathan *et al.*,[64] the DVI technique has been used to generate the geometry of the porous scaffold

which is then used for their finite volume computations (see Section 3.309.3.1.1) of the flow field. The computational domain representing a unit cell of the porous fibrous scaffold and the imposed boundary conditions on this computational cell are shown in Figure 5. The governing equations employed by them include eqns [11] and [12] with $\mathbf{F}_b = 0$.

The results for the flow field is displayed in Figure 6 which show the details of the complex flow structures prevailing around individual fibers of such a fibrous scaffold.

These state-of-the-art techniques in conjunction with the DNS methods often enable sufficiently accurate estimations of the flow field even for complex geometries. The flow fields so obtained may then be used to estimate the shear stress distributions within the porous scaffolds. The knowledge of the flow and shear stress fields can then be used to accurately evaluate the concentration fields of important species. Such a knowledge of mass transfer that takes into account the microscopic structure is a critical issue that needs to be considered in the design of scaffolds for optimizing tissue-engineering treatments.[5]

The second method for predicting the fluid flow, namely the macroscopic averaged equations is described next.

3.309.3.1.4. Macroscopic averaged equations

While the DNS simulations can provide detailed solutions on the pore scale for a given system they are still computationally expensive, and as described above, require detailed knowledge of the pore-scale microstructure. Also, the possibility of considering the differentiation and expansion of biological cells, which result in a change of the geometry, poses significant challenges for DNS. For many engineering purposes, it is sufficient to know the flow field in an average sense, the average performed over the pores, cells, and scaffold matrix phases. The volume averaging method is one such technique used to analyze flow and transport in porous media on a macroscopic scale.[27] The Navier–Stokes equations representing the transport of momentum together with the mass transport equation for every species in particular phases of the multiphase systems (the scaffold material, cells, and the liquid media constitute the different phases) can be spatially smoothed to obtain continuum equations that are valid everywhere. These equations are called volume averaged equations. The techniques of the volume averaging procedure are described in the following section for the case of Stokes flow.

3.309.3.1.5. Volume averaging technique: mathematical formulation

This method mainly consists of averaging the microscale equations over a representative elementary volume (REV), which is chosen such that it is sufficiently larger than the characteristic length scales present in the porous scaffold (the pore size and the individual biological cell size) while much smaller than the total system volume.

3.309.3.1.5.1. Mathematical formulation

Consider the REV shown in Figure 7.

Let L be the macroscopic length scale, V be the averaging volume with radius r, and l_σ, l_β be the characteristic length scales of the solid phase (scaffold matrix and cells) and the liquid phase (average pore size), respectively. In Figures 7 and 8, let $A_{\beta\sigma}$ refers to the area between the fluid and solid phases, and $A_{\beta e}$ is the area of entrances and exits for the volume V. Assuming a homogenous porous media, the size

of the REV is chosen such that the following length scale constraint holds true:

$$l_\sigma, l_\beta \ll r \ll L \qquad [27]$$

The following volume averages for any generic quantity ψ within the REV are defined as follows:

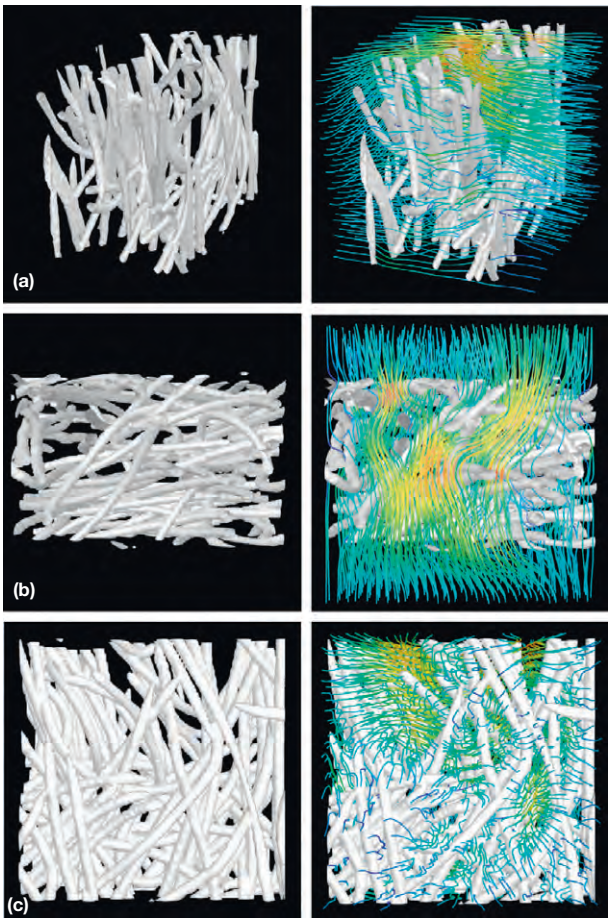

Figure 6 Flow path lines through a fibrous media rendered using results obtained from DNS: (a) isometric view, (b) side view, and (c) bottom view. Reproduced with permission from Jaganathan, S.; Vahedi Tafreshi, H.; Pourdeyhimi, B. *Chem. Eng. Sci.* **2008**, *63*(1), 244–252.

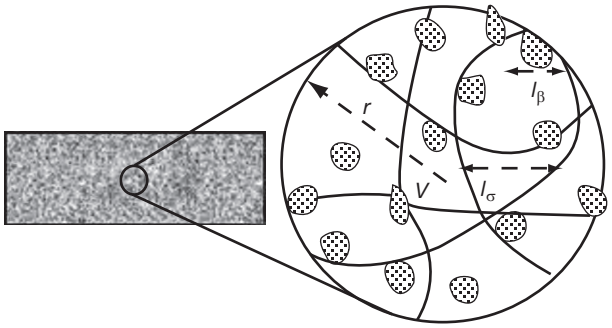

Figure 7 Schematic of a fibrous porous scaffold along with a representative element volume (REV). V is the averaging volume with radius r, and l_σ, l_β are the characteristic length scales of the scaffold matrix and the liquid phase (average pore size), respectively.

$$\langle\psi\rangle = \frac{1}{V}\int_{V_\beta}\psi\,dV \qquad [28]$$

is the superficial phase average or the average over the total volume V, and

$$\langle\psi\rangle^\beta = \frac{1}{V_\beta}\int_{V_\beta}\psi\,dV \qquad [29]$$

is the intrinsic phase average or average over the fluid phase. Here, V_β is the volume of the β-phase (fluid) contained within the representative or averaging volume V. These two averages are related by:

$$\langle\psi\rangle = \varepsilon_\beta\langle\psi\rangle^\beta \qquad [30]$$

where $\varepsilon_\beta = \frac{V_\beta}{V}$ is the porosity.

The governing equations for fluid flow for $Re < 1$ are the continuity and Stokes equations given by

$$-\nabla p + \mathbf{f} + \mu\nabla^2\mathbf{u} = \mathbf{0} \qquad [31]$$

and,

$$\nabla\cdot\mathbf{u} = 0 \qquad [32]$$

where $\mathbf{f}$ is a constant body force vector such as gravity. The associated boundary conditions are:

$$\begin{aligned}&\text{At } A_{\beta\sigma}: \mathbf{u} = 0\\ &\text{At } A_{\beta e}: \mathbf{u} = \mathbf{g}(\mathbf{r}, t)\end{aligned} \qquad [33]$$

where $\mathbf{g}(\mathbf{r}, t)$ is the velocity imposed at the boundaries of the REV.

The volume averaging method consists in applying the average procedure using eqn [28] to the governing eqns [31] and [32] in order to obtain the volume-averaged version of the continuity and Stokes equation. Along with this averaging, it is necessary to use Gray's decomposition, which is expressed as:

$$\begin{aligned}p &= \langle p\rangle^\beta + \tilde{p}\\ \mathbf{u} &= \langle\mathbf{u}\rangle^\beta + \tilde{\mathbf{u}}\end{aligned} \qquad [34]$$

where $\tilde{p}$ and $\tilde{\mathbf{u}}$ are the deviations or fluctuations about the intrinsic averaged pressure and velocity, respectively. Using eqn [34] in eqns [31] and [32] results in a set of equations containing both the averaged quantities and the deviations. In order to solve the system of equations, closure relations

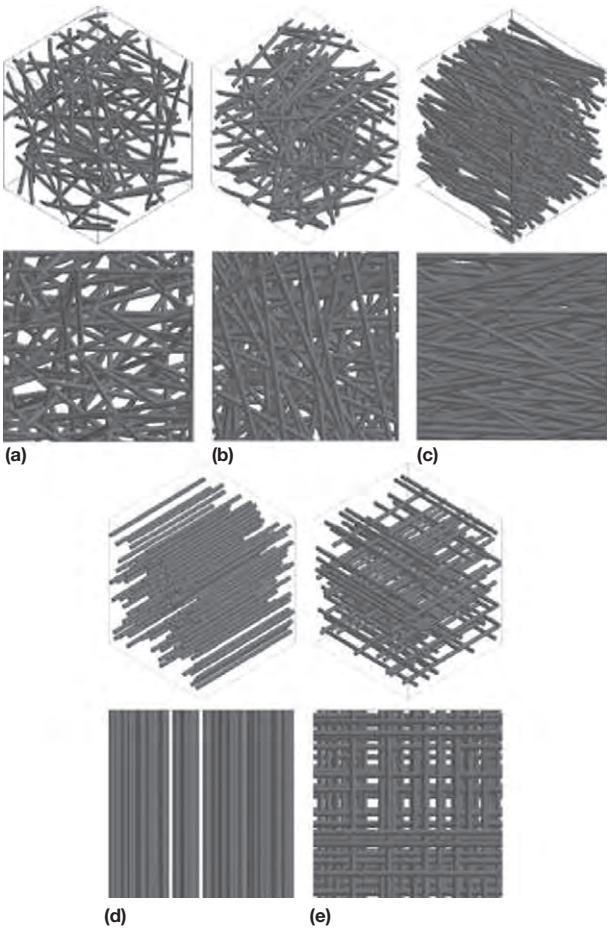

Figure 8 Different fiber orientations in isometric and side views: (a) 3D isotropic, (b) layered with random in-plane fiber orientation, (c) highly oriented layered, d) disordered unidirectional, and (e) disordered orthogonal media. Reproduced with permission from Tahir, M. A.; Tafreshi, H. V. *Phys. Fluids* **2009**, *21*, 083604.

expressing the deviations in terms of the averaged quantities are required. Following Whitaker,[65] one such closure problem is obtained by first expressing $\tilde{p}$ and $\tilde{\mathbf{u}}_\beta$ as follows.

$$\begin{aligned}\tilde{p} &= \mu\mathbf{b}\cdot\langle\mathbf{u}\rangle^\beta\\ \tilde{\mathbf{u}} &= \mathbf{B}\cdot\langle\mathbf{u}\rangle^\beta\end{aligned} \qquad [35]$$

where $\mathbf{b}$ and $\mathbf{B}$ are the unknown vector and second-order tensor used to represent the pressure and velocity deviations in terms of the averaged quantities. Both $\mathbf{b}$ and $\mathbf{B}$ are determined from the following integro-differential boundary value problems (see Whitaker[65] for more details):

$$\begin{aligned}&\nabla\cdot\mathbf{B} = 0\\ &-\nabla\mathbf{b} + \nabla^2\mathbf{B} = \frac{1}{V_\beta}\int_{V_\beta}\left[-\nabla\mathbf{b} + \nabla^2\mathbf{B}\right]dV\end{aligned} \qquad [36]$$

These equations are subjected to the following boundary conditions. At the fluid–scaffold matrix boundary ($A_{\beta\sigma}$),

$$\mathbf{B} = -\mathbf{I} \qquad [37]$$

where $\mathbf{I}$ is the identity tensor. At the entrance and exit of the scaffold ($A_{\beta e}$)

$$\mathbf{B}(\mathbf{r}+\mathbf{1}) = \mathbf{B}(\mathbf{r})$$
$$\mathbf{b}(\mathbf{r}+\mathbf{1}) = \mathbf{b}(\mathbf{r}), \quad i = 1, 2, 3 \qquad [38]$$

where $\mathbf{l}$ is the computational lattice vector. $\mathbf{B}$ and $\mathbf{b}$ are also subjected to the following conditions as well that reflect the assumption that the intrinsic averages of $\tilde{p}$ and $\tilde{\mathbf{u}}$ vanish:

$$\langle \mathbf{b} \rangle^{\beta} = \langle \mathbf{B} \rangle^{\beta} = 0 \qquad [39]$$

It is worth noting that the boundary condition related to the velocity at $A_{\beta e}$ as given by eqn [33] has been simplified and changed to a spatially periodic condition in the closure model given by eqn [38] in order to solve the closure problem.[65] However, such a change will not limit the validity of the equations to periodic structures alone and can be applied even for nonperiodic heterogeneous media as long as the scale constraints (given by eqn [27]) are satisfied.[65,66]

Based on the averaging procedure and the closure problem described so far, Darcy's law and the associated fluid mass conservation equations can be derived in the classical form and expressed as:

$$\langle \mathbf{u} \rangle = -\frac{\mathbf{K}}{\mu} \cdot \left[\nabla \langle p \rangle^{\beta} - \mathbf{f} \right] \qquad [40]$$

$$\nabla \cdot \langle \mathbf{u} \rangle = 0 \qquad [41]$$

where the permeability tensor $\mathbf{K}$ is defined as follows:

$$\mathbf{K} = \varepsilon_{\beta} \mathbf{C}^{-1} \qquad [42]$$

$$\mathbf{C} = \frac{1}{V_{\beta}} \int_{A_{\beta\sigma}} \mathbf{n}_{\beta\sigma} \cdot (\nabla \mathbf{B} - \mathbf{I}\mathbf{b}) \mathrm{d}A \qquad [43]$$

Here, $\mathbf{n}_{\beta\sigma}$ is the normal vector at the scaffold matrix–fluid interface.

An alternate and simpler form of closure equations (given by eqn [36]) can be derived based on the following transformations[27]:

$$\mathbf{D} = -\varepsilon_{\beta}^{-1} (\mathbf{B} + \mathbf{I}) \cdot \mathbf{K}$$
$$\mathbf{d} = -\varepsilon_{\beta}^{-1} \mathbf{B} \cdot \mathbf{K} \qquad [44]$$

Substituting eqn [44] into eqn [36] leads to the following Stokes-like set of equations.

$$\nabla \cdot \mathbf{D} = 0 \qquad [45]$$

$$-\nabla \mathbf{d} + \nabla^2 \mathbf{D} = \mathbf{I} \qquad [46]$$

These equations are subjected to the following boundary conditions

$$\text{At } A_{\beta\sigma} : \mathbf{D} = \mathbf{0} \qquad [47]$$

and at $A_{\beta e}$:

$$\mathbf{D}(\mathbf{r}+\mathbf{1}) = \mathbf{D}(\mathbf{r})$$
$$\mathbf{d}(\mathbf{r}+\mathbf{1}) = \mathbf{d}(\mathbf{r}), \quad i = 1, 2, 3 \qquad [48]$$

Also,

$$\langle \mathbf{d} \rangle^{\beta} = 0 \qquad [49]$$

$$\langle \mathbf{D} \rangle^{\beta} = -\varepsilon_{\beta}^{-1} \mathbf{K} \qquad [50]$$

The solution to eqns [45] and [46] subjected to boundary conditions given by eqns [47] and [48] helps in determining the permeability tensor $\mathbf{K}$ from eqn [50]. It is through the solution procedure of the above set of equations and through the averaging procedure in eqn [50] that the microscopic details of the scaffold structure enters the permeability calculations. Hence, an accurate estimation of the permeability tensor $\mathbf{K}$ depends on how well the microstructure of the porous scaffold is represented.

3.309.3.1.5.2. Numerical solution procedure

Equations [45] and [46] can be considered as a generalized Stokes problem for the components of $\mathbf{d}$ and $\mathbf{D}$. Anguy *et al.*[67] and Bernard *et al.*[68] have used an artificial compressibility method to obtain the solution for eqns [45] and [46]. Following Anguy *et al.*,[67] the equations governing the artificial compressibility method is given as follows:

$$\frac{\partial \mathbf{d}}{\partial t} + c^2 \nabla \cdot \mathbf{D} = 0 \qquad [51]$$

$$\frac{\partial \mathbf{D}}{\partial t} + \nabla \mathbf{d} - \nabla^2 \mathbf{D} = -\mathbf{I} \qquad [52]$$

where c is the artificial compressibility factor and t is pseudo-time. Equations [51] and [52] are subjected to the boundary conditions given by eqns [47] and [48] and initial conditions given as follows

$$\mathbf{d} = \mathbf{d}_0$$
$$\mathbf{D} = \mathbf{D}_0 \qquad [53]$$

where $\mathbf{d}_0$ and $\mathbf{D}_0$ are the specified initial conditions. The steady-state solution for eqns [51] and [52] yields the solution for $\mathbf{d}$ and $\mathbf{D}$, and this has been obtained using a standard finite volume solver and an explicit scheme (with $\theta = 0$ scheme described in **Section 3.309.3.1.2**). Expressions for the stable time step Δt and the artificial compressibility c have been provided in Anguy *et al.*[67] Following Anguy *et al.*,[67] for a 2D problem with a given stable Δt and grid spacings δx and δy, the expression for c is given by

$$c^2 = \min\left(\frac{1}{4\Delta t^2} (\delta x^2 - 8\Delta t), \frac{1}{4\Delta t^2} (\delta y^2 - 8\Delta t) \right) \qquad [54]$$

With the permeability tensor $\mathbf{K}$ of the medium so obtained, it may be used in the macroscopic averaged equations such as the Darcy's model given by eqn [40]. Some of the important macroscopic models including Darcy's model that are typically used in porous media calculations are listed below.

3.309.3.1.5.2.1. Darcy's law model As described earlier, Darcy's law given by eqn [40] results from the volume-averaging of the Stokes equation governing fluid flow in the porous medium. It relates the superficial average of the velocity, $\langle \mathbf{u} \rangle$ to the intrinsic average of the pressure $\langle p \rangle^{\beta}$. The superficial average velocity is chosen in the derivation because of its solenoidal characteristic represented by eqn [41]. The superficial average velocity is also directly related to the experimentally determined mass flow rate in the perfusion reactor. However, an intrinsic average of pressure is preferred because it more closely resembles the pressure that one could measure or the pressure that one could impose as a boundary condition see, Ochoa-Tapia and Whitaker.[69] The main drawback of Darcy's law is that it cannot satisfy a no-slip boundary condition at a solid surface bounding the porous material since there are no second derivatives of velocities.

3.309.3.1.5.2.2. Darcy–Brinkman model The Brinkmann model[70] was proposed to account for the presence of solid boundaries by introducing a term involving the second derivative of velocity in the Darcy's model. The semiempirical Darcy–Brinkman equation is a combination of Stokes equation [14] and Darcy's law. Following Khaled and Vafai,[71] the Darcy–Brinkman equation takes the following form:

$$\frac{\mu}{\varepsilon_\beta}\lambda\Delta^2\langle\mathbf{u}\rangle - \mu\mathbf{K}^{-1}\langle\mathbf{u}\rangle = -\nabla\langle p\rangle^\beta \qquad [55]$$

where ε_β is the porosity of the scaffold and λ is the tortuosity of the porous medium. For a highly porous medium, which is usually the case with many porous biomaterials, λ is usually taken to be equal to 1.

3.309.3.1.5.2.3. Darcy–Brinkman–Forchheimer model Both Darcy and Brinkman models do not account for the inertial effects of the fluid within the porous medium. For cases in which inertial effects ($Re > 1$) in the flow are significant, the Darcy–Brinkman equation is extended to the so-called Darcy–Forchheimer–Brinkman formulation.[72] Following Nithiarasu *et al.*,[73,74] the Darcy–Forchheimer–Brinkman model for an anisotropic porous medium characterized by the porosity ε_β and permeability tensor $\mathbf{K}$ is given as follows.

$$\frac{\rho}{\varepsilon_\beta}\left[\frac{\partial\langle\mathbf{u}\rangle}{\partial t} + \nabla\cdot\left(\frac{\langle\mathbf{u}\rangle\langle\mathbf{u}\rangle}{\varepsilon_\beta}\right)\right] = -\frac{1}{\varepsilon_\beta}\nabla(\varepsilon_\beta\langle p\rangle^\beta) + \frac{\mu}{\varepsilon_\beta}\nabla^2\langle\mathbf{u}\rangle - \mu\mathbf{K}^{-1}\langle\mathbf{u}\rangle - \rho C_F\mathbf{K}^{-\frac{1}{2}}\left|\langle\mathbf{u}\rangle\right|\langle\mathbf{u}\rangle \qquad [56]$$

where $|\langle\mathbf{u}\rangle|$ denotes the magnitude of the velocity vector at any given location. Also, C_F is the Forchheimer coefficient and is expressed as,

$$C_F = \frac{1.75}{\sqrt{150\varepsilon_\beta^3}} \qquad [57]$$

A more general form of the Darcy–Forchheimer–Brinkman model has been proposed by Bousquet-Melou *et al.*[66] that takes into account porosity variations within a porous scaffold along with a generalized form of continuity equation that are given as follows:

$$\frac{\partial}{\partial t}(\varepsilon_\beta\rho + \varepsilon_\sigma\rho_\sigma) + \nabla\cdot(\rho\langle\mathbf{u}\rangle) = 0 \qquad [58]$$

$$\varepsilon_\beta{}^{-1}\frac{\partial}{\partial t}(\rho\langle\mathbf{u}\rangle) + \varepsilon_\beta{}^{-1}\nabla\cdot\left(\varepsilon_\beta{}^{-1}\rho\langle\mathbf{u}\rangle\langle\mathbf{u}\rangle\right) = -\nabla\langle p\rangle^\beta + \mathbf{f} + \mu\varepsilon_\beta{}^{-1}\nabla^2\langle\mathbf{u}\rangle - \mu\varepsilon_\beta{}^{-1}\nabla\varepsilon_\beta\cdot\nabla(\varepsilon_\beta{}^{-1}\langle\mathbf{u}\rangle) - \mu\mathbf{K}^{-1}\cdot\langle\mathbf{u}\rangle - \mu\mathbf{K}^{-1}\cdot\mathbf{F}\cdot\langle\mathbf{u}\rangle \qquad [59]$$

where $\mathbf{F}$ is the Forchheimer correction tensor. The solution procedure for $\mathbf{F}$, which involves a closure problem similar to the one described in **Section 3.309.3.1.5**, is still an open research problem.[75] Usually, the last term of the RHS of eqn [59] is approximated by the last term of the RHS given in eqn [56]. The fourth term of the RHS in eqn [59] denotes the second Brinkman correction term that explicitly involves porosity gradients. Hence, this form of equation may be useful for modeling tissue growth in porous scaffolds. It may be noted that eqns [40], [55], and [56] are special cases of eqn [59].

All of the model equations have been employed in various recent studies to evaluate the flow within porous scaffolds. Botchwey *et al.*[76] used Darcy's law to estimate shear stresses inside 3D microcarrier scaffolds during rotation in a high aspect ratio vessel. Whittaker *et al.*[77] developed a mathematical model based on Darcy's law for forced flow of culture medium through a porous scaffold to predict the nutrient and shear-stress distributions. In this study, the authors have investigated the role of fluid flow within a porous scaffold that included both an externally driven flow using inlet and outlet pipes, and additional perfusion using porous fibers within the scaffold. The scaffold has been modeled as a uniform isotropic porous medium with distributed mass sources representing both the external flows and perfusion from porous fibers. Mathematically, this can be described using the following modified continuity equation:

$$\nabla\cdot\langle\mathbf{u}\rangle = \Psi_{\text{inlet}} - \Psi_{\text{outlet}} + \Psi_{\text{fibers}} \qquad [60]$$

where Ψ_{inlet}, Ψ_{outlet}, and Ψ_{fibers} denote the mass flow rates from the inlet pipe, the outlet pipe, and the porous fibers. The fiber core is assumed to be a slender cylinder and flow within the core is modeled using Navier–Stokes equations with inertia and radial pressure gradients neglected. The walls of the fibers are modeled as an axisymmetric and axially uniform porous medium governed by Darcy's law (eqn [40]). Chung *et al.*[78] have used the Darcy–Brinkman equation to characterize the fluid dynamics within a porous construct placed in a perfusion reactor. Using a finite volume method, Yu *et al.*[79] have numerically investigated the effect of cell density on the fluid dynamics and mass transfer of oxygen inside a porous isotropic tissue engineering scaffold placed within a rotating bioreactor. The external flow to the porous scaffold has also been considered. The microbioreactor consisted of an open cylinder chamber filled with culture medium. For the external flow, the fluid velocities and oxygen concentration fields are solved numerically using eqns [11] and [12]. The flow inside the scaffold has been modeled using the Darcy–Brinkman–Forchheimer model given by eqn [56] along with eqn [57] (also, see Yu *et al.*[80]). The external and internal flows are coupled through boundary conditions at the scaffold surface. Following Chen *et al.*,[81] the boundary conditions needed to couple the macroscopic flow described by DNS at the bioreactor macroscopic scale and the microscopic flow inside the porous scaffold governed by the Darcy–Brinkman–Forchheimer model are given as follows:

Continuity of velocity and normal stress :

$$\langle\mathbf{u}\rangle\big|_{\text{Fluid}} = \langle\mathbf{u}\rangle\big|_{\text{Porous}} = \langle\mathbf{u}\rangle\big|_{\text{Interface}} \qquad [61]$$

$$\frac{\mu}{\varepsilon}\frac{\partial\langle u\rangle_t}{\partial n}\bigg|_{\text{Porous}} - \mu\frac{\partial\langle u\rangle_t}{\partial n}\bigg|_{\text{Fluid}} = 0 \qquad [62]$$

Tangential stress jump condition :

$$\frac{\mu}{\varepsilon}\frac{\partial\langle u\rangle_t}{\partial n}\bigg|_{\text{Porous}} - \mu\frac{\partial\langle u\rangle_t}{\partial n}\bigg|_{\text{Porous}} = \gamma\frac{\mu}{\sqrt{K}}\bigg|_{\text{Interface}} + \gamma_1\rho\langle u\rangle_t{}^2 \qquad [63]$$

where $\langle u\rangle_n$ and $\langle u\rangle_t$ are the normal and tangential components of the velocity vector $\langle\mathbf{u}\rangle$ and γ, γ_1 are adjustable parameters which account for the stress jump at the interface and are usually determined from experiments (see, Ochoa-Tapia and Whitaker[82]). The parameter γ usually varies in the range -1 to 0.7[83] and γ_1 is assumed to vary in the range -0.7 to 0.7.[81]

The application of the above models for computing interstitial fluid flow within biological tissues can be found in the reviews of Khaled and Vafai[71] and Swartz and Fleury.[84]

3.309.3.1.6. Correlations for estimating porous scaffold permeability

An estimation of the macroscopic permeability tensor of the porous scaffold **K** is critical to solving the averaged equations for fluid flow described earlier. As shown in **Section 3.309.3.1.5**, the permeability tensor **K** arises as a result of the volume averaging procedure and is obtained by solving a closure problem (eqns [45]–[50]) on a reasonably well approximated porous microstructure. For the case of realistic fibrous scaffold architecture obtaining solutions for such a closure problem requires a lot of computational resource and is therefore noted to be a difficult problem (see, Serrat[85]).

Simpler models/correlations that provide a good estimate of the permeability values are often sought. Such models need to consider the dependence of the permeability on the geometry of the porous medium, the orientation of the pores/fibers with respect to the flow, and the porosity ε_β or the solid volume fraction, $\phi = 1 - \varepsilon_\beta$, of the scaffold. The dependence of the permeability on ε_β (or ϕ) is critical for tissue engineering purposes because the porosity of the microstructure changes with time as the cells proliferate and grow.

Early models that studied flow in fibrous media were confined to 2D geometries, used Stokes flow equations, and utilized a unit cell model consisting of a single fiber or a periodic array of fibers. By solving the creeping flow equations for parallel or transverse orientation of fiber axis, expressions for the hydraulic permeability were derived. A review of such models is given by Jackson and James.[37] For realistic 3D fibrous media used in biotechnology applications, the second-order permeability tensor **K** is usually diagonally dominant and the off-diagonal components are usually two or three orders of magnitude smaller Ashari *et al.*[86] The scaffold materials are approximated as orthotropic materials, and if the diagonal components are nearly the same, they are treated as isotropic materials. Based on these approximations, analytical expressions/correlations of permeabilities have been derived using simplified geometries of the porous microstructure and these serve as good estimates for modeling the flow using the averaged equations. Some of the important and more widely used correlations for the permeability of porous media involving relatively low solid volume fraction (typically, $\phi < 0.3$) are listed below.

1. Carman–Kozeny equation:

   Carman–Kozeny expression predicts a single (isotropic) scalar value for the permeability of the fibrous porous medium in terms of the porosity of the medium. The permeability expression is[87]:

$$K = \frac{\varepsilon_\beta^3}{k_k(1-\varepsilon_\beta)^2 a_p^2} \qquad [64]$$

   where, k_k is the Carman–Kozeny constant which accounts for the tortuosity and nonuniformity of the pores, a_p is the specific area of the particle, and ε_β is the porosity of the scaffold. Here, a_p is given by:

$$a_p = \frac{2(2\lambda+1)}{\lambda d_p} \qquad [65]$$

   where, d_p is the average diameter of the fibers, $\lambda = L_f/d_p$ is the aspect ratio of the fiber, where L_f is the average length of the fibers. It may be noted that for large values of λ, $a_p \approx 4/d_p$, the eqn [64] reduces to:

$$K = \frac{\varepsilon_\beta^3 d_p^2}{16 k_k (1-\varepsilon_\beta)^2}, \lambda \gg 1. \qquad [66]$$

   Values of k_k as a function of ε_β and r_p for randomly stacked fibers are given in Rahli *et al.*[87] Studies that have employed Carman–Kozeny equations include those by Botchwey *et al.*,[76] Chung *et al.*,[78,88] and Whittaker *et al.*[77]

2. Spielman–Goren model:

   Using Brinkman equation for the fluid flow, Spielman and Goren[89] have derived a set of implicit equations for the permeability of different fibrous microstructures. Their expressions for layered (eqn [67]) and 3-D random microstructures (eqn [68]) in terms of the solid volume fraction ($\phi = 1 - \varepsilon_\beta$)are given as follows (see, Jackson and James[37]):

$$\text{Layered}: \frac{1}{2} + \frac{\sqrt{K}}{a}\frac{K_1\left(\frac{a}{\sqrt{K}}\right)}{K_0\left(\frac{a}{\sqrt{K}}\right)} = \frac{1}{4\phi} \qquad [67]$$

$$\text{3D Random}: \frac{1}{3} + \frac{5}{6}\frac{\sqrt{K}}{a}\frac{K_1\left(\frac{a}{\sqrt{K}}\right)}{K_0\left(\frac{a}{\sqrt{K}}\right)} = \frac{1}{4\phi} \qquad [68]$$

   where a is the average radius of the fiber, K_0 and K_1 are modified Bessel functions of the second kind of orders 0 and 1, respectively.

3. Jackson and James model:

   Jackson and James[37] have proposed the following correlation for the permeability of 3D random arrays of cylinders based on a simple weighted averaging of the streamwise and transverse permeability values.

$$\frac{K}{a^2} = \frac{3}{20\phi}(-\ln\phi - 0.931) \qquad [69]$$

   The authors have also provided a large compilation of the values of permeabilities for various fibrous materials as a function of porosity.

4. Parallel and transverse flows through fibers:

   Drummond and Tahir[90] and Sangani and Acrivos[91] have obtained permeability expressions for parallel and transverse flows through periodic arrays of fibers aligned parallel to each other.

$$\frac{K_{||}}{a^2} = \frac{1}{4\phi}\left(-\ln(\phi) - 1.476 + 2\phi - \frac{\phi^2}{2} + O(\phi^4)\right) \qquad [70]$$

$$\frac{K_\perp}{a^2} = \frac{1}{8\phi}(-\ln(\phi) - 1.476 + 2\phi - 1.774\phi^2 + 4.076\phi^3 + O(\phi^4)) \qquad [71]$$

   where $K_{||;}$ and $K_\perp$ are the permeabilities parallel and perpendicular to the flow direction. Based on these expressions, the

permeability of the scaffold with randomly oriented fibers in three dimensions is given as follows[84,92,93]:

$$\frac{1}{K} = \frac{1}{(\phi/3)K_{||}} + \frac{1}{(2\phi/3)K_{\perp}} \quad [72]$$

5. Experimental correlation of Davies:

Davies[94] has obtained an experimental correlation for the permeability of planar fibrous sheets as described by:

$$K = \frac{a^2}{16\phi^{3/2}(1+56\phi^3)} \quad [73]$$

The values of the isotropic permeability K for some of the commonly used porous scaffolds are listed in **Table 1**. For the cases where both porosity and permeability change due to cell growth, the values provided in the table represent the initial conditions.

3.309.3.1.7. Direct methods for the estimation of permeabilities

One direct method for the estimation of the permeability tensor is through the solution of the closure equations (eqns [45]–[50]) using the microarchitecture of porous medium. The permeabilities of the porous microstructure have also been determined using the following approach based on DNS methods. First, a steady state Stokes flow field prevailing within the microstructure is solved using DNS as described in **Section 3.309.3.1**. The small Re approximation used in Stokes flow is usually justified for porous biomaterials because of the smallness of the pore size. Once the flow field is calculated, the scalar value of permeability K, along a given direction is usually obtained using eqn [40]. Specifically,

$$K = \mu\langle u\rangle\left(\frac{\Delta p}{\Delta L}\right)^{-1} \quad [74]$$

where $\Delta p/\Delta L$ is the numerically estimated magnitude of the pressure drop along the particular direction for which K is to be determined. Clague and Phillips[92] calculated hydraulic permeabilities for monomodal and bimodal, periodic and random fibrous media using the following equation:

$$K = \frac{V}{|\mathbf{F}|} \quad [75]$$

where V is the total volume of a unit cell normalized by a^3, where a is the radius of the fibers (assumed as cylindrical rods), and $|\mathbf{F}|$ is the total force acting on the cylinders in the cell normalized by the product of the imposed fluid velocity, the fluid viscosity, and the cylinder (fiber) radius. In the numerical technique employed by Clague and Phillips,[92] each fiber was represented as a line distribution of point forces, and the no-slip condition was enforced in an integral form. Although they have reported results mainly for dilute volume fractions, the method can be used for more concentrated suspensions with the addition of quadropole terms and by using additional point singularities on the rigid fiber surfaces.

In this manner, the accurate results from DNS can be used to compare the results obtained from correlations in order to check the regime under which the correlations may be used as valid simplifications. Some of the results obtained using detailed DNS simulations have been compared with the results of correlations described earlier and are presented in the following section.

Apart from DNS, other modeling techniques such as network modeling have also been employed to calculate the permeabilities of fibrous media and the methodology has been described for low and high fiber volume fractions in Thompson.[97] Here, the pore space is discretized into an interconnected set of pores and pore throats using Voronoi networks. By assigning hydraulic conductivities to pore throats based on an effective radius approach and Hagen–Poiseuille law, the flow problem is cast as a pipe network (or resistor network) problem. Mass conservation equation applied to each pore in the network produces a set of linear equations as given below that is solved for individual pore pressures.

$$\sum_{j=1}^{n} \frac{G_{ij}}{\mu}(P_j - P_i) = 0 \quad [76]$$

where G_{ij} is the hydraulic conductivity for the ijth and n is the total number of neighbors to a pore i. The solution of the system of equations also gives the total flow rate through the network (if boundary pressures are specified), or the pressure drop across the network (if the flow rate is imposed). These quantities can then be used in the Darcy's law to calculate the permeability of the fibrous medium along a given direction. If the material is anisotropic, the permeability tensor may be defined by repeating the flow calculation in the other coordi-

Table 1 Isotropic permeability values for some commonly used scaffold materials

Scaffold	*Porosity (ε_β)*	*Permeability (m^2)*	*References*

Synthetic microporous scaffolds	0.85	5.41×10^{-10}	Cantini *et al.*[36]

A dynamic viscosity of $\mu = 1\times10^{-3}\,\mathrm{N\,s\,m^{-2}}$ has been assumed for the calculation of permeabilities of some of the scaffold materials whose units are reported in $\mathrm{m^4\,(N\,s)^{-1}}$.

nate directions. In this method, the distinction between pores and pore throats has been neglected and a simplified relationship between discrete nodal pressures and flow has been assumed. However, it has been noted that the simplicity of the method in obtaining the solutions and the reasonable accuracy of the calculated permeabilities at low volume fractions of the fibrous network ($\phi < 0.3$) overweigh such limitations.

3.309.3.1.8. Comparison of direct estimations with correlations

Higdon and Ford[98] have calculated the permeability K for ordered fibrous media based on simple cubic, body-centered cubic and face-centered cubic (FCC) lattices. In this study, accurate numerical results based on spectral boundary element DNS methods for the full range of volume fractions have been presented. Their results compare reasonably well with the correlation of Jackson and James (eqn [69]) for $\phi < 0.3$. Clague *et al.*[99] have calculated hydraulic permeabilities from eqn [74] for ordered and disordered media using the flow fields obtained from LB simulations. Good agreement with the semi-analytical results of Sangani and Acrivos[91] (see eqn [71]) has been demonstrated for the ordered media simulations. The simulation results for the disordered media are in good agreement with the results of Jackson and James (eqn [69]) and the permeability calculations of Higdon and Ford's FCC lattices.[98] Jaganathan *et al.*[64] have calculated the permeabilities of 3D hydroentangled fibrous scaffolds using eqn [74]. The flow fields have been obtained using a DVI technique in conjunction with a finite volume-based flow solver. At low values of ϕ, their results for permeabilities are in close agreement with those of eqns [67] and [73]. Tahir and Tafreshi[100] have studied the influence of fiber orientation on the permeability of a fibrous medium. The different orientations of the fibers used in this study are shown in **Figure 8**. A commercial finite volume flow solver (ANSYS) was used to solve for the flow fields, and eqn [74] was subsequently employed to obtain the permeabilities for various fiber orientations. Good agreement of the predicted results with those of eqns [67], [68], and [73] are noted. In Stylianopoulos *et al.*,[101] permeability calculations are then performed for isotropic and oriented fiber networks within the fiber volume fraction range of 0.3–15% using FEM-based DNS. Good agreement is noted between their results and the results predicted with eqn [69] and also with the numerical results of Clague and Phillips,[92] and Higdon and Ford.[98]

Many of the correlations for permeabilities compare quite well with the results of direct simulations for low values of solid volume fraction that are characteristic of applications involving porous biomaterials. With the values of permeabilities so obtained, the flow velocity field within the porous scaffolds may be calculated using averaged equations. The main disadvantage of the averaging procedure is that it smoothes many of the flow structures occurring at the length scales of the pores. In some cases, averaged equations may under predict shear stress variations at the cellular scale inside the scaffolds.[102] This is shown in **Figure 9** where the shear stress results of a fibrous porous medium obtained with DNS simulations using eqns [11] and [12] using the finite volume solver Fluent (ANSYS) is compared with those obtained using the Darcy–Brinkman's model (eqn [55]). A value of $K = 2.23 \times 10^{-12}\,\mathrm{m}^2$ has been used for the Brinkman model. The values of shear stresses predicted by the DNS model are approximately twice as high as the Brinkman model predictions. Therefore, with averaged equations, there always results a trade-off between the level of accuracy obtained and the ease of calculations.

The velocity field obtained using the DNS methods or using the averaged equations may now be used to calculate the mass transport of species as described in the following sections.

3.309.3.2. Mass Transfer Equations

An understanding of the nutrient transport process within a porous scaffold represents one of the key processes in determining the success of a tissue engineering protocol. A review on the need for nutrient transport modeling within a porous scaffold is provided by Sengers *et al.*[103] If the cells are uniformly distributed within a porous scaffold saturated with culture medium, then eqn [7] governs the transport of species such as nutrients, oxygen, and waste products. Assuming a Michaelis–Menten kinetics for the consumption rate $\dot{R}$, the individual species mass transfer equations may then be expressed as

$$\frac{\partial C_i}{\partial t} + \mathbf{u} \cdot \nabla C_i = \nabla \cdot (\mathbf{D}_i \cdot \nabla C_i) - \frac{V_{\max} C_i}{K_m + C_i} \qquad [77]$$

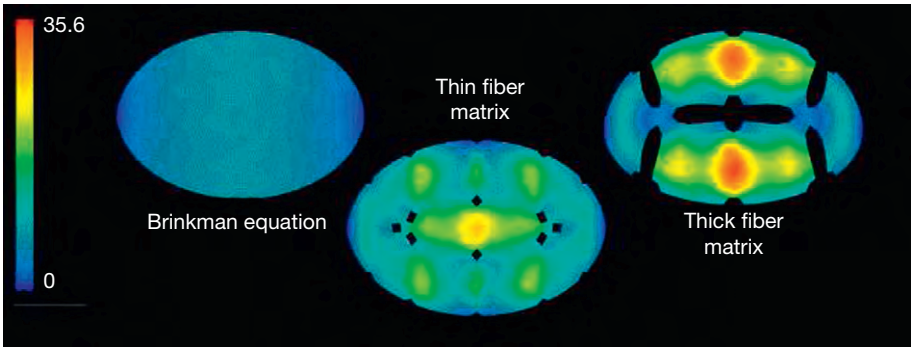

Figure 9 Comparison of shear stress results obtained for a fibrous porous media using Darcy–Brinkan model (left panel) with those obtained using DNS methods for two different fiber thickness but with same permeability, $K = 2.23 \times 10^{-12}\,\mathrm{m}^2$ (the two right panels). Reproduced with permission from Pedersen, J. A.; Boschetti, F.; Swartz, M. A. *J. Biomech.* **2007**, *40*(7), 1484–1492.

As with the flow field estimation, the mass transfer may be evaluated using DNS methods or by employing macroscopic averaged equations that are described in the following sections.

3.309.3.2.1. Direct numerical simulations

The evolution of species concentration within a porous scaffold may be accurately estimated using direct numerical simulations for a known geometry of the porous medium and the associated flow field. As mentioned under **Section 3.309.3.1** for the pore-scale geometry description, the studies of Anderson *et al.*,[54] Raimondi *et al.*,[55] Cioffi *et al.*,[56] Maes *et al.*,[57] and Jungreuthmayer *et al.*[58] have provided detailed microscale pore-level flow field evaluations using the exact geometry obtained from μCT methods. However, none of these studies have evaluated nutrient transport within the scaffolds. Cantini *et al.*[36] have used DNS methods both for the flow and mass transfer to optimize the microenvironment inside porous scaffolds placed in a perfusion bioreactor used for hematopoietic stem cell culture. For computational purposes, the porous scaffold was represented by a periodic unit cell consisting of interconnected spheres representing the pores. The steady-state Navier–Stokes equations (steady-state version of eqn [12] coupled with eqn [11]) were solved with periodic boundary conditions for pressure and velocity using the commercial finite volume code Fluent (ANSYS). For oxygen transport analysis, a nonperiodic model was used that consisted of superimposed periodic units. Oxygen transport was modeled using the steady-state version of eqn [8], with a diffusivity value set equal to $3.29 \times 10^{9}\,\mathrm{m^2\,s^{-1}}$ and partial pressure at the inlet set equal to 152 mmHg (20%). The volumetric oxygen consumption rate $\dot{R}$ representing cellular uptake was modeled using a zeroth-order kinetics and was set equal to a value 1.25×10^{-17} $\mathrm{mol\,s^{-1}}$ per cell. The cell density value ρ_{cd} in eqn [8] was set equal to 10^{12} cells per cubic meter for hematopoietic stem cells and 9×10^{12} cells per cubic meter for stromal cells.

Cioffi *et al.*[104] have quantified in detail the transport of species within a complex 3D porous scaffold using DNS techniques. In this study, a combined macroscale/microscale computational approach was used to quantify oxygen transport and flow-mediated shear stress to human chondrocytes cultured in 3D poly(ethylene glycol terephthalate)/poly(butylene terephthalate) (PEGT/PBT) scaffolds placed in a perfusion bioreactor system. Cells were assumed to form a single layer on the walls of the pores during the initial culture period and hence the wall shear stress on the scaffold surface was assumed to approximate the shear stress on cell surfaces. The boundary conditions for the DNS microscale simulations of the flow field inside the scaffold were obtained by solving an averaged macroscale model based on the Darcy–Brinkman model given by eqn [55]. For the macroscale model, the scaffold was considered isotropic and the permeability K was set to a value of $4 \times 10^{-11}\,\mathrm{m^2}$ and the viscosity value μ was set to 8.1×10^{-4} Pa s. A constant flat velocity profile computed from a specified flow rate is set as the boundary condition at the inlet. For the pore-scale DNS model, the geometry description was obtained using a μCT reconstruction of a foam scaffold. The schematic of the μCT model, the mesh, and the boundary conditions used are given in **Figure 10**.

The steady-state oxygen (O_2) mass transfer distribution was obtained by solving eqn [77] using a finite volume solver Fluent (ANSYS). The volumetric oxygen consumption rate was assumed to follow a Michaelis–Menten type kinetics (eqn [9]). The value for D_i was set equal to $3.23 \times 10^{-12}\,\mathrm{m^2\,s^{-1}}$. **Figure 11** shows the contours of oxygen distribution obtained using the DNS method inside the porous scaffold as given in Cioffi *et al.*[104]

In the DNS methods, although the presence of cells may be directly taken into account as demonstrated by Jungreuthmayer *et al.*[58] and Olivares *et al.*,[51] the modeling of transient development of an engineered tissue within the scaffold still remains an open challenge. The techniques for addressing some of the relevant issues such as tissue growth and the associated changes

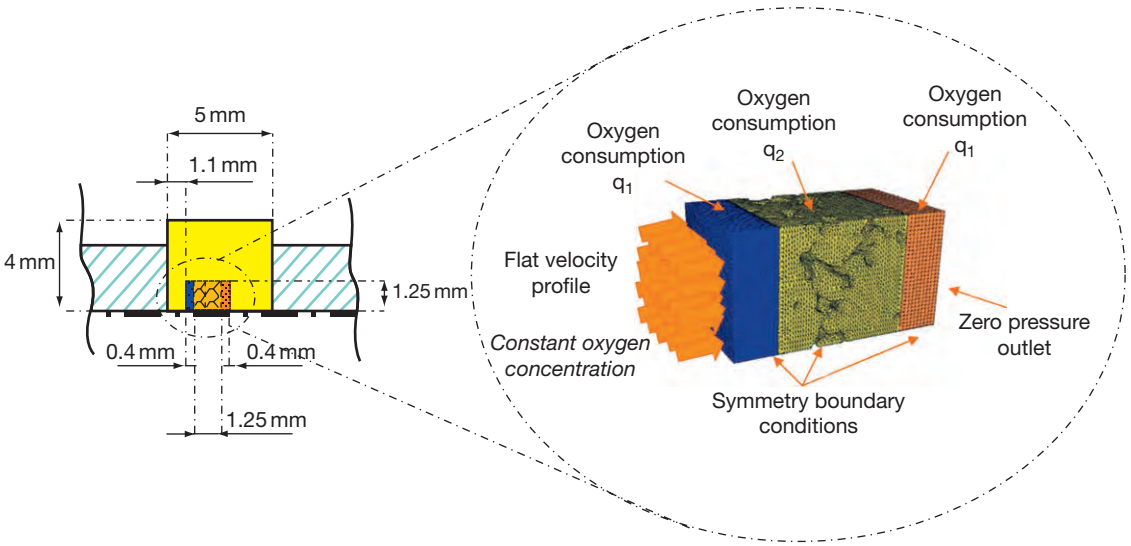

Figure 10 The schematic of μCT model of a porous scaffold used in the study of Cioffi *et al.*[104] The mesh and the boundary conditions used in the DNS simulations of the pore-scale flow and mass transfer are also shown. in porosity and permeability that are difficult to model with DNS are next addressed in the context of volume averaged equations of the mass transport process.

3.309.3.2.2. Macroscopic averaged equations

Averaged equations provide a useful and an efficient way to obtain meaningful solutions both for the flow and the mass transport within a porous scaffold. While providing a reasonable estimate of the fluid flow within a porous construct, the macroscopic averaged flow equations (see **Section 3.309.3.1**) can also account for cell density variations occurring due to proliferation. The changes in the microstructure of the porous medium due to cell growth may be accounted through the changes in porosity values ε_β. This change in ε_β (or ϕ) directly affects the permeability in the macroscopic averaged equations (refer to eqns [64]–[73]). Following Wood *et al.*,[28] a model for species transport inside a porous tissue engineering scaffold taking into account the variations in cell density and corresponding variations in permeability and porosity is presented below. Specifically, the quantification of the consumption/production rates of basic metabolites, such as glucose, oxygen, and lactate are highlighted. The following major assumptions are invoked in the development of the mass transfer models:

1. The cells are assumed to be uniformly attached to the scaffold and hence no cells are suspended in the culture medium (β-phase).
2. The cellular phase (σ-phase) comprises both the cells and the extracellular matrix (ECM).
3. Diffusion mechanism alone is considered to take place in the cellular σ-phase and the diffusion coefficients are the same both inside the cell and in the ECM.
4. The intrinsic average concentration of species in the fluid (c_i^β) and cell (c_i^σ) phases are in local thermodynamic equilibrium. Mathematically, this condition may be expressed for a species i as

$$c_i^\beta = K_{eq} c_i^\sigma \qquad [78]$$

where K_{eq} is the equilibrium constant. The physical constraints for local mass equilibrium assumptions are explained in greater detail in Golfier *et al.*[62] Usually, such conditions apply for transport in biomaterials.

Under these conditions, a single macroscale transport equation can be used to describe the species transport within the porous scaffold.[28] Let ε_β and ε_σ denote the volume fractions of the culture medium and cells, respectively. Also, let ε_s denote the constant volume fraction of the scaffold matrix (fibers). Then, from the definition of volume fractions, we have

$$\varepsilon_\beta + \varepsilon_\sigma + \varepsilon_s = 1 \qquad [79]$$

The solid volume fraction, ϕ, is given by

$$\phi = \varepsilon_\sigma + \varepsilon_s \qquad [80]$$

For highly porous scaffolds, ε_s can be assumed to be negligible. Let c_g^β, c_l^β, and c_o^β represent the intrinsic average concentrations of glucose (subscript g), lactate (subscript l), and oxygen (subscript o), respectively. Following Wood *et al.*,[28] the macroscale balance equations for each of the species may be written as

$$\frac{\partial}{\partial t}\left[\left(\varepsilon_\beta + \varepsilon_\sigma K_{eq_i}\right)c_i^\beta\right] + \nabla\cdot\left(\langle\mathbf{u}\rangle c_i^\beta\right) = \nabla\cdot\left(\mathbf{D}_{eff_i}\nabla c_i^\beta\right) + \varepsilon_\sigma \dot{R}_i \qquad [81]$$

The effective diffusivity tensor of each species is denoted by $\mathbf{D}_{eff_i}$ while K_{eq_i} is given by eqn [78]. Details on the evaluation of $\mathbf{D}_{eff_i}$ is provided in a subsequent section. Here, $\langle\mathbf{u}\rangle$ is the known fluid velocity vector obtained as described in **Section 3.309.3.1**. Glucose and oxygen are consumed by the cells in the σ-phase and their consumption rates are assumed to follow a Michaelis–Menten kinetics.

$$\dot{R}_{(g,\,o)} = -\frac{V_{max(g,\,o)}c_i^\beta}{K_{m(g,\,o)} + c_i^\beta} \qquad [82]$$

In eqn [82], $V_{max(g,o)}$ are the half-maximal rates of consumption and $K_{m(g,o)}$ are the Michaelis–Menten constants for glucose and oxygen, respectively. The lactate production rate of the cells $\dot{R}_l$, in general, depends on $\dot{R}_g$ and $\dot{R}_o$ through the metabolic mass balance equation involving both aerobic and anaerobic processes.[105,106] Generalizing the relation provided in Sengers *et al.*,[105] the following equation may be deduced:

$$\dot{R}_l = \alpha\dot{R}_g + \gamma\dot{R}_o \qquad [83]$$

where α and γ are constants and $\dot{R}_g$ and $\dot{R}_o$ are given by eqn [82]. Sengers *et al.*[105,106] have chosen the values of α and γ to be -2 and $\frac{1}{3}$, respectively. In their studies, it has been assumed that all oxygen uptake is fully used to break down glucose aerobically and none is used for matrix synthesis. In the work of Chung *et al.*,[88] a lower value of $\alpha = 1.6$ has been assumed and γ is set to 0 (the aerobic metabolic pathway is neglected). The values of the various mass transfer parameters for the kinetics appearing in eqns [81] and [82] for glucose, lactate, and oxygen are given in Sengers *et al.*[106] and Chung *et al.*[78] along with the diffusivities of each of the above species both in the culture medium and within the cell (these diffusivities are not the same as $\mathbf{D}_{eff_i}$).

Thus, the concentration of the given species c_i^β is determined by solving the coupled set of equations given by

eqns [79], [81], [82], and [83]. A finite element solution procedure using a commercial solver (Multiphysics 3.2 (COMSOL)) is described in the studies of Chung *et al.*[78,88] It should be noted that in these studies, the definition of K_{eq} is the inverse of one defined in eqn [78].

3.309.3.2.3. Cell growth kinetics

In the most general case, the cell volume fraction ε_σ is not a constant but evolves with time due to cell proliferation and cell death (apoptosis). Using a cell mass balance equation and under the assumption that the cells are immobilized (no bulk motion of cells within the scaffold), the evolution of ε_σ may be modeled using the mechanisms of cell diffusion within the scaffolds and cell growth kinetics. Here, cell diffusion occurs due to random motion of the cells within the scaffold, and in a macroscopic sense, it can be characterized by a diffusion coefficient, D_{cell}[107] and may be assumed as a constant.[78] As described by Galban and Locke,[108] the cell growth kinetics may be modeled using a modified Contois kinetics. The modified Contois growth kinetics incorporates the effect of glucose and lactate in determining the cell population. Following Galban and Locke,[108] the following equation for cell growth rate in terms of the cell volume fraction ε_σ applies:

$$\frac{\partial \varepsilon_\sigma}{\partial t} = D_{cell}\nabla^2\varepsilon_\sigma + \left[\frac{k_g c_g^\beta}{K_c \rho_{cell}\varepsilon_\sigma\left(K_{eq}^{-1} + K_{pr}^{-1}c_l^\beta\right)} - k_d\right]\varepsilon_\sigma \quad [84]$$

Here, k_g is the homogenous cell growth rate coefficient, k_d is the death coefficient (due to apoptosis), K_c is the modified Contois saturation constant, ρ_{cell} is the specific cell density, and K_{pr} is the product susceptibility constant (lactate, in this case). The values of the above parameters typically used in tissue engineering are provided in Galban and Locke,[108] and Chung *et al.*[78,88] It should be noted that other growth kinetics have also been used to study cell growth. For example, in Galban and Locke,[109] Moser and *n*th-order heterogenous kinetics for cell growth have been employed. Lewis *et al.*[110] have used a linear model for cell growth kinetics to investigate the interactions between oxygen concentration field and cell distributions within a seeded 3D scaffold structure.

3.309.3.2.4. Cell growth and modification of flow field equations

Since the volume fraction of the pores change with time, the continuity equation [41] for the fluid needs to be changed to reflect this effect. The general form of continuity equation is given by eqn [58]. If the porosity of a constant density scaffold is such that $\varepsilon_\beta \gg (\varepsilon_\sigma + \varepsilon_s)$, eqn [58] can be simplified to the following equation:

$$\frac{\partial \varepsilon_\beta}{\partial t} + \nabla \cdot \langle \mathbf{u} \rangle = 0 \quad [85]$$

This form of the continuity equation has been used in the studies of Chung *et al.*[78,88] The evaluation of $\mathbf{D}_{eff}$ required to solve eqn [81] is provided below.

3.309.3.2.5. Evaluation of effective diffusivities

Similar to the permeability tensor $\mathbf{K}$, the diffusivity tensor $\mathbf{D}_{eff_i}$ of a given species arises in the volume-averaging procedure of the microscopic mass transfer equations. The evaluation of $\mathbf{D}_{eff_i}$ requires a direct numerical solution to a closure problem very similar to the ones provided for velocity in **Section 3.309.3.1.5**. As noted in that section, the solution procedure for such a closure equation is complicated for realistically structured porous scaffolds. The direct simulation while providing accurate results also requires detailed information about the pore microstructure. One such numerical method for solving the closure problem for the effective diffusivity tensor and the associated boundary conditions has been provided in great detail in the study by Wood *et al.*[28] for the cases of biofilms and tissues. A similar procedure has also been employed and numerically solved by Lux *et al.*[61] using a flux continuous and locally conservative finite volume approach to determine the effective thermal conductivity tensor of real fibrous materials featuring local anisotropic thermal properties. While it is possible to obtain a detailed pore scale structure using methods described in **Section 3.309.3.1**, in many biotechnological applications, such a detailed solution may not be critical.[111] Many of the fibrous scaffolds used in tissue engineering are generally isotropic in the microstructure. For such isotropic systems, $\mathbf{D}_{eff_i}$ may not be very sensitive to the geometry of the microstructure.[28,111] Therefore, just as with the case of permeabilities, simplified geometries may be used to describe the microscale pore structure and analytical solutions may be derived to get reasonable estimates for the effective diffusivities. In this regard, the most popular models/correlations for evaluating the isotropic diffusivities are given below.

1. Chang's unit cell model

   Following the unit cell model given in Chang,[112] Wood and Whitaker[111] have solved the closure problem and obtained the following relation for the isotropic effective diffusivity:

$$\frac{\mathbf{D}_{eff_i}}{\mathcal{D}_{i\beta}} = \frac{3\kappa_i - 2\varepsilon_\beta(\kappa_i - 1) + 2\varepsilon_\beta\varepsilon_\sigma^{-1/3}(4\pi/3)^{\frac{1}{3}}(\gamma_i/l)}{3 + \varepsilon_\beta(\kappa_i - 1) + (3 - \varepsilon_\beta)\varepsilon_\sigma^{-1/3}(4\pi/3)^{\frac{1}{3}}(\gamma_i/l)} \quad [86]$$

Here, $\mathcal{D}_{i\beta}$ is the diffusivity of species i in the culture medium (β-phase), $\kappa_i = \frac{\mathcal{D}_{i\sigma}}{K_{eq}\mathcal{D}_{i\beta}}$ is a relative measure of the importance of intercellular diffusivity $\mathcal{D}_{i\sigma}$ to the diffusivity in the medium $\mathcal{D}_{i\beta}$, and γ_i is a parameter that measures of relative importance of extracellular transport in the β-phase to that of the intercellular reaction and is given by:

$$\gamma_i = \mathcal{D}_{i\sigma}\left(\alpha_2 + \alpha_3 c_i^\beta + \alpha_4 c_i^\sigma + \alpha_5 c_i^\beta c_i^\sigma\right)/(K_{eq}E_0) \quad [87]$$

where α_2–α_5 represent the transport kinetic parameters for facilitated membrane transport mechanism of species i, E_0 represents surface concentration of the transporter proteins, and K_{eq_i} is given by eqn [78]. The details of the facilitated membrane transport mechanisms are given in Wood and Whitaker.[113] The values of κ_i and γ_i are usually determined from experiments. Based on the available experimental data, Wood and Whitaker[111] have suggested γ_i to be in the range 0 to 10, and κ_i in the range 0 to 1. The length scale l appearing in eqn [86] is related to the diameter of a spherical cell (d_p) through the following expression[28]:

$$l = \left(\frac{1}{2}\left[\frac{4\pi}{3\varepsilon_\sigma}\right]^{1/3}\right)d_p \quad [88]$$

Table 2 Representative values for isotropic diffusivities for different species in the fluid (culture medium, β-phase) and in the cellular phase (σ-phase)

Species	$\mathcal{D}_{i\beta}$ ($m^2\,s^{-1}$)	*References*	$\mathcal{D}_{i\sigma}$ ($m^2\,s^{-1}$)	*References*
Glucose	9.17×10^{-10}	34	7.5×10^{-10}	78
Lactate	1.39×10^{-9}	34	1.15×10^{-10}	88
Oxygen	3.29×10^{-9}	33	1.59×10^{-10}	33

2. Maxwell's model

When the rate of transmembrane transport is instantaneous ($\gamma_i \to 0$), eqn [86] may be simplified to yield

$$\frac{\mathbf{D}_{\mathrm{eff}_i}}{\mathcal{D}_{i\beta}} = \frac{3\kappa_i - 2\varepsilon_\beta(\kappa_i - 1)}{3 + \varepsilon_\beta(\kappa_i - 1)} \qquad [89]$$

Equation [89] is referred to as the Maxwell's equation for effective diffusivity.

In Table 2, the representative values of $\mathcal{D}_{i\beta}$ and $\mathcal{D}_{i\sigma}$ of the important species, namely, glucose, lactate, and oxygen are provided.

In recent studies by Chung *et al.*,[78,88] eqn [89] has been used to estimate the diffusivities of glucose and lactate for predicting the mass transfer of nutrients in porous scaffolds. Other correlations for calculating the effective diffusivities as a function of $\mathcal{D}_{i\sigma}$, $\mathcal{D}_{i\beta}$, and ε_σ can be found in the review of Riley *et al.*[114,115] Coletti *et al.*[96] have coupled the macroscale and microscale mass transfer models for a porous scaffold placed in a perfusion bioreactor. They have solved for the transient mass transfer of oxygen within a 3D polymeric scaffold placed inside a perfusion bioreactor combined with cell growth kinetics described by Contois kinetics. The flow external to the scaffold has been described through the Navier–Stokes equations for incompressible fluids while the flow through the scaffold is modeled using Darcy–Brinkman model. Continuity of pressure between the external flow and the inlet of the scaffold and a continuity of velocity at the outlet of the scaffold and external fluid have been assumed. The oxygen uptake rate in the mass transfer model has been described by Michaelis–Menten kinetics. The values of the various parameters used have been provided in their study.

3.309.4. Conclusion

This chapter consists of a review of some of the most recent mathematical models used for solving transport problems involving porous biomaterial scaffolds. While the majority of discussions have been related to perfusion reactors, the model equations have been presented in their most general form and can thus be applied to other bioreactor studies as well. Both direct numerical simulation (DNS) methods and macroscopic averaged equations for porous media have been reviewed in sufficient detail. DNS methods provide the most accurate details of the flow, shear stress, and species concentration fields. The state-of-the-art imaging techniques coupled with DNS serve to be very helpful in pore-scale optimization studies of the scaffold geometry.[36,104] However, the dynamic changes in the geometry of the scaffold architecture due to cell growth and proliferation pose significant research challenges for DNS methods. Even with the advent of powerful computers, DNS calculations are still computationally intensive for large scale optimization studies. On the other hand, macroscopic averaged equations are simpler to solve and by the very nature of their construction may be scaled up for the system level (up to the length scale of bioreactors) optimization. The disadvantage of the averaging procedure is that it smoothes the flow structure at the pore scales and, in some cases, may under predict shear stress variations at the cellular scale inside the scaffolds.[102] However, in most situations, they do produce reasonable engineering estimates of the flow and concentrations fields. While each of the described methods has its own advantages and disadvantages, the choice of any particular method depends on the desired level of accuracy sought for a given application. Both DNS and averaged methods will continue to serve as powerful tools for performing quantitative engineering studies of transport involving bioreactors and biomaterials. Combining the best features of both the methods may enable multiscale optimization studies involving both the bioreactor scale (macroscale) and the pore scale (microscale).[96,104]

3.310.1. Introduction

Biomaterials have been an important consideration for medicine, specifically medical implants, for a long time. Recent advances in biomaterials have even helped expand their uses beyond compatibility, from smart delivery of drugs to directing cell fates.[1] Many synthetic biomaterials, including metals, ceramics, and polymers, are used for bone and joint replacements. Although clinical outcomes with these existing biomaterials are excellent using current surgical techniques, a fundamental understanding of biocompatibility, and possibly, the bioactivity of these biomaterials is still not complete. Evidence is accumulating that the best biomaterials elicit the normal tissue at their surface, and thereby, engender continuous transition to the tissues in which they are inserted. For example, such behavior has been described for titanium, titanium alloys, bioactive glasses, and tyrosine-derived

polycarbonates, among others, with underlying mechanisms ranging from hydroxylation to formation of calcium phosphate layers.[2,3] Such processes are initiated and sustained through rich reaction chemistry including leaching of network modifying ions and formation of Si–OH bonds; dissolution and repolymerization resulting in a SiO_2 gel layer; formation of an amorphous calcium phosphate layer, etc. Current challenges lie in unraveling the molecular mechanisms that underlie this rich chemistry surrounding the interaction of material surface with tissue, which govern bone biocompatibility.[4] Understanding these challenges involves synthesis/characterization (discussed in other chapters) as well as computational simulations (topic of this chapter) of inorganic materials and biomaterials. Rational design of such materials involves development of highly controlled surface chemistry using experimental as well as computational approaches. Experimentally, for example, model surfaces are created using self-assembling monolayer (SAM) chemistry in order to create hydroxylated surfaces, and then proceed to a controlled functionalization (e.g., calcification) of these SAM layers. Computationally, molecular-based simulation tools predict likely recognition sequences and the corresponding conformations at the interface between the material surface and the extracellular matrix (ECM) as well as the cell membrane. Focusing on the molecular mechanisms and how molecular interactions feedback into the signaling environment will lead to new insight into the bioactivity of existing biomaterials. It will be possible to utilize this fundamental knowledge to create new and improved bioengineered constructs for use in bone tissue repair therapies.

3.310.2. Computational Methods

The acceptance of multiscale simulation techniques has helped bridge the gap between theory and experiment.[5] Electronic structure (quantum level or *ab initio*) simulations can reveal how specific molecules assume stable geometrical configurations and charge distributions when subject to specific chemical environment. By examining the charge distributions and structure, it is possible to quantify and predict structural properties as well as chemical reactivity pertaining to the molecule, which are particularly pertinent when investigating novel materials. Although quantum simulations provide a wealth of information regarding structure and reactivity, it is currently not possible to model much more than a few hundred atoms at the most. Molecular dynamics (MD) simulations based on classical (empirical) force fields can model hundreds of thousands of atoms for tens of nanoseconds, and for some systems, up to microseconds. Since MD simulations can be set up at atomic resolution, they are uniquely suited to examine thermodynamic and statistical properties of (bio)materials: such properties include (but are not limited to) Young's modulus, surface hydration energies, and protein adsorption to different surfaces.[6] Coarse-grained or mesoscale simulations are used to bridge the gap between the atomistic scale of MD simulations and continuum approaches such as elasticity theory or hydrodynamics at the macroscale (i.e., milliseconds, millimeters, and beyond).[5]

3.310.2.1. Molecular Dynamics

MD simulation techniques are one of the most commonly used model systems of biomolecules and biomaterials because they can track individual atoms, and therefore, answer questions pertaining to specific material properties.[7,8] To perform MD simulations, the starting point is to define the initial coordinates and initial velocities of the atoms characterizing the model system, for example, the desired biomolecule plus the biologically relevant environment, that is, water molecules or other solvent and/or membranes. The coordinates of the desired biomolecule can usually be found as structural data (X-ray or nuclear magnetic resonance (NMR)) deposited into the protein data bank (PDB)[9] (www.pdb.org); otherwise it is possible to derive initial geometry and coordinate data from model building techniques, including homology methods (see **Section 3.310.2.2**). This step also typically includes the placement and positioning of the environment of the molecules (solvation, ionic strength, etc.). The initial velocities are typically derived from the Maxwell–Boltzmann distributions at the desired temperature of the simulation. The potential of interactions of each of the atoms are calculated using a force field, which parameterizes the nonbonded and bonded interaction terms of each atom depending on its constituent atom connectivity: bond terms, angle terms, dihedral terms, improper dihedral terms, nonbonded Lennard-Jones terms, and electrostatic terms. The potential interactions are summed across all the atoms contained in the system, to compute an overall potential energy function for the system[10–14]:

$$U(R) = \sum_{\text{bonds}} K_b(b - b_0)^2 + \sum_{\text{angles}} K_\theta(\theta - \theta_0)^2 + \sum_{\text{dihedrals}} K_\chi(1 + \cos(\eta\chi - \delta)) + \sum_{\text{impropers}} K_\phi(\phi - \phi_0)^2 + \sum_{\text{nonbonded}} \left(\varepsilon_{ij}\left[\left(\frac{R_{\min_{ij}}}{r_{ij}}\right)\right]\right)$$

Taking the derivative of the potential energy function yields the force, and from Newton's second law, this is equal to mass times acceleration. Although the process seems simple, the derivative function results in a set of $3N$ coupled second-order ordinary differential equations that must be solved numerically. The solution consists of a numerical recipe to advance the positions and the velocities by one time step. This process is repeated over and over again to generate MD trajectories of constant energy. Constant-temperature dynamics are derived by coupling the system to a thermostat using well-established formulations such as the Langevin dynamics or the Nose–Hoover methodologies.[15] Application of MD simulations to biomolecules is facilitated by several popular choices of force fields such as CHARMM[16] (www.charmm.org), AMBER[17] (www.ambermd.org), and GROMOS[18] (www.gromacs.org), as well as dynamic simulations packages and visualization/analysis tools such as NAMD[19] (www.ks.uiuc.edu/Research/namd/) and VMD[20] (www.ks.uiuc.edu/Research/vmd/).

With analysis of MD trajectories, it is possible to calculate statistical properties under a variety of initial and other external conditions[5] such as hydrogen-bond analyses for hydrophilic interactions and solvent-accessible surface area for hydrophobic interactions. For example, by analyzing the relative positions of the hydrogen-bond donors to the hydrogen-bond

acceptors with a preset cutoff angle and a bond length, the hydrogen bonds present in the majority of a given trajectory can be identified to record permanent stabilizing interactions and differentiate them from transient interactions.[21] Similarly, statistical data based on solvent accessible surface area analysis, which maps a surface area by rolling a probe sphere (typically 1.4A) on the protein surface, provides a quantitative metric of hydrophobic stabilization of the solvated protein.

A popular statistical approach to analyze biomolecular dynamics is principal component analysis (PCA).[22,23] PCA solves the eigenvalue equation: $[\sigma - \mathbf{\lambda I}]\xi = 0$ to project out principal components (PCs) or independent modes of atomic motion captured in an MD trajectory and sort them by their variance (in decreasing order). Here, σ is a two-dimensional variance–covariance matrix of atomic fluctuations about the trajectory average, with elements $\sigma_{ij} = \langle (x_i - \langle x_i \rangle)(x_j - \langle x_j \rangle) \rangle$ $(i,j = 1, \ldots, 3N$, N being the total number of atoms with position given by the Cartesian coordinates $x)$; $\xi = (\xi_1, \xi_2, \ldots, \xi_{3N})$ are the $3N$ independent (uncorrelated) eigenvectors (PCs) with eigenvalues $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_{3N})$ sorted in descending order that is, $\lambda_1 > \lambda_2, \ldots, \lambda_{3N-7} > \lambda_{3N-6}$. All global translations/rotations about the center of mass are removed prior to evaluating σ, and the six eigenvalues corresponding to these degrees of freedom are close to zero. The resulting eigenvectors represent the uncoupled PCs (modes orthogonal to each other), and the eigenvalues reflect their magnitude (strength) in the trajectory. Generally, the top ten PCs contain most of the atomic fluctuations in the MD trajectory ($>$ 40–90%); moreover, pairwise correlations between motions of atoms in an extended region of interest, such as the active site of an enzyme, can provide valuable information in relating structure to function through dynamics (or fluctuations) captured in the MD trajectory.[22]

The utility of MD simulations generally depends on the accuracy of the underlying force field. Since force fields are created using empirical energy functions, they are parameterized and tuned to a specific class of molecules; this introduces a constraint on their transferability to model non-native systems or environments and results must often be compared to experimental data, not only to verify their accuracy, but also to identify where methodological improvements can be made. Thus, there is continued development of the basic force field as well as the simulation methodology.

Another important consideration is the ability to perform sufficient sampling of the combinatorially large number of conformations available to even the simplest of biomolecules.[24,25] In this respect, a potential disadvantage of MD calculations is that there is an inherent limitation upon the maximum time step used for the simulation ($\leq$ 2 fs). Solvated systems of protein monomers typically consist of 40 000 atoms, and those of higher order complexes such as dimers or membrane-bound proteins can be as large as 200 000–500 000 atoms. For such system sizes, with current hardware and software, simulation times extending into the microsecond regime and beyond is an exceedingly difficult and labor-intensive endeavor, which requires a combination of algorithmic enhancements as well as the utilization of high-performance computing hardware infrastructure. For example, cutoff distances reduce the number of interactions to be computed without loss of accuracy for short-range interactions but not for long-range (electrostatic) interactions; to help maintain accuracy, long-range corrections such as the particle mesh Ewald algorithm[26] along with periodic boundary conditions are typically implemented. Parallelization techniques enable the execution of the simulations on supercomputing resources of thousands of processors on of a networked Linux cluster. Although a cluster of this size is a big investment, its accessibility is feasible through the US National Science Foundation's TeraGrid Initiative (founded in 2001) for academic researchers. TeraGrid resources (www.teragrid.org) currently include more than a petaflop of computing capability and more than 30 petabytes of online and archival data storage, with rapid access and retrieval over high-performance networks. Capitalizing on advances in hardware architecture, another approach is the creation of custom hardware for MD simulations, and offers one to two orders of magnitude enhancement in performance; examples include MDGRAPE-3[27,28] and ANTON.[29,30] Recently, graphical processing unit (GPU) accelerated computation has come into the forefront to enable massive speed enhancements for easily parallelizable tasks, with early data indicating that GPU accelerated computing may allow for the power of a supercomputing cluster in a desktop, see examples Friedrichs *et al.*[31] and Stone *et al.*[32]

3.310.2.2. Homology Modeling

Protein structure prediction is a fast-growing research field with applications to biotechnology.[33–35] Current experimental techniques for resolving protein structure through X-ray crystallography or NMR spectroscopy are laborious, and thus can solve only a small fraction of proteins sequenced by large-scale genome-sequencing endeavors. At present, at least 6 800 000 protein sequences have been deposited in the nonredundant protein sequence database (NR; accessible through the National Center for Biotechnology Information: ftp://ftp.ncbi.nlm.nih.gov/blast/db/), yet the PDB (http://www.rcsb.org/pdb/) contains fewer than 50 000 protein structures.[36] Given this discrepancy, computational modeling of protein structure has proven to be an invaluable tool for bridging the gap between protein sequence and structure. In particular, homology modeling, or prediction of an unknown structure by using a related protein with a known structure as a template, has been one of the most successful computational techniques for protein structure prediction[37–40]; see also several computer programs and web servers: Swiss-Model server (http://www.expasy.ch/swissmod/), CPH models (http://www.cbs.dtu.dk/services/CPHmodels/), MODELLER[41] (http://salilab.org/modeller/). Homology modeling typically consists of the following steps: search for homologous protein structures, selection of an appropriate template, target-template alignment, model construction, and model quality assessment.

The search for homologous or highly related protein structures to be used as the template for model building typically involves querying the PDB with the target sequence: the target sequence is compared with the sequence of every structure in the database, and potential templates are identified. In order to select the best template for comparative modeling, several factors must be considered. First, the higher the degree of sequence identity between the target and template, the better the quality of the template. Secondly, the similarity between

the environment (i.e., the type of solvent, pH, presence of ligands) of the template and the environment of the target should be considered.[41] In addition, the quality of the template structure, which has been experimentally derived, must be taken into account. For example, resolution of a crystallographic structure is an indicator of the structure quality. Once a template structure has been selected, a target-template alignment must be performed, which can be done by using standard sequence alignment methods.[42–44] However, if the degree of sequence identity between the target and template is below 40%, user intervention is required to correct any gaps or misaligned residues generated in the alignment. More accurate alignments can be generated by incorporating structural information from the template, and some modeling programs, including MODELLER, utilize a combination of sequence and structure information in the alignment algorithm.

Once a target-template alignment is created, several algorithms may be used to build a 3D model of the target protein.[33,35] One commonly employed method is to use distance geometry to satisfy spatial restraints determined from the target-template alignment.[45–47] MODELLER, for instance, imposes spatial restraints that are derived from two sources: homology-derived restraints on the bond distances and angles in the target structure that are based on its alignment with the template structure, and stereochemical restraints on bond distance and dihedral angle preferences that are obtained from a representative set of all known protein structures. The model is then constructed using MD methods to minimize violations of the spatial restraints.

A reliable homology modeling program should allow for modeling of insertions (i.e., loops) during model building. The *ab initio* loop modeling method involves exploring multiple conformations for the specified loop region, and each is then scored by an energy function to identify the most likely loop conformation.[48] Alternatively, a database approach may be employed, which involves identification of a main chain segment that fits the two stem regions of a loop by searching a database of many known protein structures. A limitation of the database approach is the availability of only a small number of known protein structures,[49] whereas the *ab initio* approach is more widely applicable to loop regions bound to ligands or other molecules. Currently, loop regions of up to 12 residues can be modeled accurately using these techniques, provided that the loop environment is well-defined.[41]

The final step in homology modeling is model quality assessment. Over the past couple of decades, several techniques have been developed to assess the quality and correctness of protein structural models. These methods analyze the stereochemical quality of the model, including bonds, bond angles, dihedral angles, and nonbonded atom–atom distances. Several programs, including PROCHECK (www.ebi.ac.uk/thornton-srv/software/PROCHECK[50]) and (WhatCheck swift.cmbi.ru.nl/gv/whatcheck[51]), perform this type of analysis. When there is less than approximately 30% sequence identity between the target and template, external assessment methods must be applied to determine whether a correct template was used.[52] Thus, several different alignments for the same template may be tested, in addition to alternative templates. The model can be further analyzed by computing a residue-by-residue energy profile, where peaks in the profile represent model errors. However, a potential pitfall of this method is that a segment of residues may appear to be erroneous, when in fact it is only interacting with an erroneously modeled region. Therefore, the use of energy profiles should not be the only means of model assessment.

Despite the predictive power and utility of homology modeling, several challenges persist. First, the level of target-template structural conservation and the accuracy of the alignment are key determinants of the quality of the resulting model. If the target-template sequence identity is <20%, approximately half of the residues in the model may be misaligned.[53] This issue can be addressed by modeling based on more than one template, to integrate the most relevant features from each template. Another challenge is that homology modeling programs must evolve new techniques to keep pace with the increasing number of known protein structures. Precomputing structural relationships within the PDB may be helpful in addressing this issue, as many irrelevant structures may be excluded without the need to align them explicitly.[53] An additional challenge in comparative modeling is determination of side-chain conformation. Many side-chain programs are based on rotamer libraries,[54] which contain values for side-chain torsional angles for preferred conformations of specific side chains. However, as the number of rotamers increases, the issue of sampling all potential conformations becomes a combinatorial problem. Xiang *et al.*[55] have recently shown that the use of a rotamer library based on Cartesian coordinates of known structures, rather than optimal bond lengths and angles, can successfully predict side-chain conformation. Thus, local minima for side-chain prediction may be nearly as reliable as the global minimum, and renders the combinatorial problem less of an issue. Despite these present challenges, homology modeling remains a powerful tool for reliable prediction of protein structure. As the accuracy of the technique increases over the next several years, comparative modeling will further close the gap between the number of known sequences and the number of available structures, as well as deepen our understanding of the relationship between protein structure and function.

3.310.2.3. Free Energy

The second law of thermodynamics states that natural systems seek a state of minimum free energy at equilibrium. Thus computation of free energy of a system is important in comparing the results of simulation and experiment. Several different methods have been implemented for calculation of the free energy of various biological systems, and here we will discuss two of the more commonly employed techniques, namely, the free-energy perturbation (FEP) method[56] and umbrella sampling.[57]

3.310.2.3.1. Free-energy perturbation

In molecular systems, the free-energy problem is typically presented in terms of computing a free-energy difference, ΔF, between two defined thermodynamic states, for example, a ligand-bound versus unbound molecule. The free-energy difference between the two states is expressed as[58]:

$$\Delta F = -\frac{1}{\beta} \ln \langle \exp[-\beta \Delta v(x)] \rangle_0; \ \beta = \frac{1}{k_B T}$$

where the subscript zero indicates configurational averaging over the ensemble of configurations representative of the initial state of the system, k_B is the Boltzmann constant, T is the temperature, and $v(x)$ is the potential energy function that depends on the Cartesian coordinates of the system, $[x]$. ΔF can also be computed by the reverse integration:

$$\Delta F = -\frac{1}{\beta} \ln \langle \exp[-\beta \Delta v(x)] \rangle_1$$

where the subscript '1' indicates averaging over the ensemble of configurations representative of the final state of the system. The most straightforward implementation of the FEP method involves defining the potential energy function for each state and performing an MD simulation for the initial state of the system, thus calculating the ensemble average in eqn [1]. Both forward and backward integrations may be run to obtain an estimate of the statistical uncertainty in ΔF. This uncertainty arises from configurations sampled in the ensemble representative of the initial state but not the final state and vice versa, and is typically small when the initial and final states of the system are very similar (i.e., the free-energy difference between the initial and final states is in the order of $2k_BT$, or 1.5 kcal mol^{-1}).[59] However, for systems in which the free-energy difference is significantly larger, a series of intermediate states must be defined and must differ by no more than $2k_BT$. The total ΔF can then be computed by summing the ΔF's between the intermediate states:

$$\Delta F = -\frac{1}{\beta} \sum_{i=1}^{M+1} \ln \langle \exp[-\beta[v(x;\lambda_{i+1}) - v(x;\lambda_i)]] \rangle_{\lambda_i}$$

where M indicates the number of intermediate states and λ is the coupling parameter, which is a continuous parameter that marks the extent of the transition from the initial to the final state. As λ is varied from 0 (initial state) to 1 (final state), the potential energy function $v(x;\lambda)$ passes from v_0 to v_1.

A limitation of this method is that the end points of the transformation, which correspond to the creation or elimination of a group of atoms, are subject to van der Waals (VDW) clashes that result in end-point catastrophes.[60,61] To obtain an accurate estimate of the free energy at the diverging end points, the number of windows at the beginning and end of the FEP simulations can be increased to collect data at several points with λ values close to 0 or 1. Another challenge is particularly relevant to biological systems, as there are often multiple ways that a ligand can bind to a receptor.[58] Indeed, some of these possibilities will result in comparable free-energy estimates. However, the current FEP methodology must improve upon ways to distinguish among the alternative possibilities and thoroughly sample the possible conformations at a binding site. Despite these limitations, the FEP method is capable of providing an accurate theoretical estimate of the free energy of numerous biomolecular systems.[62–65]

3.310.2.3.2. Umbrella sampling

This procedure enables the calculation of the potential of mean force (free-energy density) along an *a priori* chosen set of reaction coordinates or order parameters, from which free-energy changes can be calculated by numerical integration (see for example Chandler[66]). For the free-energy calculation, the probability distribution $P(\chi_i)$ is calculated by dividing the range of order parameter χ_i into several windows. The histograms for each window are collected by harvesting and binning trajectories in that window, from which the potential of mean force $\Lambda(\chi_i)$ is calculated; the potential of mean force $\Lambda_i(\chi_i)$ is given by[67,68]

$$\Lambda_i(\chi_i) = -k_BT \ln(P(\chi_i)) + \text{Constant; then, } \exp(-\beta \Delta F) = \int \exp(-\beta \Lambda_i(\chi_i)) d\chi_i$$

The functions $\Lambda_i(\chi_i)$ in different windows are pieced together by matching the constants such that the Λ_i function is continuous at the boundaries of the windows. Thus, the arbitrary constant associated with each window is adjusted to make the Λ function continuous. The standard deviation in each window of the potential of mean force calculations is estimated by dividing the set of trajectories in two blocks and collecting separate histograms. The calculation of the multidimensional potential of mean force (multiple reaction coordinates) using the weighted histogram analysis method (WHAM) has been reviewed by Roux,[69] which enables an easy and accurate recipe for unbiasing and combining the results of umbrella sampling calculations and simplifies considerably the task of recombining the various windows of sampling in complex systems and of computing ΔF.[68–72]

3.310.2.4. Electronic Structure Methods

Molecular simulations using the empirical force-field approach are rooted in the validity of classical mechanics. Electronic structure methods[73–75] that relieve this fundamental assumption are often necessary in force-field development as well as in understanding chemical reaction pathways and catalytic mechanisms. While electronic structure methods are computationally rather demanding, recent advances in mixed quantum mechanics molecular mechanics (QM/MM) methods also enable us to combine high-level electronic structure methods with MM.[76–87] This multiscale description of force fields provides a route to extend the electronic structure methods to the nanometer scale to enable the study of biomolecular systems. Compared to their classical counterparts,[11,88–112] the quantum approaches (such as the empirical valence bond[76,77]) and mixed QM/MM approaches are more challenging to apply in the biochemical context, though several successful demonstrations are available.[62,84,113–116] Here, we describe the utility of electronic structure methods in force-field development as well as in the study of catalytic reaction mechanisms.

3.310.2.4.1. Electronic structure methods in force-field development

In order to obtain an accurate description of molecular parameters (force field), we require specification of geometric parameters such as bond, angle, dihedral angles, etc., energetic terms such as partial charges, bond/angle/dihedral stiffness, and contributions of solvation–desolvation. Consistent with existing biomolecular force fields, it is thus essential to parameterize any new compound/molecule/chemical modification in the model and extend the force field for accurate representation of the model system. This procedure usually involves a series of steps[10,12] described below.

The geometry of new compounds is optimized using an electronic structure method such as Hartree–Fock (HF)[73] and by using a set of basis functions to represent the electronic wave function. Such calculations are facilitated by the aid of quantum chemistry software such as GAUSSIAN (www.gaussian.com[73]). Geometry optimization yields the spatial electron density 0 K, from which the partial (Mulliken) charges on each atom are inferred. Moreover, the frequency spectrum of the molecule to characterize its vibration spectrum in the ground state is also computed using the analysis of normal modes (**Figure 1(a)**). In order to represent delocalized (low-frequency) motions such as torsional oscillations, a torsional energy scan is also performed (**Figure 1(b)**).

In determining empirical force-field parameters for new compounds, consistency and compatibility with the parent force field is an important criterion. For example, the CHARMM27 force field is commonly used as an all-atom empirical force field for biomolecules; it is therefore necessary to develop force-field parameters for new compounds consistent with the rest of the CHARMM27 force field.

To obtain these parameters,[117] partial atomic charges are calculated using CHarges from ELectrostatic Potentials using a Grid based method (CHELPG)[118] in GAUSSIAN and further adjusted to reproduce interaction energy of H-bond donor/acceptor atoms in the compounds with water molecules. The intramolecular parameters such as molecule geometry and force constants are determined by using structural and vibrational data derived from electronic structure calculations (**Figure 1(a)**). Intramolecular force constants are initially assigned on the basis of existing parameters of compounds with similar structure and further refined following an automatic procedure using a genetic algorithm (GA) to optimize a merit function,[106] which matches both eigenvalues and eigenvectors estimated using the electronic structure calculations (i.e., using GAUSSIAN) to those resulting from a normal mode analysis calculated from classical molecular mechanics calculations, that is, using CHARMM[119] (see **Figure 2**).

3.310.2.4.2. QM/MM simulations

In the QM/MM simulations, the system is subdivided into two subregions, the quantum mechanical subregion (QM region) where the reactive events take place, and the molecular mechanical subregion (which provides the complete environment around the reactive chemistry).[77,79] Since electronic structure methods are limited by the number of atoms they can handle (typically 50–500), the QM subregion is restricted to a small number of atoms of the total system. For example, in an enzymatic system, the quantum region can consist of catalytic ions, water molecules within 3Å of the catalytic ions, parts of the substrate molecules, and the catalytic amino acid residues (such as aspartic acids). The remaining protein and solvent molecules are treated classically using the regular classical force field (such as CHARMM27).

In QM/MM simulations, wave function optimizations are typically performed in the quantum (or QM) subregion of the system using an electronic structure method such as density functional theory (DFT).[74] In this step, the electrostatic coupling between the QM and the MM subregions is accounted for: that is, the charges in the MM subregion are allowed to polarize the electronic wave functions in the QM subregion. The forces in the quantum subregion are calculated using DFT on the fly, assuming that the system moves on the Born–Oppenheimer surface.[79,120] That is, we assume a clear

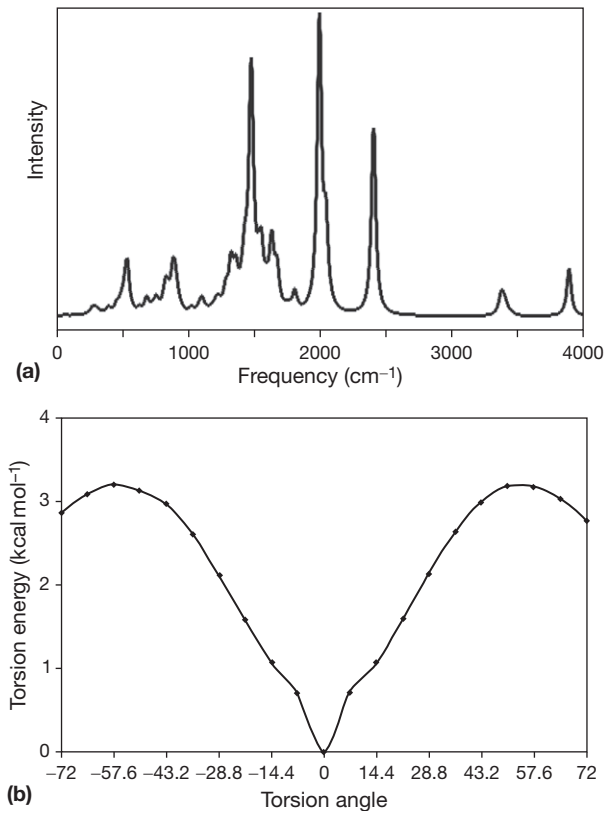

Figure 1 (a) Calculated infrared spectrum of model compound at 300 K and (b) calculated torsional energy scan of the compound.

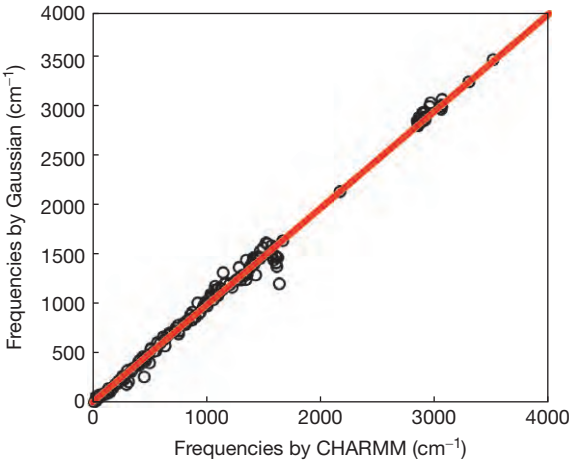

Figure 2 Frequency-matching for electronic structure and molecular mechanics calculations.

timescale of separation between the electronic and nuclear degrees of freedom, and the electronic degrees of freedom are in their ground state around the instantaneous configurations of the nuclei. The forces on the classical region are calculated using a classical force field. In addition, a mixed Hamiltonian (energy function) accounts for the interaction of the classical and the quantum subregions. Since the QM/MM boundary often cuts across covalent bonds, one can use a link atom procedure[82] to satisfy the valences of broken bonds in the QM subregion. Also, bonded terms and electrostatic terms between the atoms of the QM region and those of the classical region are typically included.[80]

From a practitioner's standpoint, QM/MM methods are implemented on the basis of existing interfaces between the electronic structure and the MD programs, one implementation is between GAMESS-UK (www.cfs.dl.ac.uk[121]) (an *ab initio* electronic structure prediction package) and CHARMM.[16] The model system can then be subjected to the usual energy minimization and constant-temperature equilibration runs at the desired temperature using the regular integration procedures in operation for pure MM systems; it is customary to carry out QM/MM dynamics runs (typically limited to 10–100 ps because of the computationally intensive electronic structure calculations) using a standard 1 fs time step of integration. The main advantage of the QM/MM simulations is that one can follow reactive events and dissect reaction mechanisms in the active site while considering the explicit coupling to the extended region. In practice, sufficient experience and care is needed in the choices of the QM subregion and the many alternative choices of system sizes, as well as the link atom schemes need to be compared to ensure convergence and accuracy of results.[80] The shorter length of the dynamics runs in the QM/MM simulations (ps) relative to the MM MD simulations (ns) implies that sufficiently high-resolution structures are usually necessary for setting up such runs as the simulations only explore a limited conformational space available to the system. Another challenge is an accurate and reliable representation of the mixed QM/MM interaction terms.[83] These challenges are currently being overcome by the suitable design of next-generation methods for electronic structure and molecular mechanics simulations.[122,123]

3.310.2.5. Methods for Determining Reaction Paths

Brute-force MD simulations of realistic models are restricted to the nano- to microsecond regimes. The development of long-time dynamics and sampling algorithms is a well-appreciated central objective of single-molecule biophysics, as the prediction of biologically relevant properties that occur in the timescale upward of a microsecond has remained a problem. Sampling the complex configurational space of biomolecules is a challenge, but can be partially overcome via smart sampling techniques,[124–127] umbrella sampling,[63,69]steered and targeted dynamics,[98,128] meta-dynamics,[129,130] Tsallis statistics,[131,132] adaptive sampling,[133] and density-of-states Monte Carlo.[134,135] Path-based methodologies seek to describe transition pathways connecting two well-defined states[93,136,137]; practical applications of this ideology are available through methods such as stochastic path approach,[138] nudged elastic band,[139–141] finite temperature string,[133] and transition path sampling (TPS),[142–144] each of which exploits the separation in timescales in activated processes, namely, the existence of a shorter timescale of relaxation at the kinetic bottleneck or the transition state (τ_{relax}), in comparison to a much longer timescale of activation at the transition state itself (τ_{TS}). Below, we review the path-based method of TPS and the related method of Bolas sampling.

3.310.2.5.1. Transition path sampling[142,143]

TPS aims to capture rare events (excursions or jumps between metastable basins in the free-energy landscape) in molecular processes by essentially performing Monte Carlo sampling of dynamics trajectories; the acceptance or rejection criteria are determined by selected statistical objectives that characterize the ensemble of trajectories. In TPS, time reversible MD trajectories in each transition state region are harvested using the shooting algorithm[144] to connect two metastable states via a Monte Carlo protocol in trajectory space. Essentially, for a given dynamics trajectory, the state of the system (i.e., basin A or B) is characterized by defining a set of order parameters $\chi = [\chi_1, \chi_2, \ldots]$. Each trajectory is expressed as a time series of length τ. To formally identify a basin, the population operator $h_A = 1$ if and only if a particular molecular configuration associated with a time t of a trajectory belongs to basin A; otherwise $h_A = 0$. The trajectory operator $H_B = 1$ if and only if the trajectory visits basin B in duration τ, that is, there is at least one time slice for which $h_B = 1$; otherwise $H_B = 0$. The idea in TPS is to generate many trajectories that connect A to B from one such existing pathway. This is accomplished by a Metropolis algorithm that generates an ensemble of trajectories $[\chi^\tau]$ according to a path action $S[\chi^\tau]$ given by: $S[\chi^\tau] = \rho(0)h_A(\chi_0)H_B[\chi^\tau]$, where $\rho(0)$ is the probability of observing the configuration at $t = 0$ ($\rho(0) \propto \exp(-E(0)/k_BT)$, in the canonical ensemble. Trajectories are harvested using the shooting algorithm[144]: a new trajectory $\chi^{*\tau}$ is generated from an existing one χ^τ by perturbing the momenta of atoms at a randomly chosen time t in a symmetric manner,[144] that is, by conserving detailed balance. The perturbation scheme is symmetric, that is, the probability of generating a new set of momenta from the old set is the same as the reverse probability. Moreover, the scheme conserves the equilibrium distribution of momenta and the total linear momentum (and, if desired, the total angular momentum). The acceptance probability implied by the above procedure is given by $P_{acc} = \min(1, S[\chi^{*\tau}]/S[\chi^\tau])$. With sufficient sampling in trajectory space, the protocol converges to yield physically meaningful trajectories passing through the true transition state (saddle) region.

The convergence of each sampling run is monitored by calculating the autocorrelation function of the order parameter. The characteristic relaxation time τ_{mol} associated with the crossing of each transition state region is given by the time taken for the gradual transition of the autocorrelation function $\langle\chi_i(0)\chi_i(t)\rangle$, where $\langle\cdot\rangle$ denotes the average over the ensemble of generated trajectories. Order parameter autocorrelation functions transition from an initial value $\langle\chi_i(0)\chi_i(\tau)\rangle \approx \langle\chi_A^2\rangle$ to a final value $\langle\chi_i(0)\chi_i(\tau)\rangle \approx \langle\chi_A\rangle^*\langle\chi_B\rangle$, to indicate crossing of the barrier region between two metastable regions A and B over

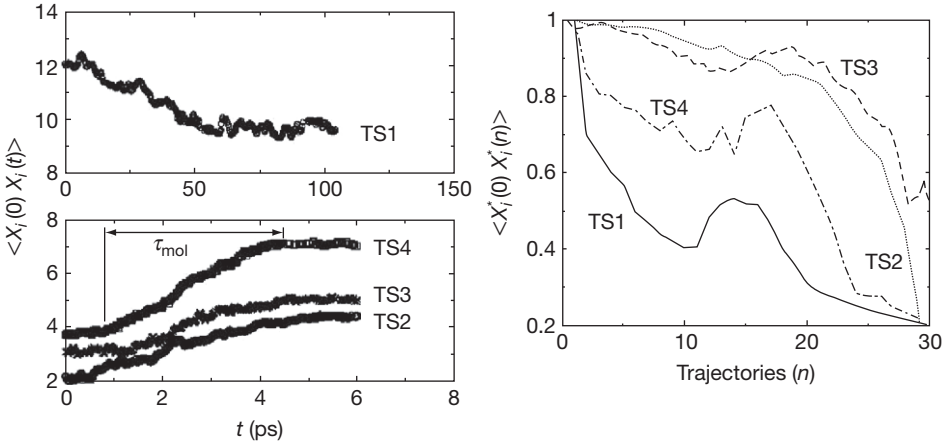

Figure 3 Convergence analysis in TPS simulations. Left: order parameter correlation functions transitioning between $\sim \chi_A^2$ and $\sim \chi_A\chi_B$ in a timescale of τ_{mol}. Right: decorrelation of transition paths.

time τ. The timescale of barrier relaxation τ_{mol} is inferred from these correlation functions graphically. Shown in Figure 3 are these functions for four different sampling runs. The top left panel captures a large subdomain motion, while the bottom left panel captures three residue flips during the closing conformational change.[145] The gradual change in the order parameters indicates the decorrelation in each TPS run. In addition to the autocorrelation functions associated with order parameters, an assessment of the quality of our sampling by checking for the decorrelation of order parameters in path (Monte Carlo) space is necessary. This is achieved by calculating the function $\langle \chi_i^*(0)\chi_i^*(n)\rangle$, where n represents the harvested trajectory number, and χ_i^* is the value of the order parameter evaluated at a particular time slice at the bottleneck of the transition. In calculating this correlation function, no shifting with respect to the first trajectory is done. This removes the trivial decorrelation because of the shifting moves. Figure 3 shows such correlation functions; it is evident from Figure 3 that, on average, every 10th to 20th trajectory is statistically decorrelated; therefore the 200–300 trajectories that are generated for each TS ensure sufficiently good sampling, see examples Radhakrishnan and Schlick[145] and Bolhuis.[146]

3.310.2.5.2. BOLAS sampling for calculating free energies

BOLAS is motivated by the method of TPS. BOLAS generates an ensemble of MD trajectories using a Monte Carlo protocol with an appropriate action S based on shooting perturbations. Below, we define the BOLAS action S and show that using BOLAS, the free energy as a function of a reaction coordinate or order parameter chosen *a priori* can be computed. The BOLAS path action (different from the TPS path action) is $S[\chi^\tau] = \rho(0)$. The need to use a modified path action for BOLAS stems from our requirement to compute the unbiased probability distribution of a given order parameter at equilibrium. In principle, configurations contained within the trajectories harvested by TPS are also obtained from the shooting algorithm. However, the bias imposed at the boundaries due to the $h_A(\chi_0)$ and $H_B[\chi^\tau]$ in the TPS action prevents the correct estimation of the equilibrium probability distribution $P(\chi)$. This is because the contribution to $P(\chi)$ comes from six classes of trajectories: trajectories that start in A and visit B in time interval τ; trajectories that start in B and visit A; trajectories that neither originate in A nor B, but visit both the states in the time interval τ; trajectories that visit A and not B; trajectories that visit B and not A; and trajectories that neither visit A nor B. The TPS action includes only the first class of trajectories; an action defined by $S[\chi^\tau] = \rho(0)H_A[\chi^\tau]$ $H_B[\chi^\tau]$ includes the first three classes of trajectories; the BOLAS action includes all six classes of trajectories.

Since detailed balance is preserved for the momentum perturbation move of the shooting algorithm and the individual MD trajectories conserve a stationary (equilibrium) distribution ρ, the configurations contained within the ensemble of the generated trajectories are also distributed according to the equilibrium distribution ρ (see derivation in Radhakrishnan, and Schlick[70]). Thus, from the ensemble of trajectories generated using the BOLAS action, the equilibrium probability distribution of the order parameter can be calculated by binning the data from accepted trajectories into histograms of the order parameters. In our implementation, the desired range of χ is divided up in terms of smaller windows and the BOLAS protocol is used to independently sample the configurations in each of these windows. This is equivalent to performing an umbrella sampling. The functions in different windows are then pieced together by using the WHAM algorithm.[69] The validity and application of BOLAS have been illustrated in several applications of protein–nucleic acid interactions.[70,145,147]

3.310.2.6. Effect of Force on Biomolecules

In single-molecule experiments, a force applied can linearly couple to a reaction coordinate and alter the free-energy landscape. If A and B denote the ground and transition states for a given transition (associated with catalysis or a ligand-binding event), then according to transition state theory the equilibrium constant for the system to switch from state A to B in the absence of any external force is $K_{eq}(0) \propto \exp(-\Delta G/k_B T)$, where ΔG is the free-energy difference between A and B.[148] Within the linear response limit, the applied force will shift the

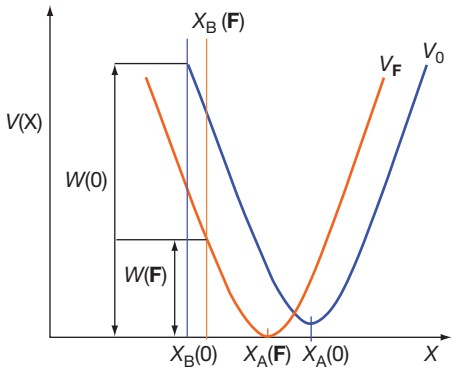

Figure 4 Schematic of the effect of the force on the free-energy landscape.

ground state equilibrium position $X_A(\mathbf{F})$ and the position of the transition state $X_B(\mathbf{F})$.[148] Thus, the change in the total (free) energy cost to transition from state A to state B, that is, $\Delta W = W(0) - W(\mathbf{F})$, under an applied force $\mathbf{F}$ acting along X is $\Delta W(\mathbf{F}) = W(0) - 0.5k_x[X_B(\mathbf{F}) - X_A(\mathbf{F})]^2$, which will alter the equilibrium constant (see Figure 4)[148]:

$$K_{eq}(\mathbf{F}) \propto \exp\left(-[\Delta G - \Delta W(\mathbf{F})]/k_B T\right)$$

Such a linear response, which assumes a perfect alignment of the applied force and the reaction coordinate, is assumed in the Bell model for receptor–ligand interactions, as well as in models of two-state transitions used to interpret single-molecule experiments.[148,149] However, the force will change X only if a coupling exists between X and the applied force. We can explore this coupling by carrying out a PCA (see Section 3.310.2.1).[23] The coupling between the applied force and a coordinate X occurs through the alignment of the force and the PCs and how the PCs impact the coordinate X. While the former can be quantified by projecting the force component along the eigenvectors, the latter can be quantified linearly combining the PCs to describe the motion along X, as we illustrate below.[150]

An external force applied to a molecule will displace atoms in a given active site. Let $\Delta\mathbf{x} = (\Delta x_1, \Delta y_1, \Delta z_1, \Delta x_2, \Delta y_2, \Delta z_2, \ldots, \Delta x_{3N}, \Delta y_{3N}, \Delta z_{3N})$ be the $3N$-dimensional displacement vector that represents the displacement of the N atoms in the active site due to the applied force $\mathbf{F}$. We can express this displacement vector in terms of the $3N$ normalized PC modes ξ_m which forms a complete basis as, $\Delta\mathbf{x} = \sum_m a_m \xi_m$, with expansion coefficients a_m. Under the quasiharmonic approximation and linear response, the Hamiltonian (energy function) for the system is given by:

$$H = \frac{1}{2}\sum_{m=1}^{3N} k_m (a_m \xi_m)^2 - \sum_{m=1}^{3N} \mathbf{F}\cdot(a_m \xi_m)$$

That is, in the quasiharmonic approximation, for each eigenvector ξ_m the spring constant corresponds to $k_m = k_B T/\lambda_m$.[23] At equilibrium, we have $\partial H/\partial a_m = 0$ for each a_m which gives:

$$a_m = \frac{\mathbf{F}\cdot\xi_m}{k_m} = \frac{|\mathbf{F}|\cos\theta_m}{k_m}$$

Here, $\mathbf{F}$ is a $3N$-dimensional vector representing the force on the active site fragment and θ_m is a generalized angle between $\mathbf{F}$ and ξ_m (PCs are normalized):

$$\cos\theta_m = \frac{\mathbf{F}\cdot\xi_m}{|\mathbf{F}|} = \frac{\sum_{i=1,\ldots,N}^{j=x,y,z} F_i^j \xi_{mi}^j}{\sqrt{\sum_{i=1,\ldots,N}^{j=x,y,z} (F_i^j)^2}}$$

where F_i^j denotes the component of applied force acting on the ith atom of the active site fragment in the direction j. In the experiments, the force is applied by tethering polymer chains (e.g., DNA) to the ends of the molecule, based on which we can define the applied force to be

$$F_i^j = F_0(i) n_j \quad \forall i \in [x_T]$$

$$F_i^j = 0 \quad \forall i \notin$$

Here $F_0(i)$ is the magnitude of force acting on the ith atom $\left(|\mathbf{F}| = \sqrt{\sum_{i=1}^{N_T} (F_0(i))^2}\right)$ and $[x_T]$ is a subset of N_T atoms subject to the force. The components n_j $(j = x, y, z)$ belong to a unit vector along the applied force direction. We generally assume that $[x_T]$ includes only the heavy atoms and that the region subject to the force is small enough so that the same force $F_0(i) = |\mathbf{F}|/\sqrt{N_T}$ acts on all the atoms. Calculations are performed by varying $|\mathbf{F}|$ to get the resultant change in the active site geometry due to the applied force $\mathbf{F}$: $\mathbf{R}(\mathbf{F}) - \mathbf{R}(0) = \sum_m a_m \xi_m$, where, $\mathbf{R} = (x_1, x_2, \ldots, x_{3N})$ is the vector representing the geometry of the active site. Here, $\mathbf{R}(0)$ is the ground state active site geometry at zero force for which $X = X_A(0)$, and $\mathbf{R}(\mathbf{F})$ is the new active state geometry due to $\mathbf{F}$ for which $X = X_A(\mathbf{F})$. The force along X which causes a displacement, $\Delta X_A(\mathbf{F}) = X_A(\mathbf{F}) - X_A(0)$ is $F_x(\mathrm{F}) = -k_x \Delta X_A(\mathrm{F})$. The spring constants k_x can simply be obtained from the distribution (histogram) of X values P_x in MD trajectories by fitting a harmonic function to the energy of the distribution $E(X) = (1/2)k_x X^2 = -k_B T \ln(P_x)$. Since the free-energy surface projected along the reaction coordinate has a maximum at the transition state, the negative curvature is approximated as $k_{ts} = -\mu(\omega_{ts})^2$, where μ is the reduced mass of the coordinate at the transition state and ω_{ts} is the passage time in transition state theory: $\omega_{ts} = -k_B T/\hbar$. Assuming that the same force acts on X throughout the system's passage from the ground to the transition state (the dynamic coupling is unaltered), the displacement of the transition state value of X, $\Delta X_B(\mathbf{F}) = X_B(\mathbf{F}) - X_B(0)$, is given as:

$$\Delta X_B(\mathbf{F}) = \frac{F_x(\mathbf{F})}{k_{ts}} = -\frac{k_x}{k_{ts}} \Delta X_A(\mathbf{F})$$

Note that the displacements $\Delta X_A(\mathbf{F})$ and $\Delta X_B(\mathbf{F})$ have opposite signs due to positive/negative curvatures of the free energy for ground/transition states. We employ the full

set of $3N-6$ PC modes to calculate the displacements $\Delta X_A(\mathbf{F})$ and $\Delta X_B(\mathbf{F})$ and obtain the ratio $K_{eq}(\mathbf{F})/K_{eq}(0) = \exp(\Delta W(\mathbf{F})/k_BT)$.[150]

3.310.2.7. Limitations and Caveats

MD simulations suffer from inherent modeling limitations (force-field uncertainties, solvent approximations, limited sampling, finite size effects, etc.). Some of these issues (e.g., finite size effects) are difficult to overcome because of constraints posed by computational resources, while others can be addressed to some degree. It is prudent to test the effect of force fields on active site geometry by comparing, for example, different force fields such as CHARMM and AMBER. While solvent effects are taken into account by explicitly treating water molecules, there is, in general, the problem of determining the protonation states. This can be dealt with at the mean field level by using Debye–Huckel calculations for titratable side-chain residues and by Poisson–Boltzmann (MMPBSA)[151] evaluation of the relative free energies for residues participating in the catalytic reaction. QM/MM calculations can be used to further assess the relative stabilities of the different protonation states. The QM/MM methodologies make some approximations as well. Perhaps the most significant is the choice of the QM/MM boundary. Since the boundary between the MM and QM regions cuts through covalent bonds, the single link atom procedure satisfies valences of broken bonds. In particular, the electrostatic terms involving the MM host atoms that connect to the QM region need to be excluded from the Hamiltonian. The test cases[80] have shown that the double link atom method yields better numerical accuracy to the other popular approaches using the local self-consistent field (LSCF) formalism and single link atom approach.[82] The study also notes that single link with partially visible MM atoms yields comparable results with the double link procedure. Other benchmark recipes for link atoms such as the pseudobond method[83] are also available. In order to handle complex chemistry, there is generally a need employ a high-level electronic structure method such as DFT, with a reliable energy functional and a high-level set of basis functions often allowing for polarization.

The issue of limited timescales explored in MD simulations can be overcome to an extent by smart sampling algorithms as discussed in **Section 3.310.2.5**. Of course, these long-time algorithms have shortcomings of their own: these include issues of multiple pathways and choice of order parameters. In general, there is a need to devise several assessment tools to monitor the quality of sampling and to control the statistical error. The limitations of PCA in extracting dominant modes of protein dynamics arise because of the finite simulation time of the MD trajectory.[152,153] While PCA is not reliable for describing the slow modes of the system beyond what is captured in the dynamics trajectory it is based on, it does provide an approximate description of the slow modes faster than the timescale of the trajectory (t). The error in the eigenvalue propagates as $(tv_i)^{-1/2}$, where v_i is the frequency of the ith mode. Despite the methodological approximations and limitations, we vouch for the notion that the predictions from such simulations can be made to have sufficient accuracy to make meaningful contact with experimental literature.

3.310.3. Applications

3.310.3.1. *Ab Initio* Simulations of Material Properties

The advantages of employing titanium (Ti) alloys in biomedical implant applications, such as hip and knee prostheses, include high fatigue resistance, good ductility and wear resistance, low cytotoxicity, and low elastic modulus[154–156] (see also **Chapter 1.102, Metals for Use in Medicine**). Ti and Ti-based alloys typically occur in either one or a mixture of two crystalline structures: the α-phase, which assumes the hexagonal structure, and the β-phase, which assumes the body-centered cubic (bcc) structure. Several recent studies have demonstrated that many of the biomedical constraints for implant applications can be met by designing Ti alloys that use the most biocompatible elements, such as Ta, Mo, and Nb, as alloy components for preferentially stabilizing the bcc β-phase over the α- or α–β-phases.[157–159] In particular, β-Ti alloys have an elastic modulus that is lower than that of most commonly used α- or α–β-Ti alloys. This is important because bone-replacing implants must have a low elastic stiffness that simulates that of the surrounding bone tissue.[155,156] Thus, key criteria for optimizing the design of Ti alloys include the stabilization of the bcc β-phase at room temperature and the reduction of the elastic stiffness relative to currently employed Ti-based alloys.

Raabe *et al.* (http://adsabs.harvard.edu/abs/2008arXiv0811.0157R) addressed these biomedical constraints by applying both quantum mechanical simulations and experiments to the design of biocompatible β-titanium (β-Ti) alloys with a small elastic modulus. Specifically, they restrained their search to binary alloys composed of Ti–Mo and Ti–Nb, and obey the following constraints: composed of nontoxic elements, stable in the β-phase, and low Young's modulus. The binary alloys were computationally represented as supercells composed of $20\times 2\times 2$ cubic or hexagonal unit cells with a total of 16 atoms. In this way, many different alloy compositions could be investigated by systematically substituting Nb or Mo atoms for Ti atoms. The group then calculated the alloy formation energy for each composition, which is the fundamental quantity representing the thermodynamic stability of an alloy in its ground state. For an alloy to be thermodynamically stable, its formation energy must be negative. Raabe *et al.* found that Mo is an intrinsic stabilizer of the β-phase (i.e., exhibited negative formation energy) even at concentrations as low as 25%, in the absence of any entropy-driven temperature effects. In contrast, stabilization of the β-phase (i.e., negative formation energy) by Nb was temperature-dependent. Thus, Nb acts as an entropy-driven β stabilizer. To experimentally validate their findings, the group determined the volume fractions of the α- and β-phases using X-ray wide angle diffraction experiments for the binary Ti–Nb and Ti–Mo alloys.

To determine the mechanical properties of the various alloys, the group first computationally predicted the Young's modulus by simulating a uniaxial tensile test along the crystallographic [001] direction of the β-phase, and then comparing it with experimental measurements of the Young's modulus using ultrasonic resonance frequency to assess the natural period of the transient vibration and results from a mechanical disturbance of the object tested. The best alloy identified, Ti–30% Nb, had a Young's modulus of 72.1 GPa, which, compared to the reference modulus of a polycrystalline Ti

sample, equates to a drop in stiffness of 37%. Thus the computational simulations allowed for a faster and more efficient method of alloy design and characterization of the alloys' mechanical properties. This shows that it is possible to screen the elastic properties of new alloys before actually preparing and casting them, resulting in a more streamlined alloy design process. Theory-guided design of biocompatible Ti alloys will help to reduce the amount of time required by conventional metallurgical alloy screening.

In a different study, Malavasi *et al.* modeled the bioactive glass 45S5, a reactive glass with low SiO_2 content and with potent effect on bone tissue formation[160] (see also **Chapter 1.110, Bioactive Glass-Ceramics**). The simulations showed that the Muliken charges were close to the ionic charges, implying that the bioglass is an ionic material. The authors also computed the bandgap of the material to be of 6.5 eV, indicating that the material is an insulator.

3.310.3.2. Surfaces with Tailored Functionality Through Self-Assembly Techniques

When a medical device is implanted, the surrounding proteins quickly adsorb onto the surface of the device. The biocompatibility is determined by the specific biochemical signaling potential of these proteins[161,162] (see also **Chapter 4.406, Protein Interactions with Biomaterials**). Therefore, the control of how proteins adsorb onto a surface can be important for the design of compatible biomaterials (see also **Chapter 3.311, Molecular Simulation Methods to Investigate Protein Adsorption Behavior at the Atomic Level**). Hydroxylated surfaces can be made in a highly controlled manner using ultrathin organic films. These films are typically prepared by Langmuir–Blodgett and SAM techniques (see also **Chapter 2.205, Self-Assembling Biomaterials**). SAMs are used as model biomaterial surfaces because they present well-defined chemistries. The substrate surface can be negatively or positively charged as well as hydrophilic or hydrophobic by selecting carboxyl-terminated, amine-terminated, hydroxyl-terminated, or methyl-terminated SAMs.

Using MD simulations and experiments, Rout *et al.* and Verneker *et al.* studied the specific contributions of variable residues to adsorption free energy between a G_4–X–G_4 peptide (G is glycine, X is variable residue) and functionalized Au–alkanethiol SAMs.[163,164] An initial challenge was that the SAMs were not parameterized in the GROMOS force field; so, using a protocol similar to that described in **Section 3.310.2.4**, the SAM model geometry and charges were assigned. Following the system simulation, the adsorption free energy was calculated by using the probability ratio method,[72] where tracking the surface separation distance (the distance between the C_α of the peptide and the plane of the SAMs) versus time is transformed into an adsorption free energy. In performing the simulations, the investigators combined an adaptive implementation of the umbrella sampling methodology described in **Section 3.310.2.3** with an enhanced sampling method known as replica exchange MD (REMD)[165–167] to help gain accuracy in the calculation of the adsorption free energy. In particular, using an adaptive implementation of the umbrella sampling in conjunction with REMD overcomes the high energy barrier inherent in solvent–solute–surface system and provides adequate sampling. The simulations and experiments were in agreement in that the G_4–G–G_4 and G_4–K–G_4 peptides showed minimal-to-no adsorption to the OH-SAM surfaces whereas the G_4–K–G_4 showed strong adsorption to the COOH-SAM surface. The simulations also predicted a relatively strong adsorption of the G_4–G–G_4 peptide to the COOH-SAM surface and both peptides were predicted to adsorb to the oligo(ethylene glycol) (OEG) surface.[163]

3.310.3.3. Slow Dynamical Modes in Adhesion, Catalysis, and Force

Theoretical and experimental studies have argued that thermal motions in proteins and their substrates with a diverse range of timescales (long-range or global as well as short-range or local motions) tend to couple to bring together the essential elements required for activity.[168–172] This implies that distal mutations can affect function by disrupting equilibrium distributions of the protein conformations to favor optimal organization of the active site and by providing a favorable electrostatic environment for the reaction.[168,173–176] Similar trends are reported for other proteins,[168,177] and show that the slow structural rearrangements of the enzyme–substrate complex play an important role in lowering the barrier for catalysis. For example, identifying the slow structural motions of the enzyme–substrate complex, which couple to the fast local coordinates at the catalytic site to lower the barrier for catalysis, may prove to be important in the delineation of reaction pathways.[71] Using novel tools for single-molecule experimentation,[178–181] pioneering studies of polymerases replicating DNA stretched under differing tensions[182,183] show that the replication rate is highly sensitive to forces exerted on the template strand (replication rate increases with forces <4–7 pN and decreases for higher values of the force); this implies that the applied force affects the rate-limiting step. Theoretical models parameterized by experimental data[182,183] and atomistic simulations[184] suggest that the rate-limiting step in this case involves the rearrangement of more than one base pair. Such models are instructive regarding the force-mediated coupling between the complex cooperative motion of polymerase and DNA degrees of freedom at the catalytic site.[150,185,186] More generally, the models help to delineate the effect of force on the recognition of receptor–ligand bonds and how the adhesion is mediated between cells and substrates.[187–191] Such interactions are also generally applicable in the context of biomaterials embedded in a tissue environment, as the interaction with the ECM will introduce forces and stresses at the biomaterial–matrix interface, which can trigger many signaling responses governed by the mechanobiology as described in an application summarized below.

3.310.3.3.1. Computational modeling of the attachment function of fibronectin

It is well known that cell adhesion to ECM proteins is primarily mediated by integrins, a widely expressed family of heterodimeric transmembrane adhesion receptors consisting of noncovalently associated α and β subunits (see also **Chapter 4.408, Integrin-Activated Reactions to Metallic Implant Surfaces** and **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**). Integrins bind to specific amino acid sequences on ECM

proteins, such as the well-known arginine–glycine–aspartic acid (RGD) motifs. Fibronectin is composed of three repeating structural motifs, one of which is the FN-III module (see also **Chapter 2.217, Fibrin**). The 10th type III module of fibronectin, FN-III$_{10}$, possesses the RGD motif. Since the attachment function of fibronectin is the result of its RGD binding domain, it is important to control the conformation and orientation of fibronectin on the surface of biomaterials, especially the accessibility of this RGD sequence. Recent experimental and computational efforts have demonstrated that external forces generated by cells regulate the conformation of fibronectin, thus altering its functional state and the accessibility of the RGD loop.[192–194] These studies have shown that integrin binding to fibronectin RGD loops on FN-III$_{10}$, resulting in the formation of a cytoskeletal apparatus that mechanically couples actin contractility to ECM fibronectin fibers. In addition, these studies have revealed that supramolecular assembly of fibronectin modules into fibrillar matrix confers functions not present in individual proteins and controls the exposure of the RGD binding site. As part of a larger supramolecular complex, fibronectin is mechanically coupled to other proteins so that the force applied to fibronectin is propagated to these molecules, thus affecting their function.

To determine how the organization of fibronectin into fibrillar matrix allows cells to control its structure, Baneyx *et al.*[195] employed intramolecular fluorescence resonance energy transfer (FRET) as an indicator of fibronectin conformation within the fibrillar matrix of NIH 3T3 fibroblasts. The FRET results revealed that in many fibrils, fibronectin was stretched by cells so that one or more FN-III modules were unfolded, yet this effect could be reversed by addition of cytoskeletal inhibitors such as cytochalasin D, which promotes refolding. The group concluded that the force generated by cells is necessary to maintain fibronectin in partially unfolded conformations, supporting a model in which fibronectin in cell fibrils is hyperextended relative to fibronectin bound to the cell membrane. The observation that fibronectin in fibroblast fibrils is stretched into partially unfolded conformations has functional implications. Hyperextension of FN-III modules may expose buried binding sites, termed 'cryptic sites,' that are inaccessible in the native state, in addition to altering the distance between binding sites or straightening the hydrophilic loops that contain binding sites.[196] Indeed, FN-III$_1$, FN-III$_{7–8}$, and FN-III$_{10}$ all possess cryptic binding sites that must be exposed to allow fibronectin matrix assembly.[197–199]

These experimental studies on FN-III modules suggest that the force-induced unfolding of FN-III$_{10}$ is capable of significantly altering the biochemical events occurring in the surrounding cells. To delineate the unfolding pathway of FN-III modules, other experimental techniques, including atomic force microscopy (AFM), have been employed[200–202] (see also **Chapter 3.302, Atomic Force Microscopy**). However, AFM studies alone cannot provide atomic-level detail of the unfolding process. As a result, computational modeling and simulation of the fibronectin unfolding pathway have been invaluable tools for dissecting the unfolding process at atomic-level resolution. Steered MD (SMD) simulations have demonstrated that, prior to complete unfolding of FN-III modules (see **Figure 5**, left), cryptic binding sites may become exposed in an intermediate state of the force-induced

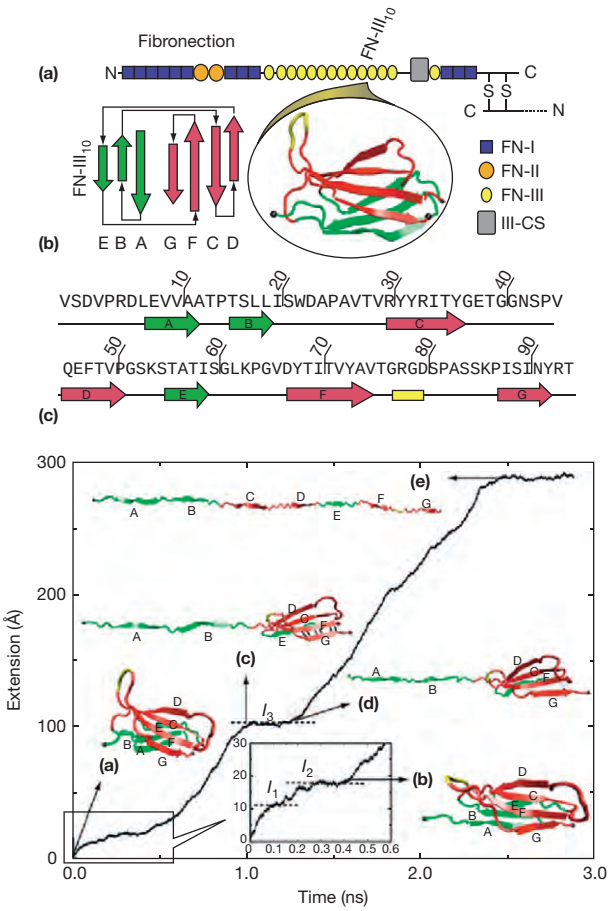

Figure 5 Unfolding intermediates of FN-III$_{10}$ by steered molecular dynamics. Left panel: schematic representation of the fibronectin monomer. (a) The modular structure. FN-III modules are shown as yellow ovals. (b) FN-III$_{10}$ is illustrated through two representations highlighting its secondary (left) and tertiary (right) structure. The RGD loop is shown in yellow. (c) Primary sequence of FN-III$_{10}$ and corresponding β-strands. Right panel: Extension–time profile from a steered molecular dynamics simulation and representative snapshots (a)–(e) illustrated during unfolding. Here (a) is the native structure and (e) is the fully unfolded structure. A total of three metastable intermediates were observed in the extension–time plot generated by SMD stretching of FN-III$_{10}$ (see right). The first and second intermediates represented alignment of the β sheets along the direction of the external force prior to unfolding of FN-III$_{10}$ β-strands. The third intermediate, which was extended by 100 Å, corresponded to unraveling of individual β-strands. Reproduced with permission from Gao, M.; Craig, D.; Vogel, V.; Schulten, K. *J. Mol. Biol.* **2002**, *323*, 939–950.

unfolding pathway.[203–205] SMD simulations also predicted that extension of the FN-III$_{10}$ module into this intermediate state decreases binding to $\alpha_5\beta_1$ integrins by increasing the separation distance between the RGD loop and its synergy site, which is required for $\alpha_5\beta_1$ (but not other integrins) binding to fibronectin.[206] The functional implication of this is that $\alpha_5\beta_1$-mediated signaling may predominate in cells bound to unstretched fibronectin, whereas other integrin-mediated pathways may begin to predominate as fibronectin is extended and the synergy site is separated from the RGD loop. If the FN-III modules become completely unraveled, the RGD loop may

straighten, decreasing integrin affinity.[204] This is one example of how regulation of the extent of fibronectin unfolding within fibrils may control the biochemical activity of the surrounding cells. The majority of these computational studies explored the early stages of fibronectin unfolding. Gao *et al.*[207] constructed an extended computational model in which FN-III_{10} was solvated in a box of water large enough to allow stretching of FN-III_{10} into its fully unfolded conformation (see **Figure 5**, right).

Based on **Figure 5**, the authors suggested that there is a consensus unfolding pathway prior to unraveling of β-strands, at which point the unfolding trajectory diverges into three alternate pathways for separation of β-strands from the main module: A-strand separating first, G-strand separating first, or both A- and G-strands separating simultaneously. The identification of multiple unfolding pathways for FN-III_{10} has several functional implications. First, the authors suggest that binding of fibronectin to specific integrins or to other fibronectin proteins may change the unfolding pathway. For example, Gao *et al.*[207] predict that binding of an integrin to the RGD loop between the F- and G-strands of FN-III_{10} may promote the interaction between these β-strands, thereby biasing the unfolding pathway toward separation of the A-strand first. The authors also suggest that the existence of unfolding intermediates lends support to a currently proposed mechanism of fibrillogenesis, which predicts that the process occurs via β-strand swapping among fibronectin modules.[208] Indeed, one of the partially unfolded intermediates identified in the SMD simulations is able to swap its β-strands with other fibronectin molecules, as the unraveled A- and B-strands can assemble with other FN-III modules. Thus, one model for fibrillogenesis is that integrin-generated force would unravel the A- and B-strands from FN-III_{10}, allowing other FN-III modules, such as FN-III_1, to assemble with FN-III_{10}. Indeed, experimental studies have found that FN-III_{10} contains a cryptic site that binds to FN-III_1 modules.[209] SMD simulations thus provide an atomic-level of detail to the complex process of fibronectin unfolding and suggest new mechanisms of fibrillogenesis that can be tested experimentally. In the future, it will be important to apply these simulation results to better control the conformation of fibronectin adsorbed to the surface of novel biomaterials.

3.310.3.4. Future Directions

As multiscale modeling techniques are becoming more sophisticated, their applications to increasingly complex biological systems are being explored. Therefore, a renewed focus on direct connection with experiments to enable proper validation is critical. One strategic approach is to compare the results of the models and experiments as well as require consistency at multiple length- and timescales, which can be realized by comparing to a hierarchy of experiments. For example, structural features can be investigated by means of a combination of experimental approaches such as Fourier transform infrared (FTIR), NMR, electron paramagnetic resonance (EPR) spectroscopy, AFM, scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction, etc. One can simultaneously employ thermal (differential scanning colorimetry (DSC) and thermogravimetry (TG)), mechanical (hardness and elastic modulus), and biological properties for validation and require the modeling to predict a range of properties. In the future, the utility of well-validated models and simulation is in directing the rational design and modifications of novel materials. This includes creation of well-controlled surfaces that mimic multiple recognition sites for compatibility with the ECM and quantifying the effect of chemical heterogeneity (OH^- and PO_4^{3-} groups distributed randomly as dangling bonds or the presence of divalent metal ions) in inducing conformational shifts in biomolecules (such as fibronectin) as well as the effect of applied force mediated through protein–ligand interactions in orchestrating and triggering signaling events in the constituent cells.

Acknowledgments

We thank Dr. Paul Ducheyne for helpful suggestions. We acknowledge funding from National Science Foundation CBET-0853539 and CBET-0853389, National Institutes of Health NIBIB-1R01EB006818 and NHLBI-1R01HL087036, and computational support from National Partnerships for Advanced Computational Infrastructure NPACI-MCB060006. S.E.T. acknowledges funding through a GAANN fellowship and a NSF graduate fellowship.

Abbreviations

CM	Classical mechanics
DDD	Distance dependent dielectric function
GB	Generalized-Born
KE	Kinetic energy
L-J	Lennard-Jones
MC	Monte Carlo
MD	Molecular dynamics
MM	Molecular mechanics
P–B	Poisson–Boltzmann
PBC	Period boundary condition
QM	Quantum mechanics

Symbols

$a(t)$	Acceleration of an atom at time t
b	Bond length parameter
b_o	Minimum-energy bond length
B_{ij}	Biased energy function acting between states x_j and x_i
B_u	Biasing energy umbrella function
E_i	Potential energy of molecular system when in conformational state x_i
$E(x_i)$	Potential energy of molecular system when in conformational state x_i
F_{ij}	Force vector acting on atom i from atom j
k_B	Boltzmann constant
k_b	Stiffness coefficient for bond stretching
k_θ	Stiffness coefficient for bond bending
k_ϕ	Stiffness coefficient for bond torsional rotation
k_u	Stiffness constant for umbrella function
k_χ	Stiffness coefficient for improper bond torsion

m_i	Mass of atom i	v_i	Velocity i
M	Number of total conformational states sampled during a simulation	$v(t)$	Velocity of an atom at time t
		V	Volume
N	Number of atoms	x_i	Molecular system in ith conformational state
N_c	Number of constraints limiting the degrees of freedom	$<X>$	Average value of parameter X
		ΔG	Change in free energy
P	Pressure	ΔH	Change in enthalpy
$P(x_i)$	Probability of system being in conformational state x_i	ΔS	Change in entropy
		β	Parameter representing $(k_BT)^{-1}$
P_{ij}	Relative probability to be in state x_j compared to state x_i	χ	Improper bond torsional angle
		χ_o	Minimum-energy improper bond torsional angle
$\overline{P}_{ij}$	Biased Relative probability to be in state x_j compared to state x_i	δ	Offset torsional rotation angle
		ε_o	Permittivity of free space
q_i	Partial charge of atom i.	ε_r	Relative dielectric constant
Q	Partition function	ε_{ij}	Minimum energy for Lennard-Jones nonbonded interaction
r_{ij}	Distance between centers of atoms i and j, or position vector from atom j to i		
		ϕ	Torsional rotation angle
$r(t)$	Position of an atom at time t	λ	Designated parameter for umbrella function
Rnd (0_1)	Random number between 0 and 1	λ_u	Value of designated parameter that umbrella function is applied around
t	time	κ	Inverse Debye length
T	Temperature (absolute scale)	θ	Bond angle
U	Average potential energy of a molecular system	θ_o	Minimum-energy bond angle
		σ_{ij}	Atomic collision diameter between atoms i and j

3.311.1. Introduction

In order to understand the importance of protein adsorption to biomaterial surfaces and its relationship to the biocompatibility of medical devices, it is first necessary to recognize that cells in the body generally do not have receptors that are able to specifically interact with a synthetic material. For this reason, cells have no means of responding to chemically stable nonbiologically-based materials that are placed inside the body. Of course, cells in the body do respond to these types of materials, which raises the question: How does this occur? The answer to this question is simply that cells do not directly respond to synthetic biomaterials placed inside the body; rather they respond to the layer of adsorbed proteins that rapidly adsorb to and coat a biomaterial surface within seconds following its contact with biological fluids, such as blood and interstitial fluid.[1] Based on this understanding, it must be understood that cellular response is largely directed by the bioactive sites that are present in this layer of adsorbed proteins, with the presence of these bioactive sites being dependent on the types of proteins adsorbed and their orientation, conformation, packing arrangement, and dynamic behavior on a biomaterial's surface.[2–4] The realization that protein adsorption is fundamental to the biocompatibility of biomaterials has caused this to be one of the major topics of investigation in the biomaterials field over the past several decades. While much has been learned from these studies, we still have a very incomplete and largely qualitative understanding of protein adsorption behavior, with little knowledge at this time of how to design biomaterial surfaces to control protein adsorption and subsequent cellular responses to biomaterials. Because of this situation, biomaterials design can still largely be only approached through trial-and-error methods.

One of the primary reasons for this lack of quantitative understanding is the lack of methods that enable protein adsorption processes to be investigated at the molecular level. This underscores the need for the development of new technologies that will provide this capability. Molecular simulation methods provide the potential to meet this need. These methods have come to represent essential technologies in areas such as biophysics for understanding protein folding behavior,[5–7] and in pharmaceutical science, for drug design.[8–10] Similar potential exists for molecular simulations to complement experimental studies in the biomaterials field to help us finally understand and control protein adsorption behavior, and to then apply this understanding to guide biomaterial surface design. However, as will be highlighted in this chapter, these methods cannot simply be borrowed from other disciplines, but rather they must be specifically developed and adapted to meet the needs that are unique to the biomaterials field.

Before we can properly understand what factors need to be addressed in order to develop molecular simulation methods for applications of biomaterials, it is first necessary to have a general understanding of the fundamental principles that govern the kinetics and the thermodynamics of protein–surface interactions. An overview of these principles is provided in Section 3.311.2. Following this, the basic principles of molecular simulation are addressed in Section 3.311.3, with a focus on all-atom classical mechanics (CM) simulation methods and their application to model protein–surface interactions. Section 3.311.4 then highlights some of the key studies that have been conducted over the past two decades toward the development and application of CM

methods to simulate protein adsorption behavior. This is followed by Section 3.311.5, which addresses some of the current limitations and future trends for further development, with final concluding remarks provided in Section 3.311.6.

3.311.2. Fundamental Aspects of Protein Adsorption Behavior

To begin to understand protein adsorption behavior, it is first necessary to understand the basic structural makeup of proteins and how a protein's structure is generally influenced when it interacts with a surface. Proteins are essentially very complex organic copolymers of amino acids.[11,12] There are 20 different types of naturally occurring amino acids, each of which have the basic chemical formula of (NH_2–CHR–COOH), with R representing the amino acid's side chain. The chemical makeup of the side chain of an amino acid determines its nature, or functionality, which is generally characterized as being nonpolar, polar, or charged. The enormous versatility provided by this type of molecular system (i.e., a copolymer with 20 different mer units) can be appreciated by the realization that even a simple oligopeptide chain that is only 15 amino acids long will thus have $20^{15} \approx 10^{20}$ different possible sequence combinations, each with a slightly different chemical and physical characteristic. To appreciate the size of this number, this is 500 times larger than the age of the known universe as expressed in seconds, which is about 4×10^{17} s (i.e., about 14 billion years).[13] Many proteins have polypeptide chains that are thousands of amino acids long.

Proteins are composed of four levels of organization, which are termed primary, secondary, tertiary, and quaternary structure.[11,12] The primary structure represents the specific sequence of amino acids along a polypeptide chain, with each amino acid referred to as an amino acid residue. The amino acids are covalently linked together by condensation reactions to form covalent bonds between the main-chain carboxyl and amine groups of adjacent amino acids along the polypeptide chain, with the first and last amino acids of the chain referred to as the N-terminus and the C-terminus, respectively, and the direction of the chain designated as running from the N- to the C-terminus. The secondary structure of a protein represents the way that the polypeptide chain of the protein is organized into helical, planar, and random loop elements, with the helical and planar secondary structures stabilized by hydrogen bonds between the amine and carboxyl functional groups of the polypeptide main chain. There are three basic types of helical structures (typically right-handed helices), which are designated as α-helices, 3_{10}-helices, and π-helices, with 3.7, 3, and 5 amino acid residues per full rotation of the polypeptide chain, respectively, each of which organizes in such a way that their side chains radiate outward from the helix. The planar secondary structures are formed by relatively straight β-strands. These elements are organized into two basic chain configurations, which are designated as parallel and antiparallel β-sheets, depending on whether adjacent strands are running in the same or opposite direction, respectively, with their amino acid side chains extending above and below the sheet in each case. Helical and β-strand elements are covalently connected by random loop segments, which, as the name implies, do not have any specifically defined structure. The tertiary structure of a protein is determined by the manner in which the secondary structures organize together, with van der Waals interactions between the side chains extending outward from each of the secondary structural elements stabilizing the tertiary structure. In addition, covalent cross-links can also exist between adjacent secondary structures by the formation of disulfide bonds between adjacent cysteine residues, which have (R: CH_2–SH) as their side-chain structures. Finally, if a protein is composed of more than one polypeptide chain, with each chain having its own N- and C-termini, it is then referred to as having a quaternary structure, with the interactions between the chains being mediated by the same types of bonds that hold tertiary structures together (i.e., van der Waals interactions and disulfide covalent bonds between the amino acid side chains making up secondary structural elements). The end result of the final folded state of a protein is the formation of bioactive sites, which are created from the functional groups presented by the specific amino acids forming the particular region of the protein combined with their spatial arrangement. These sites provide a protein with its biological activity to perform its designated function, whether that be as an enzyme, a factor in a biological process, an extracellular matrix protein, or a membrane-bound cell receptor.

Each protein has a defined native-state folded structure that is formed by the unique combination of its primary through tertiary or quaternary levels of organization. It is generally believed that this structure is determined by thermodynamics, with the native-state folded structure representing the global minimum free energy state of the protein.[12] This folding behavior has been illustrated by what is referred to as the protein folding funnel,[14,15] which conceptually represents all possible conformational states that a given polypeptide chain can exist in along the x-axis and the relative free energy state of the protein in aqueous solution along the γ-axis, as schematically depicted in Figure 1. This folding process is largely driven by the thermodynamic tendency of a protein to fold in a manner so as to reduce the solvent-accessible surface area of its nonpolar amino acid residues. Accordingly, proteins tend to fold in such a way that they bury their nonpolar residues within their structure so as to minimize their exposure to the surrounding aqueous solution while maintaining their hydrophilic amino acid residues (i.e., polar and charged amino acids) on the outer surface of the protein, thus providing aqueous solubility.

Based on this understanding of the principles that govern a protein's native-state structure and thermodynamics, we can begin to understand how interactions between a protein with a synthetic surface will take place. We start with the general thermodynamic principle that any spontaneously occurring process must result in a reduction in free energy of the system, with the change in free energy at constant temperature (T) expressed as $\Delta G = \Delta H - T\Delta S$, where ΔG, ΔH, and ΔS represent the change in free energy, enthalpy, and entropy, respectively. Accordingly, when exposed to a hydrophobic surface, there is a thermodynamic driving force to reduce the overall solvent-accessible surface area of the nonpolar groups of the system, which is generally driven by the fact that water molecules next to a nonpolar surface at room or body temperature are generally in a higher free energy state than water molecules in the

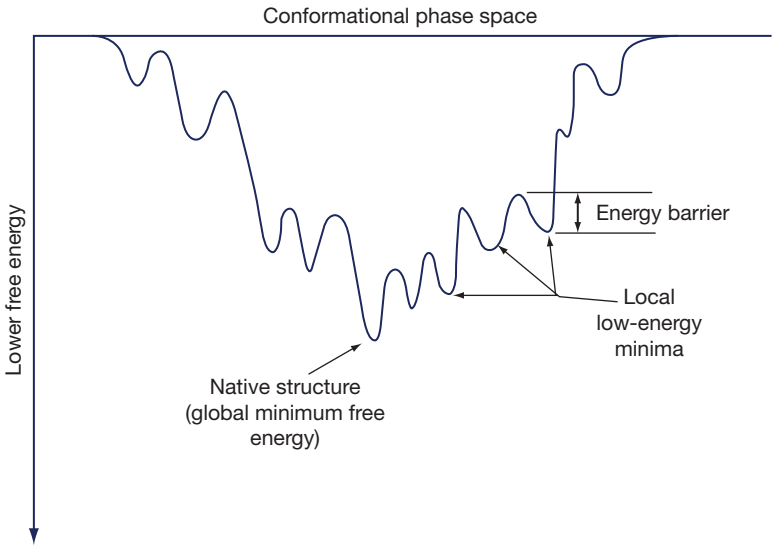

Figure 1 Illustration of the protein folding funnel for the folding of a protein in aqueous solution. Horizontal axis represents the set of all possible conformational states of the protein and the vertical axis represents the free energy state for each conformation. A protein will fold in a manner to attain its global minimum free energy conformation, which represents the protein's native-state structure.

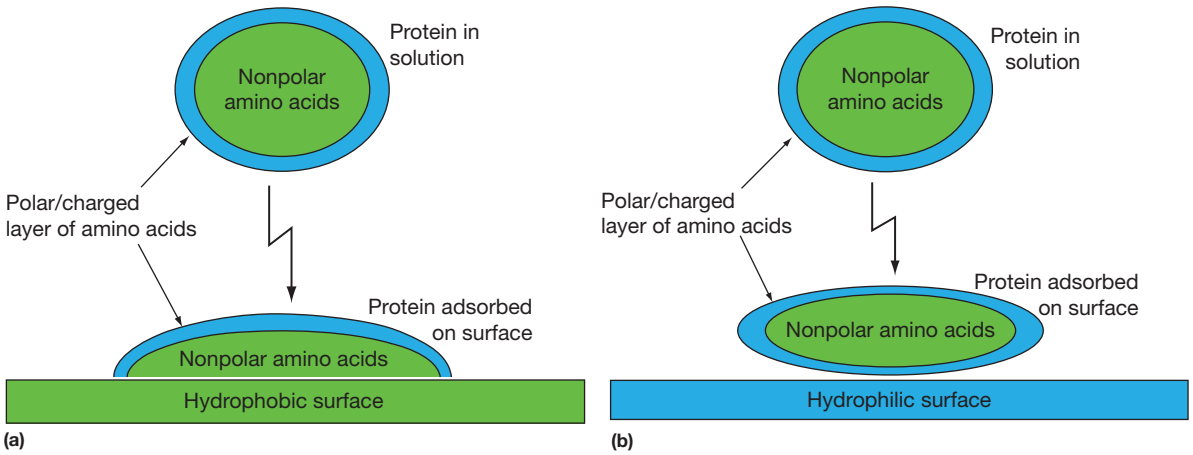

Figure 2 (a) Protein adsorption on a hydrophobic surface. An adsorbed protein tends to unfold/refold to cover the nonpolar functional groups of the surface with its nonpolar amino acid residues while maintaining a layer of polar/charged amino acid residues over its own solvent-exposed surface. (b) Protein adsorption on a hydrophilic surface. A protein tends to adsorb in a manner such that it maintains its nonpolar amino acids buried within its core to avoid their exposure to either the hydrophilic groups of the adsorbent surface or the solution.

bulk aqueous solution. This generally causes a protein to unfold and spread out over a hydrophobic surface to displace the water and cover the hydrophobic groups of the surface with its own nonpolar amino acids (i.e., hydrophobic interactions) while maintaining a layer of hydrophilic amino acids over its own solvent-accessible surface.[4,16] In contrast to this, exposure of a protein to a hydrophilic surface (i.e., a surface with polar and/or charged groups) will tend to cause a protein to adsorb and spread out over a surface in a manner where it maintains its nonpolar amino acid residues buried within itself and shielded from both the solvent and the surface, with the protein's own polar and charged residues interacting with the surface functional groups via hydrogen bonding and salt-bridge associations, possibly with a bridging, hydrogen-bonded layer of water.[4,16] The bonds formed between the functional groups of the protein and the surface can thus be considered to replace similar types of bonds that were previously formed with water and/or salt ions of the solution, resulting in relatively little change in the enthalpic state of the system. In this case, the reduction in free energy that occurs to induce protein adsorption can be understood to be largely driven by the release of bound water and ions from the surface and protein to bulk solution, which represents an increase in the entropy of the system that more than compensates for the reduction of entropy that occurs from the binding of the protein. These concepts are illustrated in **Figure 2**.

The processes involved in protein adsorption to a surface can also be illustrated by representing how interactions with a surface will perturb the shape of the protein's folding funnel.[17] As depicted in **Figure 3**, when a protein is exposed to a

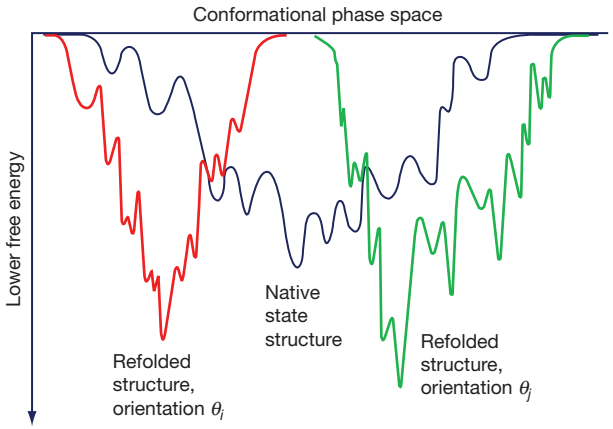

Figure 3 Illustration of the effect of the presence of a surface on the shape of the protein folding funnel. Each orientation of a protein on a surface will result in different forces being applied to the protein, which will perturb the aqueous-solution folding funnel in a different manner. One orientation will provide the overall global minimum free energy for the adsorbed protein. Large free energy barriers between local low-energy conformations and the global minimum energy conformation may cause adsorbed proteins to be trapped in many different metastable states on a surface.

synthetic surface in a given orientation, the functional groups of the adsorbing surface will exert forces on the adjacent surface of the protein that are not present when the protein is in bulk solution. These forces will tend to perturb the thermodynamics of the system, causing the protein's native conformation to no longer represent the global minimum free energy state of the system. This may result in a shifting of the protein's folding funnel in a manner to cause the protein to restructure or refold into a new low free energy conformation. Because it can be expected that each orientation of a protein will result in a different set of forces acting on the protein, each initial orientation of a protein on a surface can be expected to result in a different shape in the protein's folding funnel, with one specific orientation out of this total set of perturbed systems resulting in the global minimum free energy of the system. However, because of the ruggedness of the protein folding funnel (i.e., relatively large free energy barriers separating the various local free energy minima), a protein may be trapped in a metastable local low free energy state. This type of behavior can be expected to result in proteins existing over a wide range of orientations and metastable configurational states following adsorption from a solution onto a surface, which may then continue to change over a long period of time.

Based on the earlier description of some of the fundamentals of protein adsorption behavior, it is no wonder that it has been so difficult to obtain a quantitative atomistic level of understanding of protein adsorption behavior through the use of experimental methods alone. Complementary methods are needed that enable the interactions between the functional groups presented by a protein, a surface, and an aqueous solution to be depicted on an atomistic level. This represents a situation that is extremely well suited for the application of molecular simulation methods. However, as emphasized in the following sections, these methods cannot simply be borrowed from methods that were previously developed for other applications, but rather they must be specifically developed to meet the unique set of conditions that are needed for the accurate representation of protein–surface interactions.

3.311.3. Molecular Simulation Methods and Their Relevance to Protein Adsorption

3.311.3.1. Overview

Molecular simulation methods can basically be separated into quantum mechanics (QM) methods, which treat electrons as the fundamental interactive particles of the system, and CM methods, which treat individual atoms or groups of atoms as the fundamental interactive particles of the system. Because of the size of the molecular systems involved in the simulation of protein adsorption behavior, CM methods are most widely used, with QM methods providing a very important supporting role. In this section, a brief summary of QM methods will be first provided followed by a relatively in-depth coverage of CM methods with a focus on some of the key areas that are particularly important for the simulation of protein–surface interactions; namely, the empirical force field and its parameterization, the handling of solvation effects, and the sampling of the phase space of the molecular system.

3.311.3.2. QM Methods

QM methods can be divided up into *ab initio*, semiempirical, and density functional theory (DFT) methods.[18,19] *Ab initio* methods, as the name implies, require no empirical information about the molecular system being considered but rather apply various approximations to solve Schrödinger's equation through the use of wave functions to describe atomic orbitals for the calculation of molecular properties. Semiempirical QM (SEQM) methods use similar calculational methods, but only for valence electrons, thus substantially reducing the computational cost of the calculations. DFT methods, on the other hand, determine properties from calculations based on the electron density of the molecular system. Because QM calculations are extremely rigorous, the size of the molecular systems to which they can be applied is fairly limited. For example, high-level QM methods (e.g., Møller–Plesset (MP) methods such as MP2) are even able to account for electron-correlation effects between nonbonded atoms, thus enabling them to represent London dispersion interactions. These methods are so computationally intensive that they may only be able to be applied to systems composed of a dozen or so atoms at a time. Other less rigorous QM methods such as DFT methods can be used for systems involving hundreds of atoms. However, DFT methods have the drawback of generally not being able to account for electron-correlation effects, which may be substantially important depending on the molecular system being considered.

The current limitations in the size of the molecular system that can be handled with QM methods make them largely unsuitable for direct application to simulate protein–surface interactions. On the other hand, because these types of methods can represent both intra and intermolecular interactions very accurately without requiring any

empirical information, they are extremely valuable and widely used to establish parameter values for empirical force fields for CM simulations.[20]

3.311.3.3. Classical Mechanics Methods

3.311.3.3.1. Overview

In contrast to QM methods, CM methods are much less computationally expensive and can easily be used to conduct simulations containing tens of thousands of atoms, or even much larger systems if united-atom methods are used, thus making them well suited for the simulation of protein–surface interactions. This reduction in computational complexity, however, comes at a cost of the simulations being largely dependent on the accuracy of the empirical equation form and parameter sets that are used to determine how the atoms or groups of atoms in the modeled system interact with one another during the simulation.

CM simulation methods are subdivided into three basic types: molecular mechanics (MM), Monte Carlo (MC), and molecular dynamics (MD) methods.[18,21,22] Each of these methods use an analytical function along with an empirically derived set of constants that dictate how the atoms or particles in the system interact with one another as a function of their state of bonding and their coordinate positions; these are referred to as the force field equation and force field parameter set. MM methods are used to calculate the potential energy of a molecular structure based on the molecular configuration of the system and are most commonly used to calculate the geometry of a molecular system that will minimize its overall potential energy, which is referred to as energy minimization or geometry optimization. It should be recognized, however, that this represents the condition of the molecular structure under absolute zero temperature conditions. In addition to being useful for predicting minimum energy geometries for a given molecule or molecular system, MM methods are commonly used prior to beginning an MC or MD simulation in order to relax improperly stretched, bent, or twisted covalent bonds in a system and to avoid energetically unfavorable overlaps between atoms. This step is especially useful when representing a condensed-phase system, with the molecules of the solvent being explicitly represented.

MC and MD methods are similar to MM methods in that they use an empirical force field for the calculation of the potential energy of the system as a function of the coordinate positions and the bonded state of the atoms. These methods, however, implement additional statistical mechanics-based algorithms to incorporate temperature in the simulation, which provides the capability of evaluating the thermodynamic behavior of the system at a designated temperature (e.g., adsorption free energy at 298 K) when using MC, and evaluating both the thermodynamic and the kinetic behavior of a system at a given temperature when using MD.

3.311.3.3.2. Empirical force field equations

The empirical force field is the equation that is used in MM, MC, and MD simulations to calculate the potential energy (E) of the system as a summation of the individual energetic contributions from each atom in the system.[18] This is called a 'force field' equation because when differentiated with respect to the coordinate positions of the atoms (x_i), it yields an expression that provides the force acting on each atom (i.e., $F_i = -\mathrm{d}E/\mathrm{d}x_i$). These forces are then used in an MD simulation to determine how the atoms will move over the next time-step of the simulation (further addressed below in Section 3.311.3.3.5). Two basic types of force field equations have been primarily developed over the past several decades, which are referred to as Class I and Class II force fields.

Class I force fields, which are relatively simple in form, have mainly been developed for use with biological molecules. The general form of a Class I force field equation that is most widely used for biomolecular simulations (e.g., proteins, carbohydrates, phospholipids, RNA, and DNA) is shown in eqn [1]:

$$\begin{aligned} E = &\sum_{\text{bonds}} k_b(b-b_0)^2 + \sum_{\text{angles}} k_\theta(\theta-\theta_0)^2 \\ &+ \sum_{\text{dihedrals}} k_\phi[1+\cos(n\phi-\delta)] \sum_{\text{improp}} k_\chi(\chi-\chi_0)^2 \\ &+ \sum_{\text{L–J}} 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] + \sum_{\text{Coulomb}} \frac{q_i q_j}{4\pi\varepsilon_0\varepsilon_r r_{ij}} \end{aligned} \quad [1]$$

The first three terms on the right-hand side of eqn [1] represent the potential energy of the covalently bonded atoms in the system due to covalent bond stretching, bending, and rotation. For these terms, the parameters b, θ, ϕ, and χ represent the bond length, bond angle, dihedral angle (torsion), and out-of-plane bending (also called improper torsion), respectively, of the bonded state, relative to a reference position (designated by force field parameters b_0, θ_0, ϕ_0, δ, and χ_0). The k parameters in eqn [1] represent additional empirical force field parameters that reflect the stiffness of each of the bond types in the system. The last two terms of the force field equation represent the contributions of the nonbonded interactions to the potential energy of the system. The first of these two terms represents Lennard-Jones (L–J) 12–6 interactions, which are considered as being pairwise interactions for all nonbonded atoms (i.e., atoms separated by more than two covalent bonds along a covalently bonded chain or between two atoms in different molecules in the system). In this term, ε_{ij} and σ_{ij} represent the L-J well depth and the collision diameter between the designated pairs of atoms, respectively, for atoms i and j. The second nonbonded term represents the energy contributions from the electrostatic interactions between pairs of atoms, which are represented by Coulomb's law, where q_i and q_j represent the partial charges centered on atoms i and j, ε_0 is the permittivity of free space, and ε_r is the relative dielectric constant. ε_r is typically set to 1.0 or about 79 depending on whether an explicit or implicit solvation method is being used, respectively (this aspect is further addressed in Section 3.311.3.3.3). Some of the most popular Class I force fields in use today are AMBER,[23,24] CHARMM,[25,26] GROMOS,[27] and OPLS-AA.[28]

Class II force fields capture the same general types of energetic contributions as do Class I force fields, but include expanded sets of terms for the bonded parameters (i.e., bond stretching, bond bending, dihedral rotation) as well as cross-terms between bonded terms (e.g., a bond stretch–bend term).[29] These terms enable the behavior of molecules to be represented more accurately than Class I force fields, especially for molecular behavior under relatively highly strained

conditions; however, this comes at a cost of additional complexity and computational expense. An example of the form of a Class II force field is shown in eqn [2]:

$$\begin{aligned}E = &\sum_{\text{bonds}}\left[k_{b2}(b-b_0)^2 + k_{b3}(b-b_0)^3 + k_{b4}(b-b_0)^4\right]\\ &+\sum_{\text{angles}}\left[k_{\theta2}(\theta-\theta_0)^2 + k_{\theta3}(\theta-\theta_0)^3 + k_{\theta4}(\theta-\theta_0)^4\right]\\ &+\sum_{\text{dihedrals}} k_{\phi1}[1-\cos\phi] + k_{\phi2}[1-\cos 2\phi] + k_{\phi3}[1-\cos 3\phi]\\ &+\sum_{\chi} k_{\chi}\chi^2\\ &+\sum_{b,b'} k_{b,b'}(b-b_0)(b'-b_0') + \sum_{b,\theta} k_{b,\theta}(b-b_0)(\theta-\theta_0)\\ &+\sum_{b,\phi}(b-b_0)[k_{b,\phi1}\cos\phi + k_{b,\phi2}\cos 2\phi + k_{b,\phi3}\cos 3\phi]\\ &+\sum_{\theta,\phi}(\theta-\theta_0)[k_{\theta,\phi1}\cos\phi + k_{\theta,\phi2}\cos 2\phi + k_{\theta,\phi3}\cos 3\phi]\\ &+\sum_{\theta,\theta'} k_{\theta,\theta'}(\theta-\theta_0)(\theta'-\theta_0')\\ &+\sum_{\theta,\theta',\phi} k_{\theta,\theta',\phi}(\theta-\theta_0)(\theta'-\theta_0')\cos\phi\\ &+\sum_{\text{L-J}}\varepsilon_{ij}\left[2\left(\frac{\sigma_{ij}}{r_{ij}}\right)^9 - 3\left(\frac{\sigma_{ij}}{r_{ij}}\right)^6\right] + \sum_{\text{Coulomb}}\frac{q_iq_j}{4\pi\varepsilon_0\varepsilon_r r_{ij}}\end{aligned} \quad [2]$$

where the same variable descriptions apply as for the Class I force field shown in eqn [1], with the addition of additional constants to represent the contributions from higher order terms for bond stretching, bending, dihedral rotation, and out-of-plane bending, and cross-terms for bond stretch–stretch (b, b' combined terms), stretch–bend (b, θ combined terms), stretch–torsion (b, ϕ combined terms), bend–torsion (θ, ϕ combined terms), bend–bend (θ, θ' combined terms), and bend–bend–torsion (θ, θ, ϕ combined terms). In addition, Class II force fields typically use a 9-6 L-J potential form while using the same Coulomb's law expression for electrostatic interactions. While Class II force fields can be used to represent biological molecules, the additional complexity and subsequent computational cost is generally not considered to be necessary for these types of molecules near room temperature. Class II force fields are commonly used in the materials science field to represent the behavior of synthetic polymer, metal, and ceramic solid-phase materials and whenever the additional computational cost is needed to achieve a more accurate prediction of potential energies, structures, and vibrational frequencies of a molecule or molecular system. Examples of Class II force fields include CFF,[29] PCFF (polymer CFF),[30] the MM# series,[31] and COMPASS.[32]

A force field for a given molecular simulation is thus described by both the form of the force field equation (e.g., eqn [1] or [2]) and the values of the empirical force field parameters that are assigned for each designated set of atom and bond type in the system. For example, a C–C covalent bond in a Class I force field will have one set of defined k_b and b_0 values, while a C–O bond will have another. The L-J parameters (i.e., ε_{ij} and σ_{ij}) are handled slightly differently, with each individual atom type 'i' given its own ε_i and σ_i parameter value. These values are then combined for a given 'ij' atom–atom pair interaction using Lorentz–Berthelot combination rules,[18] in which ε_{ij} and σ_{ij} are derived for any given pair of atoms using either the geometric or arithmetic mean of the two individual atom's values (depending on the rules of the type of force field used). The values of these empirical parameters for both the bonded and nonbonded terms are generally determined from either QM calculations of small molecules containing similar functional groups with empirical parameters then adjusted to optimally match the QM-predicted behavior, or by adjusting the empirical parameters to match experimentally determined properties, such as density, heat of vaporization, or vibrational frequencies. If parameterized properly, an empirical force field can provide a very accurate representation for a given molecular system. However, if not, the predicted behavior of the system can be very far from reality.

One of the difficulties involved in force field parameterization is that an appropriate set of force field parameters for one set of atoms in one type of molecular environment may not be appropriate for the same set of atoms in a different type of molecular environment; this situation is referred to as the issue of 'force field transferability.' Force field transferability is particularly a problem for the fixed partial charges assigned to each atom type in a fixed-charge empirical force field (i.e., q_i), because, in reality, the effective partial charge state of an atom in a molecule will substantially shift depending on its polarizability and the distribution of partial charges in the atoms in its immediate surroundings. As an excellent example of this problem, van Gunsteren and coworkers[33] showed that two different sets of partial charge parameters were needed to accurately represent the behavior of the same set of molecules depending on whether they were represented in their pure condensed liquid state compared to when they were represented as individual molecules in aqueous solution. It is therefore important to use a validated set of parameters for a given molecular environment.

The question of force field transferability raises a particularly important issue for the use of empirical force field-based methods for the simulation of protein–surface interactions. Generally, a force field is validated for a given molecular system by using the force field to conduct simulations for the calculation of experimentally measurable properties of the system (e.g., density, structure, vibrational frequencies, heat of evaporation, and free energy of solvation). By comparing calculated values to experimentally measured data, the validity of the force field to accurately represent the behavior of the given molecular system can then be assessed. If substantial errors are found in the calculated values, the experimental data can subsequently serve as a benchmark set to which the force field can be tuned and validated. The difficulty that this approach presents for the simulation of protein–surface interactions is that presently there are relatively little experimental data available that can be used to determine whether the results from a molecular simulation of protein adsorption behavior are correct or not. Without such data, it is very difficult to determine whether or not a simulation realistically portrays the molecular behavior of the system. As one approach to address this deficiency, the Latour group has been conducting carefully matched experimental and simulation studies to measure and calculate the free energy of adsorption for a broad series of peptide–surface systems using a custom-designed host–guest peptide model and a series of alkanethiol self-assembled monolayer (SAM) surfaces with surface functionality set to represent common functional groups present in

polymeric biomaterials.[34–38] This approach provides a means of assessing the validity of a given force field for the simulation of protein–surface interactions. Similar efforts are also needed to develop experimental methods that can be used to quantitatively measure the orientation, conformation, and bioactive state of adsorbed proteins,[39,40] from which the accuracy of simulations of protein adsorption behavior, using a given force field, can be further assessed.

Another problem for the implementation of current sets of force field parameterization for the simulation of protein–surface interactions is the fact that the protein modeling community has primarily developed force field parameterization for the simulation of protein behavior in solution using a Class I force field equation format, while the materials science community has primarily developed force field parameterization for polymers, metals, and ceramic materials using the Class II force field equation format. Current commercially available molecular simulation programs, however, require that only one type of force field (i.e., either Class I or Class II) be used in a simulation. This then creates a dilemma for the simulation of protein–surface interactions where it is desired to represent both a protein solution phase and a solid materials phase in the same simulation. In this case, it is necessary to reparameterize one phase or the other to be able to run the simulation with a single type of force field, which would be an extremely time-consuming endeavor. To make this situation even more complicated, because the interface between two phases of such a molecular system represents a substantially different molecular environment than either phase by itself, it can be expected that separate parameterization will need to be developed to accurately represent molecular interactions at this interface. One possible approach to solving this problem, which the Latour group has been exploring, is the development of a hybrid force field molecular simulation program that is specifically designed for the simulation of multiphase systems to enable either a Class I or a Class II force field to be used to separately control the behavior of the atoms in each phase of the system, with a third set of independent parameters used to control the interactions at the interface between the two phases of the system. By this approach, a program will be able to make combined use of the decades of efforts that have already been spent on the development and validation of force field parameters from both the materials science and the biophysical science communities, while enabling the parameterization of interfacial interactions to be separately optimized to accurately represent protein–surface interactions at the solid–liquid interface.

3.311.3.3.3. Representation of solvation effects

Because most applications where protein–surface interactions are of interest in the biomaterials field take place in aqueous solution, the accurate representation of solvation effects is extremely important in a simulation of protein adsorption behavior. The most direct way of representing solvation effects in an MC or MD simulation of protein–surface interactions is to include water molecules and salt ions as explicitly represented atoms in the simulation. Many different water models, and their associated force field parameters, have been developed that generally provide excellent representations of solvation effects at around 298 K. Some of the most popular water models are SPC,[41] SPC/E,[42] TIP3P,[43] TIP4P,[44,45] TIP4P/Ew,[44] and TIP5P.[46] Decisions regarding which water model should be used for a given simulation of protein–surface interactions should primarily be made based on selecting the water model that is recommended by the force field developers to go with the force field that is being used to represent the protein. For example, the CHARMM force field was parameterized with CHARMMs version of TIP3P water.[25] The explicit representation of solvation, however, comes at a very high computational cost because it greatly increases the number of atoms that must be represented in a molecular simulation, which directly translates into the need for much greater computing capacity and/or much longer wall-clock time to perform a given simulation.

To circumvent this problem, several methods have been developed to represent solvation effects using mean-field continuum approximations, which are referred to as 'implicit solvation' methods. The simplest of these methods involves merely changing the relative dielectric constant (ε_r) in the Coulomb's term of the force field (see eqn [1] or [2]) from a value of 1.0, which is used in explicit solvation simulations, to a value of about 79, which is the relative dielectric constant of bulk water at about 298 K.[18] A related technique involves setting $\varepsilon_r = r_{ij}$, or a function of r_{ij} (i.e., the distance between atoms i and j), which provides a situation where electrostatic interactions are very strong when atoms are close to one another, but rapidly dampen out as the separation distance increases to represent the influence of intervening water molecules that effectively shield electrostatic interactions between atoms. This procedure is known as the 'distant-dependent dielectric' (DDD) method.[18] This method was developed as a very crude approach to represent the dampening of electrostatic effects for protein folding simulations. While arguably better than not representing solvation effects at all, the use of this method alone is strongly recommended against because of the substantial artifacts in simulated behavior that it tends to cause.[18,47,48] The use of dielectric constant-based methods alone for the representation of solvation effects is even more problematic for the treatment of solute adsorption behavior in aqueous solution (e.g., protein adsorption), because these types of interactions are completely dominated by nonbonded interactions without the mediating effects of covalent bonds. In this case, this procedure will completely neglect the competitive interaction of water for the atoms of the solute and the material surface through both electrostatic and L-J interactions, thus tending to substantially overestimate the strength of adsorption, particularly for polar and charged functional groups. For example, Sun and Latour[49] have shown that the use of a DDD method alone will cause polar hydrophilic groups of the amino acid residues of a protein to be attracted to polar groups on a material surface nearly as strongly as they would in vacuum. Experimental studies have shown the exact opposite behavior, with these types of interactions being extremely weak due to the competitive adsorption behavior of water for polar functional groups of both the protein and a surface.[38]

A much more sophisticated and accurate form of implicitly representing solvation effects due to electrostatic interactions is provided through the use of the Poisson–Boltzmann (P–B) equation to calculate the free energy of molecular salvation.[50,51] However, this method is generally considered to be

too computationally rigorous (i.e., slow) to be used in MC and MD simulations, and thus, its use is primarily limited to MM simulations for the calculation of the electrostatic solvation free energy contribution of molecules in a given conformation. A much less computationally expensive approximation of the P–B equation, known as the generalized Born (GB) equation, has been developed and widely applied as an implicit solvation method for MD simulations of peptide and protein folding with a reasonable degree of accuracy.[52,53] P–B and GB methods, however, only address the electrostatic component of solvation effects but do not address molecular interactions that are driven by hydrophobic effects. To address this omission, an additional term is required in the force field equation. This term is generally expressed in the form of a surface tension per unit area parameter that is then multiplied by the surface area of the molecule in solution, thus providing a thermodynamic driving force for minimizing the exposure of nonpolar surface areas of a molecule to a surrounding aqueous solution.

As with all situations with molecular modeling, any implicit solvation method that is used for a given type of simulation should be checked and validated before it can be considered to be reliable for use. This is particularly important for protein–surface interactions where solvation effects play such a dominant role in the behavior of the system, and where relatively small imbalances in the representation of solvation effects can be expected to have large effects on predicted adsorption behavior.

3.311.3.3.4. Set up, control, and calculation of properties in a CM simulation

To prepare to conduct an MC or MD simulation of a given molecular system, the first step is to establish the coordinate positions and the bonded state of the atoms in the system.[18] For simulations involving proteins, coordinate positions are typically obtained by downloading structural information of the desired protein from the protein data bank (PDB). Coordinate positions for solid-phase materials are typically obtained from experimentally determined structures using nuclear magnetic resonance (NMR) spectroscopy or X-ray crystallography. The system to be modeled is then represented in a designated spatial volume defined by boundaries. If it is desired to represent conditions where the molecules of interest are contained in aqueous solution with the use of explicitly represented solvation, the free space in the bounded system is filled with solvent molecules (e.g., water molecules and salt ions) at the desired density (i.e., 1.0 g cm^{-3}). This is then generally followed by an energy minimization step using MM methods, which serve to adjust the positions of the atoms in the system to eliminate atom–atom overlap. In order to represent a continuous system, boundaries are typically represented using what are called periodic boundary conditions (PBCs), in which case, the molecular system contained within the boundaries is treated as a unit cell, which is replicated as periodic images in all directions surrounding the central, or primary, unit cell. With this type of system representation, when an atom or molecule moves across the boundary from the primary cell to an adjacent image of the periodic system, another atom or molecule of the same type and structure enters the system through the opposite boundary, thus providing a mechanism to maintain a constant number of atoms in the system throughout the simulation (see Figure 4). Because this then effectively represents an infinitely sized system, the use of PBCs creates a problem for the calculation of the nonbonded interaction terms of the force field, since atoms in the primary cell of the system will be influenced by the atoms in the infinite array of surrounding images of the unit cell of the system. To address this problem, nonbonded L-J interactions are only considered between atoms that are separated by less than a designated cutoff distance (typically around 8–12 Å), with this cutoff applied in a manner to smoothly truncate these interactions. This type of truncation can be done with minimal artifacts for L-J interactions because of their relatively short-range behavior (i.e., L-J interactions diminish as a function of r_{ij}^{-6}). In order to minimize artifacts due to atoms contained within the primary cell of the periodic system from interacting with images of themselves that are represented in the adjacent unit cell representations of the system, which can result in nonphysical correlations in atomic motion, the dimensions of the primary unit cell of the system should be at least twice the length of the cutoffs used for the the L-J interactions between atoms in the system. The use of cutoffs is generally not advised for handling nonbonded electrostatic interactions between atoms, which diminish on the order of only r_{ij}^{-1}. Electrostatic effects are therefore generally recommended to be handled through the use of Ewald summation methods,[54,55] which effectively account for the long-range nature of these types of interactions.[56]

Once the model of the molecular system is established, MC or MD simulations can be performed to simulate the molecular behavior of the system under defined sets of conditions (or ensembles), such as constant number of atoms (N), primary cell volume (V), temperature (T) (canonical ensemble) or constant N, pressure (P), and T (isobaric–isothermal ensemble). With respect to these parameters, N and V are obviously defined by the number of atoms modeled in the simulation and the size of the primary simulation cell, while T and P are determined from statistical thermodynamic relationships. For example, for MD simulations, T and P are determined by Leach[18]

$$T = \frac{2}{(3N - N_c)k_B}\langle \mathrm{KE}\rangle = \frac{\langle m_i v_i^2\rangle}{(3N - N_c)k_B};$$
$$P = \frac{1}{V}\left[Nk_BT - \frac{1}{3k_BT}\sum_{i=1}^{N}\sum_{j=i+1}^{N} r_{ij}\cdot F_{ij}\right] \quad [3]$$

where N_c is the number of constraints in the system (i.e., reduction in degrees of freedom), the brackets ($\langle\ \rangle$) represent the average value of the property contained within the brackets, KE is the kinetic energy of the system, m_i and v_i are the mass and velocity of atom 'i,' k_B is Boltzmann's constant, and r_{ij} and F_{ij} are the position vector and the force vector between atoms 'i' and 'j,' with the summation run over all atom pairs in the system. Ideally, a simulation is first run until the system equilibrates under the designated conditions (equilibration phase of the simulation), following which the simulation is then continued with the molecular coordinates and properties periodically saved and subsequently used to calculate the average properties of the system (production phase of the simulation) by averaging the values for the entire set of sampled states. For example,

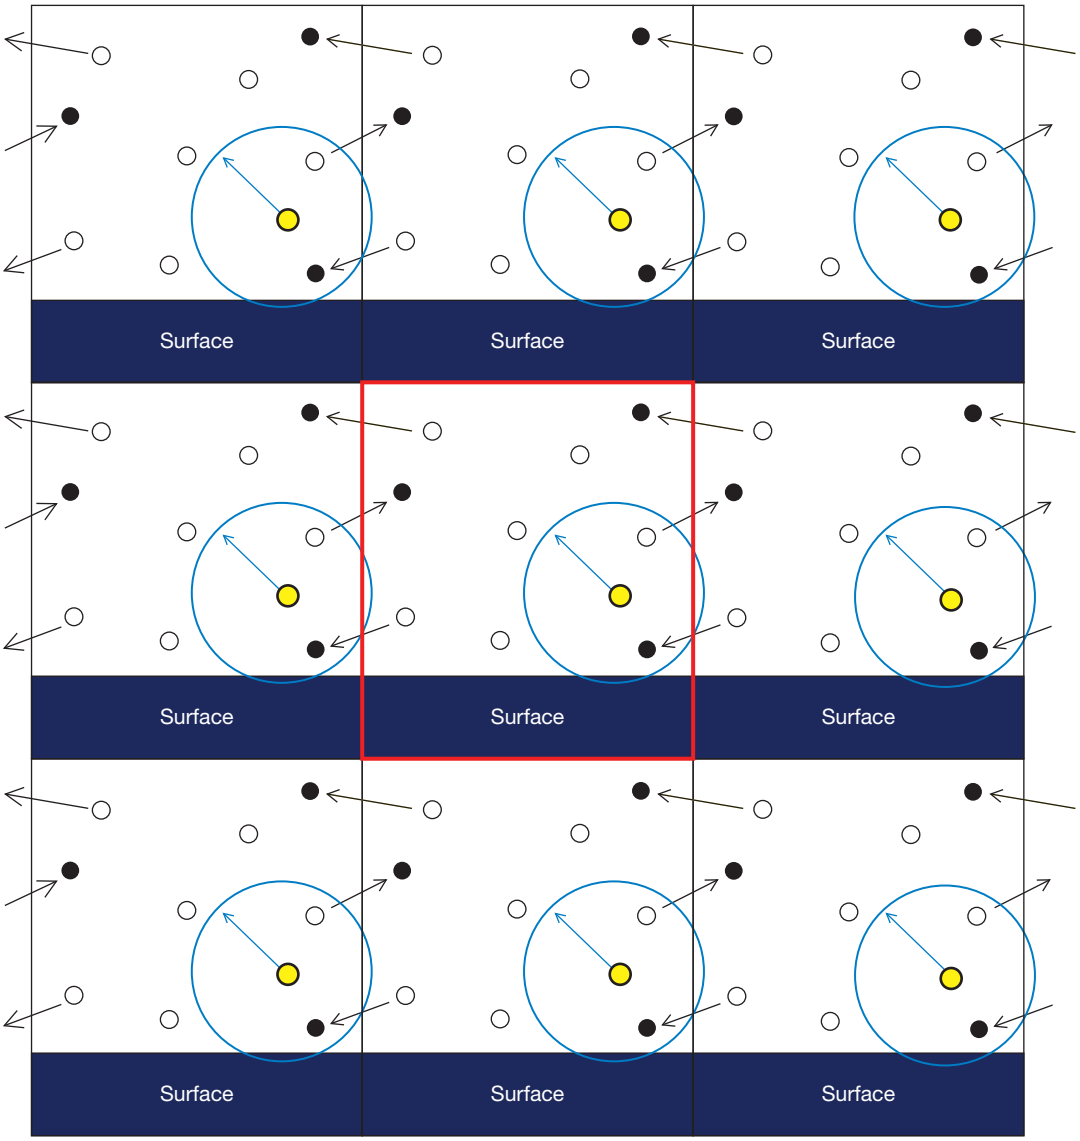

Figure 4 Illustration of periodic boundary conditions with the primary unit cell highlighted in red and surrounded by periodic images of itself. Molecules leaving the side of the primary cell enter back into the cell from the opposite side from another image, thus maintaining a constant number of atoms in the primary unit cell. The light blue circle surrounding the yellow atom indicates the cutoff radius for the calculation of L-J interactions for surrounding atoms acting on the yellow atom.

$$U = \langle E \rangle = \frac{1}{M}\sum_{i=1}^{M} E_i \qquad [4]$$

calculates the average potential energy (U) of the system, where M represents the number of individual states of the system that were sampled during the production phase of the simulation. These general methods are applicable for both MC and MD simulations. A summary of how each of these types of simulations is typically conducted is presented in the following section.

3.311.3.3.5. MC and MD methods

MC methods, which are most typically conducted in the canonical ensemble (i.e., NVT conditions), are used to efficiently search the conformational phase space of a molecular system.[18] The conformational phase space represents the potential energy surface of the system as a function of all of the coordinate degrees of freedom in the system. An MC simulation is conducted by applying various algorithms to move the positions of the atoms following a defined move set (e.g., random atom translation or dihedral rotation around a covalent bond) to efficiently explore the conformational phase space of the system. MC simulations typically employ what is referred to as 'importance sampling,' which was developed by Metropolis in the 1950s, and involves a random move to a new configurational state (x_i) combined with a decision algorithm that determines whether or not the newly sampled state should be accepted into the overall Boltzmann-weighted ensemble of

states that is being collected to represent the thermodynamic behavior of the system. The decision algorithm that provides this capability can be expressed thus:

$$\begin{aligned} &\text{If } E(x_j) \le E(x_i), \text{then accept new sampled state into} \\ &\quad \text{the ensemble of accepted sampled states} \\ &\text{If } E(x_j) > E(x_i), \text{then accept new state into ensemble} \\ &\quad \text{if } \mathrm{Rnd}(0-1) < exp[-(E(x_j) - E(x_i))/k_B T]. \end{aligned} \quad [5]$$

where $E(x_j)$ and $E(x_i)$ represent the potential energies of the newly sampled conformational state (x_j) and the previously accepted state (x_i), respectively, with these energies being calculated by the force field equation, and Rnd(0−1) represents a random number generated between 0 and 1. By design, this algorithm results in the probability of a sampled state, with energy $E(x_j)$ being accepted into the ensemble of previously accepted states with a Boltzmann-weighted probability ($P(x_j)$) equal to

$$P(x_i) = \{exp(-E(x_i)/k_B T)\}/Q; \quad \text{with } Q = \sum_i exp(-E(x_i)/k_B T) \quad [6]$$

where Q is the partition function of the system, thus generating a Boltzmann-weighted ensemble of sampled states. The implementation of this sampling process enables representative thermodynamic properties of a system to be directly determined simply by averaging the values of the accepted sampled set of states obtained from the simulation.

Because the move algorithms applied in an MC simulation are not time-dependent, MC simulations have the drawback of not providing direct information regarding the rate (or the kinetics) of a molecular process, but rather primarily only provide a means to determine the values of thermodynamic properties of a system. On the other hand, because the move set used to sample the phase space of a molecular system is not related to the kinetics of molecular motion, an MC simulation may provide an extremely fast and efficient method to sample the phase space of the system.

In contrast to an MC simulation, MD simulations use Newton's equations of motion to predict the behavior of the molecules in the system over time, typically under either NVT or NPT conditions, in a manner that reflects both the thermodynamic and the kinetic behavior of the system. In addition to needing the starting coordinates for each atom in a molecular system, an MD simulation also requires initial atomic velocities, which are typically obtained from a Maxwell–Boltzmann distribution of velocities for the designated temperature of the system,[18] with the additional requirement that the average velocity of the entire system is zero. Once the initial positions and velocities are set, the forces acting on each atom in the system are then calculated by the force field equation as a function of the atomic coordinate positions. Newton's second law (i.e., $F_i = ma_i$) is then applied to calculate the subsequent acceleration of each atom under the applied net force vector acting upon it. The acceleration is then numerically integrated over a short time-step to calculate each atom's new velocity and position, with the new coordinate positions of all of the atoms then used to calculate new force vectors for the next MD cycle. As an example, one of the commonly applied numerical integration algorithms that is used to determine the movement of atoms in an MD simulation is called the velocity Verlet algorithm, with the equations of motion expressed as[18]

$$\begin{aligned} r(t + \Delta t) &= r(t) + \Delta t\, v(t) + 0.5\Delta t^2\, a(t) \\ v(t + \Delta t) &= v(t) + 0.5\Delta t[a(t) + a(t + \Delta t) \end{aligned} \quad [7]$$

where r, v, and a are the position, velocity, and acceleration of a given atom, and t and Δt are the previous time point and the increment in time over which the system moves over each cycle of the simulation. The time-step used in an all-atom MD simulation must be small enough to enable the fastest motions of the system (i.e., covalent bond stretching vibrations) to be smoothly followed during the simulation: A time-step of 1.0 fs is often used in all-atom MD simulations, or if covalent bonds with hydrogen atoms are held fixed (by the application of algorithms such as SHAKE[57] or RATTLE[58]), a 2.0 fs time-step can be applied. This then reduces the amount of wall-clock time needed to cover a designated period of simulated time by a factor of 2 (i.e., a 2-month-long simulation can be completed in only 1 month).

As with the Metropolis MC method, the set of sampled states obtained from an MD simulation can be used to calculate the average values of thermodynamic properties of a molecular system. In this case, the probability of sampling a given state does not have to be established through the use of a Metropolis criterion, but rather the Newtonian dynamics process itself provides a Boltzmann-weighted sampling of states, ideally similar to that which occurs for the real system. The ability of both MC and MD simulations to serve as equivalent methods to determine the average properties of a molecular system is supported by the ergotic hypothesis, which states that the average value of a property determined from an ensemble average of sampled states (e.g., from an MC simulation) is equal to the time-averaged property of the same molecular system (e.g., from an MD simulation).[18,22] A critical requirement for either of these approaches, however, is that the phase space of the system must be sampled ergotically, meaning that all of the relevant conformational states of the system must be thoroughly sampled in the simulation. One of the key problems in this requirement is that it is often very difficult to know when either an MC or MD simulation has run sufficiently long (or sampled the system sufficiently well) to represent a properly equilibrated, ergotically sampled system. In fact, in systems with complex free energy landscapes, such as the case of protein folding (see **Figure 1**) or protein adsorption (see **Figure 3**), it is generally impossible with today's computational resources to run a conventional MC or MD simulation long enough to ergotically sample the system. Instead, simulations generally tend to be trapped in local low-energy regions without adequately exploring the full conformational phase space of the system, with averaged values obtained from the simulation then providing poor estimates of the desired properties. To overcome this limitation, several types of advanced, accelerated sampling methods have been developed that enable energy barriers to be more rapidly crossed that tend to trap a molecular system in a particular region of phase space, thus enabling systems to be equilibrated in a much shorter

computational time frame than can be achieved with conventional MC or MD methods. A few of these accelerated sampling methods are addressed in Section 3.311.3.3.6.

The decision of whether an MC or an MD method would be the best choice for the simulation of protein–surface interactions will depend on the system being reproduced and the properties that are desired. For example, if it is desired to conduct a simulation to address which face of a protein will be most strongly attracted to a given surface, thus addressing the issue of the initial adsorbed protein orientation, and if the solvent is being represented using a validated mean-field implicit solvation algorithm, an MC method would probably be the most efficient. In this case, the protein could be represented as a rigid molecule that is rotated and translated over a designated set of incremental moves to rapidly generate a converged set of states that depict how the potential energy of the system changes as a function of the protein's initial orientation on the surface. An MD simulation in this case would not be nearly as efficient because of the relatively slow kinetics involved for a protein rotating over a material surface. In comparison, if protein adsorption behavior were to be investigated in a simulation using explicitly represented solvation, MC moves are limited to very small increments because any large change in the position of the atoms of the protein would cause it to overlap with the neighboring atoms of the solvent, leading to unacceptably high values of potential energy due to the repulsive component of the L-J term in the force field. In this case, MC and MD methods would both be expected to provide about the same general degree of efficiency for sampling the various states of the system, with an MD simulation providing additional data regarding the predicted time course of the simulation.

3.311.3.3.6. Accelerated sampling methods

Accelerated sampling methods that are used in MC and MD simulations involve the application of specifically designed algorithms that enable energy barriers separating the various microstates in a molecular system to be rapidly crossed, thus facilitating the ability to ergotically sample a molecular system with a rugged potential energy landscape much more efficiently than in a conventional simulation. The basic principles behind most advanced sampling algorithms can be understood based on the statistical mechanics relationships that describe the probability (P_i) of a given state for a molecular system and the probability of sampling a different state, P_j, relative to P_i (i.e., P_j/P_i). These relationships can be described by the following set of equations[59]:

$$P_i = \frac{e^{-E(x_i)/k_B T}}{Q}, \quad \text{with } Q = \sum_i e^{-E(x_i)/k_B T} \text{ and } P_{ij} \equiv \frac{P_j}{P_i} = e^{-\Delta E_{ij}/k_B T} \qquad [8]$$

The first two of these equations are equivalent to those shown in eqn [6], and the third equation represents the relative probability of sampling the system in conformal state x_j verses x_i where ΔE_{ij} is the difference in potential energy between states x_j and x_i. Given these relationships, the probability of the system being in a given energy state can be adjusted by altering the value of the group of parameters in the exponential part of the probability expression (i.e., $E(x_i)/k_B T$), either by introducing a biasing energy function into the force field equation to influence the energy state of the system (E_i) or by adjusting the temperature of the system (T).

The introduction of a biasing energy function (B_{ij}) can be done by adding a user-defined term directly into the force field equation that controls how the atoms interact with one another during the simulation in a manner that lowers the energy barriers separating the various states of the system that one wishes to sample during the simulation.[60] The introduction of a biasing function can be expressed mathematically by eqn [9][36]:

$$\overline{P}_{ij} \equiv \frac{P_j}{P_i} e^{-B_{ij}/k_B T} = e^{-(\Delta E_{ij} + B_{ij})/k_B T} \qquad [9]$$

where $\overline{P}_{ij}$ represents the biased probability distribution that results from the addition of the biased-energy function. As is clear from the relationship expressed on the far right-hand side of eqn [9], if B_{ij} is set to exactly cancel the potential energy difference between two states of the system (i.e., $B_{ij} = -\Delta E_{ij}$), then the net energy difference separating them will be zero, creating a situation where there is equal probability of being in either state, thus eliminating the sampling problem. After the simulation is completed, the biased probability ratio that is obtained from the trajectory of the simulation is then corrected to remove the applied bias to obtain the unbiased probability distribution by inverting eqn [9] to obtain eqn [10]:

$$P_{ij} \equiv \frac{P_j}{P_j} = \overline{P}_{ij} e^{B_{ij}/k_B T} \qquad [10]$$

This method is highly effective if the coordinate position and the depth of a given local low-energy well are known such that a biasing energy function can be appropriately determined and applied in the simulation. If these parameters are not known *a priori*, they can be determined by running preliminary simulations to assess where the system tends to become trapped, and then adaptively adding in a biasing function until the sampling problem is removed.[61,62]

The use of a biased-energy function is most widely used to force sampling over a single designated system coordinate, such as either the dihedral rotation about a bond in a peptide chain[60,63] or the separation distance between a solute and a material surface.[36] For these types of applications, an umbrella sampling technique[60,64] is typically used in the form of

$$B_u = k_u (\lambda - \lambda_u)^2, \qquad [11]$$

which is also referred to as a 'restraining potential,' where k_u is the stiffness constant, λ_u is the coordinate parameter of interest (which is set at a designated coordinate value), and λ is the sampled value of the coordinate at a given point in the simulation. In this form, the biasing energy function (B_u) penalizes the system in a quadratically increasing manner as it deviates from the designated position, λ_u. A series of independent parallel simulations, referred to as 'windows,' can then be carried out with the value of λ_u incrementally varied over the full range of interest, with the increments set such that the neighboring sampled populations overlap one another. The resulting overlapping sampled distributions from all of these simulations can then be combined using the weighted histogram analysis

method (WHAM),[65,66] which serves to remove the applied bias from the combined set of sampled distributions and generate an unbiased probability distribution of states over the full range of the parameter of interest (i.e., over the full range of λ).

More recently, a biased-energy method has been developed, which is called metadynamics,[67,68] that adds relatively small Gaussian-shaped biasing energy functions to the system in an incremental manner to effectively 'fill up' a given low low-energy well that the simulation may be trapped in, causing the simulation to then move on to explore other areas of phase space. This process is continued in an automated manner until the energy landscape is effectively smoothed out such that all relevant energy barriers are removed, with the simulation then progressing with essentially equal probability to sample all areas of phase space. The resulting summation of the applied biasing functions then effectively represents a 'mold' of the full potential energy surface from which the thermodynamic properties of the system can be properly determined.

As an alternative to biasing the energy function in a simulation, temperature can also be used to accelerate sampling in a molecular system. In this case, sampling is accelerated not by lowering the free energy barriers, but by providing increased thermal energy to enable the barriers to be much more rapidly crossed. The use of temperature is particularly effective because it simultaneously acts on all degrees of freedom in the system. One of the most widely used methods that uses temperature to accelerate sampling is known as parallel tempering (PT),[69] which was developed for implementation in MC simulations, with a very similar type of algorithm called replica-exchange MD (REMD) being developed for MD simulations.[70,71] In each of these methods, independent simulations are run in parallel for a series of replicas of the molecular system, with each replica being simulated at an increasingly higher temperature level above the baseline temperature of interest, for example, 298 K. After a given period of simulation (e.g., 250 steps of MC or cycles of MD), a Metropolis-like statistical mechanics-based exchange algorithm is applied in the following form:

$$\text{If } E(x_j)_n \leq E(x_i)_m, \quad \text{then exchange temperatures between replicas} \tag{12}$$

$$\begin{aligned} &\text{If } E(x_j)_n > E(x_i)_m, \quad \text{then exchange temperatures} \\ &\quad \text{if } \mathrm{Rnd}(0-1) < \exp[-(\Delta\beta_{imn}\Delta E_{ij})], \quad \text{with } \Delta E_{ij} \\ &= E(x_j)_n - E(x_i)_m \text{ and } \Delta\beta_{mn} = \left(\frac{1}{k_B T_m} - \frac{1}{k_B T_n}\right) \end{aligned}$$

where $E(x_j)_n$ and $E(x_i)_m$ represent the potential energy of the system sampled at temperature T_n and T_m, respectively, with T_n being the next higher temperature interval above T_m along the 'temperature ladder' in the overall system. If an exchange is accepted, then the temperatures between the pair of replicas are swapped. If it is not, the replicas remain at their prior temperature levels for another cycle of sampling, following which the swapping decision process is repeated again. A diagram depicting this process is shown in Figure 5. By this method, a replica that is trapped in a local low-energy well that actually represents a relative high-energy state of the system tends to be exchanged upward in temperature, which provides additional thermal energy to help the replica

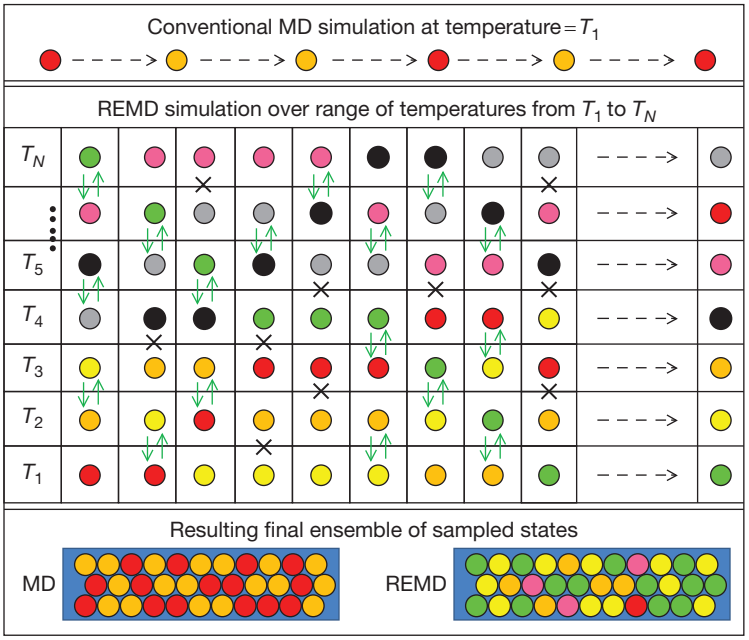

Figure 5 Illustration of a replica-exchange molecular dynamic (REMD) simulation in contrast with a conventional MD simulation. Each colored circle represents a different region of the phase space that is sampled in the simulation. The MD simulation (top of figure) tends to be trapped by the energy barriers in the system, thus greatly limiting the regions of phase space that are sampled. In the REMD simulation, the elevated temperature levels provide additional thermal energy to speed up the crossing of energy barriers. The Metropolis-like exchange process is represented by a set of green arrows (exchange accepted) and black 'Xs' (exchange not accepted). The exchange process enables the replicas to change temperature levels, which provides much better sampling over the phase space and results in a Boltzmann-weighted distribution of states being sampled at each temperature level.

escape from that local energy well to explore other regions of the phase space of the system. Similarly, replicas that move into relatively low-energy states tend to be exchanged downward in temperature, thus increasing their probability of being sampled at the baseline temperature. This somewhat complicated process greatly enhances the sampling of the conformational phase space of a given molecular system and generates a Boltzmann-weighted ensemble of states at each temperature level from which ensemble-averaged thermodynamic properties of the system can be calculated.

While PT and REMD are extremely useful computational techniques, because the number of replicas that are needed to perform a simulation is proportional to the square root of the number of atoms in the system, they can rapidly become very computationally expensive for a large molecular system. Furthermore, the time taken for a replica to move from the high-to-low temperature levels in the simulation is proportional to the square of the number of replicas used in simulation, thus substantially increasing the amount of wall-clock time required to equilibrate a system with a large number of replicas.[72] The combination of these two factors can make a conventional PT or REMD simulation too computationally expensive for practical use for the simulation of a large molecular system. To address these limitations, many different versions of these methods have been (and are being) developed to improve computational efficiency.[73,74] Along these lines, the Latour group has recently developed a new advanced sampling method, which is called 'temperature intervals with global exchange of replicas' (TIGER),[75] and a revised method called TIGER2.[72] These methods were specifically designed to uncouple the number of replicas that must be used to span a given temperature range from the size of the simulation, thus enabling REMD-like simulations to be conducted with a much smaller number of replicas than must be used for a conventional REMD simulation.

3.311.4. Application of All-Atom Modeling Methods to Simulate Protein–Surface Interactions

Atomic-level molecular simulations of protein–surface and peptide–surface interactions have been conducted over about the past two decades. In this section, an overview of several of these efforts is presented with a focus on selected studies that have addressed key issues in this field, with specific emphasis applied to the types of force fields used, the methods used to represent solvation effects, and the issues related to system sampling. As shown, the sophistication of these efforts has continued to dramatically increase over the years as computational power has continued to grow at an exponential pace, and investigators have developed a better understanding of the issues that must be addressed to accurately simulate this type of molecular system.

3.311.4.1. Early Efforts Beginning in the Late 1980s

3.311.4.1.1. Simulations with limited conformational sampling and treatment of solvation effects due to computational limitations

Some of the first studies to use empirical force field-based molecular modeling to investigate protein–surface interactions were published by Park and coworkers from 1989 to 1994.[76–78] In their first paper, simulations were conducted to calculate the initial potential energies of interaction between a set of four proteins (lysozyme, trypsin, an immunoglobulin fragment, and hemoglobin) on five polymer surfaces (polystyrene, polyethylene, polypropylene, poly(hydroxyethyl methacrylate), and poly(vinyl alcohol)), with the proteins treated as rigid elements that were rotated over a broad range of orientations over each polymer surface. The force field used to calculate interactions included terms for electrostatic, dipole (e.g., hydrogen bonding), dispersion, and overlap repulsion. At this early stage of development, a force field term for solvation effects was not included. The results from these studies predicted interaction energies ranging from about -200 to $+150\,\mathrm{kcal\,mol^{-1}}$. The results of these simulations predicted that the strongest interactions occurred for protein adsorption on the strongly hydrophilic poly(vinyl alcohol) surface rather than on the hydrophobic polymers. These results can be understood by realizing that without including solvation effects, these simulations actually represented the adsorption behavior of the proteins under vacuum conditions instead of aqueous solution, with the expected result that the polymer with the most polar functional groups (i.e., poly(vinyl alcohol)) would yield the strongest adsorption behavior. While this would be expected under vacuum conditions, the presence of the competitive interactions by water would be expected to actually make protein adsorption to this very hydrophilic polymer relatively weak compared to a hydrophobic surface such as polyethylene, where hydrophobic effects are known to cause very strong adsorption.[79] Despite these initial limitations, this work represented quite an ambitious start to model the complexities of protein adsorption behavior.

Park and coworkers followed up their initial paper with a subsequent study published in 1991[77] for this same set of proteins and polymers where the interaction energies due to solvation effects were included in their calculations. In this new set of simulations, solvation effects were based on experimental data regarding the partitioning of amino acids between water and various organic solvents. These new data predicted adsorption energies to be between about -62 and $-20\,\mathrm{kcal\,mol^{-1}}$ on the hydrophobic polymers, with positive adsorption energies for the hydrophilic polymers. These results are thus much more in agreement with the experimentally observed behavior that proteins adsorb more strongly on hydrophobic than hydrophilic polymers and nicely demonstrated the importance of including solvation effects in these types of calculations. Lee and Park then published a follow-up study in 1994[76] in which they used their methods to calculate how adsorption energy changed as a function of separation distance between proteins and polymer surfaces. In these studies, the L-J parameters were borrowed from the CHARMM force field, partial charges for atoms were borrowed from the AMBER force field, and solvation effects were treated implicitly based on experimental solvation free energies for amino acids and the changes in solvent-accessible surface area of the amino acid residues as a function of a protein's position over a surface. Due to limitations of computational power at that time, it was necessary to keep the protein and polymer molecules rigid, with interaction energies then calculated for two different orientations of each protein over each surface as the proteins were translated in 1.0 Å increments away from the surface. From these simulations, the authors predicted that adsorption

energies reduced to zero once the proteins were 20–30 Å away from the surface. They also made a specific note that while this method of implicitly accounting for solvation effects was much more reliable than using a simple dielectric constant method, there was a distinct need for increased computational power so that the solvent could be explicitly represented in the simulations. In addition, increased computing power was needed to allow mobility for both the protein and polymer functional groups, thus providing much better sampling of the system.

Another relatively early paper addressing protein–surface interactions was published by Noinville *et al.*[80] In this study, the interactions between an acidic protein (α-lactalbumin) and a basic protein (hen egg-white lysozyme) were simulated over a positively charged poly(vinyl imidazole) polymer surface, which is used in anion-exchange chromatography. In these simulations, the structure and partial charge distribution for the polymer model was predicted from SEQM simulations, and the polymer surface was constructed to provide a net surface change density of 0.10 C m^{-2} to match experimentally determined properties of this ion-exchange polymer on a silica substrate. The protein structures were obtained from the PDB and they were rigidly fixed for the simulations. The simulations were then performed by rotating the proteins in 5° increments and translating them between 1 and 100 Å over the surface for a total of 2592 different configurations over the surface. The interaction energies between the proteins and the surface were calculated for each configuration using the AMBER force field. Solvation effects were represented using a DDD function in the denominator of the Coulomb's law expression, with an additional exponential term added in the numerator of the function in the form of $\exp(-\kappa r_{ij})$ to account for the dampening of electrostatic effects due to the concentration of salts in solution, where r_{ij} represented the distance between an atom of the protein and an atom of the surface, and κ was the inverse Debye length calculated for a 150 mM Na_2SO_4 salt solution. The simulation results were subsequently used to calculate the average values of the interaction energy, predict preferred orientations of each protein over the polymer surface, and which amino acid residues of the proteins were most strongly attracted to the surface. While the results from these simulations were judged to be in general agreement with experimental results for similar systems, the authors recognized the limitations of the simulations due to the need to use an implicit solvation method to account for solvation effects and the lack of conformational freedom of the protein, with these approximations again being necessary given the limitations of computing power at that time.

3.311.4.1.2. Early MD simulations of protein–surface interactions with increased conformational sampling and explicit solvation

One of the first set of studies using MD simulation to investigate protein–surface interactions that included explicitly represented solvation effects was reported by Pitt and coworkers in 1997 and 1998.[81,82] In these studies, a small pentapeptide protein called leucine-enkephalin was modeled over a crystalline polyethylene surface. This peptide was predicted to fold into a conformation that resulted in a hydrophobic surface on one side and a hydrophilic surface on the other. In their simulations, the protein was modeled with either all atoms fixed in position or with only the α-carbons of each amino acid residue fixed, and the explicitly represented water molecules were allowed to be fully mobile. The MD simulation was performed with PBCs using the consistent valence force field (CVFF) using the InsightII/Discover software programs with a cutoff of 8 Å used for all nonbonded interactions. The protein was placed in different orientations over the surface and translated in increments of 0.4 Å from 1.5 to 9.5 Å over the surface for each orientation while MD simulations were performed to allow the solvent molecules to adapt and interact with the solute–surface system. The MD simulations were run using a 1.5 fs time-step with 300 steps of energy minimization applied, followed by 1000 steps (i.e., about 1.5 ps) for initial system equilibration to 298 K, followed by 12 000 steps (i.e., 18 ps) of production-run simulation, with the average net force acting on the protein calculated from the production-run phase of the simulation. The results from these simulations showed a significant influence of protein orientation over the surface, with an attractive adsorption force occurring when the protein was orientated with its hydrophobic side facing the surface and with a repulsive adsorption force occurring when the hydrophilic side of the protein was oriented toward the surface. The dipole orientation of the water over the polymer surface was also analyzed and found to be much more highly ordered than in the bulk water. Significant differences in the adsorption force were found to occur between simulations when the protein was held fully rigid as opposed to only fixing the five α-carbons and leaving the rest of the atoms of the protein free to move. In their discussion in their 1997 paper, Pitt and Weaver did an excellent job in assessing the limitations of their simulation methods. While their simulations yielded reasonable results, they commented on the fact that they had little basis to judge the accuracy of the L-J interactions between the protein, polymer surface, and water because these interactions were calculated using force field parameterization that was neither developed nor validated for this type of application. They also reflected on the short duration of their simulations and the influence that fixing the atoms of both the protein and the polymer surface may have had on the accuracy of the average properties determined from this very limited degree of sampling. This relatively early paper thus highlighted three key issues that are extremely important for the accurate simulation of protein–surface interactions: (i) the importance of accurately representing solvation effects through the use of explicitly represented water in their simulation, (ii) the question of the accuracy of their force field parameters to represent interfacial interactions, and (iii) the importance of adequately sampling the phase space of the molecular system.

3.311.4.1.3. Early matched experimental and simulation efforts to support force field parameterization for protein–surface interactions

Recognizing the lack of experimental studies that provide quantitative data on the thermodynamics of the interactions between individual amino acids within a polypeptide chain and surface functional groups, Latour and colleagues planned a combined set of experimental and computational studies to investigate the energetics related to the adsorption of individual lysine amino acid residues of a polylysine chain and a silica glass surface.[83–86] The experimental studies involved the generation of isotherms from the adsorption of polylysine chains

varying from about 1000 to 25 000 Da in molecular weight onto silica glass beads over a range of concentration and temperature. Simulations were conducted using SEQM methods with AM1 parameterization to calculate the enthalpy of interactions between the amine group of a lysine side chain and the hydroxyl group of individual silica rings of a silica glass surface. MM methods using MM2 parameterization were then also conducted to predict the conformational behavior of a polylysine chain to estimate the likely number of amino acid side chains that would be able to interact with a silica glass surface when a polylysine chain adsorbed. The results from the experimental studies yielded an average value of about −0.23 kcal per mol per residue for the enthalpy of interaction between a polylysine chain and silica glass. The SEQM AM1 results predicted that an individual hydrogen between a lysine side chain and a hydroxyl group of a silica ring to be $-3.7\ \text{kcal mol}^{-1}$, which was about an order of magnitude lower than the experimental value. However, the MM calculations suggested that the polypeptide chain should exist in a helical conformation with about one turn per eight amino acid residues, thus suggesting that only about one out of eight of the lysines of the polypeptide chain may actually be able to form a hydrogen bond to the silica when adsorbed. This effect combined with the composition of the silica glass, resulted in an estimated value of −0.34 kcal per mol per residue of a polylyine chain, which provides very reasonable agreement with the experimental results. The developed methods, however, also had several recognized limitations. The experimental methods had the inherent problem of limited applicability to other types of surfaces, and adsorption results were considered to be very susceptible to the conformational behavior of the relatively long polypeptide chains. Recognized limitations in the simulation methods included the fact that SEQM models were limited to only small sets of atoms, thus only being able to address the interactions between individual amino acid residues and units of silica structure as opposed to a larger polypeptide chain or protein interacting with a silica surface, and the lack of the explicit inclusion of solvation effects in the SEQM models. In addition, the calculations only represented the enthalpic contributions of amino acid–surface interactions but not the free energy of these types of interactions, which would require the inclusion of entropic effects as well. Despite these limitations, these studies provided some of the earliest attempts to combine experimental and molecular simulation studies to understand the molecular-level interactions between individual amino acid residues of a polypeptide chain and functional groups presented by a biomaterials surface, and to provide the types of experimental data that are necessary to support the evaluation, modification, and validation of force field parameters that will accurately represent protein–surface interactions.

3.311.4.1.4. Early MD simulations of protein–surface interactions with minimal constraints

One of the first MD simulations performed with a relatively large unconstrained protein was presented by Klein and coworkers in 1996,[87] in which simulations were conducted using the CHARMM19 force field to investigate the interactions between cytochrome c (an electron transfer protein) and alkanethiol SAM surfaces functionalized by either methyl (hydrophobic) or thiol (hydrophilic) functional groups. This system was of particular interest to help understand protein–surface interactions that were related to electron transfer processes in cell membranes and for the possible development of biomimetic devices. Because the intended devices were used in air, solvation effects were not included, with vacuum conditions thus being represented surrounding the protein and SAM surface. The MD simulations were conducted with the protein and SAM surface atoms fully free to move with the exception of a layer of locked sulfur atoms at the base of the SAM surface to represent a foundational support. The temperature was maintained at 300 K using a Nosé-Hoover thermostat to control temperature, with PBCs applied. The L-J interactions were truncated at 10 Å and long-range electrostatic effects were represented using Ewald summation. The simulations were conducted for about 1.1 ns using a 1.5 fs time-step. The results from these simulations showed that the protein actually interacted much more strongly with the hydrophilic than the hydrophobic surface, which is to be expected in vacuum given the fact that under such conditions, the hydrophilic groups of a surface will attract the protein through both weak dispersion and relatively stronger electrostatic interactions, while the nonpolar surface will only attract the protein by relatively weak dispersion forces. While this work represented a substantial advancement in the simulation of protein–surface interactions by treating the protein and surface in a largely unconstrained manner, the representation of vacuum conditions in the simulations was certainly less than ideal compared to experimental conditions where this protein was adsorbed to these types of surfaces under an air environment with a designated degree of humidity.

3.311.4.2. Advancements in Protein–Surface Simulations in the First Decade of the Twenty-First Century

3.311.4.2.1. Protein interactions with surfaces presenting organic functional groups

One of the first papers involving protein–surface interactions that was published in the first decade of the twenty-first century was a follow-up study reported by Klein and coworkers to investigate the influence of condensed water vapor on the adsorption behavior of cytochrome c on SAM surfaces functionalized with hydroxyl and methyl surface groups.[88] In these simulations, 100–500 TIP3P water molecules were added to the system to represent different degrees of condensation, and the hydrophilic thiol functional groups from the first study were replaced by hydroxyl groups. Not surprisingly, the results from these studies showed that the water molecules primarily clustered around the protein but not the surface for the hydrophobic SAM, while wetting both the protein and the surface for the hydrophilic SAM. As with the previous study under vacuum conditions, the 2002 study also indicated stronger interactions of the protein with the hydrophilic SAM surface, which demonstrates that simply adding a relatively small number of water molecules to a protein–surface system surrounded by vacuum to represent condensed water vapor (as purposely intended by the authors) represents conditions far different from protein–surface interactions in bulk aqueous solution. The results from these simulations showed that the angle between the plane of the heme group of cytochrome c with respect to the surface favorably compared with optical linear dichroism measurements of similar systems. While these simulations represented

some of the most ambitious and well-carried out studies to date, it must be realized that 1.5 ns still represents very limited sampling for this type of complex molecular system, with orders of magnitude longer simulation times most likely being needed for proper system equilibration.

Beginning in 2002, Raffaini and Ganazzoli[89–93] began publishing their efforts to conduct MD simulations to study protein interactions with surfaces, such as graphite and polyvinyl alcohol, using a set of methods that they have put forth as a standard approach for conducting these types of simulations. Their simulations were conducted using the InsightII/Discover software program with the CVFF force field. By their standardized approach, a protein is first placed over a surface and energy minimized with solvation effects represented using a DDD method alone. MD simulations are then run for about 1 ns at 300 K with the same implicit solvation function. The resulting structures are then once again energy minimized, following which several thousand explicitly represented water molecules are added to the simulation with an additional 10 ps of MD simulation run to provide time for a water structure to develop around the functional groups of the protein–surface system. While this group has been extremely prolific in publishing results, this procedure being applied to a broad range of protein–surface systems, it is important to realize that there are, unfortunately, several serious problems with this approach. First of all, as has been well documented by others and addressed in **Section 3.311.3.3.3**, the representation of solvation effects solely using a DDD function causes severe artifacts in a simulation, with the resulting molecular behavior being far different than that which would occur under aqueous solution conditions.[18,47,48] This type of implicit solvation method only serves to weaken electrostatic effects and does not represent the competitive binding behavior of water for polar and charged functional groups in the system. The use of this approach thus effectively represents a vacuum environment with dampened long-range electrostatic effects as opposed to an aqueous solution environment, and explains why most of the simulations conducted using these methods have predicted the complete unfolding of a protein over a surface, with the protein ending up adsorbed as a randomly coiled single-layer thickness of amino acid residues. While the subsequent addition of explicit water to the system followed by 10 ps of MD simulation is sufficient to enable a water structure to form around the functional groups of the protein and surface, this period of time is many orders of magnitude off of what would be needed to actually reequilibrate this complex type of molecular system. Therefore, while this group has made a serious attempt to develop a very computationally efficient method of simulating protein–-surface interactions, the use of a DDD function alone to represent solvation effects creates conditions very far from reality and simply should never be used alone to represent the simulation of protein adsorption behavior under aqueous solution conditions.

In another relatively early effort to provide a more realistic implicit solvation model for the simulation of protein interactions with organic functional groups, and to extend their previous modeling efforts, the Latour group conducted a series of SEQM simulations to calculate adsorption free energy versus surface separation distance (SSD) profiles for amino acid interactions with various types of functionalized surfaces.[94–97] In these SEQM simulations, solvation effects were represented using a conductor-like screening model algorithm (COSMO)[98] to represent electrostatic interactions combined with a surface energy versus solvent-accessible surface area term to represent entropic effects related to functional group desolvation. The developed free energy versus SSD profiles were then used to adjust force field parameters using the InsightII software program with InsightII's version of the CHARMM force field, with this modified force field then applied to characterize the adsorption behavior of a fibronectin fragment over various alkanethiol SAM surfaces. The protein fragment was first rotated around its long axis in 15° increments for a full 360° of rotation, with energy minimization performed at each step. The lowest energy orientation of the protein fragment over each surface was then used to perform a short 50 ps MD simulation to evaluate the initial phase of adsorption of the protein fragment on each surface. The results of these simulations were used to predict the relative adsorption strength of this protein fragment on each type of functionalized surface and the accessibility of the integrin binding sites in the protein fragment following adsorption. Despite the extremely short duration and limited degree of sampling provided by these simulations, the results were qualitatively found to be in close agreement with experimentally determined adsorption behavior of this protein fragment on similar SAM surfaces.

The Jiang group has also served as one of the pioneering groups working toward the development and application of methods to simulate protein interactions with surface functionalized with organic functional groups.[99–103] They have developed a combined MC/MD approach using the CHARMM force field. As recognized by the Jiang group, before conducting an MD simulation to investigate protein adsorption behavior on a surface, it is necessary to first select a given orientation of the protein on the surface, which poses a very complex problem in its own right. This group's approach to address this problem was to first conduct an MC simulation with the protein held in a fixed conformation while rotating and translating it over the surface to thoroughly sample the phase space for this type of defined system (e.g., 10^6 different sampled states) while calculating the potential energy of the system for each configuration. Because this type of MC simulation cannot be efficiently conducted using explicitly represented solvation, an implicit solvation method must be used. The method selected by the Jiang group for their MC simulations was once again the DDD function. While the same criticism applies for the use of this type of implicit solvation method as previously discussed, the method of using an MC simulation with implicit solvation to identify initial low-energy orientations of a protein over a surface provides a much more sophisticated approach for selecting starting orientations for MD simulations than simply randomly selecting orientations for subsequent MD simulations. Using this method, predicted low-energy orientations of the protein over the surface were identified and subsequently used as the starting structures to perform 1.0 ns long simulations in explicitly represented solvent using TIP3P water with Na^+ and Cl^- ions added to maintain charge neutrality, with both L-J and electrostatic interactions truncated at 11 Å. The Jiang group has applied these methods to study a broad range of protein–surface interactions, primarily for surfaces with organic functional groups, and have particularly contributed to understanding the molecular basis of surfaces that provide high levels of protein adsorption resistance.

3.311.4.2.2. Protein interactions focused on surfaces presenting inorganic functional groups

While the majority of molecular simulations of protein adsorption behavior conducted in the 1990s and early 2000s involved interactions with organic surfaces, more recently, several groups have been developing and applying molecular simulation methods to study the interactions of proteins on inorganic surfaces, including metals, metal oxides, and minerals. In addition, as computational power and algorithm development have continued to expand, many of these efforts have employed relatively new, more sophisticated techniques with the potential to improve the accuracy of protein adsorption simulations. In particular, increased attention has been paid to force field parameterization to accurately represent interactions at the peptide–surface interface.

As an excellent example of some of these more recent developments, the Walsh group has conducted combined MC and MD simulations to investigate the atomic-level interactions between various peptides and inorganic surfaces, including TiO_2,[104,105] quartz,[106] and carbon nanotubes.[107] In preparations for simulations to study the adsorption behavior of peptides and TiO_2 surfaces, DFT simulations were first conducted between water and TiO_2 (110) surfaces for comparison with MD simulations using a TIP3P water model in the TINKER molecular simulation program. Force field parameters for the TiO_2 surface were obtained from previous studies.[105] Comparisons between the water structure over the surface (e.g., density profile and dipole orientation distribution) predicted by both methods confirmed that the TIP3P water model was able to provide a very reasonable representation of solvation effects over a TiO_2 surface. A subsequent paper then reported on combined MC/MD simulations that were conducted to predict the adsorption behavior of specifically sequenced hexapeptides on TiO_2 surfaces.[104] These simulations were conducted using the DL-Poly simulation program, with the parameters for TiO_2 and TIP3P water obtained from their previous study and the parameters for the peptide obtained from the CHARMM force field. Similar to the approach used by the Jiang group, initial orientations of the peptide over the surface were determined by an MC simulation using implicit solvation. In this case, however, a more sophisticated implicit solvation method was used instead of the simple DDD method. The Walsh group instead represented solvation effects using the atomic solvation parameter (ASP) method, which is based on experimentally measured solvation free energies of amino acids coupled with the calculation of solvent-accessible surface areas during the simulation. In addition, recognizing that the accuracy of this solvation method still has not been validated for this type of application, a large number of alternative conformations of the peptide over the TiO_2 surface were also considered. Low-energy orientations were subsequently selected, the system was solvated with TIP3P water and counter ions, and 2.0 ns MD simulations were conducted, with PBCs and Ewald summation being used for representing long-range electrostatic interactions. The results of the simulations were then analyzed to assess the conformation and structure of both the peptide and water over the TiO_2 surface, and to determine which amino acid residues of the peptide were predicted to strongly mediate the association of the peptide with the TiO_2 surface.

The Walsh group has also recently published one of the first sets of studies of peptide–surface interactions with the use of a polarizable force field.[107,108] As mentioned in Section 3.311.3.3.2, one of the limitations with fixed-charge force fields is that atoms in the system are not able to change their assigned partial charges to adjust to changes in their local surroundings. The ability to adapt in this manner can be particularly important for accurately capturing the adsorption behavior between peptides containing aromatic amino acids (e.g., tryptophan) and surfaces containing aromatic ring structures, such as graphite and carbon nanotubes where π-stacking interactions can substantially influence adsorption behavior. Recognizing these issues, Walsh and coworkers conducted simulations of the interactions of peptides with both single-walled carbon nanotubes (SWNT) and graphite surfaces with various degrees of curvature using the AMOEBA polarizable force field in the TINKER simulation package.[109,110] The AMOEBA force field incorporates methods to address electrostatic interactions in a much more sophisticated manner than fixed-charged force fields by using distributed multipole approximations[111,112] and atom-based polarizabilities, thus enabling atoms in a CM simulation to adapt their partial charge state to their surrounding molecular environment in a manner somewhat analogous to a QM simulation. Because the AMOEBA force field was specifically developed for peptides and proteins, the Walsh group had to generate their own multipole parameters for their graphite and SWNT surfaces. These were generated by performing calculations using the Gaussian software program with functional groups represented at the Hartree–Fock (HF)/6–31G* level of theory. L-J and polarizability parameters for the aromatic ring carbons were then borrowed from the existing AMOEBA parameterization library for aromatic carbons. One of the limitations of polarizable force fields is that they are much more computationally expensive than fixed-charged force fields. For this reason, the 1.0 ns MD simulations that were performed to investigate peptide interactions with the graphite and SWNT surfaces had to be conducted with solvation effects represented implicitly, which was implemented using the ASP method. The developed methods were applied to simulate the adsorption behavior of a set of phage-display designed peptides that had been experimentally determined to exhibit a wide range of binding affinities for these types of surfaces. Analysis of the simulation results predicted trends in binding affinity that were similar to what has been observed experimentally, thus qualitatively supporting the developed simulation methods.

The simulation of peptide adsorption behavior on metallic surfaces represents another unique challenge for molecular simulation where simple fixed-charged force fields are inherently problematic. This occurs because the mobility of the valence electrons around the atoms making up a metallic surface results in a situation where the partial charge state of the metal atoms, which will be neutral when unperturbed, will shift in response to an electric field; such as the field generated by an approaching atom with ionic charge. This shift in the partial charge of the atoms in a metallic surface is referred to as the image-charge effect, and these types of dynamic responses cannot be captured when representing the atoms making up a metal surface using a simple fixed-charge force field. To address this problem for applications such as biosensor development, Corni and coworkers[113,114] have developed a force field with

atomic polarization capabilities to represent image-charge effects for a gold (111) surface for the simulation of protein adsorption behavior. Force field parameters to represent the interactions between a gold surface and surrounding water and amino acid residues of a protein were then generated based on extensive QM calculations using both MP2 and DFT levels of theory. In order to be compatible with most widely used protein force fields, parameters fitting the 12-6 L-J nonbonded term of a Class I force field were then fit to the QM results to represent the interactions between amino acid functional groups and the gold surface. OPLS-AA parameters were used for amino acid functional groups and the SPC model used for water. The validity of the developed force field parameterization was then established by comparing interaction energies from simulation results for small molecules representing amino acid-like functional groups adsorbed on gold with available experimental data sets.

While the majority of the methods that have been applied to simulate protein–surface interactions have been based on MD simulations, with MC methods occasionally used to predict initial conformations, the Gray group has developed an all-atom, fully unconstrained Metropolis MC method combined with energy minimization to predict protein adsorption behavior.[115,116] This method is based on an extension of the Rosetta protein folding program and is called RosettaSurface. Similar to Rosetta,[117] RosettaSurface uses rapid structure prediction techniques to widely sample conformational space using discrete protein fragment and side-chain rotamer libraries from high-resolution protein structures coupled with force field terms for van der Waals interactions, hydrogen bonding, and solvation energy. As previously noted, the ability to rapidly move around conformational phase space with large MC moves requires the use of an implicit method to represent solvation effects. The RosettaSurface program uses an implicit solvation method developed by Lazaridis and Karplus,[118] which is called the effective energy function (EEF1) method. EFF1 is based on the sum of functional group-based solvation energy contributions that were developed for validating protein folding applications. Prediction of statherin adsorption to hydroxyapatite surfaces using this method has been found to be consistent with solid-state NMR results, thus supporting the validity of this approach.

3.311.5. Current Limitations and Directions for Further Development

As noted in Section 3.311.4, three recurrent critical issues arise when molecular simulation methods are applied for the simulation of protein–surface interactions[119]: (i) the issue of force field transferability for protein–surface interactions, (ii) the adequate representation of solvation effects (including implicit solvation), and (iii) phase-space sampling to adequately represent equilibrated properties of a protein–surface system for comparison with experimentally observed values.

3.311.5.1. Force Field Transferability for Protein–Surface Interactions

Because protein–surface interactions are primarily governed by nonbonded interactions, the accurate representation of protein–surface interactions involves the parameterization of the L-J terms and the partial charge terms of the force field. Protein–surface interactions are particularly sensitive to these parameters because adsorption behavior is dependent on relatively small differences between protein–surface versus protein–water and water–surface interactions. Unfortunately, at this time, there is little basis to assess the transferability of existing force fields that have been developed for protein folding or materials science applications to accurately represent protein–surface interactions at the interface between a solid-phase material and a protein-containing solution phase. As presented in Section 3.311.4.2, several groups have addressed this issue by conducting QM simulations of representative amino acid functional groups and water with representative functional groups of a surface. While this should theoretically enable force field parameters to be obtained that provide a proper balance between amino acids, water, and surfaces, accurate experimental data is still needed for representative properties (e.g., adsorption free energy) that can be directly used to quantitatively evaluate the accuracy of force field parameters for the simulation of protein adsorption behavior. For this purpose, Wei and Latour[38] have generated a large experimental data set to characterize the free energy of adsorption of peptides on surfaces presenting the types of organic functional groups that are used in many different types of polymers. The results from these studies provide an experimental data set that can be used to evaluate, modify, and validate any given force field for protein adsorption behavior on surfaces presenting similar types of functional groups. Latour and coworkers[120] have used this data set to evaluate the CHARMM22 force field by conducting simulations to calculate the adsorption free energy for 38 of the same peptide–SAM surface systems that were experimentally evaluated by Wei and Latour. Comparison between the simulation results has revealed that the CHARMM22 force field substantially underestimates the strength of adsorption of amino acid residues on hydrophobic surfaces and positively charged amine surfaces, while slightly overestimating the strength of interactions between amino acid residues and neutral hydrophilic and negatively charged carboxylate surfaces. Latour and coworkers are currently working on the development of a modified version of the CHARMM program, called dual-force-field CHARMM, which will provide the capabilities to design an interfacial force field to control protein–surface interactions while using conventional CHARMM force field parameters to control the behavior of a protein in solution. This program should thus provide the capabilities to tune an interfacial force field to accurately represent amino acid residue interactions with surfaces presenting organic functional groups, thus providing a validated interfacial force field for the accurate simulation of protein adsorption behavior to these types of surfaces. Similar data sets are needed for inorganic surfaces, including metals, metal oxides, and ceramic materials, in order to obtain validated force field parameters for the accurate simulation of protein adsorption behavior to these types of surfaces as well.

3.311.5.2. Representation of Solvation Effects for Protein–Surface Interactions

The second critical issue that needs to be addressed is the development of appropriate methods to represent solvation

effects for protein–surface interactions. Presently, explicit solvation represents the gold standard for use in peptide and protein adsorption simulations; however, the appropriateness of existing water models such as TIP3P and SPC for this type of application still remains to be verified. A more difficult issue involves the development and validation of implicit solvation models for protein–surface interactions. As an initial assessment of this issue, Sun *et al.* have conducted simulations comparing several of the currently available implicit solvation models (including DDD, ASP, and EEF1) that have primarily been developed by the protein folding community.[49,121] The results from these simulations have shown widely differing predicted adsorption energies for each method, with little basis at this time to assess which method provides the most accurate results. The substantial savings in computational time that is provided by the ability to implicitly represent solvation effects create a large incentive for the development and validation of implicit solvation methods for the simulation of protein–surface interactions. There is no theoretical reason why accurate implicit solvation methods cannot be developed for this application, and this remains a promising area for continued research.

3.311.5.3. Phase-Space Sampling for Protein–Surface Interactions

The third critical issue for the development of simulation methods to accurately represent protein adsorption behavior is the need for advanced sampling methods that can be applied to accelerate the exploration of phase space for large molecular systems. As presented in Section 3.311.4, most MD simulations that have been conducted to investigate protein–surface interactions have involved the application of conventional MD sampling over time periods extending no longer than a few nanoseconds. While these simulations can represent extremely large expenditures of computational time, it must be recognized that surface-induced refolding/unfolding processes that occur when proteins interact with a surface can be expected to require many orders of magnitude and longer periods of time. As a clear example of this, a study by Agashe *et al.*[122] involved the simulation of the adsorption behavior of a relatively modest-sized 30 kDa fragment of the blood-clotting protein fibrinogen over various functionalized surfaces, including a hydrophobic CH_3-functionalized SAM surface. These simulations, which included explicitly represented SPC water, were simulated for 5.0 ns. Experimental studies of the adsorption behavior of fibrinogen on a CH_3-SAM surface have been shown to induce a substantial degree of unfolding,[16,123] which was the type of behavior expected to be observed in the simulation. However, the 5.0 ns simulation only resulted in the rotation of the protein fragment over about a 45° angle over the surface, with the nonpolar amino acid residues near the protein's outer surface strongly adsorbing to the surface and the polar and charged amino acids remaining hydrated and away from the surface. Thus, while the general initial type of interactions were observed in this simulation (i.e., the adsorption of protein to the surface via its nonpolar residues), it was clearly apparent that a much longer simulated time frame was necessary to be able to capture the anticipated unfolding behavior of the protein on the surface. As addressed in Section 3.311.3.3.6, several accelerated sampling methods have already been developed that are readily applicable to accelerate phase-space sampling for protein–surface interactions, and this also represents a very important area of continued research for the development of methods that are specifically applicable for the simulation of protein–surface interactions.

3.311.5.4. Coarse-Grained Molecular Modeling Methods

Although this chapter has primarily focused on the development and application of all-atom molecular simulation methods, coarse-grained (CG) CM methods, where individual particles in the system represent groups of atoms, also represent an important area for development for the simulation of protein–surface interactions.[102] These methods have the distinct advantage of substantially reducing the number of degrees of freedom in the molecular system, thus greatly accelerating the ability to simulate a molecular process. However, the derivation and validation of force field parameters that are needed for the development of these types of methods, which includes the implicit representation of solvation effects, represent even bigger challenges than those faced in the development of force field parameters for all-atom simulations. Indeed, the force field parameterization of most currently available CG methods were produced and validated by comparison with all-atom simulations, analogous to the way that all-atom force field parameters are often derived from QM simulations. Thus, while CG methods may provide the opportunity to extend simulations over much greater time and length scales than can be currently achieved by all-atom simulations, accurate all-atom simulation methods must first be developed before they will be able to be extended for the development of accurate CG and higher order multiscale methods.

3.311.6. Concluding Remarks

In this chapter, a general overview of the topic of molecular simulation was presented with a focus on the use of all-atom MC and MD methods for the simulation of protein–surface interactions. Emphasis was placed on addressing some of the key issues and limitations that must be considered when conducting simulations of peptide and protein adsorption behavior; namely, the validity of force field parameterization for the system being considered, the accurate representation of solvation effects, and statistical sampling to obtain converged results that are representative of an equilibrated system.

Molecular simulation methods have the potential to provide the biomaterials field with an extremely valuable tool for the design of surfaces at the atomic level that will enable the adsorption behavior and subsequent bioactivity of adsorbed proteins to be manipulated and controlled in a desired manner. This capability should directly translate into the development of biomaterial systems with improved performance for a broad range of applications in biomedical engineering and biotechnology. This situation, however, will only be realized if the biomaterials field will recognize this potential and work to further the development of these types of methods specifically for application to study protein–surface interactions. Although many challenges and limitations currently exist that prevent this potential

from being fully realized at this time, the rapidly expanding pace of the development of algorithms with improved efficiency combined with the continued exponential growth in computational system capabilities suggest that this area of research and development and the potential benefits that it can provide will only continue to grow and expand well into the foreseeable future.

Acknowledgments

I would like to acknowledge the contributions made by the graduate students, postdoctoral fellows, and research associates with whom I have worked over the past 15 years for the development of both computational and experimental methods to study protein–surface interactions. I would also like to specifically acknowledge my colleague Prof. Steven Stuart of the Department of Chemistry at Clemson University for numerous insightful discussions over the years regarding molecular simulation and statistical thermodynamics. Finally, I sincerely thank the NIH and NSF for providing funding support for my research program on the development of molecular simulation methods to simulate protein–surface interactions: NIH R01 EB006163, R01 GM074511, the NJ Center for Biomaterials (RESBIO) at Rutgers University (funded by NIH, P41 EB001046), and the Center for Advanced Engineering Fibers and Films at Clemson University (CAEFF, previously funded by NSF-ERC, EPS-0296165).

3.312.1. Introduction

Heterotypic cell interactions, that is, the interactions between cells of different types, are essential for establishing functional tissues and models mimicking organs from the body. The study of cell–cell interactions in models of higher complexity is very relevant for studies in tissue regeneration and possible application to drug and gene delivery.[1] In the past few years, nanomedicine has become a major topic along with the development of nano-scale therapeutic systems.[2] Although there is considerable knowledge about the physicochemical properties of nanostructures, much less is known about nanobiology, including the mechanisms of uptake of nanoparticles and how the human body reacts to nanostructures of different size and surface chemistry.

Nanoparticles can enter the body by passing through biological barriers, which include the skin, the cornea of the eyes, and the membranes lining the respiratory, digestive, urinary, and reproductive tracts. Epithelial and endothelial barriers separate the body from the external environment and the compartments of the body from each other. The plasma membrane of polarized cells is divided into an apical compartment which is exposed to foreign compounds and a basolateral region which communicates with the underlying structures.[3]

Tight junctions (TJs) are generated between adjacent cells and are necessary to form a functional barrier by the epithelial and endothelial cell types.[4] TJs located at the apical borders of the cells are responsible for the transport of ions and neutral molecules through the paracellular space.[5] However, this paracellular movement restricts the uptake especially of macromolecules. Desmosomes and intermediate junctions are located at the lateral borders, and the basal side is generally characterized by a basal lamina.[6] Membranes in both the apical and basolateral compartments are composed of a lipid bilayer in which proteins are integrated. These are complex systems which nano- and macromolecules have to enter or to leave via a specific transport system across the barrier.[2] The mucus layer protecting epithelial surfaces is an additional extracellular barrier, which also plays a major role in drug and gene delivery in the lung and the gastrointestinal tract (GI).[7] The mucus is formed by lipids, mucins, and glycoproteins and exists as a bilayer. An outer viscous gel-like fraction is layered upon a more firm epithelial-cell adherent fraction.[8] It is evident that all of these major components need to be considered in any assay system designed to simulate barriers in order to study biomaterial uptake.

3.312.1.1. Major Epithelial and Endothelial Barriers in Drug Transport

3.312.1.1.1. Epithelial barriers of the gastrointestinal tract

Oral administration of drugs is the most used method of drug therapy. Absorption of these drugs is given by the membrane permeability. The transepithelial electrical resistance is one of the methods used to measure the integrity and tightness of the barrier and is the lowest in the small intestine.[9] The barrier is formed by a columnar epithelial cell layer covered with a mucus membrane that protects and physically separates the epithelial cells from the gut contents. Because of the leaky paracellular TJs as compared to the other parts of the GI, jejunum, and ileum are considered as the weakest barrier and therefore the major target of drug absorption in the body.[9] Differences in anatomical structure, distinct lipid alignment of the membranes, and different expression patterns of the TJ family lead to the distinction in paracellular permeability between the regions of the GI tract.[10]

3.312.1.1.2. Inhalation barriers: airway epithelium

The respiratory tract is a main portal for inhaled particles and toxic substances. During inhalation, particles and organisms present in the inhaled air are immobilized in the mucus lining fluid and mostly filtered out by the coordinated beating of cilia. The bronchial region is an integral part of the pulmonary system and consists of the trachea, the main bronchi, and the bronchioles.[11] The trachea branches into two main bronchi that continue to branch and eventually give rise to the bronchioles which lead to the alveoli. Although the human alveolar barrier has a much larger surface area of about 120 m^2 compared to the upper airways that have a surface area of about 0.24 m^2, the upper respiratory system with the mucociliary clearance is the first line of defence against foreign substances.[12–14]

Drug delivery across the ciliated and nonciliated epithelial cells, the type I and II pneumocytes on the apical side of the alveoli, and the pulmonary endothelial cells on the basolateral side is regarded as a realistic possibility for systemic therapy.[15]

3.312.1.2. Skin

Because of its anatomical structure with a keratinized layer, the skin is the least permeable to both small molecules and macromolecules. The skin is composed of two major layers, an upper multilayer of cells (epidermis) consisting primarily of keratinocytes of varying stages of differentiation attached to one another by desmosomes and an underlying connective tissue layer (dermis) separated by a basal membrane. The upper layer of the epidermis is known as the stratum corneum and consists of various keratinocyte cells surrounded by cross-linked proteins and a covalently bound lipid membrane which is responsible for the extremely low permeability to water and solutes. Transdermal drug delivery is the most used nonoral technology for therapeutic application offering drug delivery over a large surface area.[16]

3.312.1.3. Blood–Brain Barrier

The blood–brain barrier (BBB) is the major portal of entry for drug delivery to the central nervous system (CNS) and has an essential function in protecting the brain tissue. The integrity of the BBB is guaranteed by cell–cell interactions between three major cell types, namely, the brain capillary endothelial cells (ECs) and closely apposed pericytes and astrocytes. The endothelial cells of the brain in contrast to endothelial cells from other sites of the body are attached to each other by TJs. These structures are similar to those seen in epithelial barriers and represent the morphological basis of the integrity of the BBB. The endothelial TJs of the BBB contain occludin, junctional adhesion molecule, and claudin and are linked to the cytoskeleton of the endothelial cells via zonula occludins. Furthermore, the endothelial cells of the BBB contain numerous systems that tightly regulate the transcellular transport of ions and molecules into and out of the brain. These include efflux transporters to passively transport lipophilic molecules from the blood to the brain and back again and brain endothelial-specific transporters that deliver specific nutrients such as glucose, amino acids, and vitamins from the blood to the brain. A difference between the BBB endothelial cells and the epithelial barriers in the body is that the barrier formed by the endothelial cells in the brain vasculature is entirely regulated by the interactions and cell–cell communication that take place with the endothelial cells and their close contact to the pericytes, the astrocytes, and the neural cells of the brain.

3.312.1.4. Other Routes for Drug Delivery

Besides the barriers mentioned above, other barriers are built, for example, from the olfactory system, which consists of epithelial and endothelial cells.[17] Other barriers are the cornea of the eyes and the uroepithelial barrier.[18,19] Another important one is the vascular system, made up of vessels that carry blood and lymph through the body. Micro- and nanoparticles delivery directly to the circulation will reach practically all tissues of the body, so that this portal of entry demands an effective, targeting system. The latter represents a major challenge for the life sciences with respect to defining specific molecules which characterize the various target organs.

3.312.1.5. Tissue Targeting

Drug and gene delivery is often limited by inefficient transport through the heterotypic cell interactions and complex biological environments. The route a particle takes through the epithelium is not yet known. The particle can cross the barrier for instance through the cell or can pass the barrier between the cells or can pass it via the TJs. Developments of new targeted delivery of therapeutic agents to specific tissues are often limited by the available *in vitro* models. Thus, for example, a model for the GI tract or the lungs must be able to built mucus and TJs to study the biological mechanism and to mimic more realistic conditions. Therefore, it is essential to develop biological systems for understanding the complexity of cell–biomaterial or cell–nanoparticle interactions.[1,20,21]

To avoid loss of promising compounds and biomaterials in clinical studies, the design of the study and the limitations or settings of the different models, cultures, and cells must be clarified. Several models and systems using different stages of complexity have been established and extend from whole animal studies through cell culture systems and 3D models[22–24] to the point of isolated liposomes.[25] The choice of the test system is often a compromise between high throughput or higher complexity and significance. However, not all screenings can be done in animal testing which has the transferability of the results to humans, so that *in vitro* cell culture models offer an alternative to preselect and test drug and gene delivery.[7]

In the sections below, potentials and limitations of different models of the blood–air barrier and the BBB are described with regard to their barrier properties, the uptake, intracellular transport, and localization of the compounds within the cell, and the effects on cell–cell interactions. Importantly, how these model systems can be applied to the study of novel biomaterials is described.

3.312.2. The Upper Respiratory Tract: Barrier Functions of the Bronchial Epithelium

3.312.2.1. Introduction

The respiratory tract is a main portal for inhaled particles and toxic substances. The bronchial region is part of the pulmonary

system and consists of the trachea, the main bronchi, and the bronchioles.[11] The epithelium of the bronchi consists of cuboidal cells which include several cell types, with the most prominent being basal, ciliated, and secretory cells.[26,27]

Ciliated cells amount to about 50% of the tracheal epithelium, while basal calls, Clara cells (bronchioles), and secretory cells form the rest. The secretory cells exhibit a higher number in the distal airways and are present in lower numbers in the large airways.[28] Ciliated cells are 20–60 μm tall and exhibit about 250 cilia on the apical surface of each cell and these cells play a very important role in mucociliary clearance.[29,30] Secretory cells build a viscoelastic layer about 5–10 μm in height, which covers the pulmonary system on top of the cilia.[31–33] Basal cells are flattened cells which remain on the basolateral side between the other cells but do not contribute to the apical region of the pulmonary layer.[34] These may be progenitor cells differentiating to the ciliated form as well as secretory cells.[29,35–37]

3.312.2.2. Mucociliary Clearance

Inhaled bacteria, viruses, or particles are cleared from the airways by mucociliary clearance. Mucus transport is controlled by a coordinated ciliary beating and airflow. The mucus layer forms two or three layers and lies superficial to the cilia. Oligomerized glycoproteins ensure that the mucus layer is both elastic and viscous.[38,39] It is evident that the presence of this mucus layer is highly relevant for biomaterial particle interactions with the barrier.

Mucociliary clearance is driven by two major mechanisms: primarily the ciliary action and secondarily by coughing when ciliary beating fails or is overloaded. Mucus is synthesized by serous cells, goblet cells, Clara cells, and type II alveolar cells.[40,41] The amount of mucus in a section is dependent on the number of mucus-producing cells in this particular region, so that the degree of mucociliary clearance is higher in the peripheral than in the central airways and therefore, ciliated cells per section decrease from the peripheral to the central airways.[42] Cilia beat at a rate of 700–1000 beats min^{-1}.[43] The coordinated metachronal waves generated by cilia flow is in opposite direction to the mucus flow. Mucociliary clearance which extends to the terminal bronchioles is normally complete within hours or extends up to one day.[44]

3.312.2.3. Integrity of the Bronchial Epithelium

In addition to mucociliary activity, the formation of diffusion barriers is a fundamental requirement for the physiological functioning of the respiratory epithelium.[45] To form a functional barrier, TJs[4] and adherens junctions (AJ) have to be generated between adjacent cells. Proximal lung epithelial barrier function is regulated by an apical junctional complex (AJC) consisting of proteins of TJs and AJs. TJs, located at the apical borders of the cells, are responsible for the transport of ions and neutral molecules through the paracellular space and several lung diseases are due to a disruption to these proteins.[46]

The transepithelial electrical resistance (TEER), the transbilayer electrical resistance (TER), and the paracellular movement are methods used to measure the integrity and tightness of the barrier.

3.312.2.4. Cell Culture Models of Bronchial Epithelial Cells

Although primary bronchial cells are available, cell lines are widely used for toxicological studies of the respiratory tract. Among these cell lines Calu-3, BEAS-2B, and 16HBE14o− are well established.

The immortalized bronchial cell line (16HBE14o−) was generated from a 1-year-old heart–lung patient and transformed with the SV40 large antigen. This cell line retains different epithelial functions such as the presence of both TJs and AJs.[47] 16HBE14o− cells in coculture with fibroblasts under air–liquid interface conditions induced a multilayered growth, but no bronchial tissue-like differentiation was seen.[7,48] Additionally, 16HBE14o− cells do not form an organized epithelial layer. Although 16HBE14o− cells were immortalized from primary isolated bronchial epithelial cells they did not have the capacity to differentiate to the three main bronchial phenotypes as is the case for primary isolated HBECs (human bronchial epithelial cells) cells from explant-outgrowth cultures. An additional cocultivation with the fibroblast cell line Wi-38 used in certain sudies also failed to trigger 16HBE14o− cell differentiation. Although the cellular organization of 16HBE14o− was less distinctive, 16HBE14o− in coculture with Wi-38 showed higher maximum TER and lower P_{app} values (apparent permeability coefficients) than HBEC in coculture. This effect is most likely because of the physical barrier generated by the 16HBE14o− cells, multilayered growth properties and not because of a tighter barrier formed by 16HBE14o− cells at cell–cell junctions (see **Section 3.312.2.6**).[49]

Calu-3 cells are a submucosal gland cell line, which was generated from a bronchial adenocarcinoma. Under air–liquid interface conditions Calu-3 cells grow in monolayers, producing mucus and cilia-like microvilli. Because of the presence of TJs, Calu-3 cells are often used for transport studies.[50,51]

BEAS-2B is also a human epithelial cell line which is commercially available and is an adenovirus-12 SV40 hybrid virus-transformed and nontumorigenic cell line. This cell line is often used for toxicity studies and to study airway epithelial structures, but does not form TJs.[34,52–54] In addition, there is no mucus secretion (**Table 1**).[58]

The cell lines are useful for certain studies, although they are not feasible for studies of mucociliary clearance.

3.312.2.5. Human Primary Cell Bronchial Coculture Models

A number of human bronchial models based on epithelial–fibroblast cocultures have been described[59–61] as well as a variety of animal models regarding the bronchial tract.[62] In the section below, a coculture model of the bronchial tract established by our group is described.[49,63,64]

Table 1 Expression of different mucins in the cell lines and primary cells; mucins in the coculture were measured with immunofluorescence and RT-PCR

	MUC 2	*MUC 4*	*MUC 5AC*	*MUC 5B*	*MUC 8*
16HBE14o−	−[55]	+/−[55]		+/−[55]	
Calu-3	−[55]	+/−[55]		+/−[55]	
Native lung	+[56]	+[57]	+[56]	+[56]	+/−[56]
Coculture		+	+	+	+/−

Human bronchial epithelial explant-outgrowth cells (HBECs) were isolated according to a method of Lechner[65] and modified as previously described.[49,64] Small bronchi (diameter <5 mm) were first dissected from the remaining peripheral lung tissue and cut into defined pieces of 1–2 cm^2 size. The small explants were cultivated in tissue culture flasks coated with rat-tail collagen type 1. HBECs migrated out of the explants after 1 week. The bronchial models were established as a bilayer coculture of the isolated HBEC with the lung fibroblast cell line Wi-38. For cocultures, the upper surface of Transwells was coated with a solution of collagen type 1 in 0.1 M acetic acid and air-dried at room temperature. Fibroblasts ($1 \times 10^4\ cm^{-2}$) were placed on the lower surface of inverted 24-well HTS-Transwell filter membranes and incubated for 2 h at 37 °C and 5% CO_2. The filter plates were then inverted and placed in 24 well plates filled with 1 ml medium per well. The bronchial cells ($5 \times 10^4\ cm^{-2}$) were subsequently seeded on the top surface of the HTS 24-Transwell filter membranes and grown to confluence simultaneously with the Wi-38 cells on the lower surface. After 3 days of coculture, bronchial models were placed at an air–liquid interface and only fed basolaterally with media. Media were replaced twice weekly.

After the explant outgrowth from the small bronchial tissue fragments, the HBEC showed cuboidal morphology and stained positively for the basal cell markers, cytokeratin 14 (CK14), and aquaporin 3 (AQP-3). Immunofluorescent staining for different types of mucins (MUC 2, MUC 5AC, MUC 5B) as well as for β-tubulin, a structural protein of cilia, was negative (Figure 1).

The HBEC differentiated to a ciliated pseudostratified airway epithelium in the cocultures in the 24 Transwells. During the first two weeks of cocultivation, the morphological phenotype of the HBEC changed from a more squamous to a pseudostratified epithelium. Within 21 days of coculture, all three major cell types of the bronchi (basal, ciliated, secretory) could be observed.

In coculture with the fibroblast cell line Wi-38, the HBEC showed ciliated cells after 21 days in culture (Figure 2(c) and 2(d)). At this time point, the HBEC in monoculture merely formed apical extensions similar to the cell lines 16HBE14o− and the Calu-3 (Figure 2(a) and 2(b)), but no mature cilia with the typical 9-plus-2 pattern of microtubules were detected, this being in marked contrast to that observed in the coculture (Figure 3(b)). After 21 days in coculture, a bronchial layer showing the tight junctional protein ZO-1 at the cell–cell contact areas and β-tubulin within the cilia was observed by immunofluorescence (Figure 3(c)).

During the cocultivation period, the proportion of ciliated cells slightly increased but the principal finding was that the cilia gained in length. Furthermore, the cilia generated were actively beating (frequency between 14 and 19 Hz depending on the donor). After 4 weeks of coculture, a distinct film of acid mucosubstances (Figure 3(d)) was observed on top of the epithelial layer which persisted for up to 12 weeks in culture. From 4 to 12 weeks in coculture, the thickness of the epithelial layer stayed constant but the proportion of ciliated cells and the length of the cilia increased significantly.[49]

3.312.2.6. Specific Applications

3.312.2.6.1. Transport through barriers

TEER is a measure of the tightness of intercellular TJs. The electrical resistance across the cultures is usually measured using an EVOM voltohmmeter (World Precision Instruments,

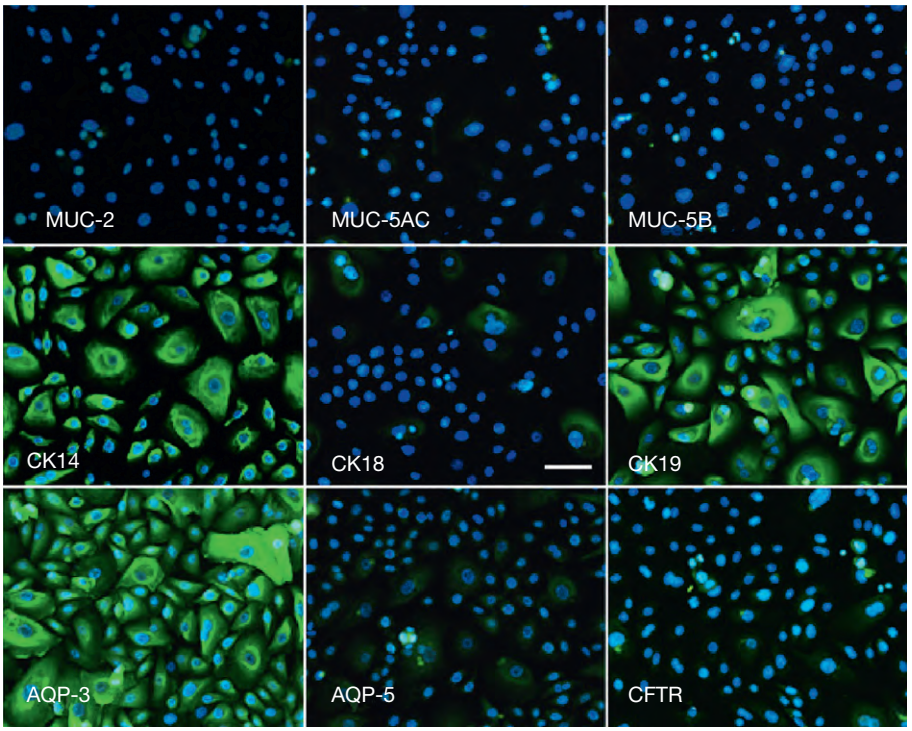

Figure 1 Immunofluorescent staining of outgrowth cells (scale bar = 20 μm; all images were taken at the same magnification).

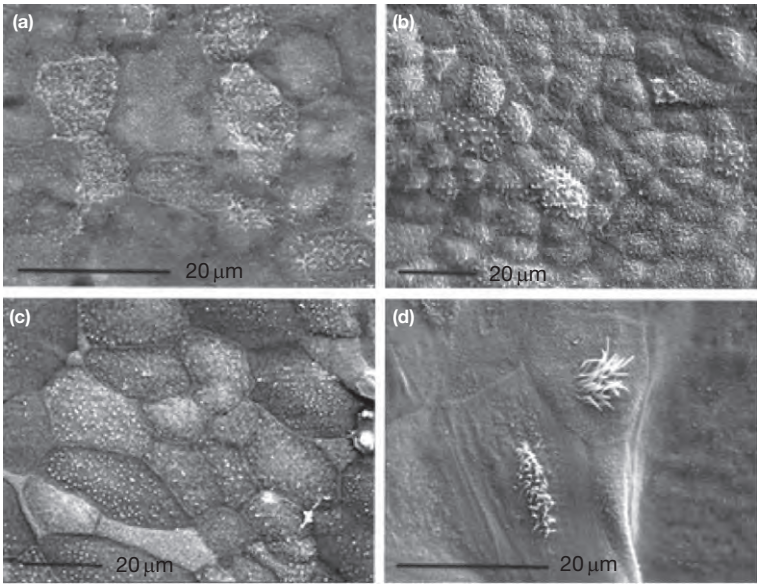

Figure 2 Scanning electron microscopic images of 16HBE14o− (a), Calu-3 (b), and HBEC (c and d) on Transwell filter membranes after 28 days in coculture with Wi-38. 16HBE14o− and Calu-3 formed apical extensions, but only cocultures with the primary HBEC formed functioning cilia.

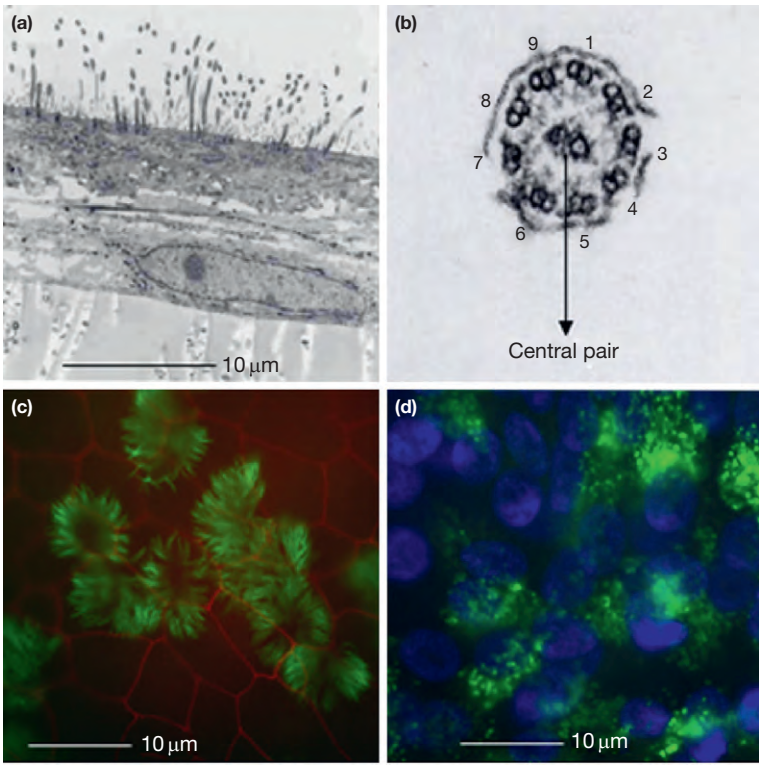

Figure 3 Image (a) shows a transmission electron micrograph of the differentiated primary cell culture model performed after 28 days in coculture, demonstrating basal, ciliated, and secretory cells. Cilia present their normal structure of nine outer doublet microtubules surrounding the central pair of single microtubules, similar to that found *in vivo* (b). Immunofluorescent staining of bronchial cells in coculture with Wi-38 on Transwell filter membranes with β-tubulin (green fluorescence) and ZO-1 (red fluorescence) is shown in (c). The apical intercellular TJ complex is present between adjacent ciliated and nonciliated cells. The mucus layer generated by the cells is shown by immunofluorescence of Muc5Ac (d).

Berlin, Germany) with chopstick electrodes. The electrical resistance is obtained by multiplying the meter readings by the effective surface area of the filter membrane. The resistance is inversely proportional to the surface area. Thus, the larger the membrane, the lower the resistance is

$$\text{Resistance of a unit area} = \text{Resistance } (\Omega) \times \text{Effective membrane area } (\text{cm}^2)$$

After 10 days in coculture, the HBEC showed a detectable transepithelial resistance. TER increased during the cultivation time to a maximum of 600–800 $\Omega\,\text{cm}^2$ (depending on the donor) at day 14–17 and remained relatively constant during long term cultivation, that is, over 3 months.[49,63,64]

The electrical resistance of the cell line 16HBE14o− is heavily dependent on the culture conditions. 16HBE14o− show TEER values of about 600–700 $\Omega\,\text{cm}^2$ after 10 days in monoculture grown under submerged conditions and about 100 $\Omega\,\text{cm}^2$ grown under air–liquid interface conditions. In coculture with Wi-38, TER values reached a maximum of 1000–1200 $\Omega\,\text{cm}^2$ during the cultivation time of 10 days and stayed constant for 4 days before TER decreased.[7,48,49,66–68]

Calu-3 reached a maximum TEER at day 10–11 of about 400–700 $\Omega\,\text{cm}^2$ under air–liquid interface culture conditions. Under submerged conditions, Calu-3 cells were able to build tighter junctions with TEER values up to 1000 $\Omega\,\text{cm}^2$ (Table 2).

Another assessment of the tightness of the barrier in the epithelial layer is to measure the paracellular movement. Substances often used for transport are the anionic hydrophilic marker sodium-fluorescein and FITC-labeled dextrans with different molecular weights. The apparent permeability coefficients (P_{app}) were calculated using the following equation:

$$P_{app} = \frac{V_{res}}{A \times c_{t0,\,don}} \times \frac{dc_{res}}{dt}\,(\text{cm s}^{-1})$$

with V_{res} value in the receiver compartment; dc_{res}/dt solute flux; A surface area of the filter; $c_{t0,\,don}$ the initial drug concentration (Table 3).

3.312.2.6.2. Ciliary beat frequency

In host defence and in the removal of foreign material, mucociliary transport plays a very important role. A dysfunction of ciliary beating may lead to a variety of respiratory problems. This sensitive system can be influenced by several factors such as hormones as well as parasympathetic or sympathetic neurotransmitters.[74] Most studies addressing the regulation of ciliary function used biopsies or freshly isolated nasal and tracheal epithelial cells where a ciliary beat frequency (CBF) comparable to the *in vivo* situation was retained for no longer than 1 week.[75] In response to a variety of substances such as ATP, NO, or β-agonists, the CBF has been shown to increase.[76,77] On the other hand, a decrease in CBF was shown when interferon-γ (IFN-γ) was added to the culture medium (Table 4).[82,83]

The ciliary beat frequency was measured using a method established by the group of König and Kummer *et al.*[38,42] using rat trachea cells. The coculture model described above with human cells was cultivated over a period of 3 months to obtain a well-differentiated ciliated epithelium. Filters were dissected and mounted on dishes filled with Sylgard gel and then studied by video-optical microscopy. Cells from the coculture were found to beat at a frequency of 14–19 Hz.[49]

In order to be useful as a model system to investigate how nanoparticles or other modulating influences interact with the barrier, the latter must be shown to be responsive to microenvironmental change. Thus, in experiments with cytokines, such as TNF-α and IFN-γ in concentrations found in the mucosa of patients with cystic fibrosis,[84] the following results were obtained: IFN-γ (100 ng ml^{-1}) elicited after 5 min a statistically significant decrease of 11–13 Hz in CBF, but cells then recovered and after 10 min the CBF value did not differ from that at the start of the experiment. The cells were still able to respond to ATP after 70 min. After adding TNF-α and IFN-γ, the cytokines induced a reduction (9–10 Hz) of CBF which was still statistically significant after 30 min. However, the 60 min value did not differ markedly from the value determined at the beginning of the measurement (Figure 4). After 70 min, cilia were again able to respond to ATP. The combination of the cytokines appeared to potentiate the effects on CBF. Such cytokine influences underline the fact the coculture assay is responsive and can undergo recovery.

3.312.2.7. Potential and Limitations of the Bronchial Models

Bronchial epithelial cells represent not only the first line of defence against various toxic and pollutant substances, but also one of the first barriers encountered by inhaled particles designed for drug and gene delivery. One of the early consequences of injury to bronchial epithelium is a change in

Table 4 Ciliary beat frequency in different tissues

Tissue	*Frequency (Hz)*	*References*
Bronchial biopsies	9–14	78,79
Nasal ciliated epithelium	11–16	80
Rat trachea	8–10	81
Coculture model	14–19	49

mucociliary function. The epithelium of the proximal airways include several cell types, among which basal, ciliated, and secretory cells are the most abundant.[26,27] To study human airway epithelial cells *in vitro*, numerous cell culture models using cell lines have been described, but most of these cultures only partially mimic the *in vivo* situation. Immortalized bronchial epithelial cell lines, such as Calu-3, BEAS-2B, or 16HBE14o−, are widely used for toxicology studies of the respiratory tract. Compared to *in vivo* studies, such cell lines have the benefit of flexibility and specific phenotypic traits.[85,86] However, they lack the ability to mimic the different cell types of bronchial epithelium *in vivo*. An alternative to the use of cell lines are primary isolated bronchial cells which contain all phenotypes of the bronchial epithelium. Unfortunately, most primary isolated bronchial epithelial cells rapidly lose their differentiated phenotype *in vitro*, possibly caused by the absence of extracellular matrix, growth factors, and essential hormones.[87]

For nasal, tracheal, and bronchial cultures, primary cells from different species that also demonstrate the formation of cilia and mucus production have been described.[62,88] A human primary coculture which utilizes epithelial–fibroblast interactions to induce a redifferentiation of explant-outgrowth bronchial cells to the main bronchial phenotypes with beating cilia is described by Pohl *et al.*[49] Such epithelial–fibroblast cocultures have also been described by other groups.[59–61]

In host defence and in the removal of foreign material, mucociliary transport plays a very important role. A dysfunction of ciliary beating may lead to a variety of respiratory problems. This sensitive system can be influenced by several factors such as hormones as well as parasympathetic or sympathetic neurotransmitters.[74] Most studies addressing the regulation of ciliary function used biopsies or freshly isolated nasal and tracheal epithelial cells where a CBF comparable to the *in vivo* situation was retained for no longer than 1 week.[75]

Ciliary beat activity of human bronchial epithelial cells *in vitro* is so far only described for human tissue-culture preparations[89] or lung slices[82] and could not be sustained for longer than 25 days. In the already described coculture tissue culture preparations or lung slices, cilia showed a synchronized beating pattern. In the coculture model, we could observe a synchronization between all cilia from one cluster and the beating activity could be maintained for a period of at least 3 months. The primary bronchial model still has to be modified in order to study mucociliary clearance, but could be very useful to investigate not only the long-term effects of toxic or pharmaceutical substances on the ciliary beat frequency, but also the possible interaction and uptake of engineered nanoparticles.

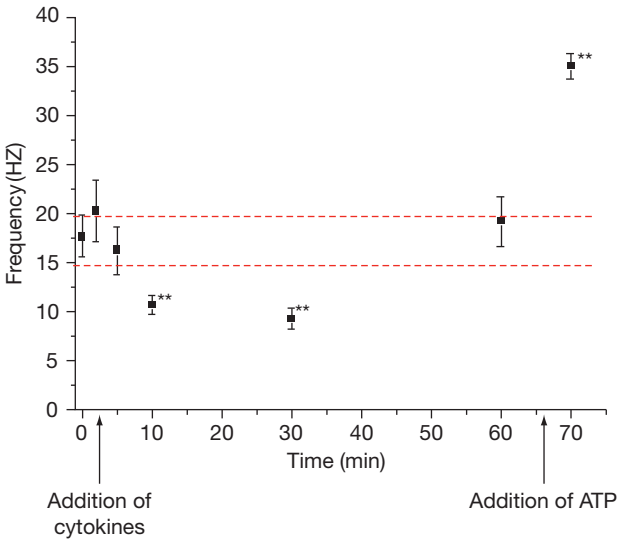

Figure 4 Ciliary beat frequency over a time period of 70 min after treatment with a combination of the cytokines TNF-α and IFN-γ. For every time point at which CBF was measured, 1000 video frames were taken and evaluated with a Fourier transformation. ATP was used as a positive control to determine whether the cilia were still able to respond after cytokine treatment. Data are depicted as means ± SD from $n = 9$ filters from three different donors. Significantly different ($^{*}p < 0.05$ or $^{**}p < 0.01$) from the vehicle-treated control.

3.312.3. The Lower Respiratory Tract: Cell Culture Models Mimicking the Biological Barriers of the Distal Lung

3.312.3.1. The Biological Barriers of the Distal Lung

In the healthy lung, the distal lung barrier is formed by several layers of defence (**Figure 5**). The surface of the alveoli is covered by a thin layer of surfactant with phospholipids and surfactant apolipoproteins acting as a surface active substance lowering the air–liquid surface tension and also functioning as a component of local defence mechanisms in the lung.[90] Alveolar macrophages occur on all epithelial lung surfaces with prevalence in the distal regions. Their number shows great variability, depending on biological parameters such as gender and behavioural parameters such as smoking.[90] With their phagocytic activity, alveolar macrophages function as a first line of cellular defence and patrol the extensive surface area of the alveolar epithelium. The alveolar epithelium itself forms a tight cellular barrier that continuously lines the distal air space, covering more than 99% of the internal surface area of the lungs.[13] It is composed of a monolayer of two morphologically distinct types of cells, namely, type I and type II alveolar

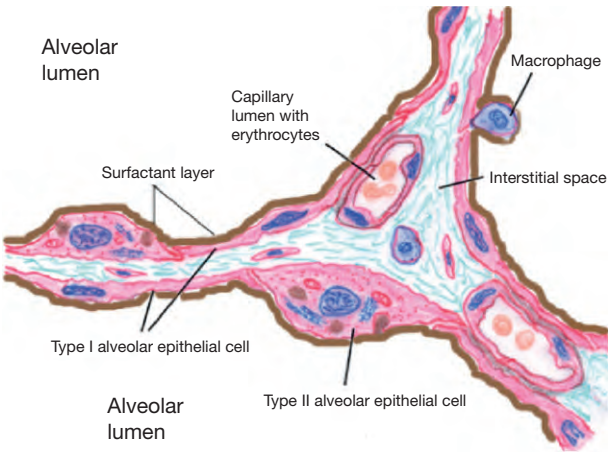

Figure 5 Composition of the distal lung tissue (lower respiratoy tract).

epithelial cells.[91] Both epithelial cell types are involved in gas exchange and fluid homeostasis (reviewed by Matthay *et al.*[92]). Type I cells are characterized by their flattened morphology and cover >95% of the alveolar surface.[93] Alveolar type II (ATII) cells are surfactant-producing cuboidal cells showing many additional metabolic and immunological functions.[4,94–96] Their apical surface is covered with microvilli and their cytoplasm is notable for numerous lamellated inclusions. While the type II cells only cover 7% of the alveolar surface area, they constitute 67% of the epithelial cell number within the alveoli[93] pointing to their biochemical importance. Together with the surfactant proteins, ATII cells play an important role in the clearance of macromolecules by means of the alveolar lining fluid. Type II cells also serve as progenitors for alveolar type I cells during normal lung development[97] or in case of type I cell injury,[98–100] as the latter cells are unable to regenerate themselves. During these repair process, type II alveolar epithelial cells undergo mitosis and a subset of daughter cells initiates the expression of type I cell-associated markers and acquires characteristic type I morphology.[98–101] This process, often termed as transdifferentiation, has also been described *in vitro*. However, the parallels between *in vitro* and *in vivo* ATII transdifferentiation remain to be fully defined, and the term ATI-like cell to represent the *in vitro*-derived ATI phenotype is often adopted. Another cell type also contributing to the distal lung barrier is capillary endothelial cells, which amount up to 30% of all lung cells. The capillary endothelium of the lung does not merely function as a barrier, but also critically regulates systemic and pulmonary vascular function, involving numerous physiological, immunological, and metabolic tasks.[102–105] Moreover, a number of different interstitial cells, mainly fibroblasts and myofibroblasts, exist in the interstitial space, comprising 37% of the total lung cells.

Both alveolar epithelial cell types are interconnected by TJs.[4] The formation of these TJs is accompanied by AJs and these two distinct junctions show not only an intimate spatial but also a functional relationship.[106–108] In contrast to the epithelium, endothelium does not show a clear morphologic differentiation into AJ and apical TJ, with both junctional structures present along the complete lateral aspect of the endothelial contacting zones.[109,110] Because of the large surface area offered by the alveolo-capillary (or air–blood) barrier, there is great interest in using this as a portal of entry for the delivery of drugs or genes in micro- or nanoparticulate form. However, because of its complexity, a rational approach to using this barrier requires a functional model *in vitro* with which to study mechanisms of surface interaction, cellular uptake, and transcellular transport. This is described in the following sections.

3.312.3.1.1. Cell culture models of alveolar epithelial cells

Primary alveolar epithelial cells isolated from rat lungs are one of the best-established and mostly used *in vitro* models for alveolar epithelium. They have been well characterized, and are accompanied by a high reproducibility, convenient availability, and economics of pathogen-free animals.[91] For several decades, these rat-based monolayers have been considered the gold standard in analysis of alveolar epithelial cell physiology and biology. Therefore, it seemed obvious that the same well-established primary rat alveolar epithelial model could be employed for drug delivery studies.[111–113] However, recently models have been developed that are based on animal species which more closely resemble human physiology, for example, porcine lung alveolar epithelial cells.[58] Moreover, a number of laboratories started establishing primary cultures of human alveolar epithelial cells.[96,114–119]

For the human alveolar epithelium, several cell culture models of interest exist, namely, primary culture of alveolar epithelial cells isolated from distal lung tissue, and in terms of cell lines, the TT1, A549, and H441 cells, which will be described in more detail in the following sections. In order to use *in vitro* results as a predictive tool to estimate *in vivo* interactions, the utility and validity of such models must be proven and optimized.[120]

3.312.3.1.2. Characterization of alveolar epithelial cells

Human alveolar type II synthesize and secrete lung phospholipids, a characteristic of pulmonary surface-active material, the surfactant proteins A, B, C, and D (SP-A, SP-B, SP-C, and SP-D),[121] and are responsible for local immunomodulation. In addition, they are the alveolar epithelial repair system after lung injury and during normal cellular turnover.[100] An exclusive marker for type II cells is surfactant protein C (SP-C) or pro-SP-C. All other surfactant proteins are also expressed in cells of the bronchial epithelium or even other epithelial cells of the body. Further markers for the ATII phenotype are the storage organelles of lung surfactant, the lamellar bodies, alkaline phosphatase activity, and the expression of thyroid transcription factor-1 (TTF-1), a transcription regulator of the surfactant proteins A, B, and C.[122,123] With respect to markers for ATI cells, there is still some discordance.[124,125] Varieties of glycocalyx appear to be expressed in ATI versus ATII cells, which can be distinguished by the binding of specific lectins.[126,127] The expression of caveolin-1, the main structural protein of caveolae, has also been used to distinguish ATI from ATII cells, as ATI (but not ATII) cells contain numerous caveolae.[128] Caveolin-1, however, is also highly expressed in lung capillary endothelial cells.[129] Furthermore, aquaporin-5 (AQP-5), a protein localized specifically in the apical plasma membrane of ATI cells[130,131] has received some attention as an ATI cell marker. Different reports from *in situ* studies have shown that transmembrane receptor for advanced glycation end products (RAGE) is localized to the basolateral plasma membrane of ATI cells.[132–134]

3.312.3.2. Primary Isolated Human Alveolar Type II Epithelial Cells

An approach close to the *in vivo* situation uses primary isolated human alveolar type II epithelial cells (hATII) derived from peripheral lung tissue after surgery.[117,118,135,136] Cultivation on permeable filter supports leads to the establishment of a confluent monolayer with hATII cells partly transdifferentiated to alveolar type I-like (hATI-like) cells within 8–10 days of culture. This model appears to be a valuable *in vitro* model for pulmonary drug delivery and transport studies, as TEER values of more than $1000\,\Omega\,cm^2$ can be detected within 8–10 days of culture.[117,118] In addition, cells exhibit TJs as well as desmosomes and show cell-specific lectin binding.[117] In terms of morphological differentiation, they demonstrate a characteristic flattening of cells and transition from a cuboidal

(type II) morphology in early culture stages to a type I-like morphology with flattened extensions.[118] Additionally, a shift in the synthesis of important marker proteins toward the type I phenotype can be shown. Thus, the protein biosynthesis switches with time in culture from low caveolin-1 and high SP-C to high caveolin-1 and low SP-C levels.[118] Moreover, the expression of AQP-5[130] and RAGE[119,130] was shown to increase during the shift of type II to type I phenotype. Nevertheless, in cultures at the age of 7–10 days, cuboidal cells are still occasionally found interspersed in the monolayer and they also contain the typical multilamellar bodies of hATII cells.[119] Figure 6 shows the characteristic transdifferentiation of the hATII cells (with numerous lamellar bodies at day 3) toward the flattened type I phenotype on Transwell filters over time.

3.312.3.3. Human Cell Lines with Alveolar Epithelial Cell Characteristics

In contrast to primary cells, cell lines are often preferred, because of their availability, purity, and reproducibility due to the lack of donor dependency. Although it is possible to isolate primary rodent ATI cells,[125] to our knowledge, there are no methods to isolate hATI cells. Recently, an immortalized alveolar type I-like cell (transformed type I; TT1) was generated by transduction of hATII cells with the catalytic subunit of telomerase and simian virus 40 large-tumour antigen.[39,137] The ATI-like cell phenotype was characterized by immunochemical and morphological methods.[137] Unlike primary hATII cells, the immortalized cells no longer expressed alkaline phosphatase, pro-SP-C, and TTF-1, but expressed increased levels of caveolin-1 and RAGE. Live cell imaging using scanning ion conductance microscopy showed that the TT1 cells were ~40 μm in size, resembling hATI cells *in situ*. Transmission electron microscopy highlighted the attenuated morphology and showed endosomal vesicles in some TT1 cells. Unfortunately, confluent TT1 cell monolayer formation with electrically tight characteristics could not yet be demonstrated.[39] However, the fact that there are characteristic endosomal vesicles in TT1 cells, similar to those found *in situ*, holds much promise as a model to investigate the uptake and transport mechanisms of micro- and nanosized carriers in hATI-like cells, without the need for primary cultures.

The cell line A549 belongs to the group of well-characterized and widely used *in vitro* models for the alveolar type II phenotype. This human lung carcinoma cell line was initiated through explant culture of lung carcinomatous tissue from a 58-year-old Caucasian man[138,139] and is available from the ATCC (American Type Culture Collection). A549 cells exhibit features of alveolar type II cells,[29,34,140] but on account of the production of mucins they also show characteristics of bronchial cells.[141] Although the cell monolayer phenotype of A549 is commonly accepted to be primarily type II in nature, A549 differ from isolated or cultured primary alveolar type II cells in several aspects. In terms of lipid content, phosphatidylglycerol, one of the characteristic phospholipids of pulmonary surface-active material in primary isolated human type II cells (8.9%), is nearly absent in A549 cells (0.1–0.2%).[142] Further distinctive indications are that A549 cells do not express detectable levels of surfactant protein A (SP-A) nor of its mRNA,[143,144] and that they lack the formation of domes (indicating active transepithelial ion transport), whereas human type II cells do.[121] Finally, A549 monolayers show TEER values close to zero even after several days of culture to confluence.[145] This absence of any significant electrical resistance in monolayers of immortalized cell lines is most likely caused by a lack of functional TJs.[146,147] The difference from the 1000 Ω cm^2 TEER values for primary cells may be explained by different intercellular junctions between type II-like cells alone (= A549), type I-like cells alone, or type I and II cells (= primary culture).[148] Differences in the expression of TJs between A549 and primary cells are confirmed by a comparative immunostaining for the TJ protein ZO-1 in primary human cells hATII/hATI-like cells and the A549 cell line. As demonstrated in Figure 7 the protein itself is present in both models. In the case of the hATII/hATI-like cells, it is located at the cell–cell contact zones showing the

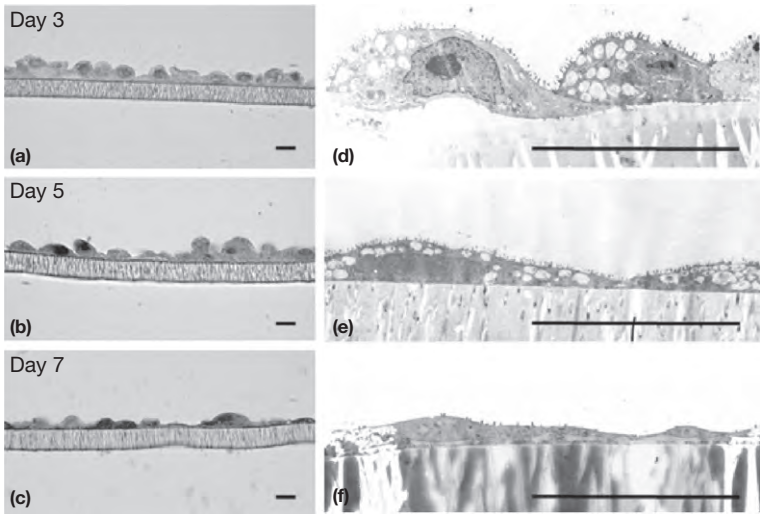

Figure 6 Cross-sections through cultured human alveolar epithelial cells (hATII /hATI-like) in monoculture at different times of culture (a–c), visualized by light microscopy or TEM (d–f). Scale bar = 10 μm.

(b) Filter-grown monolayer of NCI H441 cells and (c) A549 on day 10 in culture with 1 μM dexamethasone. Immunostaining for ZO-1 protein (nuclei appear dark). Scale bar = 10 μm. Observation by confocal laser scanning microscopy.

characteristic circumferential staining pattern, whereas the cell line A549 reveals a fragmented staining pattern of ZO-1.

The cell line NCI H441, also available from ATCC, was derived from the pericardial fluid of a patient with papillary adenocarcinoma of the lung and shows morphological characteristics of both hATII and Clara cells.[138] Clara cells and hATII cells share several markers, such as the production of surfactant proteins SP-A, SP-D, and SP-B and the associated expression of the nuclear factor TTF-1. Besides these attributes, recent studies have shown that NCI H441 exhibited responses to mitogenic growth factors similar to primary isolated hATII cells.[149] NCI H441 shows several type II characteristics, such as the formation of lamellar bodies, storage organelles for SP-B and SP-C, and associated phospholipids, such as dipalmitoylphosphatidyl-choline (DPPC),[136] and, under dexamethasone treatment, a positive immunocytochemical staining for the ATII-marker SP-C.[145] Several *in vitro* models have shown that glucocorticoids also tighten cellular contacts in mammary epithelium, retinal endothelium, and brain microvascular epithelium.[150–153] Treatment with dexamethasone caused reproducible TER values of $273 \pm 11\,\Omega\,cm^2$ for NCI H441 cells after 10–12 days of filter culture and regular distribution of ZO-1 at the cell–cell contact zones. As was shown in previous studies, A549 failed to develop substantial TER[68,146] and showed TJ of a beaded appearance in freeze–fracture studies.[154] For A549, dexamethasone treatment led to a slightly increased ZO-1 localization between adjacent cells (see **Figure 8(c)**) but no increase in TER.[145]

3.312.3.4. Cell Culture Models of the Alveolar–Capillary Barrier

When an extra-pulmonary transport as well as systemic delivery of the drug load is the goal, carriers also have to pass the adjacent endothelium before entering the pulmonary and then the systemic circulation. Therefore, to study drug and gene delivery across the distal lung barrier, a coculture of alveolar epithelial and endothelial cells is required, and this is on the basis of the close proximity of both cell types *in vivo*. A barrier-forming bilayer model permits communication and interaction of alveolar type II epithelial cells and microvascular endothelial cells cultured on opposite sides of Transwell® filter growth supports (**Figure 9**).

3.312.3.5. Characterization of Human Pulmonary Capillary Endothelial Cells

Human primary isolated pulmonary microvascular endothelial cells (HPMECs) can be isolated from peripheral lung tissue using PECAM-1 (platelet endothelial cell adhesion molecule-1) microbeads, a characteristic marker for endothelial cells.[155] Exclusive markers for a microvascular phenotype are a positive immunofluorescent staining for CD36 (thrombospondin receptor)[156] and CD105 (Endoglin).[157] Additionally, CD143 (angiotensin converting enzyme, ACE) is expressed at high level in lung capillary endothelial cells *in situ*.[158] All of these markers were shown to be present in HPMEC isolated by our group.[119] Furthermore, these cells expressed GM-CSF[103] and were able to react to proinflammatory cytokines with the

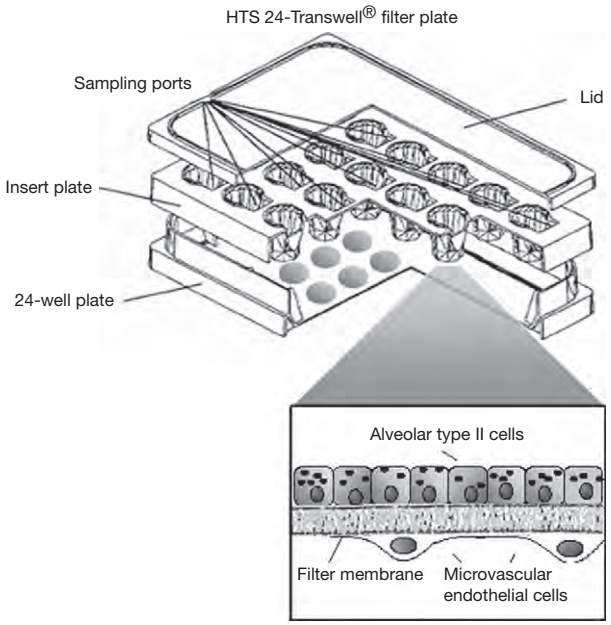

Figure 9 Schematic of the 24-Transwell® filter setup of the alveolar–capillary model *in vitro*.

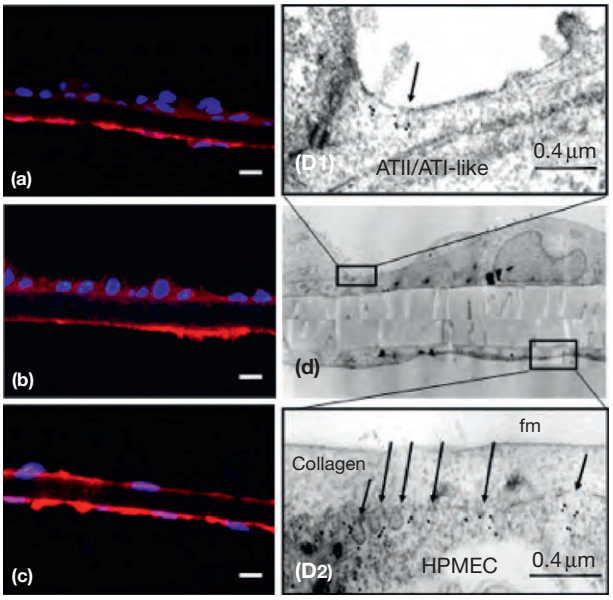

Figure 10 Cross-sections through human alveolar epithelial cells (hATII/hATI-like) cultured with HPMEC at day 3 (a), day 5 (b), and day 7 (c) of coculture, visualized by confocal laser scanning microscopy with staining of caveolin-1 or TEM with immunogold labeling of caveolin-1 at day 10 (d) in hATI-like cells (D1) or HPMEC (D2). fm = filter membrane. Scale bar = 10 µm.

induction of adhesion molecules (ICAM-1 and VCAM-1) and selectins (P-selectin, E-selectin).[159] *In vitro*, they also released several secondary cytokines, for example, IL-6, IL-8, and MCP-1 on stimulation.[119]

3.312.3.6. Primary Alveolar Epithelial Cells and Microvascular Endothelial Cells in Coculture

In this section, we describe a barrier-forming bilayer model of hATII/hATI-like alveolar epithelial cells and primary isolated pulmonary microvascular endothelial cells (HPMECs) cultured on opposite sides of Transwell® filter growth supports developed by our group.[119] Similar to monocultures, hATII cells in coculture with HPMEC established a confluent monolayer with hATII cells that partly transdifferentiated to hATI-like cells within 7–11 days.[119] The hATII cells showed nearly no caveolin-1 expression on day 3 of coculture (**Figure 10**). With ongoing culture, the HATII cells partially transdifferentiated to flattened HATI-like cells. Up to day 5, in coculture the epithelial cells on the upper surface of the filter membrane showed a slightly increased fluorescence for caveolin-1 (**Figure 10(b)**). On day 7, the intensity of the caveolin-1 signal for HATII/HATI-like cells was as strong as for the HPMEC, which showed a constant fluorescent labeling for caveolin-1 with ongoing culture (**Figure 10(c)**). Caveolar structures with immunogold labeling for caveolin-1 were visualized by TEM on day 10 of coculture (**Figure 10(d)**).

Two functional barriers were established in bilayer coculture with a maximum TER (transbilayer electrical resistance) of approximately $1730 \pm 460\,\Omega\,cm^2$.[119] Additionally, immunolabeling revealed the formation of confluent monolayers on both sides of the filter membrane with TJ and AJ for epithelial and endothelial cells. The two barriers formed, that is, the heterocellular alveolar epithelium and the microvascular endothelial cell monolayer, create a system with two distinct compartments. This compartmentalization reflects the physiological and morphological properties of the human alveolar–capillary barrier *in vivo*. Therefore, the primary coculture model appears to be a highly valuable *in vitro* model for pulmonary drug delivery studies across the main cellular barriers at the distal lung.

3.312.3.7. Coculture of NCI H441 with ISO-HAS-1

Because of a high donor variability and a limited source of human tissue specimens, there is still a need to develop an alveolar–capillary model based on cell lines. A precondition for drug delivery and transport studies is barrier formation *in vitro*. Hence, a bilayer model of the barrier-forming cell line NCI H441, exhibiting features of alveolar type II cells, with a microvascular endothelial cell line (ISO-HAS-1) was recently developed by our group.[135] The microvascular endothelial cell line ISO-HAS-1, derived from a dermal angiosarcoma, showed features most akin to microvascular endothelial cells. Reproducible maximum TER values of $480 \pm 100\,\Omega\,cm^2$ after 10–12 days of cocultivation were achieved.[135] The treatment with dexamethasone (1 µM), as well as the coculture with ISO-HAS-1, reduced proliferation of NCI H441 cells (less Ki67 positive cells compared to nontreated cells, **Figure 11(a)**, and compared to green nuclear staining, **Figure 11(d)**). Additionally, a tight polarized monolayer of NCI H441 cells was developed (regular apical ZO-1 distribution, see **Figure 11(d)**). Without dexamethasone, ISO-HAS-1 on the opposite side of the filter membrane adopted a more proangiogenic phenotype and formed vessel-like structures (**Figure 11(c)**), whereas with dexamethasone they developed a confluent monolayer

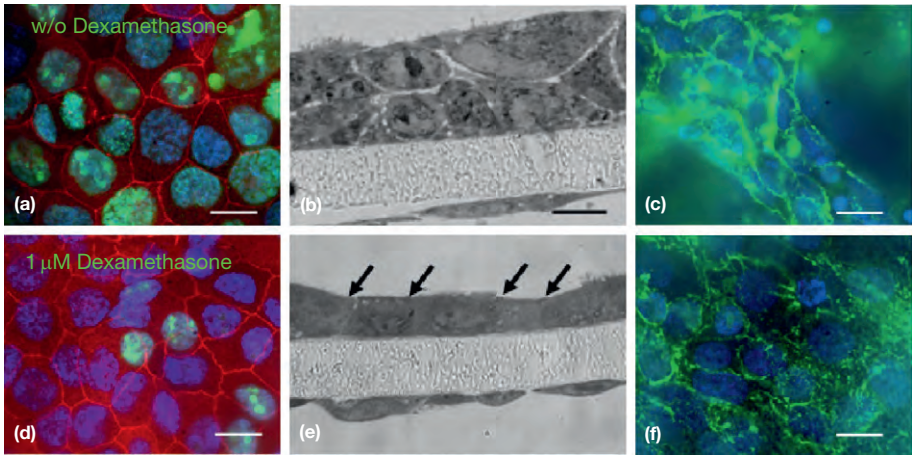

Figure 11 Cross-sections of NCI H441 or ISO-HAS-1 cell layers at day 10 of coculture without (w/o, a–c) and with dexamethasone (1 μM, d–f), visualized by confocal laser scanning microscopy with staining of ZO-1 (red) and Ki67 (green) for NCI H441 (a, d), and of VE-cadherin (green) for ISO-HAS-1 (c, f) or TEM (b, e). Scale bar = 5 μm.

3.312.3.8. Specific Applications

3.312.3.8.1. Transport studies

The paracellular movement of the anionic hydrophilic marker sodium-fluorescein or FITC-labeled dextrans with different molecular weights is often used to quantify the tightness of epithelial layers *in vitro*. Apparent permeability coefficients (P_{app}) are calculated using an equation already described in the subsection 'Cell culture models of the bronchial epithelium.' Transport studies with hydrophilic macromolecular FITC-dextrans across heterocelllular (hATII/ATI-like) epithelial cell monolayers revealed an inverse relation between permeability and molecular size.[117] **Table 5** specifies the P_{app} values for the transport of sodium fluorescein (a) or FITC-dextran 20 kDa (b) across different cell layers.

The apparent permeability coefficients of FITC dextrans (4400–150 000 Da) of A549 turned out to be more than 100-fold higher than that found in primary cultured alveolar epithelial cells.[117,148]

3.312.3.8.2. Uptake of micro- and nanoparticles

With the already described coculture systems for the upper and lower respiratory tracts, it is now possible to study systematically how micro- and nanoparticle biomaterials interact with these important barriers. The function of such carriers as drug or gene delivery systems is not merely restricted to surface adhesion. Particles that can adhere to the epithelial surface and that can be taken up in intact form could serve as carriers for labile substances that need to be delivered to the underlying tissue or the systemic circulation. However, the real situation *in vivo* is much more complex than can be modeled by taking a well-known cancer cell line, such as HeLa cells, and studying how the micro-/nanocarriers of interest enter the cell cytoplasm. In both the upper and lower respiratory tract, there are interactions with a protein–mucus layer (proximal) and a protein–surfactant layer (distal) before a micro- or nanoparticle 'sees' any plasma membrane. The presented coculture systems offer the possibility to study these sequential interactions in a manner which simulates the *in vivo* situation in a more realistic way than any monoculture model.

Inhaled micro-/nanocarriers may interact with the apical plasma membrane of the polarized alveolar epithelial cells and enter or pass them by a number of different processes, including passive (diffusive) and active mechanisms. Particles that express human proteins on their surface may be able to penetrate epithelial cells via receptor-mediated endocytosis[161] that involves caveolae-[162] or clathrin-mediated[163] lipid raft pathways and/or other yet unknown pathways of uptake. For each biomedical application, detailed mechanisms of how physical properties affect biological barrier properties, as well as the interplay between various physicochemical properties, may have to be elucidated case by case. Active transport

mechanisms by which some compounds traverse the distal lung barrier are more likely to provide new insights and improved strategies for pulmonary delivery of drugs into the systemic circulation and/or targeting drugs to lung parenchymal cells. These considerations are far from trivial. Thus, if a biomaterial carrier system is being primarily developed to treat lung diseases, the biomaterial must enter the lung and not be transported to the lumen of the pulmonary microcirculation. On the other hand, using the lung merely as a portal of entry for targeted delivery to another organ system will require active transport across all barrier components without intracellular accumulation of the carrier in the lung cells. The latter requirement is a major challenge, as our own work has shown that microcirculatory endothelial cells have an enormous capacity for uptake and intracellular sequestration of nanoparticles.[164]

To detect an uptake of micro-/nanocarriers, several methods should be combined to gain reliable results. Methods of choice are electron microscopic techniques, such as scanning or transmission electron microscopy (TEM), and, in the case of a fluorescent label, confocal laser scanning microscopy (CLSM). Trafficking of fluorescent carriers should be followed by colocalization with markers of the cellular uptake and intracellular transport machinery, for example, caveolin-1, clathrin, early/late endosomal markers, and lysosomal markers. Figure 12 illustrates the importance of the use of different methods to detect mechanisms of micro-/nanocarrier interaction with cells. Barrier-forming NCI H441 and ISO-HAS-1 cells show a clearly differing interaction with biodegradable poly(D,L)-lactic-*co*-glycolic acid (PLGA) microspheres. For polarized NCI H441 cells, the PLGA-spheres seem to adhere preferably to the apical contact zones of adjacent cells as shown by CLSM. Whereas a selective adhesion was shown, an uptake of spheres could not clearly be confirmed by SEM and TEM (Figure 12(a)). For microvascular endothelial cells in coculture, PLGA-microspheres were taken up and partly transported through the cells (Figure 12(b) asterisk). Here all applied methods of detection, CLSM, SEM, and TEM, demonstrated a perinuclear localization of PLGA-microspheres in ISO-HAS-1 cells.

3.312.3.8.3. Influence of cytokines on barrier properties

Alveolar epithelial cells are localized at the critical interface with the external environment and are the first to be exposed to inhaled irritants, allergens, and noxious stimuli. As well as maintaining their barrier function, alveolar epithelial cells also serve as a part of the local immune system. Their function in host defense has been reviewed recently. Moreover, this review covers alterations of the epithelium associated with airway diseases and potential therapeutic implications for the treatment of respiratory diseases.[165] Damage to the alveolar–capillary barrier is the major critical element occurring during many pathological processes in the lung, for example, acute inflammatory responses, as reviewed in *Lucas et al.*[166] As treatment with drugs is often necessary under such pathophysiological conditions, *in vitro* models that mimic an impaired barrier could be useful, and indeed necessary, to predict drug effects on an alveolar epithelium with altered barrier function. TJs are highly dynamic structures capable of rapid alterations in disease and in response to functional stress.[154] A basolateral exposure of the coculture (NCI H441 and ISO-HAS-1) to TNF-α and IFN-γ, for example, caused a local disruption of the TJ with the loss of ZO-1 labeling in NCI H441 cells, accompanied by a decrease of TER.[135] At these areas of local TJ disruption, an increased adhesion/uptake of Oregon green-coupled 25 kDa polyethyleneimine nanoparticles was detected. In contrast, polarized NCI H441 with intact TJ showed no adhesion/uptake of Oregon green-coupled 25 kDa polyethyleneimine nanoparticles (Figure 13).

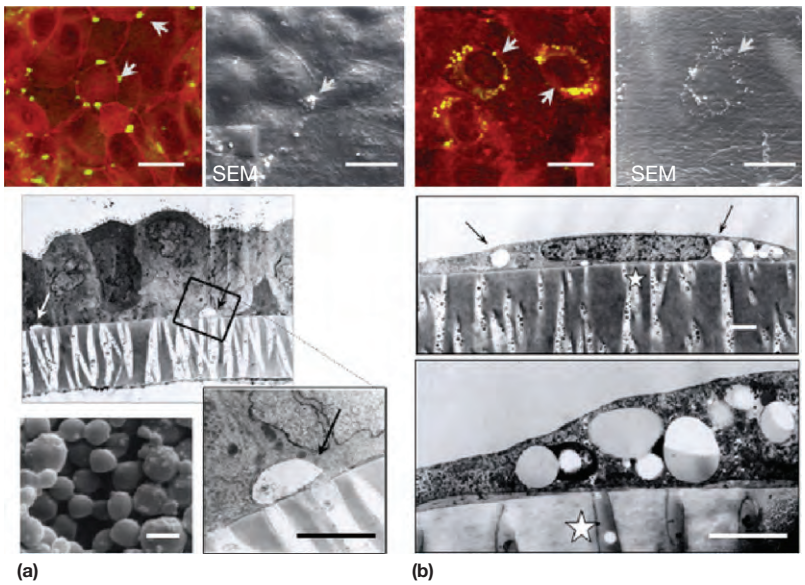

Figure 12 Selective interaction of PLGA microparticles with NCI H441 or ISO-HAS-1 cell layers at day 10 of coculture. Distribution of PLGA-Cumarin 6 (green) in NCI H441 (a) and in ISO-HAS-1 (b), visualized by confocal laser scanning microscopy with staining of the actin cytoskeleton (red), SEM or TEM. Scale bar = 1 μm.

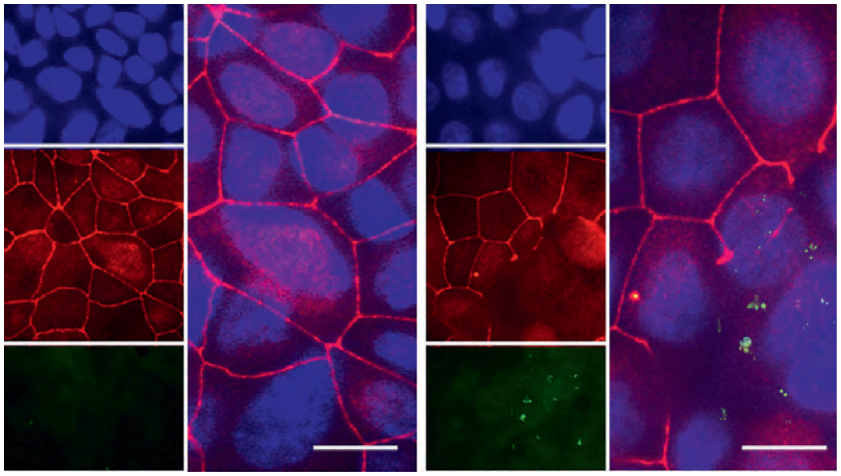

Figure 13 Selective interaction of Oregon green-coupled 25 kDa polyethyleneimine nanoparticles (PEI-OG) with NCI H441 cell layers at day 10 of coculture. Distribution of PEI-OG (green) in polarized NCI H441 (a) and in NCI H441 with disrupted tight junctions (b), cells were treated with tumor necrosis factor-α and interferon-γ for 12 h before incubation with PEI-OG), visualized by confocal laser scanning microscopy with staining of the nuclei (blue) and ZO-1 (red). Scale bar = 5 μm.

3.312.3.9. Potential and Limitations of Available Cell Culture Models

The *in vitro* model of the alveolar–capillary barrier that most closely mimics the *in vivo* situation is a primary coculture of heterocellular alveolar epithelial cells with HPMEC.[119] Because of ethical considerations, a commercial use of normal primary human cells will hardly be accepted. Moreover, the human material is mainly derived from lung surgery, that is, from tumor patients, who are often elderly people. Another drawback to be faced is the risk of biological variability, for example, smokers versus nonsmokers, as well as the incidence of lung or hereditary diseases. Finally, in addition to a quite complex isolation procedure, the sources for tissue material are limited, thus confining the availability of this model and not recommending it for first stage high throughput screening. The recently generated type I-like cell line TT1 could serve as an efficient tool to investigate the human alveolar type I phenotype. As confluent TT1 cell monolayer formation with electrically tight characteristics has not yet been shown,[39] its usefulness as a drug absorption model appears questionable, unless specific data can be generated.

Type II cell lines, such as A549, were used in human coculture models for leukocyte transmigration or microbial infection in the lower airways,[167,168] but the formation of a functional barrier was not adequately characterized. Overall, the low values for transepithelial resistance for A549 make it difficult to interpret transport data (including drug trafficking) obtained from such a cell line.[147] Nevertheless, A549 cells have in fact been used to study alveolar drug absorption,[148] metabolism,[146] and gene delivery[169] and are widely accepted as a valuable model for studies in pulmonary toxicity with widespread use even in recent years.[170–172] The great majority of studies within this scope of metabolism (e.g., of certain classes of xenobiotics) used the A549 cell line as *in vitro* model. For the cell line NCI H441, there is still a need to further characterize its metabolic properties as an acceptable substitute for alveolar epithelium. As NCI H441 cells possess functional barrier properties, they may be a suitable tool to predict micro-/nanocarrier interaction in the lower respiratory tract. The addition of the endothelium as the second barrier component raises the potential of the coculture (NCI H441 with ISO-HAS-1) as a model for the assessment of drug efficacy, toxicity, and rapid evaluation of drug permeability in the deep lung. It further allows assessment of the contributions of microvascular endothelium (systemic drug delivery) and epithelium (inhaled drug delivery) to pulmonary adsorption of new drug carrier systems, delivering drugs to peripheral lung epithelial cells and across an alveolar–capillary barrier. With ongoing refinement of such coculture systems, additional cell types (e.g., macrophages, lymphocytes, dendritic cells, and/or polymorphonuclear leukocytes) can be added to the culture to study various cell biology-related questions. Notwithstanding the difficulties and challenges in various aspects of the *in vitro* distal lung models, mechanistic studies of pulmonary drug delivery using the alveolar–capillary barrier as the main portal of entry into the systemic circulation from the lung airspaces are expected to provide us a wealth of information in coming years. These models will enable us to study more efficient ways of treating lung-specific diseases using targeting approaches as well as improved bioavailability of those therapeutics that yield very poor absorption via other routes.

3.312.4. *In Vitro* Studies with Endothelial Cells from the BBB

3.312.4.1. Introduction

The brain is not exposed to the outside environment such as the skin, the eyes, or the membranes lining the respiratory, digestive, urinary, and reproductive tracts. The brain is enclosed in the body and is protected by a barrier that prevents most foreign compounds from entering the brain. This barrier

is formed by microcapillaries that are part of the vessels that transport blood throughout the body. However, the capillaries in the BBB differ from those of other tissues. These microcapillaries are made up of brain-specific capillary endothelial cells that exhibit unique morphological characteristics, such as the presence of TJs between individual endothelial cells, the absence of fenestrations, and the near absence of pinocytotic activity. These characteristics are due to the interaction and direct contact of the microvascular endothelial cells with pericytes, astrocytes, and microglia cells found within the brain. These brain-specific endothelial characteristics also limit the types of substances that can pass into the brain. The exchange of nutrients and oxygen between blood and tissues readily takes place at the capillary walls in other parts of the body. However, many nutrients needed by the brain do not pass directly into the brain but are transported by specific systems in endothelial cells that move the substances the brain needs across the BBB. The presence of the TJs limits or excludes many useful therapeutic compounds such as antibiotics, chemotherapeutic compounds, peptides, and proteins from moving into the brain from the blood.

3.312.4.2. Characteristics of the BBB

The primary characteristic that differentiates the BBB microvasculature from the vasculature from other parts of the body is the presence of AJs and TJs which limit the permeation of solutes in the blood by diffusion between endothelial cells into the brain extracellular spaces. The TJs are formed by endothelial cells at the interface between blood and brain and are associated with astrocytes from the brain. The TJs are formed primarily by transmembrane adherens proteins such as claudins, occludins, and junctional adhesion molecules, which are in turn anchored to the endothelial cells by cytoplasmic scaffolding and the regulatory proteins ZO-1, ZO-2, ZO-3, and cingulin. Any disruption to these proteins decreases TJ resistance and results in leaky BBB. The way these proteins are organized and interact plays an important role in the degree of barrier integrity. The integrity of the BBB and the presence of TJs are demonstrated by an inhibition of ion movement via paracellular diffusion between endothelial cells and can be demonstrated by a high *in vivo* trans-electrical resistance of the BBB. The association of microglia, astrocytes, nerve terminals, and pericytes are necessary for the formation of TJs by the brain endothelial cells. These cells release vasoactive agents and cytokines that can modify TJ assembly and barrier permeability, and influence the polarized expression of specific transporters within the brain endothelial cells at the luminal and abluminal membranes. The importance of these cell–cell interactions and the formation, stabilization, and increase of TJs has been demonstrated in many *in vitro* studies by increases of the TER or trans-electrical resistance across monolayers of endothelial cells compared to cocultures.[3,20,173]

Many different and unique mechanisms have been identified for the transport of nutrients across the BBB and into and out of the endothelial cells. These include the ATP-binding cassette or ABC transporter (lipid soluble, nonpolar compounds), solute carriers (glucose, amino acids, nucleosides, small peptides), and receptor-mediated (transferrin, lipoproteins, immunoglobulins, cytokines) and adsorptive-mediated transcytosis (histones, cell-penetrating peptides). Many other mechanisms are used to specifically transport unique compounds across the microvascular endothelial cell of the BBB.

3.312.4.3. Characterization of Brain Endothelial Cells

As mentioned above, the inner layer of all microcapillary vessels in the BBB is formed by endothelial cells. Although these endothelial cells can differ in their barrier properties, they share some characteristics with endothelial cells in all parts of the body. These special endothelial cell markers allow a distinction between endothelial and nonendothelial cells. One of the major endothelial cell markers is von Willebrand factor (vWF, also called factor VIII). This blood glycoprotein is expressed by endothelial cells and after release into the blood it is important for blood clotting (*haemostasis*). The second endothelial cell marker is PECAM-1. PECAM-1 (platelet endothelial cell adhesion molecule), also called CD31 (cluster of differentiation), is expressed at the cell surface of endothelial cells. It is involved in cell–cell adhesion and interacts with other CD-31 molecules or proteins of the integrin family. Also VE-cadherin (cadherin-5), a cell adhesion protein, is specifically expressed on endothelial cells. The cytoplasmic domain of this interendothelial protein is connected to the actin cytoskeleton via α-, β-, and γ-catenins. VE-cadherin is important for the organization of new blood vessels and is involved in several regulatory processes of endothelial cells. These markers can be stained by specific antibodies and visualized by fluorescence microscopy as shown in Figure 14.

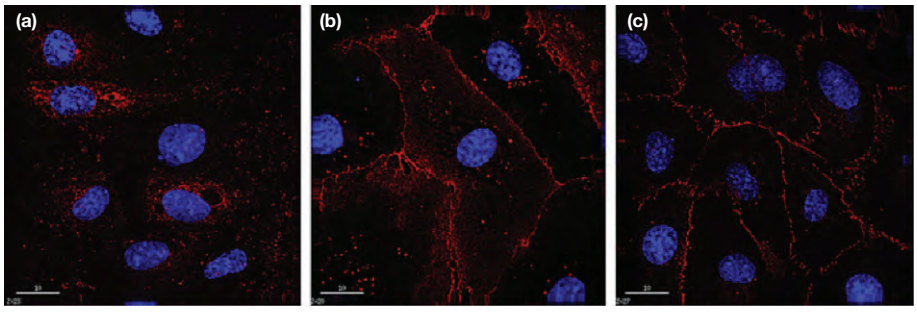

Figure 14 Specific endothelial cell markers. Typical endothelial cell markers are stained with antibodies against vWF (a), CD31 (b), and VE-cadherin (c) (all in red) in a human brain endothelial cell line. The nuclei are stained with Hoechst (blue). Fluorescence microscopy (60×).

3.312.4.4. Primary Isolated Human Brain Endothelial Cells

Different coculture models from various parts of the body such as the air–blood barrier (lung) or BBB have been developed and have been shown to exhibit structures and functions similar to those in the *in vivo* situation.[174,175] The use of freshly isolated primary cells for generating an *in vitro* model has the advantage that the isolated cells generally express most of the important cell properties and functions and under the proper conditions can generate the characteristics of a tight barrier. Major disadvantages are the difficulty in obtaining fresh human brain tissue and the purity of the cells after isolation, and the variability of cell isolation success and functions dependent on the donor. A number of brain-endothelial cell lines are available that exhibit most of the characteristics and properties, although the barrier properties of primary cells such as TER are generally higher and closer to the *in vivo* situation. Thus, most *in vitro* models utilize primary cells of different animals. A few well-established primary cell-based rat, porcine, and especially bovine BBB models are routinely used.[3,20,173] The isolated brain endothelial cells are often cocultivated with astrocytes or pericytes as this has been shown to increase the TER and TJ properties and to induce and stabilize the expression of barrier-specific proteins. In the section below various methods will be described using porcine brain endothelial cells (PBECs) with or without pericytes to examine novel biomaterials and their interaction with and uptake and transport in brain-derived endothelial cells.

3.312.4.5. Primary Porcine Brain Endothelial Cells and Pericytes

3.312.4.5.1. Isolation

We have previously developed a method to isolate human brain microcapillary endothelial cells from brain tissue.[175] This method has been adapted and found to function for the isolation of endothelial cells from porcine brain tissue. Brains from freshly slaughtered pigs were used for the isolation of primary PBECs and porcine pericytes. After carefully removing the meninges and larger blood vessels, the gray matter was separated from the white matter and used in the following isolation steps. The brain tissue was digested with collagenase type IV and afterwards the small capillaries were separated from myelin debris by a percoll gradient (GE Healthcare, Sweden). A second digestion with a mixture of collagenase/dispase and an additional percoll gradient and washing step were carried out. This step has been found to ensure high purification of the microvessels with few additional contaminating cells. The microvessels were resuspended in basic endothelial growth medium with supplement mix (PromoCell, Germany), 1% penicillin/streptomycin, and 3 $\mu g\,ml^{-1}$ puromycin (Calbiochem, USA). The medium was changed daily and addition of 3 $\mu g\,ml^{-1}$ puromycin was contined for two additional days. On day 3, cells were switched to a medium without the addition of puromycin and cultured until confluent. Puromycin is a nucleoside-antibiotic that is toxic for fibroblasts and other contaminating cells but can be transported by efflux transporters out of the brain endothelial cells without exhibition of a toxic effect. This method resulted in a significant enhancement in the purity of the porcine brain capillary-cell isolated.

To isolate brain pericytes, the microvessels were resuspended in the above medium with puromycin for 24 h, and then switched to a medium without puromycin. Pericytes exhibit a significantly higher replication rate than endothelial cells and rapidly outgrow these cells. Generally, after one to two passages, no endothelial cells remained (as detected by immunohistochemical staining; see below).

3.312.4.5.2. Characterization

The purity of the isolated cells and their proper characterization is essential for further experimentation. The characterization of cells can be done by immunostaining with endothelial cell-specific markers (see **Section 3.312.4.3**) or by using these same markers for FACS (fluorescence activated cell sorting) analysis. Also, a characterization by reverse-transcription polymerase chain reaction (RT-PCR) with primers to specific cell marker genes is possible.[175] The outgrowing PBECs after isolation of microcapillaries are shown in **Figure 15(a)**. The expression of a typical endothelial cell marker for endothelial cells (CD31) was used to stain porcine brain capillary endothelial cells (PBCECs) (**Figure 15(b)**). In comparison to the endothelial cells, the morphology and the staining of smooth muscle actin of pericytes are demonstrated in **Figure 15(c)** and **15(d)**, respectively.

A precise characterization of pericytes is difficult.[176] One criterion is the morphological structure of the cells, namely, long, thin, and stretched structure. These cells are also positive on staining the cells for smooth muscle actin (**Figure 15(d)**), desmin (class III muscle-specific intermediate filament), NG-2

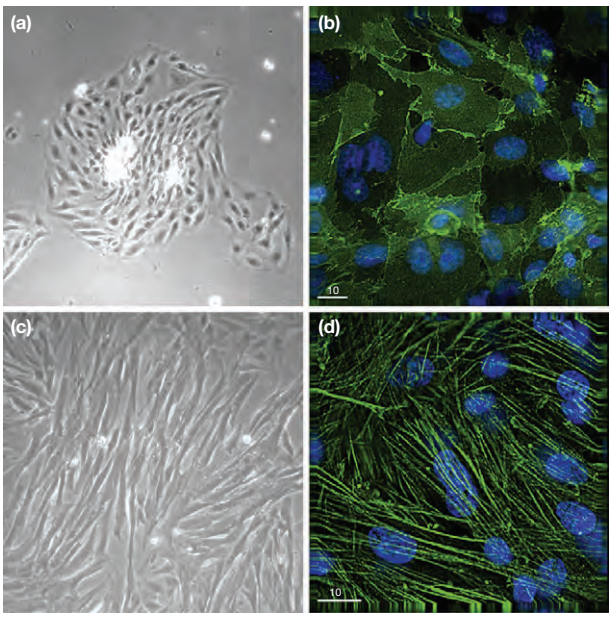

Figure 15 Morphology and staining of specific cell markers of PBECs and pericytes. Phase contrast microscope images showing the different morphologies of PBECs (a) and pericytes (c). The staining of CD31 in PBECs (b) and SMA (d) in pericytes (all in green) represents specific markers of each cell type. The nuclei are stained with Höchst (blue). Fluorescence microscopy (60×); light microscopy (20×).

(Neuron-glial 2), platelet-derived growth factor receptor (PDGFR)-β, and aminopeptidase A and N. However, none of these markers is absolutely specific for pericytes and none of the markers recognizes all pericytes because their expression is dynamic, differs depending on the location of cell source, and is dependent on the cell development stage. The identification of pericytes is generally based on a combination of staining methods, structural morphology, and a high resolution confocal imaging. Another useful pericyte marker, 3G5, has been identified and has been used for enriching these cells, but is unfortunately not commercially available.[177]

3.312.4.5.3. In vitro *coculture model with PBECs and pericytes*

A coculture of primary porcine brain endothelial cells and pericytes can be used to generate an *in vitro* model for the brain mimicking the *in vivo* situation.[178] To generate this barrier, PBECs are seeded on the top of a Transwell filter (Transwell, see section lung–air barrier) and pericytes on the other side of the filter. With time, the expression of TJ and AJ barrier proteins, such as zonula occludens (ZO-1), β-catenin, and VE-cadherin, can be seen (Figure 16). This indicates that barrier proteins are generated and correlates with higher TER values.

3.312.4.6. Analysis of Novel Biomaterials with Cells from the BBB

The investigation of new biomaterials for brain delivery is focused primarily on methods to target the BBB or to act as a carrier across the barrier. Most research strategies are focused on the use of specifically designed peptides or nanoparticles targeted to unique characteristics of the BBB in order to be transported across the barrier. Thus, *in vitro* studies of these compounds with models of the BBB are necessary to understand interactions between the new materials and living cells and to validate the possibility of transport. Carrying out studies with each new compound *in vivo* would not be possible. Therefore, to mimic the *in vivo* situation, a well-characterized *in vitro* single or coculture model is needed. On the one hand, it provides the opportunity to prevent unnecessary animal experiments and on the other hand, it allows detailed analysis of individual mechanistic characteristics in a particular cell type in the absence of other interfering cells that are operative *in vivo*. However, prior to studies with complex coculture models, or single cell cultures of primary brain capillary endothelial cells, other investigations are necessary to determine the biocompatibility and toxicological effects of the novel biomaterials. Toxicity and biocompatibility studies are best examined in monoculture cell culture systems of either brain endothelial cells or microvascular endothelial cells.

To determine whether a novel compound or nanoparticle is biocompatible and exhibits no toxic effects, a number of different tests are generally used. The MTT or MTS is the most widely used test to examine the effects of compounds on cell viability. In this test, cells are incubated in the presence or absence of the novel compound and then MTS/MTT is added. The level of the reduction of the MTS/MTT substrate by dehydrogenases located in the mitochondrial membranes of cells to formazan is directly correlated with the viability of the cells. Thus, the more the MTT enzymatically converted to formazan, the higher the cell viability is. In addtion to cell viability, cell toxicity must also be evaluated. The LDH-test is the most commonly used test for examining cell toxicity of a compound. LDH (lactate dehydrogenase) is a cytoplasmic enzyme and if a biomaterial/nanoparticle causes cell toxicity the cell membrane of the affected cell becomes leaky. After exposure of cells to a test compound, the supernatant is collected and the LDH content of the supernatant is determined and compared to controls. The more toxic a compound, the more LDH is present in the supernatant and the more substrate is converted. In certain cases, it has been found that particular novel compounds may have an inhibitory effect in one or the other test systems. Therefore, it is important to use more than one test to exclude an impairment of a test system by new biomaterials/nanoparticles.

Initial studies of the interaction of novel compounds with the BBB are conducted with single-cell systems. In addition to the toxicity studies described above, which are not directly dependent on whether the compounds are present extracellulary or intracellulary, the next step is to examine how the compounds interact with the cells. Nanoparticles are often internalized. The internalization itself can cause decreased cell viability and/or increased cell toxicity. The level of impairment of cells by nanoparticles can be associated with different properties such as the concentration, shape, size, and chemical composition of the nanomaterials or combinations thereof. In addition to the toxicological effects on the cells, if a compound is taken up, then the fate after internalization of the nanoparticles within the cell is generally the question that

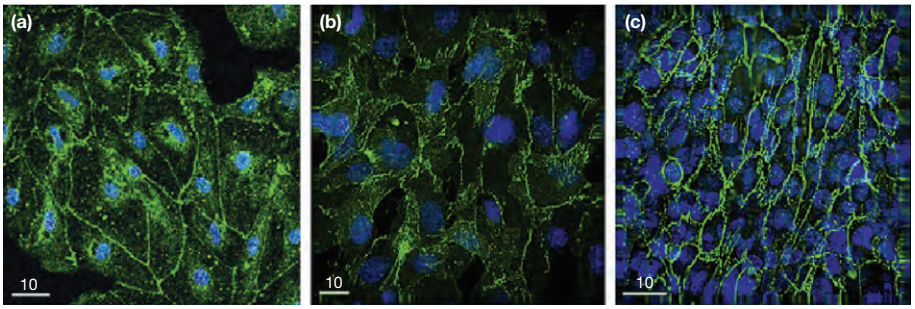

Figure 16 Staining of tight and adherens junctions in porcine brain endothelial cells. Staining pattern of different tight and adherens junction proteins on endothelial cells. (a) ZO-1 staining, (b) β-catenin, and (c) VE-cadherin; all in green. The nuclei are stained with Höchst (blue). Fluorescence microscopy (60×).

needs to be answered, especially if the nanoparticles are to be used to transport compounds across the barrier. To investigate uptake mechanisms such as pinocytosis or receptor-mediated endocytosis, specific inhibitors of these systems can be used. In addition, specific antibodies are available to stain individual intracellular structures and organelles and these can be used to follow or localize nanoparticles within cells. One criterion for studying nanoparticles or other peptides/proteins is that they contain a suitable method of detection, the optimal being a fluorescent label or visibility by light microscopy. One of drawbacks in the study of nanoparticles in cells is that the detection of the nanoparticle is limited by the numerical aperture and the wavelength of visible light attainable by microscopy. Because of the small size of single nanoparticles, these lie below the maximum resolution that is obtainable by microscopy. Generally it is only possible to detect agglomerations of nanoparticles within the cells. An example of nanoparticles in cells can be seen in Figure 17(a). Transferrin, which is taken up by clathrin-mediated endocytosis, is often used as a model to show the colocalization of transferrin and endocytotic vesicles (Figure 17(b)).

To detect single nanoparticles at the cell surface or even within the cells, it is necessary to use electron microscopes with a higher resolution maximum. Although the resolution of transmission electron microscope or scanning electron microscopes is higher compared to optical microscopes, not all nanoparticles or compounds can be detected. Only nanoparticles with a high atomic number or density such as gold or silver can be detected by these techniques. Other nanomaterials or compounds with a lower atomic number can be coated with a thin gold layer to make them suitable for electron microscopy. An example of the uptake of gold nanoparticles in brain endothelial cells is shown in Figure18.

The internalized nanoparticles are often in vesicles in the perinuclear region (Figure 18). Similar agglomerations of gold nanoparticles can also be detected by optical microscopy. In Figure 19, the difference in the amount of uptake of two nanoparticles which differ only in the surface modification is shown. Figure 19(a) shows the uptake of a gold nanoparticle with a neutral net charge while in Figure 19(b) the uptake of nanoparticles with a negative net charge is shown. Prior to the use of more complex coculture systems,

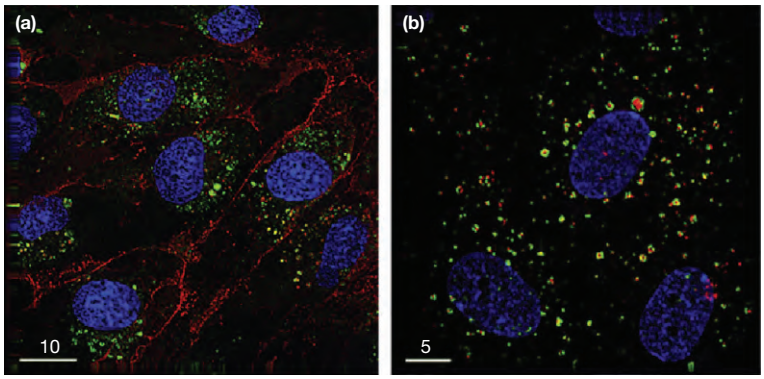

Figure 17 Uptake of 100 nm liposome nanoparticles (a) and transferrin (b) in brain endothelial cells. The uptake of fluorescent nanoparticles (liposomes, 100 nm) in human cerebral microcapillary endothelial cells is shown after a treatment for 4 h (a). The internalization of transferrin Texas Red (Molecular Probes) after 30 min of treatment and the colocalization with EEA (early endosomal marker, green) in brain endothelial cells is shown. The nuclei are stained with Höchst (blue). Fluorescence microscopy (a) 60× and (b) 100×.

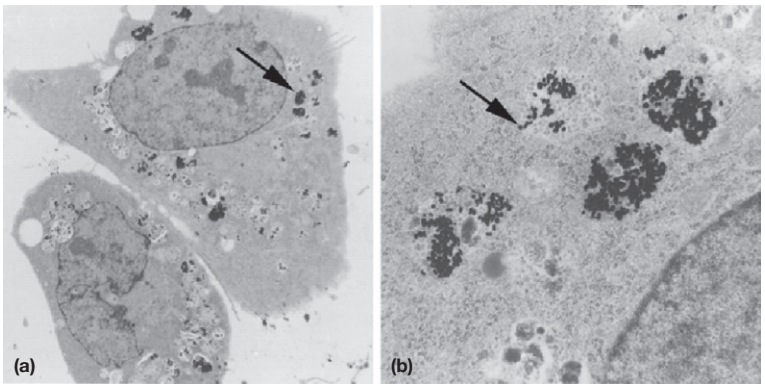

Figure 18 Transmission electron micrographs of the uptake of gold nanoparticles in human cerebral microcapillary endothelial cells (hCMEC) after 4 h. After 4 h of treatment with 100 μg ml^{-1} gold nanoparticles hCMEC were fixed and prepared for TEM analysis. (a) shows an overview of two cells with gold nanoparticles, while (b) demonstrates the uptake of gold particles and storage in vesicle-like structures in the perinuclear region. The arrows indicate the localization of gold agglomerates (a) and single gold nanoparticles (b). Magnification (a) 860×; (b) 8900×.

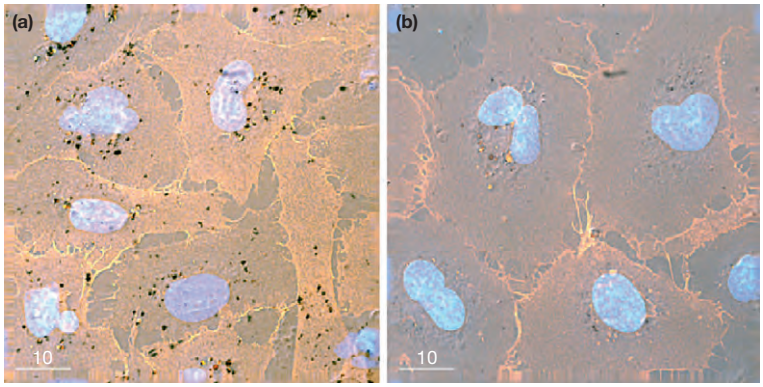

Figure 19 Uptake of gold nanoparticles (35 nm) with different surface modifications in brain capillary endothelial cells. After 4 h of treatment with 100 μg ml^{-1} gold nanoparticles (35 nm), human cerebral microcapillary endothelial cells were fixed and stained with CD31 (red) to highlight the cytoplasmic membrane. In (a), the uptake of gold nanoparticles with a hydroxpropylamine (neutral net charge) is shown. Less uptake can be detected after the treatment with gold nanoparticles coated with taurine (negative net charge; b). Fluorescence microscopy (60×).

single-cell culture systems can be used to evaluate how the size, shape, charge, surface modification, and chemical composition of a compound affect the ability of uptake and localization within a cell.

3.312.5. Conclusion and Future Perspectives

The advent of sophisticated nanocarrier-based systems for drug and gene delivery has faced the life sciences with the challenge of providing suitable model systems with which to investigate the mechanisms of cell–biomaterial interactions. Complex systems which possess an *in vivo* similarity are essential not only to adequately exclude toxic side-effects, but also to provide structure–function correlations. Thus, in design and application of nanocarriers the determination of biological response by physicochemical characteristics takes on fundamental importance. *In vivo*-like systems are best established *in vitro* using those primary human cells to be found in the various natural barriers encountered during nanocarrier delivery. This chapter has concentrated on those in the respiratory tract and the BBB. In some cases, it is possible to replace the primary cells with a phenotypically stable permanent cell line. Among the major challenges for future research are understanding the mechanisms of protein and surfactant molecule interaction with nanoparticles and the identification of specific targeting molecules which are genuine molecular addresses of the tissue and cells to be targeted. This is particularly important in any form of systemic application of nanocarriers.

Acknowledgments

The authors would like to thank S. Barth, L. Meyer, M. Moisch, K. Molter, K. Müller, A. Sartoris, and E. Stahr for their excellent technical assistance and C. Brochhausen and J. Kasper for many useful discussions. This work was supported by the German Defence Ministry, BMVg (M/SAB1/7A011) and the Integrated Project NanoBioPharmaceutics (026723-1) from the European Union.

3.313.1. Introduction

Histological evaluation of the tissue reactions to the biomaterial placed in the living body is of utmost importance and is an essential step in understanding its nature. By observing and evaluating histological sections, the aim is to determine whether or not the material is biocompatible. Histology has evolved so much and there are numerous techniques available that we can observe not only the shape of the cells, but further observe its gene expression or related protein localization. Hence, it can be said that with the tools we have today, a more precise evaluation of the tissue reactions to the biomaterial is possible. However, having multiple options for such evaluations may sometimes be a double-edged blade, since there are specific preparations for each type of sectioning, staining, or technique that one wrong step may lead to a failure, in other words, without proper preparations, we may not be able to observe the target. Therefore, before proceeding to the concrete contents, the importance of project planning and adequate project outlines should be addressed in this introduction part of the chapter.

During the course of project planning, certain issues or questions must be discussed or answered such as 'What do we want to observe?' or 'What type of evaluation, or what kind of staining?' or 'Decalcified or calcified sections?' or 'Paraffin sections or resin sections or frozen sections?' or 'How many samples are to be prepared?' or 'What is the expected size of the samples?' or 'What is the composition of the samples?' By answering to these questions, we will have a clear idea of the protocols we must follow. It is most important to obtain advice from the persons involved in the laboratory procedures at early stages of planning. The project planning must include consideration of the safety problems for the persons involved in the procedures because many steps involve using hazardous reagents.

Although the application of biomaterials has a wide range from soft tissues to hard tissues, this chapter mainly focuses on bone tissue reactions in relation to biomaterials.

The history of *artificial* materials placed in bone goes back as far as the age of the Roman empire,[1] where a wrought iron material was placed in the maxilla after tooth loss. Whether or not the material was in function will remain as a missing piece of the puzzle, this is a clear indication that we always had an idea that materials could replace once lost organs.

Around 1961, Brånemark and colleagues discovered the osseointegration phenomenon using commercially pure titanium,[2,3] and to this day, efforts to improve osseointegration have lead to a variety of innovations. And it is necessary to emphasize that the laboratory evaluation of osseointegration has always been dependent on histology. The original definition of osseointegration was based on the light microscopical level.[4] The method for preparing undecalcified sections in the 'early days' in the laboratories followed the guidelines of Hallén and Röckert.[5] These authors had modified the cutting and grinding methods that were presented by Pattern and Chase.[6] Nowadays, the specific histological sample preparation follows the cut and grinding technique described by Donath and Breuner,[7] and for a proper evaluation, the importance of sample thickness has been reported indicating its technique sensitivity.[8] Sample thickness is important for achieving proper/reliable histomorphometrical results; however, there are quite recent publications where sections of 50 μm and more are evaluated and to our knowledge, the thicker the section the greater the integration will appear.[9–11]

This chapter briefly describes some selected histological and histomorphometrical methods starting from sample preparation techniques to specific quantification methods in particular for bone tissue. Along with the basic histological staining techniques, standard immunohistochemistry, immunofluorescent stainings, enzyme histochemistry, and DNA/RNA

labeling technique using *in situ* hybridization will be presented. Furthermore, toward the end of this chapter, some state-of-the-art and novel techniques will be presented that will provide more knowledge and enhance our understanding related to histological analysis.

There are several excellent books available within this interesting field, and at the end of this chapter, we refer to some selected handbooks.

3.313.2. Preservation of Tissue

This section describes the preparation of the samples for adequate quality sections and/or stainings, focusing on fixation of the tissue. This is an utmost important task for adequate histological analyses, since the quality of the sections may easily be disturbed due to inappropriate procedures during the fixation step. Some critical aspects related to the fixation protocol are temperature, sample size and volume of fixative, pH, and time of fixation. Almost all fixatives contain toxic substances and safety aspects must be followed. For such issues, we refer to the paper by Titford.[12]

3.313.2.1. Resolution Level

Different resolution levels involved in analyses require the usage of specific fixative solutions in order to achieve the best results of tissue preservation for the intended investigation. The resolution level to be investigated must be known beforehand. This is crucial since not only sample size matters for achieving good results. Both overfixed and underfixed tissue will render 'preservation artifacts' irrespective of morphological, cytological, or histochemical level.

3.313.2.2. Storage

After adequate fixation has been performed, the samples should not be stored in the fixative since this will overfix the material. The fixation itself is a very critical part and later histological staining results will be hampered. Storage of fully fixed samples in 70% ethanol kept in a cool place is recommended. With proper handling of samples, they can be stored for a very long time and the material can be used for later analyses.

3.313.2.3. Fixation

Fixation is the first step in the preparation of the histological sections. It should preserve the tissue as it is so that we will be able to observe or evaluate the intended time point. Proper tissue fixation is important.

In general, for immunohistochemical detection of proteins in the tissue, a fixation time of 24 h at room temperature using 4% paraformaldehyde solution is adequate. If and when using 1.4% paraformaldehyde solution at 4 °C, the fixation time is prolonged and over fixation will not be a problem. However, the solution has to be changed very often because the concentration of paraformaldyde decreases with time. This low concentrated fixative can only be used on small tissue samples otherwise the fixation is too slow to protect the tissue from autolysis. Achieving excellent fixation of tissue surrounding implants is a challenge. Problems associated with histological analysis, especially in the interface region, refer to the penetration time of the fixative, that is influenced by the various different density properties involved in the sample (bone, soft tissue, biomaterial). There is the compact bone tissue on one side and the cell membranes with their semipermeable properties on the other side. Immuno- and enzyme histochemistry require a protein protective fixation. The fixative must stabilize cell membranes, render no shrinking, and thus reveal no osmotic differences. Nucleic acids need strong fixation such as 10% paraformaldehyde; however, over fixation by time renders negative results/consequences.

Preserving the tissue is intended to prevent autolysis and to immobilize the cells and/or tissues. Glutaraldehyde has a strong fixation effect due to the dual –CHO radicals, and it is mainly used for electron microscopic observations, for example, observing implant tissue interface or cells cultured on biomaterials as seen in **Figure 1**.[13] The advantage of this fixative is that it preserves the cell or the tissue morphology to be favorable for these types of observations. In normal procedures, 2–5% concentration in phosphate-buffered saline (PBS)

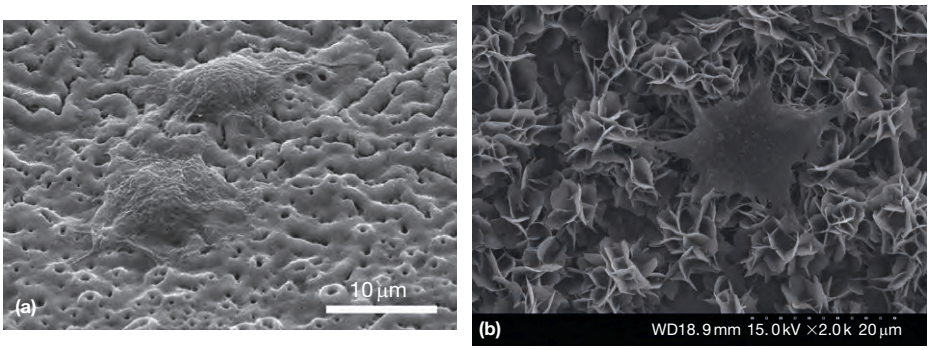

Figure 1 Scanning electron microscopic images of osteoblasts (MC3T3-E1) cultured on (a) laminin-incorporated hydroxyapatite surface (b) anodic-oxidized surface. Although observed at different time-points, the cells are well spread indicating the biocompatibility of the surface. Cells were fixed with glutaraldehyde fixatives, followed by series of dehydration. Note that the cell morphologies are well preserved after treatments. (a) Reproduced from Jimbo, R.; Sawase, T.; Baba, K.; *et al. Clin. Impl. Dent. Relat. Res.* **2008**, *10*, 55–61, with permission from Wiley.

is most commonly used. However, the time to fix takes longer compared with formaldehydes, hence most of the studies which involves electron microscopic observations use a mixture of formaldehyde and glutaraldehyde of around 2–3% each.[14] Due to their strong fixability, tissues fixed with glutaraldehydes tend to reduce their enzyme chemical reactions.[15] On the other hand, 4% formaldehyde solution in PBS is one of the most commonly used fixatives for diagnostic and research histological sample preparations. Moreover, by adding sucrose to the 4% formaldehyde solution in PBS, this will protect the cross-linking of the proteins, and this fixative is known to be effective for standard histological sections, immunohistochemistry, and enzyme histochemistry.[16]

The pH of the fixatives should be between 7.2 and 7.4 in order to prevent shrinkage or swelling of the cells. Needless to say, this adjustment will enhance the quality of the final sections, and in fact, it is crucial for obtaining good quality material/sections. The used fixative and the time for fixation cause the majority of problems in tissue preservation and later analyses. We must keep in mind that there is no standard time setting for the length of fixation, since this will differ depending on tissue type and size of the sample. In diagnostics, a sample size of $10 \times 10 \times 3$ mm is preferred and many methods and protocols are in fact designed for such sample size. As a rule of thumb, samples of this size are fixed within 6–24 h in neutral-buffered formaldehyde (NBF). For example, in our laboratories, we have a wide variety of fixation time from 24 h to more than 7 days depending on the tissue type and size as well as subsequent stainings and analysis to be performed.

3.313.2.4. Perfusion Fixation

Perfusion fixation is a research method, which will fixate the tissue by perfusing the fixative solution through the vascular system. It is known that this procedure will better fixate the samples to its smallest vessels compared to the immersion procedure. Perfusion fixation is normally operated by placing a catheter through the heart or large arteries such as the femoral or the inguinal artery. At first, blood and other residues will be removed by a reflux of saline or PBS, if necessary, anticoagulants such as heparin should be used. Thereafter, the fixatives prewarmed to body temperature should be perfused into the vessels at constant speed, preferably using a mechanically controlled pump.

3.313.2.5. Preserving the Immunoreactivity

As mentioned above, fixatives including aldehydes have a strong fixing effect. Even the formaldehyde may be too strong that the section may lose its immunoreactivity. When an antibody does not work, some blame on the quality of the antibody and never think about the fixatives and sample preparation. This section and further below may provide some ideas on what we can do to improve the immunoreactivity of the samples. High or low osmotic pressure between the tissue and the fixative will either make the tissues enlarged or contracted and may have some negative influence on the immunoreactivity and cell morphology. As mentioned before, by adding sucrose to the 4% formaldehyde solution in PBS, this will hinder the cross-binding of the proteins and thus both enzyme and immunohistochemistry can be successfully investigated.[16]

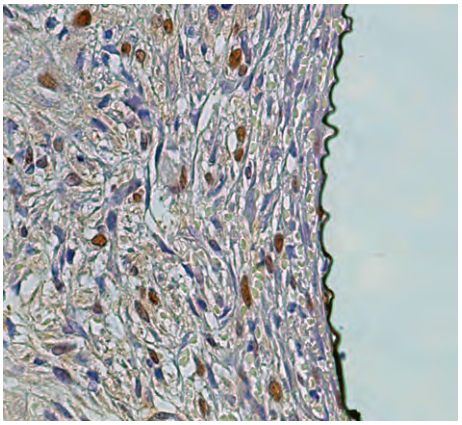

Figure 2 Immunohistochemical staining using antiproliferating cell nuclear antigen (PCNA) antibody. The objective of the staining was to observe cell proliferative activities around the implant. Magnification: ×40.

In some cases, reactivation of enzymes is possible. Samples being immersed in 4% NBF for no longer than 24 h can be 'reactivated' rendering positive enzyme histochemical detection of ALP (alkaline phosphatase) and ACP (acidic phosphatase). However, the best quality of the enzyme activity is of course obtained when using the most adequate fixative to start with.[17]

Addition of zinc ions to the formalin (4% zinc-formaldehyde, Mallinckrodt Baker B.V., Holland) has also proven to be an effective way to preserve the immunoreactivity (Figure 2). The role of the zinc ions is to prevent the cross-linkage between proteins and tissue that may disturb the immunoreactions.[18]

3.313.2.6. Fixation for Bone Biopsy Samples (1×5 mm) up to Bone Slices (8–10 mm thickness) with Implants *In Situ*

The time for fixation of smaller biopsies is usually between 12 and 24 h and takes place in different solutions depending not only upon the composition of the specimen but also on the antigen or enzyme to be labeled. The larger bone samples may need a fixation time of 1 week. To enhance the preservation of the tissue, we recommend that the fixation be performed with the aid of agitation and vacuum treatment.

In general, both for diagnostics and for research purposes, the 4% NBF is accepted and regarded as a state-of-the-art fixative. However, for specific demands, one has to go beyond the routine. Below is some useful information regarding tissue treatment for such demands of 'higher magnification investigation.'

The following methods of fixation have been used for detecting antigens or enzymes.

(a) 4% neutral-buffered formalin (0.02 mol l^{-1} phosphate buffer) – 4–8 °C for 24–48 h, suitable for all histological staining methods (tissue and cell structures), immunohistochemistry (proteins and antigens), *in situ* hybridization techniques (nucleic acids). A fixation at RT for 24–48 h is also possible if omitting the sucrose.

(b) 1.4% paraformaldehyde solution at 4–8 °C for 24–48 h and longer because overfixation will not be a problem by using this low concentration (suitable for sensitive detection of enzymes such as alkaline and acidic phosphatases and for antigens sensitive to denaturation/structural changes).

Fixative solutions

1. Paraformaldehyde stock solution (8%)
   40 g paraformaldehyde
   make up to 500 ml with distilled water
2. 1 M phosphate buffer (pH 7.0–7.4)
   112.5 g disodium hydrogen phosphate
   30.0 g potassium dihydrogen phosphate
   make up to1000 ml with distilled water
   adjust the pH to 7.0 with HCl
3. 0.4 M phosphate buffer with 10% sucrose
   40 ml 1 M phosphate buffer
   100 g sucrose
   10 ml 10% NaN_3
   make up to 500 ml with distilled water
4. Adjust the pH to 7.0 with HCl–paraformaldehyde solution (4%) = *Ready Enzyme Fixative Solution*
   100 ml paraformaldehyde stock solution (see above)
   100 ml 0.04 mol l^{-1} phosphate buffer with 10% sucrose, pH 7.4
5. Paraformaldehyde solution (1.4%) = *Ready Enzyme Fixative Solution*
   35 ml paraformaldehyde stock solution (see above)
   65 ml distilled water
   100 ml 0.04 mol l^{-1} phosphate buffer with 10% sucrose, pH 7.4

There are several variations of this fixative and the original is from Romeis.[19] In 1989, it was upgraded by Böck.[20] One variation of the fixative, with the addition of ethylenediaminetetraacetic acid (EDTA), demonstrated excellent results in standard histological staining, immunohistochemistry, and DNA isolation.[21]

The *Enzyme Fixative Solution* as mentioned above has successfully been used both for small bone biopsies as well as larger samples with implants *in situ* (Figure 3). The following steps have been followed for bone tissue with implants *in situ*.[22]

All solutions should be fresh and newly prepared as well as pH adjusted. Solutions can be stored in the refrigerator overnight before mixing. It is important to follow a strict protocol during fixation and the following is recommended for small bone biopsies:

1. Place the samples in cold (+4 °C) fixative for 6 h (keep cold)
2. Change the fixative to new solution (+4 °C) and continue 24 h (keep cold)
3. Change the fixative to new solution (+4 °C) and continue 24 h (keep cold)
4. Place samples in 70% ethanol
5. Dehydration: see Section 3.313.2.7.

3.313.2.7. Dehydration

Dehydration is routinely performed in increasing concentrations of ethanol and can be performed both manually and automatically in a suitable device at ambient temperature.

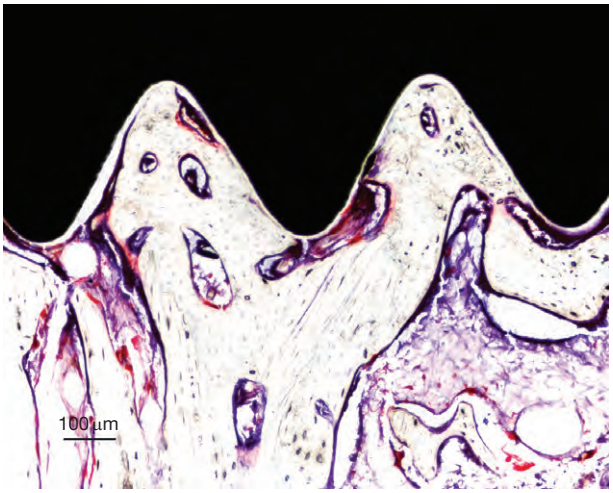

Figure 3 Cut and ground section of a sample retrieved from rabbit bone. Alkaline phosphatase (ALP) and acidic phosphatase (ACP) can be seen both in the interface region and in the bone remodeling cavities. Magnification: the distance between the thread peaks is 0.6 mm.

Two batches of xylene are then used as an intermediate solution before infiltration in resin. The time in each step varies depending on sample size, but for small biopsies 1 h per step is required. For larger samples, with implants *in situ*, agitation and vacuum will aid in all steps.

3.313.2.8. Infiltration

Our experience, with infiltration of samples to be resin embedded with the Technovit® 9100 NEW resin (Heraeus, Kulzer, Germany) suitable for enzyme and immunohistochemical investigations, is described here. Samples are immersed in three preinfiltration steps followed by infiltration in two batches of pure resin. Preinfiltration steps 1 and 2 can be performed both manually and automatically in a suitable dehydration device, whereas the two last steps should be carried out in a refrigerator. One hour per preinfiltration step is required for small spongy and cortical bone samples and pelvic biopsies. For large tissue samples (8–10 mm thickness), the times and volumes should be increased proportionally. Readers interested in additional information related to the following are referred to Wolf *et al.*[16] and Röser *et al.*[23]

The following steps are followed before embedding in Technovit® 9100 NEW:

Dehydration in ethanol (1 h per step)

1. 70%
2. 80%
3. 96% × 2
4. Absolute ethanol × 3
   Intermediate (1 h per step)
5. Xylene × 2
   Preinfiltration (1 h per step)
6. Xylene: Technovit 9100 NEW. Basic (Stabilized), 1:1
7. Technovit 9100 NEW, Basic (Stabilized) + Hardener-1
8. Technovit 9100 NEW, Basic (Destabilized) + Hardener-1
   Infiltration (1 h to 2–3 days per step for small biopsies and prolonged for larger samples)

9. Technovit 9100 NEW, Basic (Destabilized) + Hardener-1+ PMMA-powder.

The table below shows the preparation of preinfiltration and infiltration as well as stock solutions from the five components that are included in the Technovit 9100® New Kit.

Component	1. Basic solution	2. PMMA powder	3. Hardener 1	4. Hardener 2	5. Regulator	Storage
Preinfiltration	200 ml		1 g			Room temp
Infiltration	add 250 ml	20 g	1 g/2 g[a]			4 °C
Stock-sol A	add 500 ml	80 g	3 g/4 g[a]			4 °C
Stock-sol B	add 50 ml			4 ml	2 ml	4 °C

[a]The usage of stabilized Technovit 9100®NEW requires the larger amount of Hardener 1.

Preparation of embedding solution (polymerization mixture): The cooled stock solutions A and B are mixed before usage in a glass beaker during stirring in proportions; 9 parts A plus 1 part B.

3.313.2.9. Embedding of Bone Biopsies in Technovit® 9100 NEW Resin

Embedding molds vary depending on sample size, from gelatin capsule to PVC cups.

The precooled embedding solutions should be poured over the sample and a complete covering is necessary. Samples are placed in a cooled desiccator under vacuum at 4 °C for about 10 min.

The resin is hardened in an oxygen free chamber (sealed container) placed in −8 to −20 °C. The polymerization setting time is dependent on the amount of resin but in general 24–48 h. Following this, the samples are placed in a refrigerator for a few hours (overnight) before reaching room temperature.

3.313.2.10. Cutting the Small Bone Biopsies (see additional information below)

Bone biopsies can be successfully cut using a knife with a D-shaped cutting edge in a stabile rotation microtome. Use 30% ethanol as a stretching media when cutting the sections. Place sections on super frost plus slides and mount with 50% ethanol followed by covering the sections with PVC foil. Remove the excess fluid with filter paper. Place the sections in a press in an oven over night.

The following steps are recommended for deacrylation of sections before staining

1. Xylene 2–3 × 20 min
2. 2-Methoxyethylacetate (2-MEA) 1 × 20 min
3. Pure acetone 2 × 5 min
4. Distilled water 2 × 2 min
5. Alternatively 2-MEA 3 × 20 min
   Constant stirring during the steps and room temperature is recommended.

3.313.2.11. Artifacts

Biopsies with a 'foggy appearance' containing 'white spots' ('Lunker-Stellen') of polymer in the bone tissue are due to inappropriate dehydration and/or infiltration. Such artifacts negatively influence the cutting of the block as well as the quality of the sections. According to our experience, such biopsies can be divided and reinfiltrated in resin under stirring and then repolymerized. However, caution must be taken since dividing the biopsies also result in the loss of material. This treatment renders acceptable sections.

3.313.3. Undecalcified Versus Decalcified

This section refers to our in-house routine methods and thus will not cover all aspects relate to un-decalcification versus decalcification. For more information related to other decalcifying methods, the readers are referred to Sheehan and Hrapchak[24] and the review by Callis and Sterchi.[25]

3.313.3.1. Clarifications of the Intended Purpose

Bone tissue and teeth/dentin are the hardest components of the body, due to the incorporation of great amounts of calcium salts. While un-decalcified bone involves a long time for tissue processing until histological sectioning is possible, the decalcified samples can be rather quickly processed. The latter preparation is more often conducted in diagnostic/routine pathological laboratories, while the former of un-decalcifications are commonly used in research laboratories. Moreover, when biomaterials are involved in the bone tissue, most often the tissue is not decalcified since the interface between the bone tissue and the biomaterial is of great importance. Processing of un-decalcified cut and ground sections with biomaterials *in situ* are thus most often associated with research laboratories. However, there are times when the research project has a specific purpose for preparation of decalcified samples. If no biomaterial is present in the tissue and if it is urgent, it has been shown that decalcification can be successfully carried out using microwaves also for *in situ* hybridization studies.[26] The need to clarify the intended purpose of the sampling process is important and this should be kept in mind when designing the study.

3.313.3.2. Solutions/Chemicals for Decalcification of Bone Tissue

The fixed bone sample must be thoroughly rinsed in water before decalcification can start.

While various acids such as modified formic acid and acetic acid are effective, cheap, and rapid for decalcification purposes, the usage of milder solutions such as EDTA takes a longer time since calcium is removed by chelation and involves a higher

cost. However, the use of EDTA renders better quality of the histological features compared to other decalcifying solutions. In a study by Alers *et al.*[27] using EDTA, the antigenic sites, DNA, and mRNA were preserved compared to tissue dehydrated in an acidic decalcifying solution (RDO, Apex Engineering Products; Plainfield, IL, USA). Our own experience over the years, and recently on decalcified and paraffin sectioned rat bone, is that it works well for immunohistochemical analyses.[28]

Decalcifying solution EDTA with PVP applicable for enzyme- and immunohistochemical analyses

Chemicals

1. Ethylenediaminetetraacetic acid disodium salt dihydrate, EDTA
   $C_{10}H_{14}N_2Na_2O_8 \cdot 2H_2O$, MW 372.24
2. Tris(hydroxymethyl)aminomethane
   $C_4H_{11}NO_3$ M, MW 121.14
3. Potassium hydroxide, ≥85% KOH basis, pellets, MW 56.11
4. Polyvinylpyrrolidone, PVP, MW 24 000 g mol^{-1}

Method

1. Dissolve 12.11 g Tris in 800 ml distilled H_2O
2. Add 100 g EDTA
3. Adjust pH to 6.95 with KOH pellets
4. Add 75 g PVP

When completely dissolved, fill up to 1000 ml with distilled H_2O. The solution should be light-yellow.

Storage: Dark bottle in refrigerator. Durability: about 2 months. Decalcification time: several days to weeks. Posttreatment: H_2O.

3.313.3.3. Advantages and Disadvantages

Decalcification using acidic solutions destroys the structure of proteins to various degrees. Epitopes can be affected which are necessary for the immunohistological detection of certain proteins. However, the EDTA decalcifying solution can be used due to its preservation effect on the epitopes/proteins, although it is time-consuming (ref. compact vs. spongeous bone). In our laboratories, we use EDTA with addition of PVP (polyvinylpyrolidone). The PVP is added since it resists protein precipitation. However, the time to decalcify, for example, a slice of rat tibia bone (about 3 mm thick) takes around 3 weeks. This is the main disadvantage of using EDTA. The process is performed in the refrigerator, changing the solution every third day and using agitation. Paraffin sectioning of such samples and immunohistochemical detection of positively stained megakaryocytes in bone marrow, using Factor VIII (Biocare Medical, USA), were successfully demonstrated by Nyberg *et al.*[28] (**Figure 4**). The reasons for these results are probably due to a combination of a good fixative and a mild decalcifying solution. The retrieved material was immersed in 4% zinc-formaldehyde (Mallinckrodt Baker B.V., Holland). This fixative was used because of its ability to preserve enzyme activity. The disadvantages using acids are that the process must be interrupted immediately after the decalcification is ready in order not to damage the ability of a proper histological staining. The acids are prone to negatively affect the staining of nuclei and thus a poorer morphology can be expected compared to tissue decalcified in EDTA. The endpoint of fixation cannot be exactly determined beforehand. However, there are ways to investigate if a proper

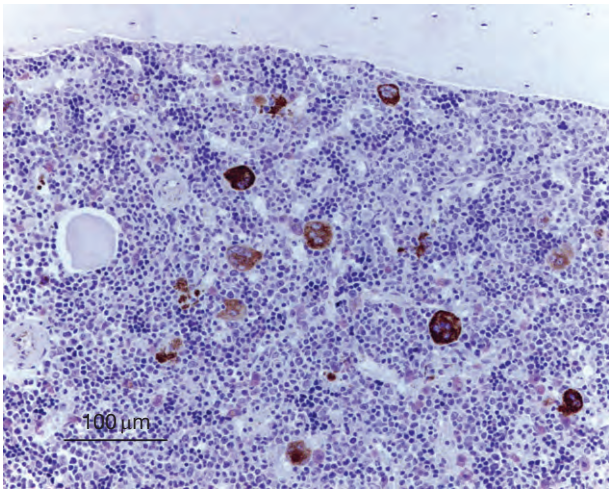

Figure 4 Paraffin section of a rat bone, initially fixed with Zn-formaldehyde solution and decalcified with EDTA (including PVP). Note the positively stained megakaryocytes in the bone marrow. Bar = 100 µm.

decalcification has been achieved, and one commonly used method is to perform X-ray tests. The existing calcium content will show up as brighter regions compared to decalcified areas being darker. In former days, the X-ray tests were a time-consuming method. Nowadays, with the state-of-the-art techniques available (ref. dental equipment), the time to perform such tests is rapid. Moreover, since the X-ray images can be stored in the computer at once, one would think that a standard recipe, guiding when the end-point should be expected, will be available. Another test, albeit rough and with persistent artifacts, is to apply the smallest needle available and pinch a part of the bone that is out of interest for later analyses. Yet another way is to include a 'test sample' with similar properties as the 'real sample' into the same decalcifying batch. This test sample can be manually tested by piercing, bending, and cutting and thus leave the real sample without man-made manual artifacts.

Most acidic decalcification protocols recommend direct posttreatment in ethanol, while EDTA samples can be rinsed in water prior to the commencement of the dehydration process.

3.313.3.4. Artifacts

Artifacts that appear due to the decalcification solutions used relate to poor morphology and destruction of intracellular components as well as impaired staining ability. With this in mind, one should balance between the fixative of choice, the speed, and the time of the decalcification in order to reduce the negative effects that appear in the morphology.

3.313.4. Embedding Techniques

Embedding tissue means that the materials will be surrounded by a supporting material that prevents the tissue from being destroyed when further processed to histological sections. The preferred embedding technique depends on the question of what is going to be observed. For light microscopic

observations, there is a greater variety of what materials and techniques one can use, while for electron microscopical purposes the choice is less and mostly resins (epoxy or acrylic) are used for the latter.

The most commonly used embedding material for diagnostic purposes on fixed, decalcified bone, dehydrated and infiltrated tissue samples without hard unsectionable biomaterials *in situ* is paraffin. However, for rapid diagnostic purposes, the tissue can be frozen and sections prepared using a cryostat, which is a cryosectioning equipment. Yet another technique, when undecalcified bone and biomaterials are involved, is to use various resins as a supporting material (see below).

3.313.4.1. Undecalcified Versus Decalcified

Bone tissue with biomaterials *in situ* requires preparation of undecalcified cut and ground sections. The state-of-the-art technique of undecalcified sectioning is referred to as the 'Donath technique.'[7,29] The advantage of this technique is that one can prepare sections from sample sizes of a few millimeter (e.g., cochlea wall implants) to THR (total hip replacements) from research animals and humans using the same equipment. The major drawback is that it is time-consuming and expensive. Moreover, a skillful technician is a must in order to obtain excellent results.

For diagnostic purposes, when the time for sample processing is urgent and when biomaterials interactions with bone tissue are not the major focus, decalcification of the bone tissue with subsequent processing to paraffin sections is the method of choice. The decalcification process itself can be speeded up with, for example, various decalcifying solutions and microwave processing.

3.313.4.2. Embedding Materials

3.313.4.2.1. Resin

A great variety of resin embedding materials exists. Commonly used ones are methyl methacrylate (MMA) and glycol methacrylate (GMA). The MMA is mostly used for undecalcified bone samples. The latter GMA can be mixed in water and thus the sample need not be fully dehydrated. However, once polymerized, it is not water soluble. Irrespective of resin used, all methacrylates must be regarded as hazardous to health.

The choice of resin is dependent on the aim of the study, and thus tissue processing and time vary substantially. For example, when processing bone with biomaterials *in situ* for subsequent processing to undecalcified sections add modum Donath, we recommend a 'hard' light-curing resin such as Technovit 7200 VLC (Heraeus Kulzer GmbH, Germany). This is due to the fact that softer resins cover the diamond/bore nitride/ layers on the sawing bands and by such clotting there will be a prolonged cutting time. The fact that the band itself is very expensive also motivates the laboratories to use harder resins for preparing cut and ground sections. Harder resins also render better quality sections, that is, more even sections without pronounced artifacts (see below).

In earlier times, we routinely used the hard grade LR White resin (polyhydroxy aromatic resin, London Resin Co. Ltd., Hampshire, England) for cut and ground-sectioning, but to our experience, this resin is 'softer' (even if using the 'hardest' one of the available ones). If the aim is to prepare various resolution levels, that is, light and electron microscopical investigations of the very same sample, both Technovit 7200 VLC and LR White are too 'hard' compared to 'ordinary SEM resins.' Technovit is more brittle compared to LR White and more problematic to section even by a very experienced electron microscopist.

For many years, there was no resin available for the purpose of preparing adequate enzyme and immunohistochemical investigations on undecalcified bone tissue (with biomaterials *in situ*). Research laboratory tests with 'in-house-made' resin on bone biopsies and bone with biomaterials *in situ* rendered excellent results of both enzyme- and immunohistochemical detection of proteins in bone tissue.[16,22,23] By trial and error, we learnt that the first and most important step in reaching such results were the fixative used (Johansson and Röser, unpublished data). Nowadays, this MMA resin, that hardens at low temperature in an oxygen free chamber and can be dissolved, is commercially available and referred to as Technovit 9100® NEW (Heraeus Kulzer GmbH, Germany). The Embedding Kit contains two components, which can be mixed in different portions, which enables the user to determine the hardness of the resin; meaning the same kit can be used for sectioning as well as cutting and grinding.

3.313.4.2.2. Paraffin

Sections for routine diagnostics purposes demand a quick processing time. For this purpose, one may need to divide the undecalcified bone into various samples where some must be treated with decalcification solutions and subsequent paraffin sectioning. If using appropriate fixatives, paraffin-sectioned decalcified bone can be investigated in terms of proteins present in the tissue.[28,30]

3.313.4.3. Tissue Tech, OCT Compounds (Optimal Cutting Temperature)

The frozen- or cryosectioning technique is never the method of choice if one need good or excellent histology. However, this technique is required for specific purposes, such as rapid diagnostics. In order to glue the prefixed thin biopsy and have it secure to the embedding-supporting plate, the Tissue-Tech compound is used. The media freezes and thaws rapidly. The tissue can be snap frozen in, for example, *iso*-pentane that is precooled in liquid nitrogen, followed by 'embedding' in Tissue Tech. For more information, we refer the readers interested in this method to the handbooks recommended in the last part of this chapter.

3.313.4.4. Artifacts

In general, all steps in tissue handling, from fixation, dehydration, infiltration as well as sectioning followed by staining and finally cover slipping are equally important irrespective of what embedding and sectioning techniques are used. Each and every step can cause artifacts. As mentioned earlier, related to fixation, both over-fixed and under-fixed tissue will render 'preservation artifacts' irrespective of morphological, cytological, and histochemical levels. Unexpected, uncommon, and unwanted artifacts arise even if the materials and

methods are routinely performed according to internal guidelines. We have experienced such artifacts appearing as severe thin crack-propagations even with brand new batches of Technovit 7200 VLC. These cracks were observed on the final sections only and not during processing. All ten bottles were tested but cracks appeared and thus the entire batch was discarded. These types of artifacts have not been noted since then. Other artifacts can occur such as large cracks and bubble formation irrespective of resin used. When such artifacts are present, the polymerization process may have been too rapidly performed or the tissue is not perfectly processed, that is, not fully dehydrated and or infiltrated.

Another type of unexpected artifact, that is, unwanted self-polymerization, occurred resulting in a large clump with several samples internalized, when using the LR White resin. Unfortunately, the reasons for these problems cannot be explained. However, such problems have so far not been noted when using the Technovit resins.

3.313.4.4.1. Artifacts related to paraffin

Inappropriate dehydration of the tissue (as well as clearing and/or infiltration of the paraffin) will result in difficulties to sectioning the paraffin block. There will be regions of 'air' in the paraffin block. Such artifacts can be minimized by slowly returning the sample to some previous steps carried out. However, if the sample is poorly handled during the primary tissue processing, no proper results will be achieved. Moreover, the melting temperature of paraffin is critical for keeping the protein structure intact.

3.313.4.4.2. Artifacts related to frozen sectioning

In general, the morphological details and the resolution of frozen sections are of less good quality compared to tissue which has been paraffin sectioned. In order to avoid freezing artifacts the sample must be frozen rapidly. Severe cracks in the tissue may be due to the fact that a too large sample is used. Moreover, the sample structure, with various components from soft and fat tissue to hard, challenges even the technician with the greatest stamina. The cryostat itself may also be a cause for artifacts of, for example, variations in section thickness.

3.313.5. Sectioning Techniques

The next step in sample processing after embedding is to prepare adequate sections for later staining procedures. In Section 3.313.4, some methods were mentioned that use various types of so called microtomes for sectioning decalcified samples. For routine diagnostic purposes, more technically advanced microtomes both for paraffin and resin embedded samples are available nowadays. The cryomicrotomes have not gone through major technical modifications, and thus such microtomes are still placed in a cooling box operated from outside. Sections from 5 to 10 μm thickness are most often prepared irrespective of microtome used.

If sectioning smaller undecalcified bone biopsy samples, our experience is that one needs a heavy-duty rotation microtome and an adequate knife (so called D-knife). The collection of sections in the latter case requires more attention, for example, related to stretching the section on the precoated supporting objective glass. Moreover, the section should be dried under pressure (preventing it from later loosening). The procedure is time-consuming but renders good quality sections that can be stained for diagnostic histology as well as enzyme and immunohistochemistry.

3.313.5.1. Ground Sections: Cutting and Grinding Technique Add Modum Donath

In order to study bone implant integration, that is, osseointegration, the biomaterial must not be removed from the tissue before sectioning since this will cause an interruption of the interfacial zone. The state-of-the-art technique for processing undecalcified samples to cut and ground sections with the implant *in situ* is referred to as the 'Donath technique.'[29] Among various cutting and grinding equipments on the market, we use the so called Exakt equipment which has been on the market for about 30 years (Exakt Apparatebau, Norderstedt, Germany). The entire machine-park consists of several units where the most used ones are: the sample polymerization unit (polymerization of the resin takes place in white- and UV light), modified band-saw with either diamond- or bore nitride-coated cutting bands, polymerization unit for sections and grinding machines where Si-coated wet grinding papers of various roughness can be mounted (with the possibility to predecide the material to be grinded off).

The cutting and grinding technique is rough and does not allow for serial sectioning and may be considered a drawback compared to other techniques. However, to the best of our knowledge, having 25 years of experience, there are no other techniques available related to cutting and grinding that can create thin (10 μm and less) sections of undecalcified bone with implants *in situ* in a reproducible manner. In brief, the technique involves all steps from retrieval of sample, preservation of the tissue with adequate fixation solution to the final section of an adequate thickness (depending on the biomaterial *in situ* this can be from some μm and up several micrometers) and histologically stained. The steps involved in our in-house routine methods and techniques related to undecalcified cut and ground sections with biomaterials *in situ* are illustrated in Figure 5.

3.313.5.2. Artifacts

According to our experience, the most common artifact that arises when preparing undecalcified sections relates to resin curing. To speed up the curing time may unfortunately result in several cracks in the resin and the greater the sample the more pronounced are the cracks if the curing time is too short. Yet another artifact arising is related to inappropriate infiltration. This is not always observed until the sample is divided, but in general, it helps out to go back and reinfiltrate the sample in resin during vacuum and stirring followed by reembedding.

By using harder resins and less weight when grinding, artifacts referred to as the water planning effect can be minimized. This will result in a more even section thickness compared to if a softer resin is being used. When the cut and ground section of an implant in bone reveals that the metal part is thicker

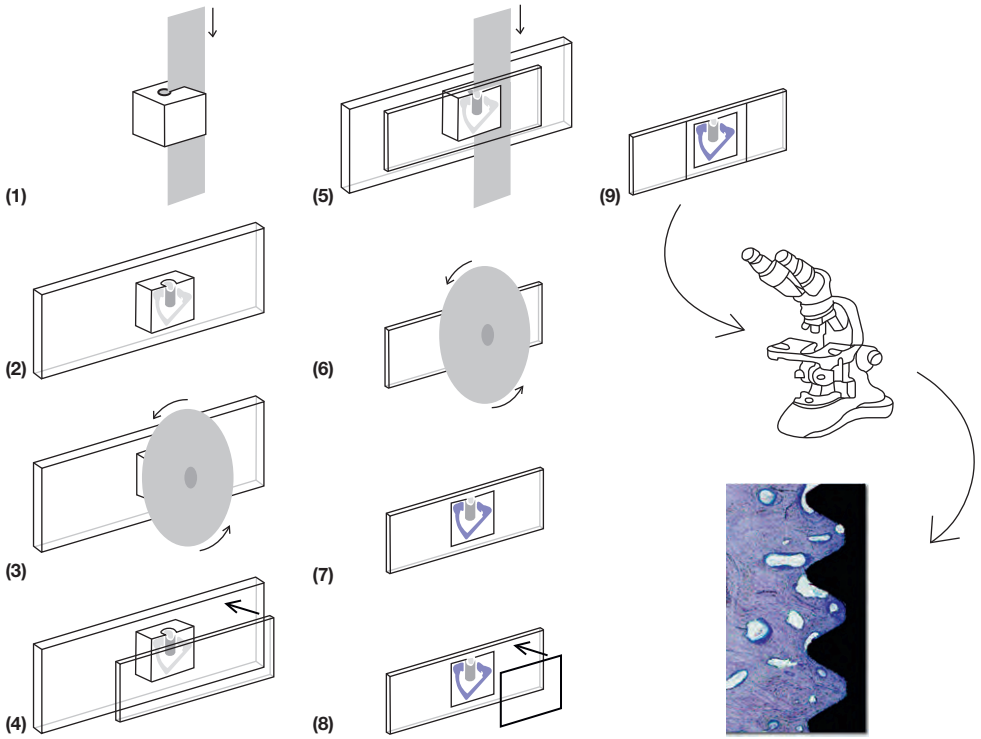

Figure 5 Schematic illustration of the cutting and grinding steps involved in preparing undecalcified cut and ground sections with implants *in situ*. The embedded sample is following the route below. (1) Divide the resin embedded sample in a band saw – resulting in two half's of the implant with surrounding tissue. (2) Attach/cement the backside of the sample(s) on a supporting plexis glass. (3) Grind the sample surface in a water-cooled grinding machine. (4) Clean the surface, measure the thickness of 'the block' (i.e., the sample including the supporting glass) and glue an object glass (of known thickness), onto the sample surface. Calculate the glue thickness since this varies depending on sample size and glue; measure the entire thickness of the 'sandwich' (= calculate the thickness of the glue: since you know the thickness of the object glass and the entire block before gluing, the glue can be calculated. This is important to know during the final grinding procedure). (5) Cut a section (~150–200 μm thick) in the band saw. (6) Grind the section in the water-cooled grinding machine to a desired thickness (start with rough and go to finer grinding papers, be careful and do not use too much weight during grinding; during grinding, control the thickness both by measurements and in the light microscope) a section thickness of 10–15 μm is routinely performed. (7) Clean the surface and stain the section followed by rinsing the section and let it dry. (8) Coverslip the sections (using mounting media of choice). (9) Qualitative inspection in the light microscope followed by histomorphometry, that is, quantification of, for example, BIC, BA, and MI around the implant. © Lotta Persson.

than the bone, this may also be due to the water planning effect. If the biomaterial is harder than, for example, commercially pure titanium, we advise to start the grinding procedure using a rough paper or even start on the diamond plate. Worn out and soft grinding papers negatively affect the preparation of plan parallel section and result in water planning effect especially if a too high weight is applied during grinding. It is a compromise between plan parallel section and scratches in such cases. The latter will most likely diminish when the stained section is coverslipped and thus later analyses will not be affected.

The very first grinding step, that is, to prepare the surface for the first section, is crucial as well. If too much grinding and too heavy weight is applied, with too smooth papers, already here the water planning effect will be introduced and later result in more problems of unevenly thick sections. These artifacts will be depicted as 'shadow effects' in the interface region when observed in the microscope.

As with all machinery in a laboratory, careful maintenance of the machine park should be a daily routine. The most commonly observed cutting artifacts on sections that relates to the band-saw is an uneven section (thick at one end and thinner at the other). There are various reasons for this and to mention but a few:

1. the cutting band is not adjusted parallel to the vacuum plate holding the sample in place,
2. the supporting vacuum-plate is not properly adjusted, that is, nonparallel to the cutting band,
3. the cutting band is clotted,
4. the ball bearings are worn out resulting in movement of the band,
5. the rubber bands on the wheels, holding the cutting band in place, are dirty and thus the bands are not hold in place during cutting,
6. too much force is applied, that is, too much weight is used during the cutting process. This can also create 'burning artifacts' and such artifacts are devastating for the tissue if the cooling water is not functioning.

Of course, there are other reasons and artifacts involved in the cutting and grinding procedure, but in general, proper maintenance of the machine-park is the first step in achieving successful results.

3.313.5.3. Microdissection

This technique involves a laser that is used for cutting out regions of interest as well as cells in a section during light microscopic observations. Applying the microdissection technique is ongoing technique especially in the tumor research field, and genetic screening of tissue from the tumor invasion front with laser microdissection was successfully performed using DNA sequencing.[31] The use of the technique as a potential and future tool for routine diagnostic purposes is not fully known but most likely it will become a state-of-the-art technique in pathology laboratories. The laser microdissection technique may be a promising tool in our research field of interest, that is, bone–biomaterials, since it is possible to collect samples from cut and ground sections in close vicinity to metal implants. Trials are ongoing and extrapolating artifacts, that is, the influence of the chemical fixatives and the used resins is a challenge.

The readers interested in the technique are referred to www.zeiss.de/microdissection

3.313.6. Staining Methods

Both qualitative and quantitative tissue reactions around biomaterials, irrespective of whether it is for diagnostic or for research purposes, rely on the primary observation of histologically stained tissue.

The basic approach in histological diagnostic is an automatic staining processing of tissue sections mounted on glass slides. However, routine-staining procedures in research laboratories is still dependent on the technician's often man-made staining by following a recipe and subsequent hand-made staining of the sections.

3.313.6.1. Staining for Histological Observations

Routine staining methods, especially for bone tissue, involve various connective tissue staining protocols. It is out of the scope to include staining recipe here since almost all handbooks mentioned in part 8 contain excellent recipes. Our experience with staining bone tissue on undecalcified cut and ground sections is that one needs routine staining methods that differentiate between various bone quality components and preferably render no overstained cellular components. The in-house routine staining that we use frequently is toluidine blue mixed with pyronin G. The bone tissue is stained in various degrees of purple (old bone pale purple compared to young bone dark purple). The toluidine blue itself stains most tissue blue, but it also demonstrates certain components such as mast cell granules being purple. This phenomenon is referred to as metachromasia. Moreover, the cellular details are well distinguished.

Irrespective of the staining used, the results should precisely demonstrate specific components. These components can sometimes be enhanced by adding a counter stain. Counterstaining the tissue means applying a contrasting color. For example, when using the bulk staining method that stains the microcracks in bone red[32] or the enzyme-histochemical method to capture ALP (blue) and ACP (red), it is common to use light green as a counter stain since this staining renders qualitative (and quantitative) discrimination between the specific parts of interest.

Counterstaining must be of a contrasting color, and it should not be too intense so that it masks the specific staining.

Special stains are important tools and the usage of such specific stains is of key importance in detecting various pathogens. From observations on the light microscopy level, one can continue with immunohistochemical protein stains as well as other technical methods not possible just a few years ago.

Molecular techniques are becoming diagnostic tools and applying such techniques enables us to identify specific genes involved in various diseases. Moreover, since the biomaterials research field focuses intensely on the implant surface morphology and the nanolevel, we foresee a combination of methods that depict the tissue reaction to medical devices in magnifications which is not possible until now.

3.313.6.2. Immunohistochemistry

Immunohistochemistry (IHC) is used to detect target antigens in the histological sections using specific antibodies. Since the following chapter is about IHC, discussing the methodology and further details will be beyond the scope of this chapter. Hence, in this section, we focus more on 'what can be done' and 'what has been done' with IHC on bone tissue samples.

It is uncommon to use IHC on cut and ground sections since IHC is rather difficult to perform on such sections. The reason for this may be the type of fixatives, type of resin used for embedding, the thickness of the sections, or it could be that the antibody we want to use is just not suited for resin cut and ground sections. However, in our laboratories, we have ongoing research to improve the immunoreactivity in the cut and ground sections.[17] The improvement will definitely provide additional information that will be useful for the evaluation of biomaterials in bone tissue. The IHC technique will clarify the localization or the intensity of the antigens. However, it is extremely important to understand the limits. IHC is not intended to determine or quantify gene expression. For readers interested in this field, we recommend *in situ* hybridization, which will be described in the next section or polymerase chain reaction using total RNA extracted from paraffin sections, the protocol of which can be easily found elsewhere.

The ability to remove the resin is an essential step in applying immunohistochemical methods on bone tissue successfully. Therefore, it is only possible on paraffin sections after decalcification of the bone with all the disadvantages mentioned above or on methylmethacrylate (Technovit 9100 New) thin or ground sections.

After removing the resin, all routine immunohistochemical methods can be carried out. All commercially available antibodies recommended to be suitable for paraffin-embedded and formalin-fixed tissue samples can be used.[16] Here, we describe a modified method taking into account that new products are on the marked with advantages regarding sensitivity and time.

Nonbiotin-HRP/DAB immunohistochemistry

1. after removing the resin, the sections were rehydrated in a descending series of ethanol till distilled water
2. rinse slides in washing buffer
3. antigen-demasking by using citrate buffer (pH 6.0) or EDTA buffer (pH 9.0) (AB dependent)

4. incubate sections for 30 min at 98 ± 2 °C
5. after cooling down rinse slides in washing buffer
6. blocking of endogenous peroxidase by incubating sides for 20 min in 1% H_2O_2
7. rinse slides in washing buffer (two times)
8. inhibition of unspecific binding by using a Powerblock-Solution (BioGenex HK085-5K): incubate for 10 min
9. Primary-AB: incubate for 30 min at RT in humidified atmosphere
10. rinse slides in washing buffer (three times)
11. Enhancer*: incubate for 20 min at RT
12. rinse slides in washing buffer (three times)
13. Polymer*: incubate for 30 min at RT
14. rinse slides in washing buffer (three times)
15. Chromogen (DAB)*: cover for max. 5 min (visual check)
16. Counter staining: hematoxylin solution for about 10 s
17. dehydration and mounting of sections

*BioGenex SuperSensitive NonBiotin-HRP/DAB; QD430-XAK.

3.313.6.3. *In Situ* Hybridization

The *in situ* hybridization (ISH) technique enables us to investigate the distribution or expression of specific DNA or RNA sequences.[33] For example, during the course of osteogenesis, the involved cells, for example, mesenchymal stem cells, pre-osteoblasts, osteoblasts, or osteocytes produce bone related proteins at appropriate time points. Figure 6 shows a paraffin section of a sectionable test implant placed in the mouse femur, *in situ* hybridized with an osteocalcin cRNA probe. It shows the distribution of responsible fibroblastic cells in the vicinity of the implant surface. With ISH, we can detect which cell is responsible for specific protein production. This is the major difference compared to IHC because IHC only allows us to detect the localization of proteins and we do not know for sure which cells are responsible for its production. For interested readers, the above reference is recommended.

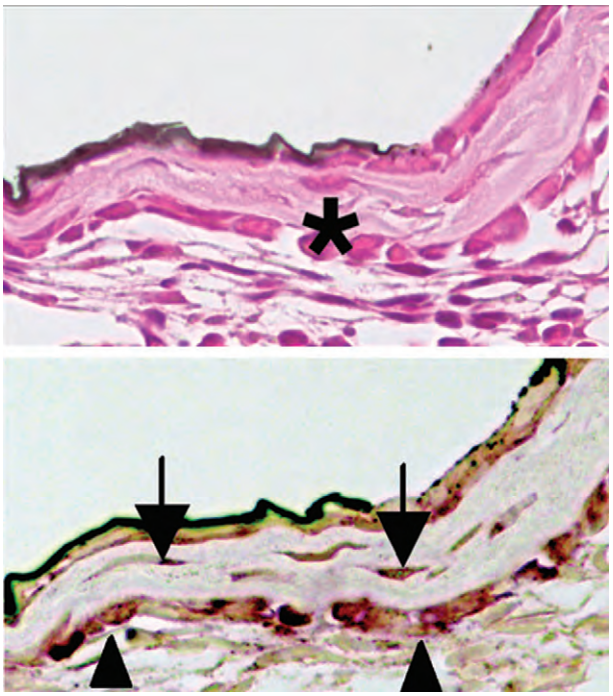

Figure 6 *In situ* hybridization using osteocalcin probe. Asterisk in the HE section indicates fibroblastic cells. Corresponding hybridized section shows that the fibroblastic cells are expressing osteocalcin mRNA. Magnification: ×40. Reproduced from Jimbo, R.; Sawase, T.; Shibata, Y.; *et al*. *Biomaterials* **2007**, *28*, 3469–3477, with permission from Elsevier.

Unfortunately, for cut and ground sections, this technique is inapplicable, due to resin embedding and contamination from cut and grinding procedures. However, we introduce this technique to the readers because when applicable to samples regarding bone and biomaterials, this technique is extremely useful and will provide us more information.

After removing the resin, all kinds of ISH techniques can be conducted on bone tissue. We used RNA ISH using Dig-labeled probes to collagen type I, II, and III as described by Plenz *et al.*[34]

Nonradioactive RNA ISH

1. Air-dried deparaffinized or deacrylated sections
2. Pretreatment with proteinase K
3. Postfixation in an ice-cold 4% paraformaldehyde solution
4. Washing in PBS
5. Acetylation: 0.1M TEA buffer (pH 8.0) + 0.25% acetic anhydride
6. Prehybridization
7. Hybridization: hybridization mix containing the dig-labeled RNA-probe; incubate over night at 42 °C in an humidified atmosphere
8. Posthybridization by washing sections in a descending series of SSC (2× SSC, 1× SSC, 0.1× SSC)
9. Detection by using antibodies targeted to dig
10. Counterstaining
11. Mounting.

3.313.7. Quantification Methods

Both quantitative and qualitative evaluation of tissue reactions around implants are of utmost importance in bone biomaterials research. Each laboratory has its own in-house standard related to histomorphometrical analysis and no 'out-house' consensus exists regarding what or how to perform such biomaterial-related analyses. The methods of sample preparation rendering high quality nondecalcified cut and ground sections with biomaterials *in situ* also vary between different laboratories although it is referred to the 'Donath technique.' Sample preparation is time-consuming and expensive and requires specially trained and experienced technicians for achieving high-quality sections. While some laboratories work with thick sections (100 µm and more), our laboratory routine is to prepare cut and ground sections of a thickness of 10–15 µm (and even thinner if the aim is related to enzyme- and immunohistochemical analyses). Such appropriately stained sections render good quality and visualization of specific cells and tissue components and thus reliable histomorphometrical interfacial analyses of, for example, bone implant contact (BIC) can be performed. We have shown that the thicker the section the greater is the overestimation of the

BIC, that is, the osseointegration. Sections of 10 and 30 μm compared to 100 μm resulted in 30% overestimations compared to sections of 10 and 30 μm only (no overestimations in the latter case). Two independent persons performed the histomorphometrical analyses, and there were no significant differences between the investigators.[8] Another study has shown the importance of sectioning directions and from those results it is obvious that all samples in a research study must be sectioned in the same anatomical manner in order not to compare 'apples to pears.'[35]

3.313.7.1. Level of Quantification

The level of quantification needs to be determined beforehand and the very same magnification must be used for the entire material involved in a study. As a rule of thumb and in order to 'get to know' your material, we always perform high magnification qualitative inspections in the light microscope before the commencement of the measurements. Moreover, the same person should perform the histomorphometrical analyses. If the person is a trainee, it is mandatory that a skilled person perform measurements on the very same material as well and that the results are discussed in order to set the baseline. For students, working on their diploma, it is mandatory that our in-house routine histomorphometry and image analyses tests are performed under the guidance of skilled persons. Naturally, questions arise and if there is lack of clarity related to the material, a consensus is called on.

3.313.7.2. What and How to Quantify?

Histomorphometrical analysis involves various bone quality aspects that can be quantified. Irrespective of what or how to quantify, it is time-consuming. Bone remodeling around implants involves both contact measurements as well as area measurements. The former is related to BIC and the latter is related to bone area (BA) both inside and outside (mirror image, MI) the inner threads. The latter quantification method may, for example, depict bone remodeling differences if ratios between inner and outer regions (threads) are compared.[36] Figure 7 illustrates the in-house routine quantitative measurement performed in the light microscope. Routine animal research experiments often involve one follow-up time, and to distinguish between the parameters to be measured, good quality histological staining reactions are of the utmost importance. Heavily stained sections are sometimes needed for illustration purposes but often these sections are overstained and thus cellular reactions cannot be depicted due to such artifacts and this results in difficulties to perform accurate interpretation of the tissue components. Accurate histomorphometry requires not only high-quality sections but also trained personnel with histological knowledge. The latter is important since artifacts arising from sample preparation must be interpreted correctly and thus does not result in false qualitative or quantitative data.

Investigations of bone remodeling around implants retrieved from patients for various reasons are ongoing in

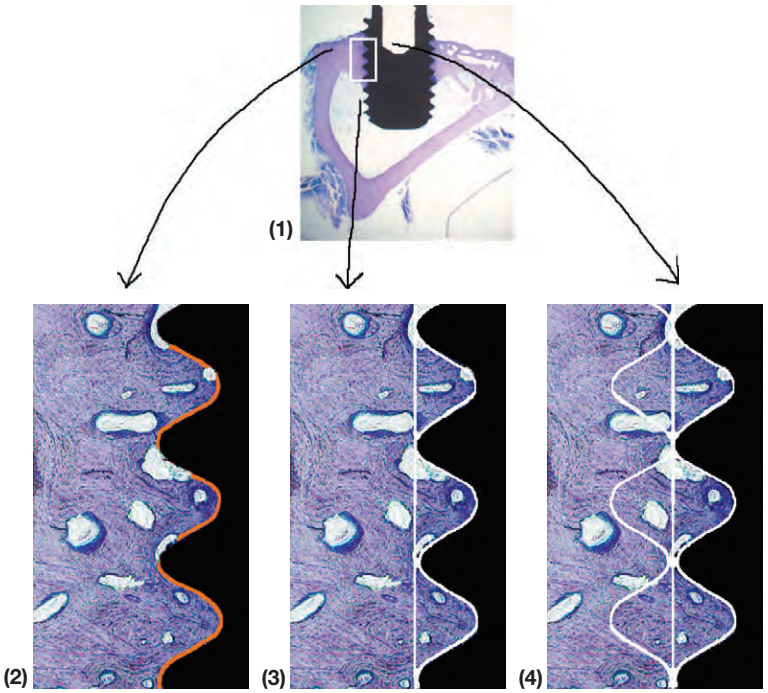

Figure 7 This is an illustration of the in-house routine quantitative measurement performed in the light microscope. The top survey picture (1) is an undecalcified cut and ground sample with an implant *in situ* stained in toluidien blue mixed with pyronin G. The enlarged sample in (2) illustrates the BIC (bone implant contact) measurement in the three best consecutive threads. (3) demonstrates the BA (bone area) measurement in the inner threads while the outlined areas in (4) demonstrate the MI (mirror image area) measurements, that is, the inner area region is mirrored out. The BA and MI measurements involve comparisons of the relationship between inner:outer area. All true measurements are performed with one thread enlarged.

several studies in-house. To mention one such study where implants of the very same design were retrieved after being (i) nonloaded and compared to (ii) various times loading (from 1 year to more than 5 years), some interesting and different remodeling activities were observed along the threads.[37] The unloaded implants had the greatest BIC below the thread peak and this percentage increased with time of loading. The bone contact in the thread peak region (often referred to as the stress shielding area) showed the greatest BIC when loaded between 2.5 and 5 years and thereafter decreased, that is, the bone resorption was most pronounced in this region up to a period of 5 years of loading. The bottom region of the thread demonstrated the lowest BIC to start with (unloaded implants) but increased with time of loading. Similar observation was made on the flat surface above the thread peak, and this region showed the highest BIC percentage after a loading time of more than 5 years (Figure 8).

Another paper related to bone remodeling activity around implants placed in the tibia of rabbits, and evaluations performed on cut and ground sections with the implants *in situ* were performed by Sul *et al.*[38] The quantitative BIC and new formed BA were greater around porous anodized implants compared to nonporous controls. The enzyme-histochemical observations focused on the activity of ALP and ACP in the interface region (both enzymes being present) as well as in the new formed bone (mostly ALP) periosteally and endosteally on the sections. Based on the overall observations, the remodeling activity was greater in the endosteal region compared to the periosteal and in general there was a greater ALP activity compared to the ACP.

3.313.7.3. Methods and Equipment/Software

Histomorphometry of bone tissue around biomaterials shows great variations both related to the methods and the equipment/software used. While some softwares are more 'general,' that is, the user must program the application needed (often a time-consuming and complex task), others are more 'application-specific,' where no programming is needed but the usability is limited.

Within the same laboratory, various equipments are used. The usage and preference of equipments depends on the question: what and how to quantify? It is our opinion, after several years of histomorphometrical analyses as well as tests and trials of various equipments, that there is no fully automatic equipment that can be used. Artifacts will render higher

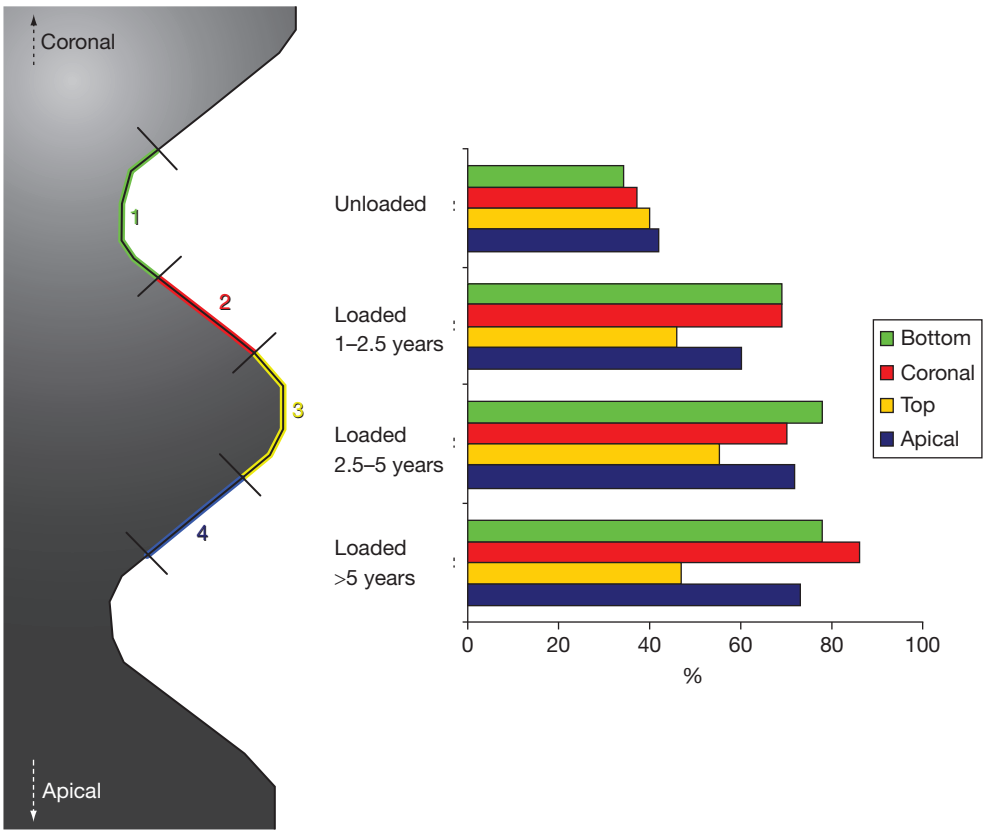

Figure 8 This is an illustration of bone remodeling data. The results obtained from cut and ground sections of retrieved human oral implants ($n = 40$) being unloaded and loaded between 1 and 2.5 years, 2.5 and 5 years and loaded more than 5 years. Histomorphometrical calculations involved of bone implant contact (BIC) in various regions along the implant thread surface. The region facing the coronal portion (1), the flat surface below (2), the thread peak (3) often referred to as the stress shielding area, and (4) is the flat portion below the thread peak. The nonloaded implants had greatest BIC in region 4. After more than 5 years of loading, the greatest BIC values were observed in region 2. Irrespective of unloaded or various loading times, the stress shielding region (3) always demonstrated the lowest BIC value.

or lower estimations automatically compared to the naked eye of experienced investigators that can differentiate between the tissue structures and components in a way that no computer as of now can. This topic of comparisons between manual and automatic methods of bone tissue remodeling around implants is ongoing within our network. Comparable and similar data of BA (bone area) and MI (mirror image area) were obtained irrespective of manual or automatic method.[39,40] However, the BIC values showed significant differences and the automatic programs rendered higher BIC percentages compared to the manual measurements performed directly in the eyepiece of the microscope oculars using the Microvid Image Analysis program (Leitz, Germany). This latter state-of-the-art quantifying method is very time-consuming, and thus within our network, we are presently working on a more user friendly and semiautomatic image analysis application. It allows the user to easily correct falsely estimated results of the analysis. Such research tools will not only speed up the histomorphometrical process but also render more time for the more complex tasks, that is, the qualitative biological responses related to osseointegration of biomaterials.

3.313.7.4. Reference Sections and Reference Quantifier: In-house Standard Rules

To the best of our knowledge, no commercially available reference section exists for histomorphometrical tests related to bone–biomaterial research. However, in the laboratories, we have utilized a variety of sections for internal comparisons both interindividual and intraindividual throughout the years. Needless to say but having good quality sections and being aware of how to interpret, for example, artifacts arising from shrinkage the histomorphometry are easy albeit time-consuming. A recently performed in-house study, comparing data obtained by three persons (with different experience in histomorphometry), from sections of various quality (i.e., artifactual staining errors as well as sections being 'perfect'), rendered similar and nonsignificant differences between the evaluators.[41]

There may be 'extreme cases' when the evaluator has difficulties to interpret the tissue reaction to the material. Such problems have occurred when evaluating bone tissue around hydroxyapatite-coated implants.[42] In such cases, we refer to 'unidentified areas' and in the latter case about 10% of such areas were presented. These regions were analyzed with a higher magnification tool (EDX) showing Ca, S, and P ions in the unidentified region, but if it was 'bone to be' or 'not to be' remained unclear.

To the best of our knowledge, artifacts or problems related to quantifications are neglected. It is an issue that is not discussed and elaborated on. Theoretically, it can be that such unidentified areas are of great importance both for the tissue tolerance to the material and for the material itself. This issue needs greater attention.

3.313.7.5. X-rays

In our laboratories ordinary X-ray images are seldom used for quantification purposes due to the poor resolution level but X-ray images are perfect for localization of buried implants. Microradiography, on the other hand, of rather thick (80 μm) cut and ground sections with implants *in situ* may sometimes be of interest and, for example, if various gray levels need to be quantified, these glass plates can be sufficient. If good quality microradiographs are prepared, it is also possible to perform automatic image analysis of bone tissue areas.[43,44] Irrespective of ordinary X-ray or microradiography and compared to histological sections, they all render 2D images.

3.313.7.6. Microcomputed Tomography and Synchrotron Radiation-Based μCT

High-resolution volume imaging techniques, that is, the 3D techniques available in bone biomaterials research are related to microcomputed tomography (μCT) and synchrotron radiation-based microcomputed tomography (SRμCT).[45,46] While the former technique is one that several laboratories have implemented as an in-house technique, the latter is not. The former 'standard' μCT device often renders physics-based artifacts such as a bright aura surrounding the implant in bone which prevents a reliable discrimination of the interface region.[47] The latter technique requires access to synchrotron facilities that exists in various countries worldwide. Beam line time is limited and the scans are time-consuming so that routine experiments cannot be performed using such facilities. We have recently performed SRμCT experiments using the facilities at the Institute for Materials Research, GKSS Research Centre Geesthacht, Germany (www.desy.de). Our studies so far reveal that the SRμCT technique provides satisfactory results of the interface region. The resolution is improved compared to the μCT device due to the parallel beam and the small beam size (**Figure 9**). The aura still exists but is limited and can be removed by image analysis methods.[48] Furthermore, the higher resolutions enable a more extensive quantitative 3D analysis which is an ongoing challenge.

3.313.7.7. Histological Versus Biomechanical Quantification

In vivo bone biomaterial integration can be performed with various biomechanical tests. The nondestructive resonance frequency analyses (RFA) test is performed clinically and relates to the 'implant stability as a function of the stiffness.' The test is referred to as 'a bending test of the implant bone complex where a transducer applies an extremely small bending force'.[49]

However, RFA tests performed in research animals is not a simple task and the readers interested in more details related to this are referred to the papers by Sennerby *et al.*[50] and Sul *et al.*[51] In the latter study, RFA measurements were performed on six groups of implants, with various topographies and surface chemical properties, at the time of installation in rabbit bone and 6 weeks later. Significant differences were observed for measurements performed both in the longitudinal and perpendicular manner of the bone comparing baseline to 6 weeks.

Destructive biomechanical tests of implant integration in research animals is performed with a variety of equipment, ranging from manual hand-hold Tonichi devices[36] to commercially available and larger apparatus such as the Instron equipment.[52–54] For the readers interested in more

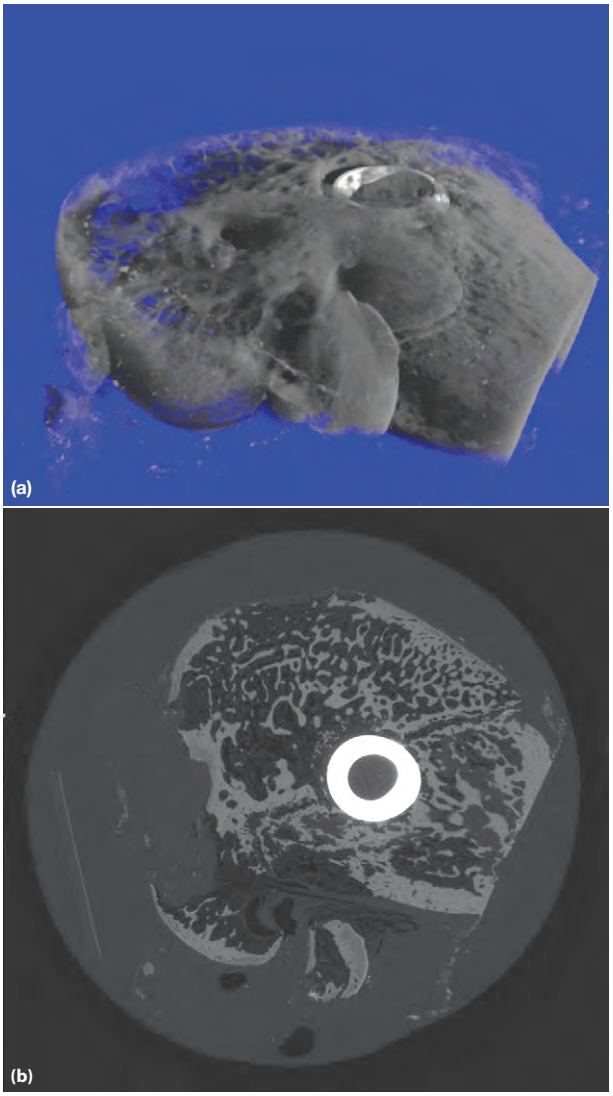

Figure 9 (a) Rendering of an SRμCT image volume demonstrating an irradiated bone sample with an implant inserted in the femur region of a rat. (b) Transverse cut from the same sample showing the destroyed femur condyle region in 2D. Implant diameter 2.2 mm.

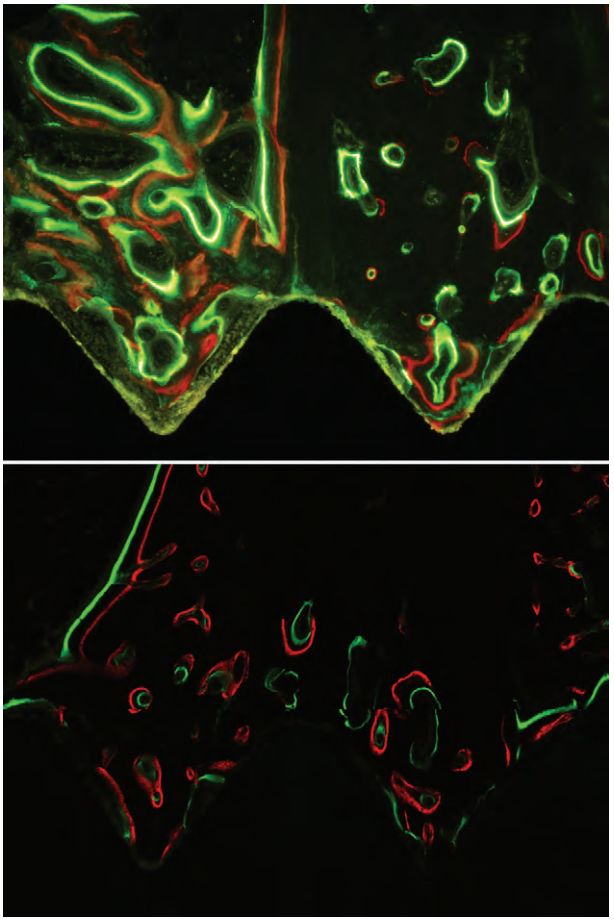

Figure 10 Fluorescent microscopic images prepared with a conventional microscope (top) and confocal laser scanning microscope (bottom), of implant interfaces with two different fluorochromes (green: calcein green; red: alizarin complexon). Note the blurry and saturated image obtained by the conventional microscope and sharp images obtained by confocal laser scanning microscope. The *in vivo* labeling regime and the preparation of samples were the same; however, there are qualitative differences. Both sections are about 50 μm thick.

information related to biomechanical tests of implant integration, we refer to **Chapter 3.316, Immunohistochemistry**.

Bone implant contact data are most often achieved from one central section only. Our in-house comparisons of 2D BIC data to 3D biomechanical data often points to the same direction, that is, if the former is high so is the latter.[55] However, both types of results are important for determining the osseointegration of a biomaterial. The ideal situation would be to combine such data. For research animal purposes, we conduct destructive biomechanical tests of screw-shaped implant integration by removal torque tests (RTQ) using an electronic device which is our in-house standard technique since several years (Detektor AB, Göteborg, Sweden). The results of such 3D measurements are given in N cm and in order to convert the data to shear strength values (N mm^{-2}) we prepare cut and ground sections of the loosened implant which is left *in situ* in the bone bed.[56] This method of conversion of the 3D removal torque data to shear strength values by measuring bone lengths on the 2D cut and ground sections was first presented and elaborated on in the paper by DeRezende and Johansson.[57] Moreover, when testing implants of various morphologies and materials *in vivo* several studies have shown an agreement between removal torque and shear strength values, although the former is a 3D measurement compared to the 2D length measurements involved in the conversion to shear strengths.[58–61] Recently, we have demonstrated a good reproducibility also when it comes to tests of new biomechanical devices on implants molded in materials with different hardness.[62] Moreover, if biomaterials with different diameters are tested, it is of the utmost importance not only to show the RTQ values in N cm but also to supply information of the N mm^{-2} data.[63] As mentioned earlier, it is a challenge to combine various quantitative and qualitative analysis techniques and to do so a titanium device was developed

by Sul *et al.*[67] that can be used for *in vivo* measurements of biomechanical and histomorphometrical tests as well as qualitative histological analysis. This device combines pull away tests measuring the bone bonding force between a disk shaped implant and bone tissue on one hand and removal torque/shear strength measurements on the other hand on the screws that are attached in bone and holds the device in place. Such a device is of great value for the investigation of biochemical bonds involved in osseointegration.

3.313.7.8. Combination of Techniques for Quantification of Bone Remodeling

3.313.7.8.1. Confocal laser scanning microscope

The confocal laser scanning microscope (CLSM) is a microscope which focuses only on a single focal plane, and the unfocused plane will not be visualized. In the past, the traditional laser microscope excited the whole thickness of the sample, resulting in saturated, blurry images and sometimes visualizing false colocalization images. Since the CLSM excites a single focal plane, this technique is suitable for quantification and visualizing 'true' images. **Figure 10** is an image of fluorochrome-labeled bone tissue around the implant obtained from a conventional fluorescent microscope[64] and from CLSM. The section thickness is similar, although it is obvious that the CLSM image is less blurry and less saturated. Another interesting feature of this microscope is that it can reconstruct 3D images by building up multiple single focal planes. The obtained data can be analyzed simultaneously using appropriate software and most of the times can be exported as an Excel file. **Figure 11** demonstrates data from trials of combining the biomechanical data with the fluorescence data, which is ongoing and such combinations seem promising. One factor to keep in mind is that the CLSM can change the intensity of the image. The advantage of this feature is that the microscope can pick up the weakest signals expressed in the sections. However, on the other hand, misuse of this feature may lead to the collection of false data. It is extremely important to set a standard for the intensity level before starting the measurements.

3.313.7.8.2. Gene expression

Gene expression analyses are approaching the biomaterial research field. Initial reports revealed the possibility to study functional attachment and the biological mechanisms related to the biomechanics data by combining information gathered from gene expression results of proteins related to bone remodeling in retrieved tissue.[65] Other gene expression studies where both the implant and the tissue surrounding the implant have been investigated reveal interesting data that will add important knowledge to the field of osseointegration not possible before.[66] Yet another recently performed study involved removal of torque data coupled to the amount of various bone formation and bone resorption as well as inflammatory genes both on the retrieved implant and in the surrounding tissue.[41] In a study comparing machined (control) and sand blasted (test) implants placed in mice femur, we found remarkable differences in bone formation histologically, and the corresponding results from northern blot analysis showed significantly higher expression of osteocalcin mRNA for the test group (**Figure 12**) (unpublished data). This field of research is now attracting more attention and is expected to advance further. Yet again, to be able to conduct as many tests as possible on the very same sample, a careful study design needs to be outlined before the commencement of the study.

3.313.8. Summary and Future Directions

Tissue preservation methods and subsequent techniques used leading to histological sections have not changed dramatically over the last decade. In fact, some techniques described in this

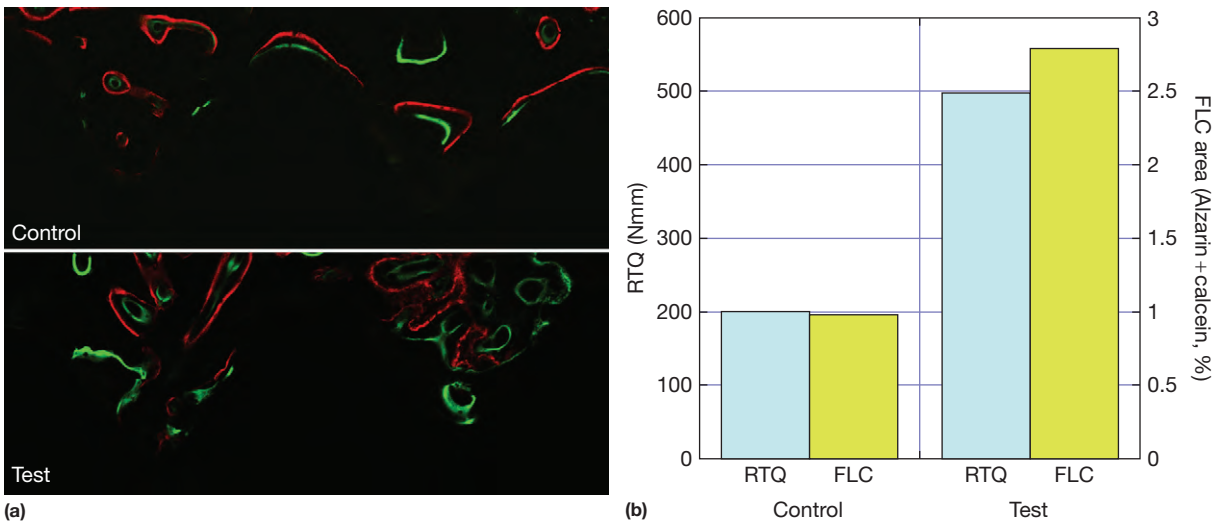

Figure 11 (a) Ongoing study comparing biomechanics (removal torque values) to the fluorochrome positive areas (images prepared with confocal laser scanning microscope). (b) Graph shows a correlation between the two parameters and clear differences between test and control group were seen for both parameters. The corresponding image shows more fluorochrome labeling for the test group compared to the control group.

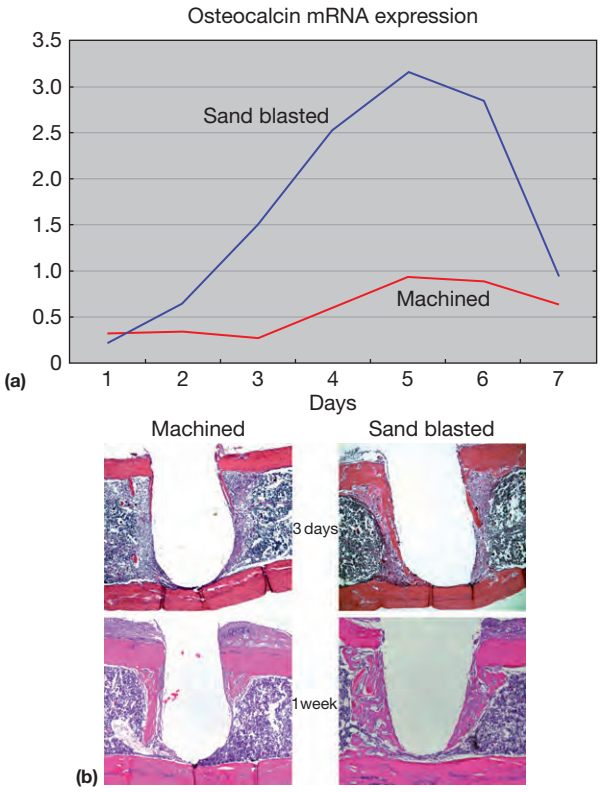

Figure 12 (a) Northern blot analysis of machined and sand-blasted implants placed in the mouse femur. The osteocalcin mRNA expression was followed from day 1 to day 7. (b) Corresponding HE (hematoxylin–eosin)-stained paraffin section at day 3 and 1 week (day 7) for both groups. The implant diameter is in millimeters.

chapter are still considered state of the art. Unfortunately, much research material is wasted not only due to inadequate knowledge and handling of the material outside the histological laboratories but also because of a poor study design. The biomaterials research field involves various, equally important, disciplines. Sophisticated manipulation of medical devices and especially nowadays focusing on the implant morphology (all surface-related aspects) may not always be observed in the subsequent and most important step, that is, tissue reactions to the materials. The reasons for this are complex but in general the first and most important step must be decided: What level is of importance for the study and what is to be used to target this level? If several levels are of equal importance one must prepare a detailed plan. The questions as to how to perform these analyses require various individual competences. The steps from ordinary light microscopical analyses to gene and chromosome levels challenge all disciplines in the biomaterials field. We foresee that a combination of several novel analysis tools should be included in the very same study to be conducted. By the end of the day, when it comes to the very important task, the histological analysis of tissue reactions to the medical devices, that is, the qualitative and quantitative analyses – these methods needs to be upgraded.

Histomorphometrical analyses are important but one should not underestimate the qualitative observations. The latter needs greater attention and demands more focus, especially nowadays when mimicking the medical devices tends to focus on the nanolevel. Here, we foresee involvement of even more various disciplines in every study. Nothing is impossible – as long as you have a good formulated question – methods can be modified accordingly.

MSCs	Mesenchymal stem cells
NVOC	Nonvolatile organic compounds
PC	Polycaprolactone
PCR	Polymerase chain reaction
PDMS	Polydimethylsiloxane
PEG	Polyethylene glycol
PLLA	Poly-L-lactic acid
PMMA	Polymethymethacrylate
PNIPAAm	Poly(*N*-isopropylacrylamide)
PS	Polystyrene
RBCs	Red blood cells
REDV	Arginine–glutamine–aspartic acid–valine
RGD	Arginine–glycine–aspartic acid
RGDS	Arginine–glycine–aspartic acid–serine
RT-PCR	Reverse transcription polymerase chain reaction
SAM	Self-assembled monolayer
SERS	Surface-enhanced Raman scattering
SLA	Titanium implant surfaces modified by sandblasting and acid-etching
VAPG	Valine–alanine–proline–glycine

3.314.1. Introduction

Surface modifications of materials have been used to control and measure cell function for several decades. An example is the possibility to control the tissue integration of medical prostheses by changing their material composition, surface chemistry, surface energy, or surface topography. Similarly, the control of material surface is also a key determinant in the efficiency of diagnostic tools, cell culture disposables, biosensors, or drug delivery systems. Cells and bacteria have been

shown to posses the ability to discriminate and react specifically to surface chemistry and surface topography at the micro and nanoscales.[1–7]

In recent years, the biological and biomedical applications of micro and nanotechnology have become increasingly prevalent because these techniques allow the production of surfaces with precise features and high aspect ratios.[8] With the advent of these techniques, it is now possible to develop devices with features on a scale relevant to cells and bacteria. These devices can be made reproducibly in large quantities. They can have a small size, and they facilitate incorporation of integrated circuit technology for biological micro-electromechanical systems (BioMEMs).[9] Moreover, the use of microfluidic perfusion in these microsystem technologies allows controlled delivery and removal of soluble molecules in the extracellular environment, the use of small culture volume, and the application of mechanical forces on cells via fluid flow.[10] The BioMEMs and other Lab-on-Chip microsystems present several advantages compared to conventional *in vitro* cell culture systems that utilize culture dishes or microwells plates. In fact, these conventional approaches are labor-intensive and time consuming, and require technical expertise and specific facilities to handle cell harvesting, media exchange, and cell subculturing procedures, which are not necessary anymore with most of the microsystems.

After a general description of how cellular and bacterial functions can be controlled by materials, this chapter focuses on how materials are used and modified in microsystems with the same goal, namely controlling cellular and bacterial function. Specifically, only studies dealing with surface modification of materials to control cell function are reviewed. The use of microfluidics or electrical and optical stimulations in BioMEMs is not the subject of this chapter, except if they are associated with a modification of materials. For further details on BioMEMs please refer to **Chapter 3.315, Biological Microelectromechanical Systems (BioMEMS) Devices**. Lab-on-Chip microsystems achieving the step of cell manipulation uniquely (culture, docking, separation, guidance, and transfection) with subsequent detection of the signal by techniques, such as fluorescence microscopy or colorimetric assays, are also considered. In the following, the term 'microsystem' is mainly used for referring to all these different systems, while 'BioMEMs' is used only for electromechanical integrated systems.

Concerning the last point, microsystems have historically been fabricated with materials related to microelectronics such as glass or silicon. On such substrates, manufacturing techniques such as lithography or etching are well established. Polymer substrates have appeared in the field more recently due to their increased biocompatibility, optical properties, and simple fabrication methods.[8] Usually, the substrate is chosen for its bulk properties and the control of its surface topography is done by photolithography and hard or soft machining.[11,12] Further, chemical modifications are applied to the material surface to confer on the microsystem its specificity for cells. Techniques such as plasma treatments, plasma polymerization, physical vapor deposition, or self-assembled monolayers are used to control the chemistry, energy, and biomolecule immobilization on the surface of materials. They are also used to develop electrodes for electrical stimulation and detection, or to control the velocity in microchannels (**Table 1**).

Concerning the control of cell function, modifications of the material surface or specific materials are used to develop innovative cell culture systems and to control cell adhesion, migration, proliferation, and differentiation as well as to achieve cocultures or three-dimensional (3D) cultures. The interest in microfabrication is due to the fact that it offers the possibility of capturing or separating cells for single-cell analysis. This is

Table 1 Chemical/physical treatments applied on materials used in bioMEMs and microsystems

Chemical/physical treatment	*Bulk material*	*Chemical functionality*	*Applications*	*References*
Plasma polymerization	Silicon, silicon nitride	Polyethylene glycol (tetraglyme, Crown ether)	Biofouling	11,13
	Platinum, gold electrodes	Acetonitrile	Control of surface wettability, biomolecule immobilization	14
	Glass	Hexamethyldisiloxane	Biomolecule immobilization	14–16
	Glass/silicon	Acrylic acid	Velocity control in microchannels	17
Plasma treatments	Polydimethylsiloxane (PDMS)	Air plasma treatment	Bonding on glass substrate, control of surface wettability	18,19

Electrostatic interactions	Glass	Poly(lysine)-*g*-poly(ethylene glycol)	Biofouling	30

particularly important in cell biology, immunology, stem cell research, and cancer research. Some experiments of cell transfection in microsystems have been developed by combining electroporation and micromachining of the substrates. The possibility to control cell migration and contact guidance by modifying surface topography and surface chemistry inside BioMEMs and other microsystems has also been largely exploited.

The use of materials with different stiffnesses has allowed probing cell mechanics and also evaluation of the forces generated by cells or their capacity to respond to mechanical stimuli. Finally, the microfabrication approach is also very useful to develop artificial machines using materials and cells. These systems use cell properties, such as the autonomous beating capacity of cardiac cells, to develop pumps, microactuators, or microrobots.

Similarly, microsystems are largely developed for studying bacteria. However, as the bacteria's capacity to live in suspension is high in comparison to mammalian cells, and even though it is now accepted that biofilms constitute the most frequent bacterial mode of life, most examples of BioMEMs and other microsystems in microbiology concern suspensions of bacteria individually or in colonies. In this review, we focus on the microsystems involving bacteria–material interactions or material modifications for achieving, improving, or studying microbial culture, docking, separation, or migration. For more details on bacterial adhesion and biomaterials surfaces please refer to **Chapter 4.407, Bacterial Adhesion and Biomaterial Surfaces**.

3.314.2. Influence of Surface Features on Cell Function

Cells are filled with cytoplasm, which is a liquid that contains organelles such as the nucleus, the Golgi apparatus, and the mitochondria. They are surrounded by a membrane made of a phospholipid bilayer containing receptors such as integrins, cadherins, etc., allowing their interactions, respectively, with extracellular matrices (ECMs) or other cells. Their architecture is maintained by a cytoskeleton made of three types of filaments: actin microfilaments, tubulin microtubules, and intermediate filaments made of vimentin, keratin, desmin, or lamin. The cytoskeleton is physically 'hard-wired' both to the plasma membrane at focal adhesions by proteins such as vinculin, paxillin, talin, etc., and to the nuclear membrane by proteins forming the LINC complex (link between nucleoskeleton and cytoskeleton). Cytoskeleton is then involved in the mechanotransduction system, which is the basis of the cell's response to surface topography. Besides this direct signaling pathway, a biochemical signaling pathway exists between the cell membrane and the nucleus, which involves integrin receptors, kinases, and transcription factors that will translocate across the cytoplasm and nuclear membrane inside the nucleus and transmit information coming from integrins connected to proteins adsorbed on the surface of the cell substrate.

The majority of cells (except blood cells) need to adhere to survive and further proliferate and differentiate. For more information on cell adhesion onto materials, the reader must refer to other reviews.[1–5]

In this section, we describe the current knowledge on the influence of surface features on cell function in general. In particular, we detail the influence of surface topography, chemistry, energy, and stiffness.

3.314.2.1. Cell Adhesion

The influence of surface roughness on cell adhesion can be separated into the influence of roughness amplitude (height), roughness organization, lateral distance between features, or shape of features at both the microscale and the nanoscale. Many experiments have demonstrated that cells react differently to surfaces with different topographies.[1–5,31–33] For details on influence of surface roughness on cells please refer to **Chapter 6.622, The Effect of Substrate Microtopography on Osseointegration of Titanium Implants** in this comprehensive. However, the difficulty in this field is the comparison of results from studies performed using different cell types or on surfaces defined by their manufacturing processes rather than by a sufficient number of roughness parameters.[34] Most authors are satisfied with some amplitude roughness parameters, while frequency, hybridization, or fractal parameters are not measured. Now, it has been shown that surface topography must be characterized for all these parameters to be correctly and totally defined.[2–5,35]

The influence of the topography on cells cannot be generalized. Different cell types can respond in different ways depending on their origin. For example, bone-derived cells are known to 'prefer' rough surfaces, whereas fibroblasts 'prefer' smooth surfaces.

An interesting approach to appreciate the influence of roughness on cell response is to use surfaces presenting a gradient of increasing roughness amplitudes obtained by the same process. We have previously shown that the topography must be considered as a function of the cell scale in order to better interpret biological results.[2–5,36–39] Human osteoblasts adhered better on rough electroeroded metallic surfaces than on smooth ones. Above the cell scale, the surfaces produced by electroerosion were considered as rough with melted relief with smooth edges, whereas below the cell scale, they were relatively smooth and presented a large number of smooth and flat areas permitting the adhesion of cells.[39]

The organization of topography has also been shown to be a major influencing factor on cell adhesion. Cells are able to differentiate isotropic and anisotropic surfaces. Notably, human primary bone cells adhered better to isotropic, rough metallic surfaces obtained by electroerosion or sandblasting compared to anisotropic or polished surfaces.[39]

Anisotropic structures have allowed us to highlight recently a fascinating phenomenon of nuclear deformation of human cancer-derived cells.[40,41] Cells were cultured on poly-L-lactic acid (PLLA) substrates presenting square micropillars with 7 μm width and 4 μm height with 7 μm spacing. The most surprising aspect of this deformation is that the cell's capacity to survive, proliferate, and differentiate was not significantly impaired. More recently, this deformation was also observed on immortalized bone cells[40,41] and keratinocytes as well as on cancer cells derived from colon (unpublished data), although normal cells did not deform their nuclei on the same substrates (**Figure 1**). The modification of the spacing between pillars or of their dimensions did not change these observations. Normal cells did not deform their nuclei whatever the

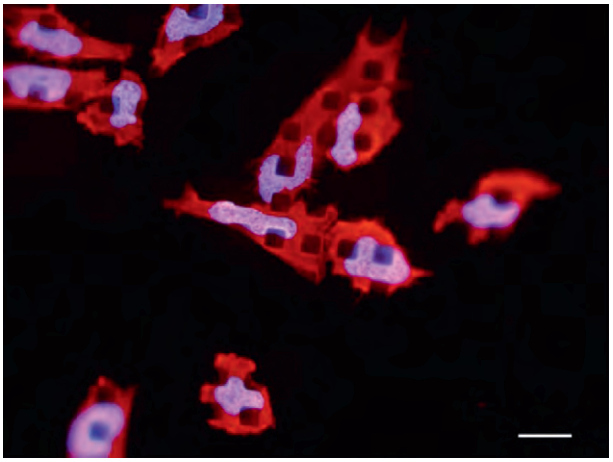

Figure 1 SaOs-2 osteosarcoma-derived cells cultured on PLLA micropillars measuring 7 × 6 μm and showing a nuclear deformation never seen before (nucleus: pink, actin cytoskeleton: red). Scale bar is 20 μm.

dimensions of the pillars, whereas this nuclear deformation was systematically observed in cancerous cells.[40,41] These observations confirm that tumor-derived cells have a lower rigidity than normal cells[42,43] which can be related to their capacity for deformation during invasion in metastasis. Moreover, these results highlight clearly that cell experiments using tumor-derived cells to study the influence of surface topography are now open to criticism because of these cells' evident abnormal response to the topography. Primary cells derived from healthy tissues must be clearly preferred.

Cell adhesion is also largely influenced by nanotopography. Using polymer-demixed nanotopography, Dalby *et al.* have shown that fibroblasts are able to identify the presence of 10-nm high nanotopographic surfaces.[44–47] Their initial adhesion was increased on islands less that 35 nm high, while long-term adhesion was increased only on 13-nm islands.[44–47] On 13-nm islands, cells displayed a spread morphology with a well-defined cytoskeleton, while on taller islands the cell cytoskeleton appeared disorganized.[44–47] Some recent studies have focused on diameter-controlled TiO_2 nanotube surfaces. Cells adhered and spread well on smaller nanotubes (30 and 50 nm), whereas on larger nanotubes they exhibited considerable elongation. Indeed, increasing the size of nanotubes did result in a smaller surface area for attachment with larger spacing, which might have disrupted the formation of focal adhesions.[48,49] For details on nanostructured surfaces and cell behavior, please refer to **Chapter 4.409, Surfaces and Cell Behavior**.

The shape of the features was shown also to influence cell adhesion at the nanoscale. Aligned nanopatterns of varying heights and tip shapes (needle- or blade-like tips) induced smaller fibroblastic cell sizes on needle-like posts and enhanced elongation on blade-like nanogrates. Fibroblasts exhibited punctuated adhesion complexes on the top of needle-like posts and dash-like adhesion complexes on nanogrates.[50]

The distance between nanofeatures is also visible for cell adhesions. Spatz *et al.* demonstrated in an elegant study, using gold nanoparticles bearing an RGD (arginine–glycine–aspartic acid) peptide and separated by polyethylene glycol (PEG) to prevent cell adhesion, that the minimal spacing to allow the formation of focal contacts by cells was in the range of 58–73 nm.[51]

In a study where nano and microtopography were voluntarily associated, it was demonstrated that nano- and microtopography exerted a synergistic influence on human osteosarcoma cell adhesion.[52]

The surface chemistry also influences cell adhesion. Some of the different ways to modify the surface chemistry are described in **Table 1**. However, the processes used to induce roughness can also sometimes have a strong influence on surface chemistry and consequently on cell adhesion.[2–5] Apparently, the chemical composition of the material can be identified by the cells. Titanium alloy modified by ion beam implantation influenced differently the spreading capacity of primary bone cells. These differences were associated with different activations of the signaling molecules.[53] Recent interesting works have focused on the influence of hydrophilicity on cell adhesion, using linear gradients with increasing surface energy. Platelet adhesion was improved by a positive charge character,[54] whereas adhesion of endothelial cells[55] or neural cells[56] was increased more on positions with moderate hydrophilicity than on the more hydrophilic or hydrophobic positions. On gradients with self-assembled monolayers (SAMs) treated by UV light, the adhesion and spreading of murine osteoblastic cells were not modified.[57] On the contrary, fibroblasts adhered better on the hydrophilic part of gradients formed by association of a hydrophobic hexane polymer and a hydrophilic allylamine polymer.[58]

In order to control the surface chemistry, some authors have coated the surfaces with another material or made replicas of the surfaces. For example, gold coatings on titanium or stainless steel substrates treated to induce various surface topography and morphology have allowed us to demonstrate that the short-term cell adhesion is mainly modulated by the surface chemistry, while the long-term cell adhesion is mainly related to the surface topography.[36–39,59] Ti-coated replicas were used to investigate the effects on cells of surfaces with varying roughness and constant chemical composition.[60,61] Another approach to control the surface chemistry is to covalently graft active molecules on the material surface. The most studied one involves the grafting of peptides or oligopeptides derived from bioadhesive molecules like proteins of the ECM, such as fibronectin or collagen. The best known peptide is RGD, which was shown to increase *in vitro* cell adhesion.[62,63] However, the use of RGD grafting for increasing *in vivo* tissue integration of implants is still controversial.[64] For more details, please refer to **Chapter 4.411, Peptide- and Protein-Modified Surfaces** in this comprehensive.

3.314.2.2. Cell Migration/Contact Guidance

After the cells have adhered and spread on the surface, their cytoskeleton will be prestressed as a result of the equilibrium between the tension applied by actin microfilaments and the compression maintained by microtubules.[65,66] Then the cells will be able to move on the surface and eventually react to or follow the surface features. When they migrate, the cells will first polarize, extend the membrane in the direction of movement, and form an attachment between the leading membrane

and the substrate. Further, the cell body will move forward and the attachment at the rear will be released. The migration and contact guidance capacity of cells are thus based on the mechanotransduction process.[65–67] The capacity of cells to follow surface features and, for example, align following the underlying grooves has been defined as 'contact guidance.' This phenomenon was first described at the beginning of the twentieth century,[68,69] and is almost universal among cell phenotypes or scales since it exists as well on nanotopography[2–5] as on microtopography.[33,70–75] Contact guidance can be explained by the inhibition of cell spreading by a physical step on the surface. The cells will follow the edge step and finally elongate following the groove direction. A recent work on living cells on nanogrooves has shown that cells emit filopodia that probe their environment. When they come across a favorable site, they form focal adhesions before forming cell protrusions. Depending on the quality of the focal adhesions formed on the grooves, the adhesion of cells is either improved or decreased. The best adhesion is obtained when focal adhesions can be formed parallel to the ridge.[76]

The first demonstration of the contact guidance capacity of cells was shown on fibroblasts.[70] Rat dermal fibroblasts oriented systematically on grooves measuring 1, 2, 5, and 10 μm wide on polystyrene (PS), whereas they oriented only on 1- and 2-μm wide grooves on titanium.[77] The orientation increased with the depth of the microgrooves[74,75] or nanogrooves.[78] Recently, interesting results have been obtained using topography gradients.[79–81] By maintaining the ridge width and depth constant (1 μm and 400 nm, respectively) but varying the groove width between 1 and 91 μm, it was shown that fibroblasts aligned more strongly along denser patterns compared to sparser patterns.[79–81] On the contrary, cells did migrate more rapidly at an intermediate ridge density. Similarly, interesting results were obtained on surfaces displaying a variable local density of square pits.[79–81] Fibroblasts migrated following the direction of patterns of higher anisotropy from spacer to denser areas. This allows us to envision more sophisticated design of biomedical devices to better control their colonization by cells. Also, the contact guidance capacity of cells has been exploited for muskuloskeletal myogenesis and for developing artificial muscular structures on grooves or fibers[82,83] mostly for the regeneration of injury gaps in neurites.[72,84–86] Interesting observations were made recently on surfaces presenting concave and convex circular structures measuring 100 μm in diameter and 50 μm in depth demonstrating the migration of fibroblasts and human mesenchymal stem cells (MSCs) toward convex structures and thus the capacity of cells to sense the curvature of surfaces.[87,88]

The surface chemistry is also a means to control cell contact guidance. Using photolithography and cold plasma discharge in oxygen, lines presenting adhesive properties have been developed on PS. Oxidized PS lines adsorbed more proteins (fibronectin or collagen) than unoxidized ones and permitted cell adhesion unlike untreated PS lines.[89,90] Adhesive guidance was developed on quartz by making aminosilane/methylsilane tracks of 5–100 μm period either parallel or perpendicular to topographic gratings of the same period and 0.1–6.0 μm in depth. This combination, on the same substrate, of adhesive and topographic guidance revealed that the adhesive response was consistently dominant.[91]

Mechanical stiffness of the substrates has also been shown to be a means to control cell migration. 3T3 fibroblastic cells were cultured on flexible polyacrylamide sheets coated with type I collagen, presenting a transition in rigidity in the central region. Cells approaching the transition region from the soft side could easily migrate across the boundary, with a concurrent increase in spreading area and traction forces. In contrast, cells migrating from the stiff side turned around or retracted as they reached the boundary. This apparent preference for a stiff substrate was called 'durotaxis'.[92] It was shown that this cellular sensitivity to substrate flexibility involves myosin-generated forces and protein tyrosine phosphorylation with highly dynamic and irregularly shaped focal adhesions on flexible substrates.[93]

3.314.2.3. Cell Proliferation and Differentiation

In the field of bone implants, the influence of surface microtopography on cell proliferation and differentiation was largely studied. It was notably shown that the proliferation and differentiation potential of osteosarcoma-derived cells on titanium was positively influenced by the roughness.[94–96] Cells were more differentiated on rough surfaces and their responses to systemic or regulation factors were also stimulated by the roughness. Their sensitivity to roughness was shown to depend on their maturity state, immature cells being more sensitive to roughness.[97] The role of integrins in the response of cells to roughness was also recently demonstrated. On roughness gradients, it was shown that rat calvaria osteoblasts showed a linear increase of proliferation with roughness, whereas human gingival fibroblasts showed the opposite, demonstrating again the influence of the cell phenotype on the response to surface features.[98]

Nanotopography also influences the cell's proliferation and differentiation capacity.[2–5]On nanotubes produced by anodization, human MSCs (hMSCs) differentiation was shown to depend on the tube diameter. Smaller tubes promoted less cellular differentiation than larger ones. This observation was related to a more dramatic cell elongation on larger nanotubes, which was supposed to stimulate their differentiation.[49] However, the same experiment with rat MSCs gave opposite results.[99–101] This was explained by the authors as due to a different nature of the nanotubes, which were anodized and amorphous in the case of Park *et al.*[99–101] versus heat-treated and crystallized in the anatase phase in Oh *et al.*,[49] illustrating the capacity of the cells to respond also to slight differences in surface chemistry.

Other fascinating results were obtained by modifying the nanotopography organization. Dalby *et al.* showed that hMSCs cultured on polymer surfaces presenting 120-nm diameter pits placed with the hexagonal, square, or displaced square (±50 nm from the center = DSQ50) organization differentiated differently. Cells cultured on DSQ50 surfaces differentiated more compared to those on other surfaces and, more surprisingly, they differentiated as if stimulated with the osteogenic medium that is generally used to induce their differentiation *in vitro*.[44–47]

As previously shown in the case of cell migration, substrate stiffness can also control the differentiation of hMSCs. Engler *et al.* have observed that soft matrices that mimicked brain were

neurogenic, that stiffer matrices that mimicked muscle were myogenic, and that rigid matrices that mimicked collagenous bone were osteogenic.[102] For more details, please refer to **Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation** in this comprehensive.

Concerning surface chemistry, it was shown, using model surfaces covered with SAMs, that the differentiation of osteoblasts was higher on hydrophilic substrates than on hydrophobic ones.[103] *In vivo* studies with SAM-coated implants confirmed these results.[104] Using gradients of polymers, the influence of surface energy on osteoblasts was elucidated.[56] Cells proliferated more on the hydrophilic positions in the gradient. This was also confirmed on gradients produced by plasma polymers.[58] These studies developed on model surfaces were also carried out on titanium implant surfaces modified by sandblasting and acid etching (SLA).[105–107] These SLA surfaces have induced high proliferation and differentiation of bone cells *in vitro*[94–96] and osseointegration *in vivo*.[108–110] However, in order to improve their performance further, a modification was proposed in which the samples were rinsed and immersed in NaCl under N_2 protection during the preparation process and storage until the implantation. These modified SLA surfaces (ModSLA) increased the differentiation of osteoblasts *in vitro*[111,112] as well as the osseointegration of implants *in vivo*.[109,113] This modification by improving the wetting of surfaces by biological fluids and the adsorption of proteins on them is a demonstration of the possibility to control cell response *in vitro* and *in vivo* not only by mechanical input on cells using surface topography or surface stiffness but also by controlling surface energy. In this case, the mediators are the proteins adsorbed on the surface.

3.314.3. Influence of Surface Features on Bacteria Function

Bacteria can live as planktonic cells but prefer to attach to a surface in community known as biofilms.[114] This assembly of microbial cells and extracellular biopolymers is the result of the initial adhesion of planktonic bacteria that have proliferated and synthesized species-dependent polysaccharides and other metabolites (proteins, lipids) once attached to the surface. The crucial step of adhesion is affected by bacterial characteristics as well as features such as the physicochemical properties of the cell wall and protein- or carbohydrate-based filament-like appendages named flagella, pili, curli, and other fimbriae, or lipopolysacharrides.[115,116] Bacterial adhesion is also highly influenced by the properties of the material on which the biofilm is developing, in particular by its chemical and topographical characteristics.[6,7] Material surface properties seem to play a relatively small role in further biofilm development, but some evidence already exists that surface properties can also affect the biofilm characteristics.

3.314.3.1. Initial Adhesion

Topographic features at the microscale are commonly considered as favorable material characteristics for bacterial adhesion. Indeed, bacteria are preferentially observed in crevices and holes of their own size, which may be attributed to the protection that these features may offer to bacteria. Various works have confirmed this phenomenon in general.[117–119] However, it is not clear whether this is the result of cell entrapment or of a real adhesion phenomenon. Moreover, analyses are usually performed by quantifying adherent bacteria without the determination of bacterial localization, which prevents us from drawing conclusions as to the potential influence not only of the topographical features but also of their organization, as already shown in the case of mammalian cell adhesion.[2–5] Concerning the chemical features, typical dimensions of bacteria of around a few micrometers lead to the conclusion that chemical patterns at the microscale, that is, larger than bacterial dimensions, play for bacteria similar roles as separate surfaces with different chemical properties. As an example, preferential adhesion can occur on surface areas functionalized with favorable chemical functionalities, such as mannose for *Escherichia coli*.[120] It has also been demonstrated that bacteria can detach differently according to surface chemistry.[121] Bacteria may be able to migrate from one favorable pattern to another. Specific material characteristics such as surface wettability or surface roughness may also affect bacterial migration, although this topic has only rarely been treated so far.

Due to their small size compared to mammalian cells, bacteria may be expected to react also to chemical and topographical surface features at the nanoscale. However, the bacterial membrane is not as deformable as the mammalian one. In particular, the bacterial membrane does not have the ability to form filopod-like appendices or to orientate cytoskeleton with grooves or other geometrical topographic surface features. Only weak modifications of the cell shape occur throughout the bacterial life. Therefore, while topographic features at the microscale should be expected to influence the adhesion of bacteria onto surfaces, the effect of nanometric features on bacterial adhesion and further biofilm formation is not obvious. The lack of deformation capability may affect also the capability of bacteria to access potentially favorable chemical patterns of nanometric size on surfaces, and therefore their capability to react to nanometric chemical surface features.

However, as pointed out above, bacteria can possess protein- or carbohydrate-based macromolecules anchored in their membranes, creating filament-like appendages of various sizes (from a few hundred nanometers to a few micrometers) according to the species and strains. These structures (flagella, pili, curli, and other fimbriae, but also lipopolysacharrides) may participate in the sensing of the surface by bacteria, allowing them to detect surface features at the nanoscale.[122,123] This hypothesis has not yet been directly proved. Nevertheless, some of the previously evoked membrane structures have been implicated in the adhesion capability of bacteria[124–127] as well as their mobility on material surfaces.[128,129] In addition, some evidence already exists that surface properties at the nanoscale are able to influence the adhesion of bacteria, although studies on this topic are rare. Several authors have concluded on the general increase in bacterial adhesion when the surface roughness increases. However, the response of bacteria to topography is a complex phenomenon, as demonstrated by frequent contradictory results published in the literature. For example, Campoccia *et al.*[130] observed similar bacterial adhesion on surfaces with various roughnesses, while the study of Mitik-Dineva *et al.*[131] showed a decrease in the number of adherent bacteria when material surface roughness increased. In addition, the organization and size of the topographic features

may play an important role as suggested by a few works,[132,133] although the relationship between feature organization and size on one hand, and bacterial localization and amount on the other, has not been addressed so far. As well, the effect of surface chemical features at the nanoscale on bacterial adhesion and retention has rarely been studied. Nevertheless, knowing that bacteria interact with chemically complex surroundings (other bacteria or tissues, for example), their capability to recognize the chemical heterogeneities at the molecular scale should be expected. A few studies have been conducted with SAM model surfaces chemically mixed at the molecular scale, demonstrating that bacteria are sensitive to variation of chemical function densities.[134–136] However, bacterial capability to distinguish between nanoscale patterns of similar chemistry but different numbers of molecules is still unknown.

3.314.3.2. Biofilm Formation

The influence of topographic and chemical surface properties on the development and the characteristics of biofilms is largely unknown. It is even commonly considered that biofilm evolution is independent of the surface. However, a few studies have already provided evidence that the surface chemistry can affect bacterial colonization at further stages than the initial adhesion. Thus, it has been demonstrated that surface colonization after 12 h (*Staphylococcus epidermidis*)[137] and the colonization kinetics (*E. coli*)[6,7] can be influenced by surface wettability, whereas initial adhesions do not differ between surfaces. Also, effect of surface charge on bacterial colonization has been shown to vary with the incubation time.[138] Nevertheless, much work has still to be done to understand biofilm development and behavior in response to specific chemical and topographic surface characteristics.

Finally, important questions about the influence of surface properties on bacterial adhesion and biofilm formation and behavior remain unclear. Thanks to the scale and precision reached by microsystem technologies, essential improvements can be expected from their use in studies addressing these questions. On the other hand, bacterial behavior in response to surface features can be exploited for improving microsystem performances. For example, bacterial response to topography should allow docking of bacteria on microsystem surfaces, resulting in easier quantification, identification, or characterization of the microbial cells. Both these aspects are addressed in the following section.

3.314.4. Applications in BioMEMs/Microsystems Fields

3.314.4.1. Cell Culture

The previous concepts have been found out essentially using classical culture techniques, that is, in 2D cultures in Petri dishes or multiwell plates. However, it is well known that these techniques present several disadvantages. The major disadvantage is that cells are cultured under conditions that are very different from their natural life conditions where they live in three dimensions and make connections with each other. Attempts have been made for several years to develop 3D cultures in bioreactors to overcome these disadvantages. However, these techniques are applicable only when large amounts of cells are available or when the objective is to produce several centimeter cubes or grams of cells, with or without ECM, for example for tissue engineering applications. Coculture systems have also been developed and used to understand the relationships between two – or maximum three – different cell types.[139–141] However, the need exists for culture techniques that allow culturing together more than two cell types under the same conditions or in their real environment, that is, in three dimensions inside an ECM and in connection with other cell types. Moreover, the maintenance of cells in three dimensions imposes the use of dynamic circulation of body fluids to oxygenate and to permit mass transport to the cells. The control of the circulation of fluids inside a bioreactor of several milliliters or more is relatively complex and does not allow the test in parallel of several fluid circulation conditions or different medium compositions.[142]

Microfluidics and BioMEMs give now the possibility to overcome most of the limitations of current culture methods. Microfluidics allow perfect control of the circulation of fluids inside the circuits, circulation of several fluids in parallel that can be mixed at will, and development of gradients of concentrations of the active products, and in a very small volume, thus allowing one to work on rare and precious products. In parallel, research in microsystems focus on the development of systems that allow 3D cultures in different materials based on natural and synthetic hydrogels fed by microfluidics. By modifying the construction of the microfluidic circuits, it is possible to coculture different cell types and to control their interactions. The approaches based on microfluidics not only allow the feeding of cocultures but also permit following dynamically the response of cells in living cultures with time. The capability of microsystems to reduce the volume of the culture and the volume of reaction allows us to consider testing in the same system several products or drugs on several cell types or associations of different cell types. Aside from improvements in sample treatment throughput for routine assays, the reduction of culture volume allows us to decrease the number of cells, which, in the case of pathogenic microorganisms, should reduce also the infection-associated risks to the environment. Finally, contrary to the classical culture techniques, in which the cell detachment necessary to isolate cells for gene expression or protein synthesis analysis is mainly carried out by enzymatic methods, the microsystems approach has allowed the diversification of the techniques for harvesting cells or for carrying out these analyses.

3.314.4.1.1. Control of adhesion, migration, proliferation, and differentiation

As described previously, the first phase of adhesion is essential for the mammalian cell survival and further cell migration, proliferation, and differentiation. The control of adhesion by the modification of surface topography and surface chemistry has been at the center of an intense research activity for several decades.[31,32,143] The quality of adhesion of the cells is mainly assessed by quantifying the energy needed to detach them.[1] In general, to evaluate directly the adhesion strength, physical constraints are applied by techniques such as fluid flow, centrifugation, micropipette aspiration, jet impingement, etc. Thermoresponsive polymers have also been shown to be particularly efficient for controlling cell detachment.[144–146] This

concept has been applied in microsystems by synthesizing the thermoresponsive polymer poly(*N*-isopropylacrylamide)–poly (ethylene glycol)-thiol (PNIPAAm–PEG-thiol), which was used for the formation of SAMs on gold substrates. The polymer chains passed from an extended and highly hydrated state above 37 °C to a collapsed coil state below 37 °C. At 37 °C, the cultivated fibroblasts adhered and spread normally on these surfaces, whereas they detached on reducing the temperature to 25 °C. Thus, the use of these SAMs in a microfluidic device allowed the quantification of the forces needed to detach cells using laminar flow.[147] The control of culture conditions in microsystems can also be done through the control of the architecture and the chemistry of the microfluidic perfusion system. Cell-adhesive surface microdomains alternating with cell-repellent coatings have been used to mimic *in vivo* spatial cues for muscle assembly. This system allowed the confinement of the fusion of myoblasts into aligned and isolated multinucleated myotubes. Moreover, the microfluidic system provided accurate control of the perfusion rates and biochemical composition of the environment surrounding the cells.[20] A microcell chip based on five layers of poly (dimethylsiloxane) (PDMS) alternating with borosilicate substrates presenting holes of various diameters was designed. It allowed the development of a microcell stimulator based on a pneumatic actuator with a flexible diaphragm, which consisted of an air chamber and several cell chambers. This system was designed to apply compressive pressure to hMSCs for inducing osteogenesis. A cyclic compressive stimulus of 5 kPa twice a day for 10 min during 7 days showed to be the best condition for stimulating cell proliferation and cell differentiation.[148] A microfluidic device was filled with a pregelled alginate solution where calcium was chelated by DM-nitrophen™. The UV exposure of the caged calcium provoked its release from DM-nitrophen causing alginate cross-linking. This elegant approach allowed the 3D coculture of endothelial cells and osteoblastic cells in a microchannel.[149] The same principle of photocaging was applied to RGDS peptides caged inside a hyaluronic acid (HA) hydrogel. Line patterns were made with this modified hydrogel material, which allowed the control of the adhesion and proliferation of fibroblasts.[150]

So far, contrary to the case with mammalian cells, the intensity of adhesion of individual bacteria to surfaces has not been measured in microsystems. Nevertheless, bacterial growth has been studied by using microdevices, mainly in suspensions. The main studies have concerned the response of microorganisms to specific environmental conditions. Extreme and unusual environments have been mimicked by adjusting, for example, fluid velocity, pH, and ammonium concentration for methanogen cultivation.[151] Even the screening at microscale of unusual growth conditions has allowed the successful cultivation of previously uncultivated bacteria.[152,153] Microtube- and microcapsule-associated microdevices have been also realized for studying the behavior of microorganisms in confined growth conditions. The microtubes proposed by Huang *et al.*[154] are transparent for cell observation and display variable diameters, which should allow the investigation of the influence of the confinement diameter on the shape and arrangement of microbial cells. Semipermeable microcapsules composed of an alginate–poly-L-lysine membrane and entrapped in microfluidic system were created by Morimoto *et al.* for encapsulating cells and microorganisms. Their permeability should allow the transport of nutrient and waste through the membrane, allowing the growth of cells encapsulated inside. This was already demonstrated for *Chlamydomonas* unicellular alga and opens the door of the easy observation of several microorganism subpopulations growing under different specific conditions.[155] Finally, microfluidic devices have been also exploited for studying the growth and detachment of bacterial biofilms (*S. epidermidis*) in response to the hydrodynamics of the local environment as well as to a hydrolyzing enzyme or antibiotic treatments. In particular, by comparing biofilm morphology according to the location in the device, and to the hydrodynamic microenvironments, this study confirmed that biofilms tend to be elongated along the flow direction when grown under high shear, whereas they tend to form filamentous streamers when grown under low shear.[156,157] Micropatterned devices have also been used for the investigation of cell–cell communication in *E. coli* communities, a prelude to quorum sensing, which is another crucial aspect of the biofilm-associated bacterial mode of life.[158]

3.314.4.1.2. Cocultures

The development of cocultures started less than 5 years ago in the BioMEMs and microsystems field. One challenge in the field is to be able to control spatially and also temporally the cocultures and the cell–cell interactions. The difficulty is (1) to reversibly control the interactions between different cell populations that are in patterns on molecularly defined surfaces and (2) to serially manipulate the surface to control the duration of the cell–cell interactions.[159] Diverse approaches have been followed. Mainly microfabrication techniques were used to develop complementary cell substrates that could be displaced or changed to control cell–cell interactions. Lee *et al.*[159] developed an original method combining a photoelectroactive surface chemistry strategy with a microcontact printing patterning method. They first used microcontact printing to pattern hexadecanethiols onto a gold surface backfilled with a mixed solution of tetraethyleneglycol-terminated alkanethiols (EG4SH) to render the unpatterned region inert to cell attachment. Nonvolatile organic compounds (NVOC)-protected hydroquinone-terminated alkanethiols were added to the unpatterned region and further deprotected, electrochemically oxidized to quinone, and grafted with oxyamine–RGD. This approach allowed the addition of a second cell type besides the first one adhering on the microcontact-printed regions, which then allowed the spatial control of their interactions. For achieving temporal control, the second cell type could be released from the pattern by the application of a mild reductive electrochemical potential to break the oxime linkage, leading to the release the RGD ligand. The possibility of developing gradient surfaces with RGD–oxyamine peptide was also demonstrated.[159] By using a micromachined silicon substrate with moving parts, Hui and Bhatia[160] studied in an elegant manner the need for cell–cell interactions in hepatocytes/stromal cells cocultures for maintenance of the hepatocellular phenotype. They developed silicon plates with comb fingers that could be placed in contact or slightly separated (**Figure 2**). After coating the silicon plates by irradiated PS, cells were cultured on the top surfaces. Sliding the two silicon plates by 1.6 mm changed the gap between fingers by

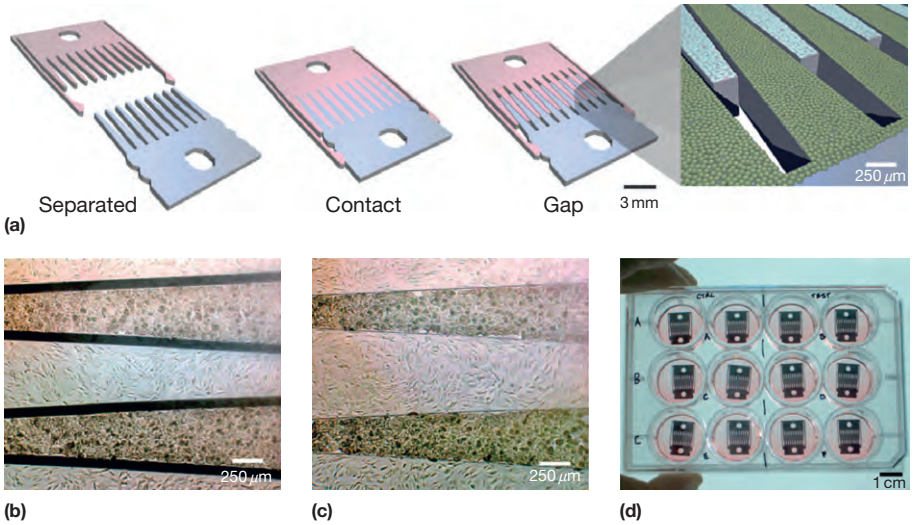

Figure 2 Micromechanical substrates enabling cell positioning with micrometer resolution. (a) Microfabricated silicon parts can be fully separated (left), locked together with comb fingers in contact (center), or slightly separated (right). Cells are cultured on the top surfaces; manual scraping can be used to restrict cells to the comb fingers only (inset). The slope of the tapered comb fingers results in a 20:1 mechanical transmission ratio; that is, sliding the parts by 1.6 mm changes the gap between the fingers by only 80 μm. Together with the integrated snap-lock mechanism, it is thereby possible to control the separation with repeatable micrometer-scale precision by using unassisted manual actuation. (b, c) Bright-field images of hepatocytes (darker cells) and of 3T3 fibroblasts cultured on the comb fingers. The silicon is first functionalized by spin-coating with polystyrene (PS) followed by plasma treatment, resulting in a surface comparable to tissue-culture plastic. Devices can be reused multiple times (>20). (d) Devices in a standard 12-well plate. Cell culture and functional assays were performed with standard methods. Actuation is also performed directly on the plate with sterile tweezers. Reproduced from Hui, E. E; Bhatia, S. N. *Proc. Natl. Acad. Sci. USA* **2007**, *104*, 5722–5726, copyright (2007), National Academy of Sciences, USA.

80 μm. Therefore, it was possible to control the separation between the two cell layers very easily.[160] The combination of two PS and PDMS complementary cell substrates covered by confluent layers of two different cell types was used to develop a tumor/endothelium model. Using this model, the migration of tumor cells toward the endothelial cells and the simultaneous retreat of these last ones were observed. The possibility of separating the two types of cells by a gap-type barrier allowed to demonstrate that when direct contact between the two cell types was prevented, the endothelial cells initially migrated toward the tumor cells before retreating.[161] Another method based on cell crushing by a controlled force applied on the top of culture chamber presenting 100-μm thick microstamps was developed. The possibility to perform cocultures after cell crushing and rinsing was demonstrated on mouse fibroblasts and liver hepatocarcinoma. The main advantage of this technique is that the same microchip can be used several times for micropatterning and microfluidic cocultures.[162] Other coculture systems were developed using Parylene-C to fabricate patterned stencils presenting round holes. After activation by plasma, the stencils were coated with HA and deposited on a fibronectin-coated substrate. Murine embryonic cells (mES) deposited at the surface adhered mainly inside the holes on the fibronectin-coated substrate. Upon removal of the Parylene-C stencil, a cell micropattern was formed. The subsequent seeding of AML-12 hepatocytes allowed the formation of cocultures that were qualified as static cultures. The possibility of controlling temporally the cocultures qualified as dynamic cultures was also demonstrated. A first coculture of mES and fibroblasts was carried out with the fibroblasts cultured on the collagen-coated Parylene-C and maintained in contact with the mES inside holes. The Parylene-C with fibroblasts was further removed and AML-12 hepatocytes were seeded around mES patches.[163] All these approaches are a means to engineer more complex cell–cell interactions in a spatially and temporally regulated manner. The development of cocultures was also applied to 3D cultures in a microfluidic device. 3D hydrogel cell cocultures have been developed notably to test the cytotoxicity of anticancer drugs while reproducing multiorgan interactions.[164] A chamber with liver cells was connected to another with colon tumor cells cultured both in matrigel, while a third chamber was filled with marrow cells in alginate gel (**Figure 3**). Two different anticancer drugs were inoculated in this microcell culture analog (μCCA), one being metabolized by enzymes in the liver to be active (Tegafur) and the other one not (5-FU). The μCCA allowed the observation of a cytotoxic effect on colon cancer cells with Tegafur in a time-dependent manner compared to control cultures in a 96-well microtiter plate. When liver cells were absent in the circuit, Tegafur showed a considerably weaker cytotoxic effect than when the liver cells were present. This indicates that Tegafur was converted in 5-FU by liver cells and that 5-FU recirculated into the tumor chamber and exerted its toxic effect on tumor cells. These results demonstrate that μCCA, which provides a more physiologically realistic environment than conventional static multiwell plate systems, can be very useful tools to test the pharmackinetic profiles of drugs.[164] The cocultures in 3D hydrogel-based cultures were also applied on liver cell cultures. Upregulation of hepatic functions was observed by cocultures with nonparenchymal liver cells.[165] Bilayered cultures of epithelium and a supporting cell layer were achieved

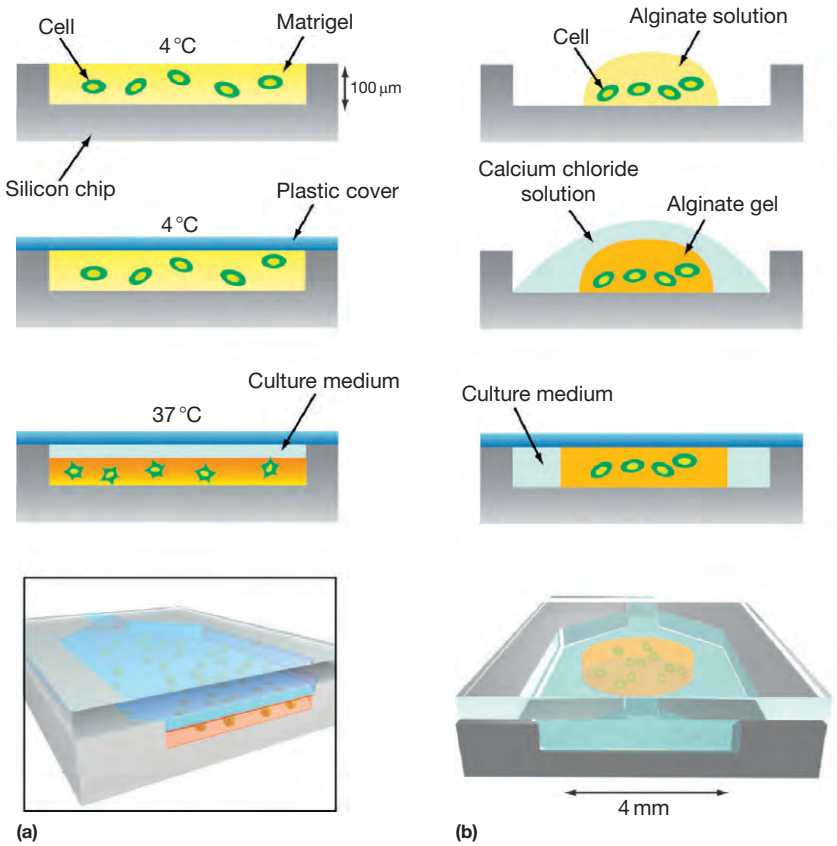

Figure 3 (a) Schematic diagrams describing the incorporation of matrigel hydrogel into a μCCA. Cell-embedded matrigel is inserted into a chamber in a liquid state and the device is sealed with a plastic top cover and a bottom housing piece. After the sealing, the gel is formed by raising the temperature. The bottom housing piece is omitted in the figure for simplicity. (b) Incorporation of alginate hydrogel into a μCCA. A drop of cell suspension in alginate solution is placed inside a chamber and the gel is formed by addition of calcium chloride solution. By sealing with the top cover, a disk-shaped hydrogel is formed inside the chamber. Reprinted with permission from Sung, J. H.; Shuler, M. L. *Lab Chip* **2009**, *9*, 1385–1394.

on the apical and basal side, respectively, of a collagen vitrigel in a microfluidic device with the objective to develop corneal microtissue patches.[166]

Lee *et al*. demonstrated recently the high potential of microfluidic coculture approaches to develop physiologically and clinically relevant models of implant-associated bacterial infection. A microfluidic system was used for imaging MC3T3-E1 murine calvarial preosteoblast proliferation in response to *S. epidermidis* environment contamination. A surface of polished TiAl6V4 alloy was integrated into a PDMS microfluidic system, and various amounts of bacteria were considered. With a small number of bacteria (10^2–10^5 colony forming units), osteoblast adhesion, spreading, and proliferation were not significantly affected during the early stages of the culture. But, interestingly, the results suggested that, when the number of bacteria was small, they did not compete with osteoblasts for the Ti alloy surface. However, when bacterial proliferation occurred, it changed the microenvironment, making it unfavorable for cell viability.[156,157]

3.314.4.1.3. 3D cultures

One challenge in the field is to develop 3D cultures that will better mimic the *in vivo* environment of cells. The microsystems associated with microfluidics are particularly convenient tools to achieve 3D cultures notably because they can be carried out in a small volume with a small quantity of the culture medium. 3D cultures in hydrogels associated with microfluidics have been used to assess the effects of pharmacological and/or microenvironmental influences on tumor cell invasion.[167–169] A microfluidic platform was built for real-time imaging of the interactions between multiple cell types exposed to autocrine and paracrine signaling molecules. Collagen and matrigel hydrogels were polymerized in alternating gel channels containing fluorescently labeled breast cancer cells and macrophage cells. A two-photon fluorescence microscope was used to visualize the migration and the capacity of collagen remodeling of cancer cells.[170] Similarly, the invasive capacity of BALB3T3/v-src cells was studied on three cell culture arrays with collagen gel-coated surfaces in presence or absence of a collagenase inhibitor.[169] Collagen gel microstructure was also used as a matrix for bacterial immobilization in on-chip incubation systems dedicated to high-throughput screening in antibacterial drug research and to pathogenic bacterial identification. Combined with electrochemical detection of the microbial respiration activity, this system allowed the cultivation of small amounts of bacteria while maintaining bacterial viability.[171]

Hydrogel-based microfluidic devices are also useful for studying cell migration. Using a system capable of generating

steady and long-term linear chemical concentration gradients, the chemotactic response of wild-type *E. coli* and differentiated human neutrophils versus attractant products was analyzed.[172] Porous polymeric materials were used instead of hydrogels to study cancer migration in a microsystem.[173] Microbioreactor arrays (MBAs) combining 12 microbioreactors have been developed in which cells were either attached to the substrates or encapsulated in HA hydrogels.[174] They were notably used to study the vascular differentiation of human embryonic stem cells (hESCs). The effects of cell density and flow regimes on hESC differentiation were tested. The hESCs cultured with a higher level of shear exhibited a higher level of differentiation, whereas the cell density had a negative effect on cell differentiation. The interest of MBAs is that each of their wells is independent, that is, without interactions with other wells, and that the medium at the outlet of each well is sent to waste instead of being recirculated back to the cells. By this way, there is no interaction between the wells and no confusion with paracrine signals. 3D pillared microstructures in PDMS were also used to induce the formation of three-dimensionally organized hepatocyte aggregates inside microsystems.[175]

3D cultures were also developed using microwell arrays. With such systems, it becomes possible to cultivate either single cells[176] or cell aggregates.[99–101,177] The modification of the geometry of the microwells displaying the same volume as one cell showed that the actin cytoskeleton of cells whose 3D shapes were fully confined by microwells was remarkably 3D and that prominent actin fibers were often aligned along the long axis of the microwells (**Figure 4**).[176] Change of the material composing the microwells was used to favor cell adhesion or, on the contrary, to inhibit their adhesion and favor the formation of aggregates.[177–181] Notably, the formation of embryoid bodies has been favored by using PEG microwells. By this way, it was possible to control the sizes and shapes of ES cell aggregates.[177]

Nanofiber polymer networks were also incorporated into cell chips to mimic the cellular microenvironment. Proliferation of hMSCs on electrospun nanofiber matrices inside cell chip was comparable to their proliferation in classical cell culture environment.[178,179] Microwells structurally bonded to a sheet of electrospun fibers were constructed from several polymers, which showed their ability to control the cell cluster environment and cocultures.[182] Pure chitosan microfibers were synthesized directly in a microfluidic circuit and used as a cell support in a bioartificial liver chip.[178,179]

In conclusion, the fabrication of biomimetic environments is one of the important issues in the current BioMEM and microsystem research fields. They must be developed and used as cell culture tools, providing miniaturized versions of conventional laboratory techniques. In addition, they will bring new insights into investigations on cell–cell or cell–ECM interactions and simulate *in vivo* situations.

3.314.4.2. Cell Docking

The capture of single cells in microfluidic devices is essential for the development of integrated microsystems for single-cell analysis. Various techniques have been used with this objective. Some are based on material surface chemistry

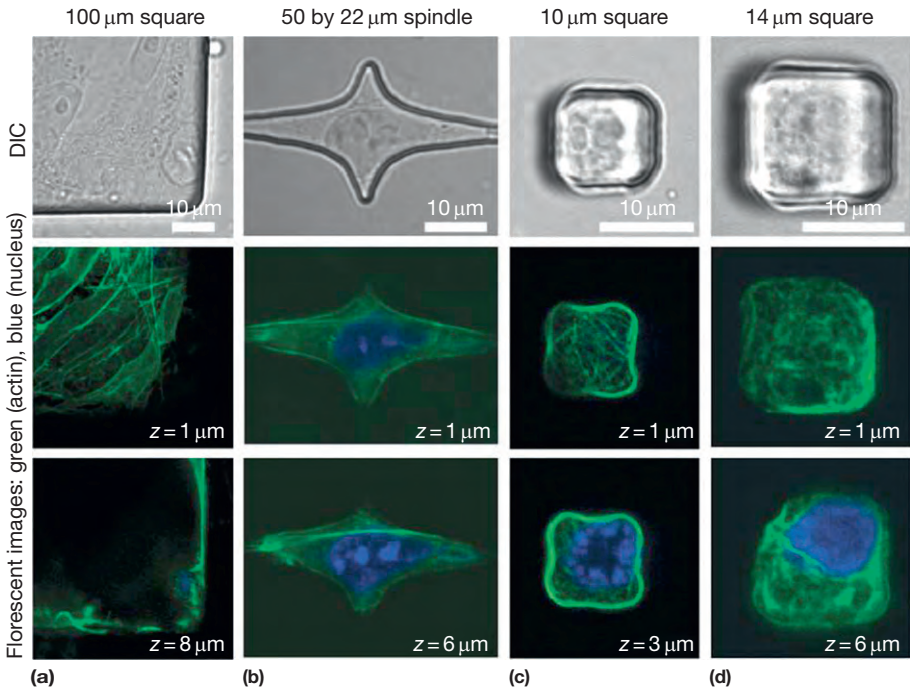

Figure 4 Differential interference contrast (DIC) and fluorescent confocal images are shown of cell nuclei (ethidium homodimer; blue) and actin cytoskeletal networks (Alexa 488-phalloidin; green). Human vascular endothelial cells (HUVECs) cultured for 24 h are shown in a large microwell (a), a spindle-shaped microwell that was slightly bigger than the confined cell (b), and 10 (c) and 14 mm square (d) microwells that adequately controlled the 3D shape of cells. Confocal slices are shown at different height positions in the microwells, where $z = 0$ indicates the microwell bottom. Reprinted with permission from Ochsner, M.; Dusseiller, M. R.; Grandin, H. M.; *et al*. *Lab Chip* **2007**, *7*, 1074–1077.

modification by microcontact printing or by grafting of biological molecules such as DNA, antibodies, or RGD peptides with the capacity to link to cell membrane by biological recognition. However, in the most part, the techniques used for docking mammalian cells are based on physical approaches such as the application of electromagnetic and acoustic wave fields, laser trapping, dielectrophoretic trapping, or micromolding to make microstructures capable of capturing cells. On the contrary, such physical techniques are only rarely proposed for docking bacterial cells. These techniques are not in the focus of this review.

However, some applications of cell docking approaches concern the concept of cell retainers for nonadherent cells such as blood-derived cells (**Figure 5**).[183–186] These cell retainers are generally produced by photolithography-based approaches. These devices have been used, for example, to investigate the effect of drugs on individual cells, which were further analyzed for their reactive oxygen species generation, intracellular enzymatic activity, calcium flux, etc., through fluorescence-based imaging and automatic analysis.[185] Another important application of cell docking approaches is the possibility to isolate embryoid bodies.[187] By controlling the size and the concentration of the cell suspension, it is possible to control the initial size of aggregates, thereby influencing the lineage commitment of embryoid bodies. Moreover, the control of the bottom of wells and notably the possibility to make them round using a laser-jet-printer-based method and replica molding have allowed the maintenance of the spherical morphology of embryoid bodies and controlling their growth and differentiation.[187]

Other ways for docking cells are based on hydrogels. Some authors have used PEG hydrogel microwells to protect cells from medium flow in channels of microfluidic systems and to dock cells within predefined locations.[188] The interest in entrapping cells inside hydrogels comes from the fact that, in the case of an alginate hydrogel, a reversible immobilization of cells can be achieved, which offers the potential of long-term cell culture.[189] Using a patterned agarose hydrogel forming a cell layer, a microelectrode array was developed to culture and study the spontaneous electrical activities of primary hippocampal neurons. This system allowed the monitoring of their response to drugs. Moreover, the development of spontaneous network activity was observed.[190] Dielectrophoretic forces (DEPs) were also used to pull cells on patterned electrodes and to accurately position single cells on a substrate. Negative[191] or positive DEP[192] has been used with this objective. Magnetic-based methods are also sometimes used for aligning cells on geometrical arrays.[193–195] By labeling cells with immunomagnetic labels and by generating magnetic flux density peaks at predefined locations, Liu *et al.*[193,194] were able to randomly array up to 136 single cells per square millimeter. Optical tweezers have also been used alternatively.[196]

Finally, many studies have utilized the functionalization of surfaces micropatterned by microcontactprinting with biomolecules such as fibronectin or RGD peptides derived from fibronectin on a background that otherwise prevents cell adhesion.[30,197] This approach has allowed the production of adhesive patches of different sizes and morphologies and the study of the adhesion of single cells on each patch. The influence of the size and shape of the patches on the formation of focal adhesions, stress fibers, and lamellipodia by the adherent cells has been studied in depth.[198–200]

The possibility to use RGD peptides to functionalize alginate gels in microfluidic channels was also demonstrated.[201,202] Peptide-functionalized alginate was adsorbed on the surface of a device and converted into a thin hydrogel layer by rinsing

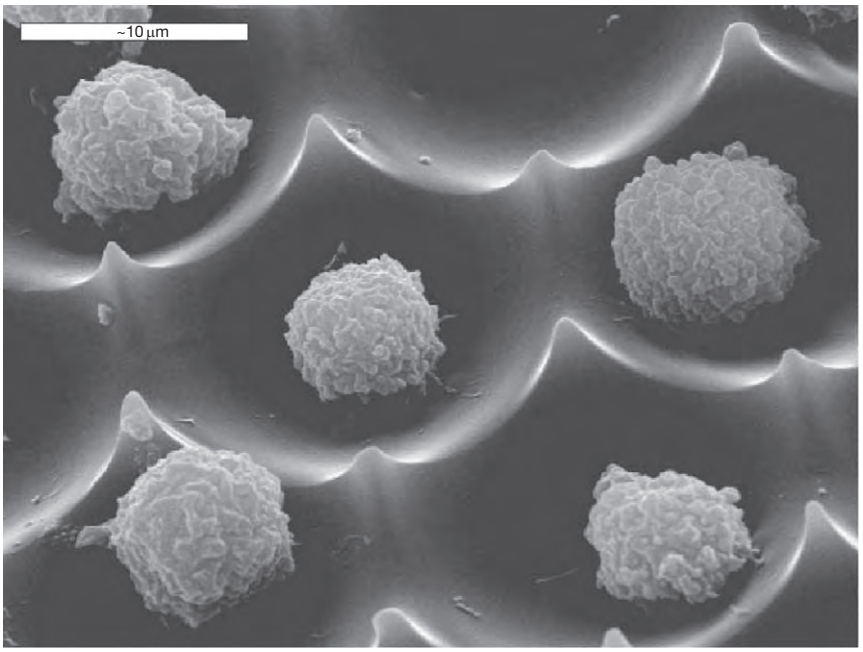

Figure 5 Scanning electron micrograph of U937 promonocyte cells in PDMS array made as described in Deutsch *et al.*[183] Reprinted with permission from Deutsch, A.; Zurgil, N.; Hurevich, I.; *et al*. *Biomed. Microdevices* **2006**, *8*, 361–374.

with a Ca^{2+} ionic solution. Primary rat cardiac fibroblasts were injected into the device, which were captured by the peptide-functionalized gel. Following capture, the hydrogel was dissolved using ethylenediaminetetraacetic acid (EDTA), thereby releasing the captured cells. This very simple method could be adapted to all microsystems operating in a low shear stress regime.[201,202] DNA was also used to capture cells directly in microfluidic devices. The interest of this approach lies in the fact that, in contrast to adhesion proteins such as fibronectin, it is independent of specific receptors possessed by individual cells. Consequently, both naturally adherent and nonadherent cells are compatible with this method. The addition of artificial DNA to the cell surface is a versatile coding strategy allowing the generation of complex cellular arrays with many cell types. Moreover, the patterning of DNA on the capture surfaces can be accomplished with standard methods used to prepare DNA microarrays.[203,204] This approach was used to develop a microdevice on an array of pH-sensitive microelectrodes for metabolic analysis.[203,204] The sensor area of the microelectrodes was functionalized with the DNA complementary strand of the cell membrane-bound single-stranded DNA. With this system, it was possible to demonstrate a higher extracellular acidification rate for Jurkat T lymphoma cells compared to normal primary T cells.[203,204]

In the field of microorganisms, cells are mainly docked for further detection and identification. Especially, this approach is of high interest for controlling water quality as well as for detecting the presence of pathogens in biological fluids. In most of these applications, the bacterial capture is provided in microsystems by immunorecognition. Antibodies specific to the bacterial species of interest are chemically immobilized on chips. Using an interesting approach, Yang *et al*. enhanced the efficiency of bacterial (*Listeria monocytogenes*) capture by coupling immunocapture to dielectrophoresis for concentrating cells prior to docking. This strategy allowed achievement of immunocapture efficiencies between 55 and 65% for *Salmonella* cells with 15–30 min DEP, while efficiencies were between 10 and 20% for similar detections time without DEP.[205] In such approaches, the targeted bacteria are usually further detected and/or identified using enzyme-linked immunosorbent assay (ELISA) methods,[205,206] immunoassays coupled to laser-induced fluorescence,[207] impedance measurements[208] or microscale polymerase chain reaction (PCR).[209]

Capture of microorganisms is also useful for selecting single bacteria or subpopulations of bacteria, in order to study their behavior under specific growth conditions. In this field, docking has been achieved by entrapment in grooves for selecting persistent individual cells in subpopulations,[210] and by encapsulation in microdroplets for screening optimum growth media in order to cultivate previously uncultivated bacteria. Encapsulation in microcapsules[155] and confinement in microtubes[154,170] are also potential new ways for capturing single cells or cell subpopulation for further cultivation or analysis.

3.314.4.3. Cell Separation and Enrichment

The isolation and characterization of single cells from a heterogeneous population are important processes in cell biology, immunology, stem cell research, and cancer research. In the development of novel cell-based therapies, there is considerable need of targeting specific cell types to allow further analysis and amplification *ex vivo*. Microfluidics was largely developed to reach this objective. This can be achieved by adapting the channel architecture and sorting cells using DEP, fluorescence or magnetic-based methods[211–214] but here we only describe examples where material surface modifications were used.

Optical tweezers were used to separate single yeast cells, which were further immobilized in a thermosensible hydrogel using a transparent microheater placed under the channels. The major interest of this approach is that single cells can be further collected and analyzed by switching off the microheater.[215]

The affinity of different cell types (endothelial cells, fibroblasts, smooth muscle cells) for different adhesion peptides was used to develop an adhesion-based negative selection method.[201,202,211] REDV (Arg-Glu-Asp-Val), VAPG (Val-Ala-Pro-Gly), and RGDS peptides were coated inside spiral-shaped microfluidic channels designed for a three-stage separation process. This process was based on the connection in series of three spiral-shaped channels of different widths. The width of channels for each stage was calculated on the basis of the optimal shear stress for separating the different cell types. Further, a heterogeneous suspension of endothelial cells, fibroblasts, and smooth muscle cells spiked with a small number of adipose-derived stem cells (ADSCs) were injected into the device and the number of each cell type in the suspension emerging from each stage was measured. Finally, by this method it was possible to recover a small number of ADSCs from the heterogeneous cell suspension. The functionalization of PDMS surfaces with aptamers was used in microfluidics to develop devices for enrichment, sorting, and detection of cancer cells.[216,217] The possibility of using an antibody-coated microfluidic chamber to negatively deplete undesired cell types, thereby obtaining an enriched cell subpopulation at the outlet, was demonstrated.[218] Association of antibodies for immunospecific cell capture as well as fibronectin for cell adhesion and growth was used for selective breast cancer cell capture and culture on self-assembled magnetic bead patterns in a microfluidic chip.[219] The immobilization of antibodies on columns was used for the separation of CD34+ and CD34– cells. The parameters such as graft copolymerization, column tilt angle, and medium flow rate were modified to control cell separation. Using this cell sorting system, it was found that populations containing a high density of CD34 could be eluted in the delayed fractions.[220]

Picoliter droplets produced by a gentle acoustic field in agarose hydrogels were used to encapsulate single to a few cells of different phenotypes at rates of 1–10 000 droplets per second.[221] This technique may be applied to extract data from single cells or to generate large cell population from single cells by direct tissue printing.

Finally, an elegant approach of label-free microfluidic method has been developed for the separation and enrichment of human breast cancer cells. The principle of this method is based on the difference in adhesion between normal epithelial and cancer cells on nanostructured polymer surfaces presenting pillars or lines. These surfaces were constructed at the bottom of PDMS microfluidic channels. The detachment of

cells on these nanostructured surfaces with increasing flow rates after some hours of culture was different between normal and cancer cells, the latter showing the lowest adhesion.[222] The differential response of normal and cancer cells to 3D microstructures was recently confirmed by us[40,41] and others.[223] In another approach, multiple arrays of crescent-shaped isolation wells were created in a microchannel to isolate cancer cells from peripheral blood (Figure 6). The gaps of 5 μm in each of the traps ensured the exit of blood constituents because of the highly deformable nature of erythrocytes and because large white blood cells are of comparable dimensions to but more deformable than cancer cells. Clogging prevention was ensured by a pitch of 500 μm between each trap. This microsystem showed a potential of isolation from 40 to 80% of cancer cells depending to the pressure differentials used.[224]

Many microfluidic systems have been developed for sorting bacteria before detecting or identifying them using fluorescent *in situ* hybridization (FISH) or PCR, for example. Given the possibility of cultivating bacteria in suspension in contrast to mammalian cells, these systems are mainly based on liquid-phase separation. Typically, bacteria are individually confined in aqueous microdroplets before sorting.[193,194,225] Separation microfluidic systems exploiting surface properties are rare. As previously mentioned (see Section 3.314.4.2), isolation of persistent microbial cells in a subpopulation has been also realized after physical docking. Using confinement in microscale grooves, the authors isolated individual bacterial cells. Replacement of the initial culture medium by a medium supplemented with appropriate antibiotics killed nonpersistent cells while allowing persistent cells to grow.[210] Bacteria have been also isolated using micro-Petri dishes based on porous aluminum oxide membranes that allow nutrients to pass through, associated to sidewalls obtained by reactive ion etching of acrylic polymer[226] or UV polymerization of PEG.[208] In these microwells, single bacteria or small colonies can be micromanipulated for specific detection or identification using immunorecognition, for example, and for further selection.[226] An elegant approach, which nevertheless does not allow separation of bacterial cells but permits their identification, allowing further selection, was reported by Grow *et al*. This approach is based on surface-enhanced Raman scattering (SERS) microscopy for label-free detection of bacteria and their toxins. After biomolecule or/and cell capture by the usual selective ligand–receptor affinity, pathogens and toxins could be individually identified by their SERS fingerprints. Moreover, the SERS fingerprint reflects the physiological state of a bacterial cell. For example, changes in pathogen virulence or viability in response to specific growth conditions can be then identified by this method.[227]

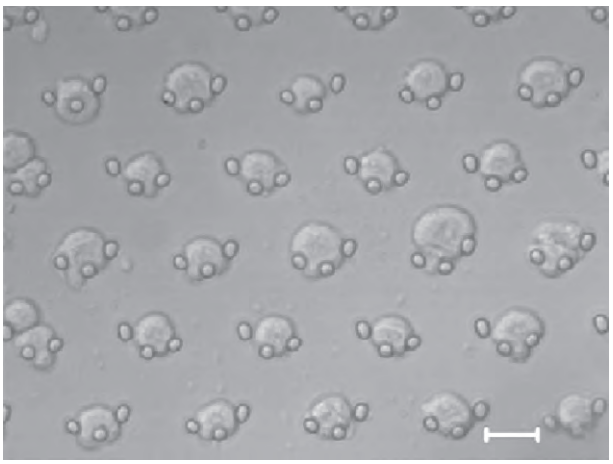

Figure 6 Cancer cell isolation and microsystem efficiency characterization. (a) Overview of the cell isolation region showing mostly single cells trapped in each crescent-shaped structure. (Scale bar represents 20 μm.) Reprinted with permission from Tan, S. J.; Yobas, L.; Lee, G. Y. H.; Ong, C. N.; Lim, C. T. *Biomed. Microdevices* **2009**, *11*, 883–892.

3.314.4.4. Cell Transfection

Besides the possibility of analyzing gene expression on single cells and even on single-cell processes such as filopod, there exists a need for gene transfection in single cells. Several methods have been developed to introduce nucleic acids into adherent cells, such as chemical-based transfection, particulate-based methods, electrotransfer, sonoporation, and electroporation. The possibility of transferring gene using microspiked electrodes has been demonstrated.[228] The combination of a novel microfluidic device and lipoplex-based transfection method allowed improving the transfection efficiency of primary rat cortical neurons.[229] However, most transfection studies on microfluidic or BioMEMS platforms were based on electroporation,[230] some of them exploiting ionic conductivity. Moreover, one difficulty is to adapt these transfection methods to microwell arrays. A nozzle array was micromachined in silicon or plastic to develop an electrosonic ejector microarray for gene delivery. The device comprises piezoelectric transducers for ultrasound wave generation, a reservoir for storing the sample mixture, and a set of acoustic horn structures that form the nozzle array. When the device is driven at a particular resonant frequency of the acoustic horn structures, the sample containing the mixture of cells and transfection agents is ejected from orifices located at the nozzle tips enabling gene transfection.[231] Jain *et al.* have recently described proof-of-principle experiments on 484-microwell arrays with electroporation-ready transparent substrate. They showed that it was possible to achieve highly efficient parallel introduction of exogenous molecules into human cell lines and mouse primary macrophages.[232]

3.314.4.5. Contact Guidance/Cell Migration

Nano and microstructured substrates have been developed to control and analyze the contact guidance and cell migration of diverse cell types. All adherent cell phenotypes are susceptible to orientate themselves and to migrate on anisotropically structured substrates. Notably, the contact guidance capacity has applications for directing axon outgrowth and migration of neurons and permitting nervous regeneration of injured tissues.[71,84–86] The study of this textural guidance has been carried out also using BioMEMS and microfluidic systems.[214,233] Mammalian neurons showed two different growth regimes as a function of textural features (Figure 7). On surfaces presenting posts of 100 μm diameter separated by 200 μm spacing,

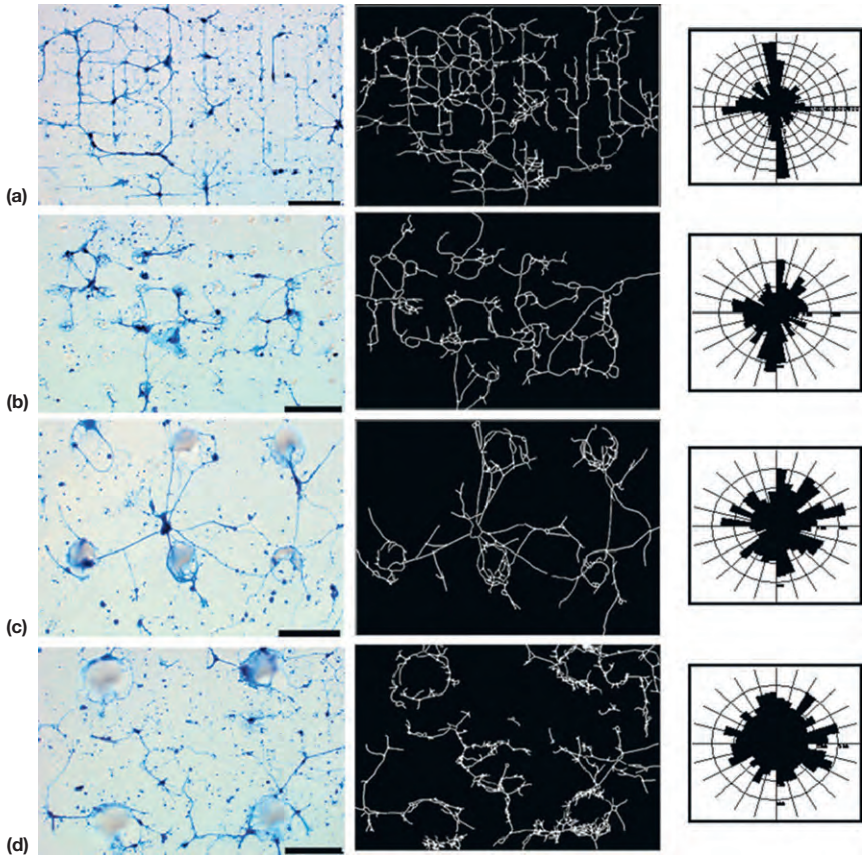

Figure 7 Optical micrographs, under the same magnification and light settings, of hippocampal neurons plated on glass substrates patterned with conical posts of PDMS (first column), the corresponding trace of neuronal networks on patterned substrates (Neurolucida) (middle column), and subsequent polar histograms (third column) representing branching angle characteristics of the neuronal network (Neurolucida Explorer) created from each trace. Polar histograms visually represent the amount of process length (scaled to total process length for each examined cell network) at a given branching angle range. (a) 10 mm diameter, 10 mm spacing; (b) 20 mm diameter, 40 mm spacing; (c) 50 mm diameter, 100 mm spacing; and (d) 100 mm diameter, 200 mm spacing. Scale bar is 90 mm. Reprinted with permission from Hanson, J. N.; Motala, M. J.; Heien, M. L.; Gillette, M.; Sweedler, J.; Nuzzo, R. G. *Lab Chip* **2009**, *9*, 122–131.

neuronal outgrowth showed a process of wrapping and looping around posts but with a low alignment of the process. On the contrary, the smaller the feature size (until $10 \times 10\,\mu m$), the more the process appeared to migrate directly to the posts as they follow the pattern.[233] This capacity was used to isolate axons and to allow their direct analysis after separation from the rest of cells by 1D or 2D electrophoresis, western blot, and RT-PCR.[214]

Cell migration is really important, notably in wound healing of soft tissues such as the skin. The influence of surface features on cell migration has been described in **Section 3.314.2**. A recent work has described the development of a microchannel-based device for the study of cell migration on defined surfaces.[234] PDMS microchannels were coated with ECM molecules before inoculating with human SaOs-2 osteosarcoma cells or mouse 3T3 fibroblasts. The significant advantage of this microfluidic-based technique was its ability to maintain a virgin surface prior to the commencement of the cell migration assay. Cells were first inoculated and cultured in a main chamber connected on each side to five migration channels. The medium did not enter the migration channels because surface tension prevented spontaneous flow down the channel opening. Thus after some hours of adhesion inside the main chamber, the migration channels were backfilled with the culture medium and photographs were taken at T_0 and after 18, 24, and 36 h to quantify cell migration. The analysis of cell migration showed that 3T3 and SaOs-2 cells migrated at different rates on various surfaces. The highest migration rate was $11\,\mu m\,h^{-1}$ for fibroblasts on untreated glass, collagen I, fetal bovine serum (FBS), and FBS blocked with bovine serum albumin (BSA), whereas the highest rate was $5.5\,\mu m\,h^{-1}$ for SaOs-2 cells on collagen I, collagen IV, collagen IV blocked with BSA, FBS, and FBS blocked by BSA.[234] A microfluidic PDMS imaging chamber was developed for the direct observation of chemotactic transmigration.[235] The chamber consisted of two channels separated by a vertical barrier with multiple bays of pores with widths varying from 6 to 16 μm and lengths varying from 25 to 50 μm. The cells were plated in the channel on one side of the barrier, while the chemoattractant was flowed through the channel on the other side of the barrier. The chemotactic transmigration of breast-cancer cells was studied in presence or absence of blebbistatin, which is an inhibitor of myosin II. Two different rates of cell migration through narrow pores were identified.

Either the cell body rapidly contracted to fit within the pore, or the cell continued to extend through the pores until the cell body was slowly pulled behind it. This microfluidic system is particularly interesting since it can improve dramatically the imaging potential relative to other *in vitro* transmigration systems such as Boyden chambers.[235] The same approach of barrier with pores was used to study the migration of cancer cells after coating the microgaps with matrigel.[236] 3D chemotaxis studies were developed using an agarose-based microfluidic platform. A gradient was preestablished in an agarose layer above the cell compartment before adding the 3D cell-containing matrix based on collagen and matrigel.[237]

Differences in cell migration velocity and flow direction under electrophoretic forces have been exploited for sorting cells. Although sorting is performed in suspension and is highly dependent on the buffer ionic strength, the chemical properties of the material surface is also of high importance for an efficient sorting since electro-osmotic flow is dependent on the surface charge of the material. In this study, polymethylmethacrylate (PMMA) and polycaprolactone (PC) were used. Their surfaces were chemically modified by the introduction of ionizable groups on the surface in order to reach appropriate electroosmotic flow. With this system, selective introduction of *E. coli* and red blood cells (RBCs) into the device's microchannel was achieved.[238]

Microfluidic devices provide an indispensable and elegant way for studying bacterial chemotaxis. In a basic research work, Takeuchi *et al*. were able to control the shape of filamentous *E. coli* (phenotype resulting from cephalexin antibiotic supplementation). Bacteria were cultivated in agarose or PDMS microchambers with diverse topographic shapes and organizations creating various shapes of confinement, and they adopted the shapes of the structures (zigzags, sinusoids, spirals) and retained them even after releasing.[239] Cheng *et al*. proposed a three-channel system created by patterning on a thin piece of agarose gel. One extreme channel was filled with buffer and the other one with attractant chemical (α-methyl-DL-aspartate), while bacterial cells were injected in the central channel. Diffusion of the attractant molecule through the hydrogel led to a concentration gradient in the central channel, which resulted in higher concentration of bacteria at the wall closer to the source channel of the attractant molecule.[172] The influence of the confined environment on the development and the migration of bacterial colonies has also been studied in a microfluidic chemostat displaying chambers of various shapes but identical depth of 1 μm, which was close to the diameter of the bacteria. Surprisingly, the orientation of cells was shown to be anisotropic at high densities, and was dictated by the chamber walls and the locations of chamber exits. This self-organization, which probably increases the access of nutrients into and the evacuation of waste out of the colonies, may be crucial for the early stage development of biofilms in small, confined growth niches.[240] Park *et al*. investigated also chemotaxis of bacterial colonies in confined environments. Using microstructured PDMS devices creating a maze, starved bacteria were shown to form colonies in the smallest confining structures. This organization was demonstrated to be the cell's response to a gradient of chemoattractant that bacteria excrete in an environment depleted in exogeneous nutrients. Bacteria actively moved and collapsed into the small cavity to form colonies, rather than waiting until the bulk density of bacteria reached the necessary threshold. Such behavior may be critical for bacterial survival during periods of stress.[158]

3.314.4.6. Cell Mechanobiology

Materials have been used to demonstrate the cell mechanics, the capacity of cells to apply mechanical strength to their environment, and the influence of the mechanical characteristics of their environment on the cells themselves.[241] Microsystems are an excellent means to deliver physical cues that affect cell mechanics, such as fluid flow, substrate topography, and stiffness, to create *in vitro* models for probing the mechanics or measuring the intrinsic mechanical properties of cells.[242] There are a wide variety of techniques available to quantify mechanical force on single cells *in vitro*.[241,243] BioMEMs have been also developed with this objective.[244] Among them, atomic force microscopy (AFM) allows characterization of the viscoelastic properties of different cell types.[245,246] A uniaxial microsystem was developed recently for imaging cell response in real time during quantitative force–displacement measurements. The viscoelastic response of fibroblasts measured using this device fitted well with the previously published values.[247] Cell deformability is an important biomarker that can be used to distinguish between healthy and cancer cells. A microfluidic channel design was used to study the biorheological behavior of benign breast epithelial cells and nonmetastatic tumor breast cells.[248] The time taken for the cell to squeeze into the microchannel as well as the speed of the cell flowing through the microchannel was measured, which demonstrated the difference in stiffness between benign and cancerous breast cells, the latter being more deformable.[248]

Culture of cells on flexible substrates was also used to demonstrate the capacity of cells to apply mechanical forces on their environment. The first demonstration of that was done by Harris *et al*.,[249] who observed that fibroblasts were able to wrinkle the silicone substrates upon which they were crawling. Alternatively, flexible posts were made in PDMS.[250–252] Platelets play an important role in hemostasis by forming a thrombotic plug that seals the vessels. A recent paper describes a means to measure the contractile force generated by platelets using a flexible post force-sensor array. By measuring the volume of the clot formed between posts from the images, the force applied per platelet was calculated to be 2.1 ± 0.1 nN after 60 min.[251] The forces of heart muscle cells suspended between elastic micropillars was evaluated to be 140 nN in the relaxed state and 400 nN in the contracted state (**Figure 8**).[250] The use of cytoskeleton inhibitors impedes the flexion of elastomeric microneedle-like posts by cells. By this approach, it was shown that cell morphology regulates the magnitude of the traction force generated by cells.[252] This approach was used recently to measure and manipulate forces from microtissues consisting of cells encapsulated within 3D micropatterned matrices and anchored to the tips of microcantilevers. Microcantilevers were used to simultaneously constrain the remodeling of the collagen gel and to report forces generated during this process. This system allowed highlighting the complex and dynamic relationship between cellular forces, ECM remodeling, and cellular phenotype, giving essential input for future engineering of 3D tissues.[253]

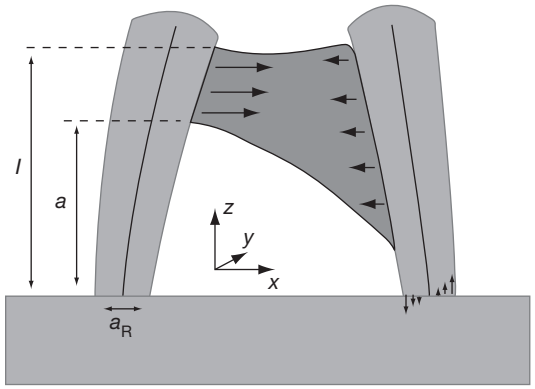

Figure 8 Basic features of the micropillar system developed by Kajzar *et al.*[250] Two micropillars (light shaded) connected by a cell (dark shaded). Cells apply transversal tensions (solid arrows) to both beams (neutral axes are depicted). The torque acting on each beam is balanced by normal tensions within the beam, depicted for the right beam. Further shown are the coordinate system and the geometrical parameters of the beams. Reprinted with permission from Kajzar, A.; Cesa, C. M.; Kirchgessner, N.; Hoffmann, B.; Merkel, R. *Biophys. J.* **2008**, *94*, 1854–1866.

The influence of substrate rigidity on cell migration and differentiation was previously described in Section 3.314.2. However, several microsystems have been developed recently for studying the influence of mechanical stimuli to cells. Individually programmable cell-stretching microwell arrays have been developed. They display flexible bottom chambers made of PDMS that can be deformed by pins moving upwards to apply strain to the cells and actuated by a refreshable Braille display.[254] Similarly, Moraes *et al.* developed a novel microarray capable of simultaneously applying cyclic equibiaxial strains ranging from 2 to 15% to small populations of adherent cells. The array consisted of 9×12 loading posts suspended over an actuation cavity within a 6.5 cm^2 area. Positive pressure applied to this cavity distended the loading post upwards, deforming a flexible cell culture substrate.[255,256] This approach was adapted for 3D cultures. As a first demonstration of this technology, nuclear and cellular deformation in response to applied compression was assessed in C3H10T1/2 mouse mesenchymal stem cells encapsulated within PEG hydrogels.[255,256] For more information on these aspects, the reader is referred to recent reviews.[79–81,241]

Compared to mammalian cells, the behavior of bacteria under mechanical stress has been rarely studied, and the main studies have been conducted using AFM. To our knowledge, BioMEMs and microfluidic devices have not been applied to this topic. However, microsystems display several advantages to address this question since hydrodynamic flow and physical confinement can be simply used to provide the necessary mechanical stress to be applied. The study published by Takeuchi *et al.*[239] on individual filamentous cells that adopted the shape corresponding to the organization and shape of the microstructures present in the microfluidic chamber can be considered as a preliminary study on this topic. Moreover, some microsystems already exist that could be used for such applications, such as the microtubes developed by Huang *et al.*[154,170]

3.314.4.7. Use of Cell Properties

Synthesis of the smallest machines capable of producing work is a challenge of today's interdisciplinary research. Biomimetic artificial machines built with hybrid components combining synthetic and biological materials offer the opportunity to develop pumps, microactuators, or microrobots using cardiomyocytes,[87,88,257–260] vascular smooth muscle cells,[258–260] or insect dorsal vessel tissue, the latter presenting the advantage to work at room temperature.[261] A pioneering work in this field was published in 2005. One hybrid machine powered by a muscle bundle was fabricated through an elegant assembly procedure. The originality of this work was that the muscle bundles were formed directly on the silicon cantilevers starting from single muscle cells. A photolithography approach was used to produce a free-standing silicon microcantilever coupled to a solid support at one end and a post a few micrometers away from the end of the cantilever, which were further filled with PNIPAAm polymer and bridged with a thin gold strip. Since the muscle cells were not able to adhere to the polymer, they aligned along the gold strip and formed mature muscle bundles. By lowering the temperature below 32 °C, the PNIPAAm polymer dissolved and released the microcantilever coupled to the post by the gold bridge covered with muscle bundle. This approach allowed the realization of the first microsystem that moves as a consequence of collective contraction of muscle bundles.[262]

Another microactuator was developed based on a cardiomyocyte-polymer hybrid.[87,88] An Au/Cr–PDMS composite membrane in the shape of a dome shape was fabricated on a bulk-etched cavity of a silicon wafer. After coating the gold surface by SAMs, it was covered with fibronectin and gelatin for permitting rat cardiomyocyte adhesion. The beating of cells started at 2 days after seeding and continued over 5–6 days. During this time, the beating of cells actuated the membrane in a vertical movement of about 8 µm, forming a net flow rate in the chamber of approximately 0.226 nl min^{-1}.[87,88] By culturing cardiomyocytes around a hollow PDMS sphere connected to Teflon capillaries, it was possible to generate a flow by each chamber contraction (Figure 9).[258–260] A microrobot was developed by designing a backbone in PDMS consisting of three strips of 'legs' connected across a 'body.' The backbone surface was grooved and coated with fibronectin in order to favor the adhesion of cardiomyocytes. This approach enabled the microrobot to 'walk' continuously for over 10 days.[257]

Several bacterial properties have been proposed to be used in BioMEMs or microsystems. Bacteria are able to produce diverse biominerals and magnetic particles, as well as a large range of bioactive molecules including therapeutic agents, surfactants, and lubricants. These components can be synthesized and used directly in a microsystem (example of biosurfactants and biolubricants) or used as template (example of extracellular polysaccharides) or scaffolds (example of functionalized flagella).[263] Microorganisms can be also used as motors, as precisely described by Spetzler *et al.*[264] in their review. In order to avoid eventual microorganism contaminations, 'ghost' mycoplasma cells obtained by membrane permeabilization were even used by Uenoyama *et al.* They demonstrated that mycoplasma cells were still capable of gliding movement

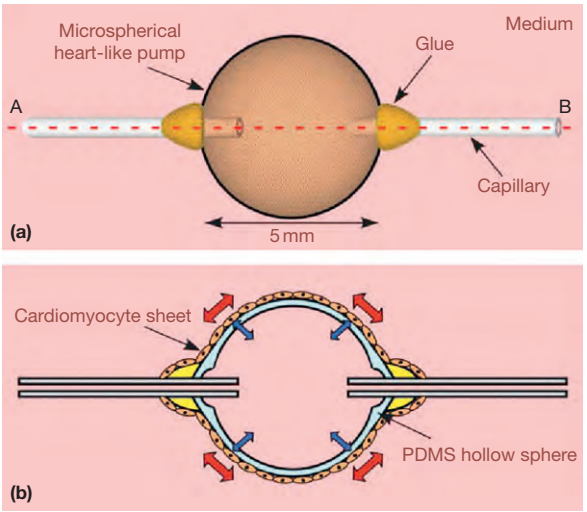

Figure 9 Design of a microspherical heart-like pump. (a) Schematic view. (b) Cross-sectional view along line A–B. A cultured cardiomyocyte sheet of contiguous pulsating cells is rolled onto a hollow sphere of poly(dimethylsiloxane) (PDMS) elastomer and allowed to adhere. The sphere is strained by the collective contractile motions of the attached cardiomyocyte sheet, and the fluid volume inside the hollow sphere chamber is reduced, producing flow into the attached Teflon2 capillary. To detect the flow generated by each chamber contraction, motion of PS microspheres is followed in the capillaries using *in situ* microscopy. The chamber diameter is of the order of millimeters. Reprinted with permission from Tanaka, Y.; Sato, K.; Shimizu, T.; Yamato, M.; Okano, T.; Kitamori, T. *Lab Chip* **2007**, *7*, 207–212.

and proposed therefore the replacement of living cells in microbial motors.[265] More frequently, bacteria have been used as a sensitive detection tool for toxicants and other pollutants. Several biosensors have been developed for water toxicity analysis, based on the use of particular bacterial strains engineered for being able to generate signals in the presence of specific pollutants.[266–268] Typically, a cascade of biological reactions is induced in the genetically engineered bacteria by the presence of toxicants, producing a directly detectable green fluorescent protein[265] or an enzyme able to convert a substrate to an electroactive species which can be further detected by an appropriate system.[266,267]

3.314.5. Conclusions

In recent years, biological and biomedical applications of micro and nanotechnology have become increasingly prevalent because it is now easy to develop devices with feature scales relevant to cells and bacteria and offering ease of *en masse* fabrication, small device size, and facile incorporation of integrated circuit technology. Moreover, the use of microfluidic perfusion in these microsystems allows controlled delivery and removal of soluble molecules in the extracellular environment and the use of small culture volumes. Finally, microsystems present several advantages since cell harvesting, media exchange, and cell subculturing procedures are easier to handle than in conventional *in vitro* cell culture systems. Here, we have highlighted how microsystems allow developing new culture devices and present a very high potential for cocultures or 3D cultures that are both difficult to achieve with classical culture methods. We have shown that working on materials and surface modifications of these materials is one of the major ways besides microfluidics to improve the growth capacity of cells inside microsystems. Moreover, BioMEMS or microsystems are the ideal tools for separating, docking, and analyzing isolated cells from a heterogeneous population. Aside from physical approaches, material modifications such as surface functionalization or microstructuration are promising routes for improving cell sorting and cell docking. Nano- and microstructuration of cell substrates are also a means to control and measure cell migration and contact guidance. Similarly, materials with different stiffnesses are particularly convenient for measuring cell mechanics, the capacity of cells to apply mechanical strength to their environment, or the influence of the mechanical characteristics of their environment on the cells themselves. By combining synthetic materials with biological ones, such as muscle cells, it is now possible to develop artificial machines with autonomous activity, such as microactuators or microrobots. The potential of BioMEMs and microsystems for controlling and measuring bacterial functions is also very important. Actually, the research in this field is highly dynamic and perhaps more developed than on mammalian cells, but the control of bacterial cells by using the material properties is less developed probably because bacteria are less adherent than mammalian cells. Finally, the materials currently used for microsystems are relatively restricted in term of diversity, and the field should profit from the research already developed in materials science. This has already started with the use of hydrogels or functionalization of silicon and glass substrates and the field should benefit more and more from the discoveries of new materials and new functionalization methods. This should further increase significantly the potential of materials in the field of BioMEMs and microsystems for applications in biology and medicine in the near future.

Glossary

Actin A protein present in all eukaryotic cells that compromises the cytoskeleton of a cell. Actin monomers polymerize together to form a double helical strand known as a microfilament or thin filament. The pointed end of actin has slower rate of adding new actin monomers to the strand than the barbed end.

Adherens junction Cadherin and catenin protein complexes at the cell membrane that serve as intracellular attachments linking neighboring cell cytoskeletons together. Traction forces can be transmitted from one cell actin structure through an adherens junction to a cell in contact.

Extracellular matrix Network of complex macromolecules that form a scaffold that cells adhere to. Common structural extracellular matrix proteins are collagen and elastin and common adhesive proteins are fibronectin and laminin.

Focal adhesion Large protein assemblies at the cell membrane that anchor a cell to the extracellular matrix through integrin receptors. Focal adhesion formation is a GTPase-dependent process and serves to transmit forces between the extracellular matrix and the cell's cytoskeleton.

Focal adhesion kinase (FAK) A tyrosine kinase present at focal adhesions that promotes turnover of cell contacts with the extracellular matrix.

Microcontact printing Protein transfer technique akin to a stamp and ink procedure that is used to control available binding sites for biomolecules or cells. A soft elastomer stamp has a protein absorbed to it and is put in contact with the target surface transferring the protein pattern over.

Myosin Motor proteins that interact with actin filaments for motile processes within a cell. Many isoforms exist, with myosin I and myosin II being the most frequently referred to. Myosin I has a single head binding domain and an ATP independent actin-binding site. Myosin II comprises two heavy chain ATPase domain heads and four light chain tails. With ATP present, heavy chains alternate attachment to an actin filament and walk along the filament to generate force.

Rho A GTPase protein encoded by the Rho genes that regulates actin dynamics. Downstream protein signal regulators include Dia1 and the ROCK subfamily. Their broad range of action affects cell adhesion, gene expression, motility, and proliferation.

Soft lithography Replication of a surface or topography by applying a liquid elastomer onto a surface, curing it, and then peeling the surfaces apart to form a negative mold. Repeating this procedure with the negative mold reproduces the original features.

Traction force The force exerted by a cell through its actin–myosin contractile apparatus that allows it to migrate. Traction forces are transmitted through the focal adhesions of a cell.

Abbreviations

AFM	Atomic force microscopy
BioMEMS	Biological microelectromechanical systems
DEP	Dielectrophoresis
ECM	Extracellular matrix
ELISA	Enzyme-linked immunosorbent assay
F-actin	Filamental actin
FAK	Focal adhesion kinase
G-actin	Globular actin
GAG	Glycosaminoglycan
GFP	Green fluorescent protein
GTPase	Guanosine triphosphatase
MEMS	Microelectromechanical systems
MTC	Magnetic twisting cytometry
PDMS	Polydimethylsiloxane
ROCK	Rho kinase
UV	Ultraviolet

3.315.1. Introduction

Cells respond to biochemical and biomechanical stimuli through changes in their proliferation, apoptosis, differentiation, secretion, contraction, motility, and adhesion. To better understand these changes in cellular behavior, researchers have developed biological microelectromechanical systems (BioMEMS) that provide a high degree of control over the stimuli that cells receive from their surroundings. Cells are cultured commonly on dishes, which are not only stiffer and flatter than a cell's native tissue, but they also lack the appropriate chemical and mechanical signals that cells experience *in vivo*. The techniques and processes from BioMEMS can provide a means to control a wide variety of microenvironmental cues in order to better understand the nature of the cellular response.[1,2] Findings that have come from the use of BioMEMS have influenced the design of biomaterials and tissue-engineered constructs because engineers and scientists can begin to incorporate the appropriate interactions for cells.

Cells in living tissue have different levels of cues than their counterparts in culture. The vascular and lymphatic systems provide cells with the appropriate nutrients and hormones for their survival and function. Likewise, the levels of oxygen and growth factors in culture can be excessive for cells and overdrive their response. These chemical interactions influence cell behavior by engaging surface receptors that activate specific signal pathways. Gradients in signal molecules can also serve to attract cells to locations or activate particular responses. In addition to these soluble factors, the insoluble cues that a cell encounters from its extracellular matrix (ECM) are different than those in tissue. Tissue culture dishes are coated usually with one kind of ECM protein such as collagen or fibronectin or reconstituted extracts such as Matrigel, whose contents are poorly defined. These insoluble factors are not well-matched to the different variety of adhesive ligands that a cell type may require. Moreover, cells experience a variety of extracellular forces from their surroundings that act on the mechanosensory structures in a cell that influence its behavior.[3,4] These forces come from the range of physiological phenomena such as pressure forces from muscle contraction, shear forces from vascular hemodynamics, traction forces from surrounding cells, or stretching forces from musculoskeletal locomotion. Emerging evidence shows that biomechanical factors such as substrate stiffness and cell geometry can influence cell functions such as migration,[5] cytokinesis,[6] differentiation,[7,8] and growth.[9,10] These findings are important because they implicate that cells in one kind of environment respond differently than those in another. Since the influence of different factors must be careful examined, robust means to explore these factors are required.

BioMEMS has provided important insights in improving the development of biomaterials or tissue-constructs to better represent the cellular microenvironment, either by closely matching the native one or specifically activating a cellular response. Many of these tools are derived from microelectromechanical systems (MEMS) such as actuators or posts but have been adapted by researchers interested in probing cells at the nanoscale. BioMEMS devices can be used to measure traction forces that cells produce against a surface, which is important to maintain stable adhesion against a substrate. These tools can also be incorporated with techniques to impart forces onto the surface of a cell to examine the mechanotransduction response. Cell culture and microfluidics can be combined to create chemical gradients or shearing forces that cells experience *in vivo*. In all these cases, BioMEMS provides a powerful way to manipulate physical forces and chemical factors that interact with a cell to better understand the role of a cell's microenvironment.

3.315.2. Cell Adhesions to the Microenvironment

Cells in living organisms bind and adhere to a network of ECM proteins. This meshwork of protein provides the structural scaffold necessary for cells to form stable adhesions (**Figure 1**). ECM proteins include collagen, elastin, laminin,

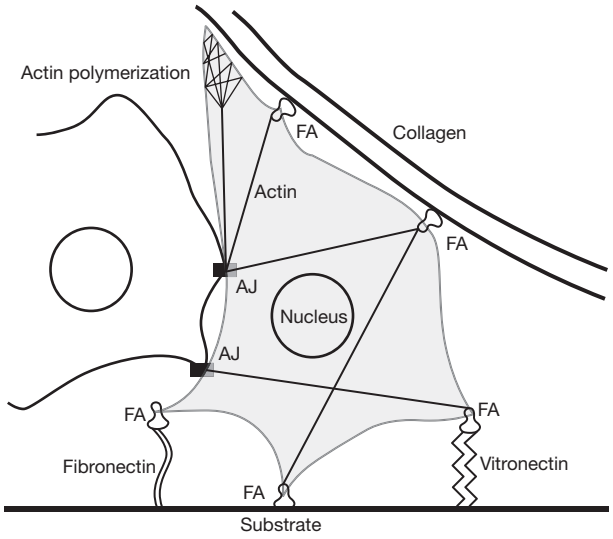

Figure 1 Cells adhere to the extracellular matrix through focal adhesion (FA) sites that connect intracellularly to the actin cytoskeleton. Neighboring cells connect their cytoskeletons at adherens junctions (AJ). A cell changes its shape in order to spread or migrate by polymerizing its actin filaments so that they can push against the cell membrane.

fibronectin, vitronectin, and many other proteins to varying degrees of concentration and spatial organization. The main function of the ECM is to provide cells with ligands for the binding of their integrin receptors, which are not only essential for cell adhesion but also activate signaling pathways that affect cell function.[11] Integrins also coordinate activities within a cell's cytoskeleton, such as actin filament polymerization and focal adhesion assembly, which are important in stabilizing the adhesion of a cell against a substrate.[12,13]

When an integrin receptor contacts a ligand site on an ECM protein, signal pathways associated with RhoGTPases Rho and Rac are activated. In eukaryotic cells, there is an abundant quantity of the monomeric, globular actin (G-actin) within the cell. Rho and Rac can activate actin-binding proteins that cause G-actins to bind to each other to create filamental actin (F-actin).[14] F-actin elongation occurs as more G-actins become recruited to the growing filament, but with the pointed end growing faster than the barbed end. F-actin growth can be prevented by capping proteins that inhibit the addition of G-actin at the free ends, severing proteins that cleave the filament at points along its length, or depolymerizing proteins that promote the dissociation of G-actin from the ends.[15] This dynamic remodeling of actin allows the filaments to push the cellular membrane forward during spreading, a critical component of cell survival[9] and migration. It also provides the freedom for the cell to adapt its structure to response to its surroundings.

When myosin and α-actinin bind to F-actin, the structure is called a stress fiber and has the ability to shorten its length to create tension inside the cell. Myosin acts to slide two or more F-actin filaments past one another so that the cell can contract.[16] A cell then produces traction forces by transmitting its cytoskeletal tension from actin and myosin to its focal adhesions where integrins are clustered together and firmly bound to ligands in the ECM. The major signaling pathway for stress fiber regulation is Rho and its downstream effectors Rho kinase (ROCK or ROK) and mDia1.[14] The dual action of ROCK directly phosphorylates myosin light chain and inhibits myosin light chain phosphatase. The Rho effector mDia1 serves as a nucleating agent at the cell membrane for new actin polymerization.[17]

Focal adhesions are not static structures, but respond to ligand binding and applied forces. They are large, multiprotein complexes that structurally connect the actin cytoskeleton to the ECM and can activate signaling networks that are essential for morphogenesis, migration, proliferation, differentiation, and survival.[18] Focal adhesions form at the cytoplasmic side of the cell membrane after integrins bind to the ECM. Focal adhesion proteins such as talin, vinculin, and paxillin colocalize with integrins and help to improve the bond strength of the adhesion site by gathering many integrins within a close proximity and also by mechanically coupling the integrins to the actin.[13] Interestingly, cytoskeletal tension from actin and myosin is needed to promote the growth of focal adhesions, indicating that these structures have a mechanotransduction response to force. Focal adhesions also serve as docking sites for signaling proteins such as focal adhesion kinase (FAK) and Src that regulate tyrosine phosphorylation pathways and guanine–nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) that regulate Rho GTPases.[18] Specifically, an important balance exists between pathways associated with Rho and FAK, which serve to encourage adhesion reinforcement or disassembly. Rho activity increases focal adhesion formation,[19] but FAK can act to suppress Rho and therefore promote detachment of focal adhesions during cell motility.[20]

The compliance in ECM proteins gives some insight into how cells interact with their microenvironment. At the molecular level, ECM proteins are surprisingly stiff materials. Collagen, for example, has an elastic modulus of around 5 GPa,[21] but as a reconstituted gel, it is significantly softer. Comparatively, bone is between 10 and 20 GPa and soft tissue is between 10 and 100 kPa,[22,23] so there is a significant range of stiffness that cells can experience in their native environment. Common engineered materials used in biological applications such as titanium alloy and stainless steel are 114 and 190 GPa, respectively[24] and many plastics, including polystyrene which is used in tissue culture dishes, have an elastic modulus between 2 and 4 GPa. Thus, it is important to be aware that in designing biomaterials and tissue-constructs that their material properties need to be matched to the native tissue so as to illicit the appropriate mechanotransduction effect on the cells.

The compliance of the ECM has been shown to play a role in the dynamic binding of a cell's integrins. Certain ECM proteins such as fibronectin can be unraveled under tension to reveal new ligand sites on which a cell can bind.[25] These 'cryptic' sites become available under force and are therefore hypothesized to be regulated by traction forces of a cell or external forces from physiological motion.[26] Cells have also been observed to bind differently to synthetic matrices that are highly compliant. On polyacrylamide gels, cells show changes in their spreading and motility that depended on the environmental stiffness (**Figure 2**).[27] Focal adhesion structures are also noticeably reduced on softer gels and have lower kinase activity as compared to cells on stiffer gels or plastic tissue culture dishes. This suggests that ECM stiffness increases focal adhesion formation in addition to cytoskeletal tension. In fact,

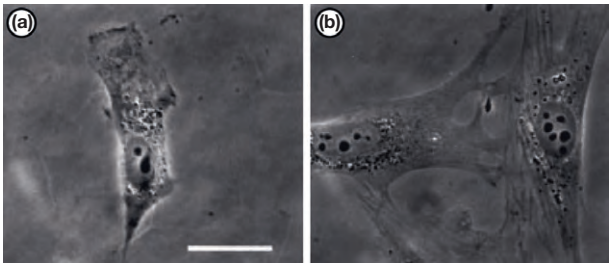

Figure 2 (a) Cell on a soft substrate spreads less than (b) cells on a stiff substrate. Scale bar is 10 μm. Reproduced from Pelham, R. J., Jr.; Wang, Y. *Proc. Natl. Acad. Sci. USA* **1997**, *94*, 13661–13665 with permission, Copyright 1997 National Academy of Sciences, USA.

gradients in stiffness can also affect the direction of cell migration as cells have been observed to move toward stiff regions and away from softer regions.[5]

Much of the native interaction that cells have with their microenvironment is lost with traditional cell culture. Common procedures seed cells onto polystyrene dishes or flasks and grow the cells in an incubator to maintain correct temperatures and pH levels. Polystyrene dishes are convenient, cost-effective, and well-established surfaces on which to culture and observe cells. Manufacturing standards have made it possible for dishes from different suppliers to elicit the same cell attachments and behaviors while remaining inert to cells and chemicals. Polystyrene is certainly the most widely used surface to culture and experiment with cells, offering high optical clarity and visibility, and complete compatible with phase light, fluorescent, and confocal microscopy techniques, but it is also a more rigid environment than cells experience *in vivo*.

By departing from traditional culture approaches, it has been possible to observe how cells regulate their function in response to the stiffness of their environment. Cardiomyocytes improve their contractile performance when plated onto gels that match the stiffness of the native myocardium.[28] Stem cells are able to commit to a neurogenic lineage on soft gels and osteogenic lineages on stiff gels based on their ability to generate cytoskeletal tension.[7] A three-dimensional matrix environment also affects cells for they show reduced levels of cytoskeletal and focal adhesion activities as compared with cells on ECM-coated substrates.[29] Thus, there needs to be a better understanding on the biochemical and biomechanical factors that drives these changes in cell adhesions and BioMEMS can provide important insights for the design of biomaterials and tissue-constructs. For additional information, see **Chapter 4.403, The Innate Response to Biomaterials**.

3.315.3. BioMEMS Devices to Measure Traction Forces

Cell force measurement tools arose in response to observations that cells in culture were motile and so it was likely that they were imparting forces to move. It was suspected that they produced traction forces against the surface of the culture dish, but techniques were limited in measuring these nanoscale forces. The advent of MEMS fabrication techniques provided a means to create tools and sensors that matched the size of the cell. Researchers adopted these techniques to create new tools that followed a common macroscale approach to measure force: direct contact with a flexible, calibrated structure and observation of its deflection under a load. Sensor structures such as these can be fabricated and designed to measure a wide range of physiological cell forces, such as single cell contraction and multicellular interactions.

3.315.3.1. Membrane Wrinkling

A pioneering development that laid the groundwork for future BioMEMS devices was Albert Harris' work in 1980. He and his colleagues observed that cells exerted traction forces by culturing cells on a deformable, silicone membrane substrate.[30] To make the surface, a layer of silicone fluid, polydimethylsiloxane (PDMS), was spread out on a glass coverslip. Flame was then used to cross-link the top layer of the silicone to create a thin, elastic film on top of the remaining liquid silicone film, which acted as a support and lubricant for deflection. Cells placed on this film distorted the top surface and caused wrinkles that were due to the tangential forces they exerted from actin and myosin contraction (**Figure 3(a)**).[31,32] By correlating the membrane wrinkle length with a magnitude of force, the technique was later able to provide a closer measure of the traction forces, but the approach was still semiquantitative.[33] An important finding from Harris' pioneering work was that fibroblast forces were far larger than what is needed for locomotion, in fact two or three magnitudes more. This led to the theory that these strong forces are necessary for the physical remodeling of the ECM.[34] When fibroblasts were seeded onto collagen gels, they observed that the traction forces of the cells pulled the gel into a dense capsule of collagen fibers similar to the formation of wrinkles in the silicone films. They theorized that the traction fields created by the cells can form the aligned collagen fiber structures seen in tissues such as tendons or ligament, rather than relying on an existing matrix to induce the alignment.

A limitation of PDMS wrinkling films is that there is low resolution in measuring traction forces because there exists a mechanical coupling between a wrinkle in a substrate and the traction forces nearby. A traction force is applied at a single focal adhesion of a cell, but the surface strains in the film leads to wrinkling over a wider area. The overlap in strains from nearby traction forces makes it difficult to determine how much each one contributes to a visible wrinkle in the film. The elasticity of the silicone film also means that the traction forces of a cell can cause a strain in the film over a widespread area, which can subject neighboring cells to an external stretch or wrinkled surface topology. Quantifying wrinkles is also a vague approach because it is difficult to interpret what is and what is not a wrinkle due to debris or surface defects in the silicone film.

Refinements were made to the silicone wrinkling technique by using surface markers that enabled a higher resolution and a better understanding of the deformations caused by traction forces. Marker beads were placed on top of the PDMS film to track displacement of the film over a high number of spatial points. To create this substrate, one micrometer diameter latex beads were deposited onto the PDMS fluid and its top surface was cross-linked in a glow discharge chamber.[35] An improved mathematical and statistical model for the deformation of the film used the tracking of the beads, rather than wrinkles.[36] Additionally, the

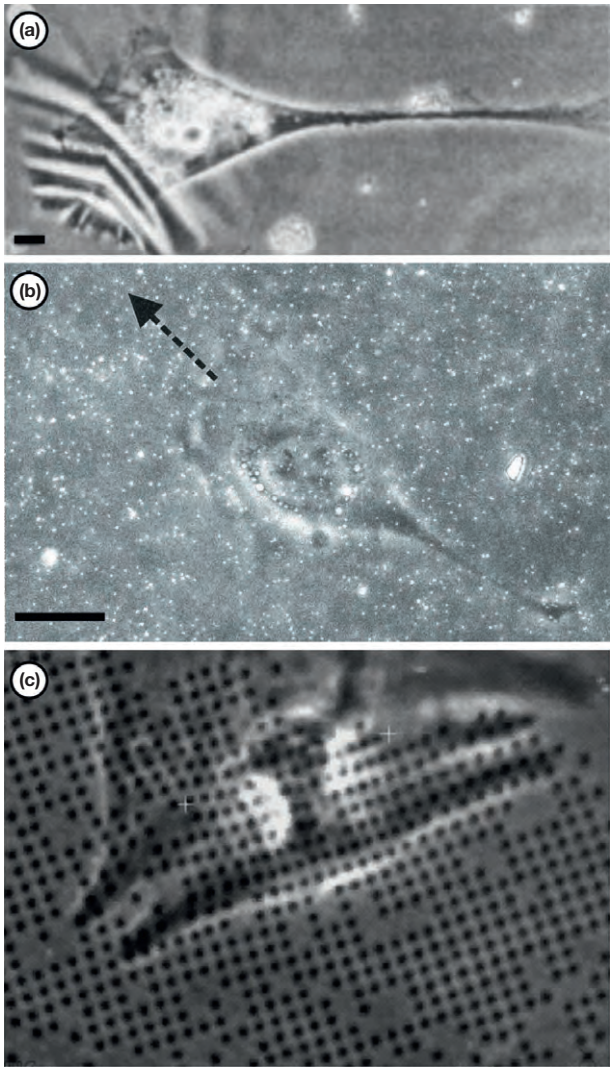

Figure 3 (a) Cell wrinkling of a silicone membrane floating on silicone fluid. Force is orthogonal to the long axis of each wrinkle and the stretch of the traction force correlates with the length of the wrinkles. Scale bar is 10 μm. (b) Traction force microscopy technique with cell on polyacrylamide gel containing embedded fluorescent beads, which act as fiduciary markers of strain at the surface of the substrate. Scale bar is 20 μm. (c) BioMEMS traction force microscopy where marker dots are patterned into a 2-μm grid pitch. Some dots are missing from the fabrication process, but surface strains are evident by the displacements of the markers from their original positions as evenly spaced rows and columns. Adapted from Harris, A. K.; Stopak, D.; Wild, P. *Nature* **1981**, *290*, 249–251; Munevar, S.; Wang, Y.; Dembo, M. *Biophys. J.* **2001**, *80*, 1744–1757; Balaban, N. Q.; Schwarz, U. S.; Riveline, D.; *et al. Nat. Cell Biol.* **2001**, *3*, 466–472.

approach allowed for an order of magnitude improvement in detectable forces compared to wrinkling membranes.

3.315.3.2. Traction Force Microscopy

A popular method to measure subcellular level forces is traction force microscopy which measures traction forces by the distortion of cells on polyacrylamide gels instead of on PDMS films.[37] The gel is mixed with fluorescent beads that are a few micrometers or smaller in diameter and spread out as a thin film on a glass coverslip on which cells can be cultured (Figure 3(b)). To engage integrins to bind and promote cell adhesion, an ECM protein such as collagen or fibronectin can be coated onto the surface of the gel. The completed fabrication process results in a deformable gel on which cells can be cultured and whose embedded fluorescent particles can be tracked to measure cellular traction forces. Cells seeded into this environment adhere to the ECM protein, form focal adhesions and actin stress fibers, and exert cytoskeletal traction forces onto the substrate. The deformation of the gel pulls with it the fluorescent particles. Their positions can be recorded under fluorescence microscopy and compared to the original, undeflected positions of the particles to obtain the deflection field. Calculation of a traction force field from a measured deflection field in an elastic material is known as a Boussinesq problem in the field of mechanics and can be readily solved. Traction force microscopy has been used to show that the forces of a cell increase with stiffness of a substrate, adhesive ligand density, and contact area.[5,38,39] Normal and transformed cells also exhibit distinct patterns of traction forces across the leading and tail edges when migrating with normal cells having organized zones of forces and transformed cells displaying weak disorganized mechanical domains.[40]

Patterns of traceable markers can be generated for traction force microscopy by using a microfabricated stamp from a silicon wafer that has arrays of dot-like features (Figure 3(c)).[41] The stamp can be used to deposit fluorescent material onto the surface of a PDMS substrate to create a uniform array of marker dots. Cells deform the surface, and traction forces can be measured with more accuracy due to the regularity of the pattern as opposed to the random placement of beads in polyacrylamide gels. One disadvantage of traction force microscopy is that it shares the same problem as silicon wrinkling films in that the gels or PDMS is a continuous material and so the solution for the traction forces is difficult to obtain without a degree of uncertainty.

3.315.3.3. MEMS Adapted Tools

MEMS techniques and devices have played a key role in developing an understanding of traction forces. Atomic force microscopy (AFM) was one of the first tools used to reveal cellular properties. Extreme sensitivity and miniscule local sampling area on the order of 0.01 μm^2 means that researchers can use it to sample very localized responses.[42] AFM takes measurements by lowering a nanometer scale tip onto the surface of interest. A piezoelectric sensor detects cantilever deflection and can also impart simple or cyclic deflections to the tip giving a way to impart force as well. The AFM technique opened the field to direct force measurements of properties of whole cells,[43] cell cytoskeletons,[44] subcellular organelles, and biomolecules.[45]

A novel approach is the fabrication of a set of horizontal cantilevers that have micrometer-scale dimensions (Figure 4).[46] Micromachining is used to create the cantilever, which is a manufacturing process where thin layers of polysilicon, silicon dioxide, and metals are deposited onto a wafer and then each layer is selective etched to create a final structure. The horizontal cantilever is built underneath the surface of the device but

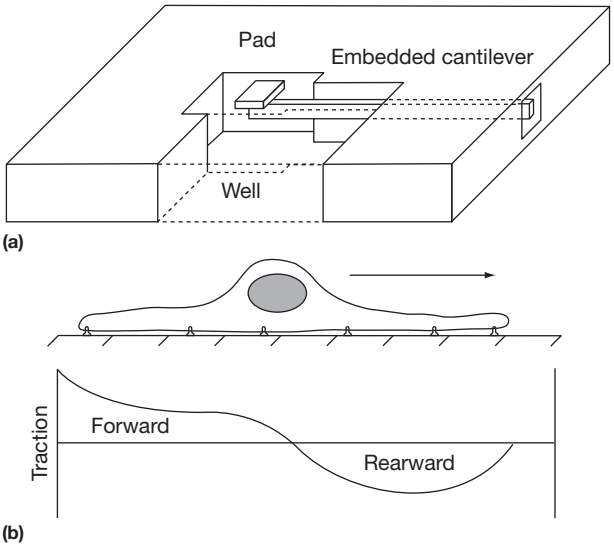

Figure 4 (a) BioMEMS traction force device with embedded, horizontal cantilever inside a well. A migrating cell can attach to the pad at the opening of the well and deflect the cantilever under its traction force. (b) Traction forces of a migrating cell measured with the device show pulling forces at the leading edge and pushing forces at the tail. Reproduced from Galbraith, C. G.; Sheetz, M. P. *Proc. Natl. Acad. Sci. USA* **1997**, *94*, 9114–9118 with permission. Copyright 1997 National Academy of Sciences, USA.

surrounded by a well that was etched to allow the cantilever to freely deflect. A pad is attached at the free end of a cantilever to allow the cell to bind and is used to mark the displacement of the cantilever tip. Cells placed onto this device can adhere and spread on the top surface. As a cell migrates, it comes in contact with a cantilever's pad and forms a focal adhesion. The traction force produced by actin and myosin causes the cantilever to bend. The deflection of the cantilever is readily visible under optical microscopy, which then allows the calculation of traction forces during migration. The use of BioMEMS cantilevers showed that the magnitude of traction forces differs across regions of the cell during migration. As the cell proceeds in one direction, the leading edge creates contractile forces toward the nucleus, increasing this traction force in the region behind the lamellipodia. These traction forces reverse in the rear of the cell, indicating the cell is pushing against the substrate to propel itself. Fibroblast cells move by continuous generation of focal adhesions at the front and release of adhesions at the rear, again through the influence of actin and myosin. The measurement of traction forces by a single cantilever, however, prevents simultaneous force measurement across all regions of the cell as seen with traction force microscopy. The force that is measured can only be determined on an axis perpendicular to the length of the cantilever, so the true strength and direction of the force are not directly resolved.

3.315.3.4. Microposts

Soft lithography can be used to create arrays of vertically aligned PDMS cantilevers, which are referred to as microposts.[47] To form the master, a thick film of photoresist is patterned on a silicon wafer using photolithography to create arrays of microposts that are up to tens of micrometers in height and a few micrometers in diameter (**Figure 5(a)**). Fluorosilane is applied during this process to act as a nonadhesive release layer. Uncured PDMS is poured on top of the microposts features of the master and subsequently cured by heat to create a negative mold with 'microholes.' The negative mold then can be used to replicate the micropost features of the master. PDMS is poured on top of the mold, cured, and then peeled off to create the arrays of PDMS microposts used for cell culture. The elastic stiffness of the posts can be controlled by the physical dimensions of diameter and height of the microposts giving the sensors multicellular capabilities with different cell types.

PDMS is a useful material for BioMEMS researchers due to its high biocompatibility, surface chemistry, and ease of use and fabrication. Favorable mechanical properties include predictable elastomeric properties, thermal stability, gas permeability for cell culture purposes, and optical transparency in imaging and observation.[48] PDMS can be sterilized through several means: immersion in 70% ethanol, UV exposure, or autoclaving.[49] It also has a hydrophobic surface that can be useful in certain applications, but it can also be modified with plasma oxidation to render it temporarily hydrophilic.[50] In microcontact printing, changing the hydrophobicity of PDMS is useful in order to allow proteins to transfer from a hydrophobic PDMS stamp onto a hydrophilic PDMS substrate.[51] In microfluidics, a temporarily hydrophilic surface is desirable to enhance the wetting of the fluid into small channels. Plasma oxidation of PDMS also allows it to covalently bond to other polymers and glass. Ozone treatment can produce a similar result as plasma oxidation, but is significantly slower and does not weaken the PDMS structure.[48] Silane is a common surface treatment for PDMS because it reacts with available hydroxyl groups on the surface to form covalently bonded Si–O–Si molecules on the surface. A wide variety of silanes are available that can be used to create new functional groups on the PDMS surface.[48,52] In replica molding of the PDMS micropost array, the negative molds are treated with fluorosilane in order to ensure easy peeling of the arrays from the mold.

Biofunctionalization of the micropost array is achieved by patterning ECM proteins onto the top surface of the micropost tips. A PDMS stamp with the appropriate pattern is molded from an SU-8 or a silicon structure (**Figure 5(b)**). ECM proteins in solution are deposited onto the surface of the PDMS stamp and then the stamp is used to print a pattern of ECM onto the tips of the micropost array (**Figure 5(c)**). Subsequent treatment with Pluronics can be used to prevent cell adhesion at any surface of the microposts that has not been stamped with ECM protein. Pluronics is a nonionic copolymer consisting of ethylene oxide and propylene oxide, whose amphiphilic nature makes it a powerful surfactant. It adheres to the unstamped regions of PDMS to form a single-molecule thick coating that prevents other molecules from adsorbing to the surface. Thus, cells are confined to form focal adhesions to only the stamped tips of the posts (**Figure 6(a)**).

In order to measure strength of the traction forces on the posts, it is important to accurately track the displacement of the tips.[53,54] Originally, the displacements were identified by immunofluorescently staining the ECM at the tips of the posts.[47] A common treatment now is to submerge the micropost arrays in DiI solution, which is a hydrophobic dye which

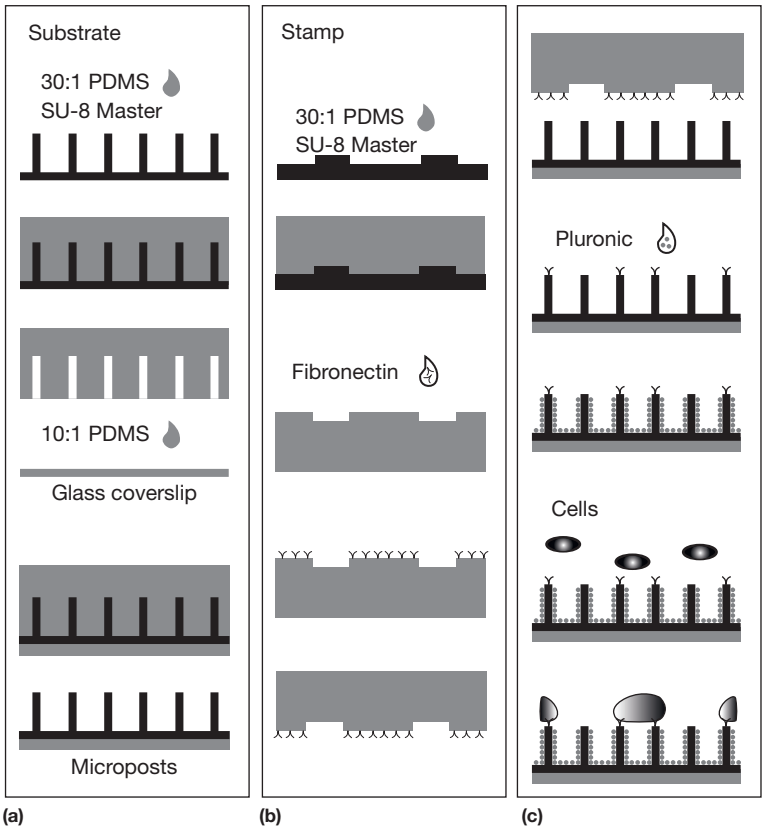

Figure 5 Micropost fabrication technique. (a) A master is created using photolithography of SU-8 or silicon (not shown) and then double-cast in PDMS to produce arrays of micropost. (b) For microcontact printing, stamps are created to pattern ECM proteins on the surface of the posts. (c) After stamping, Pluronic is used to block the adsorption of proteins onto unstamped surfaces in order to control cell adhesion.

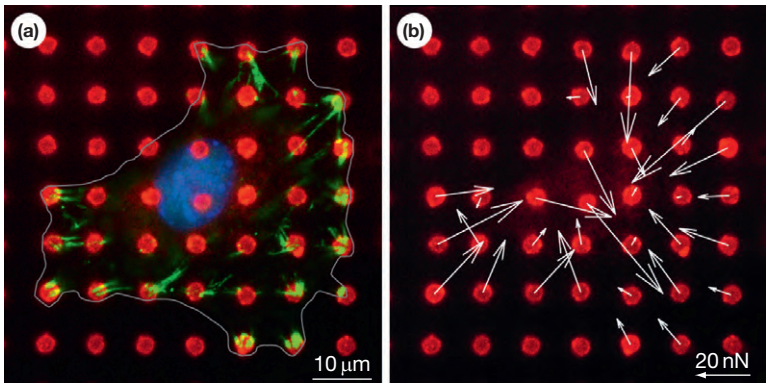

Figure 6 (a) A cell spreads across the tips of multiple microposts and forms focal adhesions. (b) Fluorescent labeling of the posts allows for traction force measurements as force vectors. labels the PDMS in the infrared spectrum. Microposts can also be marked by depositing quantum dots in the tips of the posts[55] or by phase contrast microscopy.[56,57] A local traction force is determined from the post's deflection δ and is given by $F = 3\pi ED^4\delta/64L^3$, where E is the elastic modulus of PDMS, D is the diameter, and L is the length of the post. Microposts have been made with diameters between 2 and 5 μm and lengths between 5 and 15 μm. From these measurements, it is possible to determine the traction force field that cells exert on the microposts (Figure 6(b)). By adjusting the dimensions of the microposts, it is possible to tailor the stiffness of the array to look at how cells adjust their traction forces in response to matrix compliance[58] or anisotropic material properties.[59]

Microposts are a useful tool for examining individual cells, but the idea can be extended to larger and smaller scales as well. Micropost flexibility can be adjusted by increasing the dimensions to measure the high forces generated by cardiac myocytes (Figure 7(a)).[60] Large microposts ('megaposts') have been

used to test single cardiac myocytes that have been isolated to adhere to pairs of large posts (Figure 7(b)). Observation shows periodic myocyte contraction rates and large force ranges of 140–400 nN, which is beyond the measurable range with other techniques. The megapost approach has also been used to measure tissue-construct forces that arise from the combination of cells and ECM into a microtissue.[61] The samples are made by seeding cells and collagen into molds that were hundreds of microns long and containing two megaposts at either end. As the cells gather with collagen, they pull on the megaposts revealing bulk dynamics. In an approach similar to megaposts, pairs of microposts were used to measure the contractile forces that platelets generate when they aggregate together to form a clot and then retract (Figure 7(c)).[62] Recent developments have reduced the dimensions of the microposts to create nanoposts (Figure 7(d)).[63] These smaller dimensions allow for a significantly higher packing density of posts underneath a cell that creates a quasismooth surface on which a cell can spread (Figure 7(e)). The cytoskeletons in cells on the nanoposts closely resemble those observed for cells on flat surfaces. The reduced spacing also allows cells or cellular structures to be analyzed that are too small to fit between individual microposts. As the technology to fabricate BioMEMS improves, it is likely that the adhesive and physical interactions between smaller cells and subcellular structures will be more deeply explored.

Unlike the deformation of continuous films or gels, individual microposts are independent sensors because the deflection at one post does not affect the measurement of force at another post. Thus, these arrays lend themselves to measuring a large field of forces from multiple cells and different configurations of patterning can be done to test a wide gamut of multicellular interactions. Cells in a monolayer form adherens junctions with neighboring cells, and microposts have been used to examine the mechanical interactions in sheets of cells.[56,64] Bowtie patterns can also be used so that the tugging force between pairs of cells can be measured in isolation (Figure 8(a)).[65] Fibronectin was patterned onto the microposts to confine the contact between two cells. Since the pair of cells is connected through their adherens junctions, the vector sum of traction forces of one of the cells is not zero, but is in fact the tugging force from the neighbor cell. It was found cells that had a greater length of adherens junction with each other were able to support a higher tugging force. It was found that Rho mediated the tugging force and the Rac regulated the increased adherens junction assembly length. This mechanical interplay between cells shows that with groups of cells on the microposts, maximum forces are at the edge of the monolayer and exceed those of a single cell, indicating that collective mechanical signaling may be occurring.[56] This signaling can lead to a mechanotransduction response because cells at the edges or corners of a monolayer had higher traction stresses against the ECM due to the tugging forces of their neighbors, and this stress caused increased proliferation of cells at the edge (Figure 8(b)).[64] Heterogeneous cell–cell interactions can also promote higher traction forces because individual endothelial cells within a monolayer exerted higher forces on the microposts when they were in contact with a transmigrating monocyte (Figure 8(c)).[66]

3.315.4. BioMEMS Devices to Apply Forces to Cells

Cells sense forces and modulate their cytoskeleton and regulatory proteins accordingly.[67] The three main cytoskeletal filaments actin, intermediate filaments, and microtubules transmit forces within a cell, and can become linked to neighboring cells cytoskeleton through transmembrane junction proteins such as at adherens junctions. Cells therefore relay forces to cells around them, as well as experience forces acting on them from their microenvironment. The importance of these transmitted forces in tissue is important in the development of the cardiovascular, musculoskeletal, and nervous systems, all of which have been shown to be influenced by mechanical forces.[68]

Arterial remodeling provides an interesting example of cellular mechanotransduction. Arteries are mechanically compliant, and when blood is driven through them, they expand elastically with each pressure wave from the cardiac cycle. The distensible nature of the arterial tissue acts as a stretchable substrate on which endothelial cells adhere. Strains up to 10% are normal for arterial tissue, and these strains can be recreated *in vitro* by culturing cells on flexible PDMS membranes that are stretched uniaxially. Cells have been observed to change their shape and realign their actin cytoskeletons in a direction perpendicular to the applied strain. However, when Rho activity is inhibited, these cells align in a direction parallel to the stretching, suggesting that external force is sufficient to induce actin remodeling.[69]

Mechanotransduction has been hypothesized to occur at a variety of cellular structures, but the cytoskeleton has been strongly implicated to have a central role since it connects to the focal adhesions and adherens junctions. When cells on a PDMS membrane were treated with a detergent to keep the cytoskeletons intact but strip away the lipid membranes and cytoplasmic proteins, it was found that cytoskeletons that were stretched had significantly higher amounts of focal adhesion proteins.[70] This response is similar to the growth response at the focal adhesion due to traction forces.[41] Additionally, the protein response at the focal adhesion suggests that mechanotransduction occurs from conformation changes.[71] Force may cause unfolding of focal adhesion proteins to reveal new domains for the binding of adaptor or signaling proteins or it may also expose enzymatic domains that then activate signaling activity associated with mechanotransduction. For additional information, see **Chapter 5.527, Cardiovascular Tissue Engineering**.

3.315.4.1. Micromanipulation

Tests with large strains and stresses are useful for simulating tissue level dynamics but single cell systems are of equal interest. Cellular responses to a localized force can be useful in examining a mechanosensor in a cell. The most direct approach is to use micromanipulation techniques with a glass pipette.[72] To form this tool, a pipette is heated until its melting temperatures and then pulled into a long, sharp tip before being allowed to cool. Because the tip diameter can be as small as 1 μm, its deflection can be used to measure the amount of force applied to the cells. These tool tips can be biofunctionalized by coating with an ECM protein such as fibronectin to ensure that integrins adhere to the tip and form focal adhesions. It has been observed that applied force can create growth at focal adhesions near the tip. It has also been shown that the externally applied mechanical stress can bypass the need for ROCK-mediated cytoskeletal tension in order to cause the growth of focal adhesions.

AFM has been used to impart forces to biological materials,[73] but larger forces and more degrees of freedom in positioning the manipulator may be of interest. MEMs micromachining can produce probing tools for applying localized cell forces with wider force ranges than AFM and with greater accuracy than glass micropipette techniques. A micromachined device consisting of suspended, flexible beams has been created from silicon wafers (**Figure 9(a)**).[74] A probe tip on a translatable backbone beam is connected to pairs of flexible beams that are fixed to the base silicon structure. As the probe tip is pushed against a cell, the change in lateral distance between the tip and a fixed reference point can be used to indicate the force (**Figure 9(b)**). Applying pulling force to axons has shown that tension causes vesicles that contain neurotransmitters to accumulate at the presynaptic terminal, indicating that neuromuscular synapses use tensile forces in regulating synaptic function (**Figure 9(c)**).[75]

3.315.4.2. Magnetic Bead Forces

A technique for applying forces is magnetic twisting cytometry (MTC).[76] Here, a ferromagnetic microbead is coated with an Arg-Gly-Asp (RGD) peptide sequence, which is a ligand for integrins. These beads can then be bound to the surface of a cell and mechanical stress applied by rotating the beads through a magnetic field (**Figure 10**). Probing individual

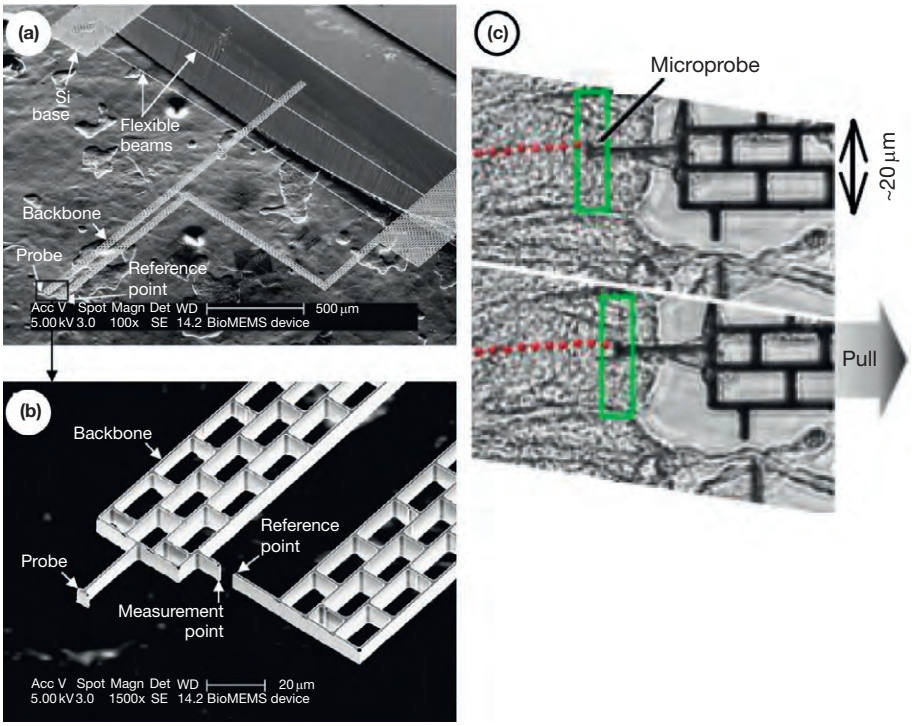

Figure 9 (a) Suspended BioMEMS manipulator structure made from silicon. (b) Force measurement is conducted by monitoring the distance between the probe and reference point on a fixed beam. focal adhesions through MTC demonstrated that a cell stiffens its mechanical attachment to the bead to prevent it from twisting. A similar response was observed with magnetic tweezers, where an integrin-bound magnetic bead is pulled into the gradient of a magnetic field.[77] Early reinforcement depends on the structural integrity of the cytoskeleton, but the active strengthening of the adhesion site to a sustained force from the bead requires Rho, ROCK, Src, and stretch-activated ion channels.[78] Combining MTC with fluorescence resonance energy transfer gives a way to visually observe the activation of proteins under applied loads.[79] In particular, Src has been observed to become activated at both the local focal adhesion where force is applied and at remote sites. The rate of activation at the remote sites is 50 times faster than what is possible through soluble factor-induced signaling and can be inhibited by pharmacologically disrupting microtubule and actin filaments to prevent the transmission of force along the cytoskeleton.[79,80] Thus, mechanical forces acting through the cytoskeleton might be a rapid and efficient signaling cue to inform cells about their microenvironment as opposed to diffusive, soluble signals. It has been revealed by using MTC that mechanotransduction signals can also propagate across adjacent cells through their adherens junctions.[81] Interestingly, vinculin, which is a protein that is associated with both the focal adhesion and with the adherens junctions, has been observed to accumulate at the E-cadherin adhesion complex under applied force.[82] Since cell–cell adhesions appear to have a similar mechanotransduction response as cell–ECM adhesions, the cytoskeleton likely plays an integral role in directing these mechanical forces to the appropriate mechanosensory structures.[83]

3.315.4.3. Optical Traps/Tweezers

Optical traps are another method that can measure and induce forces at the subcellular level. The technique uses a focused laser to produce a force on a dielectric microbead, which can be embedded at the surface or in the cytoplasm of a cell. Beads can be used to apply forces to focal adhesions, but non-ECM proteins can be coated onto the beads to probe a variety of biophysical interactions within a cell. As long as the bead's dielectric material has a higher refractive index than the surrounding medium, when the bead is in focal point of the beam, it experiences an optical force toward the center of the beam. This restoring force is due to change in momentum of the photons from refraction as the laser light passes through the bead. If the center of the beam is moved, the bead will experience a stronger restoring force that moves it toward the position of the laser's focal point. The distance of the bead from the center of the focal point is a close approximation to the strength of the restoring force and is usually measured using a photodiode.

Optical tweezers have been used to show that focal adhesion strengthening occurs with applied force.[84] Vinculin is observed to accumulate at the site of applied force using beads coated with only the cell-binding domains of fibronectin.[85] The accumulation of the focal adhesion proteins likely involves the early binding of talin to the fibronectin-integrin complex that provide initial strength to the adhesion site.[86] The applied force also activates Src, which regulates the growth of the integrin–cytoskeleton connection.[87] The stiffness at the cellular membrane can also be examined with optical tweezers, where an isoform of myosin, myosin-1a, has been found to be essential in linking the membrane to the underlying cortical cytoskeleton.[88]

Larger field effects for applying forces to cells can also be created. An optical method, known as optical stretching, uses two lasers that face one another (**Figure 11(a)**).[89] A cell trapped between the two lasers is trapped at the focal point, but also experiences a gradient of forces from the refracted beams that cause a stretch to its entire volume (**Figure 12(b)–12(d)**). This technique functions as long the refractive index of the cell is higher than the surrounding fluid environment. The stretching force that can be generated by the gradients is significantly larger than for two beads pulling with optical tweezers. Also the use of divergent beams produces less risk of radiation damage to the biomolecule or cell. An important consideration for optical stretching is that it is limited to the study of nonadhesive cells as many cells will undergo apoptosis without adequate integrin engagement.

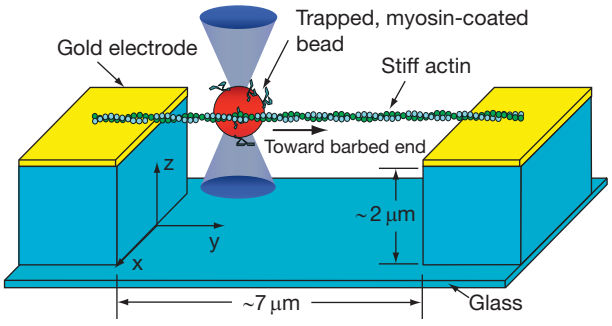

Figure 11 Myosin coated bead placed with optical tweezers migrating on an actin filament, which is held in tension between two gold adhesion pads. Adapted from Arsenault, M. E.; Sun, Y.; Bau, H. H.; Goldman, Y. E. *Phys. Chem. Chem. Phys.* **2009**, *11*, 4834–4839, with permission from Royal Society of Chemistry.

Optical techniques provide high sensitivity at the nanoscale and can be used to measure single biomolecule mechanics.[90] To do so, a bead is attached to one end of a molecule with the other end anchored to a nonmoving surface. It is possible to examine the stretch response in a molecule under an applied load by moving the optical trap away from the anchored molecule and observing the bead's change in distance from the trap's focal point. Sensitivity is so high that in fact optical traps are limited only by environmental noise from the substrate, since it is theoretically possible to resolve angstrom scale length changes. To address the noise, a second optical trap and microbead can replace the anchored point on a biomolecule, enabling even finer forces to be measured.[91] Not only does it provide a way to study how force can change the structure of a protein or biomolecule such as DNA, it also provides a measure of strain recovery times, spring constants, and internal molecular coefficients of friction, thus providing a richer mechanical analysis of single molecules.[90]

In particular, the mechanical interactions between actin and myosin can be examined to better understand how this fundamental process underlies the mechanics of cells. Optical tweezers have been used to determine that myosin bound to a nonmoving surface can produce 3 pN of force on average with each power stroke against a single actin filament that is held in an optical trap.[92] Improvements to this approach have demonstrated that actin filaments can be aligned across a gap between two gold electrode by using an AC field (**Figure 12**).[93] Tension in the filament is controlled by the electric field which allows a straight actin filament to be formed between the gold electrodes. A bead coated with myosin V or myosin X is brought in contact with the actin filament and released from the optical tweezer. Interestingly, the path that the bead took under myosin's motor action was helical as it traversed toward the barbed end of the filament. A similar helical path has been seen for myosin II,[94] suggesting that the motor action of myosin involves a degree of torque as it progresses along the length of actin.

3.315.4.4. Magnetic Microposts

A recent development in BioMEMS has been the use of PDMS micropost arrays with embedded magnetic nanowires. Magnetic cobalt nanowires are manufactured through electrochemical deposition into a sacrificial alumina template with 300 nm diameter pores. Once released from the template, the nanowires are suspended in ethanol and then aliquoted onto the PDMS negative mold under a magnetic field, which pulls the nanowires down into the wells that form the microposts. Once the ethanol is evaporated away, PDMS is then poured into the negative mold to form the micropost arrays. The PDMS encapsulates the nanowires that are deposited into the wells, and once the PDMS array is peeled from the mold, the nanowires are found to be embedded inside individual posts, which are referred to as magnetic posts (**Figure 13(a)**).[95] Biofunctionalization of the microposts is performed using the

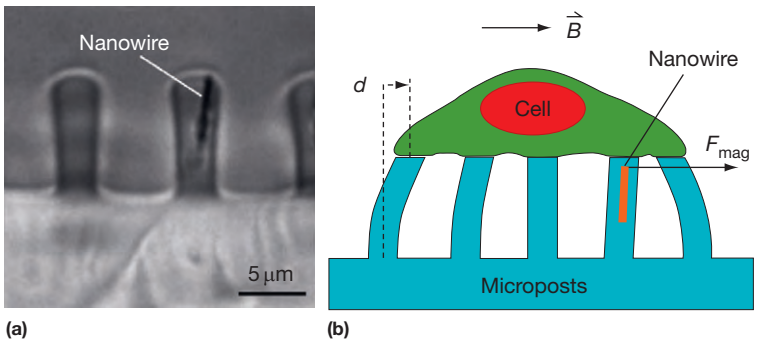

Figure 13 (a) Phase image of micropost cross section with embedded cobalt nanowire. (b) External force can be imparted to a cell at the magnetic post by applying a magnetic field, while traction forces can be measured at the nearby nonmagnetic posts. Adapted from Sniadecki, N. J.; Anguelouch, A.; Yang, M. T.; *et al. Proc. Natl. Acad. Sci. USA* **2007**, *104*, 14553–14558.

same techniques as with nonmagnetic micropost arrays. When a cell is seeded onto the surface of the microposts, they adhere at the tips and form focal adhesions and stress fibers just as if they were on flat substrates. PDMS posts that have the magnetic nanowires are able to be actuated when a horizontally applied uniform magnetic field is presented (**Figure 13(b)**). Deflection of a magnetic post introduces a controlled stress to the basal contact surface of the cell that induces growth at the local focal adhesion. Since a cell spreads onto multiple posts, its traction forces can be measured through the surrounding nonmagnetic posts. The posts are mechanically isolated from each other, so force actuation at a magnetic post does not impact the measuring ability at its neighbors. This has the advantage of being able to exert clearly measurable directionality and magnitude of force without worrying about force contributions from neighboring regions. The use of magnetic microposts has revealed that a cell responsds to an applied force at one or more of its focal adhesions with a rapid loss in cytoskeletal tension that slowly recovers after the stimulation.[54] This suggests that a cell can adjust its cytoskeletal structure in response to mechanical cues in its microenvironment.

3.315.4.5. Cytoskeletal Force Response

Under stretch from a silicone membrane, a cell's cytoskeleton tends to quickly fluidize before recovering and solidifying over time.[96] Under the solid-like state, biochemical interactions within a cell are highly specific, where the stable structures of the cytoskeleton are formed from distinct ligand-binding site interactions. Upon stretching a cell, it experiences a

structural transition into a chaotic, glassy-like phase where nonspecific interactions from proteins released from the disrupted cytoskeleton cause a crowded, molecular environment. Specifically, the stretching stimulus acts as a kind of 'enzymatic trigger' that causes the actin cytoskeleton to rapidly depolymerize. As a cell's structure turns over into a glassy-like state, there is a transitional drop in its stiffness. Newly freed G-actin monomers then polymerize into F-actin to resolidify the cell and cause its stiffness to return to prestretch levels. Treating cells with F-actin stabilizer jasplakinolide and applying stretch shows that the cell has a larger decrease in stiffness, but also recovers quickly to its pretreatment stiffness. Recent research has also examined fluidization and recovery in response to stretch using traction microscopy tools. Cells placed on polyacrylamide gels with isotropic or anisotropic stretches have traction forces that rapidly decrease after stretch which then recovers over time. These responses are seen in other diverse cells such as smooth muscle, endothelial, and osteocytes.[97]

3.315.4.6. Nanoscissors

The structural recovery of actin can be observed directly by snipping actin stress fibers inside a cell using a highly focused, femtosecond laser. Actin filaments in cells expressing GFP-actin can be targeted for ablation without causing large spread heating effects to the cell.[98,99] Cutting actin with a laser causes the filaments to instantaneously pull apart and continue to retract over many seconds. This is interpreted as the release of elastic tension in the strand, as well as gives insight to the viscoelasticity of the filaments and the fluid resistance of the cytoplasm.[98] Combining nanoscissor with traction force microscopy gives researchers the ability to measure the force contributions of single stress fibers. Severing a single fiber revealed a progressive loss in cytoskeletal tension for a cell. For cells on stiff substrates, cutting a fiber with the laser resulted in very minor cell elongation. On soft substrates, however, the severed stress fiber caused significantly higher cell elongation. Traction force mapping showed that the focal adhesion linked to the severed stress fiber displaced outward from the cell, furthering the evidence that cytoskeletal tensions are responsible for cell morphology and adhesion stability. The viscoelastic relaxation seen for cutting a single fiber is distinct from the rapid relaxation for cells stretched on silicone membranes or pulled on with magnetic posts. It is likely that local severing of actin causes a slow response because the remaining cytoskeletal structure is intact while the other techniques stimulate focal adhesion signals that cause massive disruption to the cytoskeleton's structural integrity.

3.315.5. Microfluidic Systems

BioMEMS provides tools that give better control over the microenvironment of the cell and, in particular, can be employed to present a myriad of mechanical and chemical factors to the cells. Constant or varied fluidic shear can be applied across single or multiple cells. Other factors that cells would see in their native environment such as stretch or pressure responses may be added. The microscale approach lends itself to the analysis of single cells in a high-throughput manner, which can be useful in filtering out heterogeneous responses within a subpopulation of the cells.[100] Moreover, more than one cell type may be cocultured together in a microfluidic system to gauge responses to released soluble factors and transmembrane signaling at their cell–cell contacts.

An added benefit of microfluidics is the high degree of control over waste product removal and nutrient addition. Typical protocols require that one changes a culture's nutrient media every 48 h.[101] Common growth factors such as serum become depleted in these intermittent times, while proliferating cells produce increasing amounts of undesirable waste products. Compared to static cell cultures, microfluidic systems and bioreactors typically have large volumes of media which translates to a volumetric buffer that minimizes chemical profile changes over time. The motion of the media also continuously refreshes the local media at the cell level, maintaining a steady amount of available biomolecules. Compared to static culture, cells in microfluidics can be confined to far narrower bands of available growth factor or signaler molecule concentrations.

3.315.5.1. Fluid Shear Stress

In many biological systems, mechanical shear stress from fluid flow plays a vital role in regulating cell morphology and function. These effects can be seen in flow systems as diverse as cardiovascular blood flow and interstitial cell flow. It has been well documented that the structure and physiology of the vasculature is heavily influenced by shear rate and flow type.[4,102] Vascular cells are exposed to a wide variety of flow conditions ranging from highly turbulent flows in the heart and major arteries to extremely laminar flows in arterioles and venules.

Mechanotransduction response by endothelial cells is of particular interest because of its close relation to atherosclerosis development. In normal function, the endothelium acts as a nonadhesive and nonclotting layer that protects arterial tissue from developing fatty lipids and invasive leukocytes in the intima. When the endothelium is damaged by shear, its barrier function deteriorates and lipids and macrophages are found to be in abundance in the artery wall. Once there, cytokines released from the affected area recruit additional leukocytes to the site where they accumulate lipids and swell the artery wall. Vascular smooth muscle cells proliferate within the damaged region and contribute to wall thickening by further releasing growth factors, chemoattractants, and vascular cell adhesion molecule.[103]

Initial damage can be caused by direct injury or endothelial cell remodeling in response to below average shear or disturbed shear regimes with high shear gradients. Endothelial cells express an atheroprone gene profile when exposed to these flow conditions.[104] However, laminar shear stresses cause a conformal remodeling of individual cells to reinforce their barrier function by promoting cell–cell junctions.[105] As mentioned previously, cells can align in response to applied stretch. However, different cells have different mechanotransduction responses. Mouse 3T3 fibroblasts align parallel to the applied strain, while endothelials align perpendicular.[69] Specific response also exists in shear stress as endothelial cells align parallel, but vascular smooth muscle cells align perpendicularly.[106] Endothelial cell realignment under fluidic shear has

also been confirmed with AFM examination of the surface topology.[107] Results show that shear-aligned cells display distinct surface ridges comprised of cytoskeletal actin. Non-sheared cells have smooth surfaces devoid of these features.

Platelets are another blood cell type that respond to mechanical shear. Decelerating hemodynamic shear microgradient profiles can activate platelets and cause thrombus formation.[108] Microfluidic experimentation has been a way to reveal this behavior. Other studies have shown that a critical rate of shear and exposure exists that, once passed, initiates activation regardless of shear conditions afterward. This can present problems downstream in the vasculature.[109] Platelet formation from megakaryocytes can be examined using BioMEMS apparatuses as well. Megakaryocytes are grown in a layered chamber separated by a porous membrane. Shear forces are applied to the system by gentle agitation. The megakaryocytes are seen to extend proplatelet-like protrusions through the membrane with an observation that agitated cells break off fragments of themselves.[110]

In examining the cellular response to shear, it is critical to know the flow conditions that a cell experiences *in vivo*, as well as the flows that are produced within a bioreactor or microfluidic device. Computer simulation of actual arteries utilizes magnetic resonance imaging or ultrasound scanning to generate a contoured interior surface of vessels for fluid flow simulations.[111] Direct methods exist for characterizing the flow inside a microchannel or flow chamber. Microscale particle image velocimetry is a technique that can be used to visualize and measure patterns in the flow field.[112] Here, microbeads or other tracer particles are added to a fluid and as they are carried along with the fluid, they report the local direction and velocity of the flow. These techniques are helpful in calibrating the flow conditions applied to cells.

3.315.5.2. BioMEMS Reactors

BioMEMS microfluidic devices are frequently used to apply moving fluid to cells. To do so, a channel is formed with biocompatible materials and functionalized. Channel shape, dimensions, and flow rates are all parameters that can be adjusted to control the flow dynamics. A proven and well documented method of channel fabrication is through PDMS replication molding of channels on a silicon wafer created through surface micromachining or photolithography techniques.[50] Complex geometries can be fabricated with this method, and valves and multiple flow conditions can be incorporated into one device. The material used to fabricate the device is flexible in many cases. For most applications, glass is the desired material due to its optical clarity, robustness, nonporous nature, and resistance to all sterilization techniques. However, machining glass and maintaining optical clarity and surface smoothness is a difficult task. Other common biocompatible replacement materials are acrylic, polystyrene, and polycarbonate. These offer similar optical transparency, can still be sterilized, and are easy to reconfigure in a laboratory setting. Plasma treatment of glass or a polymer creates a highly adhesive surface that forms a watertight seal with PDMS and is employed in many bioreactor designs.[48] For live-cell observation, a glass coverslip makes an ideal bottom surface of a bioreactor due to its thinness, a requirement for high magnification microscope objectives.

Cells are introduced to microfluidic systems by suspending them in media and injecting media through the microchannel. The cells settle and adhere to the surface and washing steps remove unattached cells. Since the vascular wall is comprised of more than endothelial cells, researchers have examined the effects of coculture on alignment and adhesion.[113] First, a layer of smooth muscle cells is seeded onto a substrate and grown to quiescent confluence. Next, endothelial cells can be directly seeded on top of the first layer and allowed to proliferate to confluence. The result is a bilayer of cells that closely resembles the endothelium in structure. The two cell types are able to form transmembrane gap junctions for chemical signaling, as well as respond to mechanical stresses through adherens junctions.

3.315.5.3. Bioreactor Pumping

To create fluid flow, different pumping schemes are used to achieve the desired flow in the microchannels. In the most basic flow device, pressure produced either through a raised fluid reservoir or gas source can drive fluid through a microfluidic system while a pump cycles the fluid back into the reservoir source. However, the lack of feedback-control means that researchers require more precise means. Syringe pumps provide excellent control if low flow rates are needed, but with limited volumes. Configuring multiple syringes and valves together can create a unidirectional flow that can recirculate to maintain the supply volume. Large flow rates use a peristaltic pump, also known as a roller pump, to have precise control of the flow. Peristaltic pumps produce a nonsteady pressure to the flow, which can be desirable if researchers want pulsatile flow. In most cases, a steady flow rate is desired, so air dampeners are placed in the fluid path to remove the effect of the pulses.[114] For additional information on other types of fluid flow devices, see **Chapter 5.511, Rotating-Wall Vessels for Cell Culture**.

3.315.5.4. Bioreactor Configuration

In BioMEMS microfluidic applications, ducts are the most common channel shape because shear is well defined and can be controlled precisely by dimensional considerations (**Figure 14(a, 1–8)**). Certain assumptions about the length-to-width aspect ratio mean that the wall shear stresses in the microchannels can be approximated to shear stress in parallel-plate flow. Shear forces at the wall can be calculated using: $\tau = 6\,\mu Q/WH^2$, where τ is shear stress, μ is viscosity, Q is fluid volumetric flow rate, W is the width, and H is the height of the channel. With steady pumping schemes, a constant level of shear stress gradient is produced at the wall surface. Adding a weir or obstruction in the channel initiates a disturbance in the flow that causes recirculation or vorticity at a region downstream. Between the weir and the vorticity reattachment point, a range of shear stresses and shear stress gradient exists.

Research has been done to determine the role of shear on endothelial cell morphogenesis. Endothelial cells placed into a duct with weir configuration display alignment characteristics that depend on their location in the channel. In steady, positive-direction laminar shear or steady, negative-direction laminar shear, the cells align parallel to the direction of flow.

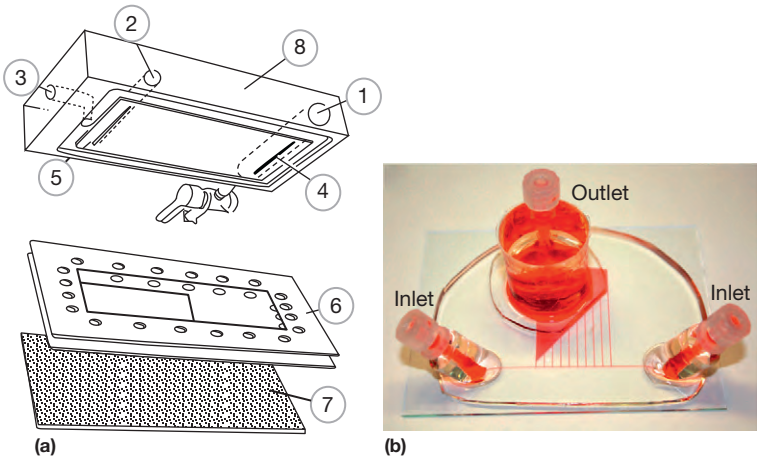

Figure 14 (a) Fluidic shear chamber utilizing parallel-plate channels. Fluid enters at (1), runs into the channel at slit (4), out of the channel (5), and leaves the device at (2). A gasket (6) seals a glass cover slide (7) with the polycarbonate top plate (8). Vacuum pressure through the (3) perimeter channel forms a seal for the device. (b) BioMEMS can be used to create multiple fluidic shears that are applied simultaneously to a common culture of cells by using differing channel lengths. The device is fabricated from replica molding of PDMS and treated with plasma to bond it to an underlying glass slide. Adapted from Chiu, J. J.; Wang, D. L.; Chien, S.; Skalak, R.; Usami, S. *J. Biomech. Eng.* **1998**, *120*, 2–8; Chau, L.; Doran, M.; Cooper-White, J. *Lab Chip* **2009**, *9*, 1897–1902.

Cells in regions with vorticity and below average shear stress have visible gaps between the cells, indicating a breakdown in their protective barrier function. Immunofluorescent imaging for F-actin filaments and microtubules additionally shows cytoskeletal fibers align in the direction of steady laminar flow and with no distinct alignment for low shear.[115]

A BioMEMS device fabricated with multiple channels of different lengths produces shear stress over a range of different magnitudes to the same culture of cells (**Figure 14(b)**).[116] The advantage here is that a single passage of cells can be used in the experiment and scarce samples can be tested efficiently. Mechanosensing of endothelial cells activates Weibel–Palade bodies to secrete von Willebrand factor, a glycoprotein that mediates the adhesion of platelets. Endothelial cells tested in this device display shear regulation of von Willebrand factor, supporting the idea that mechanosensing is a necessary component of hemostasis and wound healing.

Fluidic shear stresses not only influences morphogenesis, but also migration behavior. Endothelial cell mechanotaxis under hemodynamic flow is an important function for wound healing and vascular repair. Cells at the edge of a wound increase their motility toward regions that are damaged, extending the leading edge and possibly modifying the ECM to allow other cells to proliferate and move in that direction. Microfluidic devices are used to investigate this behavior by applying a shear across monolayers of cells. Wounding assays are commonly done by dragging a sterile glass pipette or razor blade across a confluent layer of endothelial cells creating a fissure in the monolayer. By taking time-lapse images of the cells at the fissure, it is seen that cell migration is the dominant response in wound healing versus cell proliferation. Regardless of the wound direction, whether it is parallel or perpendicular to the fluid flow, shear stress increases wound closure rates. Migration rates through mechanotaxis have an impact on angiogenesis in developing organisms and vascular health and so the use of a bioreactor device aids in research understanding.[117] Other methods for creating wound simulation is to seed cells onto a surface with a thin film PDMS layer containing cut out areas. Cells grow to confluence and the film is removed exposing a patterned monolayer of cells.[118] The wound model demonstrates that cells at the leading edge of the wounded area sense the void and exhibit 'leader-cell' behavior, becoming highly mobile and acting to drag the cell layer into the missing region.

Microfluidics can be combined with other systems to better replicate *in vivo* conditions. Most commonly, factors or chemicals are added to media which is washed over cells. Combinations or gradients of factors can be created within devices to perform many experiments simultaneously.[119] Cell seeding density determines the number of cells in microchannels and can be changed to isolate single cells or create confluent monolayers. Force during the transmigration of leukocytes can be studied by combining fluid shear and endothelial cells on microposts. As cells such as neutrophils adhere during shear and pass through the endothelium, they impart forces to push the endothelial cells apart, which in experiments is detected by underlying micropost sensors.[120] Coculture of cells through the use of integrated three-dimensional ECM scaffolds in microfluidic devices can examine capillary growth, endothelial cell migration, and gradient growth factor effects.[121] For additional information, see **Chapter 5.512, *In Vivo* Bioreactors**.

3.315.5.5. Interstitial Shear

Mechanical shear is experienced by cells outside the vascular system as well. Interstitial flow is the slow movement of lymphatic fluid or blood plasma between ECM structures and cells. The fluid driving force is thought to be from difference in hydrostatic and osmotic pressures between the lymphatic system and vascular capillaries. The slow nature of the fluid flow is also explained by the presence of the proteoglycans fiber network that impedes the flow. Proteoglycans in the ECM are formed out of protein filaments with many glycosaminoglycan (GAG) side chain connections. These GAGs are able to bind to signal molecules or cytokines in the fluid by being negatively

charged. The physical geometry of the GAG side chains means that they present a densely packed but porous structure of overlapping strands. The combination of the hydrostatic or osmotic pressure differences and the flow resistance presented by the cell–ECM architecture work together to control the interchange rates of lymphatic fluid.

Interstitial flow is of interest due to its role in molecular transport within tissue and cells. In particular, tumors have been shown to have more permeable vasculature but a limited lymphatic path outward, causing them to tend to retain biomolecules. Specific micro- or nanoparticles can be designed to become concentrated in tumors and deliver therapeutic drugs.[122] Cell–ECM constructs or size controlled membranes are one route to simulate and examine interstitial flow on cultured cells while molecular fluorescent-labeling allows observation of the particles exchange rates. Integrated microfluidic systems that incorporate three-dimensional scaffolds and cell encapsulation can create interstitial flow effects by creating pressure differentials across different surfaces of the cell, maintaining a more native-like environment for examining phenomenon such as angiogenesis.[123]

3.315.5.6. Single Cell Analysis

In some cases, cell responses from a large population of cells can be misleading. One may observe that the expression levels of a particular protein is not centered on a point, but may have two distinct peak levels due to a bimodal behavior. Bulk measurements through immunoassays or gel electrophoresis techniques would suggest that the expression level is the average of the two peaks; however, this is flawed because it fails to resolve the two individual peaks. Probing individual cells is important to capture these phenomena.[124] BioMEMS cytometry tools exist such as fluorescent flow and laser scanning cytometry.[125] In fluorescent flow cytometry, cells in suspension have their specific biomolecules labeled with a fluorescent probe and are flowed past an illumination source and sensor. Concentration of the biomolecule on the surface of the cell is gathered through signal intensity and large numbers of cells can be screened this way. Laser scanning cytometry also uses fluorescent labeling, but individual cells in culture are positioned under the sensor for measurement. Advantages of this include being able to take time-lapse images of many cells in one experiment, and the cell does not need to be adherent. However, the process is slower than with flow cytometry.

BioMEMS techniques for physical trapping also exist, such as creating substrates with arrays of wells with room for cells. Cells are seeded into the wells, and nonadherent cells are washed away. This approach has been used to monitor the differentiation of mesenchymal stem cells that were exposed to different mixtures of adipogenic or osteogenic media conditions.[126] Confined growth channels have been applied to create micropatterns of muscle cells for long-term differentiation studies and fluorescent labeling.[127] Fluidic forces can be utilized like in hydrodynamic trap devices, which use small cross-flow channels to position cells within larger microchannels. Configurations have been used to examine cell–cell interactions by placing hydrodynamic traps across a channel to capture single cells and bring them in contact.[128] Microfluidic systems can also physically separate individual cells for analysis.[124] Examples include a novel design of microchannels that divert cells into cup-shaped wells. The hydrodynamics of a well with an occupied cell site prevents further cell occupation and allows for arrays of single cells to be analyzed (**Figure 16**). By creating channel systems with integrated valves, flow paths can be systemically changed to isolate out single cells for extraction of biomolecules such as messenger RNA[129] or by combining it with on-device electrophoresis, amino acid contents of single cells can be examined as well.[130]

3.315.5.7. Cell Sorting

Microfluidic sorting is possible with other BioMEMS tools. Antibody capture is one method that can select out target cells from a population because of cell surface chemistry changes upon differentiation. An antigen or antibody is applied to microstructures with high surface areas such as arrays of microposts or serpentine channels, and suspended cells are flowed across. Cell surface affinity for the antibody draws the cells to the structure while nontarget cells continue to pass (**Figure 15**). This is a robust technique that has been used to sort circulating prostate tumor cells from cell groups.[131]

As mentioned previously, optical traps have been used to stretch cells, but this technique can also be used to detect phenotypic difference between normal and cancerous cells and then sort the cells into different groups.[132] Cancerous cells have different cytoskeletal elastic and viscoelastic properties than normal cells. Research using normal 3T3 mouse fibroblast and malignant SV-T2 mouse fibroblasts under stretch has shown that optically induced deformations are statistically higher in the cancerous cells. Refractive index between the two cells is generally indistinguishable so similar optical stretch forces are exerted on both types. Cellular deformation then directly reflects the cytoskeletal deformation and compliance. Breast epithelial cells can also be distinguished despite a relatively low sampling count. Normal MCF10 breast epithelial cells have the least compliance, or are the stiffest. Cancerous MCF7 cells have more compliance and metastatic modMCF7 cells are the most compliant. This technique has a high throughput compared to previous techniques and a statistical conclusion can be reached rapidly. Phenotype sorting can be performed without potentially damaging physical or biochemical alteration to the cell populations such as with genomic techniques.

Optical sorting of dielectric particles and whole cells can be achieved by splitting a laser beam and focusing it to create interferometric patterns. These can be arranged into optical lattices of any dimension. Microchannel flow through these lattices generates a directional gradient that exerts different forces to alter the trajectory of the particle through a microchannel for sorting.[133] Optimization of the lattice focusing can give high sorting accuracy comparable with fluorescence sorting or flow cytometry techniques.

Integrating electrical fields on microfluidic systems can be done to use dielectrophoresis (DEP) for sorting and cell micromanipulation. A cell's membrane can act as a dielectric material and when an electrical field is applied, the field exerts a force on the cell in the direction of the strongest gradient. These forces can be used to trap cells in suspension for analysis using arrays of electrodes to generate standing electrical gradients.[134]

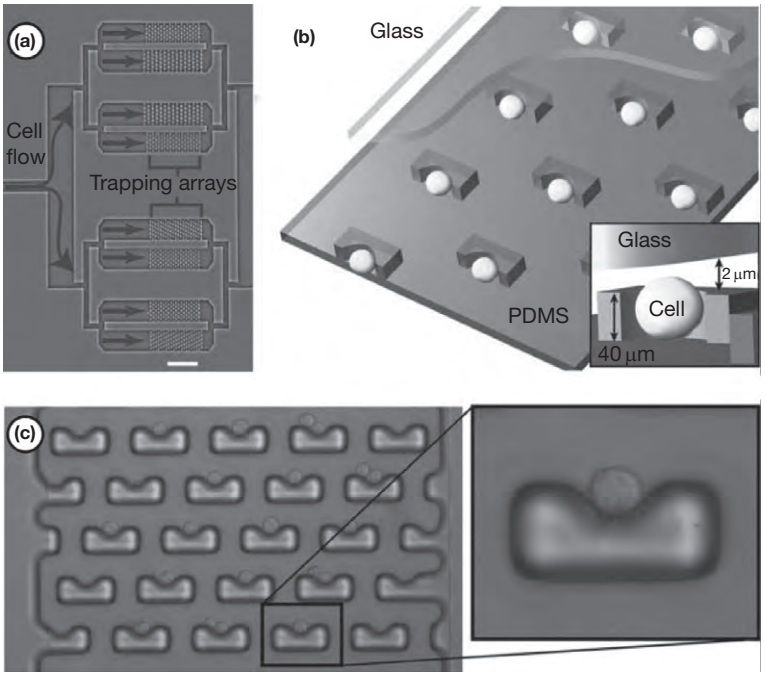

Figure 15 (a) Cell separation using (b) dimensioned heights and wells to (c) isolate single cells. Adapted from Di Carlo, D.D.; Wu, L.Y.; Lee, L.P.; *Lab Chip*, **2006**, *6*, 1445–1449, with permission from Royal Society of Chemistry.

The electrical properties of a cell's membrane can change depending on the proteins, biomolecules, or ions present in a cell during different differentiation states or cellular activities.[135] When a population of cells is exposed to electrical fields, DEP forces are exerted to differing degrees on the cells and allows for sorting them in a microfluidic system.[136]

3.315.5.8. Organ on Chip Microfluidic Devices

Research into the engineering of complete organ systems has benefited from microfluidic device studies as well. It has been possible to culture microtissue consisting of the heptatocytes in a fluidic bioreactor that supports cell viability and metabolic functionality of the liver.[137,138] Recently, a significant microfluidic system has been achieved that recreates the coculture cues and mechanical stimuli for cells of the pulmonary system.[139] The lung comprises individual alveolus which exchanges gas and chemicals with the blood. Similar to the endothelium, the alveolus are comprised of a single layer of alveolar epithelial cells with a meshwork of capillaries covering them. Gas and molecular exchange occurs through a thin ECM layer separating the epithelial cells and the endothelial cells of the capillaries as blood is pumped through the alveolus. There is also a strain effect induced as the alveolus fills with air during each respiratory cycle, with the elastic ECM aiding to expel the waste gas afterward. This is a complex system that is difficult to recreate with macroscale devices but has been achieved with a microfluidic system. First, a set of three parallel microchannels were constructed and bonded between a porous membrane (Figure 16(a)). The membrane is etched away in the left and right channels, but in the middle channel, it is partially etched so that a thin membrane separates the upper and lower

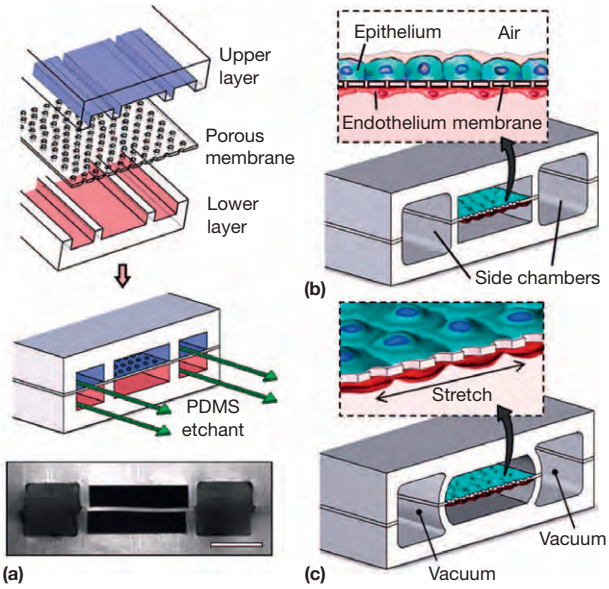

Figure 16 Lung-on-a-chip microdevice fabricated by (a) bonding two parallel PDMS microchannels around a PDMS membrane containing arrays of holes and etching steps. (b) Endothelial and epithelial cells can be grown on opposing sides of the membrane and exposed to shear and (c) stretch from applied vacuum. Adapted from Huh, D.; Matthews, B. D.; Mammoto, A.; Montoya-Zavala, M.; Hsin, H. Y.; Ingber, D. E. *Science* **2010**, *328*, 1662–1668.

channels. Alveolar epithelial cells can then be grown in the upper, center channel and pulmonary microvascular endothelial cells in the lower, center channel (Figure 16(b)). The left and right channels can be used to simulate strain from

respiratory cycling (Figure 16(c)). Researchers have used such devices to study coculture interactions between pulmonary cells and found that the barrier function of the alveolar epithelial cells and endothelial cells improved. Mechanical stretch used to mimic the motion of breathing accentuated the proinflammatory response to nanoparticles. These types of devices greatly improve the environmental cues seen by cells and can possibly replace animal testing by recreating whole-tissue physiology. For additional information, see **Chapter 3.309, Fluid Mechanics: Transport and Diffusion Analyses as Applied in Biomaterials Studies**.

3.315.5.9. Analysis of Mechanotransduction or Morphogenesis Biomarkers

In many BioMEMS applications and experiments, the presence or concentration of a protein is of interest to better understand the biochemical and biomechanical response of cells. To measure these, cell lysis is necessary to release intercellular contents of interest and can be performed through different BioMEMS techniques. Purely mechanical methods exist, such as forcing cells against micromachined barbs.[140] Another tool has been the development of micro system incorporated electroporation to disrupt the cell membrane without damaging organelle membranes.[141]

Immunofluoresence labeling is popular with researchers due to its target specificity. By using protein antibodies, single or multiple proteins to be examined together in one experimental sample to look at colocalization or compare expression levels. It is possible to perform the steps of immunostaining to cells inside a microfluidic device. To do so, the cells are washed with a fixative such as formalin or paraformaldehyde, whose aldehyde groups form methylene bridges between the nitrogen atoms of neighboring proteins. This treatment effectively cross-links the structure of the cell in place. The cell membrane is made permeable by adding a surfactant such as Triton X-100. Immunofluorescent staining utilizes a primary IgG antibody with affinity for specific antigens in a target protein of a cell. Blocking of nonspecific ligands in the cell can be accomplished by exposing samples to serum, which washes out unbound antibodies and serves to occupy nontargeted sites. A secondary antibody consisting of a fluorescent molecule conjugated to an IgG antibody to the primary antibody is then washed over the cell. The secondary antibody excites under a specific wavelength and emits photons at a higher wavelength. Single or multiple proteins can be placed on different excitation wavelengths to avoid signal interference. Because only targeted proteins or ligands are fluorescent, comparison between images for experimental and control samples gives researchers a method to cross-examine protein expression levels through signal intensity and an accurate way to identify protein colocalization sites. ELISA assays work under similar principles of antibody/antigen reactivity to detect presence or concentration in a sample. ELISA plates are scanned by a plate reader, and the intensity of the fluorescent signal indicates the amount of protein present in the sample. Microfluidic systems that perform ELISA on-chip have been used for disease detection and have an advantage over traditional assays by only requiring small amounts of biomarkers and reagents.[87]

In genomic techniques, microfluidics is a growing technology because of scaling advantages in biomolecular analysis.[142] In laboratory settings, amplification of DNA is traditionally done through polymerase chain reaction (PCR) techniques, but these generally require a sizeable sample from a population of at least 5000 cells, for which rare cells such as stem cells or circulating tumor cells may be difficult to obtain in large quantities. PCR and other amplification methodologies using BioMEMS can require as little as 150 cells, or only 300 pg. This technology and the level of sensitivity and detection have been demonstrated through human genome-wide transcriptome analysis.[143] Since external fluid handling is kept to a minimum, there is an improved sample accuracy in sensitive analyses such as PCR and electrophoresis.[144] In addition to mammalian cells, systems exist for the analysis of bacterial pathogens and viruses such as influenza.[145]

An interesting set of tools and assays are lab-on-disc or lab-on-CD technologies. These devices use microfluidic channels, gates, and switches imprinted into a spinning disc to perform many parallel evaluations of experimental samples. The microchannels are formed on a disc by photolithography and PDMS molding or injection molding plastics such as PMMA.[146] Force generated by spinning the device powers centrifugal pumping of fluid through the microchannels.[147] Different spin speeds cause the fluid to travel through channels that are gated by hydrophobic zones that act as burst valves. A fluid is able to move past a burst valve when the centrifugal force is large enough to overcome the surface tension of the fluid at the hydrophobic zone. Laser diode switchable gates can also be used to dynamically control the flow through the channels as the heat locally melts a barrier to the flow.[148] The design of the devices allows for processes such as mixing, metering, washing, reacting, and observation to occur in serial, entirely on disc, and is controlled by the spin speed profile.[149] Cell culture capabilities include growth and handling processes such as cell lysis.[150] ELISA assays have been converted to operate on discs and require less reagents and time than the standard large-scale assay.[151] Lab-on-disc is not limited to just fluids in the system but can also incorporate reagents bound on microbeads to increase surface area available for reactions. Immunoassays of whole blood in lab-on-disc have been performed to screen for diseases such as hepatitis and incorporate such protocols.[146] These microfluidic systems create a new opportunity to more completely investigate the spatial and temporal aspects of cell behavior by controlling the biochemical and biomechanical factors that a cell experiences and subsequently analyzing the response with integrated detection assays.

3.315.6. Future Directions

Many researchers are working toward better prosthetic integration with natural tissue. Currently, prosthetics are still largely perceived as foreign objects by the body. Few human-made materials can be accepted by living tissue on a cellular level and become incorporated with the native tissue. Through an understanding of migration, proliferation, differentiation, and adhesion that is aided by BioMEMS tools, future designs can better enhance biomaterial acceptance. This progress can be achieved by tailoring the material properties or soluble biochemistry to encourage migration through mechanotaxis or chemotaxis. BioMEMS tools also allow researchers to better control a cell's

microenvironment in order to elicit desirable behaviors from a cell. The development of new tools can offer better control of the biochemical and biomechanical environment properties or provide more powerful measurements. BioMEMS will continue to adapt from traditional MEMS application in order to improve. One such novel implementation has been the use of microfabricated nozzles for inkjet printers, which have been modified to deliver plasmids to targeted cells for gene transfection.[152] Microfluidics is particularly useful for engineering improvements for the cardiovascular system. For example, endothelial cell permeability from hemodynamic shear could be exploited for increased targeting of drugs to atherosclerotic lesions. Bioreactors could be used to culture megakaryocytes in order to generate large numbers of platelets to aid in blood transfusion. Surgical materials for stents can be biofunctionalized to prevent reocclusion of vessel walls after angioplasty, or can be constructed entirely of native ECM that can become fully incorporated into the tissue by encouraging cell motility and wound healing. Tools to impart microenvironment control for stem cells can enable better tissue engineering techniques in the future. These and many more examples demonstrate the potential for BioMEMS techniques and microenvironmental theories, which have merit for closer investigation.

3.316.1. Introduction to Immunohistochemistry

Antibodies are an essential component of the immune response. Their function is to identify and then specifically bind foreign molecules, which results in the generation of immune responses such as complement activation and phagocytosis. In order to maintain a proper defense, an antibody must have exquisite specificity for the foreign molecule. This ability of antibodies to specifically recognize numerous distinctive molecules makes them indispensable research tools. In addition, their ability to identify biological molecules in cells and tissues serves as a foundation for an immunohistochemical approach.

Karl Landsteiner first demonstrated a specific binding of antibody to antigen in the 1930s. An antigen-binding site, also known as an epitope, consists of amino acid sequences and confers antigen recognition. A simplified antibody structure depicting an antigen-binding site is shown in Figure 1. Typically, the epitopes for antibodies raised against native proteins develop clusters of three-dimensional protein conformation (tertiary structure). Therefore, the conformation of the protein is a key determinant of antibody recognition when the antibody is raised against a native or recombinant protein. Many traditional immunohistochemistry methods employ fixation, tissue processing, and antigen retrieval, which may significantly alter the target protein's tertiary structure. These changes in the protein structure can be due to chemical modification, such as oxidation, reduction of disulfide bonds, and modification of primary amines by cross-linking fixatives such as formaldehyde. In addition, gross changes in protein structure can be caused by denaturation, fixation, proteolytic cleavage, changes in pH, and dehydration. Moreover, antibodies raised against peptide immunogens that mimic continuous epitopes on the target protein may detect both folded and denaturated protein.

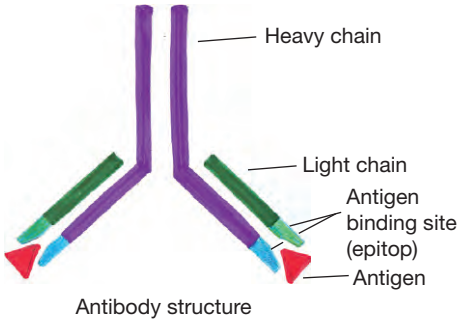

Figure 1 Schematic antigen structure depicting heavy chain, light chain, and antigen-binding site (epitope).

Therefore, testing various fixatives and antigen retrieval solutions and optimization of the tissue preparation and staining techniques are needed to understand whether the antibody will recognize the antigen after tissue processing. Thus each new antibody has to be evaluated individually for each experimental condition and immunohistochemical application.

3.316.2. Factors Contributing to Antibody–Antigen Interaction

3.316.2.1. Affinity

Antibody affinity is defined as strength of the binding interaction between antigen and antibody. It depends on the closeness of the stereochemical fit between antibody sites and antigen determinants, the size of the area of contact between them, and the distribution of charged and hydrophobic groups. In stable condition, where the associated form of the antigen and antibody is favored, the antibody is referred to as being of higher affinity. Normally the binding of an antibody to an antigen occurs within 1 h at room temperature, when the antibody–antigen system achieves equilibrium. Antigen–antibody interaction is slower at a lower temperature (usually at 4 °C) and will require more time for antibody incubation (usually overnight). While the affinity of monoclonal antibodies can be characterized, the affinity of polyclonal antibodies cannot be determined, because polyclonal serum contains a combination of antibodies with different affinities.

3.316.2.2. Avidity

Antibody avidity also considerably contributes to the success of immunohistochemical staining and refers to the strength of antigen–antibody binding. Avidity is a measure of the contribution of multivalent interactions to the stability of the antigen–antibody complex – which is different from affinity – that describes the strength of a single bond. Multivalent interactions can take place when there is a high local concentration of the protein of interest, or when an antigen contains multiple copies of an epitope. Thus, the intrinsic flexibility of antibody structure allows the recognition of various antigens in an array of conformations. Antigens displaying multiple epitopes can be cross-linked by antibodies to form stable complexes, resulting in signal amplification and further enhancement of the experimental results. An excess of either the antibody or the antigen, however, may limit the formation of stable complexes and lead to signal loss. This phenomenon is observed occasionally during immunohistochemical staining experiments.

Therefore, optimizing each of the parameters – particularly titration of the primary antibody – is critical to successful immunostaining, and higher concentration of an antibody may not always be better for immunological applications. Additional common problems in immunohistochemical techniques include background staining, which is influenced by primary antibody concentration, tissue preparation, and endogenous enzyme activity, and unwanted cross-reactivity with proteins other than the target protein.

3.316.2.3. Specificity

The specificity of an antibody is its ability to distinguish between different epitopes. The specificity of some antibodies can be so precise that they are able to discriminate between enantiomers (one of a pair of optical isomers) of the same molecule, but this term is more commonly used in reference to the variety of species that an antibody is raised against or to refer to a target protein. In immunohistochemistry, specificity is harder to determine, as compared to Western blotting or immunoprecipitation, as subcellular staining is limited to nuclear or cytoplasmic localization. Inclusion of suitable controls (e.g., negative control antibodies, control tissues, control cell preparations) is required to confirm observations. The most appropriate control samples are knockout tissues or cell preparations, but data interpretation may be complicated by compensatory expression of related proteins that show cross-reactivity with the primary antibody.

3.316.2.4. Stability

Antibodies are stable proteins, and usually, with careful handling, the shelf life of a purified antibody can be as long as 10 years. The stability of antibodies depends on their purification method. For example, exposure to acidic conditions can cause aggregation and affect antibody stability. This, in turn, may influence the results obtained from immunohistochemical experiments by increasing nonspecific background staining. In addition, conjugation to fluorophores, enzymes, and small molecules can also have an effect on antibody stability, shelf life, and background staining, and should be considered when troubleshooting unexpected patterns.

Antibodies are susceptible to freeze–thaw cycles and should be properly aliquotted and stored. In the long term, most antibodies are best preserved at −80 °C in a freezer that does not go through repeated freeze–thaw cycles. If glycerol is present as a cryoprotectant, antibodies can be stored at −20 °C, because at this temperature, the antibody solution does not freeze. Short-term storage at 2–8 °C is also possible to facilitate handling, but care must be taken to prevent bacterial or fungal growth. Antibody contaminated with bacterial or fungal matter should not be used, as it will result in unspecific background staining.

3.316.3. Visualization of Antibody by Enzymatic or Fluorescent Labeling and The Advantages and Disadvantages

A reporter label is used to visualize an antibody–protein reaction in a tissue section. An enzymatic or fluorescent label could bind directly to the primary antibody, which is raised against the target protein to a secondary antibody, which in turn recognizes the primary antibody or a compound of an amplification system. The enzymatic labeling technique is broadly used in research and clinical laboratories. The recent advances in the fluorochrome-conjugated antibody approach have made possible the creation of brightly colored images and multilabeled stains because a fluorochrome absorbs and emits light in a specific spectrum viewed under a particular filter. Several fluorochromes can be used simultaneously, enabling the study of immunobiological processes in depth and in combination with other fluorescence approaches (e.g., near-infrared fluorescence molecular imaging).

The selection of the proper reporter label detection system is not trivial as both enzymatic and fluorescent labels have their advantages and disadvantages. Hence, the appropriate and careful choice of histological methods and microscopy techniques enables the successful localization of the target (Figure 2). In general, it is preferable to begin immunohistochemical studies using enzymatic labeling, which requires no more than bright-field microscopy. Light microscopy allows researchers to identify cell-specific protein expression in association with overall morphological changes in the tissue. Follow-up fluorescence microscopy studies, and particularly double or triple labeling, could be done afterward to address more specific questions regarding protein–protein colocalization.

3.316.3.1. Enzymatic Labeling and Common Chromogens

Several labeling enzymes are used in immunohistochemistry in combination with various chromogens. The chromogen determines the color of the reaction precipitate product. The chromogen choice is largely dependent on personal preference and overall research design. Peroxidase and phosphatase enzymes are commonly used as enzymatic labels in both research and clinical laboratories. Particularly, peroxidase-chromogen combinations such as 3-amino-9-ethylcarbasole (AEC) and

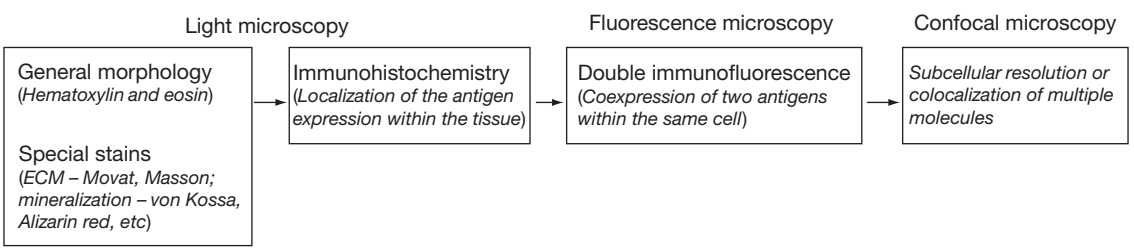

Figure 2 Sequence of histological techniques and microscopy methods for successful target identification.

3,3-diaminobenzidine (DAB) are the most frequent choices because they provide optimal contrast with counterstains (e.g., hematoxylin) and because they are simple to use, reducing the workload involved in time consuming and labor-intensive experiments. AEC produces a bright red product, which is soluble in alcohol, and therefore, requires an aqueous mounting medium. The disadvantage of AEC is that the intensity of the staining decreases over time, especially with exposure to light; hence, AEC-developed slides should be stored in the dark. DAB generates a brown or black polymerized precipitate that is insoluble in alcohol. DAB-developed slides require dehydration in increasing concentrations of alcohol, followed by mounting in organic medium. The advantage of DAB is that it produces permanent preservation of the immunohistochemical signal, with a favorable signal-to-background ratio. But DAB is a carcinogenic chemical, and care must be taken to handle it properly.

The intensity of an enzyme–chromogen reaction signal depends on the amount of target protein, the concentration of primary and secondary antibodies, and the development time. A tissue containing a large amount of target protein or stained using a highly concentrated antibody is expected to produce a strong signal in <3–5 min. A tissue containing a small amount of target protein requires incubation for up to 30 min. As reaction time fluctuates, it is strongly recommended to examine the sections regularly using a light microscope during the development stage until the desired result is achieved.

3.316.3.2. Fluorescence Labeling and Fluorophores

Immunofluorescence technique employs fluorescent labels to visualize the subcellular distribution of the molecule of interest. Usually tissue sections are incubated with fluorochrome-conjugated secondary antibody or avidin–biotin complexes. In some cases, primary antibody conjugated with fluorescent labels is applied directly to tissue sections. This direct labeling decreases the number of steps in the staining protocol, and more importantly, often prevents cross-reactivity and high background staining. Following immunofluorescence staining, the tissue sections are viewed using a fluorescence microscope equipped with a set of filters for imaging fluorochromes according to their emission and excitation characteristics. In immunohistochemistry, the most commonly used fluorescent dyes are fluorescein (e.g., fluorescein isothiocyanate (FITC), green, excitation 494 nm, emission 521 nm) and rhodamine (e.g., Texas Red, red, excitation 595 nm, emission 615 nm) derivates. Other derivatives of rhodamine include fluorophores such as Alexa Fluor dyes. The excitation and emission spectra of the Alexa Fluor series cover the visible spectrum and extend into the infrared (e.g., Alexa Fluor 350, blue; Alexa Fluor 488, green; Alexa Fluor 680, red). This new group of fluorescent dyes has been recently developed for various applications where higher photostability, increased brightness, different spectra characteristics, or different attachment groups are needed (e.g., molecular imaging).

As with most fluorescence techniques, a significant problem with immunofluorescence is rapid photobleaching. Reducing exposure to light, increasing the concentration of the flourophore, or employing more robust fluorophores such as Alexa Fluors can control the loss of signal intensity caused by photobleaching. Notably, image acquisition and quantification should be done within days after the staining procedure. Interestingly, in some cases, tissue-inherent autoimmunofluorescence properties can be used as a landmark to help with the orientation of the tissue section. For example, elastin autofluorescence serves as an excellent marker of arterial media (Figure 3). Overall, excellent color contrast, high resolution, and the capacity to produce simultaneous multicolor imaging of proteins in the same cell make immunofluorescence imaging a convenient and reliable tool for studying pathobiological processes.

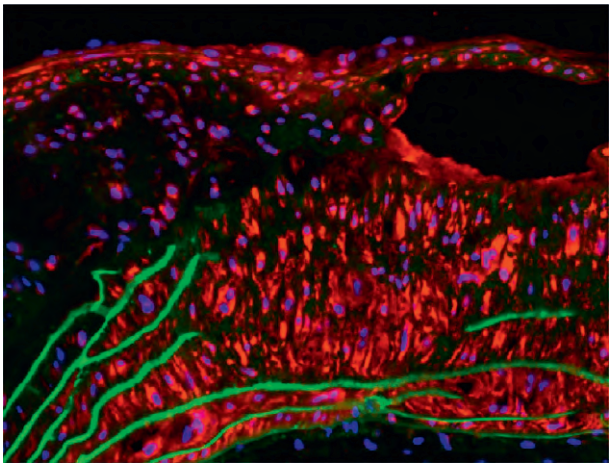

Figure 3 Immunofluorescence staining with anticathepsin S antibody (Texas Red). Autofluorescence of elastin in the media of mouse aorta (green). Original magnification ×200. Modified from Aikawa, E.; *et al*. *Circulation* **2009**, *119*, 1785–1794.

3.316.4. Basic Immunohistochemistry Protocols and Their Advantages and Disadvantages for Biomaterial Science

3.316.4.1. Tissue Preparation

Tissue preparation is a critical step in obtaining reliable and reproducible results in immunohistochemistry. There are two major types of specimen preparation commonly used in immunohistochemistry staining experiments: paraffin-embedded and fresh-frozen tissue samples. These two conventional tissue preparation techniques are remarkably successful in small soft tissues; however, there are many sample types for which these techniques do not work well, including large samples, complex samples containing soft and hard tissue parts, and hard tissues. In particular, the biggest obstacle to the application of cryosectioning and paraffin sectioning to large samples is that the tissue structure is extensively damaged during cutting. Therefore, occasionally a polymer embedding is preferable, and methyl methacrylate (MMA) can be a good alternative to glycolmethacrylate (GMA) embedding as it preserves both enzymatic activity and tissue antigenicity. Although this chapter is primarily focused on the most commonly used immunohistochemistry protocols, the various

issues concerning tissue preparation – including the processing, fixation, orientation, and embedding of specimens in relation to biomaterials and tissue engineering – will be discussed in greater detail.

3.316.4.1.1. Paraffin-embedded tissues

Paraffin-embedded tissues are a common type of specimen used for immunohistochemistry. Prior to paraffin embedding, tissues undergo fixation and processing.

3.316.4.1.1.1. Fixation

The choice of a fixative should be made with several considerations in mind, including the preservation of antibody–antigen interaction properties and short-term and long-term storage. Fixation preserves tissues by preventing autolytic changes, and thus allows tissues to remain unchanged during subsequent treatment. It is crucial that tissue is collected and fixed immediately after harvesting, as delay will promote hypoxia, proteolytic enzyme activation, autolysis, and drying – factors deleterious to antigen preservation. On the other hand, fixation causes changes in the protein structure, rendering it biologically inactive. In addition, cross-linking fixatives create marked differences in the chemical and antigenic properties of the proteins compared to their native forms.

For special studies, a wide variety of fixatives are available. The investigator should be aware of the advantages and disadvantages of each fixative and the artifacts associated with them. The most popular fixatives used for immunohistochemical staining techniques are aldehyde fixatives (e.g., paraformaldehyde (PFA), formalin, glutaraldehyde), protein-denaturing agents (e.g., methanol, ethanol), and acetone.

3.316.4.1.1.1.1. Formalin Ten-percent buffered neutral formalin is considered the best general fixative for pathological specimens because it preserves the broad range of biological structures, requires a relatively short fixation time, penetrates rapidly, and can be used for long-term storage. Tissue samples can remain in 10% buffered formalin for many months without undesirable effects or unwanted precipitates. Formalin does not precipitate protein or harden albumin. Cellular components such as nucleic acids, carbohydrates, and lipids are not fixed directly, but rather trapped in the network of insoluble cross-links. Of note, formalin reacts with DNA and RNA only at 65 and 45 °C, respectively, due to uncoiling of DNA and RNA at these temperatures. Such temperatures can be reached only in the tissue processor when wax impregnation takes place; by that time, however, the majority of the fixative has been washed out. Although formalin fixation provides excellent preservation of tissue morphology and architecture, it often results in antigen masking due to aggressive and excessive cross-linking of proteins. In addition, fixation with formalin increases tissue hydrophobicity, leading to an increased incidence of general background staining.

3.316.4.1.1.1.2. Paraformaldehyde Based on the experience of our laboratory, low concentrations of PFA (2–4%) are most favorable for immunohistochemical applications. While providing excellent ultrastructural preservation, PFA fixation keeps antigen masking to a minimum. A disadvantage of 4% PFA fixation is that tissue penetration is slow, and as a result, incubation requires more time and a small sample size is preferred.

3.316.4.1.1.1.3. Ethanol, methanol, and acetone Ethanol, methanol, and acetone penetrate tissue poorly and are generally used on tissue sections only before staining rather than on pieces of tissue. Absolute alcohol preserves glycogen but causes distortion of nuclear detail and shrinks cytoplasm. Fixation with acetone creates undesirable morphological changes, such as the loss of cell membranes and chromatolysis. In addition, extended fixation with acetone makes tissue brittle.

3.316.4.1.1.2. Antigen retrieval

The antigen-masking effects of fixation are reversible to varying degrees by a process known as antigen retrieval. It involves exposing the tissue sections to heat or proteolytic enzyme digestion before performing immunohistochemical staining. The success of retrieval depends on the fixative, the duration of fixation, and the antigen of interest. The mechanism of antigen retrieval is disruption of the methylene bridge cross-links formed between proteins during fixation, which allows antibody access to the epitope. The harsh conditions of heat and proteolytic enzyme digestion methods often cause tissue sections to lift off the slides. Therefore, tissue–adhesive-coated slides should be used.

3.316.4.1.1.3. Tissue processing

Basic tissue processing consists of three stages: dehydration, clearing, and infiltration. These steps are intended to remove the fixative and water and replace them with a medium that solidifies tissue. Use of graded alcohols from a lower to a higher concentration is a standard procedure for tissue dehydration. The dehydration step is followed by the replacement of alcohol with xylene, a clearing solution. Recently, many immunohistological laboratories have used automatic tissue processors, which promote tissue infiltration using heat, vacuum, pressure, and agitation. But such tissue processors are costly and space consuming. In addition, the heat used in the tissue processors melts paraffin wax at 50–60 °C, which can be harmful to antigen staining. Paraffin-embedded tissue sections are also exposed to high temperatures during oven slide drying in order to increase tissue adherence to the slide. The duration and intensity of heating tissues during embedding or slide drying should be kept to a minimum.

In biomaterials research, the tissue samples collected for patho-immunohistological analyses are considerably larger than clinical samples (e.g., biopsies) and often contain biopolymers and other hard materials. The tissue processing therefore may require more time. Taking shortcuts in processing may result in poorly and incompletely dehydrated, cleared, and infiltrated specimens, which will cause further problems with sectioning, staining, and examining the tissues. A protocol for paraffin embedding of relatively large ($\sim 2.5 \times 2.5$ cm) tissue samples is given below.

Protocol for paraffin embedding

1. 80% alcohol, 1 h
2. 95% alcohol, three changes, 1 h each
3. Absolute alcohol, three changes, 1 h each
4. Xylene, three changes, 1 h each
5. Paraffin, three changes, 1 h each
6. Embedding

3.316.4.1.1.4. Specimen orientation

The quality of a tissue section depends on every step of processing. Even with adequate fixation, processing, and sectioning, a tissue section can be destroyed by improper orientation. Every tissue fragment, especially tissue containing heterogeneous material (e.g., graft, tissue-engineered scaffold, and stent), should be analyzed in order to decide how to position the tissue in the block. A broad knowledge of gross tissue structure and anatomy and explicit communication with the pathologist are critical for proper tissue placement. Tissue sections should be embedded entirely flat to assure that a complete section will be obtained. Care must be taken to prevent causing artifacts by rough handling of the specimen. Large or dense specimens should be oriented at a slight angle to the knife-edge in order to minimize the risk of pulling the tissue out of the block and diminishing knife vibration. Importantly, tubular structures such as arteries should be placed as vertically as possible, so that the knife cuts perpendicular to the long axis of the tube and across the lumen.

3.316.4.1.1.5. Embedding

Paraffin is the most popular and widely used embedding medium. Care should be taken, however, to prevent the paraffin wax from overheating (as described earlier in the section on tissue processing). The paraffin-embedding technique used in immunohistochemistry is similar to that used in general histological methods, and therefore will not be described in this chapter.

3.316.4.1.2. Frozen tissues

Fresh-frozen, unfixed tissue is the most suitable preparation for immunohistochemistry, but improperly frozen tissue introduces ice crystal artifacts that can make morphological interpretation difficult. If frozen slowly, large ice crystals are allowed to form in the tissue, creating cracks, enlarging intracellular and extracellular spaces, and rupturing cell membranes. Alternatively, 'snap freezing' employs liquid nitrogen (−190 °C) for rapid freezing. While quick freezing is achieved, liquid nitrogen still has its disadvantages, as tissue often cracks due to the rapid expansion of ice, thus producing problems with sectioning. The vapor phase of liquid nitrogen can act as an insulator, resulting in uneven tissue freezing and contributing further to ice crystal formation. The artifacts due to slow and rapid freezing techniques can be overcome by freezing the tissue in chilled/dry ice isopentane (2-methylbutane) where the tissue freezes without expansion and the resultant tissue damage. Therefore, this freezing method is preferable for histological and immunologistochemical applications. Handling the tissue after freezing should be kept to a minimum to prevent thawing.

Protocol for dry ice/isopentane freezing

1. Place the container with isopentane onto dry ice 15–20 min before embedding so that the isopentane becomes cold.
2. Dissect the tissue (~1 × 1 cm).
3. Incubate the tissue in optimal cutting temperature (OCT) compound at room temperature (two to three changes, 1 min each).
4. Add OCT into plastic cryomold.
5. Place tissue in cryomold with OCT (make sure that tissue is completely covered by OCT).
6. Using long forceps, place the cryomold into cold isopentane until OCT stops bubbling (~1–3 min).
7. Place frozen mold onto dry ice until isopentane fumes evaporate before going to −80 °C freezer.

Following cryotomy, frozen sections are transferred to slides and then left to air dry at room temperature up to 30 min. The contrast in heat melts OCT compound on the slide, thus providing better tissue adhesion. The sections are then stored at −20 or −80 °C until needed. This brief freeze–thaw cycle usually does not have any harmful effects on immunohistochemical staining.

Occasionally, it is required to freeze tissue samples that have previously been fixed. The advantage of prefixed tissues is that fixation prevents the diffusion of enzymes and antigens during freezing. The increased water content of the tissue may contribute to severe ice crystal formation and tissue artifacts, but this can be avoided by immersing the tissue samples into sucrose solution. As it has a lower freezing temperature than water, sucrose solution acts as a cryoprotectant and prevents ice crystal formation.

3.316.4.2. Immunohistochemical Staining Protocols

Immunohistochemical staining protocols can vary from one-step procedures, where the label is conjugated directly to the primary antibody, to multiple-step procedures, where the label is conjugated to a secondary antibody or avidin–biotin complex (Figure 4). These protocols can easily be adapted for use with fresh-frozen and formalin-fixed paraffin-embedded tissue sections or enzymatic and fluorescent labels. To achieve the highest intensity of positive specific staining with the

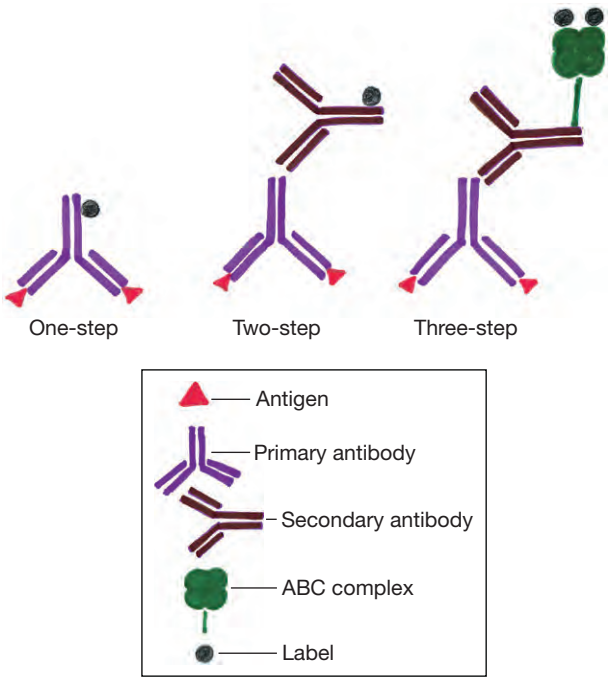

Figure 4 Single (one-step) and multiple (two-step and three-step) indirect immunohistochemistry. ABC, avidin–biotin complex.

lowest amount of background staining, an optimization of antibody dilutions should be performed using a known positive-control tissue. This section provides the most common immunohistochemistry staining protocols that are being successfully used in our laboratory.

Immunohistochemical (indirect, three-step) staining protocol for formalin-fixed, paraffin-embedded sections

1. Place slides in oven 60 °C for 1 h.
2. Let slides cool for 30 min at room temperature.
3. Place slides in xylene for 5 min, two changes. In a similar fashion, place slides for 5 min each in: 100% ethanol, two changes; 95% ethanol, two changes; 70% ethanol, two changes. Rinse slides for 5 min in dH_2O.
4. Place slides in 0.3% H_2O_2 solution for 3 min to inhibit endogenous peroxidase activity. Wash well in dH_2O. Wash in phosphate buffered saline (PBS) for 5 min.
5. Prepare the moisture chamber with water-soaked paper towels. Remove excess moisture around the section using a Kimwipe. Do not let the sections dry out.
6. Perform any necessary antigen-retrieval techniques. Wash in PBS for 5 min.
7. Cover each section with blocking serum (4% normal serum, depending on primary antibody source) for 30 min in moisture chamber.
8. Tap off blocking serum and wipe excess solution off the slide with a Kimwipe. Cover each section with primary antibody solution (make the appropriate dilution of antibody in the blocking solution). Incubate in the moisture chamber for 60–90 min.
9. Tap off the primary antibody solution and wash twice, 5 min each time in PBS.
10. Cover each section with the appropriate secondary antibody solution (1:100) and incubate for 30 min in moisture chamber. Prepare ABC solution (see Step 11).
11. Tap off the secondary antibody solution as above and wash the slides in PBS (twice, 5 min each).
12. Cover each slide with ABC (horseradish peroxidase) kit, prepared in Step 9 (solution must stand for 30 min at room temperature after being prepared).
13. Wash the slides in PBS (twice, 5 min each).
14. Prepare the chromogen solution. Check the reaction under the microscope.
15. Rinse in H_2O twice, 5 min each.
16. Counterstain with Harris's hematoxylin solution for 3–5 min.
17. If DAB is used, dehydrate slides. Place slides for 3 min each in: 70% ethanol, 95% ethanol, 100% ethanol, xylene, twice in each solution. Place one drop of Permount on section and coverslip.

Immunohistochemical staining protocol for frozen sections

1. Dry sections for 30 min at room temperature.
2. Wash the slides in PBS (twice, 5 min each).
3. Fix sections in 4% PFA (5 min).
4. Wash the slides in H_2O and PBS (twice, 5 min each).
5. Place slides in 0.3% H_2O_2 solution to inhibit endogenous peroxidase activity for 1 min. Wash well in dH_2O. Wash in PBS for 5 min.
6. Do not let the sections dry out. Draw a circle around each section with a wax pencil.
7. Cover each section with blocking serum (4% normal serum, depending on primary antibody source) for 30 min in moisture chamber.
8. Tap off blocking serum and cover each section with primary antibody solution (make the appropriate dilution of antibody in the blocking solution). Incubate in the moisture chamber for 60 min.
9. Tap off the primary antibody solution and wash twice, 3 min each time in PBS.
10. Cover each section with the appropriate secondary antibody solution and incubate for 30 min in moisture chamber. Prepare ABC solution (see Step 11).
11. Tap off the secondary antibody solution as above and wash the slides in PBS (twice, 3 min each).
12. Cover each slide with ABC (horseradish peroxidase) kit prepared in Step 9 (solution must stand for 30 min at room temperature after being prepared).
13. Wash the slides in PBS (twice, 3 min each).
14. Prepare the chromogen solution. Check the reaction under the microscope.
15. Rinse in H_2O for 3 min twice.
16. Counterstain with Gill's hematoxylin solution for 1 min.
17. If AEC is used, rinse with tap water for 5–10 min and coverslip with aqueous mounting medium.

Immunofluorescence protocol for frozen sections (single and double labeling)

1. Fix cryostat sections (6–7 mm) in 4% PFA for 5 min and wash the slides in H_2O followed by PBS (twice, 5 min each).
2. Block nonspecific binding of primary antibody with 4% species-appropriate normal serum by incubation for 30 min. Do not rinse sections after blocking.
3. Apply primary antibody diluted in PBS supplemented with 4% of the species-appropriate normal serum and incubate for 90 min. Wash in PBS (3 times each).
4. Apply biotinylated secondary antibody diluted in PBS supplemented with 4% of the species-appropriate normal serum and incubate for 45 min. Wash in PBS (3 times each).
5. Incubate with Streptavidin-conjugated Texas Red for 20 min. Wash in PBS (3 times each).
   For single labeling, continue to Step 8.
   For double labeling, continue to Step 6.
6. In the case of double immunolabeling, the sections after the first part of staining undergo two blocking procedures:
   a. Treatment with an avidin–biotin blocking kit (Vector): solution A (15 min) followed by 15 min washing; and solution B (15 min) followed by 15 min washing.
   b. Blocking with 4% appropriate normal serum (20 min).
7. For the second antigen, apply primary antibody (overnight at +4 °C), followed by biotinylated secondary antibody (45 min) and streptavidin-coupled FITC (20 min). Wash in PBS (3 times each).
8. Counterstain nuclei with 4'6-diamidino-2-phenylindole (DAPI) for 2 min.
9. Coverslip and place in the box at +4 °C.

3.316.4.3. Counterstaining and Mounting

3.316.4.3.1. Counterstaining following immunohistochemical staining

Many investigators underestimate the importance of nuclear counterstaining after completion of immunohistochemical staining. It is necessary, however, for the evaluation of overall tissue morphology and the nuclear-cytoplasmic structural relationship. In general, counterstains are designed to provide a contrast of nucleus with cytoplasmic immunostaining and surrounding tissue. It is important to use a color that is different from that of the enzymatic label in order to avoid confusion. The most common colors are blue (e.g., hematoxylin, toluiding blue, methylene blue), red (e.g., fast red), and green (e.g., light green). Hematoxylin is the most popular nuclear counterstain and provides the perfect contrast when used with AEC or DAB chromogens, which produce red and brown reaction products, respectively. Hematoxylins can be used in progressive (Mayer's or Gill's) or regressive (Harris's) staining protocols. During regressive staining, tissue sections are incubated with hematoxylin for a long time to achieve overstaining, and then differentiated to remove extra stain by immersion in an acid solution. Initially, hematoxylin stains nuclei red, until the pH changes to alkaline and the color changes to blue. This is an important step to reach visible contrast between nuclei and cytoplasm, and the reaction is commonly accomplished by washing the slides in tap water (in most locations, running tap water provides enough alkalinity) or in a solution of ammonia. When using AEC chromogen that is soluble in alcohol, the use of nonalcohol-containing hematoxylins (e.g., Mayer's or Gill's) is preferable. If Harris's hematoxylin is used, the staining duration should be kept to the minimum because it contains alcohol. Harris's hematoxylin is a good choice, however, for DAB.

Staining intensity depends on several factors, including the concentration of the hematoxylin solution, the duration of staining, the duration of differentiation time, and tissue preparation (paraffin-embedded vs. fresh-frozen). It is important to maintain a balance between obtaining a good nuclear morphology and not overstaining the other tissue components.

3.316.4.3.2. Mounting following immunohistochemical staining

Mounting medium is used to protect stained tissue sections from physical damage and to improve the clarity and contrast of the image during microscopy. The choice of mounting medium depends largely on the label and the chromogen used. Mounting media can be categorized into two groups: organic and aqueous. Organic mounting medium is designed for the permanent preservation of insoluble chromagen substrates such as DAB; it is not suitable for fluorescent labels. Aqueous mounting medium is suitable for all enzymatic label/chromogen combinations, as well as fluorescent labels. Tissue sections mounted in such medium do not need dehydration or clearing steps; however, the clarity and contrast tend to be of poor quality compared to organic mounting medium.

3.316.4.4. Data Interpretation

The interpretation of staining results relies heavily on the skill and experience of the reader, and is often the most difficult aspect of immunohistochemistry. The reader, usually a pathologist, should identify the antigen while taking into consideration all possible artifacts due to fixation, tissue processing, sectioning, and staining. In addition, the interpreter must know what the staining should look like both in normal tissue and in a pathological specimen. Assessment of the pattern of staining is a critical step. Specific staining could associate with cytoplasm, nuclei, or cell membrane. Staining could be focal or diffuse. Focal staining localizes with smaller, distinct areas of cells, while diffuse staining associates with larger areas and is often nonspecific. Nonspecific or background staining usually associates with connective tissue, adipocytes, and collagen, and is often present when polyclonal antibodies are employed. Problems with staining interpretation frequently occur due to poor blocking of endogenous enzyme activity or lack of fixation. Poorly fixed tissue may have a preserved antigen, but morphology is often sacrificed. While longer fixation will preserve tissue morphology, antigens may be altered, masked, depleted, or destroyed. Cells that have undergone necrosis, autolysis, or have been damaged will likely show nonspecific staining. The most challenging staining to interpret is immunofluorescence because in addition to nonspecific staining, various tissues and cells have inherent autofluorescence (e.g., collagen, elastin, macrophages/foam cells). Tissue fixed in formalin provides additional problems in interpretation due to autofluorescence. Therefore, interpretation of immunofluorescence staining should always be done in conjunction with bright-field microscopy.

3.316.5. Detection of Pathobiological Processes and Associated Cellular Events in an Implanted Site

Implantation of an artificial prosthesis in the body interferes with the function of the tissue site of implantation, initiating the processes of 'host integration' and inducing a wound-healing response. Wound-healing response is determined by the degree of surgical trauma, the mechanical stresses applied to the tissue by an implant, and biocompatibility of the biomaterial. Normal healing is a complex cascade of cellular events characterized by three phases: inflammation, proliferation, and maturation/remodeling. In addition, newly formed blood vessels connect the construct to the circulation to provide the constructs with oxygen, which is critical for maintaining viability of the implanted cells. Finally, the immune response to the implanted construct plays a key role in the long-term outcome by defending the body from foreign matter. These three biological responses – wound-healing, angiogenesis, and immune response – are multicellular processes that are highly regulated as a series of interacting events. Each process can be characterized by cell-specific phenotype, growth factors, and cytokine expression, and therefore can be detected using specific antigen–antibody reaction. In addition to a normal wound-healing reaction, tissue interaction with an implant involves biomaterial-specific responses (e.g., foreign body reaction, encapsulation). Understanding of biomaterial–tissue interactions requires consideration of local and systemic effects of material on host tissues (e.g., inflammation, pannus formation, encapsulation) as well as biological effects of host environment on material (e.g., calcification). In this section, immunohistochemistry is presented in the context of

biomaterial implantation and tissue engineering. We focus on current understanding of the mechanisms of healing and rejection of biomaterials and provide a brief summary of wound-healing-associated cellular events that can be characterized using immunohistochemistry.

3.316.5.1. Wound-Healing Response

Wound-healing is a coordinated tissue process characterized by an inflammatory phase (hours), a proliferation phase (days), and a maturation/remodeling phase (weeks).

3.316.5.1.1. Inflammatory phase

The cellular aspect of the inflammatory phase occurs within hours of injury.

3.316.5.1.1.1. Neutrophils

Neutrophils are the predominant cell type during the first 48 h after implantation but they do not appear essential to the wound-healing process. Phagocytic neutrophils clean bacteria and necrotic material from the wound and release proinflammatory mediators. In some cases, the neutrophil number is low, but their absence does not prevent healing. This inflammatory phase can be detected by immunohistochemistry, using antineutrophil cytoplasmic antibodies, a group of IgG antibodies against antigens of neutrophil granulocytes that show a diffusely granular cytoplasmic staining pattern.

3.316.5.1.1.2. Macrophages

Once at the site of injury, monocytes differentiate into macrophages. Macrophages are essential to healing and are the most important cell type in the early phase of wound-healing. Phagocytic macrophages eliminate necrotic debris and bacteria. Recent studies identified two distinct phases of monocyte/macrophage participation in wound-healing, and showed the divergent properties of these cells in this process. Ly-6C^{hi} monocytes dominate early (phase I) and exhibit phagocytic, proteolytic, and inflammatory functions. Ly-6C^{lo} monocytes dominate later (phase II), have attenuated inflammatory properties, and express vascular endothelial growth factor (VEGF). Consequently, Ly-6C^{hi} monocytes digest damaged tissue, whereas Ly-6C^{lo} monocytes promote healing via myofibroblast accumulation, angiogenesis, and deposition of collagen.

Macrophages also secrete collagenases (matrix metalloproteinases MMP-1 and MMP-13), gelatinases (MMP-2 and MMP-9), and elastolytic cathepsins (cathepsin K, cathepsin S) that break down injured tissue. In addition, macrophages release platelet-derived growth factor (PDGF), a cytokine that stimulates the chemotaxis and proliferation of fibroblasts and smooth-muscle cells. In particular, it plays a significant role in angiogenesis. Macrophages also secrete several substances such as chemotactic factors, coagulation factors, and complement components that are important for healing. Thus, immunohistochemical assessment of macrophage subsets – their function, activation, and expression of cytokines and growth factors – may reveal delayed or defective wound repair.

The following macrophage markers could be assessed using immunohistochemistry:

- AM-3K: immunohistochemical staining of routinely processed specimens demonstrated that this antibody recognized a specialized subpopulation of antiinflammatory macrophages that are distinct from inflammatory or classically activated macrophages;
- CD 68: a classical macrophage marker expressed by human monocytes and tissue macrophages;
- F4/80: the best macrophage marker to date;
- HAM-56: a pan-macrophage marker; can be expressed by endothelial cells;
- MAC-1/MAC-3: monoclonal antibodies against the human mannose receptor, a specific marker for macrophages;
- CD 163: a specific marker of macrophages in paraffin-embedded tissue samples; is not restricted to 'mature' macrophages;
- 25F9: a late-stage inflammation marker;
- Ly6C: an early-stage inflammation marker;
- RM3/1: an intermediate- and late-phase inflammation marker;
- 27E10: a distinct marker of macrophage activation and differentiation, an early-stage inflammation marker;
- ED-1: used as a marker for rat macrophages;
- ED-2: a resident macrophage marker;
- Carboxypeptidase M (CPM): a marker of macrophage maturation *in vivo* and *in vitro*;
- Chitotriosidase: a marker of macrophage stimulation;
- Cathepsin K: a marker of macrophage differentiation; also expressed in osteoclasts.

3.316.5.1.1.3. Lymphocytes

T lymphocytes migrate into the wound during the inflammatory phase, ~72 h after injury. These cells are attracted to the wound by the cellular release of interleukin 1 (IL-1). Lymphocytes secrete lymphokines, such as heparin-binding epidermal growth factor (EGF) and basic fibroblast growth factor (bFGF), which have been shown to play a role in wound-healing and angiogenesis. Lymphocytes also play a role in cellular immunity and antibody production. Lymphocytes, their subsets, and lymphocyte-derived factors can be detected using commercially available antibodies (see **Section 3.316.5.3**).

3.316.5.1.2. Proliferative phase

Formation of granulation tissue or foreign body reaction is a central event during the proliferative phase. Inflammatory cells (mostly macrophages and foreign-body giant cells (FBGC)), fibroblasts, and newly formed vessels immersed in extracellular matrix (ECM) (fibronectin, collage, and proteoglycans) comprise the granulation tissue. FBGC are multinucleated cells thought to form through fusion of macrophages. These cells retain the functional capability of macrophages, and in that capacity, they contribute to the healing process. Granulation tissue formation occurs 3–5 days after injury and overlaps with the preceding inflammatory phase. This phase and the extent of involvement of each component are highly variable, depending on the form, type, and topography of the biomaterial surface.

3.316.5.1.2.1. Epithelialization

Epithelialization is the formation of epithelium over a wound incision, which involves the migration of cells at the wound edges over a distance of <1 mm. In humans, incisional wounds

are normally epithelialized within 24–48 h. Epidermal cells undergo structural changes and secrete collagenases that break down collagen and plasminogen activator, which stimulates the production of plasmin to promote clot dissolution. This epithelial layer provides a seal between the wound and the external environment.

3.316.5.1.2.2. Fibroblasts

Fibroblasts are critical components of granulation tissue. Fibroblast accumulation begins 3–5 days after injury and may last up to 14 days. Following biomaterial implantation, fibroblasts undergo a response known as 'activation,' characterized by a transition of quiescent cells into myofibroblast-like phenotype. Stimuli that initiate fibroblast activation mostly derive from macrophages. Responses of fibroblasts to activation include proliferation, fibrinogenesis, and release of cytokine and proteolytic enzymes. The number of fibroblasts increases in the healing wound while the number of inflammatory cells decreases. Increased numbers of fibroblasts around the implant occur primarily due to local proliferation in response to fibronectin, PDGF, and fibroblast growth factor (FGF). Detection of fibroblasts through immunohistochemistry is difficult, and only a couple of antifibroblast antibodies are available – including mouse antihuman fibroblast monoclonal antibody (clone 5B5), vimentin, and polyclonal anti-DDR2 (Discoidin Domain Receptor 2), which regulates fibroblast proliferation and migration. (Personal communication with Dr. Thomas K. Borg, Medical University of South Carolina.)

3.316.5.1.2.3. Myofibroblasts

A myofibroblast is an activated form of fibroblast that is capable of contraction due to the presence of cytoskeletal proteins that are normally found in smooth-muscle cells – in particular, α-smooth muscle actin. These cells participate in wound repair by contracting the edges of the wound.

The detection of myofibroblasts is complex, and thus a combination of different antibodies should be used (see below). The following myofibroblast markers could be assessed by immunohistochemistry:

- α-actin (α-SMA): a commonly used myofibroblast marker, also expressed in smooth-muscle cells; a marker of fibroblast-to-myofibroblast phenotypic modulation;
- Desmin: should be used in combination with α-smooth muscle actin;
- Vimentin: an intermediate filament;
- Palladin 4lg: a novel marker of myofibroblast conversion *in vivo* and *in vitro*;
- TGF-β1 (transforming growth factor β1): a marker of myofibroblast proliferation, differentiation, and survival.

3.316.5.1.2.4. Smooth muscle cells

Smooth muscle cells are a phenotypically heterogeneous cell population. Studies of these cells, therefore, have long been hampered by the lack of suitable markers. For example, both smooth muscle cells and myofibroblasts are characterized by the expression of α-smooth muscle actin. To distinguish smooth muscle cells from myofibroblast-like cells, a combination of specific markers of smooth muscle cells should be employed.

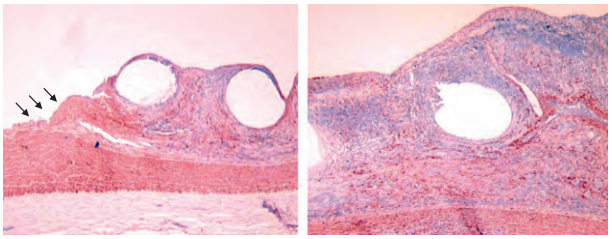

Figure 5 Left: 'good' healing with minimal inflammatory reaction around stent studs. Note, pannus formation/tissue overgrowth (arrows) detected using anti-α-smooth muscle actin antibody. Right: poor healing with abundant inflammation and substantial granulation tissue formation around stent studs. Original magnification ×100.

The following markers of differentiated smooth muscle cells can be assessed by immunohistochemistry:

- α-actin (α-SMA): expressed in differentiated and undifferentiated smooth-muscle cells and myofibroblasts; important component of pannus formation due to tissue overgrowth on the site of anastomosis or implantation (Figure 5);
- Calponin: most highly expressed in terminally differentiated and nonreplicating smooth muscle cells;
- Caldesmon: a specific marker of fully differentiated and nonproliferating smooth muscle cells;
- Smoothelin: a structural protein of differentiated, contractile smooth muscle cells;
- Transgelin (SM22): a marker of differentiating smooth muscle cells;
- SM2: a smooth muscle myosin heavy chain (MHC) isoform; an excellent marker for differentiated phenotype of smooth muscle cells;
- SM1: a MHC isoform; an excellent marker of mature smooth muscle cells;
- SMemb: a nonmuscle myosin that is expressed in embryonic smooth muscle cells or activated mesenchymal cells;
- Desmin: an intermediate filament protein of both smooth and striated muscles.

3.316.5.1.2.5. Differentiation of fibroblast, myofibroblasts, and smooth muscle cells using immunohistochemistry

We identified fibroblasts, myofibroblasts, and smooth muscle cells using a panel of antibodies that work on formalin-fixed paraffin-embedded human samples. We demonstrated the following expression patterns of cell-type markers:

Fibroblasts: α-SMA−, vimentin+, desmin−, SMemb−, SM1−, SM2−

Myofibroblasts: α-SMA+, vimentin+, desmin±, SMemb+, SM1−, SM2−

Smooth muscle cells: α-SMA+, vimentin±, desmin−, SMemb−, SM1+, SM2+

The challenge to detect 'dedifferentiated' cells remains, as they may lose their cell-type-specific markers.

3.316.5.1.3. Maturation/remodeling phase

3.316.5.1.3.1. Collagen

Remodeling begins ~21 days after injury, and may continue indefinitely. The synthesis and deposition of collagen is a critical event in wound-healing. Collagen is secreted to the extracellular space in the form of procollagen. Cleaved procollagen is converted into tropocollagen, which then aggregates to form collagen filaments. Filament, fibril, and collagen fiber formation occur within a matrix gel of glycosaminoglycans, hyaluronic acid, chondroitin sulfate, and heparin sulfate produced by fibroblasts. Collagen remodeling is controlled by the presence of collagenases, so that a balance exists between the formation of new collagen and old collagen. Approximately 80% of the collagen in healthy tissue (e.g., heart valve, artery, skin) is type I collagen, while type III collagen is the primary component of early granulation tissue and is abundant in embryonic tissue. During remodeling, collagen becomes increasingly organized. Fibronectin gradually disappears, and hyaluronic acid and glycosaminoglycans are replaced by proteoglycans. Water is resorbed from the scar, which allows collagen fibrils to get closer together, ultimately decreasing scar thickness. During scar maturation, the collagen subtype synthesis may shift, and type III collagen is replaced by type I collagen. Therefore, immunohistochemical characterization of collagen subtypes, followed by digital image analysis, can be used to quantify collagen organization and tissue maturity.

3.316.5.1.3.2. Proteolytic enzymes

The MMPs or proteolytic enzymes are able to initiate ECM degradation during tissue remodeling. Both macrophage- and fibroblast-derived MMPs contribute to this process. There are at least three mammalian collagenases capable of initiating the degradation of interstitial collagen – collagenase-1 (MMP-1), collagenase-2 (MMP-8), and collagenase-3 (MMP-13). Although increases in total proteolytic activity have been reported in tissue response for a long time after implantation of biomaterials, it is likely that early local expression and activity of these enzymes are necessary for the initial activation of resident fibroblasts. The other proteolytic enzymes that play important roles in tissue remodeling and cell activation include gelatinases (MMP-2 and MMP-9) and elastases (cathepsin S and cathepsin L). The antibodies for identification of these enzymes and other proteolytic enzymes are readily available from various sources.

3.316.5.1.4. Cytokines

Cytokines are important mediators of wound-healing that are released from various cell sources, including neutrophils, macrophages, and myofibroblasts. The following are key mediators that participate in wound-healing responses:

- FGF is a mitogen for endothelial cells, myofibroblasts, and fibroblasts. FGF is also an important activator of angiogenesis. This factor stimulates production of collagen, fibronectin, and proteoglycans, thereby contributing to wound-healing and remodeling.
- PDGF is released from the α-granules of platelets and is responsible for the stimulation of neutrophils and macrophages and the production of TGF-β. PDGF is a mitogen and chemotactic agent for fibroblasts and smooth-muscle cells. This factor stimulates angiogenesis, collagen production, and collagenase expression.
- VEGF is mitogenic for endothelial cells and plays an important role in angiogenesis.
- TGF-β is an important stimulant for fibroblast proliferation, activation, and phenotypic differentiation into myofibroblasts. This factor promotes the production of collagen, proteoglycans, and fibrin, as well as the accumulation of the ECM and fibrosis.
- Tumor necrosis factor α (TNF-α) is produced by macrophages and stimulates angiogenesis, collagen synthesis, and collagenase expression.

3.316.5.2. Angiogenesis

In order for the cell-based construct to function appropriately and integrate into host tissue, blood vessels should form to connect the construct to the circulation, for access to nutrients and oxygen and to remove waste. New blood vessel formation is a complex process that begins with the release of angiogenic factors such as VEGF, angiogenin, angiotropin, and fibronectin from macrophages, platelets, or ECM. The newly formed vessels extend by release of MMPs, which degrade surrounding ECM and facilitate endothelial cell migration and proliferation. Finally, these newly formed vessels are stabilized by recruitment of surrounding mesenchymal cells. New vessels that become unnecessary disappear by apoptosis.

The following endothelial cell markers could be assessed by immunohistochemistry:

- CD 31 (PECAM 1): a cell adhesion and signaling molecule that is enriched at the endothelial cell junctions;
- VE-Cadherin (7B4 antigen): an endothelial-specific marker that plays a role in the organization of lateral endothelial junctions and in the control of permeability properties of vascular endothelium;
- vWF (von Willebrand factor): routinely used to identify vessels in tissue sections;
- VCAM-1 (vascular adhesion molecule-1): a marker of endothelial cell activation, expressed during development and pathological conditions such as inflammation, transplantation, and rejection; mediator of cell migration from blood into tissue;
- CD 34: human progenitor cell antigen, localized on endothelial cells;
- CD 54 (intracellular adhesion molecule-1, ICAM-1): participates in endothelial cell migration;
- ICAM-2 (intracellular adhesion molecule-2): mediates angiogenesis, expressed at the endothelial junctions of vascular endothelial cells;
- CD 62P (P Selectin): a platelet activation marker;
- E Selectin: a marker of endothelial cell activation;
- CD 105 (Endoglin): a highly specific endothelial cell marker expressed on proliferating endothelial cells;
- CD 146 (P1H12): a novel cell adhesion molecule localized at the endothelial cell junction;
- Eotaxin-3: expressed in IL-4-stimulated vascular endothelial cells;
- CD 141 (Thrombomodulin, TM): a marker for microvasculature, but not macrovasculature, endothelial damage;

- VEGF: a key regulator of angiogenesis;
- VEGFR-1 (Flt-1): a high-affinity tyrosine kinase receptor for VEGF, expressed almost exclusively on vascular endothelial cells;
- GBP-1 (guanylate-binding protein-1): a novel endothelial cell marker expressed in a broad range of human tissues; characterizes the activated phenotype;
- MECA-32: a monoclonal antibody that shows high specificity for mouse endothelium in both embryonic and mature tissues;
- MECA-79 antibody: stains HEV (high endothelial venule)-like vessels at various sites of inflammation;
- BNH9/BNF13: reacts with endothelial cells in routinely fixed and embedded tissues;
- Nucleolin: a specific marker of angiogenic endothelial cells within the vasculature;
- D2-40: a recently available antibody that has been used as a lymphatic endothelial cell marker;
- LYVE-1: expressed by endothelial cells of normal lymphatic vessels, but not blood vessels.

3.316.5.3. Immune Response

The immune response to the implanted construct plays a key role in defending the body from foreign matter. It is composed of two complementary pathways known as innate and adaptive immunity. The innate immune system is the dominant system of host defense that responds to pathogens in a generic way. There are two arms of the innate system: biochemical and cellular. The biochemical cascade involves at least 20 proteins of the complement system, which attacks the surfaces of foreign bodies. The cellular components are innate leukocytes that include both phagocytic cells (e.g., macrophages and neutrophils) and natural killer cells. These cells destroy foreign particles by conveying them to intracellular lysosomes. Adaptive immunity allows for a stronger immune response and immunological memory. It also has two arms of defense: humoral and cell-mediated. B and T lymphocytes are two major cell types involved in adaptive immunity. B cells are involved in the humoral immune response, and T cells are involved in cell-mediated immune response. As with B cells, each type of T cell recognizes a different antigen that can be determined using immunohistochemistry:

- CD 4 and CD 8: functionally analogous molecules expressed on mature T cells; the cells have either CD 4 or CD 8 but not both;
- CD 11a/CD 18 (lymphocyte functional antigen-1, LFA-1): a member of the β-integrin family, present on most leukocytes;
- Intracellular adhesion molecule-3 (ICAM-3): an adhesion molecule present on many leukocytes following lymphocyte activation;
- CD 2 (LFA-2) and CD 58 (LFA-3): a pair of molecules involved in T-cell activation;
- CD 2: expressed on all T cells;
- CD 3: expressed on mature T lymphocytes;
- CD 28 and CD 152: present on mature T cells and critically involved in T cell activation;
- CD 80 and CD 86: induced on activated B cells;
- CD 40: a surface protein present on B cells, macrophages, and endothelial cells;
- CD 40L (CD 154): the ligand for CD 40, induced transiently on activated T cells;
- CD 45 (leucocyte common antigen): a phosphatase present on all leukocytes.

3.316.5.4. Encapsulation

Complete tissue regeneration and restoration of function is rare. Fibrous encapsulation is the more typical course of isolation of the implanted biomaterial. Granulation tissue that began to form earlier in the healing process builds to form a capsule that surrounds the implant, isolating it from the local tissue environment. At this point, it is possible for normal local processes to resume and function to be restored if the degree of injury permits. This stage is characterized by collagen accumulation and organization (scar formation) and reduction of the number of inflammatory cells. Overall tissue morphology at the stage of implant encapsulation can typically be demonstrated by hematoxylin and eosin staining and special stains showing collagen (e.g., Masson's, Movat's, picrosirius red), as reagent cost and technician effort are greater when immunohistochemistry is used.

3.316.5.5. Calcification

Calcification often occurs as a consequence of medical device implantation owing to reaction to tissue damage and inflammation. It was recently proposed that arterial and aortic valve calcification, particularly in prevailing dysmetabolic populations, is an inflammatory disease. Advanced calcification such as hydroxyapatite, the crystalline form of calcium phosphate, can be determined by routine histological methods such as von Kossa or alizarin red. However, earlier stages of host tissue mineralization (osteogenic activity and phenotypic changes of smooth muscle cells and myofibroblasts to osteoblast-like cells) could be revealed only using special immunohistochemical staining.

The following osteogenic and chondrogenic markers could be assessed by immunohistochemistry:

- Osteocalcin: a marker of differentiated osteoblasts;
- Osteopontin: a noncollagenous protein; inhibitor of calcification;
- Osteonectin: an inhibitor of hydroxyapatite formation;
- Cbfa1 (Runx2): a master osteoblast transcription factor;
- Osterix: a transcription factor downstream of Cbfa1;
- BMP (2, 4, 7): regulate mesenchymal progenitor cells differentiated along smooth muscle cells, chondrocyte, osteoblast, or adipocytic lineages;
- Osteoactivin: osteoblast-related glycoprotein that plays a role in osteoblast differentiation and function (downstream mediator of BMP-2);
- SOX9: master chondroblast transcription factor;
- Smad6: antagonist for BMP2/4 signaling;
- Osteoprotegerin (OPG): inhibitor of vascular calcification/osteoblastic phenotype;
- LRP5: plays an important role in osteoblastogenesis via β-catenin signaling pathway;
- Msx-2: promotes calcification.

3.316.6. Implant Evaluation Using Immunohistochemical Methods

Teamwork among surgeons, biomaterials engineers, and pathologists is extremely important for success in implant evaluation. Evaluation of the implant without understanding the specific pathological processes in the surrounding tissues will be incomplete. As described above, the key pathological tissue changes at the site of biomaterial implantation involve the wound-healing and host responses. In addition, the evaluation of cell viability, proliferation/apoptosis ratio, and phenotypic changes will be needed to assess devices that modify healing or improve tissue regeneration. Therefore, immunohistological techniques offer an important tool for the assessment of various cellular pathobiological events in implanted tissues.

3.316.6.1. Heart Valve Prostheses

Currently, cardiac valve replacement is the only treatment for calcific aortic valve disease. Approximately 172 000 valves are implanted worldwide each year. The majority of implanted valves are carbon bileaflet tilting disk valves (St. Jude Medical), and flexible-stent-mounted porcine aortic valve bioprostheses (Carpentier-Edwards and Hancock models) fabricated from a gluteraldehyde-fixed pig aortic valve. Patients with mechanical valves have a high risk of thromboembolic complications, while patients with bioprosthetic valve leaflets are susceptible to tissue deterioration, including calcification. Most implant retrieval involves examination of failed valves that are surgically removed or obtained at autopsy. Explanted valves should be inspected for evidence of thrombosis, infection, paravalvular leaks, and calcification. Combined histological and immunohistochemical approaches can be used to assess tissue ingrowth into cloth-covered studs, inflammation, and dystrophic calcification. Immunohistochemical analyses may include evaluation of pannus formation using α-smooth muscle actin antibody; macrophage (e.g., CD 68) and T-cell (e.g., CD 3) infiltration; and noncollagenous proteins (e.g., osteopontin, osteocalcin, osteonectin).

3.316.6.2. Polymer-Based Engineered Tissues

In 1986, Weinberg and Bell reconstructed blood vessels in test tubes using endothelial cells, vascular smooth-muscle cells, adventitial fibroblasts, and collagen. Since then, the field of cardiovascular tissue engineering has advanced significantly and considerable research has been conducted using seeded synthetic scaffold vascular grafts implanted in large and small animal models. One of the major problems related to these polymer scaffolds, however, is their long-term presence at the site of implantation as foreign bodies. As a result, in addition to normal wound-healing, the tissue-engineered vascular grafts would generate biomaterial-specific responses, such as foreign body reaction and encapsulation/scar formation. Notably, the leaflets of implanted tissue-engineered cardiac valves would undergo more severe destructive changes compared to the vascular wall, due to higher hemodynamical stresses. That would likely result in systemic responses to blood-circulated polymer particles.

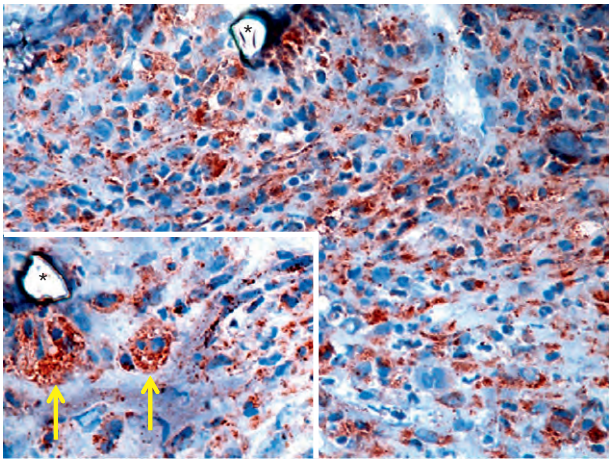

Figure 6 Macrophages detected using anti-mac 3 antibody (red reaction product) in vascular tissue engineered graft implanted into mouse carotid artery. Original magnification ×400. Inset: Giant cells (arrows) adjacent to polymer residue (asterisk). Magnification ×600.

We recently demonstrated the remodeling potential of tissue-engineered small-diameter vascular grafts implanted in mouse carotid artery, using comprehensive immunohistochemistry and molecular imaging analyses. We showed that remodeling is initiated by macrophage invasion, and that by 35 days after implantation, the majority of the initially seeded human mesenchymal cells were replaced by host murine cells, as detected by immunohistochemistry to mouse-specific antibodies (Figure 6). Over time, the remodeling enzyme expression (e.g., MMP-2, MMP-9, cathepsin B) and activity decreased, and grafts displayed layered collagenous structure. Multispectral intravital molecular imaging corroborated our histological findings. This imaging approach offered the advantage of data collection in real time without animal sacrifice and thus could be an additional diagnostic tool for evaluation of small-diameter tissue-engineered vascular grafts implanted in mice.

3.316.6.3. Vascular Grafts

Transplantation medicine has provided insights into the mechanisms of organ rejection that could be applied to tissue-engineered vascular grafts and xenografts. Xenografts are typically rejected by complement-mediated hyperacute mechanisms, but delayed forms of rejection also have been described. Therefore, analyses of immune responses, as well as of inflammation induced by xenogenic matrices or tissue-engineered scaffolds, are required for successful evaluation. Assessment by immunohistochemistry includes but is not limited to analysis of immune cell subpopulations (e.g., CD 3, CD 4, CD 8), expression of activation markers (e.g., CD 25, HLA-DR), cytokines (e.g., TNF-α, IFN-γ), and markers of cell proliferation (e.g., Ki 67). Specifically, examination should record the extent of endothelialization, perigraft tissue reaction, and anastomotic tissue structure (e.g., cell morphology and phenotypes, thickness, and tissue ingrowth).

3.316.6.4. Intravascular Stents

The purpose of stents is to decrease thrombus formation and reduce intimal thickness due to angioplasty. As most stent types use metal struts, the method used for tissue sampling and sectioning must either initially remove the metal inclusions or use specialized techniques for tissue processing and embedding. In such circumstances, a resin MMA-embedding method could be useful, as it preserves both enzymatic activity and tissue antigenicity. Prior to immunohistochemistry, the sections should be deplasticized and permeabilized in 1% Tween 20-PBS. Most cellular reactions to stents occur immediately around the struts, and include cell proliferation (e.g., PCNA), inflammation (e.g., CD 68, HAM 56), endothelialization (e.g., vWF), and tissue overgrowth and pannus formation (e.g., α-SMA, vimentin). These antibodies have been shown to work on resin-embedded tissue sections.

3.316.6.5. Cardiac Assist Devices and Artificial Hearts

Immunohistochemical assessment of explanted cardiac assist devices or artificial hearts may include examination of pseudointimal thickness along the pumping bladder surface for inflammatory cellular components such as leukocytes (neutrophils and macrophages). Endothelialization of the device surface is possible, and can be assessed using endothelial cell markers (e.g., CD 31, vWF). Fibroblasts and noncellular ECM components such as fibrin could be evaluated using an appropriate antibody. Pump bladder calcification in experimental devices has been reported, but the underlying mechanisms are unknown. Therefore it would be of interest to perform analysis of osteogenic regulating proteins and transcriptional factors, including osteocalcin, osteonectin, osteopontin, BMP (2, 4, 7), Cbfa 1, and Osterix.

3.317.1. Introduction

Numerous studies document the potential role of biomaterials in tissue engineering and regenerative medicine.[1–4] Biomaterials can modulate a wide range of cellular phenomena, including cell attachment, spreading, migration, survival, growth, differentiation, and immune response.[5–10] The characterization of chemical and mechanical properties of biomaterials is a well-established field of study. However, the biological characterization of cellular responses to biomaterials is typified by a large number of divergent readouts that are challenged by the lack of standardized conditions and objective standards. Methods based on optical imaging, in general, and fluorescence microscopy, in particular, have witnessed rapid growth and gained widespread acceptance in real-time, high-resolution studies of cell cultures as well as high-throughput cell screening assays. Not surprisingly, these advances have inspired the application of a new generation of techniques to the field of cell–biomaterial interactions. Some of these leading methods are reviewed in this chapter.

Advances in fluorescence microscopy have heralded the development of single-cell and intracellular imaging methods and fluorophores. As epifluorescence microscopy became an entrenched tool in cell biology laboratories, multilabeled indirect immunofluorescence techniques enabled biologists to examine the associations of different antigens within the same subcellular compartments.[11] Thereafter, advances in fluorescence *in situ* hybridization (FISH) permitted the localization

of individual genes on chromosomes and specific mRNAs.[12–15] The more recent introduction of high-resolution confocal and multiphoton microscope systems has made it possible to capture three-dimensional (3D) images resolving the organization of structures within cells, with speeds in the order of milliseconds.[16–19]

Fixed cellular images acquired from high-resolution immunofluorescence techniques have revealed the remarkable complexity of cellular architecture and provided important insights into major cellular structures, including different cytoskeletal proteins, the nucleus and its various compartments, and membranous organelles.[20–22] However, images of fixed and stained cells are static, providing only a brief snapshot of the organization and properties of these structures. This drawback has inspired biologists and microscopists alike to develop fluorescence-based methods with high sensitivity for studying specific types of molecules and multicomponent complexes in living cells.

Some of the first proteins that were tracked via fluorescence imaging were cytoskeletal proteins such as actin, paxillin, or vinculin directly conjugated with a fluorophore such as X-FITC or X-Texas Red. These fluorophore-conjugated proteins were microinjected into cells, resulting in the FITC or Texas Red incorporation into targeted endogenous structures.[23–25] More recently, fluorescent imaging technology heralded the development of genetically encoded fluorescent proteins that could be expressed in cells and organisms through the use of green fluorescent protein (GFP), a protein that revolutionized the use of fluororeporters in cell biology.[26] The use of GFP-tagged proteins has many advantages as described later in this chapter, but primary among these is the ability to capture more time-resolved images, which enables the tracking of the dynamic properties of tagged molecules for extended periods of time.

This chapter is divided into two major sections. In Section 3.317.2, the technical aspects of cell imaging are presented. In Section 3.317.3, specific cell–biomaterial case studies are presented.

3.317.2. Principles, Instrumentation, and Methodology for Cell Imaging

3.317.2.1. Epifluorescence Microscopy and Deconvolution Microscopy

Epifluorescence microscopy, also referred to as wide-field fluorescence microscopy (WFM), is the most commonly used fluorescence microscopy method in life sciences. Fluorescence microscopy allows visualization of cell morphology, cellular/subcellular compartments as well as cellular markers of disease (e.g., cancer vs. normal cells) or phenotype (e.g., stem cell lineage). The optics of an epifluorescence microscope are illustrated in Figure 1(a). Briefly, light of a specific wavelength (usually in the ultraviolet or blue, green regions of the visible spectrum) is generated by passing multispectral light from an arc-discharge lamp or other source through a wavelength-selective bandpass filter (excitation filter). Selected wavelengths passed by the excitation filter are then reflected from a dichromatic mirror or beamsplitter through the microscope object to expose the specimen with intense light. If the specimen fluoresces, the emission light gathered by the object passes back through the dichromatic mirror and is subsequently filtered by another bandpass filter (emission filter), which blocks the unwanted excitation wavelengths. Emitted light is then collected by a detector such as a CCD camera.

The application of an array of fluorophores has made it possible to identify cells and subcellular components with a high degree of specificity amidst nonfluorescing material. Through the use of multiple-fluorophore labeling, different probes can simultaneously identify several target molecules. Conventional epifluorescence microscopy can also be used to visualize 3D samples from a series of 2D images taken at different focal planes. The drawback of this method is that light emitted from planes above and below the in-focus regions are also captured in each optical section. This is because the entire specimen is illuminated by excitation light source, which causes the whole sample specimen to emit fluorescence in the form of radiated light that is collected by the CCD camera (detector). This results in a reduction of both lateral resolution and depth discrimination.

In order to remove unwanted out-of-focus information from each 2D image in the series, deconvolution, based on the underlying physics of image information, can be used to improve the quality of images. Deconvolution methods determine how much out-of-focus light is expected for the optics in use and then seeks to redistribute this light to its points of origin in the specimen. In order to restore the original 'clean' image from the convolved 'blurred' 3D image, mathematical algorithms are utilized to segregate the original distribution of point sources that gave rise to the specimen image. Widely used methods include: nearest neighbors, wiener filters, linear least squares, nonlinear least squares, maximum likelihood, blind deconvolution, and Lucy–Richardson deconvolution.[27–31] In general, there is no 'universally optimal' deconvolution algorithm. Methods that require more computing power yield better image restoration results. However, the advent of confocal and more recently two-photon imaging has limited the use of deconvolution-based methods.

3.317.2.2. Confocal Microscopy

Confocal microscopy on the other hand addresses this problem physically by introducing pinholes to reject out-of-focus light.[17,32] In contrast, deconvolution seeks to solve the 'image restoration problem' in a mathematical/computational way. The principles and schematics of confocal microscopy are illustrated in Figure 1(b) and are described below.

The name 'confocal' originates from the configuration based on the use of point illumination and a pinhole in an optically conjugate plane in front of a detector to eliminate out-of-focus information. Excitation light that is focused on the specimen by the object is initially passed through a small aperture, often a slit or a pinhole. Fluorescence emissions that originate from above or below the plane of focus are then blocked by a second aperture or slit in front of the detector. The smaller the second aperture, the higher the rejection rate of out-of-focus light and the thinner the resulting optical sections. Thin optical sections have greatly improved contrast and axial resolution, but they are obtained at the expense of overall specimen brightness or signal strength.

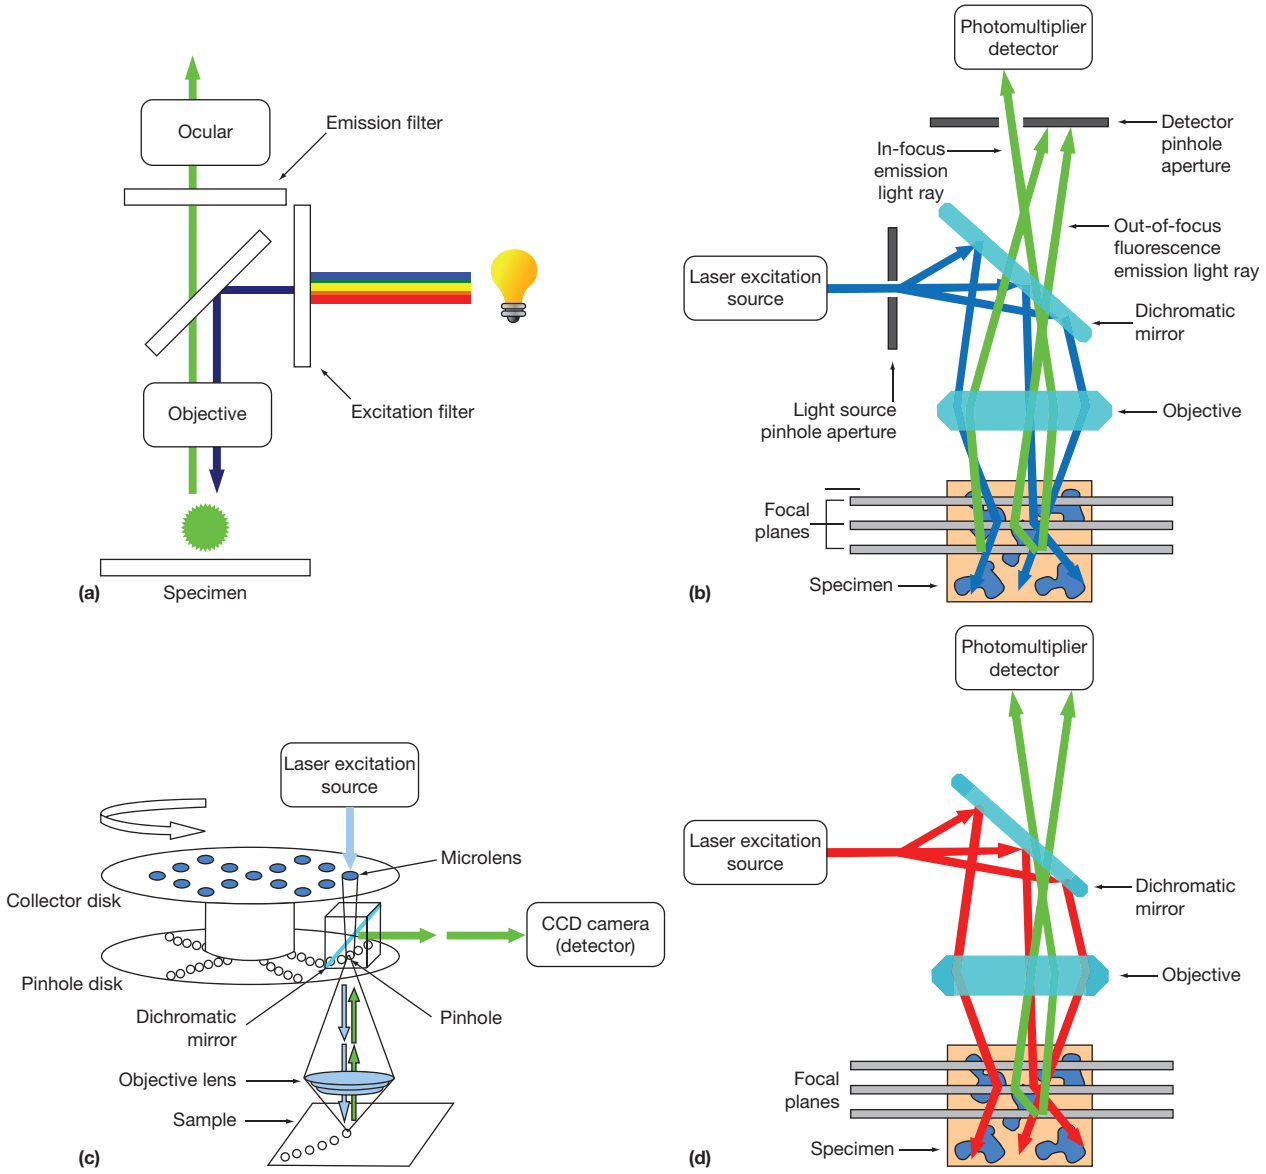

Figure 1 Schematic of various fluorescence microscope systems. (a) Epifluorescence microscope system, (b) laser scanning confocal microscope system, (c) spinning disk confocal microscope system, and (d) multiphoton (two photon).

There are two major approaches to achieve confocal microscopy using commercial instruments: point scanning confocal laser scanning microscopy (CLSM) and spinning disk confocal microscopy. CLSM is the most widely used confocal microscopy in life sciences; the basic principle is illustrated in Figure 1(b). An excitation laser source is scanned across the specimen in a point-by-point raster pattern. The emitted light is then collected by the object, passed through a small pinhole, and detected by a photomultiplier tube (PMT). The output from the PMT is assembled into an image and displayed by the computer.

CLSM has many advantages. It allows for extremely thin optical sectioning of specimens, permitting the imaging of structures and intracellular features in greater detail than conventional epifluorescence microscopy. The drawbacks of CLSM are that these systems compromise detectable fluorescence in order to deliver their high degree of confocality. Because of the small apertures of the pinhole, a large amount of light gets rejected, thus detectable emissions from the specimen must be bright enough to be captured through the use of high numerical aperture (NA) objectives. The use of intense lasers addresses the low-light emission problem; however, it also has its own shortcomings. The intensity of the laser light causes photobleaching in fluorescent probes and phototoxicity in the specimen itself. Additionally, CLSM's point-by-point acquisition technique is time consuming, making this system less capable of recording short-time biological events. For example, acquiring a 1024 by 1024 high-resolution single optical section image from most laser scanning confocal microscopes requires approximately 0.5–1 s. This is not rapid enough to capture

certain dynamic cellular phenomena, in particular, intracellular dynamics such as the visualization of calcium ion transients that occur in 1/10th to 1/5th of a second.[33–35]

The speed limitations imposed by CLSM can be overcome by using the second approach used to achieve confocal microscopy: a spinning disk confocal system. An array of beams can be used in parallel, which make it potentially useful for higher speed image acquisition in comparison to CLSM. The inherent parallelism of a spinning disk confocal system avoids fluorophore saturation, enabling higher levels of excitation to be used.[36–39] The spinning disk confocal is also called the Nipkow spinning disk confocal system, named after Paul Nipkow, who first proposed the principle of generating images using an array of pinholes in 1883.[39]

Figure 1(c) shows a diagram of the Nipkow spinning disk system. A conventional light source (mercury or xenon arc lamp) or laser passes through an excitation filter before being directed onto a spinning Nipkow disk in which 20 000–200 000 pinholes are arranged in spirals of constant pitch.[38] As light falls on one side of the disk, a subregion corresponding to about a thousand pinholes is illuminated and imaged. A partial rotation of a Nipsow disk (ranging from 1800 to 5000 rpm) scans the sample; the induced fluorescence (reflected light) produced by the specimen is collected by the objective lens and reflected off a beam splitter to highly reflective mirrors which amplify the collected light to the conjugate apertures on the other side of the spinning disk. Thin in-focus fluorescence from the specimen passes through the conjugate apertures and a barrier filter before being detected. In contrast, out-of-focus light from the specimen does not have a conjugate aperture to pass through, and is blocked by the disk. The time taken to traverse the field of view is so short that images can be seen in real time by an eyepiece or acquired using a camera that is synchronized with the rotation of the disk.[36–39]

Many of the biological applications using microscopy entail imaging living specimens or deep tissues. The complex nature of cellular materials means that the passage of light is affected in ways that cannot be accurately modeled, resulting in image quality falling well below theoretical resolution limits. Different imaging systems are not equally affected by this decrease in spatial accuracy as the focal plane moves further from the sample. CLSM is generally more tolerant to increasing working distance than wide-field microscopy systems, where out-of-focus light poses a major challenge. Absorption and scattering of light also contribute to the reduction in image quality, particularly, in thicker 3D specimens, although these factors become less pronounced with increasing excitation wavelength. The typical spatial limit of penetration of confocal microscopy for highly scattered cells/tissue samples is about 200 nm,[16,32,40] which may limit imaging of living specimens or deep tissues. This is one of the main reasons multiphoton microscopy (MPM) is the technique of choice for 3D tissue imaging.

3.317.2.3. Multiphoton Microscopy

Multiphoton microscopy (MPM) presents a major advantage over confocal microscopy because of deeper tissue penetration (on the order of millimeters), more efficient light detection, reduced photobleaching/phototoxicity, and enhanced spectral accessibility and flexibility.[16–19,41,42] The term MPM is a generic term for the following techniques: two-photon excitation (TPE) microscopy, three-photon excitation microscopy, second-harmonic generation MPM, and third-harmonic generation MPM.[19] All of these techniques use nonlinear excitation to generate fluorescence limited to a thin raster-scanned plane. With the advent of ultrafast (in the order of femtoseconds) pulsating lasers, such as Ti:Sapphire and Nd:YLF lasers, MPM, particularly TPE microscopy has become a viable tool to monitor complex biological samples.

The phenomenon of TPE arises from simultaneous absorption of two photons in a single quantized event.[19] Since the energy of a photon is inversely proportional to its wavelength, the two absorbed photons must have a wavelength of about twice that required for one-photon excitation. For example, a fluorophore that normally absorbs blue light (~488 nm wavelength) can also be excited by two photons of infrared light (~960 nm wavelength). Since TPE depends on simultaneous absorption, the resulting fluorescence emission varies with the square of the excitation intensity. In order to produce a significant number of two-photon absorption events, photon density must be ~1 million times that required to generate the same number of one-photon excitations.

In a MPM microscope, TPE is generated by focusing a single pulsed laser through the microscope optics. As the laser beam is focused, the photon density increases as it approaches the focal plane and the probability of two photons interacting simultaneously with a single fluorophore increases. The laser focal point is the location with highest probability along the optical path where the photons are crowded enough to generate significant occurrence of TPE. **Figure 1(d)** illustrates the generation of TPE in a fluorophore-containing specimen at the microscope focal point and peripheral areas. Above the focal point, the photon density is not sufficient for two photons to pass within the absorption cross-section of a single fluorophore at the same instant. However, at the focal point, the photons are so closely spaced that it is possible to find two of them within the absorption cross-section of a single fluorophore simultaneously.

The narrow localization of TPE to the illumination focal point is the basis for the technique's most significant advantages over confocal microscopy. In a conventional confocal microscope, although fluorescence is excited throughout the specimen's entire illuminated volume, only signals originating from the focal plane pass through the confocal pinhole, allowing background-free images to be collected. By contrast, TPE only generates fluorescence at the focal plane, and since no background fluorescence is produced, a pinhole is not necessary.

This dramatic difference between the excitation regions of confocal and TPE microscopy results in divergent photo bleaching patterns in each method. The laser of a confocal system excites fluorophores above and below the focal plane, contributing to the bleaching observed in these extensive areas. In contrast, TPE only occurs at the focal plane; therefore, bleaching is confined to this area.

The most powerful advantage of TPE is the ability to provide superior optical sectioning at greater depths in thick specimens than conventional CLSM or WFM due to the effect of three factors[16,18,19,40,43]: (i) absence of out-of-focus absorption allows for more of the excitation light photons to reach the

Table 1 Comparison of wide-field, confocal microscopy, and multiphoton microscopy

Imaging techniques	*Wide field*	*Confocal*		*Multiphoton excitation*
		Laser scanning	*Spinning disk*	
Light source	Wide band lamp	Narrow band laser (UV-far red)	Wide band lamp or narrow band laser	Tunable infrared laser
Lateral resolution	Poor	~250 nm	~250 nm	Slightly worse than 250 nm
Axial resolution	Poor	500–800 nm	500–800 nm	~500 nm
Detection approach	Volume detection	Limit detection to single plane		Limit excitation to single focal plane
Aperture requirement	No	Yes	Yes	No
Image penetration depth	–	<200 μm	<200 μm	Up to 1 mm
3D sectioning capability	No	Yes	Yes	Yes
Multiobjectives	No	No	Yes	No
Comments	Good for regular uses	High resolution but relatively low sensitivity and low speed. High intensity excitation can cause photodamage and limits use for some live cell imaging	Equipped with thousands of microlenses. Imaging of entire field. Fast imaging speed, less photodamage. Not as flexible as CLSM. Good for time-lapse imaging	Longer wavelength excitation renders deeper penetration. Less photodamage

desired specimen region, and (ii) red and infrared light scatters less than light at shorter wavelengths, (iii) the effects of light scattering are less detrimental in TPE than in conventional CLSM systems. Further comparisons between multiphoton and confocal microscopy can be found in **Table 1**.

It should be noted that the image resolution obtained with TPE is not better than that achieved in a well-aligned confocal microscope in spite of the advantages of TPE mentioned earlier. The utilization of longer excitation wavelengths actually results in a larger resolution spot. If a biological structure cannot be resolved in an ideal confocal microscope, it will similarly not be resolved in a TPE laser scanning microscope. It is also important to note that imaging thin specimens using TPE microscopy does not necessarily benefit significantly over conventional CLSM. The reason is that slightly increased photobleaching may occur in the focal plane when using TPE over CLSM in thin specimens, although total photobleaching in a thick specimen is greatly reduced in TPE when compared to CLSM.

Despite the advantages of MPM in 3D tissue imaging, the depth of penetration and image quality are limited by the ability to effectively label thick samples such as tissues. Introducing fluorescence labels into tissues becomes increasingly difficult at greater depths. One way to overcome this difficulty is by expressing GFP within transgenic animals and imaging with TPE mode *in vivo*, where conventional immunolabeling deep into tissue organs is barely accessible.[42]

3.317.2.4. Other Advanced Fluorescence Imaging Techniques

We briefly review two other high-resolution imaging approaches that have been adapted to the study of cell–biomaterial interactions, but with limited success. These methods are fluorescence resonance energy transfer (FRET) imaging and total internal reflectance fluorescence microscopy (TIRFM).

FRET, a widespread technique in molecular biology and biophysics, has been typically used to screen molecular conformation, molecular proximity, protein–protein interactions, and biosensing in cell biology.[44–46] More recently, FRET has been adapted to quantitatively analyze parameters of cell adhesion-related phenomena, such as molecular changes in matrix proteins, bonds between integrins and ligands, and changes in the cross-linking density of hydrogel-based extracellular matrix analogs.[47]

FRET is an interaction between the electronic excited states of two dye molecules. Excitation is transferred from a donor molecule to an acceptor molecule without the emission of a photon. The emission spectrum of the donor must overlap the excitation spectrum of the acceptor; the extent of this overlap determines the FRET efficiency. Furthermore, donor–acceptor transition dipole orientations must be approximately parallel.[44–46,48] FRET's intermolecular separation depends on the inverse sixth power of the distance, so it falls off rapidly with distance, usually in the order of 10 nm which is comparable to dimensions of biological macromolecules. When FRET occurs, the fluorescence of the donor molecule is quenched, the emission of the acceptor fluorophore is sensitized, and the donor lifetime is reduced. Therefore, FRET has a direct effect on rates of donor photobleaching and acceptor fluorescence depolarization. There are several ways that FRET can be measured depending on which of the consequences is being monitored. These methods are based on: quenching of donor fluorescence, sensitized emission of acceptor fluorescence, reduction in donor lifetime, and depolarization of acceptor fluorescence.

Because energy transfer is limited to distances of <10 nm, the detection of FRET provides valuable information about the

spatial relationships of fusion proteins on a subresolution scale. Moreover, it gives us a powerful tool for measuring the proximity of molecular species at a level beyond the resolution of any optical microscope.

Another high-resolution imaging approach that has been recently adapted to study cell–biomaterial interactions is TIRFM. TIRFM has gained popularity in the study of cellular processes and single biological molecules. Briefly, it utilizes an evanescent field generated in the lower refractive index medium during total internal reflection. Light from the fluorescent molecules can then be collected by an objective lens and recorded using a detector such as a CCD camera.[49] The chief advantage of this method is the thinness and exponential decay of the illumination.

Currently, TIRFM can be broken down into two categories: prism-type TIRFM and objective-type TIRFM. Prism-type TIRFM makes use of a prism made of higher refractive material than the biological sample. Light at an acute angle travels through the prism, a refractive index-matched immersion fluid, and the sample's coverslip until finally reaching the interface between the sample and the coverslip, where it undergoes total internal reflection. Since the prism is on the coverslip, prism-type TIRFM usually requires illumination and the light collection to come from opposite sides of the microscope. In contrast, objective-type TIRFM uses a high-NA objective lens instead of a prism to introduce light at a supercritical angle, which is implemented either through the use of an opaque disk in the conjugate back focal plane of the microscope (to block all subcritical angles of light), or by focusing a laser beam off-axis toward the back focal plane of the objective lens. Light focused at the back focal plane by either method is then redirected toward the sample with angles dependent upon the position of the focused beam with angles of excitation increasing with distance from the center of the back focal plane.

TIRFM has a wide range of applications in cell and molecular biology, particularly, for viewing single molecules anchored to planar surfaces and to study the position and dynamics of molecules and organelles in living culture cells near the contact regions with glass substrates.[50] In the biomaterials community, TIRFM has been applied to study cell adhesion-related responses on biomaterials, such as changes in the contact area and adhesion strength on biomaterial surfaces, analysis of bond strength, and real-time measurement of cell/substrate separation distances following exposure to flow.[51,52]

Despite the simplicity of TIRFM, it provides remarkably good optical sectioning equal to or better than any other technique. However, its utility is limited to the study of fluorescent molecules within 100 nm of the sample's coverslip. Thus, it cannot be applied to the necessary resolution of cell–biomaterial interactions in 3D scaffolds or thick tissue sections.

3.317.3. Probing Cell–Biomaterial Interactions

3.317.3.1. Introduction to Fluorescence-Based Probes

The high-resolution imaging methods presented in this chapter would not be possible without the use of fluorophores. Fluorophore-tagged markers are capable of identifying specific molecular targets and have been used for numerous applications, including the observation and analysis of various cell–biomaterial interactions. In this section, an overview of three different fluorophore markers is discussed: fluorophore-tagged antibodies, quantum dot-based probes, and fluorescent proteins.

3.317.3.1.1. Fluorophore-tagged antibodies

Immunostaining is a general term in biochemistry that applies to any use of an antibody-based method to detect a specific protein in a sample. Tagging of a fluorophore to an antibody improves the visualization of the antigens or antigen epitopes where the antibody binds. Antibodies can come in different varieties known as isotypes or classes. There are five antibody isotypes: IgA, IgD, IgE, IgG, and IgM.[53] They are each named with an 'Ig' prefix that stands for immunoglobulin, another name for antibody, and differ in their biological properties, functional locations, and ability to deal with different antigens. Due to their high specificity, IgGs are the most common antibody isotype for immunostaining applications. The Ig monomer is a 'Y'-shaped molecule that consists of two identical heavy chains and two identical light chains. Each chain is composed of structural domains called Ig domains. While the arms of Y-shape antibodies have antigen-recognition sites, the root of the antibodies where the heavy chains reside provide a site to tag a fluorophore.

There are two ways to detect target protein molecules. A directly labeled fluorophore-conjugated primary antibody can be used to detect a target protein; this immunostaining technique is known as the direct method. Alternatively, a broader species-specific fluorophore-labeled secondary antibody is used to detect and attach to a primary antibody bound to a target protein; this is known as the indirect method.[20,54–57] Both methods have their respective advantages and disadvantages. The direct method is simpler, more convenient, and less prone to artifacts than the indirect method. Although the indirect method is more cumbersome, it offers better signal amplification. This is achieved by several fluorophore-conjugated secondary antibodies binding to a single primary antibody. Moreover, secondary antibodies with fluorophores at various excitation/emission spectra are readily available from commercial sources, which make it easier to select probes for multicolor imaging applications.

3.317.3.1.2. Quantum dot-based probes

Quantum dots, also known as fluorescent semiconductor nanocrystal probes or qdots, are increasingly being used for biological applications. They are a new class of inorganic fluorophores that have gained extensive recognition as a result of their exceptional photophysical properties.

Quantum dots are nanoscale semiconductors and defined as particles with physical dimensions smaller than the exciton Bohr radius.[58] Metal and semiconductor nanoparticles, usually composed of groups II–VI or II–V elements, with 2–6 nm in diameter have been used extensively due to their similarity in physical size to biological components such as nucleic acids and proteins.[59] Quantum dots have been used in the following applications: FRET analysis, gene technology via qdot-conjugated oligonucleotide probes, fluorescent labeling of cellular proteins, tracking of cellular movement, pathogen and toxin detection, *in vivo* imaging, and tumor biology research.[45,58,60–68] Despite the growing impact of qdots, there

are several barriers that need to be overcome, such as cytotoxicity and alteration of cell functions that accompanies the cellular uptake of qdots.

3.317.3.1.3. GFP and variants

GFP was originally derived from the jellyfish Aequorea Victoria.[69] It has 238 amino acid residues and a green fluorophore which is comprised of only three amino acids: Ser65–Tyr66–Gly67. The stable protein structure is formed by beta sheets, which have a conformation that makes up an 11-stranded drum-like structure.[26] The stability of GFP allows it to withstand pH levels ranging from mildly acidic (pH = 5.5) to extremely basic (pH = 12) and can also resist temperatures of up to 65 °C. GFP has major and minor excitation peaks at wavelengths of 395 and 475 nm, respectively. Several modifications have been made from the original GFP, most notably the reduction of the dual excitation peaks of 395 and 475 nm down to one excitation peak of 488 nm, which is in the visible blue-light range. The emission peak of original and modified GFP is detected at 509 nm, which is in the visible green region of the electromagnetic spectrum.[26,69] XFP variants with spectra that range from blue to red (shown in Table 2) can be used for live cell–biomaterial interaction imaging.

In order for biomaterial scientists to utilize GFP fusion proteins to capture cellular and subcellular responses to biomaterials, the construction and expression of GFP can be easily accomplished via standard molecular biology techniques. While a complete discussion is beyond the scope of this chapter, the readers are referred to molecular biology protocols, and in particular, to the book by David L. Spector, Robert D. Goldman, and Rusty Lansford.[70] By introducing GFP into host cells, one can visualize GFP-tagged whole cells, subcellular organisms, and cytoskeletal structure/organization. This form of targeting allows the microscopist and the biomaterial scientist alike to study cellular behavior by observing GFP-tagged proteins and capture information at a level that was previously inaccessible, both spatially and temporally.[71] Apart from aforementioned GFP-based markers, phytochromes, light-sensitive photoreceptor, along with other proteins in the phytochrome signaling network, have been utilized to reversibly control the translocation of proteins to the cell membrane.[72]

Table 2 List of common fluorescence proteins

Species/ source	*Fluorescence proteins*	*Excitation (nm)*	*Emission (nm)*
Green	EGFP	489	508
Cyan	ECFP	434/453	477/501
Yellow	EYFP	514	527
Red	DsRed	558	583

3.317.3.2. Case Studies of Imaging Cell–Biomaterial Interactions

In this section, we highlight four different case studies that utilize these labeling methods and advanced fluorescence imaging modalities to capture cellular interactions with polymeric biomaterials. All case studies use members of a tyrosine-derived polycarbonate library with generic composition poly (desaminotyrosyl-tyrosine alkyl ester carbonates) (Figure 2).[73]

In the first study, WFM was used to track cells tagged with GFP-actin, and confocal microscopy was utilized to characterize the nuclear translocation of GFP-GAPDH when cells were cultured in a library of polycarbonate-derived substrates.[74] In the second study, we review the application of MPM to visualize cells in 3D synthetic biomaterial scaffolds.[43] The third case study illustrates the concept of using high-content imaging to identify cell adhesion, spreading, membrane modifications, and cytoskeletal organization on biomaterials.[75] In the final study, an advanced method combining high-throughput and high-content imaging platforms is highlighted in terms of its ability to screen cellular responses to gradient properties of biomaterials. This case study represents one of the future directions in biomaterial design and optimization.[76]

3.317.3.2.1. Case study 1: Fluororeporter imaging of cell cytoskeletal remodeling and apoptosis on biomaterials

This case study shows the role of reactive oxygen species (ROS) in cell apoptosis on biomaterials. Polymers derived from the amino acid L-tyrosine were used as synthetic matrix substrates.[74] Tyrosine-derived polycarbonates were synthesized by copolymerizing hydrophobic L-tyrosine derivatives with uncharged hydrophilic poly(ethylene glycol) (PEG, MW = 1000 Da), and negatively charged desaminotyrosyl-tyrosine (DT). These substrates were characterized in terms of their intrinsic ability to generate ROS, as well as their ability to regulate intracellular ROS production, actin remodeling, and apoptosis in Saos-2 cells (Figure 3(a)).

PEG-containing substrates induced both exogenous and intracellular ROS production, whereas the DT-containing anionic polymeric substrates reduced the production of both types, indicating a coupling of exogenous ROS generation and intracellular ROS production. The effects of ROS activity on the cytoskeletal actin reorganization was probed using a GFP-fluororeporter for actin (Figure 3(b)). In order to visualize dynamic changes in actin, live time-lapse imaging

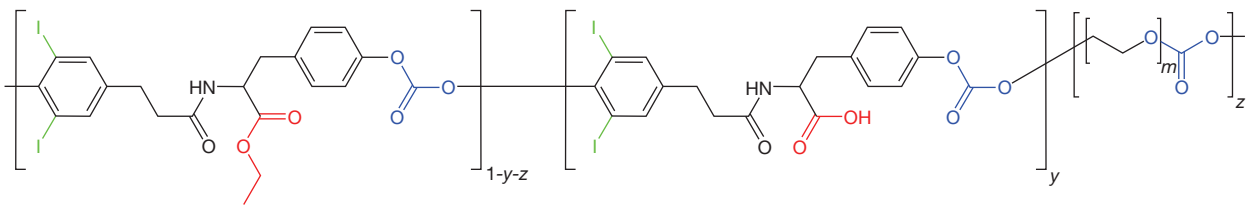

Figure 2 Chemical structure of a library of tyrosine-derived polycarbonates.

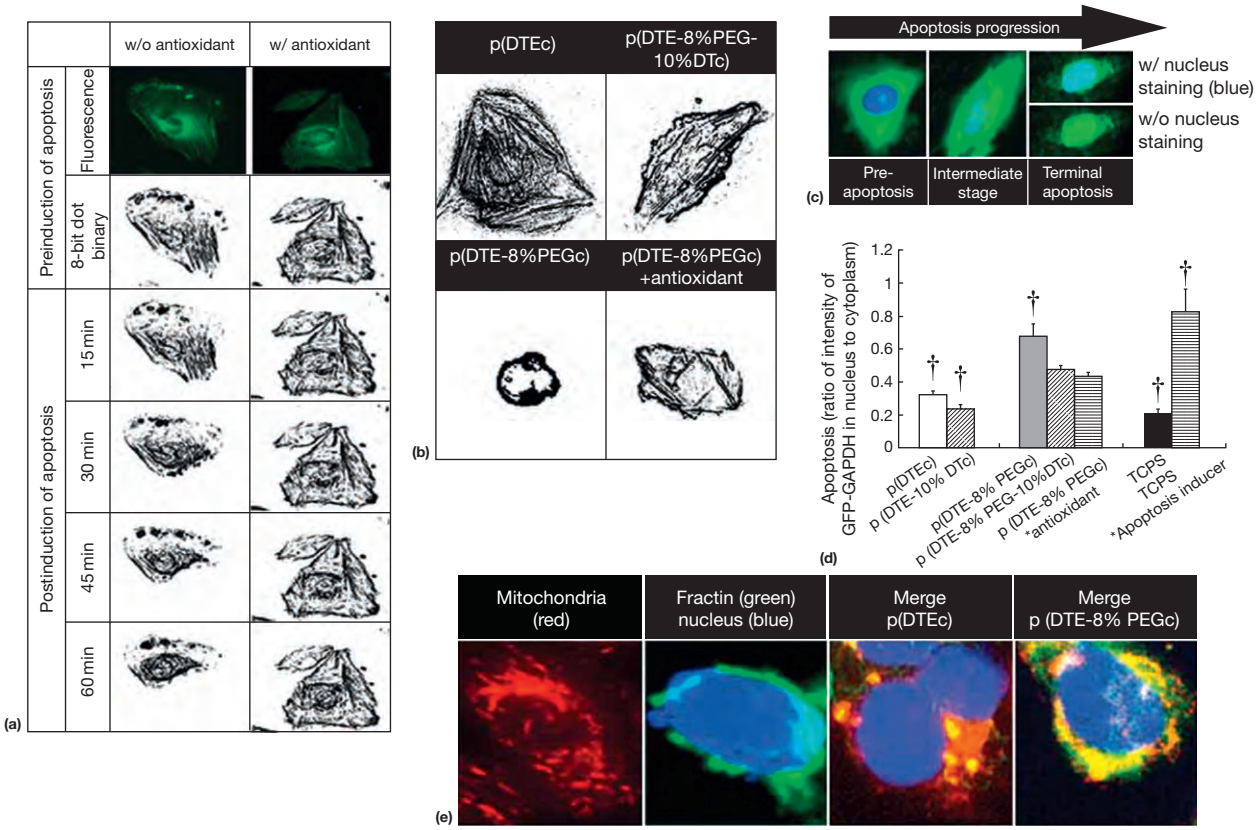

Figure 3 Imaging of cytoskeleton (GFP-actin) and functional reporters (GFP-GAPDH) during the process of apoptosis in the context of biomaterials. (a) Time lapse of GFP-actin Saos-2 cells during apoptosis with apoptosis promoter treatment. Morphologic changes over time were observed with and without the presence of an antioxidant. (b) Visualization of actin organization (GFP-actin Saos2 cells) on various biomaterial substrates with and without the presence of antioxidant. Images were converted to 8-bit binary images to improve the identification of the actin cytoskeleton. (c) Demonstration of nuclear translocation of GFP-GAPDH (green) to the nucleus (blue) during apoptosis. (d) Ratio of GFP-GAPDH signal within the nucleus to the cytoplasm was utilized to assess oxidative stress resulting from substrate chemistry. (e) Visualization of fractin formation via staining with a polyclonal antifractin antibody. Fractins (green) localized to the mitochondria (red). Colocalization (yellow) was more evident in PEG-containing samples. † indicates statistical differences.

of GFP-actin Saos-2 cells were performed on a heated chamber (Harvard Apparatus, Holliston, MA) perfused with carbon dioxide (CO_2). Images were taken every 3 min for 1 h with a Zeiss fluorescence microscope fitted with a 60X objective lens (Carl Zeiss MicroImaging, Inc., Thornwood, NY). Six single cells from three independent experiments were imaged in each condition ($n=6$, where n is the total number of cells imaged). Image contrast and brightness were adjusted to equalize fluorescence intensity using Microsoft PhotoDraw v2 (Microsoft). Contrast-adjusted images were then filtered utilizing a series of flattened filters in Image Pro Plus Version 5.1 (Media Cybernetics, Bethesda, MD). Fluorescence pixels were then converted to 8-bit dots with a constant thresholding process to allow the individual actin proteins to be segmented using ImageJ software (NIH). The 8-bit dot images provided a higher resolution of actin organization. To measure actin area fraction, 12 single cells were live-imaged at 72 h postseeding on four replicates of each substrate type ($n=12$, where n is the total number of cells imaged). From the 8-bit dot image, a summated dot area, which represents the total actin area, was obtained through particle analysis using ImageJ. A ratio of the actin area to the whole cell area was presented as an actin area fraction.

This study showed that the dynamic processes of actin remodeling were regulated by biomaterials induced with ROS and played causative roles in cellular apoptosis. Briefly, PEG-mediated ROS induction caused nuclear translocation of glyceraldehyde-3-phosphate dehydrogenase and an increase in caspase-3 activity, confirming a link with apoptosis. PEG-rich prooxidant substrates caused cytoskeletal actin remodeling through β-actin cleavage by caspase-3 into fractins. The fractins colocalized to the mitochondria and reduced the mitochondrial membrane potential. The remnant cytosolic beta-actin was polymerized and condensed, events consistent with apoptotic cell shrinkage (**Figure 3(c)–3(e)**). The cytoskeletal remodeling was integral to the further augmentation of intracellular ROS production. Conversely, the antioxidant DT-containing charged substrates suppressed the entire cascade of apoptotic progression. It was demonstrated that ROS activity serves as an important role in 'outside-in' signaling for cells grown on substrates. The ROS activity couples exogenous stress, driven by substrate composition to changes in

intracellular signaling. This signaling causes cell apoptosis, which is mediated by actin remodeling.

3.317.3.2.2. Case study 2: Multiphoton fluorescence imaging of 3D polymer scaffolds and cellular organization

Because confocal imaging of 3D substrates is limited by light scattering, MPM was used as an alternative approach to image and quantitatively characterize the microstructure and cell–substrate interactions within microporous scaffold substrates fabricated from synthetic biodegradable polymers. Poly(desaminotyrosyl-tyrosine ethyl carbonate) (pDTEc) and poly(desaminotyrosyl-tyrosine octyl carbonate) (pDTOc) were blended, and a fluorescent dye was mixed with the blend to visualize the scaffold architecture. The porosity of pDTEc/pDTOc blend scaffolds was varied to achieve the distribution of microporous and macroporous regions in the porous scaffolds. The GFP-engineered fibroblasts were seeded onto the scaffolds, which allowed the imaging of both cell morphological patterns and the porous scaffolds (Figure 4(a)). The porosity, pore size and distribution, strut size, pore interconnectivity, and orientation of both macroscale and microscale pores in the 3D scaffolds were effectively quantified and validated using complementary imaging techniques. MPM was used to obtain images of scaffold thicknesses $>100\,\mu m$, with a high signal-to-noise ratio that resulted in reduced bulk photobleaching and eliminated the need for deconvolution (Figure 4(b)). In this study, the morphology and cytoskeletal organization in cells located inside the scaffolds could be tracked with high resolution within the limits of penetration of the excitation beam. Thus, this study showed that MPM offers a promising integrated platform for imaging cell–material interactions within polymeric biomaterial scaffolds.

3.317.3.2.3. Case study 3: Confocal microscopy of cell-based fluororeporters for high-content imaging of cell–biomaterial interactions

Traditionally, the mainstream high-throughput cell assays were primarily fluorescent intensity-based detection systems such as plate readers and flow cytometers. Such cellular assays only focused on bulk changes in intensity of fluorescent probes of whole cell or cell lysates. Such cell assays can provide quick readouts but provide much less information than can be captured by analyzing cells at the microscopic level. Methods such as flow cytometry can render pseudo high-content readouts by detecting multiple fluorescent probes associated with individual cells.

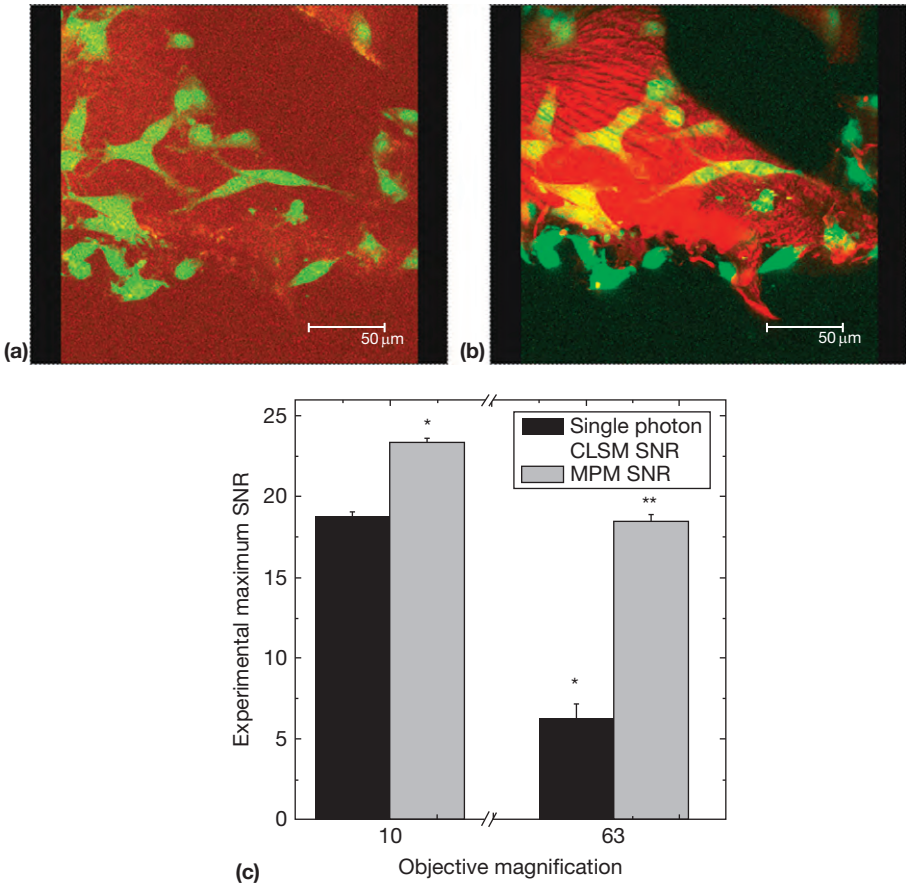

Figure 4 Comparison of multiphoton microscopy (MPM) and confocal laser scanning microscopy (CLSM) images of green fluorescent protein (GFP)-fibroblast cells in Texas Red dyed pDTEc/pDTOc scaffolds. (a and b) CLSM and MPM images of GFP-fibroblast cells on 50/50 pDTEc/pDTOc blend scaffold. (c) Comparison of experimental maximum signal-to-noise ratio of CLSM and MPM images of Texas Red doped pDTEc/pDTOc blends scaffold with macro and micro pores. A single asterix (*) represents a statistically significant difference, $p<0.05$, compared with 10X single-photon CLSM images. A double asterix (**) represents a statistically significant difference, $p<0.05$, compared with 63X single-photon CLSM images.

A recent study utilized a high-content imaging approach to correlate cytoskeletal organizational responses of cells to systematically varied chemical changes in biomaterial substrate chemistry.[75] Cell–biomaterial interactions were captured utilizing high-resolution images obtained with confocal microscopy. Mammalian cell lines (CHO and Saos-2) were transfected with GFP fusion proteins to highlight functional and morphological responses of the cells. The fusion proteins used in this study were GFP-actin, GFP-actinin, and GFP-paxillin. Actin, actinin, and paxillin represent cytoskeletal proteins involved in both the structural determination of cell shape as well as integrated members of a number of biochemical pathways that mediate the 'outside-in' signaling of cells. High-resolution images of the GFP-transfected cells in the context of a subset of a library of polycarbonates were captured using confocal microscopy. Single-cell morphometric features (cell descriptors) were then extracted from the images through the use of commercially available software Image Pro Plus 5.1 (Media Cybernetics Inc., MD). The general feature extraction steps include contrast enhancement, background subtraction, segmentation of whole cells and individual cytoskeletal proteins (actin), and parametric measurement. The extracted cell descriptors contain three categories of subcellular features including: (i) cellular morphologic parameters such as area, perimeter, mean radius, mean diameter, roundness, protrusions, and protrusion length; (ii) reporter localization and texture parameters such as heterogeneity of actin stress fibers, clumpiness, average fiber length/width, focal adhesions per cell, strength of focal adhesion region, and total area of paxillin-rich structures per cell; and (iii) reporter expression parameters such as integrated optical density per cell, and mean fluorescence (**Figure 5(a)**).

As an example, the morphological changes of reporter cells in response to changes of substrate properties are summarized in the 'heat map' shown in **Figure 5(b)**. A strong statistical difference in descriptor value (Student's *t*-test, p value $\rightarrow 0$) is represented by blue, a moderate difference by turquoise, a minor difference by orange, and no statistical difference (p value $\rightarrow 1$) by red. This study shows how descriptors can be used to discern combinatorial variations in substrate composition, and how living GFP reporters are uniquely suited to generate such descriptors unlike fixed tissue preparations.[75]

A more recent study shows how high-content imaging can be used to discern early morphological changes in stem cells cultured on synthetic biomaterials.[77] Actin-based morphology, texture, and intensity descriptors were obtained by single-cell imaging of human mesenchymal stem cells. The descriptors were reduced in dimensionality using multidimensional scaling (MDS), which combines the large number of descriptors into three groupings. The use of such groupings allowed the classification of heterogeneous subpopulations of stem cells within the first 24 h of stem cell culture on biomaterials. The use of high-content imaging allowed this classification early on, much before biochemical and molecular assays established the lineage classification of stem cells toward osteogenic (bone) versus adipogenic (fat) lineages. Thus, the quantitative approach of fluororeporter cell imaging provides information-rich high-content datasets that may be valuable for elucidating and benchmarking cell–biomaterial interactions.

3.317.3.2.4. Case study 4: Combination of high-content and high-throughput fluorescence imaging for cell–biomaterial interactions on biomaterials with spatially graded properties

Advances in polymeric biomaterial synthesis have allowed for the transition from synthesizing a small number of materials to the design and execution of large libraries of bipolymer blends derived from systematic combinations of biomaterials.[78–80] In a recent report, a combination of high-content imaging and higher throughput screening was proposed in the context of cell–biomaterial interactions. The substrate processing platform was based on different combinations of polymer blends exhibiting a continuous range of chemical and

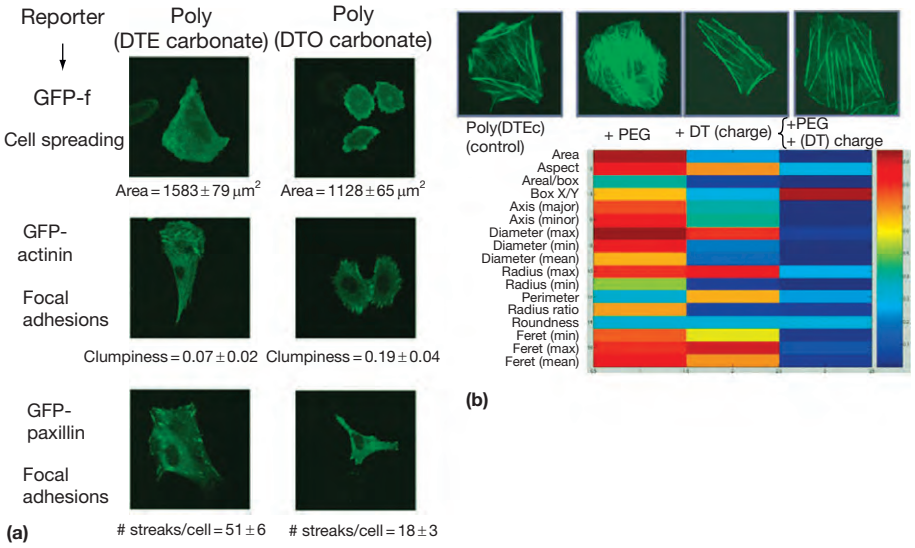

Figure 5 Various green fluorescent protein (GFP)-tagged subcellular reporters on a subset of tyrosine-derived polycarbonates. (a) Confocal micrographs of GFP-engineered Saos-2 cells on two polymeric substrates with different backbone compositions leading to differing hydrophobicities. (b) Cell responses to a combinatorial variation in substrate properties can be discerned using high-content imaging of GFP reporters and a heat map representation of variations in morphometric descriptors.

topographical properties on a single 42 mm round cover glass. As an example, the tyrosine-derived polycarbonates, pDTEc (E: ethyl) and pDTOc (O; octyl) homopolymers and their blends (70/30, 50/50, 30/70 ratio pDTEc/pDTOc, by mass), were flow coated on round glass cover slips. The fabricated pDTEc/pDTOc blends exhibited well-characterized surface gradients in hydrophobicity and surface roughness. Human Saos-2 cells transfected with GFP-tagged farnesylation (GFP-f) gene were examined for their responsiveness to the surface texture gradients of pDTEc and pDTOc blends. The morphology and organization of Saos-2 cells were examined in real time using a temperature-controlled chamber on the motorized stage of a confocal laser scanning microscope (CLSM).

The adhesion of Saos-2 cells was rapidly screened via tile scanning and was found to be maximized at intermediate regions, characterized by intermediate levels of roughness and the steepest roughness gradient (Figure 6(a)–6(c)). Through high-content imaging, we identified different morphometric parameters of the organization and intensity of GFP-f that correlate with the most adhesive substrate compositions (chemistry) or with the degree of surface roughness (Figure 7(a)–7(d)). The correlation between defined polymer blend parameters and cellular function was obtained. In conclusion, this study showed that by quantifying descriptors of GFP-f Saos-2 cells, the cellular adhesive responses to texture and compositional variations of polymer blends could be dissected via CLSM.

3.317.4. Looking to the Future

The field of imaging cell–biomaterial interactions has matured significantly over the past two decades. Earlier studies were largely focused on qualitative approaches related to epifluorescence and transmitted light microscopy. More recent methods have integrated advances in high-resolution imaging platforms such as confocal and TPE microscopy, new generation fluorophores and fluororeporters, and real-time intracellular imaging. These methods now enable a substantial paradigm shift in design criteria for screening and evaluating synthetic biomaterials, fully integrating principles from cell and molecular biology. Although considerable progress has been made already, ongoing challenges remain in capturing the dynamics of multiple cellular functional readouts and signals in physiological and complex biological milieu. A major challenge lies ahead regarding imaging of cellular phenomena within 3D microscale scaffolds. With newer imaging modalities, one of the limitations may be the maximum attainable resolution as photons become scarce within

small imaging volumes. New powerful imaging techniques such as 4Pi confocal microscopy and stimulated emission depletion (STED) microscopy are currently being commercialized. The commercialization of STED and other emerging imaging techniques such as three-photon excitation imaging and second-harmonic imaging should further complement the current high-resolution platforms. The convergence of better transgenic animal models, radio-opaque or fluorescent biomaterials, and improved imaging hardware platforms should improve our ability to resolve tissue remodeling and track the long-term fates of implanted biomaterials *in vivo*. Another challenge is that of *in vivo* high-content imaging to allow for better *in silico* predictions of the *in vivo* fates of biomaterials. For example, microscale computer tomography-based molecular imaging methods may be particularly promising.[6,81,82] Combination of confocal and micro-CT approaches is also being proposed[83] to bring a full complement of the size scales over which these two methods enable imaging.

Acknowledgments

We gratefully acknowledge primary support under the auspices of NIH Grant P41 EB001046 for the biomedical technology resource RESBIO. Er Liu was supported by the RESBIO program. Sebastian Vega was also supported by a NSF DGE 0801620 IGERT fellowship on stem cells. Glossary

Blood half-life The time it takes for the blood plasma concentrations of a contrast agent (or other substance) to be reduced to half its initial concentration.

Dendrimer nanoclusters A nanoparticle formed by chemically cross-linking dendrimers.

Dendrimers Spheroid polymeric nanostructures that repeatedly branch outward from an inner multimeric core.

Molecular imaging (Society of Nuclear Medicine Definition) The visualization, characterization, and measurement of biological processes at the molecular and cellular levels in living subjects.

Photoacoustic imaging A form of imaging where nonionizing laser pulses are delivered into biological tissues and ultrasonic emission is returned and detected. The delivered photons are absorbed and converted into heat, leading to thermoelastic expansion and creating the ultrasonic emission.

Polymersomes A class of self-assembled nanovesicles that are composed of amphiphilic synthetic block copolymers.

Quantum dots (QDs) Luminescent semiconductor nanocrystals with a typical diameter of 2–100 nm containing roughly 200–10 000 atoms of periodic group II–VI (e.g., CdSe, CdTe, CdS, and ZnSe) and III–V (e.g., InP and InAs).

Reticuloendothelial system Part of the immune system that consists of phagocytic cells, primarily macrophages, macrophage precursors, and specialized endothelial cells lining the sinusoids of the liver, spleen, and bone marrow.
Sentinel lymph node The first lymph node to be reached by metastasizing cancer cells from a primary tumor.
Superparamagnetic nanoparticles Nanoparticles that are strongly magnetic in an applied magnetic field but nonmagnetic when the field is removed. In the absence of a magnetic field, Brownian motions are sufficient to randomly orient the nanoparticles.
Surface-enhanced Raman spectroscopy (SERS) Raman spectroscopy is based on the inelastic scattering of photons by molecules, thus the energies of the incident and scattered photons are different. The energy difference is related to the vibrational energies of the molecule. SERS is a technique that results in the enhancement of the Raman signal by molecules absorbed on rough metal surfaces.
TAT peptide A polycationic peptide derived from the HIV-Tat protein. The TAT peptide is often used to transport contrast agents into cells. The process of internalization is thought to involve the nonspecific association between the positively charged peptide and the negatively charged cell membrane followed by macropinocytosis.

Abbreviations

ASG	Asialoglycoprotein
AuNP	Gold nanoparticles
BRET	Bioluminescence resonance energy transfer
CAM	Cell adhesion molecule
CCK	Cholecystokinin
CL	Caprolactone
CLIO	Crosslinked iron oxide
CNS	Central nervous system
CT	Computed tomography
DC	Dendritic cell
DMAA-IPA	3-N-[(N0, N0-dimethylaminoacetyl)amino]-α-ethyl-2,4,6-triiodobenzenepropanoic acid
DNA	Deoxyribonucleic acid
DNC	Dendrimer nanoclusters
DTPA	Diethylenetriaminepentaacetic acid
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
EPR	Enhanced permeability and retention
Fab	Antigen-binding fragment
FISH	Fluorescence *in situ* hybridization
FITC	Fluorescein isothiocyanate
Gd-DTPA	Gadolinium-diethylenetriaminepentaacetic acid
HUVEC	Human umbilical vein endothelial cells
IF	Interdigitation-fusion
ITO	Indium tin oxide
LBL	Layer-by-layer
LMV	Large multilamellar vesicle
LUV	Large unilamellar vesicle
MION	Monocrystalline iron oxide nanoparticle
MR	Magnetic resonance
MRI	Magnetic resonance imaging
NIR	Near infrared
NIRF	Near infrared fluorophore
NMR	Nuclear magnetic resonance
PAMAM	Polyamidoamine
PBD-PEO	Polybutadiene-polyethylene oxide
PEG	Polyethylene glycol
PEI	Polyethylene imine
PEO	Polyethylene oxide
PEOCL	Polyethylene oxide-b-polycaprolactone
POPC	1-Palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine
PSMA	Prostate-specific membrane antigen
QD	Quantum dot
QY	Quantum yield
R1	Longitudinal relaxivity
R2	Transverse relaxivity
RES	Reticuloendothelial system
RGD	Arginine–glycine–aspartate
RNA	Ribonucleic acid
RSD	Relative size distribution
scFv	Single-chain variable fragment
SERS	Surface-enhanced Raman spectroscopy
siRNA	Small interfering RNA
SPIO	Superparamagnetic iron oxide
SPR	Surface plasmon resonance
SSPIO	Standard superparamagnetic iron oxide
SUV	Small unilamellar vesicle
T1	Longitudinal relaxation time
T2	Transverse relaxation time
TOPO	Trioctylphosphine oxide
USPIO	Ultrasmall superparamagnetic iron oxide
UV	Ultraviolet
VCAM-1	Vascular cell adhesion molecule-1

3.318.1. Introduction

Molecular imaging is a relatively new, rapidly developing, and multidisciplinary field that seeks to improve upon conventional anatomic imaging by providing information on the molecular profiles of tissue. Owing to the large number of clinical and academic areas involved, there are many working definitions of molecular imaging. However, the official definition from the Society of Nuclear Medicine,[1] which states "molecular imaging is the visualization, characterization, and measurement of biological processes at the molecular and cellular levels in humans and other living systems," is

appropriately concise and comprehensive. It should be clear to the reader that molecular imaging spans a range of techniques, imaging modalities, and pathologies. As such, the field of molecular imaging can be organized and discussed from a number of different perspectives. The objective of this chapter is to provide an introduction to molecular imaging from the standpoint of materials science. After a brief general discussion of molecular imaging, a number of materials commonly used in molecular imaging applications are highlighted with a discussion on their properties, current use, and future challenges.

Medical imaging traditionally has been a diagnostic tool based on anatomy, allowing physicians to visualize the presence, location, and extent of disease. Many molecular imaging agents have these same objectives. For example, the nuclear medicine 'octreotide scan' allows the radiologist to diagnose and pinpoint the location of carcinoid tumors.[2] These rare tumors can be very difficult to detect with conventional anatomic imaging since they are frequently small and can reside in a wide variety of locations. However, one of the defining characteristics of these neuroendocrine tumors is their avidity for somatostatin. Therefore, radiolabeled octreotide (a pharmacological analog of somatostatin) localizes to carcinoid tumors with a high degree of specificity, not only identifying the source of the tumor but also allowing the surgeon to detect metastatic lesions and assess whether curative resection is possible. This serves as a simple and illustrative example of diagnostic molecular imaging since specific molecular information is obtained and subsequently influences the clinical management of the disease (see **Chapter 3.326, Imaging and Diagnosis of Biological Markers**).

Another important role for molecular imaging is the validation and monitoring of biomarkers that can allow physicians to assess a patient's response to treatment even before detectable anatomic changes are manifested. For example, the most common way to assess tumor response to chemotherapy and radiation regimens is to measure tumor shrinkage with conventional anatomic imaging modalities. It is commonly accepted, however, that changes at the molecular level (metabolism, apoptosis, and cellular proliferation) precede gross anatomic changes. Molecular imaging, therefore, could allow physicians to confirm treatment response much earlier and, perhaps more importantly, predict treatment failure and modify regimens without losing valuable time.

Additionally, the ability to characterize pathology at the molecular level can allow for treatments to be better tailored to the patient on an individual basis. For example, breast cancer patients are often treated with therapeutic agents that target the Her2 receptor (Herceptin, a monoclonal antibody) and the estrogen receptor (selective estrogen receptor modulators, e.g., tamoxifen). However, these treatments have little benefit for patients whose tumors do not express these receptors, and so knowing the receptor status of the tumor is critical for selecting the best treatment. Often, this information can be obtained through tissue biopsy, but a noninvasive imaging approach may be preferable, especially if the tumor is in an organ that is difficult or more risky to sample (e.g., brain, liver) or the patient cannot readily tolerate biopsy. This information is also very valuable to pharmaceutical companies as they develop treatments and assess them in clinical trials. Molecular imaging can help confirm *in vivo* if an agent designed to interfere with a particular pathway indeed does so. Also, tremendous amounts of time and money can be saved by using molecular imaging to select the best subset of patients most likely to respond to the treatment (i.e., only enroll patients with Her2-positive tumors in a clinical trial for Herceptin), and by terminating a trial early if molecular imaging studies suggest that no response to the treatment is occurring.

Current research in molecular imaging has not only been applied to clinical applications, but has also played an important role in basic biomedical research. For example, molecular imaging strategies have been used to visualize and characterize molecular mechanisms of disease in cell cultures and animal models, providing insight into cell function and fate. The use of minimally invasive molecular imaging agents hand-in-hand with other staples of the biomedical research toolkit (e.g., reporter systems, gene disruption, animal models of disease, etc.) offers insight into the pathogenesis of disease, and the two/they have even been used to identify targets for diagnosis and treatment.

Now that a preliminary description and the potential value of molecular imaging have been provided, the remainder of the chapter will highlight some of the materials that have been commonly incorporated into molecular imaging agents. In particular, quantum dots (QDs), gold nanomaterials, superparamagnetic iron oxide (SPIO), liposomes, polymersomes, and dendrimers will be discussed.

3.318.2. Nanomaterials

3.318.2.1. Quantum Dots

3.318.2.1.1. Structure and properties

Semiconductor nanocrystals, also known as quantum dots (QDs), are luminescent nanostructured particles with a typical diameter of 2–100 nm containing roughly 200–10 000 atoms from periodic groups II–VI (e.g., cadmium selenide (CdSe), cadmium telluride (CdTe), cadmium sulfide (CdS), and ZnSe) and III–V (e.g., InP and InAs). Compared to organic fluorophores and fluorescent proteins, QDs exhibit unique optical properties, including size-tunable spectra, superior photostability, and exceptional brightness. Since their invention in 1982,[3,4] QDs have extended their applications from microelectronics and optoelectronics to molecular imaging within single cells and animals. Key advances that have enabled the use of QDs in biological applications include the synthesis of highly luminescent and water-soluble QDs, and novel surface modifications that allow for the facile bioconjugation of targeting ligands (see **Chapter 5.523, Carbon Nanotubes: Applications for *In Situ* Implant Sensors** and **Chapter 3.324, Fluorescent Nanoparticles for Biological Imaging**).

The fluorescence properties of semiconductor materials are dictated by the minimum energy required to excite an electron from the ground state (i.e., valence band) to a higher energy level (i.e., conduction band) via absorption of a photon of energy greater than this bandgap. This transition results in a positively charged hole in the valence band. The promoted electron and the positively charged hole are collectively termed an exciton or Coulomb correlated electron–hole pair. The exciton can be thought of as analogous to the excited state of traditional fluorophores; however, excitons typically have much longer lifetimes (up to approximately microseconds). Relaxation of the excited electron from the conduction band

to the valence band results in a fluorescence emission of a photon. In bulk (macrostructured) semiconductors, energy levels within each energy state (band) are very close together so that they resemble a continuum. As a result, bulk semiconductor materials elicit fluorescence emission that is characterized by the fixed energy of the bandgap, which is solely determined by the composition of the materials. For QDs, however, the size of the semiconductor crystal becomes so small that it approaches the size of the material's Exciton Bohr Radius (i.e., the average physical separation between the electron and hole). Consequently, the electron energy levels within each band can no longer be considered continuous and must be treated as quantized. In this manner, the addition or subtraction of just a few atoms to the QD can alter the size of the bandgap, resulting in different emission properties. Generally, the smaller the size of the crystal, the greater the difference in energy between the valence band and the conduction band. Therefore, more energy is needed to excite the dot, and concurrently, more energy is released when the crystal returns to its resting state. This effect has been exploited in the synthesis of QDs. As larger crystal sizes are produced, lower frequency emission is obtained, resulting in a color shift from blue to red emission (**Figure 1**). Recent advances in the synthesis of QDs allow for precise size (and, therefore, emission) tunability.[5–10]

Since their first biological application, QDs have become an important class of optical probes and an attractive alternative to both organic fluorophores and fluorescent proteins for molecular imaging in living subjects. Due to their large absorption cross-section, QDs have large molar extinction coefficients, typically on the order of $0.5–5 \times 10^6\,M^{-1}\,cm^{-1}$.[11,12] Excitation wavelengths span a spectrum of UV to visible, with the extinction coefficient generally increasing at shorter excitation wavelengths. In comparison to organic dyes and fluorescent proteins, QDs are 10–100 times brighter, owing to their high photon absorbability. In addition, QDs are 100–1000 times more photostable than organic dyes and hence possess the potential for long-term intracellular and *in vivo* tracking experiments. Furthermore, a single excitation wavelength can be used to excite QDs with different emission wavelengths, permitting simultaneous imaging of multiple molecular targets. Finally, recall that the emission of QD can be tuned by controlling the size and the composition of QD. For example, CdSe QDs may be size-tuned to emit in the 450–650 nm range, whereas CdTe QDs can emit in the 500–750 nm range. In marked contrast to organic fluorophores, QDs have broad adsorption spectra and very narrow emission spectra (i.e., ~13 nm of full-width at half maximum at room temperature) thereby permitting imaging of multiple targets simultaneously, each indicated by a different color.[12]

3.318.2.1.2. Synthesis

Since the first synthesis of QDs in 1982 by Efros and Efros[3] and Ekimov and Onushchenko,[4] various methods have been developed for preparing them in different media, including aqueous solution, high boiling point organic solvents, solid substrates,[13–15] and amphibious baths.[16] Traditionally, QDs were prepared in an aqueous solution under thermodynamically favorable conditions for crystal growth in the presence of stabilizing agents (i.e., thioglycerol or polyphosphate), which function to kinetically control crystal growth and limit their size within the quantum-confinement size regime. However, this procedure yielded QDs with poor luminescent properties and large size variations. These qualities of QDs were improved significantly in 1993 when Bawendi and coworkers created highly luminescent and monodisperse QDs from CdS, CdSe, or CdTe in organic solvents using a high-temperature organometallic procedure.[17] In brief, the synthesis began with the rapid injection of organometallic reagents into a hot coordinating solvent to produce a temporarily discrete homogenous nucleation. Slow growth and annealing in the coordinating solvent resulted in uniform surface derivatization and regularity in core structure. The size of QDs can be controlled by varying the duration, temperature, and ligand molecules used in the synthesis. Once the QDs have reached the desired size and emission wavelength (i.e., the emission of QD has been size-tuned), the reaction mixture may be cooled to room temperature to arrest growth. Size-selective precipitation provides powders of nearly monodisperse nanocrystals that are soluble in organic solvents. For instance, CdSe QDs exhibited nearly perfect crystal structures and much improved size distribution (RSD $<5\%$) compared to traditional methods. Since then, QD synthesis has been predominantly carried out in polar organic solvents.

Although QDs synthesized via the high-temperature organometallic procedure exhibited much improved monodispersity, they generally exhibit a low fluorescence quantum yield

Figure 1 Ten distinguishable emission colors of ZnS-capped CdSe quantum dots excited with a near-UV lamp. From left to right (blue to red), the emission maxima are located at 443, 473, 481, 500, 518, 543, 565, 587, 610, and 655 nm. Adapted from Han, M.; Gao, X.; Su, J. Z.; Nie, S. *Nat. Biotechnol.* **2001**, *19*, 631–635, with permission from Nature Publishing Group.

(the ratio of emitted to absorbed photons) of ~10%. The low quantum yield is likely due to the large surface area to volume ratios of QDs, whereby a large fraction of the constituent atoms are exposed to the surface, resulting in atomic and/or molecular orbitals that are incompletely bonded. These dangling orbitals serve as defect sites to quench QD fluorescence. One common strategy to address this issue is to grow a shell of another semiconductor with a wider bandgap onto the surface of the core, providing electronic insulation. In particular, ZnS and CdS are the two commonly known shells that are used for capping CdSe QDs.[18–20] The resulting CdSe/ZnS core/shell QDs exhibit much improved photoluminescence efficiency (QY of 40–50%). In addition to the high quantum yields, surface capping also helps reduce the sensitivity of QD luminescence to the local environment. Specifically, it has been shown that ZnS/CdSe core/shell QDs exhibit enhanced chemical stability and photostability against oxidation, afforded by the capped ZnS shell being much more resistant to oxidation than CdSe.[21] The addition of the shell may also improve the colloidal stability of QDs in organic solvents.[22] This is because Zn^{2+} atoms bind more strongly than Cd^{2+} atoms to most basic ligands such as alkyl phosphines and alklyamines (hydrophobic molecules that are required to improve the solubility of QDs in organic solvents).

Because synthesis of core/shell QDs takes place in organic solvents, they are highly hydrophobic. Solubility in aqueous solution, a necessity for biological applications, can be achieved by modifying the surface structure of the QDs. In one method known as ligand exchange, a suspension of trioctylphosphine oxide (TOPO)-coated QDs is mixed with a solution containing excess of a heterobifunctional ligand, which has one functional group that binds to the QD surface and another functional group that is hydrophilic. In this manner, hydrophobic TOPO ligands are displaced from the QDs through mass action while the new bifunctional ligand absorbs to the QD, generating water solubility. Using this method, (CdSe)ZnS QDs have been coated with mercaptoacetic acid and (3-mercaptopropyl) trimethoxysilane. Both of these consist of basic thiol groups that bind to the QD surface atoms, and either carboxylic acids or silane monomers, respectively, that are presented to the solvent.[12,23] However, ligand exchange can decrease fluorescence efficiency and does not fully resolve the problem of QD instability in aqueous buffers. Similarly, QD solubilization has also been achieved by ligand exchange with dendrons,[23] oligomeric phosphines,[24] and peptides.[25]

In an alternative approach, hydrophobic QDs may be encapsulated into an amphiphilic polymer shell.[26,27] The hydrophobic block of the polymer provides additional stability on the surface of QD through hydrophobic interactions. Other water-soluble shells, such as in phospholipids micelles,[28] silica shells,[29] or polymer beads,[30] have also been used. Regardless of the type of the shell employed, in general, the size of QDs increases significantly when encapsulated into a water-soluble shell, compared to those coated with a monolayer of ligand.

It should be noted that synthesis of QD in organic solvents and the subsequent solubilization in aqueous solvents by either ligand exchange and/or encapsulation methods typically can be lengthy and cumbersome. Over the past decade, scientists have gone back to the synthesis of QDs in purely aqueous solvents.[28,31,32] For instance, Schumacher *et al.*[32] prepared CdSe/ZnS-based QDs in a one-pot synthesis in an aqueous solution using microwave irradiation to provide superior control of nucleation and growth of the QD colloids. These particles can be engulfed more readily by macrophages than QDs solubilized by traditional schemes. However, it has generally been observed that QDs prepared in aqueous solvents rarely achieve the level of monodispersity, stability, and fluorescent efficiency as the QDs produced in organic solvents.

To extend their utility for biological applications, the surface of the water-soluble QDs can be further coated with bioinert polymers such as polyethylene glycol or bovine serum albumin,[28] improving biocompatibility and preventing nonspecific binding. Furthermore, the surface of the QDs may also be functionalized to have reactive species, such as amines, thiols, and carboxyl groups, allowing the subsequent conjugation of QDs to biomolecules such as proteins,[31] antibodies,[33] oligonucleotides,[34] or receptor-specific ligands.[27]

3.318.2.1.3. Biological interaction

For most *in vivo* imaging applications, QDs have been introduced into the bloodstream via systemic intravenous delivery. Once in circulation, the two parameters that seem to influence the biodistribution, circulation time, and mechanism of QD clearance the most are size and susceptibility to opsonization by serum proteins. For instance, renal clearance of QDs is highly related to the hydrodynamic diameter of the QDs, with the renal filtration threshold being 5–6 nm.[35] QDs below this size threshold are quickly removed from circulation by the kidneys, for example, QDs that were 4.36 nm in diameter exhibited a blood half-life of only 48 min and were found intact in the urine. As the QDs are increased in size, their circulation time is also increased, and they are generally removed from circulation by the reticuloendothelial system (RES), which includes the liver, spleen, and the lymphatic system.[36–38] For example, QDs with a diameter of 8.65 nm exhibited a blood half-life of 20 h and high uptake by the liver. When calculating the size of QDs *in vivo*, the influence of surface-adsorbed proteins on the overall size should be taken into consideration. The shape and surface chemistry of QDs will, of course, also affect the rate of RES uptake. It should be noted that although it is generally observed that increased circulation time increases the chance of directing targeted QDs to specific tissues, thus resulting in higher tissue contrast, rapid renal clearance may be preferred since long residence times may lead to the biodegradation of QDs into toxic components.

Before clinical applications of QDs can be undertaken, concerns about their safety must be addressed thoroughly. It has already been established that cadmium and selenium, two metals commonly used in QD cores, can cause acute and chronic toxicities in vertebrates, likely through the generation of reactive oxygen species and oxidative stress. However, it is still not clear whether these toxic ions, when incorporated into a nanocrystalline core, surrounded by biologically inert molecules (i.e., ZnS) and encapsulated within polymers, would still be toxic to living subjects. Some studies report that intense UV excitation may degrade QDs and thereby release Cd^{2+} from the core.[39] However, contradictory observations supporting

the robustness of the shell (i.e., ZnS) in preventing leakage of the encapsulated materials have also been reported.[39–41] It has been suggested that the surface coating (i.e., polyethylene glycol (PEG) or polymers) may further inhibit degradation of QDs. But again, a recent study questions the protective effect of surface coating, as hypochlorous acid and hydrogen peroxide, both produced by phagocytic cells, may readily diffuse across polymeric secondary coatings and cause QD lattice defects and solubilization of the core.[42] Furthermore, some studies suggest that the size of QDs may be an inherent source of toxicity, regardless of the presence or absence of secondary coating. It has been observed that increased toxicity may be correlated with a decrease in QD size,[43,44] although once the renal filtration threshold is reached, rapid and efficient urinary excretion is expected to result in reduced biotoxicity.

Clearly, the disagreement in literature regarding the potential hazards of QDs may stem from the fact that not all QDs are the same, each exhibiting distinct physicochemical properties, core/shell chemistry, water solubility, and surface modifications, all of which influence the overall potential for toxicity. The confusion is further exacerbated by the limited number of toxicological studies and the variety of QD dosages and exposure concentrations tested in the literature. To propel QDs into human clinical use, a standardized and systematic toxicology methodology capable of addressing particle distribution, excretion, metabolism, pharmacokinetics, and pharmacodynamics *in vivo* must be established. Until then, the scientific community is unlikely to reach a consensus concerning QD safety.

3.318.2.1.4. Applications

The ability to functionalize the surface of water-soluble QDs with proteins, ligands, or antibodies that are specific for biomarkers of interest has allowed their use in many biomedical applications. In contrast to organic fluorophores, which typically have broad emission spectra, the narrow emission spectra of QDs can facilitate the studying of multiple targets simultaneously by eliminating the need for spectral unmixing. In fact, wavelength-and-intensity multiplexing with QDs in biological assays can distinguish vast numbers of unique nucleic acid or protein sequences.[45] QDs also have bright fluorescence emissions and do not suffer from photobleaching, making them ideal for imaging targets that are expressed in low copy numbers. Sensitivity can be further improved by photobleaching the autofluorescent signal present in cell samples. Specifically, while autofluorescence undergoes photobleaching with UV illumination,[46] QDs are highly photostable. Therefore, the specific QD signal can be easily distinguished from autofluorescence by preirradiating the specimens.

3.318.2.1.4.1. Cellular imaging

To date, QDs have been predominantly used in fixed specimens – for immunolabeling of fixed cells and tissues,[47] and fluorescence *in situ* hybridization of chromosomes[48] and DNA.[49] Applications of QDs for live-cell imaging have also emerged over the past few years, particularly for the imaging and tracking of cell membrane receptors. For instance, QDs have been conjugated to epidermal growth factor (EGF) for the targeting of erbB/HER membrane receptors on human cancer cells[50] and also to an antibody fragment specific for the targeting of glycine receptors on the membranes of living neurons.[51] The diffusion of various plasma membrane proteins (including tyrosine kinases,[52] integrins,[53] G-protein coupled receptors,[54] and membrane lipids associated with apoptosis[55]) has also been characterized using QDs.

3.318.2.1.4.2. In vivo imaging

In vivo applications of QDs for molecular imaging have thus far, generally been limited to animal models and have primarily focused on vascular and lymphatic imaging, tumor imaging, and cell tracking. In particular, QDs have been used for the nontargeted imaging of various vascular systems, ranging from illumination of the capillaries of adipose tissue and skin of a living mouse,[56] to imaging the blood vessels of chicken embryos,[57] to mapping the coronary vasculature of a rat heart.[58] Additionally, active targeting in the vasculature has been accomplished using QDs conjugated to antibodies recognizing different cell adhesion molecules (CAMs).[59] For example, following intravenous injection of the QD-conjugates into a diabetic rat, fluorescence angiography revealed CAM-specific increases in fluorescence within the retinal vasculature. In this manner, the floating, endothelial rolling and leukostasis of individual leukocytes were all successfully monitored.

When QDs are used to image the lymphatic system, the extent of the lymphatic network that can be imaged is primarily dictated by the size of the QD. For example, it has been observed that following intradermal administration of QDs of large hydrodynamic diameter (>16 nm), they are translocated to sentinel nodes and can be observed fluorescently up to 1 cm beneath the skin surface.[60] On the other hand, QDs of smaller size (~9 nm) can migrate further along the draining lymphatic system. In this manner, it may be possible to tailor QDs for specific applications (e.g., allowing the identification of lymph nodes downstream from the lungs,[38] esophagus,[61] or subcutaneous tumors,[62] or even mapping lymphatic drainage networks[63]) by manipulating the overall hydrodynamic size of the QDs.

QDs are excellent candidates for cell-tracking experiments, which allow the researcher to identify the origins and progeny of various cell populations within an organism. This is typically achieved by preloading cells with QDs (i.e., by nonspecific uptake, receptor-mediated endocytosis, or peptide-mediated macropinocytosis – Qtracker) and subsequently administering them into a living subject. For instance, following subcutaneous administration of cancer cells loaded with QDs into mice, the cells divided to form a solid tumor, and the portion of cells within the tumor mass that retained the QDs could be visualized fluorescently through the skin.[26] QDs have also been proposed as a means to monitor the efficacy of stem-cell therapy. For instance, QD-loaded stem cells have been seeded into an extracellular matrix that was implanted to help rescue canine hearts from surgically induced defects.[64] The locomotion and fate of the stem cells were then followed and used to assess therapeutic efficacy.

The potential of QDs as optical contrast agents for *in vivo* imaging of tumors has also been realized for many years. QDs can be directed to tumor sites via 'passive' or 'active' targeting. For passive tumor targeting, extravasation of QDs from the leaky tumor vessels at the tumor site, combined with poor lymphatic drainage, results in the accumulation of QDs in

the tumor microenvironment (i.e., the enhanced permeability and retention (EPR) effect).[65] To facilitate the uptake of QDs by tumor tissues and improve specificity, QDs have also been conjugated with targeting molecules such as antibodies or affinity peptides that recognize protein targets overexpressed on the surface of tumor cells (i.e., active targeting). Some targets that have already been examined include, but are not limited to, epidermal growth factor receptor,[66] the transferrin receptor,[67] the folate receptor,[68] integrin,[69] and prostate-specific membrane antigen (PSMA).[26]

3.318.2.1.5. Perspectives and challenges

Although molecular imaging applications using QDs as optical biosensors have proven tremendously useful in biological and medical research, several hurdles remain before their utility can be fully exploited in clinical applications. As discussed earlier, concerns about their safety *in vivo* have persisted for many years and a consensus has yet to be reached. Also, the ability to use QDs to track intracellular biomolecules is still limited by the lack of an appropriate intracellular delivery method. Furthermore, when viewed individually, QDs exhibit blinking behavior that may prevent their use for live-cell tracking of individual molecules that correlate with pathology. The latter two of these issues are elaborated subsequently.

In contrast to the widespread application of QDs for targeting and labeling cell surface biomarkers, the ability to use QDs to image and track intracellular biomolecules is very limited. The addition of biocompatible coatings (i.e., PEG) significantly increases the size of QDs, which severely impedes their ability to penetrate the cell membrane and gain access to targets in the cytoplasm of living cells. Studies have shown that QDs delivered to cells via commonly utilized methods, such as passive uptake,[70] receptor-mediated internalization,[33] macropinocytosis via cell-penetrating peptides (e.g., TAT peptide),[71] chemical transfection (i.e., lipofectamine),[72] or electroporation,[39] tend to aggregate inside cells and are often trapped in endocytotic vesicles. Although it has been shown that QDs can potentially be released from endosomes by coating them with multivalent and endosome-disrupting surface coatings such as polyethylenimine (PEI)[71] or via osmotic lysis,[73] none of the aforementioned procedures is capable of achieving uniform distribution of QDs within the cytosol. To date, microinjection is the most promising method to accomplish cytosolic delivery, but the technique is known to be tedious, time-consuming, and not feasible for the analysis of large numbers of cells. Regardless of the method of choice, however, it has often been speculated that the large size of QDs may result in slow diffusion within the cytoplasm, which is a complex environment containing solutes, RNA, and an assortment of cytoskeletal proteins organized in a lattice-like mesh. Such cytoplasmic scaffolding allows small solutes to 'sieve' freely through the cell but likely would restrict the movement of QDs. Consequently, the synthetic methods that reduce the size of QDs, while maintaining their brightness and photostability, are essential for intracellular studies to progress. Recently, researchers have turned from the standard PEG coating to multifunctional multidentate polymer ligands and synthesized biocompatible QDs with hydrodynamic sizes <10 nm.[74]

Potentially, an additional concern over using QDs to image cytosolic targets is that they tend to be 'sticky,' binding nonspecifically to intracellular biomolecules. In particular, QDs with highly charged surface groups, such as carboxylic acids and amines, have already been shown to bind nonspecifically to a variety of cells and tissues.[75] This nonspecific binding can cause a high level of background fluorescence (as nonspecifically bound QDs cannot be distinguished from QDs that have engaged their target), significantly reducing the signal-to-noise ratio, specificity, and detection sensitivity. While nonspecifically bound QDs can generally be washed away in fluroescence *in situ* hybridization (FISH) or immunohistological studies, this is clearly not possible for *in vivo*. It is likely that an 'activatable' QD probe (such as QD-BRET[76]), which can differentiate target-bound from unbound QDs, is needed for intracellular analysis of specific biomolecules.

Even though QDs could be successfully used to target intracellular (or extracellular) targets in living cells, the use of QDs to continuously track the fate of a single biomolecules is severely limited by the fact that they 'blink.'[77,78] That is, under continuous excitation and individual observation by fluorescence microscopy, QDs turn on and off intermittently. Over the past decade, significant effort has been devoted to investigating the mechanisms underlying the blinking behavior of single QDs. Although still not fully understood, it is generally proposed that blinking is caused by extra charges in the nanocrystal that greatly enhance nonradiative decay rates.[77,78] These charges arise from the separation of photoexcited electron–hole pairs and are long-lived, since one charge carrier of the pair probably resides at the QD surface, in a deep-trap energy state. Consequently, a charged nanocrystal could have its photoluminescence temporarily quenched because of the high efficiency of nonradiative (e.g., Auger) recombination processes between the extra charge and a subsequently excited electron–hole pair. Photoluminescence could resume only after the nanocrystal's charge becomes neutralized again. One route to suppress blinking would be to eliminate trap sites. Over decades of research, studies have found that it is possible to attenuate the blinking events by coating the QD core with a thick crystalline shell to electronically insulate it and prevent ionization,[79,80] or by adding surface-bound ligands.[81,82] While blinking is significantly reduced (i.e., QDs remain 'on' for 97% of the time), it has yet to be eliminated, since the fundamental processes responsible for blinking still persist.

Recently, significant progress in the field has been made by Wang *et al.*[83] who successfully synthesized alloyed core nanocrystals of CdZnSe capped with a semiconductor shell of ZnSe (CdZnSe/ZnSe). At the single-crystal level, these QDs exhibit complete suppression of blinking for hours, despite the presence of extra charges. It has been speculated that the gradient alloyed structure of these QDs allows them not to blink, because light is continuously emitted even when the QD is ionized. It is expected that continued refinement of the CdZnSe/ZnSe QD synthesis with regard to biocompatibility via surface modification (as has been done for traditional QDs) will lead to their widespread application in biology and medicine.

3.318.2.2. Gold Nanomaterials

3.318.2.2.1. Structure and properties

Gold nanoparticles (AuNPs), which are typically sized between 0.5 and 250 nm, have been used as contrast agents on multiple

imaging platforms and possess size and shape-tunable properties. AuNPs have been prepared in a wide variety of shapes, including spherical (nanospheres) and rod shapes (nanorods), with no partitioning of material contents (Figure 2). AuNPs have also been synthesized with a thin gold shell surrounding a dielectric and insulating core (e.g., silica), that is, nanoshells. Gold 'nanodogbones' have even been reported.[84] The use of AuNPs in biological applications began in 1971 when Faulk and Taylor[85] invented the immunogold staining procedure for electron microscopy. The straightforward synthesis, excellent stability, and ability to easily attach targeting ligands have permitted the application of AuNPs to both live-cell and *in vivo* imaging.

AuNPs are an attractive contrast agent since they can be visualized with a variety of modalities. In general, a number of properties can be controlled by varying the absolute size (for nanospheres), the aspect ratio (for nanorods), or the relative dimensions of the core and shell layers (for nanoshells). For example, AuNPs strongly absorb and scatter visible light, and their propensity to scatter versus absorb incident light can be modulated by changing the nanoparticle size. Furthermore, when electromagnetic radiation of a wavelength much smaller than the diameter of the AuNP interacts with the particle, it induces coherent and resonant oscillations of the metal electrons across the nanoparticle. These oscillations are known as the surface plasmon resonance (SPR) effect. The fluorescent emission of AuNPs is also tunable based on size and shape, permitting the labeling of cellular structures with different colors. Moreover, AuNPs >20 nm can be visualized with optical microscopy in phase contrast or differential interference contrast mode. When AuNPs aggregate, they can exhibit a phenomenon called plasmon–plasmon interaction, by which a colloidal solution of dispersed spherical AuNPs changes color from red to blue. This photo-switching effect based on AuNP aggregation has been useful in designing colorimetric assays for detecting biomolecules such as cell membrane receptors. Further, light absorbed by AuNPs leads to the generation of heat, making AuNPs useful contrast agents for photoacoustic and photothermal imaging.[86,87] Lastly, the ability of AuNPs to attenuate electron waves and X-rays has allowed them to be used for transmission electron microscopy and X-ray imaging applications.[88]

3.318.2.2.2. Synthesis

Synthesis of gold nanospheres can take place in both aqueous solution and organic solvents via nucleated growth of gold salts.[89,90] In typical syntheses, gold salts such as $AuCl_3$ are reduced by the addition of a reducing agent, leading to nucleation of Au ions and the subsequent growth of the nanoparticles. In addition, a stabilizing agent is also required, which is either adsorbed or chemically bound to the surface of the Au nanoparticles. The stabilizing agent is typically charged, so that the like-charged nanoparticles repel each other and aggregation is prevented. For the synthesis in aqueous solution, citric acid can serve as both the reducing agent that triggers nucleation and as the stabilizing agent because of its negative charges. However, for a typical synthesis in organic solvent, the reducing agent is often different from the stabilizing agent, and colloidal stability of the AuNPs in organic solvents is typically imparted by the addition of surfactants, with hydrophobic alkane chains bound to the particle surface. Synthesis of nanorods can be achieved via seed-mediated growth in the presence of rod-shaped templates. Templates can include porous alumina,[91] polycarbonate membranes,[92] carbon nanotubes,[93] and micelles[94,95] whose shape can be modulated by varying the chemical and physical conditions. Small-size spherical AuNPs are first prepared to serve as seeds, and then the nanorods are grown under template-mediated shape control in the presence of a surfactant. The aspect ratios can also be partly controlled by varying the ratio of gold seed to gold salt. Lastly, the synthesis of gold nanoshells typically involves growing a layer of gold on the surface of a dielectric core, serving as a scaffold.[96] The relative thickness of the core and the shell can thus easily be modulated to influence the optical properties of the nanoshells.

After the synthesis of gold particles, the stabilizer molecules can be replaced by other stabilizer molecules in a ligand exchange reaction. Ligand exchange allows the transfer of AuNPs from an organic to aqueous phase (and vice versa) by exchanging hydrophobic surfactants and hydrophilic surfactants.[97] Like QDs, the utility of AuNPs for biological applications can be facilitated by coating the surface of the particles

with bioinert polymers such as polyethylene glycol or bovine serum albumin, which improve biocompatibility and prevent nonspecific binding.[98] Biomolecules such as proteins, antibodies, oligonucleotides, or receptor-specific ligands can be tethered to AuNPs directly or attached to reactive species such as amines, thiols, and carboxyl groups that have been introduced onto the AuNP surface.[89,90,99]

3.318.2.2.3. Biological interactions

It is generally perceived that AuNPs are safer than QDs, since gold is much less toxic than the primary materials composing QDs (cadmium and selenium). In fact, gold (as a bulk material) has been used clinically in the form of the antiinflammatory agents, Auranofin® and Tauredon®, for the treatment of rheumatoid arthritis.[100] However, some groups do question the safety of AuNPs and argue that as the size decreases to nanoscale dimensions, gold may behave very differently than in bulk.[101,102] Specifically, some research has found gold nanostructures to be toxic in the body, where elemental gold can become soluble by undergoing oxidation or cyanidation.[103,104] Studies have shown that gold is heavily concentrated by the kidneys (causing nephrotoxicity) and can also initiate eryptosis (erythrocyte suicidal death).[105,106] As with QDs, some of the disagreement concerning the safety of AuNPs is likely due to differences in size, surface charge, and shape exhibited in the extensive literature (see **Chapter 3.319, Characterization of Nanoparticles in Biological Environments**).

3.318.2.2.4. Applications

Although gold nanorods are not a molecular imaging application, they are being investigated as photothermal agents for *in vivo* use. In general, for the nanorods of smaller axial diameter (~10 nm), absorption dominates, whereas scattering is the primary effect for larger axial diameter nanorods (>35 nm).[107] Consequently, for *in vivo* applications of tumor ablation, small diameter gold nanorods are being used as photothermal converters of near infrared (NIR) light, due to their high absorption cross-sections. Short laser pulses can be directed onto AuNPs present in the tumor, and the laser energy converted into heat energy that destroys the tumor cells, which are typically more heat-sensitive than that of normal cells.[108]

3.318.2.2.4.1. Cellular imaging

The ability to functionalize AuNPs with various biomolecules allows for the targeting of intracellular contents in fixed cells. For instance, immunostaining is one of the traditional uses of AuNPs in biology. The labeled cellular structures can be visualized in bulk via fluorescence microscopy or at the single molecule level via electron microscopy. Immunostaining can also be performed on live cells with AuNPs. For example, AuNPs have been used to monitor the movement of cell surface receptors such as EGFR. Here, binding of multiple AuNPs on a single epidermal growth factor receptor (EGFR) resulted in a detectable red-shifted fluorescent signal.[109] However, as with QDs, live-cell imaging is generally restricted to imaging membrane receptors due to problems with intracellular delivery of the nanoparticle.

Importantly, the ability to detect cell surface receptors with AuNPs is not limited to conventional microscopy techniques but can also be accomplished by photoacoustic imaging. In this case, the local aggregation of the nanoparticles provides an enhanced photoacoustic signal that is not generated when the particles are dispersed in solution.[110]

3.318.2.2.4.2. In vivo imaging

In contrast to QDs, the literature is more coherent in its indication that AuNPs should be safe to use as contrast agents within living subjects. Consequently, over the past few years, there has been a push to use AuNPs as platforms for *in vivo* molecular imaging. For instance, AuNPs have been used to target tumors *in vivo* and have been detected using surface enhanced Raman spectroscopy (SERS).[111] The nanoparticles were encapsulated within a thiol-modified PEG coat that afforded biocompatibility and improved circulation time. These AuNPs were also surrounded by Raman reporters that led to light emission over 200 times brighter than QDs. Finally, the pegylated AuNPs were conjugated with an antibody (or an antibody fragment such as scFv) against EGFR to specifically target tumor cells. Using these AuNPs and SERS, the location of tumors was clearly delineated.

Recently, AuNPs have also been used as X-ray contrast agents. The small AuNPs (1.9 nm in diameter) were injected intravenously into tumor-bearing mice, and images were acquired over time with a standard mammography unit.[112] Tumors and other organs such as the kidneys were visualized with high spatial resolution. Furthermore, imaging of the microvasculature was possible, and increased vascularization and angiogenesis could be detected. Perhaps most interestingly, the large attenuation of AuNPs was found to provide superior contrast enhancement compared with iodine-based agents.

AuNPs have also been readily detected by photoacoustic tomography.[87] When AuNPs, ~50 nm in diameter, were injected intravenously into tumor-bearing mice, the tumors could be easily distinguished due to EPR of the AuNPs.

3.318.2.3. Superparamagnetic Nanoparticles

3.318.2.3.1. Structure and properties

Another nanomaterial at the forefront of current research in molecular imaging is the SPIO nanoparticle. The versatility, functionality, and magnetic properties of these nanoparticles make them attractive agents for a number of passive and active targeting applications in magnetic resonance imaging (MRI). Although over 45 years have passed since iron oxide particles were first used as magnetic contrast agents,[113] there has been increasing interest in their use over the past decade, primarily due to refinements in synthetic methods that have led to improved magnetic susceptibility and the introduction of new/modified surface coatings that have imparted diverse functionality. Importantly, both oral and intravenous forms of SPIO nanoparticles are currently approved for clinical use.

The basic structure of most SPIO nanoparticles currently under investigation consists of an iron oxide core and a hydrophilic surface coating. The iron oxide core is composed of magnetite (Fe_3O_4) and/or maghemite (γFe_2O_3) nanocrystals, and endows the particles with an MR detectable signal. Depending on the type of SPIO nanoparticle, the iron oxide core may be composed of a single individual nanocrystal or multiple crystals. Both magnetite and maghemite crystals have

similar lattice dimensions of 0.8396 and 0.8346 nm, respectively.[114] The two types of crystals also have similar magnetic properties, although maghemite does have a slightly lower saturation magnetization.[115,116] Further, magnetite has an inverse spinel crystal lattice structure, while maghemite has a cubic geometry and vacancies in the cationic sublattice. Post-synthetic oxidation of the iron core by exposure to oxygen and heat or oxidizing agents converts magnetite into maghemite and also leads to a visible change in color from a dark black-brown to a lighter red-brown.

The nanoscale size of the iron oxide core gives rise to the characteristic superparamagnetism of SPIO nanoparticles. Larger size crystals of magnetite and maghemite are ferromagnetic as a result of aligned unpaired electron spins, and consequently, magnetization is evident in these materials even in the absence of an external magnetic field. When a ferromagnetic material is not magnetized, magnetic domains (called Weiss domains) are aligned at short range, but antialigned at long range. Therefore, the bulk material consists of randomly oriented magnetic domains that exhibit no net magnetization. The transition between magnetic domains is termed the Bloch wall. At the nanoscale (~14 nm and below), the formation of such Bloch walls becomes thermodynamically unfavorable, resulting in the formation of single-domain crystals.[117,118] These single-domain crystals are classified as superparamagnetic, since they have significantly larger magnetic susceptibility than typically observed in paramagnetic materials, essentially because the entire nanocrystal aligns itself with the applied field as a single unit. The distinguishing features of paramagnetic materials are their ability to lose their magnetic remanence in the absence of a magnetic field. In other words, superparamagnetic materials align their magnetic dipoles with externally applied magnetic fields, creating a small positive magnetic susceptibility (i.e., the ability to strengthen the field into which they are placed), but once the magnetic field is removed, they become randomly oriented due to Brownian fluctuations, and the net magnetization of the solution is lost. Brownian forces are also capable of preventing the aggregation of SPIO nanoparticles that might otherwise be observed because of their magnetic attraction in solution.[119]

This ability of SPIO to generate local disturbances in the magnetic field results in the rapid dephasing of surrounding hydrogen nuclei and, therefore, produces a detectable change in their MR signal (**Figure 3**). Therefore, the imaging capability of SPIO nanoparticles arises through their influence on the longitudinal and transverse relaxation of surrounding protons, rather than inherently from the nanoparticles themselves. SPIO nanoparticles possess both high longitudinal relaxivity (R1) and transverse relaxivity (R2).[120,121] Accordingly, it has been demonstrated that they can generate levels of T1 and T2 contrast sufficient for biomedical applications. Nevertheless, the majority of molecular imaging applications have exploited SPIO as T2 contrast agents.[122–124]

A particularly important attribute of SPIO nanoparticles that are used for biological applications is the hydrophilic surface coating, which not only imparts improved colloidal stability and biocompatibility, but also allows for a variety of surface functionalizations and chemical conjugations.

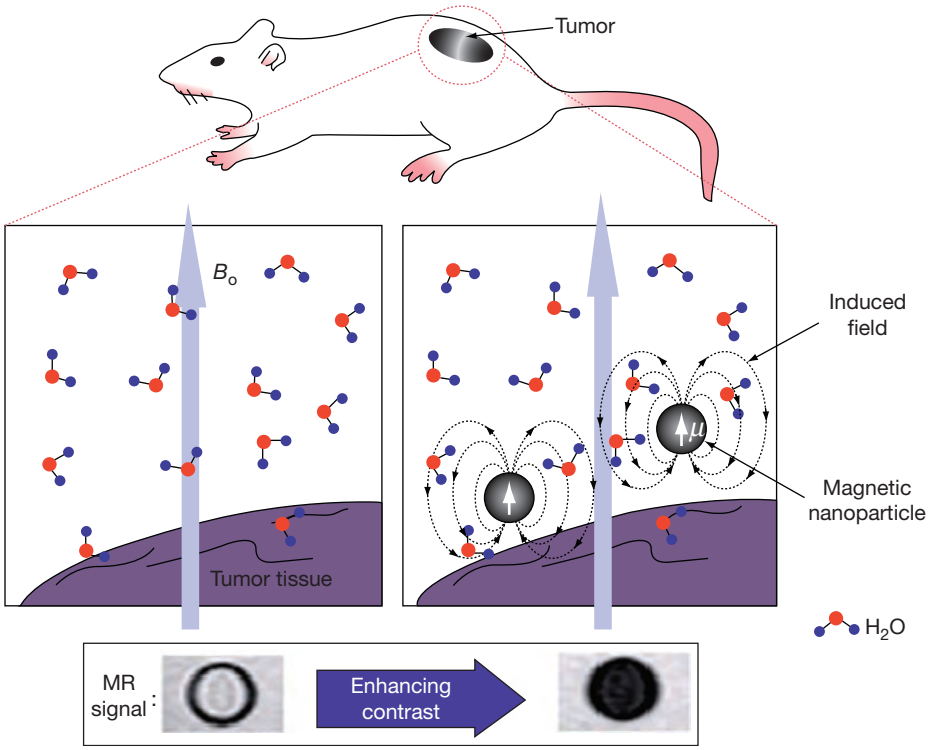

Figure 3 The presence of superparamagnetic iron oxide nanoparticles generates disruptions in the local magnetic field, leading to the rapid dephasing of nearby protons. Fast T2 relaxation results produces darker voxels on T2 weighted images. Adapted from Jun, Y. W.; Lee, J. H.; Cheon, J. *Angew. Chem. Int. Ed. Engl.* **2008**, *47*, 5122–5135. Copyright Wiley-VCH Verlag GmbH & Co.

These surface materials can also increase the circulation lifetime of SPIO[125] *in vivo*, as the coating prevents the rapid opsonization suffered by bare iron oxide.[126] To date, a wide variety of surface coatings have been used, but typical coatings are polysaccharides or synthetic polymers. An assortment of chemical modifications can also be applied to the surface-coating material to impart further improved stability, including stability at elevated temperatures. For example, the coating polymer may be crosslinked wih agents such as epichlorohydrin[128,129] or dextran may be substituted with carboxylmethyl reduced dextran[127] modifications. Depending on the synthetic method used, the coating material can either be adsorbed onto preformed bare iron oxide nanocrystals or incorporated onto the nanocrystals *in situ* as they are formed.

The size of SPIO nanoparticles can range over several orders of magnitude. For example, bare SPIO nanocrystals formed by citrate-inhibited growth are 2–3 nm,[130] polymer-coated polycrystalline SPIO nanoparticles are generally tens of nanometer in size, and ones formulated as orally ingestible contrast agents reach the micrometer scale. Although larger diameter particles have been synthesized and have utility for applications of cell tracking,[131,132] cell separation,[133] cell rheology,[134] membrane deformation,[135] and gastrointestinal contrast,[136] particles of this size have a limited role in molecular imaging since they cannot access neo- and microvasculature.

The classification and nomenclature for SPIO nanoparticles are based primarily on their overall hydrodynamic diameter, which includes the hydrated surface coating.[137] Particles >300 nm, ranging up to 3.5 μm, are termed oral-SPIO; standard SPIO (SSPIO) are ~60–150 nm; ultrasmall SPIO (USPIO) ~10–40 nm[138]; and monocrystalline iron oxide nanoparticles (MION – a subset of USPIO[139]) are ~10–30 nm.[140] MION nanoparticles are so named to denote that they have only a single SPIO nanocrystal in their iron oxide core, whereas the core of nanoparticles >50 nm typically comprises multiple iron oxide nanocrystals. Another commonly encountered classification is cross-linked iron oxide (CLIO), which denotes an SPIO nanoparticle with a cross-linked dextran surface coating. Generally, all SPIO agents with a hydrodynamic diameter <50 nm are used for similar molecular imaging applications *in vivo*, and therefore for the purposes of this review, all agents of this size will simply be referred to as SPIO.

3.318.2.3.2. Synthesis

Several synthetic methods that have been employed in the production of magnetic iron oxide nanoparticles will be briefly described below. The choice of the method used depends largely on the researcher's preferences for ease of synthesis and nanoparticle uniformity. The most commonly used procedure for SPIO nanoparticle synthesis involves the dropwise addition of concentrated base to effect the coprecipitation of ferrous and ferric salts.[141–143] This method is very popular for biomedical applications (along with microemulsion) since it is relatively simple to use, even if it produces a more polydisperse population of nanoparticles than other methods. When carried out in the absence of surface-complexing materials, it yields bare SPIO magnetite nanocrystals that typically have a mean diameter of ~10 nm and are roughly spherical in shape[144] (although these properties are highly dependent on the synthetic conditions). The original precipitate is collected by centrifugation or magnetic decantation, treated with nitric or perchloric acid, and then colloidally dispersed in water to produce an acidic magnetic sol. Alternatively, alkaline magnetic sols can be generated by substituting tetramethylammonium for the nitric or perchloric acid. A surface coating can then be subsequently applied to the nanoparticles through nonspecific adsorption.[145] Often however, the coating material is directly included in the original coprecipitation reaction mixture.[146] When nanoparticles are formed this way in the presence of dextran, the mean hydrodynamic radius of the polydisperse polymer-coated SPIO varies from 20 to >100 nm and can be controlled by adjusting several synthetic parameters such as the iron/dextran ratio. In general, the iron oxide core of these nanoparticles ranges from 2 to 15 nm.[147]

In an effort to reduce the polydispersity inherent in coprecipitation methods, synthetic techniques involving microemulsion (both oil-in-water and water-in-oil) are being pursued, since the size of microcavities formed can be tightly controlled between 2 and 12 nm.[148] Although some microemulsion approaches initially produce hydrophobic SPIO,[149] such nanoparticles can subsequently be given a water soluble surface coating.[150] Nanoparticles can be synthesized in the oil-in-water approach by suspending a ferrous salt-surfactant precipitate in an aqueous solution, and then adding a base, such as methylamine, to form the magnetic precipitate.[151] Alternatively, surfactant (oleic acid)-coated nanoparticles can be added to a solution composed of both a melted lipophilic suspension and an aqueous phase. Dispersing the warm transparent phase in cold water accomplishes lipid coating of the colloidal magnetite.[152] For biomedical applications, however, water-in-oil microemulsion is the more common approach. Typically, nanodroplets of aqueous iron are enclosed in a surfactant coat that separates them from the surrounding organic phase, forming reverse micelles.[153–155] Alkaline nanodroplets are then added to the solution, and SPIO is subsequently precipitated and oxidized inside the nanoscale micelle. Varying the temperature of reaction, as well as metal and base concentrations, yields nanoparticles of 3–12 nm diameter.[156] A major drawback of all microemulsion techniques is the relative inability to produce larger SPIO nanoparticles due to problems with disordered crystallinity at these sizes.[157]

Several other methods of SPIO nanoparticle synthesis have been explored, but they will be discussed only briefly here since they are still less commonly used. Ultrasound irradiation (sonochemical synthesis) uses the rapid collapse of sonically generated microcavities to produce nanosecond lifetime hot spots of ~5000 K in which ferrous salts are instantly driven to form SPIO. Following stabilization with oleic acid, a monodisperse colloid of 8 nm nanoparticles is formed.[158] SPIO nanoparticles have been produced via layer-by-layer (LBL) self-assembly, based on the repeated submersion of a substrate or colloidal template in solutions of oppositely charged polyelectrolytes.[159] In the method of spray pyrolysis, a solution is sprayed into a series of reactors where the solute condenses as the solvent evaporates. Ferric ions are reduced to a mixture of ferric and ferrous ions in an organic solvent, generating SPIO.[160] In laser pyrolysis, a laser heats a mixture of iron pentacarbonyl in air, producing nuclei that form small nanoparticles.[161]

This method requires less reaction volume than spray pyrolysis and allows uniform and well-crystallized nanoparticles to form in a single step.[162] Although these procedures offer high production rates, they require expensive equipment and meticulous control over the synthetic conditions.

One particularly promising approach for the ultra-large-scale synthesis of monodisperse iron oxide colloids relies on the thermal decomposition of various iron oxide precursors, at 250–300 °C in octylamine and trioctylamine.[163] This approach has generated a great deal of excitement because the synthetic process is inexpensive and utilizes nontoxic iron salts as reactants.

3.318.2.3.3. Biological interactions

For biological and medical research, the biodegradability and lack of toxicity of SPIO has made them a valuable tool for both imaging and therapeutic applications. In fact, the use of dextran–iron complexes *in vivo* stretches back over half a century, initially as a substitute for the ferritin complex as a treatment for anemia.[164,165] These complexes allowed the intravenous administration with much lower toxicity than soluble iron salts.[166]

The diameter and surface characteristics of SPIO significantly impact their clearance, cellular interactions, and toxicity. In general, nanoparticles above ~10 nm in diameter are sequestered in the liver and spleen as a consequence of uptake by phagocytic cells. On the other hand, particles under 10 nm are rapidly cleared through extravasation and renal excretion.[167] With regard to surface characteristics, amphiphilic coatings are preferred for generating prolonged plasma half-life; they can extend the circulation time from minutes to hours,[168] and thereby increase the targeting capabilities of SPIO contrast agents.

Polymer-coated SPIO nanoparticles have been shown, to date, to have minimal impact on cell viability and function. For instance, PEG-coated nanoparticles did not affect the cell adhesion behavior or morphology of cultured fibroblasts.[169] Similarly, dextran-coated SPIO labeled with TAT peptide demonstrated no significant effect on the cell viability, clonogenic efficiency, immunophenotype, or biodistribution of human hematopoietic cells.[170] However, studies have indicated that nanoparticle surface properties can influence nanoparticle uptake by phagocytic cells. Specifically, compared to dextran-coated SPIO, carboxydextran SPIO appear to be internalized more readily by macrophages.[171] Nevertheless, nanoparticle uptake is not associated with cell activation since no release of interleukin-1 is observed.[172] Following cellular internalization, SPIO generally accumulate in lysosomes where low pH exposure degrades the iron oxide core into iron ions, which are funneled into the hemoglobin pool.[173] Additionally, for dextran-coated SPIO nanoparticles, intracellular dextranase further assists with the degradation process.

As noted earlier, SPIO nanoparticles have already been used as contrast agents in living subjects. Adverse events associated with intravenously administered dextran-coated SPIO have been observed but are noted to be mild in severity and short in duration.[174] The most common reactions are headache, back pain, vasodilatation, and urticaria.

3.318.2.3.4. Applications

SPIO nanoparticles have been used as contrast agents in a wide range of applications involving the passive and active targeting of both anatomical sites and cell surface markers. They have also been used to track cell migration and trafficking,[175–178] and as highly sensitive biosensors (commonly referred to as magnetic relaxation switches[179–182]) to detect targeted cells, viruses, or biomolecules in aqueous samples. Magnetic relaxation switches and cell-tracking applications lie beyond the scope of this chapter and will not be discussed. Most applications for molecular imaging fall into the category of active targeting, and so these will be the primary focus of this section, following a brief introduction to passive targeting of SPIO (see **Chapter 3.327, Intracellular Probes**; **Chapter 3.328, Biosensors Based on Sol–Gel-Derived Materials**; **Chapter 3.329, Hydrogels in Biosensing Applications**; and **Chapter 3.330, Carbon Nanotube-Based Sensors: Overview**).

Nanoparticle probes lacking explicit molecular specificity are well known in the literature for the imaging of biological systems via naturally directed physiological processes. These include EPR in tumors, nontargeted cellular uptake, macrophage phagocytosis, and accumulation in the RES (liver, spleen, and lymph nodes). In these approaches, T2-weighted images reveal the presence of SPIO through the T2 relaxation shortening effect resulting from the accumulation of nanoparticles.[183–185] Perhaps the most important factors for passive targeting are the hydrodynamic radius and surface charge of the SPIO – properties that are dictated by the surface coating of the SPIO. These parameters control the circulation time of the nanoparticles as well as their accessibility to tissues, opsonization, and rate of cellular uptake.

For example, it has been demonstrated that larger nanoparticles (~150 nm hydrodynamic radius) such as dextran-coated SSPIO AMI-25 are nonspecifically engulfed by Kupffer cells in healthy liver tissue. The absence of Kupffer cells in liver lesions is then exploited as a means of discerning between healthy and malignant tissue through SPIO-enhanced contrast.[186–188] In contrast, smaller SPIO nanoparticles (~30 nm hydrodynamic radius) are found to extravasate into the interstitial space and are carried via lymph vessels to lymph nodes where they accumulate.[189,190] The presence of metastases in lymph nodes leads to disturbances in the flow of lymph and thus interferes with the ability of the SPIO nanoparticles to reach the node. This differential accumulation has allowed for significant increases in the positive predictive values and diagnostic accuracy of node metastases.[191] Finally, the observation that SPIO are efficiently internalized by macrophages and other phagocytic cells has led to their evaluation as contrast agents for the detection of inflammatory and degenerative disorders associated with the activity of those cells. For example, SPIO nanoparticles have been used to examine sites of transplant rejection,[192] atherosclerotic plaque,[193] ischemic strokes,[194] multiple sclerosis foci,[195] and CNS tumors.[196]

Active targeting is preferred to passive targeting, since it not only provides physiologic information but also offers insight into specific molecular mechanisms. Such information could allow for the early detection of disease and more accurate and specific grading. In order to achieve active targeting of SPIO nanoparticles against specific biomolecules, it is first necessary to conjugate targeting agents or ligands onto the SPIO surface – either directly or onto its hydrophilic coating. As mentioned earlier, one of the primary benefits of a polymer coating is its ability to be modified to possess a variety of reactive functional

groups (e.g., amines, sulfhydryls, carboxyls, etc.), which subsequently allow for more control over chemical conjugation to targeting ligands.

It should be noted that one of the primary weaknesses of MR as an imaging modality is its relatively low sensitivity. Therefore, perhaps the greatest hurdle for active targeting of SPIO is localizing adequate levels of nanoparticles at the disease site to generate sufficient contrast. Numerous approaches have been evaluated to improve the site-specific accumulation of SPIO, and thus enhance MR sensitivity. The most widely accepted technique is intracellular trapping,[197] whereby receptor-mediated uptake of SPIO nanoparticles leads to elevated levels of the contrast agent within the targeted tissue. An alternative strategy to improve MR contrast is two-step amplification.[198] Specifically, a biotinylated pretargeting antibody or antibody fragment is introduced intravenously and allowed to localize at the pathology of interest. Streptavidin-labeled SPIO nanoparticles are then administered to label each pretargeted antibody with multiple contrast agents. Although further development of this targeting method is still necessary, the extremely high binding affinity of the avidin–biotin system and the potential to extend this method to a wide range of targets just by using unique pretargeting antibodies make this approach quite promising.

Numerous studies have already demonstrated the ability of SPIO nanoparticles to actively target a wide variety of biomolecules implicated in a broad spectrum of disease states. By way of introduction to this fascinating and rapidly developing field, the following sections will highlight applications involving the detection of cancer, apoptosis, and cardiovascular disease.

3.318.2.3.4.1. Cancer imaging

In the field of cancer imaging with ligand-directed SPIO nanoparticles, the achievement of satisfactory image contrast generally requires that the target not only be overexpressed specifically on the tumor cells, but also undergo receptor-mediated endocytosis, allowing SPIO to accumulate intracellularly. One example of such a target is the transferrin receptor, which is overexpressed on a variety of malignant cell types – most notably, breast cancer.[199] Numerous studies have demonstrated that SPIO conjugated with transferrin can be used to monitor the expression and regulation of the transferrin receptor both *in vitro* and *in vivo*.[200–203]

Similarly, SPIO nanoparticles conjugated with folate experience rapid and efficient uptake by tumor cells that overexpress the folate receptor. *In vivo* MR postcontrast images of folate-receptor positive tumors revealed an average T2 intensity decrease of 38% from precontrast images.[204–206] In another study, the underglycosylated MUC-1 tumor antigen (uMUC-1) has been targeted with SPIO nanoparticles conjugated with the affinity peptide EPPT1.[207] This antigen is commonly found on a variety of epithelial cell adenocarcinomas, including breast, pancreatic, colorectal, lung, prostate, and gastric. Matrix metalloproteinase-2[208,209] (a membrane-bound endopeptidase found upregulated on gliomas) and Her2/neu tyrosine kinase receptor[210,211] (also called c-erb B-2, overexpressed on 25% of metastatic breast cancer) have also been imaged. These initial studies have set the groundwork for SPIO-enhanced imaging of tumors, and the number of cancer biomarkers being targeted *in vivo* continues to expand.

A parallel strategy for identifying tumors involves targeting receptors that are specifically expressed on normal cells of a particular type but not on cells that have undergone malignant transformation. Such an approach has been pursued for pancreatic tumors by targeting the cholecystokininA (CCKA) receptor present on normal pancreatic acinar cells. Upon administration of SPIO-CCK in rats, a significant decrease in T2 relaxation time was noted in areas of normal pancreatic tissue, but was not observed in the cancerous tissue.[212] Another organ to which this strategy has been applied is the liver, a common site for metastases from a variety of primary tumors, including breast, lung, and colorectal. Since detection of liver metastases is very important for cancer staging, and metastatic infiltration is not always clearly distinguishable from healthy liver, much effort has been expended in the research of liver-specific MR-contrast agents. One promising target is the asialoglycoprotein (ASG) receptor, which is expressed on normal hepatocytes but is missing from both primary and metastatic tumors in the liver.[213] Initial studies have shown that SPIO nanoparticles conjugated with the ASG receptor ligand arabinogalactan have allowed for enhanced tumor contrast in rats.

3.318.2.3.4.2. Apoptosis imaging

One specific cellular pathway that is critical to the pathogenesis of cancer and is being explored as a possible target for SPIO nanoparticles is apoptosis. Additionally, apoptosis plays a role in neurodegeneration, myocardial infarction, and chronic inflammation. Therefore, SPIO targeting of apoptotic cells could offer improved imaging of these disease processes and also allow for real-time monitoring of drug efficacy and treatment response. Recently, *in vivo* MR detection of apoptotic cells has been accomplished using the first C2 domain of synaptotagmin I as the targeting moiety.[214] SPIO nanoparticles conjugated with this element were able to generate significant increases in image contrast in regions of tumor with high apoptotic index. Another method of detecting apoptosis uses Annexin V-conjugated nanoparticles to target phosphatidylserine.[215] Apoptotic cells were detected with this method both *in vitro* and *in vivo*. In one study, distinct MR signal distributions were observed following ischemic and oxidative injury to heart tissue, suggesting that this approach may help identify 'at risk' cardiac cell populations.

3.318.2.3.4.3. Cardiovascular imaging

In addition to cancer and apoptosis, molecular imaging with SPIO nanoparticles has also made great strides to improve the contrast and early detection of various cardiovascular diseases, including atherosclerosis, thrombosis, and myocardial infarction. For example, detection of early atherosclerotic signatures was recently performed with SPIO conjugated to an anti-VCAM-1 (vascular adhesion molecule-1) antibody[216] or VCAM-1 affinity peptide.[197] Since VCAM-1 has been identified as an early marker of endothelial inflammation, it is envisioned that these nanoparticles could lead to earlier diagnosis and treatment. In the case of the affinity ligand, phage display was used to identify a VCAM-1 specific internalizing peptide. Through the increased uptake and subsequent compartmental accumulation of SPIO, sites of atherosclerosis were identified in an apolipoprotein-deficient mouse model through the resultant decrease in T2 signal. Reportedly, this targeting

peptide resulted in a 12-fold higher target-to-background signal ratio compared to SPIO targeted with the anti-VCAM-1 antibody. In addition to VCAM-1, E-selectin, a proinflammatory endothelial marker of atherosclerosis, angiogenesis, and tumor vasculature proliferation,[217–219] has also been validated as a potential target for SPIO. Using SPIO nanoparticles conjugated with antihuman E-selectin F(ab), the marker was detected in human endothelial cell culture with significant contrast enhancement over control cells.[220]

The molecular imaging of thrombi has recently been accomplished by the specific detection of αIIb-β3 integrin (expressed on activated platelets) and activated factor XIII[221] (a tissue transglutaminase in the coagulation cascade). For αIIb-β3, the targeting moiety used was RGD, a cyclic arginine-glycine-aspartate peptide well established to specifically bind the integrin.[222] SPIO-RGD resulted in better *ex vivo* thrombus visualization than nontargeted SPIO, and using its MR-contrast enhancement, clot visualization *in vivo* was achieved with an in-plane resolution of <0.2 mm by 0.2 mm.[223] Finally, for imaging of myocardial infarction, antimyosin Fab (R11D10), which is immunospecific for necrotic myocytes, was conjugated with SPIO. MR Imaging demonstrated significant signal decrease in the infarct relative to surrounding healthy myocardium.[140]

3.318.2.3.5. Perspective and challenges

Many of the advantages and disadvantages of SPIO nanoparticles as molecular imaging agents are inherent to the imaging modality in which they are used – magnetic resonance. One of the most powerful features of MR as a platform for *in vivo* molecular imaging is that molecular information can be gathered simultaneously with high-resolution anatomic information, regardless of tissue depth or the presence of overlying structures. In contrast, nuclear, optical, and ultrasound are limited by comparatively poor anatomic resolution and/or issues of signal penetration.

To date, the major shortcoming of MR (besides cost and availability) has been its relatively low sensitivity of detection. When compared to nuclear approaches that can detect probes down to the picomolar level,[224] the sensitivity of MR is several orders of magnitude worse. While it is possible to counter the inherently low signal-to-noise ratio of MR with longer scan times, this is difficult to achieve in the clinical setting, since the patient must remain very still throughout the image acquisition. Sensitivity can also be improved with the advent of higher magnetic field strengths. While MR instruments used for *in vivo* imaging in animal models have increased to 9.4 T or stronger, the majority of clinical instruments operate at 1.5 T. Nevertheless, it should be noted that imaging of individual cells can still be accomplished on a clinical scanner when some modifications are made.[225] Ultimately, the best approach to achieve higher signal and contrast-to-noise ratios in SPIO molecular imaging applications will be the various amplification strategies that were discussed (intracellular accumulation of targeted SPIO or pretargeting with a molecule possessing multiple binding sites for subsequent contrast agent). Another notable disadvantage of SPIO imaging (and MR in general) is the inability to simultaneously image multiple biomarkers, as is very commonly done with optical imaging.

Also, many SPIO-inherent challenges remain in the pursuit of ideal nanoparticle probes for molecular imaging. Chemical conjugation methods could be simplified and streamlined, synthetic approaches could be made to produce larger quantities of less polydisperse nanoparticles, and costs could be reduced. Also, there are some safety concerns over the CLIO particles that are commonly used in molecular imaging studies regarding the ability to completely remove the cross-linker. Nevertheless, given the versatility of SPIO, the large ongoing efforts in their research, and their established use in clinical medicine, these nanoparticle agents will continue to be a significantly important material in the future of molecular imaging.

3.318.3. Nanovesicles

3.318.3.1. Liposomes

3.318.3.1.1. Structure and properties

Liposomes are small artificial bilayer vesicles composed of either naturally occurring lipids or a number of commercially available synthetic products (**Figure 4(a)**). The natural or synthetic phospholipids have a hydrophobic lipid 'tail' and a polar 'head' constructed from various glycerylphosphate derivatives. Due to their amphiphilic nature, when phospholipid molecules are dispersed in aqueous media, they can self-assemble into spherical, closed structures consisting of an aqueous core surrounded by a highly ordered phospholipid bilayer.

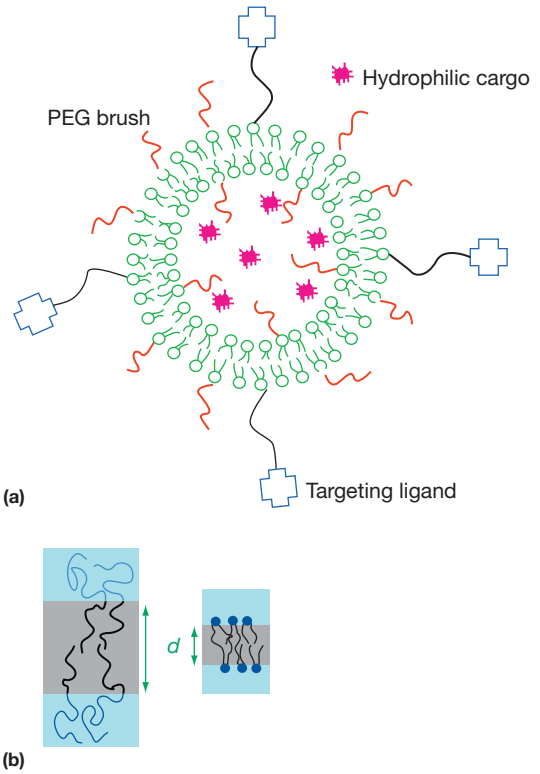

Figure 4 (a) Schematic representation of a multifunctional liposome. (b) Comparison of the liposome (right) and polymersome (left) bilayer membranes. The increased bilayer thickness of polymersomes (~8 nm) gives them improved mechanical stability. Adapted from Nallamothu, R.; Wood, G. C.; Pattillo, C. B.; *et al. AAPS PharmSciTech* **2006**, *7*, E32, with permission from Springer. Discher, B. M.; Won, Y. Y.; Ege, D. S.; *et al. Science* **1999**, *284*, 1143–1146, with permission from The American Association for the Advancement of Science.

Consequently, liposomes can encapsulate hydrophilic compounds in their aqueous cores and intercalate hydrophobic compounds in their lipid bilayers.

Liposomes vary widely in size, number of lamellae, surface charge, permeability, and bilayer rigidity, depending on the preparative technique, synthetic conditions, and types of lipids used. Liposome sizes range over three orders of magnitude, from tens of nanometers to tens of micrometers, and they can contain one, several, or many discrete bilayer membranes. These structural parameters affect the behavior of liposomes both *in vitro* and *in vivo*. Therefore, it is critical to carefully select the liposome constituents and preparative technique for the intended application. For example, conventional liposomes are rapidly cleared from the circulation by the phagocytic cells of the RES. Therefore, for *in vivo* applications, steps such as pegylation or steric stabilization must be taken to prolong circulation time.

Besides their application as contrast agents for molecular imaging, which will be highlighted in this section, liposomes have a wide variety of other uses. Since the lipid bilayer is the basic structural component of cell membranes, liposomes have been used extensively as a model system in basic research for studying the structure, properties, and functions of cell membranes. In addition, liposomes have been widely investigated for use in drug and gene delivery, cellular targeting, catalysis, food chemistry, cosmetics, energy conversion, and chemical separations. Liposome technology is a rapidly evolving field spanning both basic and applied science.

3.318.3.1.2. Synthesis

The most commonly used method to generate liposomes involves the hydration of dry lipid films. In general, this procedure consists of three steps: preparation of the lipid for hydration, hydration of the lipid with mechanical agitation, and liposome sizing to generate a homogeneous distribution of vesicles. First, the lipids must be dissolved in an organic solvent (typically chloroform or a chloroform–methanol mixture) to assure a homogeneous lipid mixture. Next, a thin lipid film is produced by evaporating the solvent with a stream of dry nitrogen or argon, or by rotary evaporation. Any residual organic solvent is removed by placing the film overnight in a vacuum pump evacuated chamber.

Second, hydration of the dry lipid film is accomplished by incubating an aqueous solution over the film and agitating the container. If the encapsulation of hydrophilic compounds in the liposomal core is desired, these compounds are simply included in the aqueous hydrating solution. During incubation, the temperature of the hydrating medium should be above the gel–liquid crystal transition temperature of the lipid. The products of hydration are large, multilamellar vesicles (LMV).

Finally, once a stable, hydrated LMV suspension has been produced, the liposomes can be reduced in size by a variety of techniques, including sonication or extrusion. Disruption of LMV suspensions using sonication typically produces small, unilamellar vesicles (SUV) with diameters in the range of 15–50 nm. Extrusion through filters of defined pore size typically yields large, unilamellar vesicles (LUV). The extrusion method yields liposomes with the most homogeneous size distribution, especially for larger (100–400 nm) diameters.

Several other synthetic approaches have also been employed in the construction of liposomes. In a similar procedure called the hydration/rehydration method, a lipid film is generated, dried under vacuum, and hydrated as before, to form a liposomal dispersion. This solution is then partially dehydrated a second time until the suspension becomes viscous. Then, an appropriate volume of water is reintroduced and the liposomes are allowed to equilibrate at a temperature above the phase transition point of the lipids.

Another synthetic variation using lipid films is the electroformation procedure. Again, the lipids are dissolved in a chloroform–methanol solvent and the resulting solution is spread onto glass coated with a conducting indium tin oxide (ITO) film. The film is dried under a vacuum for 1 h and then rehydrated while an AC electric field is applied and progressively increased, typically from 0 to 1.1 V, throughout the incubation.[226]

In the reverse-phase evaporation procedure, appropriate amounts of the lipid are dissolved in a chloroform–methanol mixture. Subsequently, isotonic buffer and additional methanol are added to yield a clear solution after brief sonication. The organic solvents and a small amount of water are then removed under nitrogen at a temperature above the phase transition temperature. Solvent removal proceeds until all foaming in the solution ceases.

Finally, liposomes can be prepared by simply injecting a lipid and ethanol solution directly into an aqueous solution. This ethanol injection method is a suitable technique to obtain the spontaneous formation of liposomes with small average diameter. Several parameters, including buffer composition and ionic strength, must be optimized in order to obtain the desired final formulation.

Once liposomes are formed, a variety of techniques, such as dynamic light scattering, electron microscopy, force microscopy, ultracentrifugation, viscometry, nuclear magnetic resonance (NMR) spectroscopy, and gel chromatography, are used for their characterization. These techniques report a number of different liposomal parameters such as size, shape, polydispersity, surface area, encapsulated volume, and stability. Analysis of these parameters is important in evaluating liposomes for subsequent use *in vivo*.

3.318.3.1.3. Applications

One of the most attractive attributes of liposomes is the functionality imparted by their amphiphilic structure. For example, one of the most promising applications of liposomes is drug delivery. Hydrophilic drugs can be loaded in the aqueous core and the hydrophobic domain serves as a natural carrier environment for hydrophobic drugs. The ideal liposomes for *in vivo* applications will encapsulate molecules with high efficiency, protect these molecules from degradation in plasma, and have a narrow size distribution, with dimensions allowing them to access the extravascular compartment. Furthermore, the ability to incorporate a wide range of lipids allows for enhanced liposome stability in circulation and a variety of surface modifications. The literature has many examples of liposomes with these features.

For instance, cationic lipids enhance the efficiency of gene delivery to cultured cells *in vitro*, in part because compared to the fate of free DNA, liposome-entrapped DNA is protected

to a varying extent from degradation or immediate dilution. Secondly, in order to prepare liposomes with prolonged circulation lifetimes *in vivo*, other specialized lipids (such as monosialoganglioside G_{M1} or PEG-modified phosphatidylethanolamine) have been investigated.[227] It has been proposed that these PEG-lipid conjugates provide 'steric stabilization' of the surface by virtue of the hydrophilic brush coat provided by the PEG polymer. The coat has been shown to inhibit serum protein binding to the liposomal surface, thereby stabilizing the liposomal membrane, limiting complement activation, and reducing reticuloendothelial system (RES) sequestration[228] (see **Chapter 4.424, Nanoparticles for Nucleic Acid Delivery**).

In addition to improved stability, the active targeting of liposome-encapsulated drugs or contrast agents to specific organs or pathologies further enhances the utility of liposomes for therapy and diagnosis. Targeted delivery of liposomes *in vivo* has been achieved by covalent and noncovalent coupling of site-directing ligands (such as monoclonal antibodies, proteins, vitamins, peptides, and glycolipids) to the surface of liposomes.[229] For example, PEG-shielded liposomes functionalized with cyclic RGD were used to target the antivascular agent combretastatin A4 to tumor vasculature.[230]

The significant majority of molecular imaging applications for liposomes involve the incorporation of contrast agents into the vesicles. When liposomes are used as carriers for imaging agents, they help overcome the rapid clearance, nonspecific cellular interaction, and toxicity of free contrast, all of which result in images of diminished contrast and resolution.[231] The following sections emphasize the development of novel liposome-based imaging contrast agents, organized by modality: MRI, optical imaging, computed tomography (CT), and ultrasound.

3.318.3.1.3.1. Optical contrast agents

As previously mentioned, liposomes have become a useful tool as drug delivery vehicles for the treatment of various diseases, including cancers. It is very important to track these nanocarriers at the cellular and subcellular level and to monitor drug distribution and concentration. Due to this need and the high sensitivity and good spatial resolution of optical methods, liposome-based optical contrast agents are being developed rapidly. Organic fluorophores are most commonly used in these preparations, since a large number of them are commercially available and possess interesting photophysical features. For *in vivo* optical imaging, NIR dyes are often chosen, since they offer deeper tissue penetration than dyes emitting in the visible region of the spectrum. For example, Mikhaylova *et al.* developed a nanocarrier based on liposome-mediated delivery of small interfering RNA (siRNA) to downregulate specific pathways in cancer growth and progression. To optically image the localization of these siRNA-containing liposomes *in vivo*, a DY647 moiety was covalently linked to the siRNA. Fluorescence was detected in tumor sections as early as 30 min following intravenous injection. Intracellular localization of DY647-labeled siRNA was observed in the tumor tissue even 24 h postinjection.[232]

Although organic fluorophores are versatile and easy to use, they present several limitations such as photodegradation and a high sensitivity to environmental factors. Consequently, there is growing interest in the development of new kinds of vesicle-based optical contrast agents by combining liposomes with QDs. As discussed previously, QDs are characterized by high photostability and their insensitivity to environmental factors. For example, Weng *et al.* developed multifunctional QD-conjugated immunoliposomes for imaging tumor cells *in vitro* and *in vivo*. Carboxyl-functionalized CdSe/ZnS core/shell QDs were chemically linked to amine-functionalized phospholipids present in the liposome bilayer. QD605 (λ_{max} ~605 nm) was used for *in vitro* analysis and pharmacokinetic studies, while QD800 (λ_{max} ~800 nm) was used for *in vivo* imaging experiments where deep tissue penetration is required. These studies indicated that QD-conjugated liposomes were able to provide (in a single nanoscale construct) tumor cell-targeting, imaging, and drug delivery functions.[233]

3.318.3.1.3.2. MR-contrast agents

Most MR agents in current clinical use are small, nontargeted, gadolinium (Gd)-based molecules that passively distribute into the intravascular and interstitial spaces to help generate clear anatomical images of the brain, spine, heart, and soft tissue. Recently, liposome-based MR-contrast agents have generated a particularly high degree of interest because of their ability to carry a large payload of these small Gd contrast agents, which can either be encapsulated within the liposome core or immobilized on the membrane surface. Such paramagnetic liposomes have been tested in many *in vivo* MRI studies in animal models.

The most common preparation involves encapsulating gadolinium-diethylenetriaminepentaacetate (Gd-DTPA) in different liposomal formulations.[234,235] For example, Freedman *et al.* developed a nanosized immunoliposome loaded with Gd-DTPA for detection of small metastases in lung cancer. Although current imaging methods can identify lung cancers, there are limits to the size of detectable nodules. Evidence also suggests that these current methods have difficultly in correctly distinguishing malignant nodules <7 mm from similarly appearing benign lesions. Thus, in an effort to improve specificity, Freedman *et al.* conjugated an antitransferrin receptor single-chain antibody fragment onto the surface of the liposomes loaded with Gd-DTPA. These paramagnetic liposomes can successfully enhance very small lung nodules (2–4 pixels, or even a single pixel in size).[234]

It should be noted that the ability of Gd-DTPA to provide effective T1 contrast relies on its ability to access and relax water protons. Thus, the relaxivity of liposome-encapsulated Gd-DTPA can decrease (or be 'quenched') by the low water permeability of the liposome membrane. This apparent disadvantage has been only partially overcome by the development of liposome MR probes with modified bilayers to improve water permeability, allowing bulk water molecules to exchange with water in the aqueous core and interact with the Gd-DTPA.[236] Therefore, the immobilization of chelated Gd on the surface of the bilayer membrane has become the preferred embodiment for liposome-based MR agents, since surface Gd has much better water access than that of core-encapsulated Gd. These liposomes can be made simply by doping the lipid bilayer with Gd-chelated phospholipids during preparation. For example, Mulder *et al.* incorporated Gd-DTPA-bis(sterylamide) into the bilayer of liposomes to generate paramagnetic MR agents. These liposomes do not leak upon incubation in

serum and also have a PEG coat and an anti-E-selectin antibody coupled to the distal end of the PEG-chains. MR studies revealed the specific association of the liposomal agent with stimulated human umbilical vein endothelial (HUVEC) cells. These data provide initial evidence that liposome-based MR-contrast agents can serve as useful diagnostic tools to investigate pathological processes *in vivo*.[237]

3.318.3.1.3.3. CT contrast agents

Recent reports have also explored the possibility of using liposomes as CT contrast agents. Heavily iodinated organic compounds are included primarily in the inner water compartment of liposomes or incorporated into the liposome membrane. These constructs have been shown to be effective CT contrast agents for enhancement of the liver in a number of different species, including rats, rabbits, pigs, and dogs. For example, Fouillet *et al.* developed vesicular agents using iomeprol-containing liposomes to detect small liver tumors in rats. After injection of these iomeprol-containing liposomes at a dose of 70 mg of (liposome-entrapped) iodine per kilogram of body weight, the normal liver parenchyma showed a contrast enhancement of more than 60% over precontrast intensity. As discussed earlier, liver tumors contain few or no Kupffer cells, and so are not enhanced, appearing as dark areas within the normal parenchyma. Both tumors and precancerous lesions as small as 3 mm in diameter could be distinguished using this noninvasive method.[238]

Seltzer *et al.* used interdigitation-fusion (IF) liposomes to carry the CT contrast agent iotrolan in their aqueous core. A high initial uptake (63–96% of the injected dose) was found in the liver and spleen. At 250 mg iodine per kilogram body weight, liver elimination proceeded with a half-life of 12.9 days. Thus, liposome-based CT contrast agents show promising attributes, including favorable biodistribution, clearance, and imaging properties.[239]

3.318.3.1.3.4. Ultrasound contrast agents

Ultrasound is a very attractive clinical imaging modality, since it is widely available, inexpensive, and easy to perform. Therefore, ultrasound contrast agents that exhibit an affinity for specific tissues or pathologies would have considerable clinical value. Since liposomes can be prepared by conjugating various targeting antibodies to the surface of the lipid bilayer, it thus becomes feasible to develop liposome-based ultrasound contrast agents. These vesicles can be used not only to identify and delineate diseased areas, but also release and activate a therapeutic agent *in situ*.

Ultrasound-activated liposomes are synthesized by incorporating air and the pharmaceutical of interest into liposomes of submicrometer size. These encapsulated air pockets are approximately tens to hundreds of nanometers in diameter, and thus can be considered nanobubbles. Exposure of these liposomes to suitable ultrasonic pulses disturbs the physical structure of the liposome bilayer and results in drug release. Because liposome activation by ultrasound can be controlled both spatially and temporally, these liposomes are potentially powerful tools for tissue or organ-specific drug delivery. Furthermore, the encapsulated air in the nanobubbles inherently produces ultrasound contrast, enabling the process of drug release and activation to be imaged in real time.

Recently, Tartis *et al.*[240] examined the cellular effects of ultrasound-mediated delivery of paclitaxel (a lipophilic chemotherapeutic agent) using acoustically activated lipospheres *in vitro*. In addition, Chen *et al.*[241] showed that acoustically activated liposomes can deliver DNA into cardiac muscle and pancreatic islet cells *in vivo*. Lastly, Kopechek *et al.*[242] compared ultrasound-mediated release of both hydrophilic and lipophilic agents from echogenic liposomes and found that water-soluble drugs were better candidates for the design and development of liposome-based ultrasound-controlled drug delivery systems (see **Chapter 4.422, pH-Responsive Polymers for the Intracellular Delivery of Biomolecular Drugs**).

3.318.3.1.4. Perspective and challenges

Liposomes demonstrate a lot of promise for advanced molecular imaging applications. However, to successfully bring these agents to fruition in the clinical environment, several challenges remain to be addressed. First, although effective on a small-scale basis, current synthetic methods lack the ability to produce commercial quantities of liposomal preparations with high entrapment efficiency of contrast agents. Also, even with the development of PEG-phospholipid-doped liposomes (sometimes referred to as stealth liposomes), further improvements are necessary to obtain the optimal chemical and physical stability that is important for biological application within the membrane-rich cellular environment.

3.318.3.2. Polymersomes

3.318.3.2.1. Structure and properties

Polymersomes represent a class of self-assembled nanovesicles that are composed of amphiphilic synthetic block copolymers. Compared to liposomes, polymersomes are far more robust, have lower membrane permeability, greater stability, and can be finely tuned through polymer selection to yield vesicles with diverse functionalities (**Figure 4(b)**). The improved stability largely stems from the higher molecular weight of the diblock copolymers and the presence of a thick hydrophobic domain, typically ~8–10 nm. This is significantly larger than the hydrophobic domain of most liposomes, which are typically ~3 nm in thickness.[243] Of course, with increasing membrane thickness, polymersome membrane fluidity and deformability generally decreases, bringing them closer to viral capsids than liposomes, in terms of mechanical properties (see **Chapter 1.129, Engineering the Biophysical Properties of Basement Membranes into Biomaterials: Fabrication and Effects on Cell Behavior**).

The vast majority of polymersomes are formed from diblock copolymers, with polyethylene oxide (PEO) as the hydrophilic block. This creates a relatively inert, brush-like outer shell, which imparts 'stealth-like' characteristics to the polymersomes and allows them to effectively avoid the RES.[244] Combined with their high stability, polymersomes have been found to exhibit long circulation times and low toxicity, qualities that are valued in molecular imaging applications.[244]

The amphiphoilic polymersomes are easily transformed into contrast agents through the encapsulation of hydrophilic contrast agents (e.g., Gd-DTPA, fluorescent dyes, etc.) within the aqueous core and/or hydrophobic fluorescent dyes within the hydrophobic domain. The exterior surface can also be readily functionalized with biologically active ligands for

targeted imaging applications.[245] Hence, polymersomes hold enormous potential as nanostructured biomaterials for future *in vivo* diagnostic imaging applications.

3.318.3.2.2. Synthesis

Polymersomes are synthesized using techniques similar to those used to form liposomes. Most often, the thin film hydration method is adopted, whereby diblock copolymers are first suspended in a volatile organic solvent and dried onto a glass or Teflon surface.[246] The film is then hydrated in an aqueous solution, sonicated, and extruded to the desired size. For imaging applications, most polymersomes are reduced to <150 nm in diameter to encourage long circulation times[247,248]; however, because of the high membrane stability, polymersomes that are tens of microns in diameter can also be synthesized.[246] It should be noted that polymersomes typically cannot be synthesized with diameters below 100 nm due to energetic constraints imparted by the thick hydrophobic domain.[247]

As an alternative to thin film hydration, polymersomes can also be formed by electroformation.[243] In this method, the diblock copolymer is dried on platinum wire electrodes and an alternating electric current is applied to form the vesicles. This method is generally preferred when large vesicles are desirable, since most of the polymersomes have diameters >10 μm. More recently, microfluidic techniques have also been used to produce polymersomes.[249] By varying the flow rates of several independently controlled fluid flows, the size, number of bilayers, and loading of the polymersomes can be controlled.

3.318.3.2.3. Biological interactions

The improved structural stability of the polymersome bilayer architecture has made them an attractive alternative to liposomes, which are often limited in clinical applications by their rapid dissolution in the circulation. Moreover, the high PEG (100%) content on the outer membrane of polymersomes has been shown to confer resistance to plasma protein deposition, resulting in longer circulation times.[245] Recent reports have indicated that polymersomes, ~125 nm in diameter, have a blood half-life of >15 h.[250] These findings provide evidence that the polymersomes can effectively evade the RES, which is generally desirable for targeted imaging studies.

It is generally agreed upon that the brush-like PEG layer on the outer shell also makes polymersomes highly biocompatible. To date, no obvious effects on cell proliferation have been noted, nor have any acute or chronic toxicities in vertebrates been reported. Of course, long-term toxicity data are lacking, as is information on the residence time and metabolism of the polymersome degradation products in living subjects. It is likely that any toxic side effects identified will depend largely on the composition of the diblock copolymers.

In anticipation of clinical translation, many studies have recently focused on the synthesis and evaluation of biodegradable polymersome formulations. Although PEG continues to be widely used as the hydrophilic block, a number of biodegradable polymer chains have been used within the hydrophobic block, including polylactic acid,[251] polycaprolactone,[252] poly(trimethylene carbonate),[253] and poly(2-vinylpyridine).[254] Alternatively, biodegradable linkages (e.g., disulfides[255] and poly(propylene sulfur)[256]) have also been inserted between the hydrophilic and hydrophobic blocks to promote the ultimate metabolism and clearance of polymersomes.

3.318.3.2.4. Applications

To date, polymersomes have been predominantly used as vehicles for drug delivery; however, several studies have demonstrated that they can also be transformed into very effective contrast agents. In the following sections, we will discuss how the unique properties of polymersomes have been exploited to create very promising optical and MR-contrast agents.

3.318.3.2.4.1. Optical contrast agents

Polymersomes have been transformed into optical contrast agents by simply introducing hydrophilic dyes into the aqueous core and by inserting hydrophobic dyes into the membrane. Membrane dyes have generated a particularly high degree of interest because the thick lamellar membrane allows for the insertion of dyes that would normally cause the dissolution of liposomes. For example, Ghoroghchian *et al.*[257] have successfully loaded multimeric porphyrin-based near infrared fluorophores (NIRFs), which are large in size and possess a rigid hydrophobic nature, into the hydrophobic bilayer of polybutadiene-polyethylene oxide (PBD-PEO) polymersomes. The porphyrin-based NIRFs exhibited photophysical properties within the polymersomal matrix that were akin to those observed when the dyes were in organic solvents. As a result, the total fluorescent signal emanating from the polymersomes was of sufficient intensity to penetrate through 1 cm of solid tumor.[257] Further, when these NIR-emissive polymersomes were injected into the tail-vein of mice, the biodistribution of the nanoparticles could be tracked noninvasively.

NIR-emissive polymersomes have also shown promise as contrast agents for cellular tracking. Christian *et al.*[258] have demonstrated the ability to label dendritic cells (DCs) *ex vivo* with polymersomes encapsulating porphyrin-based NIRFs; the TAT peptide was conjugated to these NIR-emissive polymersomes to facilitate efficient uptake of the polymer vesicles by DCs. It was found that DC surface-associated polymersomes shed over the first 24–48 h; but polymer vesicles that were fully internalized by the DCs remained stably incorporated for over 3 days.

3.318.3.2.4.2. MR-contrast agents

Recently, polymersomes have also been transformed into MR-contrast agents through the encapsulation of Gd-DTPA within the aqueous core. Although the entrapment of Gd within the lumen of polymersomes would normally result in a dramatic reduction in Gd relaxivity, this shortcoming was at least partly overcome through the introduction of pores within the bilayer. Two different approaches have thus far been taken to create porous polymersomes. In the first approach, polymersomes were produced from the aqueous assembly of diblock copolymers, PEO(1300)-b-PBD(2500) (PBdEO), and phospholipids, 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) at an 85:15 molar ratio.[248] The PBdEO was cross-linked using a chemical initiator and the POPC was extracted with surfactant, generating a highly porous outer

membrane. The encapsulated Gd chelates were attached to dendrimers to prevent their leakage through the pores. It was estimated that, on average, nearly 44 000 Gd were encapsulated within each polymersome. As a result of the slower rotational correlation time of Gd-labeled dendrimers and the porous outer membrane, the paramagnetic porous polymersomes exhibited an R1 relaxivity of 7.2 mM^{-1} s^{-1} per Gd and 315 637 mM^{-1} s^{-1} per vesicle. This corresponds to a relaxivity that is amplified by a factor of $\sim 10^5$ compared with Gd-DTPA.

In the second approach, paramagnetic porous polymersomes were prepared using a synthetic method that did not require polymer cross-linking, thus reducing the number of required synthesis and purification steps and also likely improving biodegradability.[247] Specifically, the porous polymersomes were produced through the aqueous assembly of the polymers, polyethylene oxide-b-polybutadiene (PBdEO), and polyethylene oxide-b-polycaprolactone (PEOCL). Subsequent hydrolysis of the caprolactone (CL) block resulted in a highly permeable outer membrane. Again, to prevent the leakage of small Gd-chelate through the pores, Gd was conjugated to polyamidoamine (PAMAM) dendrimer via diethylenetriaminepentaacetic acid dianhydride (DTPA dianhydride) prior to encapsulation. These functional nanoparticles were found to exhibit a relaxivity similar to the cross-linked porous polymersomes described above. These polymersomes were also found to exhibit unique pharmacokinetics with a circulation half-life of >3.5 h and predominantly renal clearance, suggesting slow dissolution in circulation. This could provide an important advantage in regard to reducing toxicity compared with other long-circulating MR-contrast agents, which generally require metabolism of the contrast agent in the liver and exhibit prolonged retention in the body.

3.318.4. Polymeric Assemblies

3.318.4.1. Dendrimers

3.318.4.1.1. Structure and properties

Dendrimers are spheroid polymeric nanostructures that repeatedly branch outward from an inner multimeric core (Figure 5). Dendrimers are highly uniform with extremely low polydispersity and, in many cases, are monodisperse. Dendrimers are usually produced in an iterative sequence of reaction steps, in which every additional iteration leads to a higher generation material. Such a configuration results in an exponential increase in molecular weight for a geometric increase in volume.[259]

Lower generation dendrimers have highly asymmetric shapes and possess more open structures. As the chains are grown from the core, the dendrimers become densely packed, globular structures. When a critical branched state is reached, dendrimers cannot grow uniformly because of steric constraints.[260] For imaging applications, the most commonly used dendrimers are PAMAM dendrimers. These dendrimers are based on either an ethylenediamine core or ammonia core and possess amino groups on the surface, which provide attachment points for the conjugation of contrast agents.[261–264] Typical PAMAM dendrimers range in size from just over 1 nm to just over 10 nm, and the number of surface groups increases geometrically. For example, a generation 2 (G2) dendrimer has a diameter of 2.9 nm and 16 amine groups, while a G10 dendrimer has a diameter of about 13.5 nm and 4096 amine groups (Dendritech, Inc.).

Because of their molecular architecture, dendrimers show several significantly improved physical and chemical properties when compared to traditional linear polymers. For instance, dendrimer solutions have significantly lower viscosity than linear polymers. The presence of many chain-ends is responsible for high solubility and miscibility, and for high reactivity. Dendrimer solubility is strongly influenced by the nature of surface groups. Due to their globular shape and the presence of internal cavities, dendrimers can also encapsulate guest molecules in the macromolecule interior, a feature that has been exploited for a number of drug delivery applications.[265]

3.318.4.1.2. Synthesis

Dendrimers are generally synthesized using either divergent or convergent methods.[266,267] In the divergent methods, dendrimer branches are grown outward from a multimeric core through repetitive growth and activation steps. Specifically, each arm of the core molecule is reacted with a monomer that possesses one group capable of reacting with the core polymer and two groups that are blocked. Following the reaction between the core and the monomer, excess monomer can

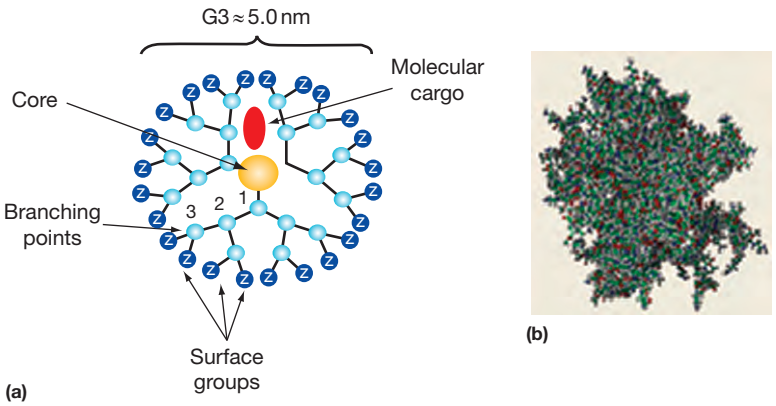

Figure 5 (a) Schematic 2D presentation of a G3 dendrimer containing three generations (branching points), as indicated by the numbers. (b) 3D presentation of G3 dendrimer as a space-filling structure. Copyright 2008 by Drug Delivery Solutions LLC.

be removed and the blocked groups can be activated. As a result, each functional group on the core is replaced by two new functional groups. This process can be repeated to build the dendrimer one generation at a time, until the desired size and/or number of functional groups is reached. PAMAM dendrimers are commonly synthesized using the divergent method, albeit with some slight modifications. Specifically, the ethylene diamine or ammonia core is first alkylated with methyl acrylate through Michael addition. Each amino group reacts with two methyl acrylate monomers. This step is followed by amidation of the resultant ester terminal group with excess ethylene diamine, creating a new dendrimer generation with twice the number of amines. Recently, the divergent synthetic method has been simplified by using two different monomers alternately during the growth process. This approach eliminates the need for an activation step and thus fewer synthetic and purification steps are required.[268] Of course, various dendrimer structures may be obtained by altering the initiator core, repeat units, and the surface groups; however, our discussion of dendrimers will be primarily limited to PAMAM dendrimers, since they have almost exclusively been used for molecular imaging applications.

In convergent methods, dendrimers are built from the outside in, that is, starting with the end groups and progressing inwards. Once dendron arms of sufficient size have been prepared, they are attached to the multimeric core molecule. Convergent methods are sometimes preferred because the number of simultaneous reactions is reduced, that is, fewer branching reactions are carried out in any given step. This results in more highly monodisperse samples and fewer side reactions.

3.318.4.1.3. Biological interactions

The cytotoxicity of dendrimers is largely governed by the size of the dendrimers and of the surface groups. Higher-generation dendrimers are generally found to promote more destructive interactions with the cell membrane, resulting in high cytotoxicity. This can perhaps be attributed to the higher charge density found on larger particles. For example, when cationic PAMAM dendrimers were incubated with V79 Chinese hamster lung fibroblasts (24 h), there was a size-dependent decrease in cell viability. The concentration producing 90% cell death was 1 mM for generation 3, 10 μM for generation 5, and 100 nM for generation 7.[269]

As would be expected, cytotoxicity has also been found to be dependent on the nature of the dendrimer surface.[270] For example, the cytotoxicity of the cationic dendrimers selected from a melamine-based dendrimer library including amine, guanidine, carboxylate, sulfonate, phosphonate, or PEGylated surfaces, showed that cationic dendrimers were much more cytotoxic than anionic or PEGylated dendrimers.[271] Similarly, quaternised PAMAM–OH derivatives showed a lower level of cytotoxicity than PAMAM–NH_2 because of shielding of the internal cationic charges by surface hydroxyl groups.[272] Therefore, despite the broad applicability of PAMAM dendrimers, it is generally necessary to modify the surface amino groups with neutral or anionic moieties to avoid cellular toxicity.

The biodistribution of intravenously administered dendrimers has been widely studied, particularly in relation to their development as imaging and therapeutic agents. In general, smaller generation dendrimers are subjected to rapid renal elimination, with blood half-lives of only a few minutes.[273] Those with charged (cationic or anionic) or hydrophobic surfaces are also rapidly cleared from the circulation, but tend to accumulate in the liver.[270] Therefore, it is generally desirable to neutralize the surface charge on PAMAM dendrimers to avoid accumulation in the liver. Dendrimers with a hydrophilic surface (e.g., –OH termini or pegylated dendrimers) exhibit much longer circulation times with blood half-lives that can reach many hours.[270]

To improve biocompatibility, some dendrimers have been designed to be biodegradable. Common approaches include using a cystamine core or the incorporation of monomer units that are chemical intermediates or products of metabolic pathways. Examples include peptide-based dendrimers formed from polylysine, dendrimers with PEO backbones, and polyester dendrimers incorporating monomers such as glycerol and lactic acid.[263,273,274]

3.318.4.1.4. Applications

The flexibility that dendrimers offer in terms of their size, shape, branching, length, and surface functionality have made them an attractive platform for drug delivery[275] and contrast agents. In the following section, we describe how dendrimers have been utilized as optical and MR-contrast agents in molecular imaging applications.

3.318.4.1.4.1. Optical contrast agents

Dendrimers are readily transformed into optical imaging agents through the attachment of NIR dyes to the terminal amino groups. Since the dendrimer itself simply provides a platform for attaching any organic (or inorganic) fluorophore, multiplexing experiments only require that each dendrimer be labeled with an optically distinct fluorophore. In one study, five-color optical lymphatic imaging was conducted using a multiple-excitation spectrally resolved fluorescence imaging technique.[276] Of course, fluorescently labeled dendrimers can also be targeted to cell surface biomarkers. Patri *et al.* functionalized generation 5 PAMAM dendrimers using fluorescein isothiocyanate (FITC) and J591 antibody, which is specific for the PSMA. This agent was used to monitor targeted prostate cancer therapy via confocal microscopy. Confocal microscopy studies also confirmed the binding and internalization of the antibody – dendrimer conjugate, while the dendrimer alone did not show significant binding or uptake into the cells.[277] It should be noted that while dendrimers can be used as fluorescent imaging agents, they do suffer from several inherent shortcomings. Most notably, only a small fraction of surface amines can be labeled with organic fluorophores before self-quenching becomes evident. Further, even though larger dendrimers can have thousands of amines, increasing dendrimer size does not generally allow for a corresponding increase in the number of fluorophores that can be conjugated before self-quenching is observed.

3.318.4.1.4.2. MR-contrast agents

The defined structure and large number of available surface amino groups of dendrimers has led to their use as platforms for the conjugation of large numbers of chelating agents for creating macromolecular MR-contrast agents. The earliest

dendrimer-based MRI contrast agents consisted of PAMAM dendrimers covalently labeled with Gd-DTPA.[261,278] Because self-quenching effects are not relevant for an MR-contrast agent, the number of Gd-DTPA that can be attached to a single dendrimer is only limited by steric effects. Gd-DTPA dendrimers have been used to enhance conventional MR images and 3D time of flight MR angiograms. It has been found that Gd-DTPA dendrimers with molecular weights of 8508 and 139 000 g mol^{-1} have enhancement half-lives of 40 and 200 min, respectively, much longer than the 24 min measured for Gd-DTPA alone.[279]

Langereis *et al.*[280] investigated different generations of Gd(III)DTPA-terminated poly(propylene imine) dendrimers (G0–G5) in terms of (1) longitudinal and transverse relaxivities in mouse blood plasma, (2) concentration detection limits *in vitro*, and (3) contrast-enhanced MR imaging in mice. They found that G0, G1, G3, and G5 dendrimers were all well suited for nontissue-specific MRI of submillimeter-sized blood vessels and evaluating tumor microcirculatory characteristics in mice. However, relaxivity, and thus sensitivity, did increase nonlinearly with molecular weight. Consequently, higher molecular weight dendrimers ($\geq$G5) are typically preferred for targeted molecular imaging applications.[280]

Recently, it was found that a significant improvement in MR sensitivity could be achieved through the formation of Gd-labeled dendrimer nanoclusters (DNCs).[281] DNCs are composed of individual Gd-DTPA-labeled PAMAM dendrimers that have been cross-linked to form larger nanoparticulate carriers. The improved MR sensitivity stems from the extremely high Gd payload per particle that was achieved. It was estimated that each DNC particle (~150 nm in diameter) was conjugated with ~300 000 Gd-DTPA and exhibited an R1 relaxivity of 3.6×10^6 mM^{-1} s^{-1} per particle. Further, it was shown that the Gd-labeled DNCs could readily be functionalized with targeting ligands (e.g., folic acid) and used for *in vivo* molecular imaging. Although this technology was validated on a tumor model, presumably by conjugating appropriate targeting ligands, the ultrasensitive MR detection of various diseases may be possible.

Before any new Gd-based contrast can be extended to the clinic, their toxicological profile must be carefully evaluated, especially with the increasing concerns over Gd-mediated toxicity (i.e., nephrogenic systemic fibrosis).[282] This is particularly relevant for Gd-labeled nanoparticles that are too large to be cleared via renal filtration, since they generally exhibit longer circulation and residence times.

3.318.4.1.4.3. CT contrast agents

Although, dendrimers have predominantly been used as nanoplatforms for MR and optical contrast agents, there have also been a few reports in the literature where dendrimers were used to support CT contrast agents. For example, Schumann and coworkers[283] synthesized water-soluble tin-based metallodendrimers as CT contrast agents and evaluated their toxicity in mice. Recently, another water-soluble iodinated dendritic nanoparticle, G-4-(DMAA-IPA)37, was developed by Yordanov and coworkers[284] and used as CT contrast agents. These particles consisted of a generation 4 Starburst PAMAM dendrimer core and 3-*N*-[(*N*′,*N*′-dimethylaminoacetyl)amino]-α-ethyl-2,4,6-triiodobenzenepropanoic acid (DMAA-IPA) molecules covalently attached to the surface. They possessed high iodine content (33.06%) while retaining their overall charge and water solubility. More recently, Fu *et al.* reported another type of dendritic iodinated contrast agent that has a PEG core with two dendritic polylysine dendrons and triiodobenzene derivatives at both PEG termini.[285] These dendrimers demonstrated several favorable characteristics, including prolonged intravascular enhancement in an animal model, adjustable and large apparent molecular weights, near monodispersity in size, high X-ray attenuation, high water solubility and hydrophilicity, low osmolality, and good chemical stability. It is expected that this new class of iodinated dendrimers will be applied in angiography and, more importantly, in the quantitative microvascular characterization of a wide variety of diseases and abnormalities including cancer, ischemic injury, inflammation, and altered states of angiogenesis.

3.318.5. Future Outlook

Molecular imaging gives scientists the ability to detect, visualize, and quantify cellular and molecular events *in situ*, opening up a myriad of possibilities to advance our understanding of biological systems. Consequently, molecular imaging, despite its relatively short history, has already made significant contributions to basic scientific research as well as academic and clinical medicine. As interest in the field continues to increase and more investigators from diverse disciplines join the effort, there is little doubt that molecular imaging will continue to progress exponentially and shape the future of biomedicine. Furthermore, since molecular imaging applications rely on the construction of specialized molecular probes, it should be evident that materials science plays a particularly invaluable role in the development and progress of molecular imaging. Materials scientists should, therefore, be conscious of this added impact of their work and consider molecular imaging applications when formulating potential research projects.

3.319.1. Introduction

The investigation and the general discussion of the impact of nanoparticles on biological environments are accompanied by a steadily growing interest both within the scientific community and outside. This impact is being treated with increasing weariness, and therefore, the challenging tasks of understanding the structure–property relations and mechanisms of interactions on different levels have become increasingly important.

This chapter deals with the characterization of nanoparticles in biological environments and their interactions, mainly in aqueous-based solutions. After a short definition, the basic interactions between nanoparticles and their stabilization are summarized, followed by a short overview of some important methods of nanoparticles characterization. The last part then describes some aspects of interactions between nanoparticles and biomaterials in order to illustrate the current challenges.

3.319.1.1. Definition of Nanoparticles

It has been commonly accepted until now that nanoparticles possess dimensions between 1 and 100 nm. Additional important parameters are the size polydispersity, shape, and stabilization against aggregation.

Single particle properties differ from those of agglomerates and aggregates. Typically, agglomerates are a group of particles that are held together by relatively weak forces, including van der Waals (VDW) forces, electrostatic forces, and surface tension, whereas aggregates are heterogeneous particles in which the various components cannot be easily taken apart.

One of the prominent features of nanoparticles is the increase in their surface-to-volume ratio with decrease in size. Specific surface areas of up to a couple of thousand square meters per gram are theoretically possible. The characterization of nanoparticles is extremely challenging due to (i) their small size, which is typically below the wavelength limit of direct optical detection via light microscopy and (ii) their tendency to agglomerate or aggregate upon change in surrounding medium.

The interaction between material and biology is typically summarized by the term 'biocompatibility,' which refers to "the ability of a biomaterial to perform its desired function with respect to a medical therapy, without eliciting any undesirable local or systemic effects in the recipient or beneficiary of that therapy, but generating the most appropriate beneficial cellular or tissue response in that specific situation, and optimizing the clinically relevant performance of that therapy."[1] Proper and context-sensitive characterization is necessary to understand the impact of nanoparticles on biological environments.

3.319.2. Interactions of Nanoparticles

A recent review by Nel *et al.* very nicely summarizes the main features and properties that have to be dealt with when nanoparticles are under investigation. In a medium under investigation, important nanoparticle characteristics which determine the properties are the particle's chemical composition, surface functionalization, shape, and typically, also its polydispersity.[2–4] Other quantifiable properties, such as effective surface charge (ζ-potential), particle aggregation, state of dispersion, and stability are influenced by the characteristics of the suspending media,[2] including its ionic strength, pH, temperature, and the presence of large organic molecules (e.g., proteins) or surfactants.[5] Particle characteristics actively contribute to the interactions with the medium by promoting the adsorption of ions, proteins, natural organic materials, and detergents or by double layer formation.[6,7] Many of these particle properties determine the forces that operate at the particle–medium interface, and they have characteristic decay lengths[7] (Figure 1). These forces include those arising from attractive VDW and (typically) repulsive electrostatic interactions, plus short-range forces arising from steric and solvent interactions[7,8] (Table 1). Media interactions (e.g., protein interactions) could also induce large-scale changes, such as agglomeration, nanoparticle dissolution, or ion leaching.

At first glance, the interactions between nanoparticles and, for example, cells seem to embody some of the same principles as those between colloidal particles. VDW, electrostatic, salvation, and steric forces still apply, but due to their small size, many atoms are located at the surface of the nanoparticles.[7,9,10] Therefore, the accompanying VDW forces depend on the position of the atoms and their standard bulk permittivity functions (Table 1 and Figure 1).[10] This complexity further increases in biological media.

Typical interactions between silica particles in water involve VDW, electrostatic, and solvation forces (Figure 1).

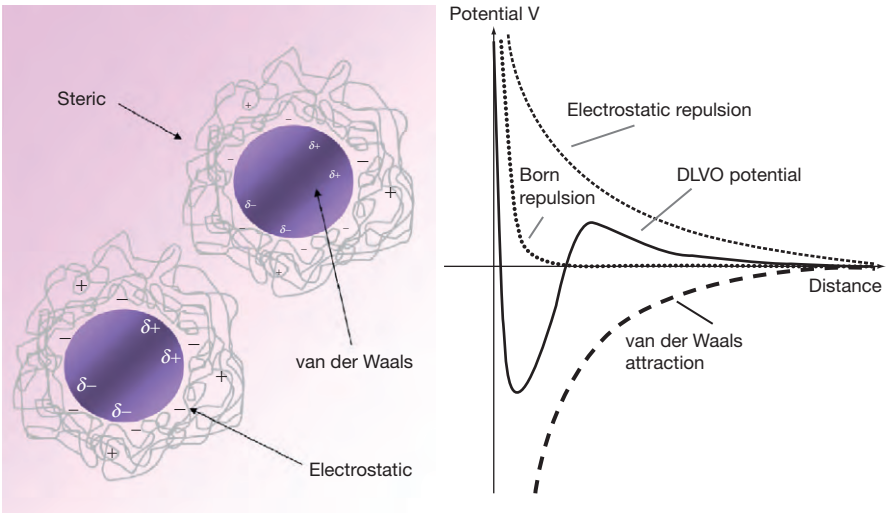

Figure 1 Interactions between nanoparticles. Traditional forces for colloidal stabilization (e.g., electrostatic, van der Waals, steric) that occur when particles are dispersed in aqueous media (left). van der Waals forces are attractive whereas the electrostatic forces are repulsive over a typical length scale (right). The Derjaguin–Landau–Verwey–Overbeek theory in colloid science considers the sum of these forces.

Table 1 Forces and their consequences on nanoparticle characteristics

Force	*Description*	*Range (nm)*	*Consequences*
Electrostatic interactions	Charged surfaces attract counter-ions and repel co-ions by Coulomb forces (double layer formation)	1–100	Typically repulsive, because most of the material carries negative charges in aqueous media; attractive for opposite charges
Electrodynamic interactions	van der Waals interactions through all interacting materials	1–100	Attractive in aqueous solution
Hydrodynamic interactions	At the nanoscale, classical Brownian diffusion and hydrodynamic forces are often hindered or enhanced	Typically $\gg$100 nm	Increase of frequency of collision of nanoparticles
Solubility	Interactions with solvent molecules	1–10	Influence on the thermodynamic stability of dispersed nanoparticles
Steric interactions	Polymers bound to the nanoparticles surface give rise to repulsive interactions	1–100 (depending on the length of the polymer)	Typically increase stability of individual particles

VDW forces result from the dynamic interaction of dipoles. At any moment, dipoles fluctuate and eventually induce a dipole moment in the atoms of the silica particle, thereby causing an attractive force. The electrostatic force in the system results from surface charges that are present on the silica particles. Silanol (Si–OH) groups dissociate in aqueous solution at pH greater than ~2 to yield negative surface charges, which then generate repulsive electrostatic forces between particles. For silica particles, the sum of the attractive VDW and repulsive electrostatic forces yields the well-established Derjaguin–Landau–Verwey–Overbeek (DLVO) potential[7,8,11] (Figure 1).

In biological fluids, the ionic strength is often about 150 mM, leading to the restriction of the electrostatic forces to a few nanometers from the surface. The high ionic strength also influences the zero frequency contribution of the VDW forces, whereas the higher frequency dispersion interactions still remain. Moreover, solvation is another issue that is important for nanoparticles, especially in aqueous solvents (Figure 1). The water molecules form a protective surface layer which decreases the tendency to adhere to other nanoparticles, leading to increased stability. In contrast, rapid dehydration and aggregation will occur if the relative affinity of two interacting surfaces for water molecules is much lower than that between the water molecules themselves ('hydrophobic effect'). All of these forces are described by theories.[10] Corresponding experimental measurements also tend to be reasonably consistent.

3.319.3. Characterization of Nanoparticles in or from Solution

The above-mentioned properties are a challenging task when nanoparticles are being characterized. This holds true for bare nanoparticles and becomes even more important when nanoparticles are analyzed in biological environments. The following part describes some of the main methods that are generally employed nowadays, especially for the characterization of nanoparticles in or from solution. This includes (i) scattering methods such as static and dynamic light scattering (SLS, DLS), small angle X-ray and neutron scattering (SAXS, SANS), and electrophoretic light scattering; (ii) microscopy-based methods, namely transmission electron microscopy (TEM) and atomic force microscopy (AFM); and (iii) field-flow fractionation (FFF).

3.319.3.1. Scattering Methods

Light, with wavelength in the visible range, is commonly used for static and dynamic light scattering (SLS, DLS), and the light scattered by dilute solutions is detected and subsequently analyzed.[12] Dust, which in solution is typically present in the size range of micrometers, needs to be removed, because the scattering intensity increases with the particle radius R as $I \sim R^6$. The time-averaged scattering intensity is detected in SLS and is used to determine the average molecular weight (M_w), the second virial coefficient (A_2), and the radius of gyration (R_g) of the particles in solution. The latter can only be determined if the size of the particles exceeds ~1/20 of the wavelength used. The scattering due to a known standard is used to calibrate the scattering intensity. The scattering itself is based on both concentration and density fluctuations (and of course, the difference in refractive index compared to the solvent; if this is zero, the particles become invisible); therefore the scattering due to the solvent is subtracted from that of the solution. Care should to be taken so that no additional effects, such as absorption or fluorescence, influence the measured intensity. The resulting inverse, reduced scattering intensity, the so-called Rayleigh ratio, is proportional to the scattering angle which is expressed in terms of the scattering vector q, and the sample concentration c. For particles with radii between ~10 and 50 nm, the application of the Zimm equation should yield a linear dependence of the inverse Rayleigh ratio and q^2 and c.

$$\frac{Kc}{R(\theta)} = \frac{1}{M_w}\left(1 + \frac{1}{3}q^2\left\langle R_g^2\right\rangle_z\right) + 2A_2c$$

where K is the optical constant (depends on the refractive index increment, the refractive index n of solvent, and the employed wavelength in vacuum l_0); c, the concentration; $R(\theta)$, measured Rayleigh ratio (defined as $R(\theta) = \frac{I_{solution} - I_{solv.}}{I_{std.}} R_{std.}$, scattering intensity of the solution, the solvent and a standard (typically toluene), and the independently determined Rayleigh ratio of the standard); θ, the scattering angle; M_w, the weight average molar mass; q, absolute value of the scattering vector ($q = |\vec{q}| = \frac{4\pi n}{\lambda_0}\sin(\theta/2)$), $\left\langle R_g^2\right\rangle_z$, z-average of the squared radius of gyration; and A_2 is the second osmotic virial coefficient.

Deviations from the linearity are observed if the particle size – and unfortunately also if the polydispersity – increases. In addition, this is also an important consideration in the case of charged particles in extremely low salt-containing solutions (such as deionized water), due to their potentially large interaction ranges.

In DLS, the time-dependent scattering intensity is detected, from which an autocorrelation function $g_1(t)$ can be derived. DLS yields particle hydrodynamic size (hydrodynamic radius R_h) in solution by the determination of the translational diffusion coefficient D. A recent review by Jones and Grainger points to the potential pitfalls that accompany DLS experiments:

> However, such nano-sizing analyses by DLS require a high degree of skill to perform, careful instrument calibration, positive and negative controls, attention to reagent purities, and some knowledge of optical data modeling algorithms to predict a sizing outcome consistent with many assumptions about the optical scattering physics in the solution. Many particle sizing studies, spanning metals, metal oxides, and polymers, treat the technique blindly as an automated method with default scattering models and curve-fitting assumptions that are neither described, justified nor validated for various sample types.[13]

The autocorrelation function $g_1(t)$ depends on D and the scattering angle (via θ), which, in the case of SLS, means that additional effects may need to be taken into account, especially with respect to the particle size and the polydispersity. In addition to the above, in the case of DLS, the anisotropy of the particles also needs to be taken into account, as it influences their diffusion properties.[12] For monodispers, spherical particles, $g_1(t)$ is defined by:

$$g_1(t) = \exp\left(-q^2\langle\Delta R^2(t)\rangle_\tau/6\right) = \exp\left(-Dq^2t\right) = \exp\left(-\frac{t}{t_D}\right)$$

$\langle\Delta R^2(t)\rangle_\tau$ is the average mean square displacement and t_D is the relaxation time.

For small spherical particles with moderate size distribution, DLS yields the inverse z-average of the hydrodynamic radius. The Stokes–Einstein relation combines the diffusion coefficient and the corresponding hydrodynamic radius. Typically, an extrapolation of $q \to 0$ and $c \to 0$ is needed to obtain $\langle D\rangle_z$. Otherwise, only apparent values are obtained.

$$\langle D\rangle_z \propto \langle R_h^{-1}\rangle_z, \quad R_h = \frac{k_B T}{6\pi\eta D}$$

where k_B is the Boltzmann constant; T, the absolute temperature; and η is the viscosity of the solvent.

Many nanoparticle systems in aqueous-based solutions are stabilized by electrostatic forces, as already discussed above. Therefore, contact with biological media such as cell culture medium often leads to destabilization due to the decrease in Debye length, and subsequently, to the formation of aggregates. This makes it challenging to distinguish between the impact of single dispersed nanoparticles and their aggregates in, subsequently performed cell experiments (Figure 15). One example of silica nanoparticles, analyzed by DLS in a low ionic strength aqueous solution and in a cell medium, is shown in Figure 2.[14,15]

Basically, small angle X-ray and neutron scattering (SAXS, SANS) are comparable to SLS. Major differences are the wavelength employed (typically in the order of 0.1–10 nm), and the scattering contrast, which in case of SAXS is the difference in electron density, and in case of neutrons, is the scattering length. Depending on the size of the particles, the determined angular-dependent scattering intensity of dilute solutions can yield the radius of gyration R_g and additional information about the shape and the internal structure of the particles, and is commonly expressed by a theoretically derived particle form factor $P(q)$ (Figure 3). Increasing polydispersity also leads to an increase in the ambiguity in the results.[16–18]

Specifically, during the characterization of nanoparticles, interesting particle properties can be derived from SAXS and SANS, including their internal structure (often called the fractal structure) and the ratio of surface to volume of the particles (in the so-called Porod regime).

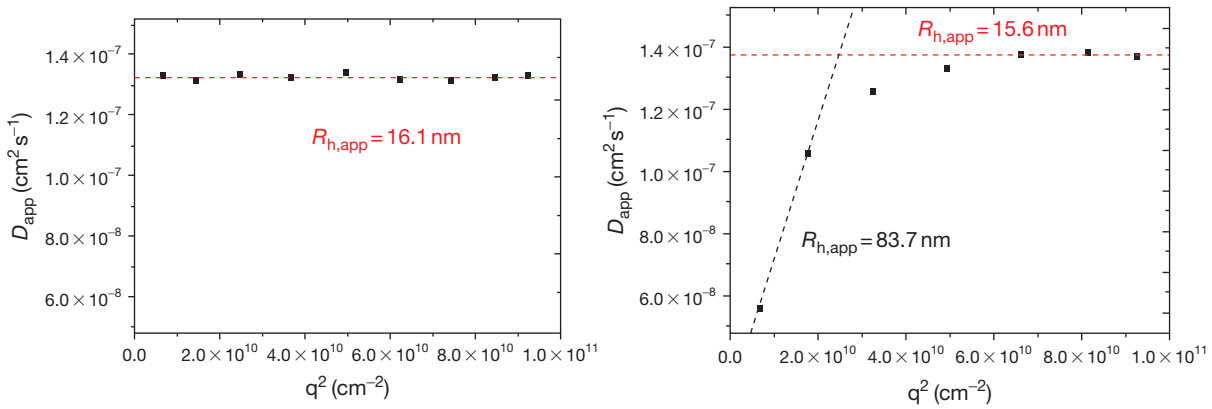

Figure 2 Apparent diffusion coefficient determined by dynamic light scattering for commercial silica nanoparticles (dispersions) in aqueous solution (concentration $c = 0.3\,g\,l^{-1}$, 24 h after sample preparation); left: in 0.01 M NaBr; right: in cell culture medium RPMI1640. Also shown are the corresponding extrapolation-based hydrodynamic radii; in case of medium, the extrapolations for high and for low q-values are shown.

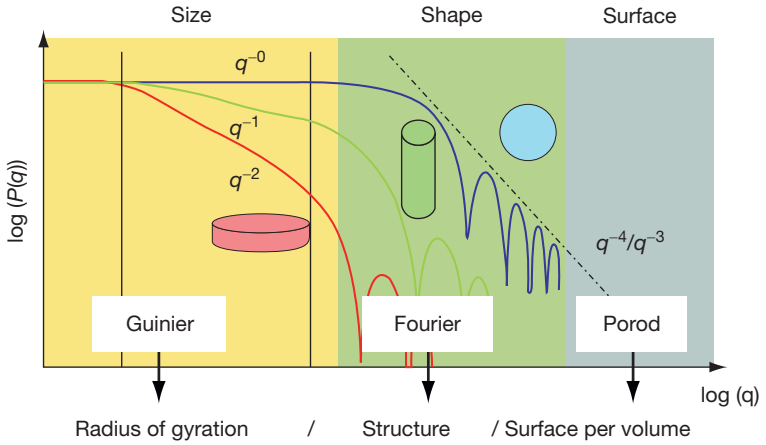

Figure 3 Evolution of the particle form factor $P(q)$ for different particle shapes.

Finally, electrophoretic light scattering is used to determine the effective charge in terms of the ζ-potential of the nanoparticles in solution.[11] In a very simple approach, the electrophoretic mobility μ of the particles can be linked to the ζ-potential according to:

$$\zeta = \mu \frac{4\pi\eta}{\varepsilon\varepsilon_0}$$

where h is the solvent viscosity; e_0, the permittivity; and e is the dielectric constant of the solvent.

Basically, the same parameters, as already discussed above for DLS, have to be considered here. In addition, the simple approach shown here becomes increasingly invalid in case of physiological conditions, mainly due to the high ionic strength of the solution.

3.319.3.2. Microscopy-Based Methods

Electron microscopy, especially transmission electron microscopy (TEM) is used to visualize nanoparticles and determine their size, polydispersity, and shape.[19] Typically, dried samples are analyzed on carbon-coated copper grids, which can potentially lead to additional effects such as induced aggregation. To minimize this effect, especially for aqueous-based solutions, a cryogenic sample preparation method can be employed (cryo-TEM, Figure 4).

The particle solution is again deposited on a carbon-coated copper grid, but now, typically, a Holey carbon film is used. After deposition, the sample is shock frozen in liquid propane, transferred into liquid nitrogen, and analyzed under external cooling. This preparation results in a thin, amorphously solidified water film that contains the nanoparticles.[20] As in light scattering, a high degree of the skill is needed, and in addition, the number of particles detected needs to be large enough to reduce the influence of potential artifacts due to insufficient statistical power. A comparison between ordinary sample preparation, including drying, and a cryogenic preparation of commercial silica nanoparticle dispersions, both analyzed by TEM, is shown in Figure 5.

The dry sample preparation shows aggregation of the particles upon drying. No reliable information on the existence of aggregates in solution is possible. On the other hand, the cryogenic sample preparation clearly shows individual particles.

A second modern technique to visualize nanoparticles on solid substrates, such as mica or graphite, is atomic force microscopy (AFM).[21] A small tip (typical radius of ~10 nm) is located on a cantilever and brought into contact with a surface to be analyzed (Figure 6).

Different modes of operation can be used, and mostly depend on sample characteristics and the forces involved. A topological picture of the surface is generated by incremental scanning of the surface. This can be used to obtain a topological picture of the surface or to measure force–distance curves. Modern instruments allow the characterization of the surface after drying or, especially for water-based solutions, in solution (after adsorption of the nanoparticles from solution). An example of polyorganosiloxane nanoparticles analyzed by AFM is given in Figure 7.[14]

3.319.3.3. Field-Flow Fractionation

FFF is a family of techniques, where a physical field acts perpendicular to a commonly ribbon-like channel, through which a solvent is pumped.[22,23] If the solvent viscosity is low enough, a laminar flow is generated. One method of exerting a force perpendicular to the channel is by inserting a semipermeable membrane as a physical barrier (Figure 8). The resulting

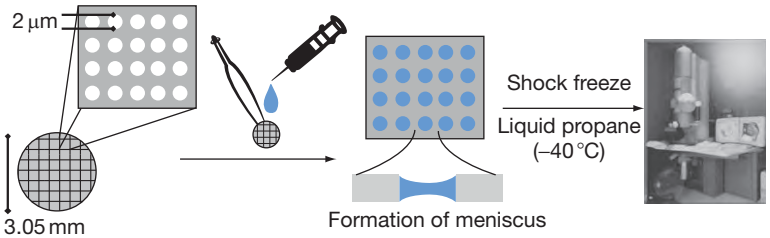

Figure 4 Sample preparation on cryo-TEM: Holey carbon-coated cupper grid (left), deposition of a solution droplet, pore spanning liquid film (middle), shock freezing in, for example, liquid propane and transfer into the TEM (right).

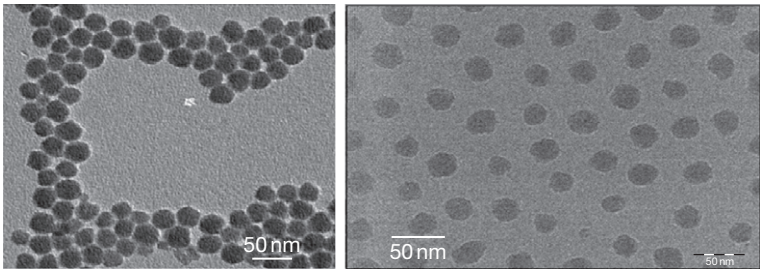

Figure 5 Transmission electron microscopy pictures of the same aqueous silica dispersion: after deposition on a carbon-coated cupper grid and subsequent drying (left) and after cryogenic sample preparation on Holey carbon-coated cupper grids (right).

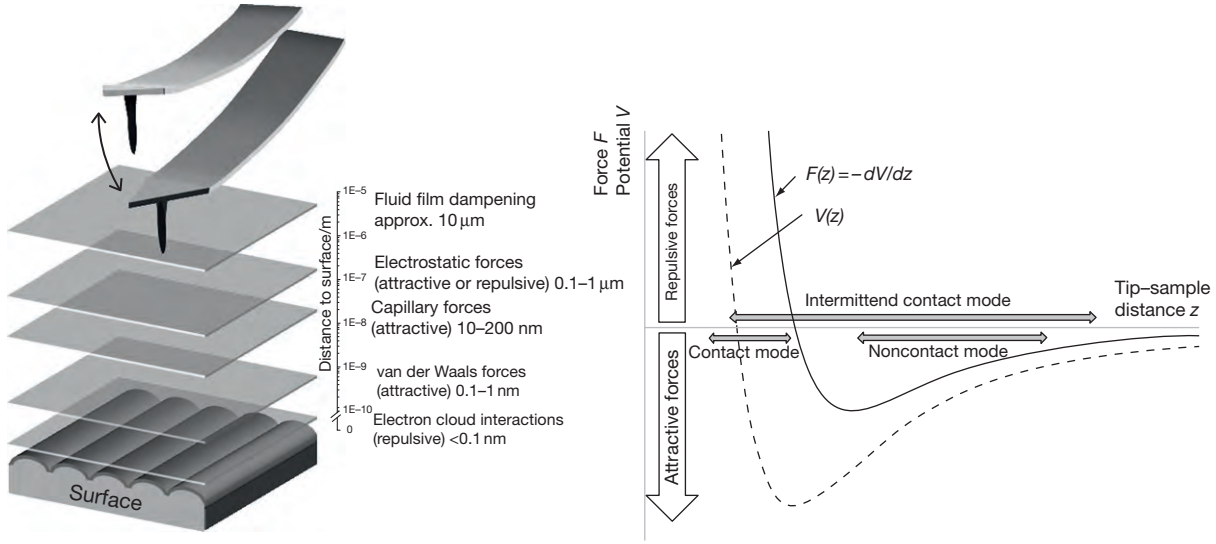

Figure 6 Schematic representation of the different modes used in AFM and the corresponding forces involved. (Adapted from Elings, V., Digital Instruments Nanoscope Command Reference Manual, Santa Barbara/CA (1995), now Bruker Nano Surfaces Division).

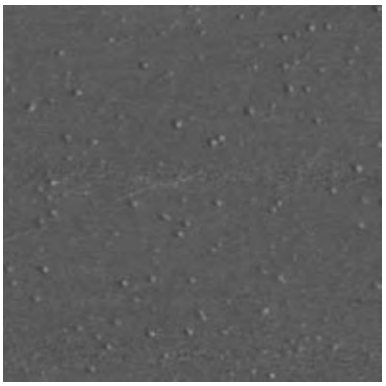

Figure 7 Atomic force microscopy picture (noncontact mode) obtained from an aqueous polyorganosiloxane–nanoparticle dispersion (average size 30 nm), spin cast from solution onto mica and subsequently dried; picture size 1 × 1 µm^2.

technique is commonly called asymmetrical flow FFF (AF-FFF) and works quite nicely, especially for aqueous-based solutions.[24] In this case, membranes typically used for ultrafiltration can be employed.

After the introduction and focusing of particles, a concentration profile is established from the membrane, depending on the diffusion coefficient. In a simple picture, and depending on the cross-flow, the smaller particles diffuse further into the channel compared to the larger ones. Subsequent turn-on of the laminar flow through the channel, while maintaining the cross-flow, leads to particle separation and subsequent detection (Figure 9).

This simple description breaks down when gravity needs to be included, or in other words, when the particle size increases to, for example, beyond micrometers in size, and is also dependent on the density of the particles. For smaller particles, the theoretical description yields a linear relation between the retention time t_R of the nanoparticles and their hydrodynamic radius R_h.

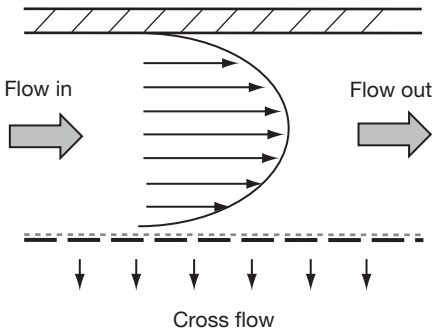

Figure 8 Schematic cut through an asymmetrical flow field-flow fractionation channel.

$$t_R = \frac{\pi\eta\dot{V}_c w^2}{\dot{V}k_B T}R_h$$

Where η is the solvent viscosity, $\dot{V}_c$, the cross-flow rate; w, the channel height; $\dot{V}$, channel flow rate; k_B, Boltzmann constant; and T is the absolute temperature.

An example of the AF-FFF characterization of polyorganosiloxane nanoparticles is shown in Figure 10.[25,26] In this case, a linearly decreasing cross-flow has been used to shorten the measuring time.

Due to technical constraints, such as compressible membranes or programmed flow conditions, AF-FFF is typically calibrated with particle standards of known sizes.[27]

3.319.4. Examples of Nanoparticles in Biological Environments

The expanding use of engineered nanoparticles (ENPs) has spurred an interest in defining their effects in biological environments.[2,28–30] The size-related properties of ENPs raise concerns about their potential adverse effects on biological and ecological systems, as a variety of studies have indicated

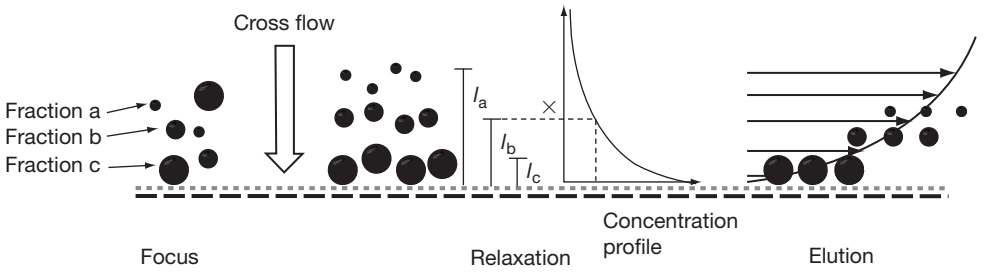

Figure 9 Scheme of the separation process in asymmetrical flow field-flow fractionation. Sample injection (left), evolution of the corresponding concentration profiles (middle), and separation after turn-on of the laminar flow (right).

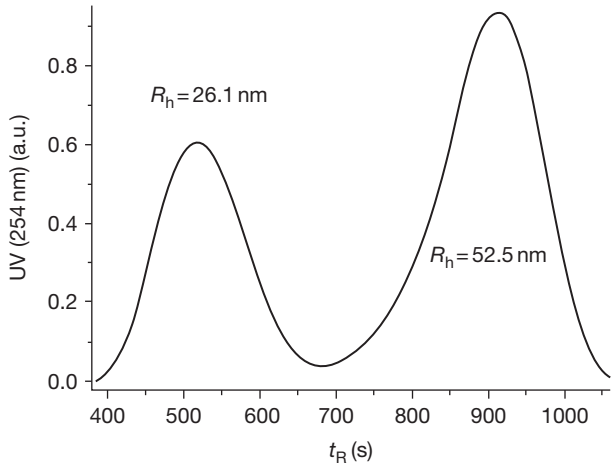

Figure 10 Separation of a bimodal nanoparticle mixture of polyorganosiloxanes in aqueous solution (10 mM NaCl, 100 mg l^{-1} TWEEN 20) by asymmetrical flow field-flow fractionation using a linearly decreasing cross-flow: UV signal at 254 nm versus retention time.

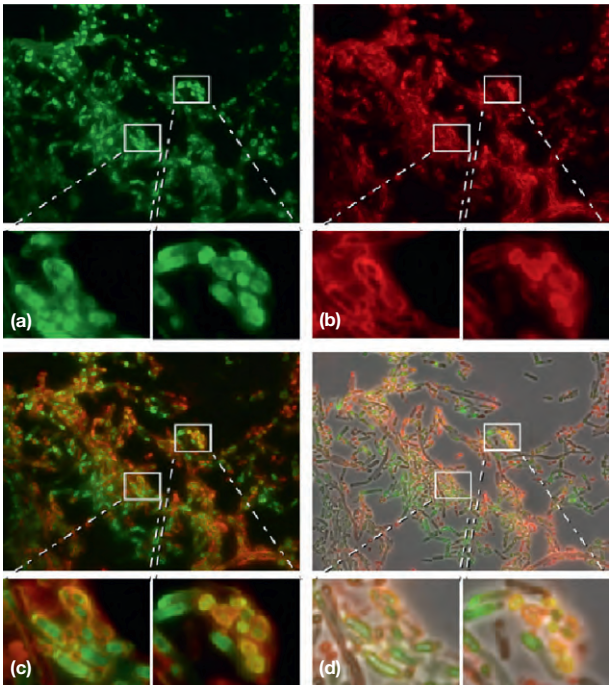

Figure 11 Binding of silica-engineered nanoparticles (SiNPs) to bacteria. *Escherichia coli* XL-2-bacteria expressing the green fluorescent protein (GFP) were incubated with red fluorescent silica NPs (10^{12} SiNP per milliliter) in PBS for 30 min, washed with PBS, and examined by fluorescence microscopy (for methods see Rücker *et al.*[37]). (a) GFP-expression marks bacterial cells. (b) Red fluorescent SiNPs bound to the outside of bacteria were detectable upon excitation with 509 nm. (c, d) Merge (yellow), combined with phase image.

that ENPs could exert toxic effects and pose hazards to the biological environment.[31–34] Traditionally, the *in vivo* biological and toxic effects of ENPs have been characterized by animal studies. However, the biological environment not only includes humans and higher animals, but also plants and simple microorganisms such as yeast, bacteria, phyto- and zooplankton[2,30,35,36] (Figure 11).

To even add a further level of complexity, certain ENPs may also enter the intracellular organelles, including the nucleus, which is a critical storage compartment of the genetic information.[2,29,38] Hence, the nano–bio interface, comprising the dynamic physicochemical interactions, kinetics, and thermodynamic exchanges between nanomaterial surfaces and (bio) molecules or ions present in the various biological environments, still awaits comprehensive characterization.[29,39] Such interactions lead to the formation of NP (protein) coronas which affect (intracellular) uptake and biocatalytic processes and may ultimately have biocompatible or bioadverse outcomes. Consequently, probing these various interfaces using the sophisticated methodologies described in the previous chapters is mandatory for the development of predictive relationships that describe the processes that occur at the nano–bio interface; these will be crucial for the safe use of nanomaterials.[1,40]

3.319.4.1. The Fate of Nanoparticles in Living, Biological Environments

The field of nano-eco(toxico)logy is highly relevant but complex.[35,41] Hence, we wish to focus on mammalian systems, and, predominantly on humans. Nanoparticles for medical applications are frequently delivered directly via parenteral administration. Among the most discussed entry sites for environmental ENPs are the skin and the respiratory and gastrointestinal tracts; the respiratory tract is considered as one of the main accidental entry routes for ENPs and can potentially lead to local or even systemic adverse effects[30,32,42,43] (Figure 12).

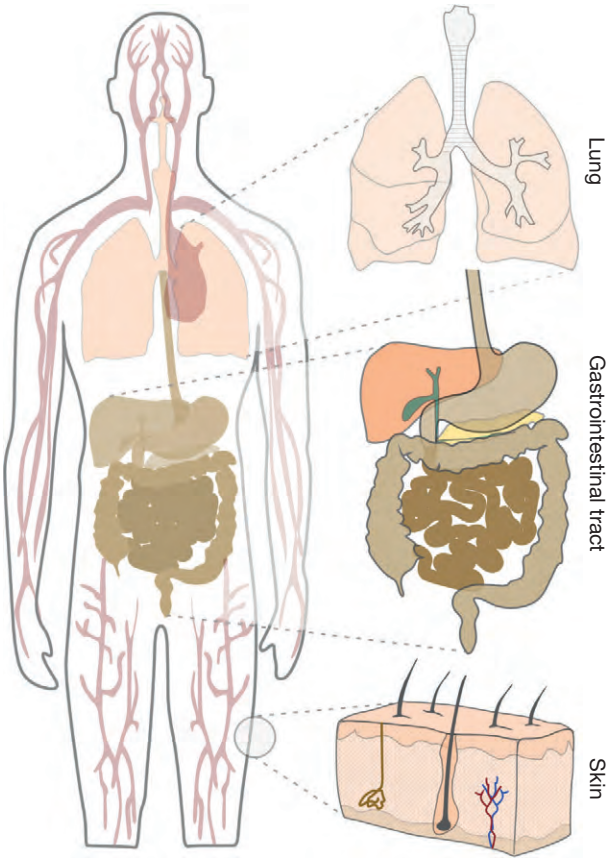

Figure 12 Schematic overview of the most relevant entry routes for nanoparticles into the human body.

The nasal mucosa, which is known to react to environmental toxins with irritation, infection, and allergies, is the first relevant biological interface that comes into contact with ENPs. The nasal mucosa has even been suggested to allow access of ENPs to the central nervous system.[44–46] Second, because of its large surface area (~120 m^2), and the less effective recognition of ENPs by alveolar macrophages which constitutes the first line of defense against particulates that have escaped the mucociliary escalator, the bronchial-/alveolo–capillary barrier is considered to be the key target of inhaled ENPs.[43,47] Moreover, only a thin barrier, composed of alveolar epithelial type I/type II and pulmonary capillary endothelial cells, separates the airspace from capillary blood (**Figure 13**), thus raising concerns about the potential systemic entry of ENPs.

After deep lung inhalation, ENPs may trigger (patho) biological effects not only by direct cell damage but also indirectly by inducing chronic inflammation, similar to that reported for carbon nanotubes.[48] Such inflammatory responses include alveolar macrophages and also alveolar epithelial type II (ATII) cells that can respond to noxious stimuli by producing proinflammatory cytokines.[38,49,50]

Irrespective of the entry route, the intrinsic characteristics of the ENPs are modified upon contact with the various biological matrices. Particularly, ENPs that target the respiratory and gastrointestinal tract first encounter mucus, a complex mixture containing glycoproteins (mucins), enzymes, immunoglobulins, and inorganic salts. Thus, ENPs in the deep lung do not directly interact with cellular membranes, but first meet the lung surfactant present over the epithelial cell layer (**Figure 13**).[51] The pulmonary surfactant is a lipid–protein composite that covers the air–water interface in vertebrate lungs. In this interface, the lipid monolayer regions most likely

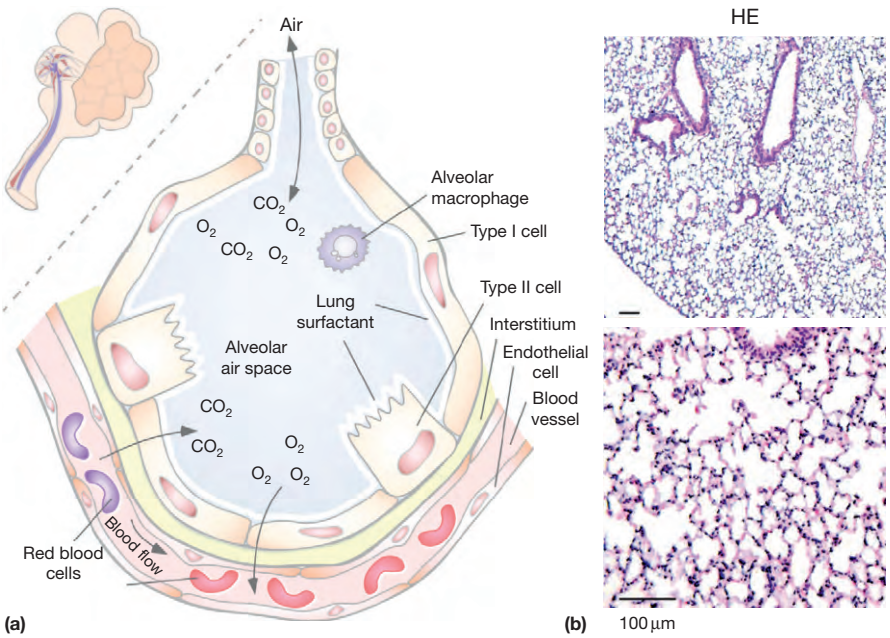

Figure 13 (a) Schematic illustration of alveolo–capillary barrier components. (b) Histologic specimen of murine lung tissue counterstained with hematoxylin and eosin. Bars: 100 μm.

coexist with surfactant protein containing multilayer structures, which may be disturbed by incoming ENPs. The essential function of the surfactant during the breathing process is to reduce the surface tension in order to prevent the collapse of the alveolar system during expiration, and to reduce the work of breathing.[52,53] Malfunction or lack of this crucial material might lead to diseases like the *Neonatal Respiratory Distress Syndrome*.[52] As ATII cells synthesize, secrete, and recycle the pulmonary surfactant, any interference in these processes by ENPs may affect the homeostasis and function of the pulmonary surfactant, and thereby contribute to ENP-induced (patho)biological consequences. Although animal studies have significantly aided in the discovery of such toxic effects,[48,54] the complexity of the alveolar microenvironment hampers studies on ENP-mediated effects at the molecular and mechanistic level. Therefore *in vitro* models mimicking the different biological layers of the alveolo-capillary barrier are used and are accepted as reliable experimental tools to investigate and predict the (patho)biological effects of ENPs.[49,55]

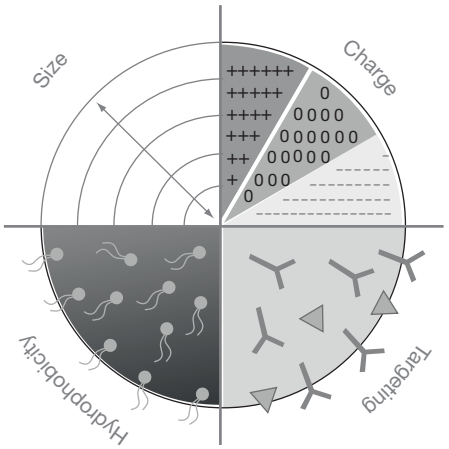

Figure 14 Schematic illustration of engineered nanoparticle characteristics affecting the nano–bio interface.

3.319.4.2. Influence of the Nano–Bio Interface on Nanomaterial-Mediated Biological Effects

The response of ENPs to the various biological environments is complex and results from the interplay of critical biophysicochemical forces that are active at the interface between nanomaterials and biological systems.[29,56] Nevertheless, such associations of proteins/biomolecules with nanoparticles are almost always the first step when nanoparticles enter a biological fluid.

Although clearly dependent on the entry route, for example, intravenous injection of ENPs for medical applications versus accidental inhalation, most ENPs, upon contact with biological matrices, are swiftly coated by proteins, leading to the formation of a so-called protein corona.

Such nano-biofilms largely define the biological identity of the particle, its interactions with biological surfaces, and hence, the induced (patho)biological responses. Several studies indicate that these responses tend to correlate with surface area rather than mass.[57,58] Nanoscale materials have far greater surface-to-volume ratios compared to larger particles, implying that more biomolecules/proteins will bind to a nanoparticle relative to its mass, compared to a particle of larger size.[57] Additionally, particle composition as well as its surface characteristics (e.g., size, radius of curvature, charge, hydrophobicity, etc.) will determine which types of biomolecules will interact with that particle and with what affinity[29,56,57] (**Figure 14**).

Thus, it is critical to characterize and understand the various chemicophysical binding forces that are involved in building the (dynamic) nano-biomolecule corona in order to be able predict the nature of the decorated particles that biological systems can face, and hence, their evoked biological responses (**Figure 15**).

Several proteins are already known to form (transient) complexes with nanoparticles. For example, upon intravenous ENP injection, human serum albumin and fibrinogen appear to dominate the particle surface, but it is not yet understood whether they also influence the biological effects induced by such particles. Likewise, albumin, immunoglobulins,

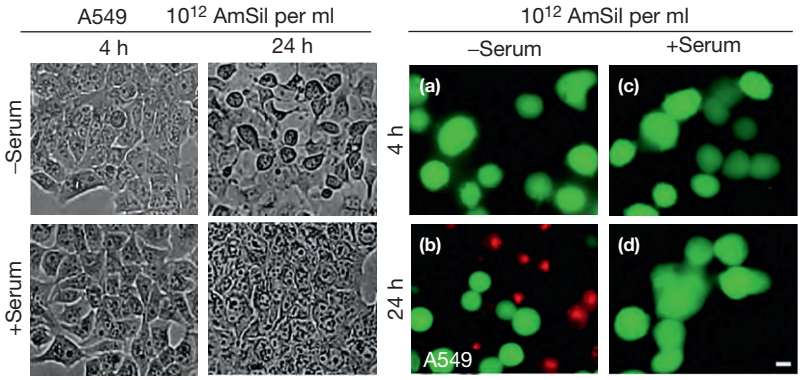

Figure 15 Serum proteins ameliorate the cytotoxicity of silica nanoparticles (NPs). The epithelial lung carcinoma cell line A549 was incubated with the indicated amounts of amorphous silica NPs (AmSil) suspended in cell culture medium (RPMI1640) in the absence or presence of 10% fetal calf serum (FCS). Four hours later, the medium was replaced by RPMI1640/10%FCS, and the cells were further cultivated for 24 h. At the indicated time points, cell morphology and vitality were analyzed by light microscopy (left, phase contrast images) or by using the *LIVE/DEAD® Viability/Cytotoxicity Kit* (Molecular Probes) (right, green fluorescence indicates vital cells, red fluorescent nuclei mark dead cells. Bar: 10 μm). AmSil-induced cell death was significantly reduced when exposure was performed in the presence of serum.

complement, fibrinogen, and apolipoproteins have been reported to bind most strongly to carbon nanotubes, iron oxide, and polymeric nanoparticles.[28,51] However, whether such nano-biofilms exist and are biologically relevant even upon inhalation or ingestion of these materials remains to be resolved. Again, depending on the respective biological microenvironment, the protein coating appears to determine the fate of the particular NP. Complement and immunoglobulin binding may trigger particle opsonization, thus leading to phagocytic ingestion; whereas particle-bound ligands may activate extracellular receptor-signaling and/or receptor-mediated endocytic uptake.[59,60] Reported cell-signaling pathways activated by NPs include receptor-tyrosine kinases, stress-activated protein kinases, pattern recognition receptors, as well as mitogen-activated protein kinases.[29,61] Also, direct NP penetration of the plasma membrane, without the need to involve endocytic compartments, has also been suggested, and this may contribute to nanomaterial toxicity.[60]

In addition to the complications described above, nanoparticles have a tendency to agglomerate, or form multiple single particle clusters when in a biological environment. Consequently, the observed differences in (patho)biological responses elicited by nanomaterials in the absence or presence of proteins (**Figure 15**) may also be due to protein-mediated NP aggregation, which reduces the effective cellular exposure dose[28,62] (**Figure 2**).

3.319.5. Conclusions and Outlook

Analyzing and predicting the impact of nanomaterials on biological systems is particularly complex. It combines numerous methodological challenges ranging from particle characterization in the absence and presence of biological fluids, their interactions with biological nanoscale or nanostructured surfaces as well as the dissection of NP-induced (patho) biological effects.

As outlined above, there are currently numerous highly sophisticated techniques available that allow the physicochemical characterization of nanomaterials in their respective (biological) environments. Also, various disciplines in the areas of life science hold an immense knowledge of how cells, organs, and whole organisms react to environmental nanoscale stimuli, such as viruses, proteins, and metabolites.

Despite this knowledge, we still lack an in-depth, mechanistic, molecular understanding of whether and how NP-induced biological responses are triggered; whether predominantly by extra- and/or intracellular NPs, and to what extent the physicochemical properties of these particles, as well as a (specific) protein/biomolecule-corona, is critical for these effects. This hurdle can only be overcome by an interdisciplinary joint endeavor. The identification and understanding of the large number of forces that determine these processes, such as the formation of the protein corona, cellular contact and signaling, particle entry as well as intracellular biocatalysis, demand systematic experimental approaches and improved technologies. The obtained insights will help us to comprehend the orchestration of the nano–bio interface and thus permit prediction of whether the nanomaterial is biocompatible or bioadverse for a given application.

3.320.1. Introduction

Immobilized proteins have long found use in various applications including biosensing,[1] diagnostics,[2] and fine chemicals synthesis.[3] More recently, much effort has focused on immobilization of proteins in defined patterns resulting in arrays that allow for high-throughput, parallel assessment of proteins in proteomics studies[4] as biomarkers for cancer and other diseases,[5] and in drug discovery.[6] Present technologies rely in large part on patterns exhibiting micron- to millimeter-scale features. However, protein patterning on the nanoscale becomes ever more desirable as the scope of biochemical screening and demand for high-density platforms increase. As pattern density continues to increase, so will the scope and throughput for profiling of disease markers and other targets. Other potential benefits of nanoscale array platforms include lower sample volume requirements[7] and enhanced sensitivity for detection of low-abundance analytes.[8,9]

Furthermore, nanoscale patterning strategies enable the study of biophysical processes on length scales that are commensurate with the key protein effectors themselves. Cells and tissues exhibit hierarchically ordered structure including regular nanoscale morphologies such as collagen fibers in the extracellular matrix and hydroxyapatite crystals in bone tissue. Nonbiological substrates with defined nanotopography have been designed to mimic these biological structures as well as to elicit new responses from cells and tissues. Indeed, these designed substrates have been used to study and modulate processes including cellular adhesion, surface antigen presentation, and intracellular signaling pathways.[10] These processes are influenced not only by the physical topography of cellular nanostructures, but also by the arrangement of cell surface ligands and other chemical cues. As described below, nanoscale biochemical platforms have been developed to study spatial determinants of processes such as cell motility and apoptosis.[11,12] Further development of protein nanoarrays with defined topography may therefore create new fundamental biological knowledge.

Recent reviews have highlighted patterning of proteins and other biomolecules on the nanoscale by a variety of processes including photolithography and electron beam lithography (EBL), 'soft' lithographic techniques including microcontact printing, and scanned-probed microscopy (SPM)-based techniques such as dip-pen nanolithography.[13–15] Stamping processes allow for simple and rapid patterning of large areas, albeit with lower resolution than serial processes such as SPM- and EBL-based techniques. These serial processes can be more complicated and are relatively slow, although various

strategies have been developed to overcome throughput limitations. In total, these techniques have resulted in high-resolution protein patterns covering large areas.

Self-assembly of block copolymers (BCPs) is an attractive strategy for fabrication of materials systems with nanoscale control of biomolecules. This is because BCPs are characterized by well-defined nanometer-scale features due to the microphase separation of chemically incompatible polymers that are covalently linked together.[16,17] The size of the morphologies depends on the molecular weight ratio of the various blocks. Long-range order can be achieved with a variety of techniques, including annealing with selective solvents[18–20] or elevated temperatures;[21,22] application of external electric fields[23,24] and shear forces;[25] and use of topographically defined substrates.[26,27] This ready processability holds great promise for straightforward control of protein organization over large areas. BCP thin films and bulk preparations have been extensively utilized in various materials applications as templates for the synthesis of inorganic and magnetic materials,[28,29] masks for photolithography and other patterning techniques,[30] scaffolds for nanodevices,[30] and functional membrane materials.[22,31,32] The structure and functionality of conventional BCP thin films can be augmented through the incorporation of small molecules, homopolymers, and inorganic nanoparticles.

Several recent studies have demonstrated that biological molecules such as proteins can be incorporated in BCP assemblies, as reviewed in the following pages. In certain cases, systems have been developed for defined nanoscale patterning of proteins for biochemical assays as well as biological ligands for study of surface-mediated cellular processes. In other cases, polymer nanostructure has been used to modulate materials interactions with biological media, such as blood, in the context of biomedical devices. This review is limited to studies of protein interactions with surfaces of BCPs (as well as some polymer blends) in condensed phases – namely, BCP thin films. BCP self-assembly in solution has led to several examples of hydrogel and micelle materials that are particularly interesting as delivery vehicles for therapeutics and other cargo. While those solution-based systems are outside of the scope of this review, films and surface coatings containing BCP micelles for delivery applications are described. The reader is also directed to additional chapters in these volumes – including **Chapter 4.401, The Concept of Biocompatibility**; **Chapter 4.409, Surfaces and Cell Behavior**; **Chapter 1.129, Engineering the Biophysical Properties of Basement Membranes into Biomaterials: Fabrication and Effects on Cell Behavior**; **Chapter 4.411, Peptide- and Protein-Modified Surfaces**; and **Chapter 4.413, Patterned Biointerfaces** for in-depth review of nanostructured materials and their interactions with proteins, cells, and tissues.

3.320.2. Controlled Protein Adsorption on BCP and Polymer Blend Surfaces

3.320.2.1. Protein Adsorption on Homopolymer Blend Surfaces

Blending of immiscible polymers can result in composite materials with unique and useful physical and chemical properties. The thermodynamics of polymer–polymer phase behavior has been investigated experimentally and theoretically, and macrophase separation of immiscible polymers typically results in domains that are on the order of microns in size.[33] Polymer blend surface coatings, micropheres, and nanofibers have been studied with respect to cell culture, drug delivery, and tissue engineering in various biological systems.[34–36] Understanding of protein adsorption phenomena on polymer biomaterials is critically important because protein adsorption is usually the first event upon introduction to biological milieu, as in the case of *in vivo* implantation of biomedical devices. Adsorbed proteins, in turn, direct interactions with cells and tissues and control downstream biological processes.[37] For further insight on polymers and related protein adsorption phenomena, refer to **Chapter 4.406, Protein Interactions with Biomaterials**; **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**; and **Chapter 1.124, Polymer Films Using LbL Self-Assembly** in this series.

Libera and colleagues have studied the adsorption of ferritin, a protein nanocontainer with an iron core, on binary blends of hydrophobic poly(desaminotyrosyl-tyrosine dodecyl ester carbonate) (PDTD) with poly(ε-caprolactone) (PCL).[38,39] Adsorption was conveniently characterized by transmission electron microscopy (TEM) because of ferritin's electron-dense core, and pH-dependent behavior was discussed in terms of both hydrophilic and electrostatic interactions with the polymer surface. Near physiological pH, selective adsorption occurred on PDTD domains, which was attributed to repulsion of negatively charged ferritin by carboxylate groups of hydrolyzed PCL (**Figure 1(a)**). Selective adsorption did not occur under acidic conditions, when polymer surface charges are effectively neutralized.[39] When acidic ferritin residues were alkylated with dodecylamine, the resulting positively charged protein nanoparticles demonstrated strong preferential adsorption on negatively charged PCL phases (**Figure 1(b)**).[38] Direct incorporation of modified ferritin in PDTD/PEO blends was also investigated.[40] Alkylation of acidic amino acid residues with dodecylamine or amine-terminated poly (ethylene oxide) (PEO) imparted solubility in organic solvent to the ferritin nanoparticles. When blended with PDTD/PEO mixtures and cast in films, ferritin behavior depended on the surface functionalization. The ferritin–PEO conjugate was found to localize within PEO domains, while the ferritin–dodecylamine conjugate was localized within PDTD domains.

A number of analytical techniques have been employed for the study of protein adsorption on polymer surfaces and other materials. TEM and atomic force microscopy (AFM) provide direct visualization of protein adsorption with high resolution, while techniques such as X-ray photoelectron spectroscopy (XPS), time-of-flight secondary ion mass spectrometry (TOF-SIMS), and surface plasmon resonance (SPR) can be used to probe the proteins' chemical and biophysical properties.[41] For review of these and other analytical techniques (see **Chapter 3.302, Atomic Force Microscopy** and **Chapter 2.219, Biophysical Analysis of Amyloid Formation**). Recently, protein adsorption on polymer blend surfaces has also been used as a model biological system in the development of soft X-ray spectromicroscopy techniques.[42,43] These techniques have the potential to quantitatively probe chemical complexity with a resolution of 50 nm or better, on the basis of the distinct X-ray absorption fine structure

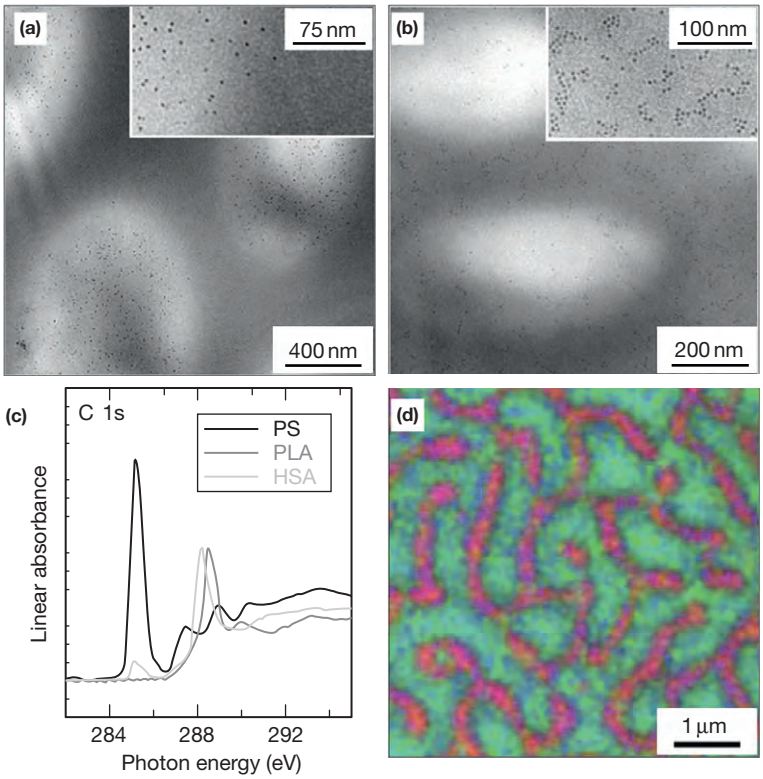

Figure 1 (a) and (b) Selective electrostatic adsorption of ferritin nanoparticles on homopolymer blend surfaces consisting of poly(desaminotyrosyl-tyrosine dodecyl ester carbonate) (PDTD) and poly(ε-caprolactone) (PCL). (a) At pH 5.8, unmodified wild-type ferritin adsorbs to PDTD domains (dark regions in TEM micrographs), which is attributed to repulsion of negatively charged proteins by negatively charged PCL domains. (b) Positively charged alkylated ferritin particles adsorb to negatively charged PCL domains (light regions in TEM micrographs) at pH 5.8. of individual protein or polymer constituents (Figure 1(c)). Scanning transmission X-ray microscopy (STXM) measures wavelength-dependent optical density through a column of bulk material, and the technique can be applied to samples under vacuum, in air, or in a liquid cell. X-ray photoelectron emission microscopy (XPEEM) records the wavelength-dependent distribution of electrons ejected from a surface after X-ray absorption. XPEEM may therefore provide superior sensitivity for investigation of surface phenomena, as sampling depths are in the order of 5–10 nm, although the technique requires high-vacuum environments that may not be compatible with certain biological samples.

Protein adsorption behavior as characterized by XPEEM and STXM is consistent with phenomena as discussed above, although this behavior was observed to vary depending on the hydration state and sample treatment. Human serum albumin (HSA) was found to preferentially adsorb to the polystyrene (PS) domains in films consisting of a blend of PS and poly (methyl methacrylate) (PMMA), as characterized by XPEEM (Figure 1(d)). This was attributed to the hydrophobicity differential, as PS is more hydrophobic than PMMA. Highest adsorption levels, however, were observed at PS/PMMA interfaces.[43] Differential localization with varying pH was attributed to known conformational changes of HSA that modulate protein surface hydrophobicity.[42] When the same system was investigated under hydrated conditions using STXM, adsorption of HSA at PS/PMMA interfaces was observed along with adsorption of loosely bound HSA on PMMA.[44] This loosely bound protein could be removed with washing, and the resulting samples more closely resembled those characterized by XPEEM and other *ex situ* techniques. Other systems investigated by these X-ray techniques include adsorption of fibrinogen[45,46] and HSA[45,47] on polyurethane (PU) composite surfaces[45] and PS/polylactide (PLA) blends.[47]

3.320.2.2. Protein Adsorption on BCP Thin Film Templates

When immiscible polymers are tethered covalently as BCPs, self-assembled morphologies are reduced to length scales in the order of tens of nanometers.[16] As discussed above, BCP systems in this size regime may provide access to experimental platforms for basic research and new biotechnology. Hahm and coworkers demonstrated patterning of proteins via adsorption on self-assembled diblock-copolymer thin films.[48–51]

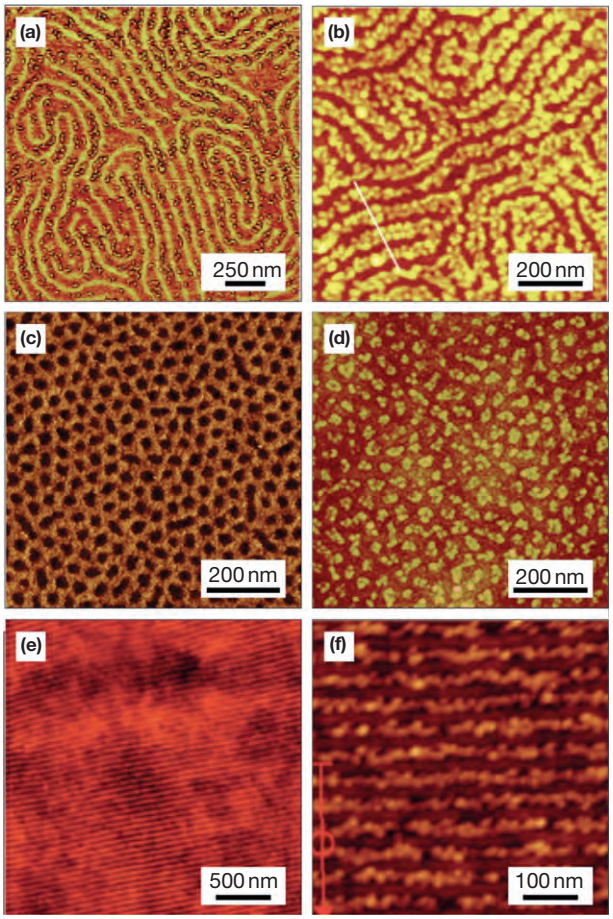

Figure 2 Patterning of proteins on thin film templates via preferential protein binding to hydrophobic microdomains. (a) and (b) IgG adsorbed on PS-*b*-PMMA thin films exhibiting lamellar morphology. IgG selectively adsorbs on PS microdomains, and density of adsorbed protein depends on solution concentration. (a, b) Reprinted from Kumar, N.; Hahm, J. Commun*. **2010**, *46*, 1911–1913, with permission from The Royal Society of Chemistry.

Thermally annealed PS-*b*-PMMA thin films were prepared on silicon substrates, leading to phase-separated lamellar nanostructured films. Preferential adsorption of immunoglobulins (IgGs) and protein G, an IgG binder, on PS domains was demonstrated, as observed by AFM (Figure 2(a) and 2(b)).[48] Patterns were found to conform to the underlying film morphology, and hexagonal protein arrays were generated using copolymers with a minor PS fraction. Subsequent investigation demonstrated preferential adsorption at PS/PMMA interfaces, where films composed of diblock copolymers and homopolymer blends led to higher levels of protein adsorption than homogenous films composed of homopolymers alone.[50] Furthermore, a distance dependence was observed for homopolymer blend films where the number of adsorbed proteins decreased as distance from the interface increased. This suggests that film topography plays an important role in segregation behavior, and that BCP films – which are characterized by well-defined polymer interfaces at regular intervals – are uniquely suited to creation of high-density protein arrays.

Enzymatic activity of immobilized enzymes horseradish peroxidase (HRP) and mushroom tyrosinase was demonstrated, as judged by oxidation of small-molecule substrates such as tetramethylbenzidine and pyrocatechol in colorometric assays.[49] HRP, in particular, retained approximately 85% activity as compared to free enzyme in solution, indicating that the structure of the adsorbed proteins was maintained during patterning on BCP films.[51] Notably, maintenance of enzymatic activity over several months was demonstrated. Preservation of protein structure was also supported by confocal fluorescence microscopy experiments, which demonstrated the retention of structure-dependent fluorescence of enhanced green fluorescent protein (eGFP) and binding of fluorescently labeled IgGs by adsorbed protein G.

Patterning strategies have been developed for various iterations of other amphiphilic BCP systems. Preferential segregation of HRP and IgG was observed on PS phases of films consisting of polystyrene-*b*-poly(4-vinylpyridine) (PS-*b*-P4VP) micelles. Micelle morphology was controlled by exposure to selective solvent vapors, which in turn dictated the protein pattern morphology.[52] Derivatization of poly(acrylic acid) (PAA) blocks in PS-*b*-PAA thin films with amine-functionalized silanes resulted in positively charged domains that were used for patterning of negatively charged actin filaments via electrostatic interactions.[53]

Lau and coworkers employed PS-*b*-PMMA thin films as an antibody-array platform for immunoassays and DNA detection.[54–56] Gold-coated substrates were modified with a neutral brush layer consisting of poly(styrene-*r*-benzocyclobutene-*r*-methyl methacrylate)[57] prior to casting and thermal annealing of PS-*b*-PMMA films. The resulting templates exhibited hexagonally packed PS cylinders surrounded by a PMMA matrix (Figure 2(c) and 2(d)). After preferential adsorption of IgGs to PS domains in a manner similar to that described above, nonspecific binding of proteins during downstream operations was prevented by blocking with bovine serum albumin (BSA). Capture of rabbit-α-mouse antigens (RxM-IgGs) from solution by the patterned goat-α-rabbit antibodies (GxR-IgGs) was probed using SPR as shown in Figure 3.[55] Greater sensitivity was observed when the patterned GxR-IgGs were tested as antigens for mouse-α-goat antibodies (MxG-IgGs) in solution. This was interpreted as a result of randomly oriented immobilized IgGs leading to partial restriction of antigen binding. Fluorescence-based DNA detection was also demonstrated in a sandwich assay utilizing immobilized streptavidin and biotinylated peptide–nucleic acid probes. Interestingly, the protein patterns could be stabilized for use over extended periods by covalently cross-linking the adsorbed proteins.

The SPR techniques used in these experiments allowed for a quantitative study of binding preference on different BCP phases. As observed in other studies, IgGs exhibit preferential adsorption at PS/PMMA interfaces.[54] The amount

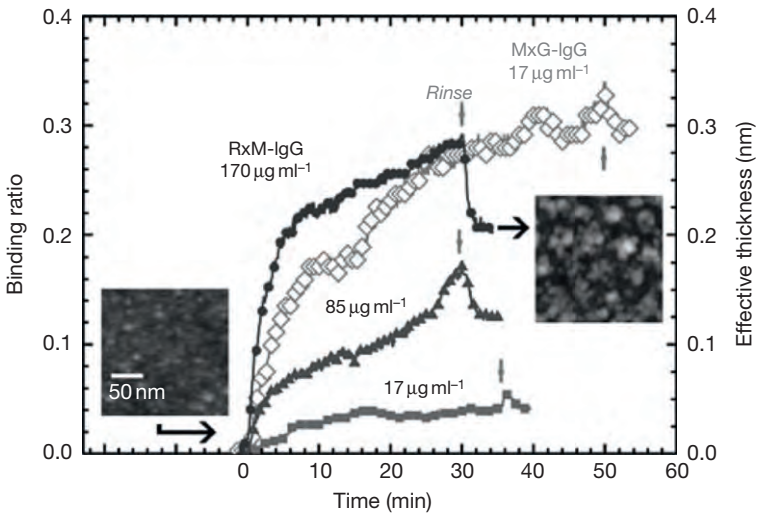

Figure 3 SPR analysis of antigen binding to GxR-IgG patterned on PS-*b*-PMMA templates. Binding of MxG-IgG to the immobilized antibodies is more efficient than capture of RxM-IgG by the immobilized antibodies. Film thickness (indicated on right axis) increases because of antigen binding, and bound antigens can be removed when rinsed with buffer (indicated by gray arrows above SPR traces). Antibody patterns are filled with BSA to block nonspecific antigen binding, resulting in smooth surfaces (as indicated by AFM topography image in left inset). Binding of antigens to immobilized antibodies results in reappearance of the nanoarray pattern (right inset). Reprinted from Lau, K. H. A.; Bang, J.; Kim, D. H.; Knoll, W. *Adv. Funct. Mater.* **2008**, *18*, 3148–3157, with permission from Wiley.

of 'excess' adsorbed protein on a given substrate (i.e., the amount exceeding levels expected based solely on the surface fractions of PS and PMMA) was found to depend on the length density of domain interfaces. Indeed, no direct relationship between excess adsorption and domain morphology or the surface fraction of either phase was discerned. Adsorption at domain interfaces was estimated to be approximately three times higher than on PS domains and approximately seven times higher than on PMMA domains.

Long-range ordering of BCP thin films can be achieved by a variety of means as described above. Recently, a controlled film thickness gradient was used to create PS-*b*-PMMA templates exhibiting highly aligned lamellae over large areas (**Figure 2(e)** and **2(f)**).[58] These thin film templates were then used for adsorption of serum proteins as well as cell adhesion proteins such as fibronectin (FN) and collagen. Again, protein adsorption was largely confined to hydrophobic PS domains as observed by AFM. Flexible fibrinogen fibers were observed to align along the length of the PS lamellae, whereas more rigid collagen fibers spanned both PS and PMMA lamellae in a grid-type morphology. The authors concluded that protein physical characteristics such as rigidity may play a significant role in determining the morphologies of resulting protein patterns.

Protein nanopatterning has not been limited to amphiphilic copolymers such as PS-*b*-PMMA. Protein nanopatterning using a diblock copolymer with two hydrophobic blocks, polystyrene-*block*-polyisoprene (PS-*b*-PI), was recently demonstrated.[59] Protein distributions were characterized by AFM and SIMS. BSA segregation on 'hard' (glassy) PS domains was observed, while 'soft' (rubbery) PI domains remained free of protein. Interestingly, pattern fidelity on this hydrophobic template was observed after BSA adsorption at higher concentrations ($\sim$1 mg ml^{-1}) and longer incubation times (>1 h) than for amphiphilic templates such as PS-*b*-PMMA, which could broaden the applicability of the technique for various patterning uses. Control of protein adsorption on nanostructured surfaces using fully hydrophilic BCPs requires polymer attachment to the underlying substrate in order to prevent film degradation in aqueous environments. Recently, surface-initiated atom transfer radical polymerization was employed for covalent modification of silicon substrates with poly(oligo (ethylene glycol) methacrylate)-*block*-poly(2-methacryloyloxy) ethyl trimethylammonium chloride (POEGMA-*b*-PMETAC).[60] Resulting surfaces contained a protein-resistant POEGMA matrix and protein-binding PMETAC domains. Phase separation of the two hydrophilic domains was induced by addition of sodium chloride, shielding positive charges in the polyelectrolyte PMETAC block, and various copolymer morphologies were achieved by adjusting the volume fraction of PMETAC in the copolymer. Quantification of ^{125}I-labeled protein adsorption was carried out by scintillation counting, and selective fibrinogen binding on PMETAC domains was observed by AFM. This preferential adsorption was attributed to electrostatic interactions between the protein and polyelectrolyte. Patterning employing fully hydrophilic polymers may prove useful for proteins that are particularly sensitive to denaturation caused by nonspecific hydrophobic surface interactions.

3.320.3. Protein and Cell Binding via Affinity Interactions Templated by Polymer Surfaces

3.320.3.1. Protein Immobilization and Patterning on Polymer Affinity Templates

Thus far, the systems outlined here rely primarily on nonspecific hydrophobic or electrostatic adsorption of proteins to polymer surfaces. This approach is operationally simple and widely employed to fabricate high-density biomolecular arrays, although significant drawbacks include restricted functionality due to randomly oriented proteins as well as reduced

activity due to varying degrees of denaturation. On the other hand, immobilization of target proteins via specific interactions with biological ligands can ensure proper protein orientation and limit denaturation. Furthermore, complex targets such as whole cells could be recruited to surfaces for the study of specific biological processes. Several studies have capitalized on such affinity interactions for specific protein binding on polymer surfaces.

Cresce and coworkers demonstrated chelation of nickel ions by poly(norbornenedicarboxylic acid) in a norbornene–norbornendicarboxylic acid BCP.[61] The nickel-BCP chelate was cast in thin films and used in the template binding of recombinant histidine-tagged GFP, which was observed by fluorescence spectroscopy. Selective GFP localization on the Ni-containing block was inferred from control experiments that indicated a lack of protein binding on thin films consisting of BCP in the absence of added nickel. Recently, histidine-tagged GFP was immobilized on PB-*b*-PEO surfaces bearing Ni^{2+}–nitrilotriacetic acid (NTA) groups at PEO chain ends.[62] In this case, a PB-*b*-PEO monolayer was formed at the air–water interface and transferred to a graphite substrate such that the surface layer was composed entirely of the PEO block. GFP binding to PB-*b*-PEO micelles in aqueous solution was also characterized. In another example, flexible patterned polymer substrates were fabricated by compressing alternating layers of polyethylene and an ethylene-*co*-(acrylic acid) (EAA) copolymer.[63] The resulting material was sectioned with a microtome to expose patterns containing 7-micron stripes, and the EAA layers were subsequently derivatized with amine-functionalized biotin via amide bond formation. Binding of dye-labeled streptavidin to the biotinylated EAA layers was observed by fluorescence microscopy, while the ethylene layers remained free of protein. Because streptavidin contains multiple biotin-binding sites, the streptavidin patterns could be used to recruit other biotinylated molecules of interest to the patterned surfaces.

3.320.3.2. BCP Nanolithography and Its Application in Cell Biology

Spatz and coworkers have developed an elegant and versatile technique, termed block-copolymer micelle (BCM) nanolithography, and used it to create nanopatterned surfaces with biological ligands placed at defined intervals (**Figure 4**).[64] In this technique, gold salts are complexed with the poly(vinylpyridine) block of PS-*b*-P2VP micelles. Films are formed by immersing a substrate in a micelle solution and withdrawing it at a controlled rate. Following exposure to gas plasma that removes the polymer and reduces the gold salts, hexagonal arrays of spherical gold nanoparticles are observed on the substrate surface. Biological ligands are introduced on the nanoparticle surfaces via formation of stable gold-thiol bonds, and bare regions of the substrate are passivated with coatings such as PEO. Much work has been done using cyclic RGD-containing peptides as ligands, which are bound by integrins on cell surfaces.[65–67] Substrates fabricated via BCP micelle nanolithography resulted in patterns of RGD with precise spacings of 30–90 nm, depending on the volume ratio of the PS-*b*-P2VP employed. The RGD patches in the arrays were ~8 nm in diameter, providing a binding site for one 8–12 nm integrin. MC3T3 osteoblasts were shown to adhere to patterns with RDG spacings ≤58 (**Figure 5(a)** and **5(b)**), but this behavior was drastically reduced with spacings ≥73 nm (**Figure 5(b)**). Furthermore, smaller RGD spacings led to greater spreading of cells, and recruitment of several key adhesion molecules (including integrin, vinculin, focal adhesion kinase, and actin) to focal adhesion points was visualized by immunohistochemical staining (**Figure 5(c)** and **5(d)**). Refer to **Chapter 3.316, Immunohistochemistry**; **Chapter 3.317, Fluorescence Imaging of CellBiomaterial Interactions**; and **Chapter 3.318, Molecular Imaging** for discussion of analytical techniques used in these and other cell-based experiments.

To determine whether this was due to an increase in ligand density rather than a decrease in ligand spacing, patterns were fabricated with small nanoparticle spacings and low nanoparticle densities through a combination of BCM nanolithography and EBL. Significantly lower numbers of RGD ligands promoted cell adhesion and spreading when ligand spacing was sufficiently low (58 nm), demonstrating that this effect arises primarily from ligand arrangement rather than ligand quantity. Such behavior was observed for a number of cell lines, including B16 melanocytes, REF52 fibroblasts, and 3T3 fibroblasts, suggesting a universal requirement that must be met for optimal integrin-mediated adhesion.[65,66]

The flexibility of the BCM nanolithography technique allows for patterning of other ligands for the study of other cell types. Neuron activity on nanopatterned surfaces was investigated by

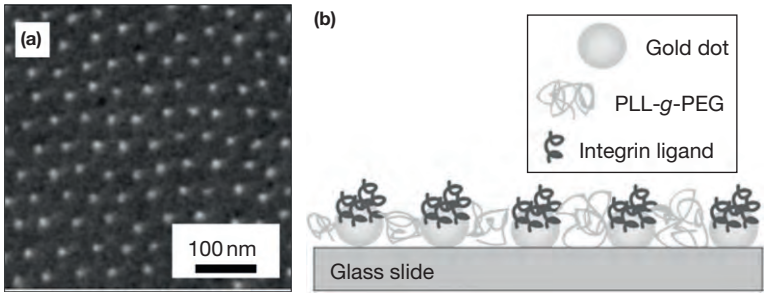

Figure 4 (a) SEM micrograph of gold nanodot array on a glass substrate, fabricated by BCP nanolithography. Dot spacing (55 ± 12 nm shown here) is dictated by the molecular weight and weight fraction of the PS-*b*-P2VP employed in the nanolithography process. (b) Schematic representation of a cell adhesion template based on the nanodot array. Glass surfaces are passivated with a cell-repellant PLL-*g*-PEG copolymer, and thiol-bearing integrin ligands (such as cyclic RGD-containing peptides) are covalently bound to the gold nanodots. patterning the extracellular domain of DM-GRASP, an integral membrane protein and cell adhesion molecule from the immunoglobulin superfamily.[68] The patterns were fabricated by binding a recombinant, histidine-tagged DM-GRASP construct to gold nanoparticles modified with Ni^{2+}–NTA complexes. Resulting patterns were found to support adhesion of neuroblastoma cells via homophilic trans-interactions with DM-GRASP expressed on cell surfaces. Greater adhesion was observed for DM-GRASP patterns with smaller spacings, that is, 58 nm versus 78 nm, although neither pattern supported neurite growth.

Primary neuron behavior was investigated using dorsal root ganglion (DRG) cell culture containing neurons as well as mesenchymal stem cells. DM-GRASP patterns with small and large spacings were found to support adhesion, and 58-nm spacings were found to support neurite growth from neuron clusters. Neurites growing from single neurons were not observed on the nanopatterned surfaces, and furthermore neuron clusters were always in contact with mesenchymal cells. These results indicate that the patterned substrates are able to support but not initiate neurite formation. The authors note that the smaller DM-GRASP spacing, 58 nm, is commensurate with the dimensions of other molecules that are recruited to the focal adhesion sites and mediate adhesion and signaling. Other adhesion molecules including agrin[69] and cadherin[70] have also been arrayed via histidine/Ni^{2+}–NTA affinity patterning and studied with respect to neuronal cell culture. Tumor necrosis factor (TNF) was patterned to examine spacing effects on binding by TNF receptors on cultured cells and downstream apoptotic processes.[12]

BCM nanolithography can be engineered to fabricate patterns with varying degrees of complexity and to accommodate a range of substrate materials. As discussed above, the technique can be combined with photolithography or EBL to create hierarchically structured materials with micron-scale and nanoscale features.[65,71] Nanoparticle spacing can be varied along a controlled gradient by altering the draw velocity of substrates from BCP micelle solutions, and this spacing gradient has been shown to induce cell polarization and migration.[11,72] Initially fabricated on substrates such as glass, the nanoparticle patterns can be transferred to soft materials by coating nanoparticles with linker ligands that either physically attach or chemically bond to overlaid polymeric substrates. These soft substrates lend themselves to curved and rounded three-dimensional architectures that mimic tissue surfaces such as blood vessels and are difficult to realize on rigid materials.[73]

3.320.3.3. Other BCP Platforms for Cell Culture Studies

Cooper-White and colleagues have also developed a system for patterning of cell adhesion molecules employing covalent modification of BCP thin films. Initial investigation by AFM, quartz crystal microbalance (QCM), and fluorescence microscopy established that PEO microdomains in PS-*b*-PEO resist protein binding and prevent fibroblast adhesion and culture.[74] PS-*b*-PEO was then covalently modified at PEO chain ends with maleimide functionality. Subsequently, thin films were prepared and cysteine-bearing RGD peptides were covalently bound to the PEO microdomains via reaction with the maleimide groups. Histidine-tagged FN fragments were also bound to a Zn^{2+}-peptide chelate that was covalently immobilized on the PS-*b*-PEO template.

NIH-3T3 fibroblast adhesion on the templates was studied by fluorescence microscopy and found to occur only in the presence of both polymer maleimide functionality and immobilized RGD or FN peptides.[75] This result is consistent with cell adhesion due to binding of RGD and FN by integrins on fibroblast surfaces. This effect occurred in serum-free media, while adsorption of adhesion proteins to BCP surfaces from culture in serum led to nonspecific cell binding. This activity could be blocked with application of BSA or Pluronics to BCP films before cell experiments. PEO domain spacing was controlled via addition of PS homopolymer in the blends. As observed in experiments with BCM nanolithography-based templates, cell spreading was found to increase as spacing between PEO domains (and associated cell adhesion molecules) decreased. This property of the system might therefore be exploited to direct differentiation of mesenchymal stem cells, a process that is sensitive to mechanical stimuli such as cell spreading. This work was extended to three-dimensional cell culture scaffolds with hierarchical structure.[76] Temperature-induced macrophase separation of homopolymer PS and PS-*b*-PEO in solution followed by solvent removal resulted in porous bulk materials that exhibited microphase-separated nanostructure associated with the BCP (**Figure 6**). Following attachment of RGD adhesion peptides as described above, effects on adhesion and cell spreading were characterized as for the two-dimensional films. Use of PS-*b*-PAA in this system was also explored.

Other diblock-copolymer systems have been used to modulate cell adhesion and proliferation on tissue culture substrates. Khor examined the response of cultured fibroblasts and mesenchymal progenitor cells to BCP thin film morphology.[77] Ultrathin films composed of PS-*b*-P4VP and PS-*b*-P2VP were prepared on mica substrates resulting in patterns exhibiting dots and lamellae, respectively, following thermal annealing. The films were stable to sterilization and cell culture procedures, and cell growth was monitored using phase contrast and confocal laser microscopy. BCP nanopatterns, particularly the lamellar pattern, elicited earlier cell adhesion and greater proliferation than bare mica substrates. Microtubule and actin filament distribution varied as the substrate pattern changed, as did the morphology of the lamellipodia that propel the adhered cells across the substrates. Extracellular matrix proteins deposited by the cells on the substrates appeared to conform to the underlying nanostructure. Other recent studies have examined BCP thin films containing poly(2-methacryloyloxyethyl phosphorylcholine) (PMPC) blocks that resist protein adsorption and hydrophobic poly(dimethylsiloxane) (PDMS) that binds proteins.[78] Copolymers that contained higher weight fractions of PDMS were shown to adsorb higher levels of antibodies and FN, and these materials in turn led to more fibroblast adhesion. The materials supported adhesion only in the presence of serum, indicating that protein binding is necessary prior to cell adhesion.

3.320.4. Coassembly of BCPS with Peptides and Proteins in Thin Films

The examples discussed above primarily employ multistep processes in which proteins are adsorbed to or bound by preformed polymer templates. Relatively few studies have explored the simultaneous coassembly of polymers with peptides and proteins. Coassembly strategies are attractive because they may allow for integral incorporation of hierarchical structural complexity and functionality within the resulting materials. Ideal composite materials would also exhibit the superior processability of the polymeric matrices, enabling the incorporation of sensitive proteins in surface coatings, particles, and fibers. Practically speaking, coassembly requires cosolubilization of the BCPs and proteins. This constitutes a primary obstacle due to the chemical incompatibility of the two classes of materials. Peptides and proteins naturally exist in aqueous solution at or near physiological pH and usually have poor solubility in organic solvents.[79] BCPs, however, are frequently processed using volatile hydrocarbon solvents that can denature peptides and proteins. Many protein functionalities require noncovalent binding of small-molecule cofactors, so conditions must be also be chosen so as to preserve these cofactor complexes or to promote their reconstitution.[80,81] Meanwhile, conditions must allow for ready formation of BCP nanostructures in thin films. Solvents should be sufficiently volatile to allow for film casting, as well as for subsequent annealing if ordered structures are desired.

Russell and colleagues demonstrated patterning of ferritin-based nanoparticles in thin films via coassembly with poly(2-vinylpyridine)-*block*-poly(ethylene oxide) (P2VP-*b*-PEO).[82] Notably, covalent binding of PEO to ferritin, a protein-nanocage with an iron core, imparted solubility in organic solvents to the protein and allowed for direct incorporation in P2VP-*b*-PEO blends. Several developments in polymer–protein conjugation may be used in this manner to enhance protein stability and compatibility in polymeric systems.[83–85] The appended polymers may furthermore direct assembly of proteins within desired BCP microdomains, in the manner of homopolymer addition to BCP thin films.[19]

Recently, we reported the coassembly of PS-*b*-PEO with model heme proteins and enzymes.[86] A coiled-coil α-helix bundle was studied as a model protein because it is one of the simplest tertiary peptide motifs that retains a specific function, namely, small-molecule cofactor binding. The design of the peptide bundle employed in this case, termed H10H24, was based on the diheme cytochrome b subunit of cytochrome bc1.[87,88] In comparison to their natural counterparts, designed

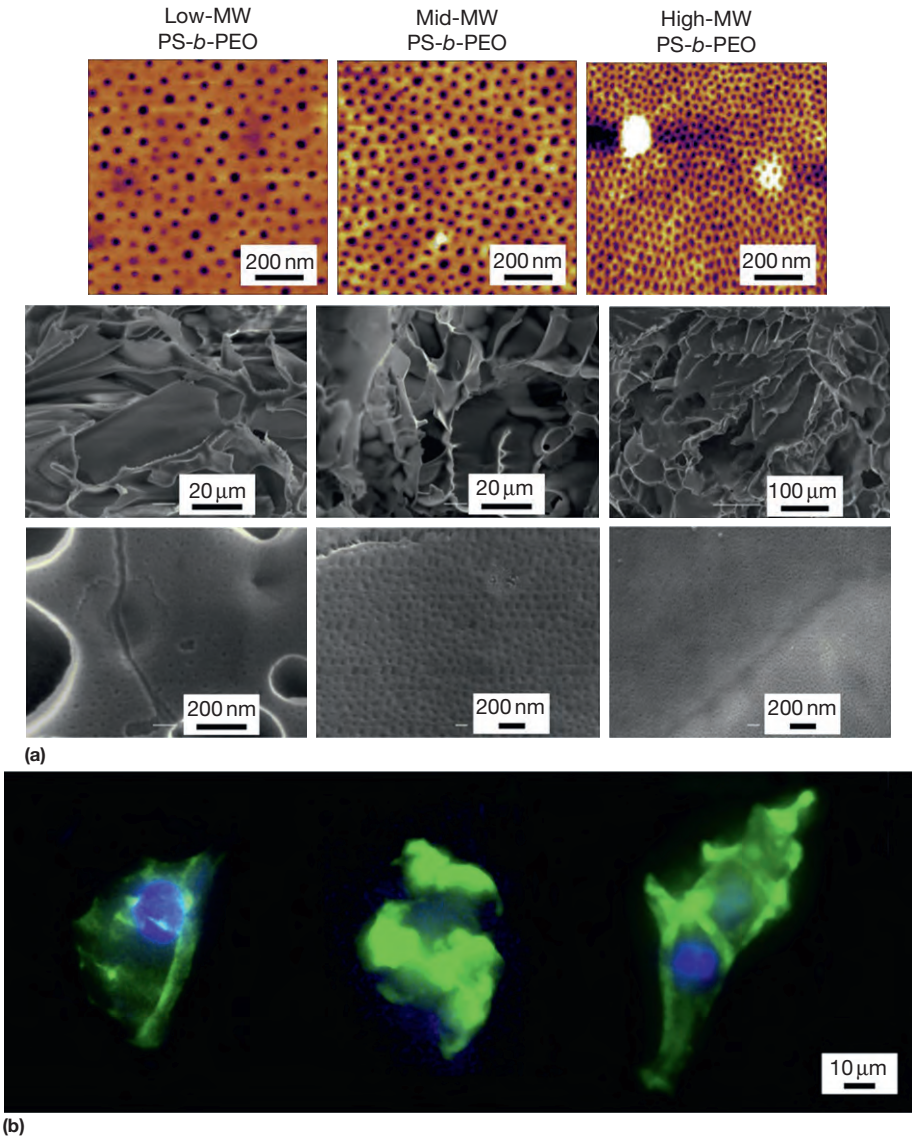

Figure 6 Fabrication of hierarchically ordered BCP scaffolds for 3D tissue culture. (a) AFM images (top row) depict dependence of PEO domain spacing on the molecular weight of the PS-*b*-PEO employed, with smaller spacings occurring for lower molecular weights. SEM images (middle and bottom row) depict polymer scaffold structure resulting from temperature-induced phase separation of PS-*b*-PEO and homopolymer PS, containing micron-scale porosity as well as nanoscale BCP morphologies. (b) Fluorescence microscopy images of NIH-3T3 fibroblasts cultured inside BCP scaffolds with stained actin (green) and nuclei (blue). Reprinted from George, P. A.; Quinn, K.; Cooper-White, J. J. *Biomaterials* **2010**, *31*, 641–647, with permission from Elsevier.

peptides have simple and robust secondary and tertiary structures and present an ideal starting point to explore the principles governing the coassembly of natural proteins with synthetic BCPs. Initially, the inherent chemical incompatibility between protein and polymer components prevented solution processing of the composite materials into thin films. As demonstrated previously in the case of ferritin, however, conjugation of PEO to helix bundles and larger heme proteins improved solubility in organic solution and compatibility with PS-*b*-PEO. In addition, polar cosolvents were used to solubilize the protein–PEO conjugates with the hydrophobic PS-*b*-PEO. Ordering of PS-*b*-PEO was induced by solvent annealing with a benzene–water vapor mixture.

Helical secondary structure of H10H24-PEO conjugate (H10H24-P2K) was maintained during thin film assembly and processing, as assessed by CD (Figure 7(b)). Binding of heme cofactors via bis-histidyl ligation as observed by UV-visible absorption spectroscopy was consistent with maintenance of the helix bundle tertiary structure (Figure 7(c)). The system was extended to include more complex, naturally occurring heme proteins. A myoglobin–PEO conjugate was compatible with thin film processing, and retention of enzymatic activity was consistent with preservation of protein structure within the composite materials. Conjugation of synthetic polymers to protein surfaces is expected to direct localization of protein–polymer conjugates within specific BCP microdomains,

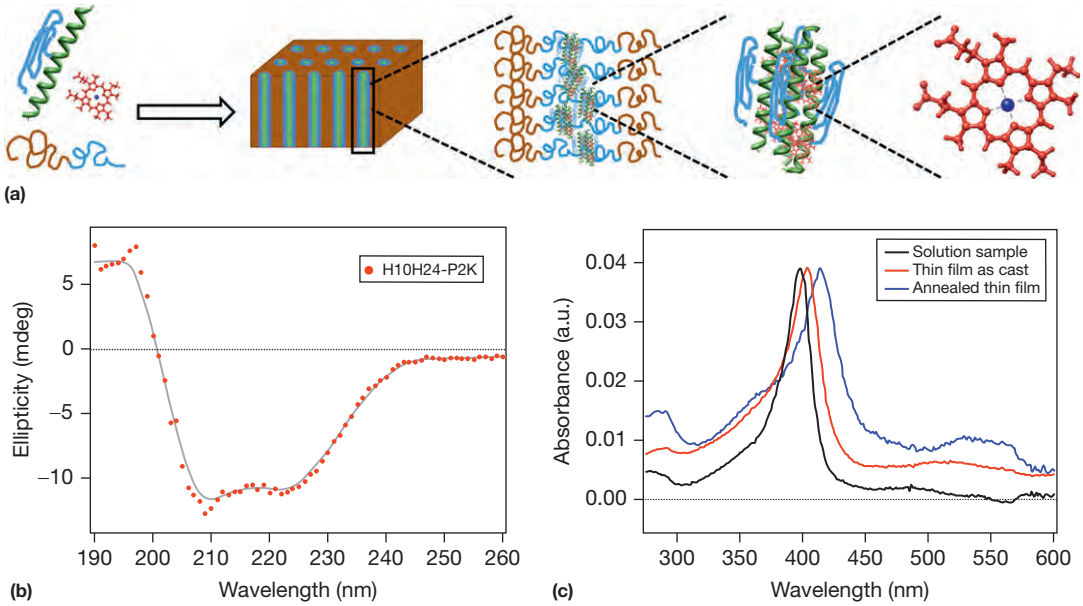

Figure 7 Coassembly of BCPs and heme proteins. (a) Schematic depiction of PS-*b*-PEO coassembly with a helix bundle peptide-PEO conjugate (H10H24-P2K) and heme cofactors. (b) Helical secondary structure of H10H24-P2K is retained, as indicated by circular dichroism. (c) Red-shifting and resolution of heme spectral features upon thin film casting and annealing, as observed by UV-vis absorption spectroscopy, are consistent with heme binding by H10H24-P2K and assembly of coiled-coil helix bundle tertiary structures. as depicted schematically in Figure 7(a). Soft X-ray scattering techniques are currently being developed to unambiguously determine the location of the protein conjugates in the thin films.

3.320.5. BCP Surfaces for Biocompatibility and Antifouling Applications

3.320.5.1. Biocompatibility of Poly(2-hydroxyethyl methacrylate)-Based Copolymers

In contrast to the protein patterning strategies described above, much effort has been directed toward the prevention of protein and cell binding on polymer surfaces. Unwanted adsorption (termed biofouling) can prevent proper function of biomaterials and medical devices, causing problems such as thrombus formation in patients. The earliest systematic investigations of protein adsorption and cell adhesion on BCP surfaces in the context of biofouling prevention employed model polymer surfaces composed of triblock A–B–A copolymers containing poly(2-hydroxyethyl methyacrylate) (PHEMA) and PS.[89,90] TEM micrographs indicated that different serum proteins adsorb preferentially on different polymer phases, with albumins preferring hydrophilic PHEMA domains and γ-globulins preferring hydrophobic PS domains.[89] This is a particularly significant result because albumin is known to passivate surfaces against platelet adhesion, while the globulins and FN promote adhesion and thrombus formation. Surface antifouling properties might therefore be tuned by adjusting the copolymer composition and resulting protein distribution. When PHEMA polymer surfaces were exposed to whole blood, reduced platelet adhesion and deformation were observed on the BCP surfaces as compared to homopolymer or random copolymer surfaces (Figure 8(b)) similarly exposed.[90] Similar results were found for BCPs containing PEO, poly(propylene oxide) (PPO), and PDMS blocks in place of PS.[91,92] When used as a coating for various polyurethane (PU)-based arterial shunts *in vivo*, the HEMA copolymers were found to prevent thrombosis for significantly longer periods than uncoated or homopolymer-coated shunt tubing.[93]

Platelet adhesion to copolymer-coated surfaces was not abolished, suggesting that the BCP antithrombogenicity may be due to the prevention of platelet activation/deformation rather than the elimination of all surface binding. Indeed, decreased platelet activation was reflected in lower intracellular calcium levels detected with Ca^{2+}-specific probes as well as decreased release of serotonin, a known hemostatic agent, assessed by radiochemical techniques.[93,94] Platelet movement on different polymer surfaces has been characterized using computer-assisted analysis of microscopy images. Platelet movement on PHEMA copolymer-coated surfaces was qualitatively different from that on PEG-grafted surfaces. Rolling, spinning, and vibrating was observed to occur in an ATP-dependent fashion, and addition of sodium azide reduced cell metabolism and platelet mobility. Meanwhile, passive 'nonbiological' Brownian motion was observed on PEG-grafted surfaces. These results highlight the fact that contact with PHEMA copolymer surfaces alters biochemical processes that modulate cell adhesion, while the nonfouling character of PEG surfaces arises primarily from physical phenomena such as water structuring and excluded volume effects.[95,96] The authors of this study note that the dimensions of the phase-separated copolymer morphologies (on the order of 50 nm) are commensurate with biological structures, such as lipid rafts and integrin clusters in cell membranes, that play important roles in surface interactions and downstream processes.

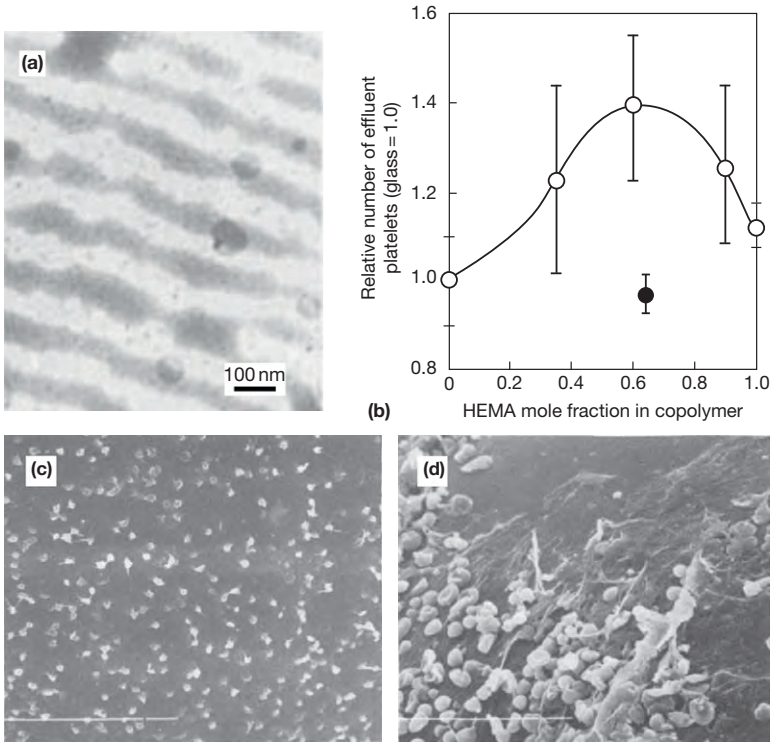

Figure 8 (a) TEM image of PS-PHEMA ABA triblock copolymer film containing a PHEMA weight fraction of 0.608, stained with osmium tetroxide. (b) Quantification of platelet binding to copolymer surfaces, assessed by platelet counting in canine blood effluents from columns packed with BCP-coated glass microspheres. Open circles correspond to block copolymers and the closed circle corresponds to a random copolymer. Platelet adhesion is lowest for copolymers with intermediate volume fraction of either block. (c) and (d) SEM images (2000× magnification) of platelets adhered to glass microspheres coated with triblock copolymer with a PHEMA weight fraction of 0.608 (c) and a random copolymer with a PHEMA weight fraction of 0.640 (d). Reprinted from Okano, T.; Nishiyama, S.; Shinohara, I.; *et al. J. Biomed. Mater. Res.* **1981**, *15*, 393–402, with permission from Wiley.

3.320.5.2. Structural Implications for PU Biocompatibility

PUs are the copolymers that are perhaps most relevant in the context of biocompatibility or antithrombogenicity, as they are widely employed in medical devices including catheters, cardiac devices, blood tubing, and wound dressings. For review of this important family, refer to **Chapter 1.125, Polyurethanes and Silicone Polyurethane Copolymers**. PUs possess several advantages including good mechanical properties, fatigue resistance, and low biofouling, and are marketed under several brand names with various compositions. So-called 'segmented' PUs are in fact multiblock copolymers consisting of hard segments (PU blocks derived from diisocyanates such as methylene bis(4-phenylisocyanate) and chain extenders such as butane diol or ethylene diamine) and soft segments (consisting of polyesters, polyethers, polycarbonates, or polyolefins). Various aspects of the biomedical applications of PUs have been reviewed elsewhere.[97,98]

Segmented PUs have exhibited better blood compatibility than their component homopolymers, as assessed by platelet adhesion and deformation, and compatibility was associated with the degree of surface microphase separation.[99] Blood compatibility is influenced by the weight fraction and chemistry of the soft segments,[100,101] as well as the diol or diamine chain extender contained in the hard segments.[102] A range of modifications has been made to PU surfaces to tune surface charge or hydrophobicity, improving blood compatibility to varying degrees.[103–106] However, few studies have directly examined protein adsorption on the length scale of the surface microdomains. Reorganization of PU microphases is known to occur upon hydration in biological samples, and polar hard segments typically orient toward the surface. Nevertheless, direct observation of PU surfaces by TEM[107] and AFM[108] has demonstrated that microphase-separated nanostructures remain present on hydrated surfaces. Protein adsorption has been shown to occur preferentially on soft segments consisting of hydrophobic polymers such as poly(tetramethylene oxide) and polybutadiene.[107,108] These and other studies have indicated that biocompatibility of PU and PUU materials is influenced by nanoscale microphase-separated morphology, although opinion on this matter appears to vary widely.[101]

3.320.5.3. BCP Surfaces for Marine Antifouling Applications

Several BCP systems have been studied as marine antifouling agents, preventing adhesion of organisms such as bacteria, algae, barnacles, and diatoms to surfaces in aquatic environments.[109] Most systems have consisted of di- and triblock copolymers of PS and various blocks including P2VP;[110] PMMA;[110] PAA and poly(4-vinylbenzoic acid) esterified with Zonyl FSO-100, a fluoroalkylalcohol-modified PEO;[111,112]

poly(ethylene-*ran*-butylene);[113,114] and amphiphilic blocks derived from epoxidized poly(isoprene), PEO, and fluoroalkanes.[113,114] Poly[poly(ethylene glycol)methyl ether methacrylate]-*block*-poly(2,3,4,5,6-pentafluorostyrene) has also been studied as an antifouling coating in marine environments.[115] Many of these systems have been specifically designed to incorporate extremes of wettability, and biofouling resistance has been attributed to both the low interfacial energy of PEO-like blocks in water and the low adhesiveness of fluorinated blocks.[114] Certain systems have high resistance to protein adsorption in general, which almost certainly contributes to prevention of marine organism adhesion in particular.[116] Another desirable characteristic of antifouling coatings is the ability to release adhered organisms from submerged surfaces, a property associated with pliant materials possessing low elastic moduli.[117] The elasticity of coating materials can be tuned by incorporating base layers of pliant polymers, such as PDMS and styrene-based elastomers, beneath BCP surface layers.[113,114] Surface topography has been indicated as an important variable affecting adhesion and release of fouling agents,[118] and the well-defined morphologies of phase-separated BCPs may make them particularly useful as antifouling coatings.

3.320.6. BCP Micelle Surfaces for Controlled Release Applications

BCMs have been studied extensively for their applications in drug delivery.[119,120] Amphiphilic BCPs assemble in aqueous solution to form core–shell BCMs, and highly versatile systems can result from chemical and physical tailoring of both the core and shell blocks. Small-molecule drugs can be sequestered in the BCM core, for example, while bioactive ligands can be conjugated to the BCM surface to target the therapeutics to specific cells or tissues *in vivo*. The discussion below focuses on solid-state films and surface coatings that incorporate BCMs for drug-delivery applications. Such materials may allow for fabrication of new implants or other biomedical devices with special therapeutic properties.

Special emphasis is placed on the fabrication of films and coatings by layer-by-layer (LbL) deposition of polymers that interact via electrostatics, hydrogen bonding, or covalent reaction.[121,122] The LbL technique has been employed to create a number of surface coatings incorporating small-molecule drugs, peptides and proteins, and nucleic acids for gene delivery.[123] These processes are largely conducted in aqueous solution, so the use of BCMs is particularly advantageous for incorporation of hydrophobic drugs without the functionality required for successful incorporation in LbL films. The multilayer nature of the films imparts a diffusion barrier and is expected to lead to a more controlled release of the incorporated cargoes. The incorporation of stimuli-responsive BCMs in LbL films will allow for drug loading and release that can be controlled through external parameters such as pH, temperature, and ionic strength.[124] Because various properties of micelles – such as size, morphology, and loading/release profiles – can be controlled with precision, novel nanomaterials may result from the combination of two or more BCMs in LbL films. Progress in this direction is expected to lead to the development of a general, versatile, and robust route to bringing multiple functional agents into layered and ordered thin films in a highly controlled manner.

Assembly of BCMs at surfaces has been investigated in organic and aqueous solvents, resulting in micelle assemblies that are physically adsorbed or covalently bonded to underlying substrates.[125–127] Surface assembly of BCMs has given rise to applications including BCP nanolithography as discussed above. Emoto and colleagues reported one of the earliest systems employing BCMs for release of small-molecule cargoes from surface coatings.[128,129] BCMs contained a methacryloyl-terminated PLA core and an acetal-terminated PEO corona. Cross-linking of the PLA core prevented micelle disruption upon contact with surfaces, and acetal hydrolysis resulted in aldehyde groups for BCM immobilization on amine-modified surfaces and multilayer formation with polyallylamine via reductive amination. Release of pyrene cargo from the PLA core was investigated, and loading capacity and release rate were found to depend on the number of layers in the LbL films. Pyrene release occurred on a timescale of minutes to hours.

Nguyen *et al.*[130] reported the LbL assembly of thin films formed by electrostatic interactions between anionic PAA and BCMs containing a cationic corona. The BCM corona consisted of dendritic poly(amidoamine) (PAMAM) and the hydrophobic core consisted of linear PPO. The BCMs were loaded with triclosan, a hydrophobic bactericide, and incorporated in the thin LBL films, which exhibited sustained drug release over a period of at least 2 weeks in a diffusion-controlled manner. The use of the linear-dendritic copolymer for BCM formation is this study led to significantly slower release of hydrophobic molecules than in earlier studies of LbL films containing BCMs consisting of linear–linear amphiphilic BCPs, including PS-*b*-PAA and (PAA-*b*-P4VP).[131,132] In another strategy employed for the delivery of multiple therapeutic agents using BCM films, cationic P2VEP-PCL micelles were loaded with hydrophobic drugs and assembled with polyanionic therapeutics heparin or dextran sulfate (**Figure 9**).[133] Controlled degradation was achieved through the incorporation of a degradable poly(β-amino ester) in the LbL films, and the release profiles were also found to depend on the identity of the anionic layering agents. Films containing both paclitaxel and heparin were found to be most effective against a human smooth muscle cell line.

LbL films based on hydrogen-bonding interactions between constituents are of interest because they are potentially responsive materials that are sensitive to changes in pH of their environment. Hammond and coworkers reported the incorporation of BCMs within polymer thin films by exploiting hydrogen bonding interactions.[134] Thin films were formed through hydrogen bonding between biologically compatible PAA, an H-bond donor, and BCMs consisting of poly(ethylene oxide)-*b*-poly(ε-caprolactone) (PEO-*b*-PCL), an H-bond acceptor. The biodegradable PCL micelle core was loaded with triclosan, and the LbL films were found to release the loaded micelles into the surrounding medium because of PAA deprotonation under physiological conditions and resulting disruption of H-bonding. In order to increase film stability and extend triclosan release over longer periods, PAA sidechains were thermally cross-linked to yield anhydride-stabilized LbL films. Drug-loaded BCM films were found to release significant amounts of triclosan to inhibit the growth of bacteria.

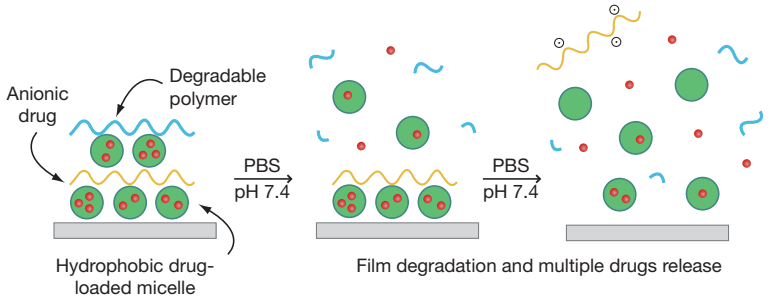

Figure 9 Assembly and evaluation of LbL films for multiagent drug delivery. A degradable polymer helps to stabilize interactions between polyanionic therapeutics and drug-containing micelles with a cationic corona. Upon hydrolysis of the degradable polymer under physiological conditions, polyanionic and hydrophobic therapeutics are released. Films with both small molecules and polyanions are most effective against cultured cell lines. Reprinted from Kim, B. S.; Smith, R. C.; Poon, Z.; Hammond, P. T. *Langmuir* **2009**, *25*, 14086–14092, with permission from American Chemical Society.

Hydrogen-bonded films assembled with a polymeric acid such as PAA as an H-bond donor are only stable in acidic media and spontaneously deconstruct at pH levels above the pK_a of the polyacid. In order to exploit hydrogen-bonding interactions for construction of stable BCM multilayer films at physiological pH, use of tannic acid, a water-soluble polyphenol (pK_a ~8.5), as the H-bond donator has been reported.[135] LbL films were formed through H-bonding between tannic acid H-bond donors and PEO H-bond acceptors in PEO-*b*-PHEMA BCMs. HEMA side chains were conjugated to chemotherapeutic doxorubicin (Dox) via a pH-sensitive carbamate linkage. Controlled release of Dox from the multilayers was found to elicit cytotoxic effects in human cervical cancer HeLa cell line. Furthermore, tannic acid is an attractive molecule for inclusion within surface films because of its known biofunctional properties, such as antitumor, antienzymatic, antibacterial, antimutagenic, and antioxidant activities.

The development of drug delivery systems where the drug release could be modulated by temperature changes is highly desirable. In one of the very few examples in the literature regarding the incorporation of BCMs in thin films for the design of temperature-responsive materials, Zhu and Sukhishvili[136] reported temperature triggered reversible swelling transitions in poly(*N*-vinylpyrrolidone)-*block*-poly(*N*-isopropylacrylamide) (PVPON-*b*-PNIPAM) BCMs assembled in LbL films with PMAA. PVPON-*b*-PNIPAM BCMs reversibly swelled within the films in response to decrease in temperature from 37 to 20 °C, reflecting collapse and dissolution of the micelle PNIPAM cores. The release of pyrene encapsulated in micelles was found to depend on the swelling rate of the film with slower release at higher temperature. Reversible swelling behavior and temperature-dependent release characteristics indicate promise for future controlled delivery applications.

3.320.7. Conclusion

As described here, several polymer platforms have allowed for the directed assembly of proteins on micron and nanometer length scales, as well as for the control of interactions of biomaterial surfaces with cells and tissues. BCPs in particular could potentially allow for rapid assembly of hierarchically ordered composite materials. In order to fully realize this potential, however, these systems will require further investigation and engineering. The BCPs used for solid-state nanostructure generation, in particular, usually consist of hydrophobic blocks that are virtually incompatible with proteins. 'Biofriendly' polymers, such as Pluronics and a few other amphiphilic BCPs, have been used effectively for immobilization of proteins in biosensor devices.[137,138] Much work remains, however, in order to direct the nanoscale assembly of these polymers and control long-range ordering. Certain amphiphilic polymersomes in solution have been employed for successful protein incorporation, and these studies may inform the development of biofriendly polymers for assembly of BCP/protein hybrid materials.[139] Such polymers may also be applied to delivery of proteins and peptides from BCM films and coatings designed for controlled-release applications. Multiplexing patterns and nanostructures to include more than one protein constitutes another significant challenge that has yet to be addressed. Use of multiblock copolymers, BCP blends, and BCP-based supramolecules can enrich the structural and functional complexity of polymer assemblies, which may provide multiple domains for protein attachment or sequestration.[140–142] Combination of BCP assembly with top-down patterning techniques such as EBL or soft lithography may also result in multielement protein arrays.[143,144] These functional hybrid materials, in turn, will facilitate fundamental research and enable new biotechnology.

3.321.1. Introduction

With the introduction of DNA microarrays in the 1990s, different types of arrays have gained increasing popularity in biosciences. The microarrays, which can comprise tens of thousands of spots on a single glass slide at addressable locations, have been extensively used in genomics with DNA- or protein-based probe molecules.[1–3] Moreover, the microarray format provides an ideal platform for the rapid assessment of material–cell interactions as it uses many materials in a manner that is amenable to cell culture. Cell propagation and cell encapsulation require some type of interaction between the cells and the supporting material to enable growth, function, and/or delivery,[4,5] and the cells are usually cultured in the presence of biomaterials. The response of cells to biomaterials is often initiated by cell contact and their adhesion to the biomaterial surface, and cell adhesion is regulated by proteins that are either part of the matrix or have adsorbed on the surface of the biomaterials.[6] Therefore, biomaterials can be used to provide the cells with specific, desirable matrices that mimic the native environment of the cells. Greater knowledge of the characteristics of the cells is also important for biomaterials research, and microarrays may be suitable for screening and testing a large number of combinations of biomaterials and microenvironments for cell adhesion, proliferation, and differentiation.[7]

On the other hand, biomaterials have been used for a variety of biomedical applications or as scaffolds in tissue engineering for many years.[4,8] In biomaterials research, many materials have been selected as being useful based on trial and error, availability, and macroscopic properties. Since the late 1800s, synthetic polymers are being increasingly used for biomedical purposes, and they are desirable as their chemical, biological, and mechanical properties can be easily engineered. Furthermore, biomaterials such as hydrogels provide a three-dimensional (3D) environment within which cells can be encapsulated. In addition, biomaterials provide sites for cell adhesion and initiation of matrix-generated signal transduction pathways, and also regulate stem cell differentiation through matrix elasticity and biomechanical cues.[9]

In this chapter, the potential of microarray methodology in biomaterials research and cell-based studies will be discussed.

3.321.2. Principle of Microarray

3.321.2.1. Microarray Technology Method

Microarray technology is emerging as a powerful platform for biological exploration as it allows entire genomes to be examined on glass chips. The microarray assay has five main steps: biological question, sample preparation, microarray reaction, microarray detection, and data analysis and modeling.[10] Therefore, every microarray experiment should begin with a biological question or query and proceed stepwise.

3.321.2.1.1. Biological question

Microarray analysis not only preserves the practice of query-based biology but has also made biological questioning

more important than ever; a recent proposal places 'the biological question' as the first step in a microarray experiment. Given the enormous power of microarray assays as data-generating devices, a single set of microarray experiments can generate a large amount of data and may require several months to analyze. Microarray analysis is fundamentally different from the traditional assays that employ gels and nylon membranes. In traditional assays, the ratio of analysis time to experimental time is small but in the microarray, this ratio is enormous. It is therefore suggested that a biological or technical question precede the other four basic steps of every microarray experiment.[10]

3.321.2.1.2. Sample preparation and microarray reaction

Microarray assays generate a large data flow, thus placing a premium on high-quality nucleic acid samples (RNA or DNA samples). Laser capture microdissection (LCM) can also be used in concert with microarray analysis to analyze gene expression. The LCM is used to capture specific cells from a section of cells, and the isolated RNA is converted to double-stranded complementary DNA (cDNA) using primers that contain T7 promoter sequences. The double-stranded cDNA is transcribed *in vitro* using the T7 polymerase to yield a large amount (~100-fold amplication per round) of amplified RNA (aRNA). The aRNA is then labeled with fluorescent nucleotides using reverse transcriptase to yield a fluorescent cDNA mixture that is hybridized to a DNA microarray. The location and extent of fluorescence provides a quantitative measure of gene expression in the sample. The use of multicolor schemes allows sensitive analysis of differential expression in multiple biological samples.[10]

3.321.2.1.3. Microarray detection, data analysis and modeling

Detection is the fourth step in a microarray experiment, and this critical step is currently being influenced by an explosion in fluorescence detection technology. DNA microarrays contain sequences of the known, predicted, or unknown genes and are probed with cDNA that has been labeled with different fluorophores (e.g., Cy3, green; Cy5, red). The relative abundance of each RNA message is measured by directly comparing the signals from the competitive hybridizations resulting in a red/green expression ratio for each gene. These microarray experiments generate an enormous amount of data, thus placing bioinformatics at the core of the microarray system. Attention has to be paid to output and data modeling, and once values are quantified from the microarray, the data are displayed in a variety of ways. One common method of depiction is the scatter plot, in which all the data points are plotted as a function of ratio and signal intensity; data points having a ratio >1.0 are plotted above the diagonal and those with ratios <1.0 plotted below the diagonal. The scatter plot provides a means of viewing, at a glance, very large datasets such as those involving expression profiles of thousands of genes (**Figure 1(a)** and **(b)**). Once the data are quantified and genes of interest are identified, a common method of data mining allows genes to be grouped or 'clustered' according to their expression profiles. The biological basis for clustering derives from the fact that gene expression correlates well with biological function. The clustering tools help in the identification of functionally related genes, such as those in common signaling pathways and those that share common biological activity.[11]

3.321.3. Application of Microarray

DNA microarrays also consists of a molecular technology that enable the process of gene interaction analysis. The data are analyzed by means of dedicated bioinformatics software which allows the detection of genes whose differential expression is signficant. This technology has been applied to a variety of studies, including those on cell differentiation, infection, inflammation, and cancer research.[12] A recent study has demonstrated that microarrays can be used to analyze pathways of genes involved in the differences in cellular proliferation between stem cells.[13] It can also be used to better understand the effects of different biomaterials on gene expression.[14]

3.321.3.1. Various Approaches to Biomaterial Research

The need for more informative biological assays and models has been essential in the development of predictive preclinical methods for drug discovery and clinical application processes. It has been stated that the study of cell–biomaterial interactions can be useful in a number of applications, such as tissue engineering,[15] drug discovery,[16] and so on. It is also important to control and understand the cellular microenvironment as it can affect gene expression and its regulation.[17]

Until now, differentiation of the cells had been studied using immunohistochemistry[18] and by atomic force microscopic (AFM) evaluation of cell morphology[19] and sizes.[20] They provide basic information about the response of the cell in the biomaterial environment. A more thorough characterization and analysis of these cell responses would require the study of gene expression either by PCR, DNA arrays, or proteomics. In general, these methods such as DNA array and proteomics have a limitation in that the analysis of the cellular responses is not easy, as these methods require large samples. It is often difficult to extract cellular material for analytical methods such as PCR or flow cytometry from cells that are embedded in biomaterials.[21] However, these methods, which can obtain greater information, play an important role in the analysis of selected biomaterials after the culture has been scaled to a larger size. Another dimension in cell assays is cellular manipulation by the use of transfections.[22] Transfections result in gene upregulation (with DNA or RNA) or knock down (with miRNA, siRNA, or antisense). This allows a systematic biological approach to the studies on cell responses. Reverse transfection is a commonly used procedure in cell array research and is related to the study of biological mechanisms. Such arrays allow studies on the mechanisms of the disease and a search for new drug targets. This is a powerful approach because it allows a systematic mapping of the cellular machinery by knocking down individual genes with siRNA and then noninvasively measuring the cellular response using fluorescent assays.[23] This functional assay must be selected case-by-case, and it depends on the cell type, end points, and goals of the study.

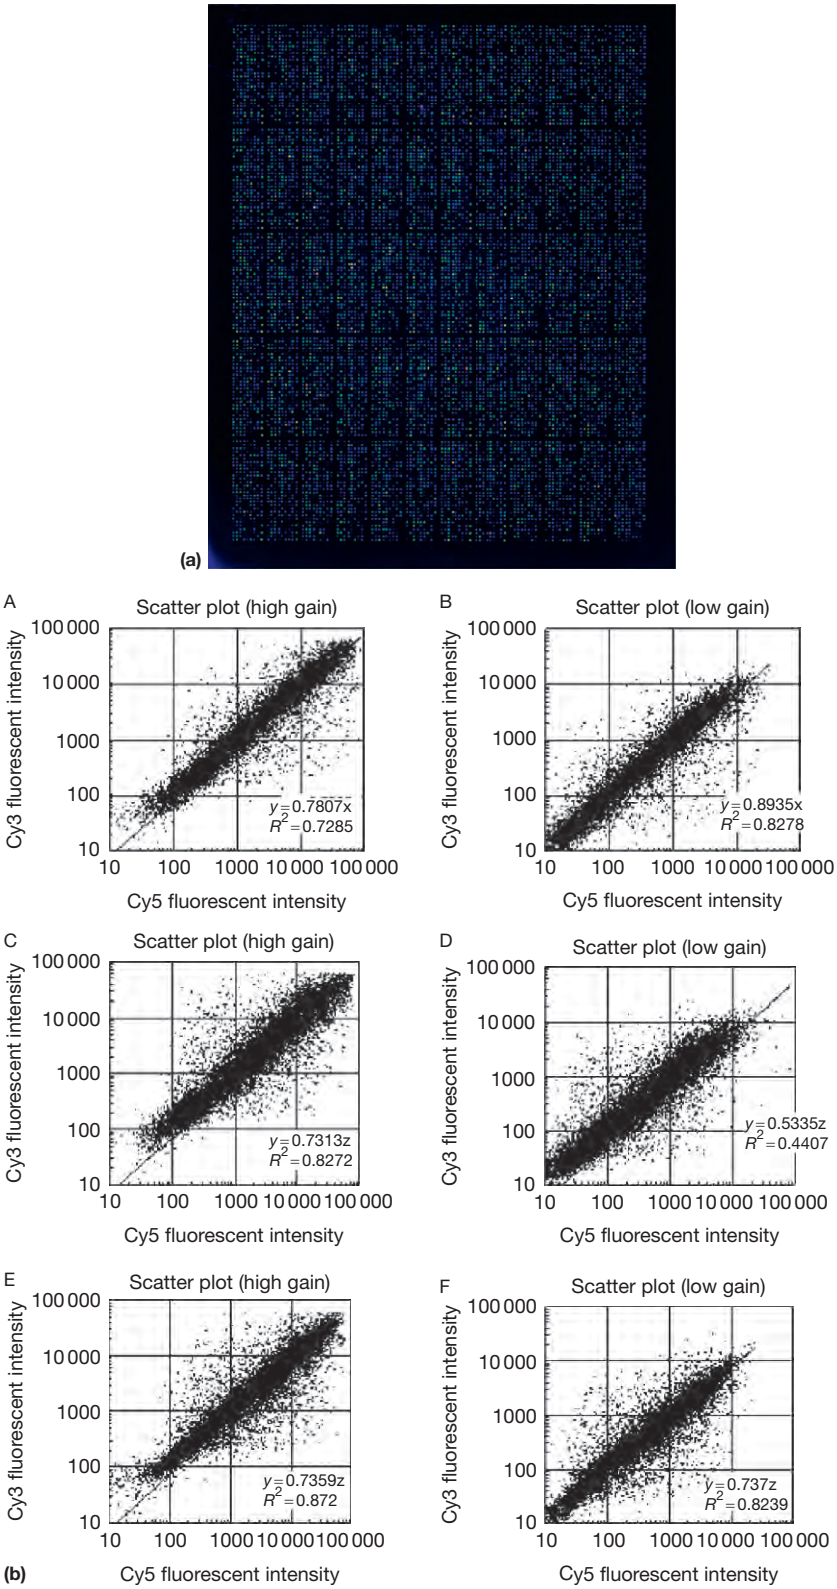

Figure 1 (a) Microarray scanned image. (b) Global comparison of the levels of gene expression in high (A, C, and E) and low (B, D, and F) gain human dental pulp stem cells (hDPSCs) or human mesenchymal stem cells (hMSCs). Each dot corresponds to the Cy3 and Cy5 fluorescent intensity of one single element on the microarray. The dot plot shows a (A): high or (B): low gain between hMSCs and hMSCs (osteoinduction), a (C): high or (D): low gain between hMSCs and hDPSCs, a (E): high or (F): low gain between hMSCs and hDPSCs (osteoinduction). Reproduced from Yamada, Y.; Fujimoto, A.; Ito, A.; Yoshimi, R.; Ueda, M. *Biomaterials* **2006**, *27*, 3766–3781, with permission from Elsevier.

3.321.3.2. Functional Application of Microarray

DNA microarrays are a useful means of quantifying tens of thousands of discrete sequences in a single assay. The most widespread use of microarrays, expression profiling,[24] has many applications, including in the discovery of gene functions,[25] pathway dissection,[26] and in the classification of clinical samples.[27] The development of microarray methods has enabled rapid and quantitative studies on the interaction between cells, such as stem cells and their microenvironment.

3.321.3.2.1. Essential stem cells study for biomaterial research

One emerging trend in biomaterials research is the design of biofunctional materials that can modulate cellular responses via the incorporation of necessary, instructive signals into the biomaterials. While much progress has been made in biomaterial design and application, the rational design of biomaterial cues to control stem cell behavior and differentiation has remained challenging due to the complexity of

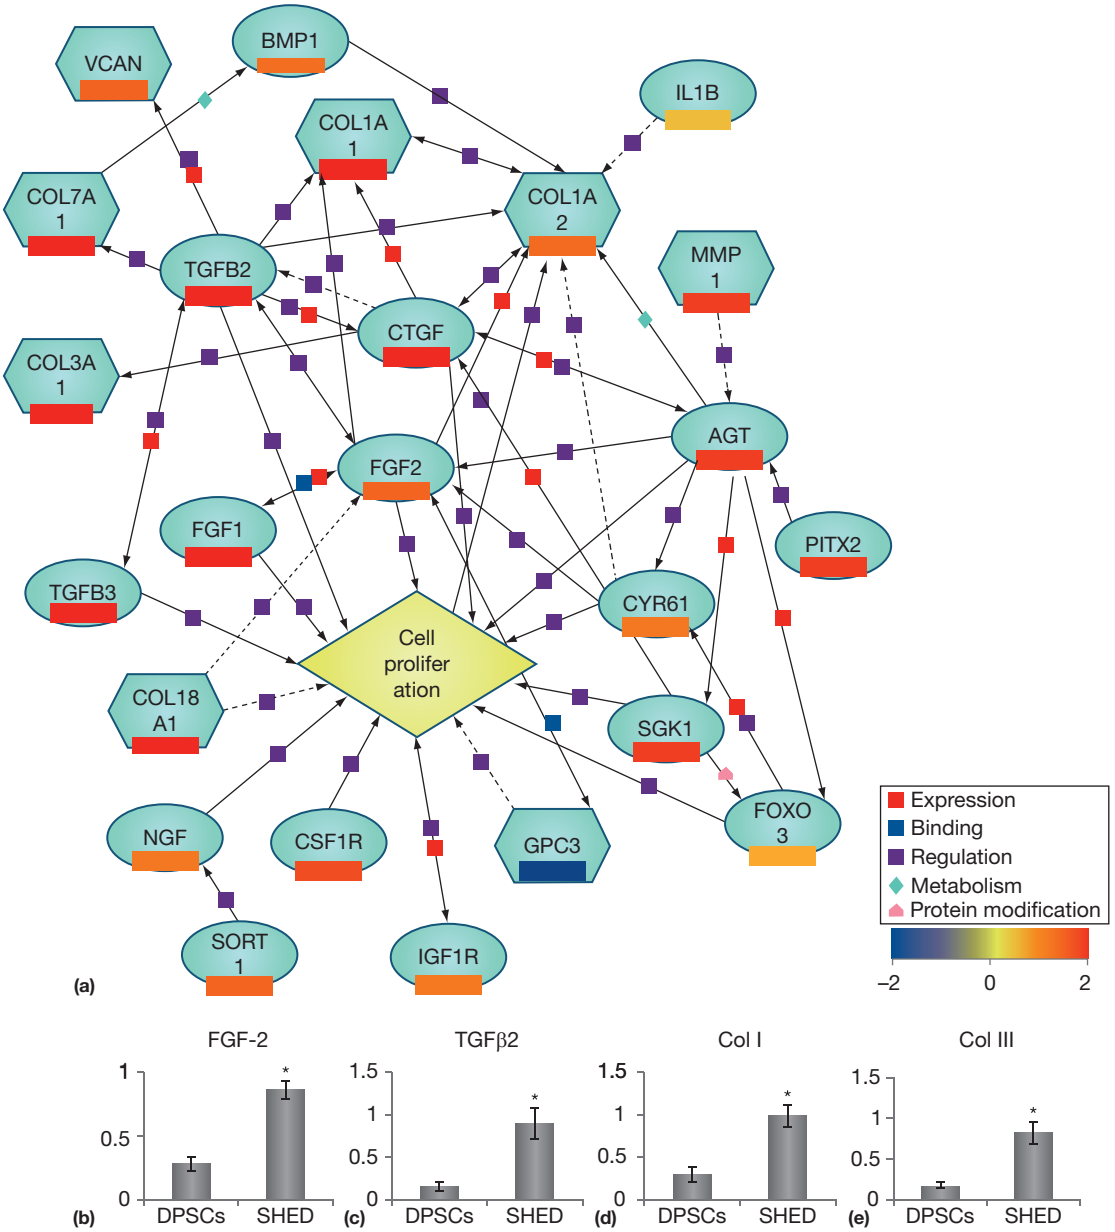

Figure 2 (a) Pathway analysis of gene categories that were prominent in stem cells from human exfoliated deciduous teeth (SHED) compared to dental pulp stem cells (DPSCs). The cell proliferation pathway was accelerated in SHED. The network is displayed as nodes (genes) and lines (biological relationships between nodes). Genes colored red showed increases, while genes colored blue showed decreases. Dotted lines denote downregulation. (b)–(e) Real-time PCR analysis was performed to validate the expression level of the genes involved in the cell proliferation pathway. FGF-2, TGF-β2, Col I, and Col III showed a significantly higher expression in SHED compared to DPSCs ($p < 0.05$). Reproduced from Nakamura, S.; Yamada, Y.; Katagiri, W.; Sugito, T.; Ito, K.; Ueda, M. *J. Endod*. **2009**, *35*, 1536–1542, with permission from Elsevier.

cell–biomaterial interactions.[28] On the other hand, stem cells are an essential element in the concept of tissue engineering for tissue regeneration. Tissue engineering is a relatively new field, in which new tissue is created for repair or replacement. According to this concept, it is possible to regenerate various tissues using three elements – living stem cells, appropriate scaffolds, and growth factors.[4] In recent tissue engineering studies, somatic stem cells, such as mesenchymal cells (bone marrow-derived mesenchymal stem cells (MSCs), dental pulp stem cells (DPSCs), stem cells from human exfoliated deciduous teeth (SHED), etc.), have been applied to regenerate tissues, as these stem cells readily self-replicate and are capable of replenishing the supply of tissue-forming cells. MSCs would also play an important role in tissue regeneration. DPSCs are able to differentiate into cells of the odontoblastic and osteoblastic lineage and have been reported to have the potential for use in cell-based therapy for systemic disease, such as neurological and cardiac diseases, and to ameliorate ischemic disease.[29,30] It must be stressed that tissue-engineered constructs, *ex vivo* cell propagation, and cell encapsulation–all require some type of interaction between cells and the supporting material for growth, function, and/or delivery, and stem cells are usually cultured such that they are in contact with biomaterials (as scaffolds or matrices). Therefore, information on the characteristics of cells is also important for design of biomaterials to be used as scaffolds. Microarray analysis or functional evaluation of the cellular gene expression profile has important implications for understanding stem cell characteristics, especially the mechanisms of cell capacities.

3.321.3.2.2. Pathway dissection analysis

There are two ways to carry the data analysis, beyond gene-ontology (GO) classification, deeper into biology: by going to the molecular level, which is promoter and regulatory network analysis, or by employing the vast knowledge that has already accumulated in the literature. The pathways focus on physical and functional interactions between genes rather than taking the gene-centered view of GO-based analyses.[31] Therefore, it is intriguing to map the list of significantly regulated genes onto the commonly precompiled pathways in order to elucidate the entire chain of events observed in a microarray experiment.

For example, it pays attention to the somatic stem cells of important role in clinical application. However, stem cells, such as SHED, DPSCs, and BMMSCs, which include a large proportion of the high growth- and differentiation-potential skeletal stem cells, have similar characteristics. On the

other hand, because of their high proliferation ability, SHED and DPSCs, instead of BMMSCs, could be useful cell sources for cell-based therapy. Thus, there is an increasing focus on SHED and DPSCs and further analyses have been performed. cDNA microarray technology and pathway analysis have been used to compare multiple gene expression profiles that are representative of SHED and DPSCs. A fold-change cutoff of 2 for both upregulation and downregulation of genes and a *p*-value cutoff of 0.05 were set to identify the differentially expressed genes. One of the most significantly altered pathways was cell proliferation. The network of genes involved in cell proliferation is shown in **Figure 2(a)**. Extracellular matrix genes, including collagen (Col I, III, VII, and XIII) and proteoglycan (glypican and versican), were altered in the cell proliferation pathway. In addition, several cytokines were related to this pathway, and the results also showed that SHED expressed several growth factors such as FGF, TGF-β, CTGF, NGF, and BMP at higher levels (**Figure 2**).[13] A functional evaluation of the gene expression profile has important implications for understanding the stem cell characteristics, especially the mechanisms of cell potency. As it is quite important to have high proliferative capacity in order to be able to use MSCs in various medical applications, the high proliferation ability of SHEDs could be a great advantage. The pathways and individual genes that have been identified in this study might support SHED as an alternative useful cell source for future clinical applications that involve a novel therapy for systemic diseases.

3.321.3.2.3. Clustering analysis

A method for cluster analysis of genome-wide expression data from microarray hybridization that uses standard statistical algorithms to arrange genes according to the similarity in patterns of gene expression has been described. It combines clustering methods with a graphical representation of the primary data by representing each data point in color which quantitatively and qualitatively reflects the original experimental observations. Relationships among genes are represented by a dendrogram whose branch lengths reflect the degree of their similarity, as assessed by a pair-wise similarity function. Genes are displayed in the following colors: those with a log ratio of 0 (ratio of 1.0: genes unchanged) in yellow; those with increasingly positive log ratios in red of increasing intensity; and those with increasingly negative log ratios in blue of increasing intensity. The results suggest that the clustering algorithm successfully identifies cooperatively regulated genes according to their expression profiles. It thus enables a further clustering analysis of expression profiles of functionally categorized genes in order to investigate the relevance of the expression profiles and their functions. For example, gene expression patterns and functional classifications were investigated in human dental pulp stem cells (hDPSCs) and human mesenchymal stem cells (hMSCs) (**Figure 3**). The analyses of gene expression patterns indicated that several of the genes encoded extracellular matrix components, cell adhesion molecules, growth factors, and transcription regulators. Functional and clustering analyses of the differences in gene expression levels revealed genes involved in cell signaling, cell communication, or cell metabolism (**Table 1**).[32] In general, the classification scheme, such as functional and clustering analysis, consisted of six

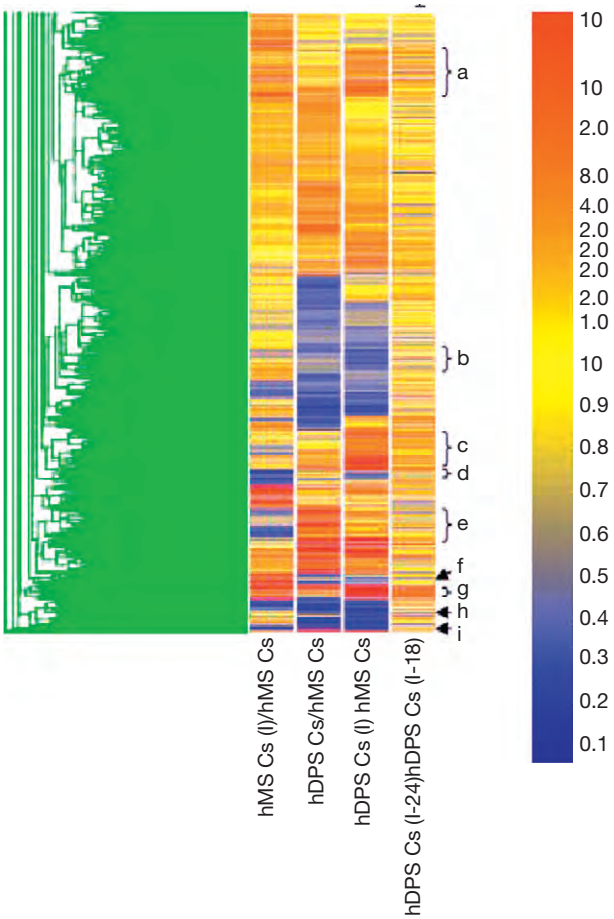

Figure 3 Representative global view of expression level changes by hierarchical clustering analysis. Significantly upregulated or downregulated genes were analyzed according to the clustering method. The cluster in yellow denotes no significant difference between samples; the clusters in red and blue denote transcripts which are more and less abundant in each cell, respectively. The intensity of the color is proportional to an *n*-fold increase or decrease, with the maximal intensity corresponding to a 15-fold increase or decrease as represented in the color scale (bottom). Annotations for the clusters given by the microarray data analysis software are shown on the right (magnified): the annotations in the clusters are a, b, c, d, e, f, g, h, and i. Reproduced from Yamada, Y.; Fujimoto, A.; Ito, A.; Yoshimi, R.; Ueda, M. *Biomaterials* **2006**, *27*, 3766–3781, with permission from Elsevier.

major functional categories (cell division, cell signaling/cell communication, cell structure/motility, cell/organism defense, gene/protein expression, and metabolism) with several minor functional categories within the major categories. The clustering analyses provided novel insights into cellular functions and enabled comprehension of the transcriptional regulatory mechanisms of several genes in each sample. Such information on the gene expression patterns of hDPSCs and hMSCs might be useful in determining the detailed functional roles of the relevant genes and may also be applicable in stem cell therapies. Moreover, these cells could also be used as sources of multipotent cells for gene technology and tissue engineering technology.

3.321.4. Future Prospects of Microarray

Microarray analysis is very appropriate for biomaterial research, especially for studying the interactions between cells, cellular behavior, and the microenvironment around biomaterials. Although the gene expression profiles should be further confirmed with other molecular biological methods such as quantitative real-time PCR, the method is valuable in its own right. In other words, gene microarray systems for profiling and analysis of gene expression offer abundant and useful information. They enable a functional classification of genes based on their protein-encoding functions. However, the assay should be selected case-by-case, depending on the cell type, end point, and goals of the study. In addition to gene expression profiles, technologies for pathway and clustering analysis using microarrays can provide new knowledge on how biomaterials interact with cells; this will enable progress in biomaterials research.

Glossary

Apparent diffusion coefficient (ADC) Diffusion coefficient measured in the presence of barriers to diffusion. The ADC is smaller than the true diffusion coefficient of the diffusing molecules in the absence of structural hindering.

Cartesian imaging techniques Most common MRI method in which data are collected on a Cartesian grid, thereby allowing image reconstruction by 2D or 3D Fourier transformation.

Cross-polarization NMR method designed to transfer polarization from one nucleus (e.g., protons) to another (e.g., phosphorus).

Fabric tensor Symmetric second-rank tensor that characterizes the structural anisotropy of porous material microstructure such as trabecular bone networks.

Free induction decay (FID) Magnetic resonance signal induced in a receive coil by the precessing magnetic moments.

Larmor frequency Resonance or precession frequency of spins in a static magnetic field. The Larmor frequency is proportional to the magnetic field strength with a proportionality constant equal to the gyromagnetic ratio.

Mean intercept length Number of intersections between bone and surrounding narrow space along test lines of predetermined direction.

Pulse sequence Set of instructions to a MRI imaging device to turn magnetic field gradients and radio frequency fields on and off for the purpose of exciting spins and detecting their response.

Relaxation rate Reciprocal of relaxation time.

Relaxation times Time constants for the recovery of the nuclear magnetic moment or magnetization to its equilibrium state following a perturbation, with T_1 governing the return of the longitudinal magnetization and T_2 governing the return of the transverse magnetization.

Relaxivity Relaxation rate per unit concentration of the relaxant.

Solid-state MRI MRI technique designed to capture signals and image nuclei with extremely short transverse relaxation times as they occur in solids.

Spatial autocorrelation function Describes correlation among data as a method to probe the regularity of trabecular bone lattices.

Topology Study of spatial properties that are preserved under continuous deformation of the object, including stretching, an approach used for the characterization of trabecular bone networks.

Abbreviations

2D	Two-dimensional
3D	Three-dimensional
ACF	Autocorrelation function
BVF	Bone volume fraction
CBVF	Cortical bone volume fraction
CPMG	Carr–Purcell–Meiboom–Gill
CT	Computed tomography
DTA	Digital topological analysis
DXA	Dual-energy X-ray absorptiometry
FID	Free induction decay
HRpQCT	High-resolution peripheral quantitative computed tomography
MIL	Mean intercept length
MRI	Magnetic resonance imaging
NMR	Nuclear magnetic resonance
PSF	Point spread function
RF	Radiofrequency

S/C	Surface-to-curve	**μCT**	Micro-CT
SMI	Structure-model index	**YM**	Young's modulus
SNR	Signal-to-noise ratio		

3.323.1. Introduction

Bone is a composite, living biomaterial that dynamically adapts to the direction and intensity of the stresses to which it is subjected through a process called 'remodeling.' The same process enables the material to repair damage such as microcracks that form after the bone has undergone myriads of loading cycles during daily living through an elaborate interplay of cells (the osteoblasts or bone-forming cells and the osteoclasts or the bone-resorbing cells), mediated by osteocytes acting as pressure transducers and modulated by hormones and signaling molecules.

Remodeling-induced changes in bone material density can have significant implications on the bone's ability to withstand stresses. For example, decreased loading due to lack of exercise or prolonged exposure to microgravity leads to bone loss and thus increased fracture susceptibility. Similarly, depletion of estrogen levels following menopause in women causes a negative remodeling balance.

Bone derives its salient mechanical properties, in particular its high tensile and compressive strength, from its unique material composition and nanostructural organization.[1,2] Bone material is organized hierarchically starting at the molecular level, with basic building blocks being tropocollagen as the organic component and crystals of nonstoichiometric calcium hydroxyapatite interspersed in gaps in the collagen triple helix. An assembly of these basic building blocks forms fibrils, which, in turn, are organized into fibers. Arrays of parallel fibers make up sheets (lamellae) winding around Haversian canals, which, in cortical bone, make up the osteon, the basic building block at the microstructural level.

Bone's intrinsic material modulus ranges from about 15 to 25 GPa and is anisotropic, being stiffer in the direction of the osteonal axis than perpendicular to it. Bone is also unique in its toughness: that is, its capacity to absorb energy, critical to fracture resistance. In distinction to the mechanical properties (e.g., stiffness or ultimate strength) that are intrinsic to the material itself are their structural counterparts. Clearly, a given material density incompletely characterizes the bone's mechanical behavior, which is determined by the spatial distribution and the loading mode. The structural and mechanical properties of bone are well understood and have been described in detail in terms of continuum mechanics engineering math (see, e.g., Cowin[3]).

Imaging at virtually all length scales of resolution ranges from X-ray diffraction to scanning electron and confocal microscopy as tools to evaluate bone material nanostructure and microstructure, while the macrostructure is evaluated with X-ray radiography and computed tomography (CT). More recently, infrared and Raman spectroscopy and their spectroscopic imaging counterparts have provided new insights into the chemical makeup of the bone matrix and the mineral phases. However, other than CT, these imaging modalities are confined to the study of bone tissue *ex vivo* in cadaver specimens or bone biopsies.

This chapter briefly reviews the current state of the art and potential of magnetic resonance imaging (MRI) and nuclear magnetic resonance (NMR) spectroscopy for evaluating the structural and material properties of trabecular and cortical bone, both *ex vivo* and *in vivo* in live human subjects.

3.323.2. Fundamentals of Magnetic Resonance

MRI is currently the preeminent diagnostic imaging modality for most organ systems, including the musculoskeletal system. However, its salient strength lies in visualizing soft tissues and their abnormalities in tendons and ligaments, cartilage, muscle, intervertebral disk, bone marrow, etc.

While this is not the place to introduce the physics underlying the method, MRI's potential cannot be appreciated by the reader without some grasp of its fundamentals. MRI, or its parent, NMR, is based on detecting an electrical signal elicited by the nuclear magnetic moments (most typically protons in hydrogen, such as tissue water or lipids) after having been subjected to an intense, static, and homogeneous magnetic field B_0 of several tesla intensity ($1\,\mathrm{T} = 10\,000\,\mathrm{G}$). In this manner, the nuclear magnetic moments become polarized, or aligned with the field, thereby creating a macroscopic magnetic moment, also called *magnetization*. When then a second circularly polarized (radiofrequency, rf) magnetic field of amplitude B_1 is applied perpendicular to the static field for a short period of time, the magnetization is deflected into a plane transverse to the static field. The action of the rf pulse applied at the spins' resonance frequency ω_0 causes the magnetization to precess around the axis of the static field, thereby inducing a voltage in a suitably positioned receiver coil (Faraday's law of induction). The maximum signal that can be obtained with a given experimental arrangement is obtained by turning the field on for a period sufficient to rotate the magnetization by 90° into the transverse plane, that is, the plane perpendicular to the direction of the static field. The frequency $\omega_0 = \gamma B_0$ is called *Larmor* frequency, where γ is a nuclear constant. At a typical field strength of 3 T of a magnetic resonance imager, the resonance frequency is 128 MHz.

The signal obtained in this manner, also called *free induction decay* (FID), is a damped sinusoid with the damping time constant T_2, the *transverse relaxation time*. The finite lifetime of the signal results from mutual interference of the spins due small local variations in the magnetic field caused by external perturbations or mutual interactions among the nuclear magnetic moments. T_2 for protons in soft tissues ranges from a few milliseconds to about 100 ms. We will see later that the magnitude of T_2 critically affects our ability to detect the signal and, in general, that increased viscosity shortens T_2, resulting in extremely short values in the solid state. Examples are protons that are part of bone's collagen matrix or the phosphorus spins in calcium phosphate of the bone's mineral constituent.

Another time constant that affects the MRI signal is the longitudinal relaxation time T_1, so called because it characterizes the dynamics of the longitudinal component of the magnetization. Following a 90° rf pulse, for example, the longitudinal magnetization returns to its equilibrium value with a time constant T_1. Both T_1 and T_2 of the water protons in mammalian tissues are dependent on the strength of the static field, with T_1 increasing and T_2 decreasing. T_2 is 1–3 orders shorter than T_1, ranging from about 0.5 to 4 s.

In 1973, Lauterbur[4] showed that the NMR method lends itself to obtain cross-sectional images by spatially encoding the nuclear magnetic moments. Whereas in a uniform magnetic field all nuclei resonate at the same frequency, as pointed out above, this is no longer the case when a small, spatially variant field (a gradient magnetic field) is superimposed on the main field B_0. The effective field strength the spins experience then becomes a function of spatial position and, according to the Larmor relationship, also of their resonance frequency. By Fourier analysis of such a signal, which is a complex superposition of multiple sinusoids, a projection representation of the object is obtained, analogous to CT. By rotating the gradient field in small angular increments, a series of projections are collected, from which an image can be reconstructed using filtered backprojection.

While the above is not the most commonly used method for MRI, all current methods are based on spatial encoding with gradient magnetic fields. In the most commonly used Cartesian imaging techniques, two orthogonal gradient fields are applied, one immediately after excitation by a short pulse of the B_1 field, and a second one subsequently during signal collection. During each excitation signal-readout cycle, the pre-encoding gradient (also called phase-encoding gradient) assumes a different value. In this manner, a matrix of, for example 256×256, signal samples of the imaging object is obtained, each characterized by an amplitude and phase. The cycle of excitation and detection, followed by a recovery period, is called a *pulse sequence*. The recovery period inserted before the next following excitation is necessary to allow the magnetic moments to relax by exchanging their excess energy to their surroundings, also called 'lattice,' a process typically occurring with an exponential time constant T_1. An image is then obtained by subjecting the data to a two-dimensional (2D) Fourier transformation, upon which a 256×256 digital representation of the object is obtained wherein the amplitude of each picture element (pixel) is proportional to the proton concentration at a particular spatial location.

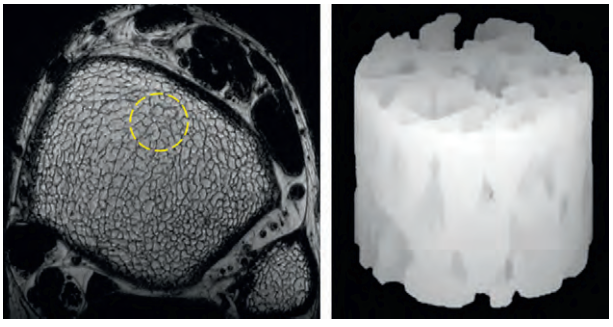
The smallest signal-producing element is the voxel (acronym for volume element), which is equal to the product of pixel area and slice thickness. Therefore, the relative signal strength is proportional to voxel volume. However, the quantity of relevance is the *signal-to-noise ratio* (SNR). The noise has a complicated dependence on various parameters, which include the field strength, size and design of the rf receive coil, and the volume of tissue 'seen' by the coil. Because of its stochastic nature, the noise amplitude increases only as the square root, whereas the signal increases linearly with the number of signal averages. Hence, it is possible to increase the SNR by repeatedly summing the signal from successive data collections.

Resolution in digital imaging modalities is often defined in terms of the length of the imaging voxel, Δr_i $(i = x, y, z)$, typically termed 'voxel size.' Equal voxel size along the three orthogonal directions ($\Delta x = \Delta y = \Delta z$) yields what is referred to as *isotropic* resolution. (The term is a misnomer since the resolution in non-orthogonal directions is less.) While a useful figure of merit for quantifying resolution, actual resolution is almost always less than suggested by voxel size in that true resolution is determined by the point spread function (PSF) of the imaging device. In Cartesian MR imaging, the PSF is at least 20% greater than voxel size. Nevertheless, for simplicity I shall here equate resolution with voxel size. This is not inappropriate as long as we compare different resolution regimes for essentially a given imaging method.

Figure 1 shows a cross-sectional high-resolution image of the distal tibia obtained *in vivo*, along with a volume-rendered 'virtual core' providing detailed insight into the architecture of the trabecular network.

3.323.3. Quantitative MRI of Trabecular and Cortical Bone Microstructure

Under typical imaging conditions, bone has near background intensity (unlike in X-ray imaging where the grayscale is determined by the attenuation coefficients, with hard tissues appearing with highest intensity). The contrast achieved, for example, between bone trabeculae and marrow, is caused by the large signal strength from the protons in fatty and hematopoietic marrow. The lack of a detectable signal from bone arises from the relatively low proton density and extremely short transverse relaxation times, in particular, not only of the protons in collagen of the osteoid (10–20 μs)[5] but also of the water in the Haversian and lacunocanalicular system as well as the significant fraction bound to collagen via hydrogen bonding, which possesses a T_2 on the order of 400–800 μs.[6] We will see in a later section in this chapter that bone water can be detected by appropriate imaging pulse sequences designed to capture the FID.



(a) (b)

Figure 1 (a) Magnetic resonance image at the location of the distal tibial metaphysis in a 37-year-old male, clearly showing trabecular and cortical bone at background intensity contrasting against the intense signal from fatty marrow in the endosteal cavity and other soft-tissue structures periosteally. The image obtained at 7 T field strength is one of 32 contiguous slices of 410 μm thickness and 137×137 μm^2 pixel size. (b) Volume-rendered 'virtual core' at the site indicated in panel a (circle), clearly showing the tubular, highly anisotropic, plate-like architecture with preferential orientation of the trabeculae along the bone's major loading direction.

In this section, we shall be concerned with imaging the marrow and reconstruct images of the 3D trabecular and cortical bone architecture by virtue of the contrast between the signal-less bone and the surrounding soft tissue. For details on imaging technology, including pulse sequences, image reconstruction, and processing, the reader is referred to some of the pertinent reviews on the subjects.[7–10]

The primary motivation for characterizing the 3D architecture of bone on the basis of structural images is to evaluate the relationship between mechanical competence and structure. Two fundamentally different approaches are being practiced. The first is to exploit structural information as a surrogate for measures of bone mechanical competence by quantitatively characterizing structure in terms of parameters of scale (typically bone volume fraction (BVF), mean trabecular separation, trabecular or cortical thickness[11]), topology (Euler numbers,[12] structure-model index (SMI),[13] digital and volume topological analysis),[14,15] and orientation.[16,17] The second approach seeks to directly estimate measures of the bone's mechanical behavior, such as compressive and shear moduli, failure strength, etc., via finite-element analysis after converting the binarized images into a mesh of finite elements directly from the voxel array.[18]

3.323.3.1. Role of Architecture: Structural Studies in Specimens

One needs to make a clear distinction between structure analysis performed at high spatial resolution – here defined as imaging at a voxel size less than the structural elements to be discerned, for example, the thickness of individual trabeculae – and the *in vivo* imaging regime where the voxel size is on the order of or exceeds trabecular thickness. Such a resolution is achievable on high-field microimaging systems designed to image specimens or small rodents *in vivo*. In this 'high-resolution' regime, bone and marrow phases can relatively easily be separated by simple threshold-based segmentation, which makes the data amenable to processing and analysis.[19]

A number of studies have been reported on extracting structural parameters from specimen MR images of human or animal trabecular bone.[19–25] The approach chosen involves marrow removal and immersion of the bone in water or saline doped with a relaxation reagent serving as a substitute for bone marrow to avoid artifacts from air inclusions due to fluid leaking out of the marrow matrix.[19] In recent years, specimen MRI of trabecular and cortical bone has largely been supplanted by micro-CT (μCT) (see, e.g., Stauber and Muller[26]), which provides superior SNR and thus resolution. We shall see that this situation is quite different for *in vivo* structural imaging application where radiation dose is a significant hurdle in CT imaging.

The role of 3D imaging of bone architecture is illustrated compellingly in a study by Hwang *et al.*[23] designed to predict the elastic modulus in trabecular bone on the basis of structural measures derived from high-resolution MR images. The work comprised 23 cylindrical trabecular bone specimens cored from the distal radius of 16 donors imaged at isotropic voxel size of 78 μm at 9.4 T on a microimaging system. The data suggested a moderate association between Young's modulus (YM) for compressive loading and Bone Volume Fraction (BVF) ($R^2 = 0.57$, $P < 0.0001$), confirming earlier studies relating YM to density.[27–29] From the 3D rendered images in **Figure 2(a)**, we see that the trabeculae are highly oriented along the radial axis, albeit to a variable extent. To quantify this effect, the authors conceived a method based on spatial autocorrelation analysis by

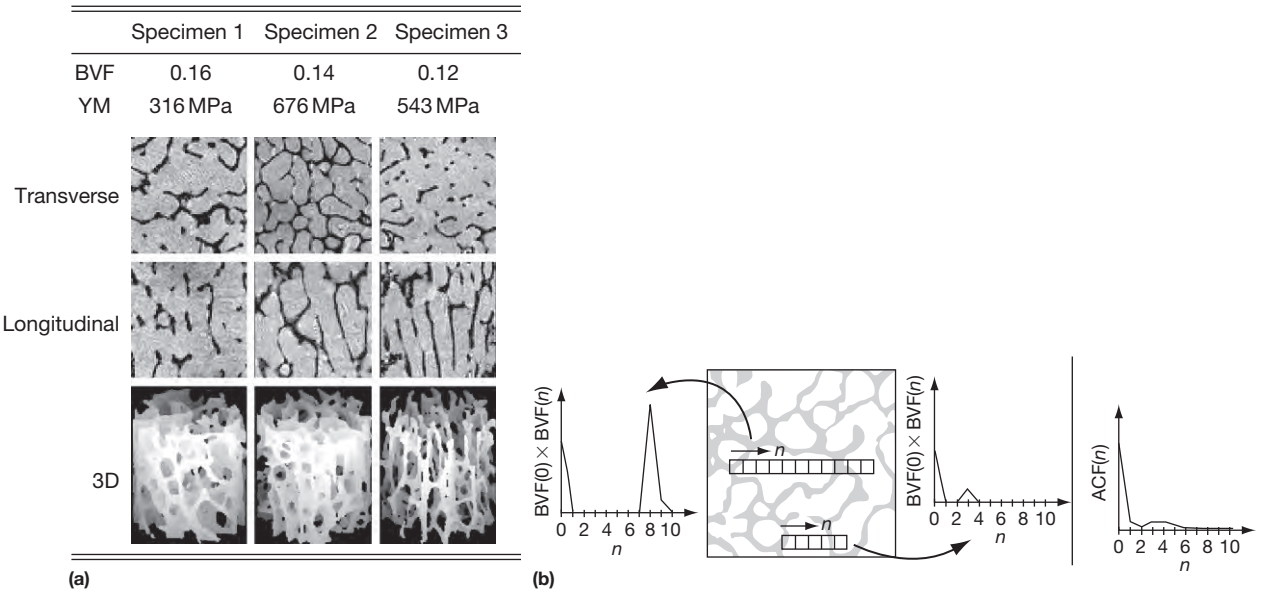


Figure 2 (a) The structural variability of trabecular bone in transverse, longitudinal, and 3D volume-rendered magnetic resonance images of specimens from a 76-year-old man (specimen 1), an 80-year-old man (specimen 2), and a 53-year-old woman (specimen 3). Note that in spite of highest BVF, the bone from specimen 1 has the lowest modulus. (b) Plots schematically showing the two-point probabilities for the two rows of voxels superimposed on the trabecular bone structure. The ACF is the average of the two-point probabilities of all pairs of voxels with a given offset with the distance between the peaks corresponding to the distance between trabeculae. Reproduced from Hwang, S. N.; Wehrli, F. W.; Williams, J. L. *Med. Phys.* **1997**, *24*, 1255, with permission from American Association of Physicists in Medicine.

treating the trabecular network as a quasiregular lattice. The principle of the method is illustrated in Figure 2(b). Whereas BVF of a voxel may be regarded as the probability $P(x, y, z)$ that a single randomly chosen point in voxel (x, y, z) is in bone, this concept was extended by considering the probability that two randomly chosen points are both in bone (Figure 2(b)). Here, we see that the distance to the second peak is equal to the distance between the trabeculae. Averaging of the two-point probabilities for all pairs of voxels with a given offset results in the autocorrelation function (ACF), which has previously been used to characterize porous materials (see, e.g., Barrall *et al.*[30]):

$$\mathrm{ACF}(n_x, n_y, n_z) = \langle P_1(x,y,z) P_1(x+n_x, y+n_y, z+n_z) \rangle_{x,y,z} \quad [1]$$

In eqn [1], $n_{x,y,z}$ are the voxel offsets in 3D space and the brackets indicate a spatial average over all possible voxel locations (x, y, z). Thus,

$$\mathrm{ACF}_{\mathrm{longitudinal}}(n_z) = \mathrm{ACF}(0, 0, n_z) = \langle P_1(x,y,z) P_1(x,y,z+n_z) \rangle_{x,y,z} \quad [2]$$

is the longitudinal spacing expressed as the distance to the second peak in the autocorrelation in axial (z) direction. We see from Figure 2(a) that the mean spacing between successive trabeculae is much larger in longitudinal than in transverse direction since the main loading direction is along the radial axis. On the other hand, there are significant interindividual differences in the degree of structural anisotropy. Hwang *et al.* developed a multiparameter model showing that a function of BVF and longitudinal spacing could predict over 90% of the variation in YM in this set of specimens, providing evidence that parameters other than density relating to the spatial distribution of the bone are important. Specifically, the data highlight the mechanical significance of structural orientation, first formulated theoretically by Cowin, who showed that the elastic properties of structured orthotropic materials can be described quantitatively in terms of 'fabric' and density.[31] We shall return to this topic in a later section of this chapter and review methods for quantification of structural orientation from 3D digital images.

It is also possible to obtain information on structural and possibly material properties by MRI without the need to resolve the trabeculae by making use of the induced inhomogeneous field caused by the difference in magnetic susceptibility between bone and marrow (or, for studies *ex vivo*, bone and water in the marrow spaces). Bone has been shown to be more diamagnetic than water – and, similarly, than hematopoietic or fatty marrow – by 2.5–3 ppm (Système International, S.I.)).[32,33] The induced inhomogeneous field in the vicinity of the bone trabeculae causes phase scrambling of the spin isochromats manifesting in a net loss of signal, particularly in gradient-echo imaging sequences in which dephasing effects are not reversed by a phase-reversal rf pulse. This effect has been studied extensively, both theoretically[34–37] and experimentally, in models of trabecular bone.[38,39]

3.323.3.2. *In Vivo* Spatial Resolution Regime

The holy grail of biomaterial science is to extract quantitative structural and mechanical information noninvasively by imaging, ultimately taking the place of bone-biopsy-based histology. A significant advantage of this approach is that it allows for time-series studies in which each subject or animal serves their own control, thereby significantly enhancing power. The author's laboratory has, during the past 15 years, striven toward this goal by developing image-based methods, leading to what has been referred to as 'virtual bone biopsy',[8–10] in analogy to a physical bone biopsy.

During the past decade, high-resolution MRI has proven its potential as a method to provide 3D images of trabecular and cortical bone at peripheral skeletal locations, including the distal and proximal tibia, calcaneus,[40–42] and distal radius.[43–46] Attempts have also been made to image the proximal femur.[47,48] MRI is of particular interest not just because of the absence of ionizing radiation but also because of the very wide availability of the technology. The latter is in contrast to MRI's closest competitor, high-resolution peripheral quantitative CT (HRpQCT), designed specifically for generating images at a resolution adequate to visualize and quantify essential features of the trabecular network at acceptable radiation dose (see, e.g., Khosla *et al.*[49]). Two areas of particular medical significance and interest involve the association between fracture susceptibility and structure and the evaluation of the structural implications of aging, disease progression, and regression in response to intervention.[43,50–53]

The resolution achievable *in vivo* is considerably below that possible in small specimens. As pointed out previously, resolution is largely determined by available SNR, which, in turn, is given by voxel volume. For image-analysis algorithms to operate reliably, SNR (typically expressed as mean marrow signal amplitude divided by the standard deviation of the background) should not fall below about 6–8,[54,55] even though SNR levels of >10 would be desirable. While signal averaging improves SNR, the gain scales as $\sqrt{T_s}$ with T_s being the total scan time. The practical upper limit of scan time is 10–15 min, which is largely governed by patient tolerance. At the current state of the art, adequate SNR and volume coverage are achievable at 3 T field strength to acquire images of the distal extremities with a voxel volume V_v of $4\times10^{-3}\,\mathrm{mm}^3$ in 11 min scan time.[56] This voxel volume yields an *apparent* linear resolution R_L, in all three orthogonal directions, of 160 µm ($R_L = \sqrt[3]{V_v}$).

Images such as those shown in Figure 1 are suited for deriving structural parameters that express various properties, which can broadly be categorized into *measures of scale* (BVF and thickness, either trabecular or cortical, and porosity), *orientation* (governed by the directional intensity of stresses, Wolff's law), and, lastly, *topology*. While topology has strict mathematical definition, it suffices to remember that topology is preserved under rubber-sheet deformation. Hence, stretching or twisting an object – in our case a hypothetical trabecular network – would not alter its topology. In contrast, breaking a connection between trabeculae or causing a perforation of a trabecular plate – both are common phenomena during aging and osteoporotic bone loss – would alter the structure's topology. It is readily recognized that the latter processes can have mechanical consequences that are disproportionately large relative to the amount of bone loss.

In the following, advanced methods designed to evaluate parameters falling into each of the three categories are briefly discussed and illustrated with data derived from *in vivo* images.

3.323.3.3. Characterization of Trabecular Bone Architecture in Terms of Scale, Topology, and Orientation

3.323.3.3.1. Trabecular bone volume fraction and thickness

As long as the voxel size is substantially less than trabecular thickness, the intensity histogram is bimodal (assuming the image contains only bone and marrow structures) and the image can easily be binarized by setting a threshold at the midpoint between the marrow and bone peaks. The resulting image has two discrete phases, that is, bone and marrow. Under these conditions, BVF can be obtained by summing all voxels within a 3D region pertaining to the phase assigned to bone. This approach is no longer possible once resolution becomes comparable to trabecular thickness since the histogram becomes monomodal and the choice of threshold becomes rather arbitrary. Contributing to the loss of bimodality is noise, since *in vivo* images typically have far lower SNR than their *ex vivo* counterparts. The loss of bimodality is caused by a process denoted 'partial volume averaging'; that is, the majority of voxels contain both bone and marrow even though the pure phases have unique intensity. While this appears to be an intractable problem, it actually is not and it has been shown that both BVF and trabecular thickness can be accurately retrieved in this regime.[54,55,57] An elegant algorithm conceived by Saha is based on the fuzzy distance transform, which allows computation of trabecular thickness under conditions of *in vivo* resolution and in the presence of noise.[55]

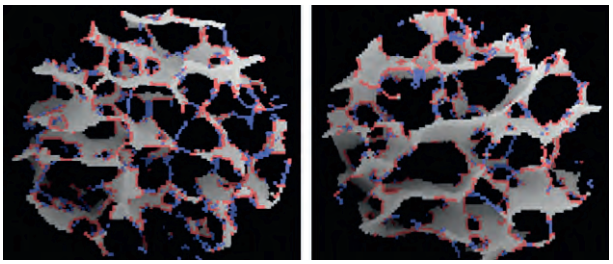
3.323.3.3.2. Topology of trabecular networks

Feldkamp *et al.*[12] were first to describe algorithms for extraction of topological quantities from digital images of trabecular bone obtained by 3D μCT. Connectivity, a quantity that characterizes the integrity of the trabecular network, can be derived from the 3D Euler number $N^{(3)}$. For an open network structure, the Euler number can be calculated from the number of nodes n and number of branches b, as $N^{(3)} = n - b$. For a network where at least one path exists between two nodes, the quantity $1 - N^{(3)}$ is a measure of connectivity in that it expresses the number of branches that can be broken before the structure becomes broken into disconnected elements. This approach requires the image to be skeletonized into a 3D line graph, which is a rather extreme form of data reduction since there is no longer a distinction between plates and rods. Nevertheless, the use of this metric has been practiced in the context of MRI of trabecular bone with some success.[24,58]

It is well known that at virtually all skeletal locations trabecular bone is a network of interconnected plates and rods, but that during aging, and particularly osteoporosis, heterogeneous erosion causes perforation of plates[59] leading to a more rod-like structure. Hildebrand and Rüegsegger[60] conceived an elegant algorithm for quantifying the bone's relative 'platelikeness' expressed by a quantity denoted structure-model index (SMI). The method is based on computing the relative change in surface area upon radial expansion of the structure. It is readily seen that for a rod-like element represented by a cylinder, the change in volume is far greater than for a plate. Using a normalization scheme, the SMI is calculated so as to yield values of 0 and 3 for perfect plates and rods, respectively. One difficulty with the SMI is that it is not easily applicable to *in vivo* MR or CT images since it requires triangulation of the surface and thus a binary image.

An alternative approach that has been widely applied to *in vivo* trabecular bone MR images is based on Saha and Chaudhuri's method termed digital topological analysis (DTA),[61] which was subsequently shown to yield detailed information on the topology of trabecular structures.[14] In DTA, a BVF image set is first derived from the raw images as a noiseless representation of the object, whereby each voxel represents the fractional occupancy of bone at each location in digital 3D space. To improve apparent resolution, the BVF maps are upsampled using interpolation (typically performed in k-space).[62] Another strategy is what has been referred to as 'subvoxel processing,' a method that mimics image acquisition at higher resolution.[63] The idea is to partition each voxel into subvoxels and redistribute the bone in such a way that each subvoxel receives additional material based on its proximity to bone under retention of total BVF. Thereafter, the images are binarized and skeletonized, converting trabecular plates to surfaces and rods to curves. Inspection of the $3 \times 3 \times 3$ neighborhood of each voxel then allows determination of its topological entity as to whether it is part of a surface or curve, or junctions between these basic structures, essentially using lookup tables.[64] A convenient measure for characterizing the bone's platelikeness is in terms of the topological surface-to-curve (S/C) ratio, which is essentially the sum of all surface-type voxels divided by the sum of all curve-type voxels. The substantial structural differences between subjects are illustrated with the color-coded 3D skeleton maps derived from high-resolution MR images of the distal tibia in **Figure 3**.

There is significant evidence that greater S/C is associated with lower prevalence of fractures of the vertebrae (quantified in terms of vertebral deformity index), even though the structural measurements were performed at a peripheral anatomic site, in this case the distal radius.[65,66] The method was also shown to be able to detect structural changes longitudinally, such as degradation of the trabecular architecture immediately following menopause and, conversely, maintenance of structural integrity with estrogen supplementation.[51] Another study showed large positive changes, exceeding those in BVF, in men with hypogonads after receiving testosterone.[50]



(a) (b)

Figure 3 Skeleton maps obtained showing surface interior voxels in gray, surface edges in red, and curves in blue in two subjects with substantially different topological makeup of the bone as expressed by their surface-to-curve ratio. Images are skeletonized from 7 mm diameter virtual core from the anterior distal tibial metaphysis: (a) woman, age 40 years, surface-to-curve ratio 5.61; (b) man, age 32 years, surface-to-curve ratio 9.11.

More recently, several other approaches have been described to characterize trabecular structure in terms of topology from MR or CT images at resolution and SNR levels achievable *in vivo*. Vasilic *et al.* describe a method that produces a continuous classification of voxels as belonging to plate-like or rod-like structures that determines their orientation and estimates their thickness. The method, denoted local inertial anisotropy (LIA), treats the *BVF* image as a distribution of mass density while the orientation of the trabeculae is determined from a locally calculated tensor of inertia at each voxel location.[67]

3.323.3.3.3. Structural orientation

We have seen above that structural orientation plays a pivotal role and that, even at a given anatomic site such as the distal radius, significant interindividual differences exist. It was Whitehouse who first showed that, when tracing the mean intercept length (MIL) through marrow as a function of orientation in polar diagram, the data trace an ellipse.[17] Harrigan and Mann showed that the degree of orientation in orthotropic materials can be described in terms of a second-rank tensor.[16] However, it was not before the advent of 3D digital imaging that this tensor could be mapped in a straightforward manner. Chung *et al.*, on the basis of 3D MR images of specimens, showed that the approach furnishes the MIL and fabric tensor that is characterized by three eigenvectors and three eigenvalues.[21] They developed an algorithm for determining MIL as a function of direction from 3D volume images through parallel test lines across the imaging volume. The MIL was then measured as the mean distance between adjacent trabeculae. The procedure is somewhat akin to that described by Dalstra *et al.*,[68] except that in that work 3D data were reconstructed from serial sections rather than volumetric imaging data. The orientation of the test lines, controlled by the polar and azimuthal angles, was chosen so as to uniformly sample the measurement volume. The MIL data obtained from all orientations were then transformed to a Cartesian coordinate system and fitted to the equation of an ellipsoid

$$ax^2 + bxy + cxz + dy^2 + eyz + fz^2 = 1 \qquad [3]$$

via least square error analysis, yielding the six coefficients from which a 3×3 matrix representing the fabric tensor in the measurement coordinate system is constructed[16]:

$$M = \begin{pmatrix} a & b/2 & c/2 \\ b/2 & d & e/2 \\ c/2 & e/2 & f \end{pmatrix} \qquad [4]$$

The eigenvectors of $\boldsymbol{M}$ correspond to the three orthogonal principal directions of the MIL ellipsoid. The lengths of the principal axes then are obtained as the reciprocal of the square root of the three eigenvalues of $\boldsymbol{M}$.

Figure 4 shows the MIL ellipsoid, which quantitatively measures the structural anisotropy, obtained from fitting the data measured directly from the 3D image set, along with volume-rendered projections for seven angles.

More recently, MIL in its 3D implementation has also been applied to *in vivo* MR images of trabecular bone of the distal tibia.[56,69]

Since bone models and remodels in response to the stresses to which it is subjected (Wolff's law), it is not surprising that structural anisotropy parallels mechanical anisotropy, shown experimentally by Odgaard *et al.*[70] Cowin had previously formulated a mathematical frame work relating the fabric tensor to the elasticity tensor for linearly elastic porous materials with intrinsically isotropic material properties.[71]

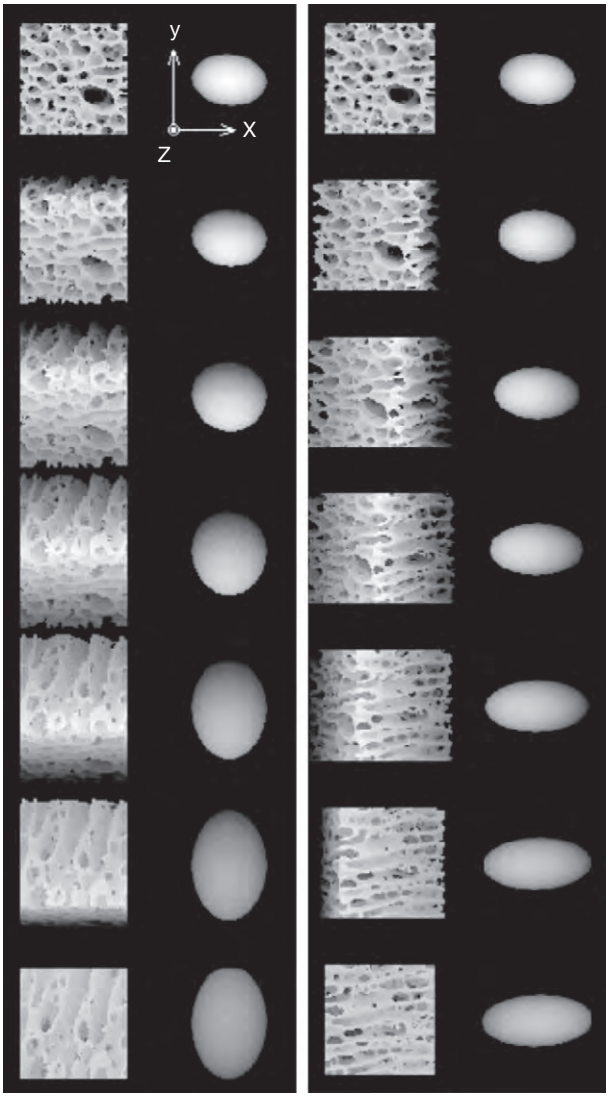


Figure 4 Volume-rendered projection magnetic resonance images of a bovine tibia specimen, along with anisotropy ellipsoid (magnified thrice). The $7 \times 7 \times 7$ mm^3 volume of interest is shown rotated in equal angular increments around (a) *x*-axis and (b) *y*-axis. The *z*-axis approximately corresponds to the anatomic long axis of the tibia. Adapted from Chung, H. W.; Wehrli, F. W.; Williams, J. L.; Wehrli, S. L. *J. Bone Miner. Res.* **1995**, *10*, 1452, with permission from Wiley.

3.323.4. Bone Water and Porosity

MRI and NMR spectroscopy have also provided detailed insight into the nature of water in the various compartments of osteonal bone.[72] Water plays a key role in bone by serving as a medium for transport of nutrients and waste products to and from osteocytes. Much of this transport is diffusion-driven

beyond the vascular conduit of the Haversian system. Moreover, water at its various locations in the matrix confers to bone its viscoelastic properties and its presence thus has important mechanical implications. Between 40 and 70% of the bone water, according to recent measurement in the author's laboratory, is bound to collagen of the osteoid, with most of the balance residing in the Haversian and Volkmann canals and a small portion occupying the osteocyte lacunae and canaliculi that interconnect osteocytes.[73] Haversian canals are 70–100 μm in diameter and thus are only resolvable *ex vivo* with μCT in small specimens.[74]

Quantification of porosity P, in particular if this were possible *in vivo* in patients, would of interest because it is inversely correlated with elastic modulus and ultimate strength. Currey found a roughly cubic relationship between YM and cortical bone volume fraction (CBVF): that is, $\mathrm{CBVF} = 1 - P$.[75] In a cadaver study, McCalden *et al.*[76] found that ultimate stress, strain, and energy absorption decreased by 5, 9, and 12% per decade, respectively, with porosity accounting for 76% of the reduction in strength. Cortical porosity increases with age,[77] particularly in women,[78] and the impaired mechanical competence is a major cause of hip fractures. The femoral neck, unlike other anatomic locations prone to fracture, has a significant portion of cortical bone. The etiology of age- and disease-related expansion of the Haversian canal system is believed to be the formation of composite osteons.[79]

We have seen in **Figure 1** that cortical and trabecular bone in MR images generally appear with background intensity. This is a consequence of the short T_2 relaxation time of bone water protons (<1 ms[6]) and the relatively low water proton density (~20%).[80] Key to capturing these signals is an imaging strategy that relies on radial sampling of the FID in conjunction with pulsed excitation[81,82] or excitation schemes that rely on frequency sweep approaches.[83]

Robson *et al.* reported images of the human midshaft tibia in which bone appears with high signal intensity, while suppressing signal from soft-tissue protons.[81] Again, we shall not be concerned with the details of the image acquisition process, for which the reader is referred to pertinent reviews of the subject.[84] The visibility of the proton bone, generally ascribed to bone water, can be further enhanced by selectively suppressing the signal from protons in soft tissue, including bone marrow and muscle, for which several strategies have been described.[81,85,86]

The large majority of the proton MRI signal detected with these techniques in cortical bone is due to water (rather than, e.g., protons in collagen or other organic matrix constituents. Evidence for this assignment stems from experiments involving heavy water (D_2O) exchange in cortical bone specimens, leading to almost complete loss of the signal[5]). More recently, Techawiboonwong *et al.* have developed a method for quantification of cortical bone water based on coimaging a sample of similar proton density and relaxation characteristics.[87,88] They ascribed the much greater bone water concentration measured at the midshaft tibia in a small group of postmenopausal women, relative to their premenopausal peers, to increased porosity in these subjects.[87]

There exist other MR-based indirect measurements of pore volume fraction, some of which allow estimation of the volume fractions of water on the basis of inverting the signal decay of either the FID (which yields T_2^*, the effective transverse relaxation time) or a Carr–Purcell–Meiboom–Gill (CPMG) spin-echo train (yielding T_2).[89,90] In the absence of exchange of water between the compartments, the signal consists of a weighted sum of exponentials

$$S(t) = \sum_i A_i \exp(-t/T_{ci}) \qquad [5]$$

where A_i and T_{ci} are the amplitude and time constant (T_2 or T_2^*) of the ith component from which a T_2 or T_2^* spectrum can be obtained via inverse Laplace transformation. Ni *et al.* recorded the CPMG decay signal at 2 MHz on a custom-built NMR system in cadaver specimens from the human femur and generated T_2 spectra.[89] They assigned the two peaks in the T_2 spectrum to water in Haversian canals and osteocytes, respectively, with the relative fractions in good agreement with data from porosimetry. For signal assignment, the authors resorted to Brownstein and Tarr's model[91] in which the T_2 relaxation rate is expressed as

$$1/T_2 = \rho(S/V) \qquad [6]$$

where ρ is the surface relaxivity and S/V the surface-to-volume ratio, based on the notion that smaller pores have larger S/V and thus the pore water greater relaxation rate. The approach described, while providing important insight into the nature of pore water, is only applicable *ex vivo*. In lieu of measuring T_2, the same methodology has more recently been practiced in order to obtain T_2^* spectra[90] by collecting the proton FID at 27 MHz and decomposing the signal, using the same inversion procedure. **Figure 5** shows the FID and relaxation spectrum from data of two donors, with three peaks centered at around 0.015, 0.15, and 200–200 ms, attributed to 'solid hydrogen,' bound water, and mobile water, respectively. The very short T_2^* protons are likely to arise from collagen backbone protons, which would be in agreement with observations in the authors' laboratory[5] the two remaining peaks have been ascribed to matrix water, presumably collagen-bound and pore water.

Fernandez *et al.* studied transport rates of water in cortical bone by analyzing the exchange of the native water in specimens of rabbit cortical bone immersed in D_2O and monitoring the temporal increase of the H_2O signal in the D_2O bath.[80] The area of the water signal is thus proportional to the amount of water diffused from bone into the D_2O bath. Since the cortical bone samples were shaped as thin plates, the H_2O–D_2O exchange is dominated by diffusion perpendicular to the sample's largest surface. If one assumes the bone to be homogeneous and the apparent diffusion coefficient to be constant, there exists an analytical solution for the relative signal amplitude[92]:

$$I(t) = I(\infty)\left[1 - \frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\exp\left(-\frac{D_a(2n+1)^2\pi^2 t}{d^2}\right)\right] \qquad [7]$$

In eqn [7], $I(t)$ and $I(\infty)$ are the integrated signal intensities at time t and at equilibrium, D_a is the apparent diffusion coefficient of water through the bone matrix, d is the specimen thickness, and t is the exchange time. For small values of t, eqn [7] can be shown to be approximated by

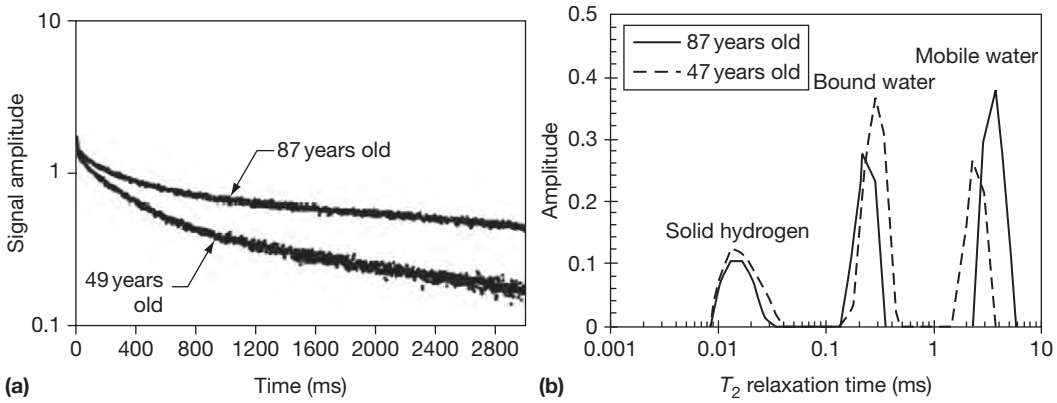

Figure 5 (a) FID signals from two specimens. (b) T_2^* relaxation spectrum in which the normalized signal intensity separated into three components. Reproduced from Nyman, J. S.; Ni, Q.; Nicolella, D. P.; Wang, X. *Bone* **2008**, *42*, 193–199, with permission, from Elsevier.

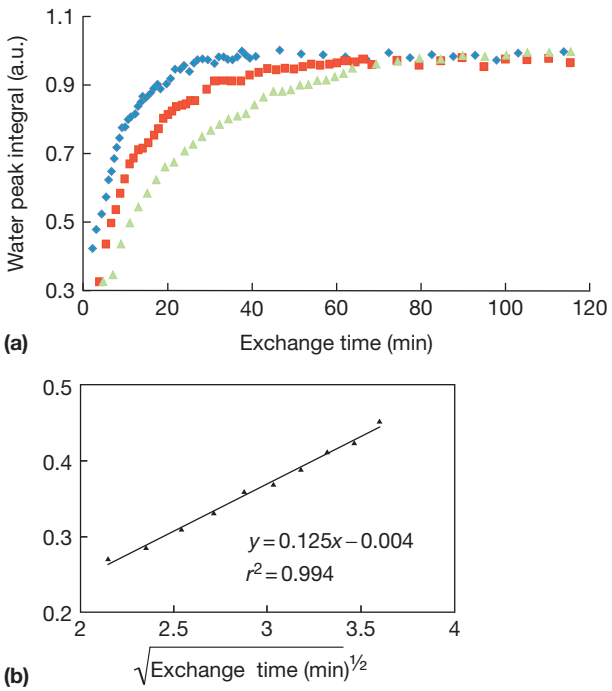

Figure 6 (a) Experimental exchange curves obtained at 25 °C (▲), 40 °C (○), and 55 °C (×) showing the temperature dependence of the diffusion rate. (b) Linear regression line obtained by fitting the 10 initial experimental data points for the data at 25 °C. The slope was used to compute D_a from eqn [8].

$$I(t) = I(\infty)\frac{4}{\pi^{1/2}}\left(\frac{D_a t}{d^2}\right)^{1/2} \quad [8]$$

The temporal evolution of the proton signal in the immersion fluid is shown in Figure 6(a). In Figure 6(b), the initial data is plotted along with a fit to the square root of the exchange time for one of the temperatures. From the apparent diffusion coefficient ($D_a = (7.8 \pm 1.5) \times 10^{-7}\,\text{cm}^2\,\text{s}^{-1}$) measured at 40 °C (i.e., near physiological temperature), the authors concluded that diffusive transport of small molecules from the bone vascular system to the osteocytes occurs within minutes, values that are in good agreement with those obtained by Tate *et al.*[93] by means of fluorescent tracers in rat bone. Finally, activation energy for water diffusion, derived from D_a measured at four different temperatures, indicated significant energy barriers to diffusion to be overcome for interactions between water molecules and matrix pores.

3.323.5. NMR Spectroscopy and MRI of Bone Matrix and Mineral

The study of bone mineral chemistry has a long history, and NMR spectroscopy has provided unique insight into this complex problem. Wet chemistry is problematic for this purpose since dissolution of the mineral into its ionic constituents provides limited information on the crystal structure of the calcium phosphates present in bone, typically regarded a non-stoichiometric calcium hydroxyapatite.

The advent of solid-state NMR with magic angle spinning, cross-polarization, and high-power proton decoupling in the 1970s[94] provided new tools to study bone mineral and synthetic phosphates by ^{31}P NMR (see, e.g., Rothwell *et al.*[95] and Wu *et al.*[96]). Rothwell *et al.* measured isotropic chemical shifts and principal components of the ^{31}P chemical shift tensors in various synthetic calcium phosphates as a means to detect these compounds in bone or enamel.[95] They found the isotropic shielding to increase upon protonation of the phosphate. Further, the chemical-shift anisotropy was found to be small for PO_4^{3-} groups, but significantly larger for HPO_4^{2-} and H_2PO^- constituents.

Even though it is known that synthetic calcium hydroxyapatite differs from bone mineral, only relatively recently spectroscopic techniques, notably infrared[97] and Raman microspectroscopy,[98] have provided detailed insight into the chemistry of bone mineral *in situ*. These techniques can provide compositional information such as the phosphate-to-amide or carbonate-to-phosphate ratio, based on the characteristic resonance bands, thereby providing information on mineralization and the nature of the anions balancing the positive charges of Ca^{2+}. But the techniques are unable to distinguish, for example, between different protonation states of the

phosphate, for instance. During the past two decades, ^{31}P and proton solid-state NMR have provided new insight into bone mineral chemistry during growth and remodeling as well as in osteoporosis.[96,99] Using a differential cross-polarization and magic angle spinning solid-state NMR spectroscopy technique, Wu *et al.* succeeded in selectively detecting minor phosphate constituents not present in synthetic Ca hydroxyapatite while suppressing the dominant orthophosphate (PO_4^{3-}) signal.[96] The ^{31}P isotropic chemical shift of this phosphate group was consistent with that of HPO_4^{2-} in octacalcium phosphate [$Ca_8(HPO_4)_2(PO_4)_4{\cdot}5H_2O$)], rather than brushite [$CaHPO_4{\cdot}2(H_2O)$]. In contrast, the bone acid phosphate anisotropic chemical shift parameters were found to be close to those of brushite, differing substantially from those in octacalcium phosphate. The authors concluded that the intimate structure of the hydrogen phosphate group in bone mineral is unique and does not match the nuclear shielding characteristics of the known synthetic calcium phosphates. Using 2D solid-state ^{1}H–^{31}P heterocorrelation NMR spectroscopy, researchers from the same laboratory determined the hydroxyl ion content in bone, variably reported previously as virtually absent, in spite of its presumed role as a constituent of the hydroxyapatite lattice.[100] In a series of elegant experiments in which the authors examined mixtures of brushite and hydroxyapatite and also of bone from various species, they identified a resonance at 0.2 ppm chemical shift, which could be unambiguously assigned to the hydroxyl moiety since in this experiment the corresponding phosphorus signal results from cross-polarization via contact with the hydroxyl proton. Figure 7 shows 2D solid-state ^{1}H–^{31}P heterocorrelation NMR spectra of synthetic apatite, showing characteristic cross-peaks assigned to the hydroxyl proton and phosphate resonances.

Matrix and mineral constituents are also amenable to imaging by proton and ^{31}P solid-state MRI techniques. One of the first reports showing the capability to obtain 3D images of bone mineral is by Wu *et al.*[101] The authors used a 3D radial projection imaging method in conjunction with nonselective rf pulses and achieved quantification of phosphorus density by relating the image intensities to those in reference samples after adjusting for relaxation times. Comparison of the results with dual-energy X-ray absorptiometry (DXA), gravimetric analysis, and chemical analysis of calcium and phosphorus demonstrated the method to be quantitatively accurate.

Among the motivations for solid-state MRI as opposed to X-ray-based densitometric techniques are absence of ionizing radiation, beam hardening, and other CT-specific artifacts. Further, the approach provides for direct measurement of a specific constituent of the mineral, thereby obviating reliance on assumptions about tissue composition. The latter is of particular importance for evaluating the two most common disorders of bone mineral homeostasis – osteoporosis and osteomalacia – which cannot be distinguished by densitometric techniques since both lead to loss of mineral, albeit via different mechanism. Osteomalacia is characterized by demineralization under volume retention, whereas in osteoporosis bone volume is lost while the bone is generally normally mineralized. However, in order to quantify true mineralization, the tissue volume needs to be known. Cao *et al.* developed and validated a solid-state ^{1}H MRI-based method in which protons from soft tissues are effectively suppressed, showing good agreement with independent measurements based on amino acid analysis and reference samples of known composition mimicking the properties of bone matrix protons.[102] Anumula *et al.* demonstrated the potential of high-field ^{31}P solid-state MRI and proton MRI in specimens of cortical bone from rabbits that had been subjected to a hypophosphatemic diet as a model for osteomalacia.[103] A second group of animals was, after induction of osteomalacia in the above manner, returned to a normophosphatemic diet for some period to evaluate whether the loss in mineralization was reversible. As expected, osteomalacia lowered phosphorus density, commensurate with a reduction in CT density and ultimate strength. However, these adverse effects on the bone's material and mechanical properties were largely reversible (Figure 8).

It is interesting that bone water (quantified in three different ways by proton–deuteron exchange NMR as described previously,[5] proton solid-state MRI, and drying) showed the

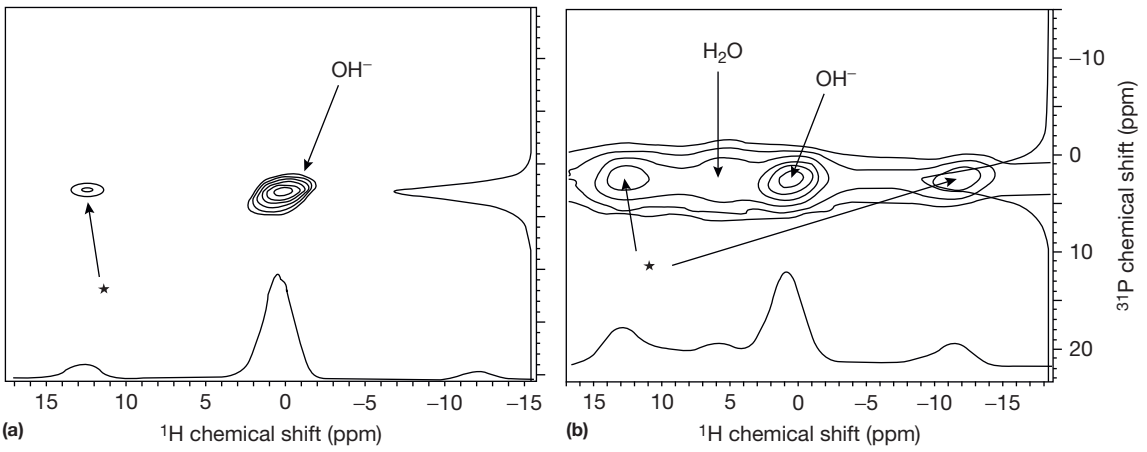

Figure 7 (a) 2D ^{1}H–^{31}P heterocorrelation NMR spectra of 95% hydroxyapatite/5% brushite at contact time = 0.3 ms. (b) Bovine cortical bone at contact time = 0.2 ms. In both spectra, a prominent hydroxyl proton cross-peak is present. A weak water peak is also observed in the bone spectrum. Peaks labeled with an asterisk are spinning sidebands. Figure 8 Volume-rendered solid-state ^{31}P (a) and ^{1}H (b) magnetic resonance images of sections of rabbit tibia at 9.4 T with reference capillary in the marrow cavity used for quantification of bone phosphorus and water content. (c) Group differences showing lower measures of bone phosphorus quantified by solid-state ^{31}P magnetic resonance imaging (wt%), ash (wt%), ultimate strength (US) in N mm^{-2}, and degree of mineralization of bone (DMB) in mg cm^{-3} in the hypophosphatemic group, measured by quantitative microcomputed tomography: HYI, hypophosphatemic animals; NOI: control group. Bars indicate means ± SD and *P* represents the statistical significance. (d) Same relationships shown for a second group of hypophosphatemic animals (HYII) after having been placed on normophosphatemic diet, again compared with age-matched controls (NOII). Modified from Anumula, S.; Magland, J.; Wehrli, S. L.; Ong, H.; Song, H. K.; Wehrli, F. W. *Bone* **2008**, *42*, 405–413, with permission from Elsevier.

reverse behavior, that is, increased water content in osteomalacic animals, commensurate with the notion that mineral and water densities are inversely related to each other.[104]

There have been several reports providing evidence that rapid bone turnover, as in ovariectomized rats or postmenopausal estrogen loss, leads to decreased mineralization density, as quantified, for example, by microradiography[105] or synchrotron micro-CT[106] and that, conversely, antiresorptive treatment increases mineral density.[105,107] In recent work from the author's laboratory, ^{31}P solid-state MRI performed in cortical bone from ovariectomized rats showed a reduction in phosphorus density by 8% relative to sham-operated animals.[72] Treatment with 25 μg kg^{-1} day^{-1} of alendronate for 50 days immediately after ovariectomy increased phosphorus density by 14% to values above those observed in sham-operated animals. Commensurate with these changes was increased bone water concentration in the ovariectomized animals and loss after alendronate treatment.

3.323.6. Summary and Conclusions

Magnetic resonance techniques, both NMR spectroscopy and MRI, are powerful tools for the study of bone architecture at multiple resolution levels, both *ex vivo* and increasingly *in vivo* in patients with degenerative and metabolic bone disorders. Recent work has shown that knowledge of trabecular structure, in terms of scale, topology, and orientation of the network, has important implications on the bone's mechanical competence independent of material density. MRI thus can provide new insight not previously amenable, and do so without exposing the subject to ionizing radiation. The technology has also proven its potential as an investigational tool to provide detailed information on mineral and matrix chemistry not amenable by other means. While much of the latter type of research has been conducted in specimens of bone, translation to human subject studies is in progress.

RRE	Rev responsive element
SLN	Sentinel lymph nodes
SPR	Surface plasmon resonance

3.324.1. Introduction

The invention of the fluorescence microscope has provided us with a powerful tool for direct viewing of dynamic protein interactions, intracellular networks, and materials transport in living cells. By labeling proteins, DNA, and other biomolecules with fluorescent tags, researchers can now track and study the behaviors of these biomolecules both *in vitro* and *in vivo*.[1] The widely used, traditional, fluorescent tags are organic dyes or genetically encoded fluorescent proteins.[2] However, their low photobleaching thresholds make them more vulnerable to light excitation.[3] To overcome these problems, fluorescent nanoparticles were introduced into the bioimaging arena and this opened a new vista in the research of biomolecular interaction and intracellular mechanics. Nanometer-sized fluorescent particles have unique functional and structural properties which distinguishes such particles from either discrete molecules or bulk materials.[4–8] For an individual fluorescent nanoparticle, the overall fluorescence signal output is proportional to the product of its fluorescence efficiency and loading density of the encapsulated dyes. As, typically, a large number of fluorophores are encapsulated inside a single nanoparticle, the nanoparticle produces a strong emission signal when properly excited. Thus, adaption of fluorescent nanoparticles is expected to overcome the weak fluorescence signal limit of the single-molecule fluorophore and therefore contribute to further developments in fluorescence imaging.

Among lots of fluorescent nanoparticles, semiconductor quantum dots (QDs), fluorescent dye-doped silica nanoparticles, metal fluorescent nanoparticles, and polymer fluorescent nanoparticles have garnered most of the research interest, from both the fundamental and technological viewpoints. The QDs

have the properties of size-tunable light emission, superior signal brightness, resistance to photobleaching, and broad absorption spectra for simultaneous excitation of multiple fluorescence colors. The fluorescent dye-doped silica nanoparticles are highly luminescent, exhibit minimal dye leaching and have excellent photostability.[9,10] The metal/metal oxide fluorescent nanoparticles combine magnetic and fluorescent properties into a single nanocrystal which enables simultaneous evaluations using magnetic resonance and fluorescence imaging techniques and thus provides more accurate diagnoses in biomedical applications.[11,12] The polymer fluorescent nanoparticles, made by polymerizing thousands of chromophores into a single nanoparticle, typically maintain their fluorescent properties, thus providing more optical features in bioimaging research.[13–19]

When conjugated with biomolecular ligands such as antibodies, peptides, DNA, and protein, these fluorescent nanoparticles can be used to trace intracellular transportation, to target tumors, monitor virus infection, and investigate biomolecular interaction. Recent advances have led to the development of many new types fluorescent nanoparticles, such as dual color fluorescent nanoparticles, photoswitchable fluorescent nanoparticles,[20,21] and magnetic fluorescent nanoparticles.[13,15,16,22] Exhibiting novel optical or magnetic properties, fluorescent nanoparticles have potential use in various applications such as high resolution imaging, bioseparation, and biosensing.[14,23,24] In this article, we will discuss recent developments in the synthesis and modification of myriad fluorescent nanocrystals, as well as their *in vitro* and *in vivo* applications in the bioimaging fields. Finally, we suggest some possible improvements to the design and construction of the fluorescent nanoparticles for future applications.

3.324.2. Fluorescent Nanoparticles: Synthesis and Surface Modification

3.324.2.1. Quantum Dots

QDs are semiconductor nanocrystals with all the three dimensions smaller than the Bohr exciton radius, within 1–10 nm, in most cases.[25–27] Typical QDs are constructed either from the elements combining from groups II and VI or groups III and V of the periodic table. In a typical semiconductor, an electron jumps from the filled valence band to the largely empty conduction band upon excitation, resulting in a positive vacancy 'hole' in the valence band. The photoluminescence of QDs originates from the radiative recombination of an excited electron–hole pair. The spatial separation (Bohr radius) of such an electron–hole pair, namely, the exciton, is typically in the range of 1–10 nm. The quantum confinement occurs when one of the dimensions of the semiconductor nanocrystals falls into the same range as that of the Bohr exciton radius, and therefore, leads to a finite band gap and discrete energy levels. QDs have many desired photophysical and electronic properties including good photostability, high quantum yield, and size-tunable photoluminescence ranging from visible to near-infrared (NIR) with narrow Gaussian emission profiles. Specifically, the past two decades have witnessed a great advancement in using QDs for biological applications ranging from immunoassays to cell and tissue imaging,[28–42] ever since Nie[43] and Alivisatos[44] reported their pioneering research in using QDs as fluorescence probes for biological imaging.

After the pioneering work of QD synthesis in the early 1980s,[45,46] great efforts have been invested in the synthesis of high quality fluorescent QDs.[47–61] In the earlier stages, QDs were mainly synthesized in an aqueous environment using stabilizing agents. For instance, a reverse micelle (w/o microemulsion)-based strategy was employed for the synthesis of the QDs.[62–65] QDs prepared using such a strategy usually displayed broad size distributions and poor fluorescence quantum yields. By introducing a high-temperature (~300 °C) organmetallic procedure, Bawendi and coworkers made a revolutionary breakthrough in 1993. In this procedure, high-quality QDs were synthesized by rapidly injecting the organometallic precursors into a hot coordinating organic solvent, which caused organmetallic reagents to undergo pyrolysis.[47] The presence of semiconductor-binding agents or surfactants enabled kinetic control of crystal growth, and consequently, helped maintain their size within the nanoscale.

For biological applications, QD synthesis typically involves four sequential steps. In the first step a QD core like CdSe is synthesized. In a typical protocol, an organometallic precursor containing cadmium is rapidly injected into a hot and vigorously stirred organic solution containing the other selenium precursor and ligands that bind to the QD surfaces. After the formation of nanocrystal nuclei at a high temperature (~300 °C), a large amount of solution is injected into the reaction to cool the reaction system and to stop nucleation. Next, an Ostwald ripening process takes place and the remaining precursors grow on the existing nuclei at a lower temperature. Once the QDs have reached the desired diameter, cooling the reaction system to ambient temperature stops the growth process. Second, the shell of another semiconductor is grown on the QD core to passivate the surface defects of the core by providing electronic insulation, and consequently, enhancing the photoluminescence efficiency.[46,47] An epitaxial growth strategy is usually involved in core–shell structures. Specifically, it is possible to make QDs with the same size but with different emission wavelengths by tuning their core sizes and shell thickness. The QDs formed using aliphatic coordinating ligands are soluble only in nonpolar organic solvents because they have hydrophobic alkyl monolayer caps their surfaces. Thus, the challenge has been to make these hydrophobic QDs water-dispersible for biological applications. Third, phase transfer of QDs from the organic solvent to an aqueous environment, using either ligand exchange or amphiphilic polymeric encapsulation, was required. The ligand exchange strategy replaced hydrophobic capping with an amphiphilic ligand, QDs thus having one functional group anchored at the shell and another hydrophilic group enabling water dispersibility.[43,44] The disadvantage of such a strategy is that the transformed QDs commonly display a decrease in luminescence quantum yield and are more vulnerable to aggregation and precipitation in biological buffers. As an alternative, encapsulation circumvented the aforementioned problems by retaining the native structure of the QDs while simultaneously adding amphiphilic polymers like polyethylene glycols (PEG), silica, or hydrophilic groups, thiol (–SH), carboxyl (–COOH), and amine (–NH_2) groups.[66–73] **Figure 1** depicts a surface modification and a bioconjugation, respectively.

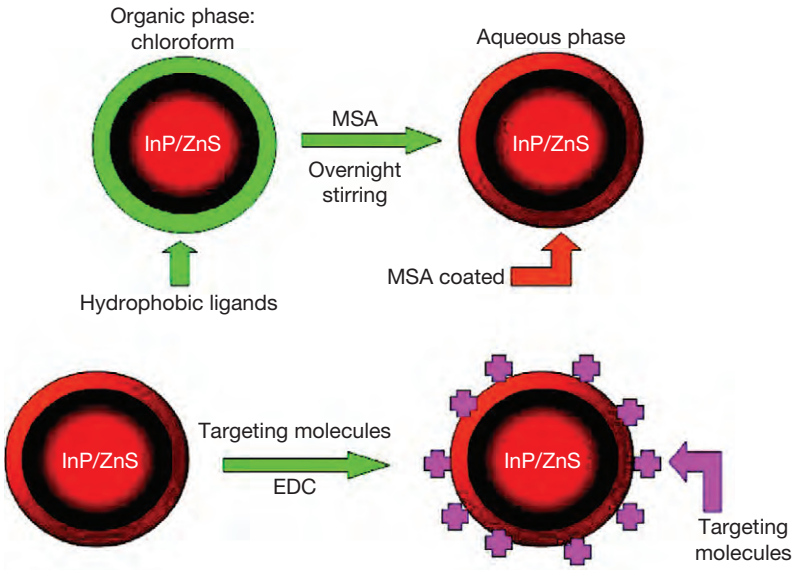

Figure 1 Schematic illustration shows the surface modification and bioconjugation of InP/ZnS quantum dots. MSA mercaptosuccinic acid, EDC 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride. 3.324.2.2. Fluorescent Silica Nanoparticles

Organic fluorescent dyes that are employed in biological labeling, suffer from rapid photobleaching and poor photostability. A strategy to overcome these problems is to incorporate multiple organic fluorophores into metal oxide-based scaffolds or hybrid siloxane-oxide networks which effectively protect the fluorophore dyes from environmental oxygen, and thereby, provide enhanced photostability. Among the various host matrices, silica is advantageous because it is biocompatible,[74] optically transparent,[75] and can be easily doped with functional organic moieties.[76] Additionally, dye-containing fluorescent silica nanoparticles contain a large number of dye molecules inside the silica matrix and therefore have greatly enhanced luminosity when compared to single-molecule fluorophores.[77] Also, encapsulation of fluorophores within silica matrices allows surface modification of the shell to enhance their hydrophilic character and cell uptake.[78–81] Therefore, silica is widely used to design hybrid organic–inorganic materials for various biological and medical applications.[82,83]

Traditionally, fluorescent dyes are incorporated into silica nanoparticles either by simple doping or by covalent attachment. In the doping strategy,[78,79,84–88] the fluorescent dyes are first solubilized within the core of the microemulsion and then trapped in the silica matrix during polymerization. In the absence of any covalent attachment, the dye molecules may leach out of the nanoparticles over time, consequently increasing the background signal and leading to cytotoxicity in some biological applications. In the covalent incorporation strategy, however, the fluorescent components are chemically bonded to the silica network.[89–92] This method effectively avoids any dye leaking during subsequent biological labeling. Subsequently, the silica nanoparticle surfaces can be modified using either amine ($-NH_2$) or carboxyl (–COOH) moieties. In most cases, such surface modification is done using a functional silane reagent, such as 3-(aminopropyl) triethoxysilane, during the condensation process, as shown in Figure 2.

3.324.2.3. Metallic Fluorescent Nanoparticles

Nanoparticles made from conventional noble metals such as gold and silver, usually do not fluoresce. These nanoparticles, however, are used in biological imaging as colorimetric contrast agents, induced by surface plasmon resonance (SPR) or as metal-nanostructures enhancing fluorescence (MEF). SPR contributes to bioimaging and biosensing by providing frequency dependent light absorption, which collectively originates from the electric field-induced oscillation of the conduction electrons at the surface of nanoparticles.[93,94] MEF, however, enhances the fluorescence of the fluorophores between the metallic nanoparticles.[95–98]

Nanoparticles containing rare-earth metals have been increasingly involved in biological applications for their unique optical properties, like for instance, upconversion luminescence and lower toxicity compared to QDs.[99–109] Many strategies were developed to construct rare-earth-metal-containing nanoparticles. The solvothermal approach was generally employed to synthesize such nanoparticles.[100–107] For instance, Xu and coworkers synthesized $NaYF_4$:Yb, Er nanoparticles using this method and subsequently constructed core–shell nanoparticles by coating $NaYF_4$:Yb, Er nanoparticles with a silica shell using the Stöber method.[103] In these composite nanoparticles, Yb^{3+} ions act as sensitizers that absorb NIR excitation light and Er^{3+} ions act as activators that emit upconversion luminescence with atomic-transition characteristics. Nanoparticles with similar structures and properties have also been synthesized by Zhang and coworkers.[105,106] Highly luminescent Eu^{3+} chelate nanoparticles with an alkyl alkoxysilane coating were synthesized by McNeill's group using the

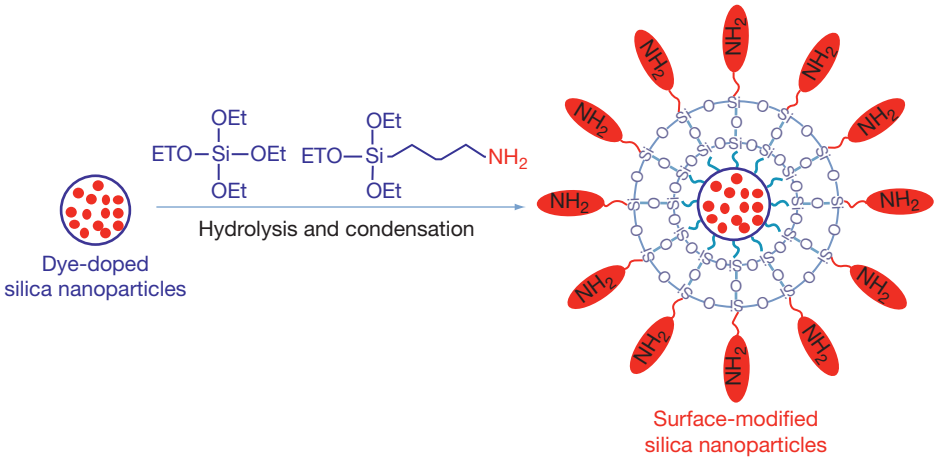

Figure 2 Schematic illustration shows the surface modification of dye-doped silica nanoparticles to result in dye-doped silica nanoparticles with shell containing primary amine groups for bioconjugation.

reprecipitation-encapsulation method.[108] In addition, rare-earth-metal-containing nanoparticles with different host materials were also synthesized by other groups. For example, a strategy based on the continuous supercritical water hydrothermal synthesis was applied by Lester's group[109] and Eu^{3+} doped ZrO_2 fluorescent nanoparticles were synthesized; and lanthanide-doped $NaYF_4^-$ PMMA (poly(methyl methacrylate)) composite nanoparticles were synthesized in Veggel's group via a situ polymerization approach.[110] Many strategies have been developed for the surface modification of these rare-earth nanoparticles, as shown in **Figure 3**.

3.324.2.4. Polymer Fluorescent Nanoparticles

Polymer fluorescent nanoparticles have also attracted considerable interest in diverse biological applications such as bioimaging and biosensing. For instance, fluorescent polystyrene nanoparticles were employed as probes to monitor the oxygen level in the brain and thus study the correlation between oxygen concentration and blood–brain barrier permeability to extravasated nanoparticles.[111]

Various strategies have been developed to synthesize polymer fluorescent nanoparticles. The commonly used strategy involves loading fluorescent components, for example, in most cases, organic fluorescent dyes, into an optically inactive polymer matrix, either by simple entrapment or by covalent linkage. Specifically, the microemulsion polymerization technique was used. Microemulsions are thermodynamically stable, transparent, or translucent equilibrium phases that contain immiscible liquids such as oil and water stabilized by a surfactant. Ranging from 10 to 100 nm in size, single-microemulsion droplets act as the microreactors for polymerization and polymer nanoparticles with sizes in the same range are synthesized.[112] For instance, Kopelman and coworkers[113,114] developed a strategy to fabricate spherical optical nanosensors by entrapping fluorescent indicators within the poly (acrylamide) nanoparticle matrix during microemulsion polymerization. By entrapping different fluorescent dyes, the resultant nanoparticles could be used as indicators to analyze pH, oxygen, and calcium concentration in living cells. Applying a similar strategy, Wu and coworkers[115] synthesized copolymer fluorescent nanoparticles with noncovalently embedded fluorescein dyes.

Nanoparticles with noncovalently encapsulated dyes carry the risk of the dye leaching out in biological applications. Thus, strategies that employed covalent linkage were preferred. Using a slightly modified microemulsion copolymerization method, Li and coworkers[13–16,116] synthesized core–shell fluorescent nanoparticles with fluorescent components that were covalently bonded to the core of the polymer nanoparticles, which significantly circumvented the problem of dye leaching and demonstrated excellent photostability. Additionally, these nanoparticles displayed greatly enhanced fluorescence brightness as compared to the molecularly dispersed solution sample because of their unique hydrophobic–hydrophilic core–shell structure. Another noteworthy advantage of such copolymerization over the other strategies is that the copolymer composition and sequence can be easily tuned. As a result, the surface properties of the final nanoparticles, for example, the nonspecific interactions with biological targets, could be largely controlled.[13] With a similar strategy, fluorescent polymer nanoparticles were also synthesized by other groups.[117–121] Besides the microemulsion polymerization approach, an atmospheric pressure plasma polymerization (APPP) technique was also developed to synthesize fluorescent polypyrrole nanoparticles by Yang and coworkers.[122] Many π-conjugated polymers are known to possess high extinction coefficients and high fluorescence quantum yields, making them feasible candidates for fluorescent nanoparticles. Such fluorescent nanoparticles primarily containing pi-conjugated polymers were synthesized in Masuhara's and McNeill's groups via a modified reprecipitation strategy.[123,124] Specifically, these fluorescent nanoparticles displayed high brightness in biological imaging applications. Surface –COOH groups on the polymer nanoparticles enabled convenient bioconjugation. For instance, Li and coworkers[13,14] synthesized photoswitchable fluorescent polymer nanoparticles and decorated their surfaces with the HMGA1 (high mobility group A1) protein and subsequently performed live cell fluorescence imaging.

3.324.3. Fluorescent Nanoparticles: *In Vitro* Applications

3.324.3.1. Replacing Fluorescent Dye in Cell Labeling and Imaging

Many superior properties make fluorescent nanoparticles good candidates for use in cellular labeling and imaging. For example, QDs have many advantages. The dye-doped nanoparticles also have high quantum yields and high molar extinction coefficients along with good resistance to both chemical and photodegradation. At the same time, the dimensions of the fluorescent nanoparticles are approximately three orders of magnitude smaller than that of the cell, and are thus small enough to stain the cells evenly.

Wu *et al.* used QDs linked to immunoglobulin G (IgG) and streptavidin to label the breast cancer marker Her2 on the surface of fixed and live cancer cells, to stain actin and microtubule fibers in the cytoplasm, and to detect nuclear antigens inside the nucleus.[125] They found that all labeling signals were specific for the intended targets and that the signals were brighter and considerably more photostable than comparable organic dyes. Lin *et al.*[126] evaluated the performance of different QDs in labeling mouse embryonic stem (ES) cells. They found that ES cell viability, proliferation, and differentiation were not adversely affected by QDs, and QD 800 offered the greatest fluorescent intensity compared to the other QDs tested.

Furthermore, the QDs were effective for simultaneously visualizing multiple proteins and nucleic acids in fixed tissues or cells. Compared to organic dyes, QDs have an attractive property – broad absorption spectra that gradually extend from the visible region to the ultraviolet region,

and the spectral positions of absorption and emission are tunable by particle size. Thus a light of single wavelength can excite different QDs, producing multiplex imaging. Sweeney *et al.*[127] used different QDs conjugated to biotinylated primary antibodies, thus enabling simultaneous multiplex staining of three proteins, CD34, Cytokeratin 18, and cleaved Caspase 3, in tonsillar tissue. This method enabled rapid measurement of multiple colocalized biomarkers on a single paraffin tissue section and was very useful in clinical trial studies. Smith *et al.*[128] used QD conjugates and molecular beacons to simultaneously detect the levels of expression of multiple biomarkers in tumor cells and tissue. Their multiplex imaging strategies provided important information that correlated the level of mRNA expression and the subsequent level of protein production for a given biomarker in the same sample.

The dye-doped nanoparticles have also been used for cell staining. He *et al.*[129] reported a method for staining HepG liver cancer cells using dye-doped fluorescent silica nanoparticles covalently linked to anti-human liver cancer monoclonal antibody HAb18. They observed that the bioassay, based on the dye-doped nanoparticles, could identify the target cells selectively and efficiently and that fluorescent nanoparticle labeling exhibited much higher photostability compared to traditional fluorescent dyes. In another paper, Santra *et al.*[130] applied dye-doped fluorescent silica nanoparticles successfully to stain human leukemia cells. The advantage of using dye-doped nanoparticles in the above papers was that many dye molecules were incorporated into one nanoparticle, hence the nanoparticle was much brighter and more photostable than a single dye. As the dye molecules were doped inside the protective silica network, the surrounding environment could not affect their emission properties. Thus dye-doped nanoparticles have very good optical properties compared to individual dyes.

3.324.3.2. Imaging and Tracking Endocytosis

Endocytosis is one of the most important functions of cells by which cells absorb molecules from the surrounding environment. Endocytosis intimately regulates many processes, including nutrient uptake, receptor signaling, pathogen entry, neurotransmission, cell growth and differentiation, and drug delivery. Research on endocytosis has been a hot topic since the invention of the fluorescence microscope.

QDs are the most frequently used fluorescent nanoparticles during endocytosis imaging. Functionalized by biomolecules, QDs can be endocytosed by many types of cells. Cambi *et al.*[131] exploited ligand-conjugated QDs to monitor antigen binding, its entry and trafficking in living dendritic cells (DCs). They demonstrated that DCs internalized virus-sized, ligand-conjugated QDs via clathrin-dependent endocytosis and the that internalized QDs could be detected inside living cells even after prolonged (up to 48 h) incubations. In this case, the biomolecule was covalently bound to the QDs.

Similarly, Lidke *et al.*[132] used biotinylated epidermal growth factor (EGF), complexed to commercial streptavidin QDs, to bind and activate the EGF receptor on CHO and A431 cells. They found that EGF-QDs were rapidly internalized into endosomes that exhibited active trafficking and extensive fusion. Through continuous monitoring of the moving EGF-QDs by confocal microscopy, they documented a previously unreported retrograde transport of the EGF-QDs from the filopodia to the cell body. Their results also demonstrated that noncovalently bound biomolecules on QDs still maintained their biological function; thus the QD-ligands should find widespread use in basic research and biotechnological applications.

The retrograde transport of nerve growth factor (NGF) was also observed in differentiated neurite-like PC12 cells using streptavidin-QDs coupled to monobiotin-NGF.[133] Due to the photostability and brightness of QDs, Echarte *et al.* were able to perform real-time analysis of the trafficking of individual QD–bNGF–receptor complexes within neurites. Their quantitative single particle tracking revealed a bidirectional step-like motion along the microtubules during endocytotic precession.

In addition to imaging endocytosis, QDs have also been used in the search to identify and localize proteins needed for endocytosis. Ogunkoya *et al.*[134] used quantum immune-electron microscopy to localize clathrin, the key protein in clathrin-mediated endocytosis, in a human adrenal cortical cell line SW-13. Their results demonstrated that the images obtained with QDs were much better than those obtained using traditional immunocytochemical light microscopic techniques, thus allowing accurate and specific localization of clathrin and the clathrin adaptor protein, AP-2, within cellular organelles.

The dye-doped fluorescent nanoparticles have also been used to monitor the endocytosis pathway. Xing *et al.*[135] have investigated the uptake of rhodamine 6G isothiocyanate (RITC)-doped silica-coated nanoparticles by HeLa cells. Their results indicated that the uptake of silica-coated nanoparticles by HeLa cells was a concentration-, time-, and energy-dependent, endocytic process. The silica-coated nanoparticles could be transported into HeLa cells partially through adsorptive endocytosis and partially through fluid-phase endocytosis.

Most recently, Li's group have applied the polymer fluorescent nanoparticles in endocytosis research.[13,136] Functionalized by high mobility group proteins A (HMGA protein), dual color or photoswitchable fluorescent nanoparticles were used to acquire images of cell endocytosis. Using confocal live-cell microscopy, they monitored the entire endocytic process in which the internalized HMGA1a-decorated nanoparticles were transported by motor proteins on microtubules and eventually arrived at the late endosomes/lysosomes (**Figure 4**).

3.324.3.3. Analyzing Biomolecular Interactions

Recent advances in single-molecule detection and nanotechnology hold exciting promises for *in vitro* biomolecular interaction analyses. The typical use of fluorescence nanoparticles in such studies is based on a technology named Forster resonance energy transfer (FRET), which is an interchromophore relaxation process that transmits the electronic excitation from an initially excited donor to a ground-state, acceptor fluorophore. FRET can be used to detect the proximity between two fluorophores separated by distances of 1–10 nm, thus allowing a study of the interactions of two or more fluorescent-nanoparticle-labeled biomolecules *in vitro*, even at the single-molecule level.

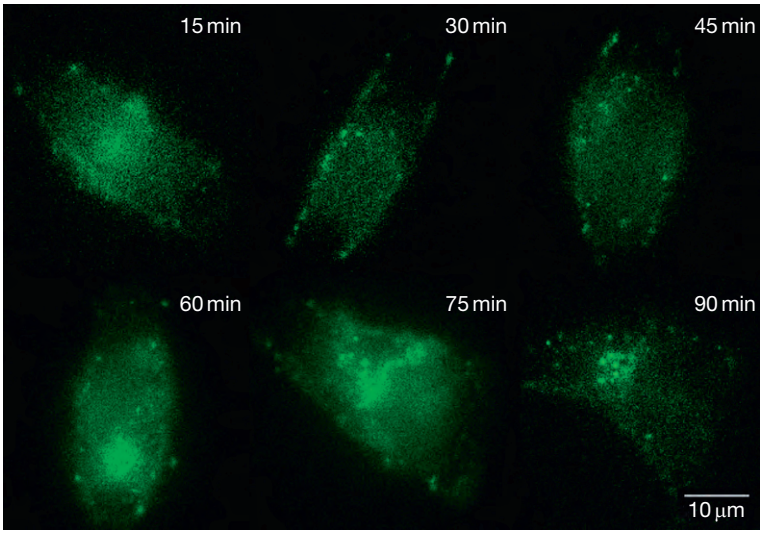

Figure 4 High mobility group AT-hook 1a (HMGA1a)-dual color fluorescent nanoparticles endocytic time trajectories. HMGA-functionalized nanoparticles and Hela cells were incubated together in DMEM medium. The cells were continuously cultured up to 90 min and every 15 min, a plate of cells was fixed and imaged using a 488-nm laser and representative images revealed HMGA-dual color nanoparticles inside the cell endosomes (green spots). Reprinted from Wu, W.; Wan, W.; Li, A. D. *J. Cell Biochem.* **2009**, *108*, 791–201, with permission from John Wiley and Sons.

One example of using fluorescent nanoparticles to investigate biomolecular interactions is the research on H(+)-ATPsynthases. The H(+)-ATPsynthase consists of a hydrophilic F1 part with subunits a3b3cde and a hydrophobic membrane integrated F0 part with subunits ab2c10. The whole H(+)-ATPsynthase couples transmembrane proton transport through the F0 subunit with ATP synthesis and hydrolysis within the F1 subunit. The coupling is occurs by the rotation of the rotor (subunits cec10) relative to the stator subunits a3b3dab2. When ATP molecules are produced, the relative positions of these subunits change. Galvez *et al.*[137] used QDs to label the subunits of the H(+)-ATPsynthases and studied the interactions of different subunits in real time. Using single-molecule spectroscopy and single-pair FRET analyses, they demonstrated the presence of three different conformations of the enzyme. Their results showed that the high photostability and brightness of the QDs allowed longer observation times of the same molecule compared to traditional dye labeling. Importantly, they showed that long observation time is the key to monitoring enzyme dynamics.

Zhang *et al.*[138] used QDs as the labeling tags to study protein–RNA interactions at the single-molecule level. Rev protein is an important HIV regulatory protein, which binds to the RRE (Rev responsive element) sequence in the RNA genome of the virus and is critical for HIV-1 replication. The sequence-specific binding between RRE RNA–Rev provides a useful *in vitro* system for evaluating the inhibitory effect of drugs on the RRE–Rev interactions in real time. In their experiments, the biotinylated RRE IIB RNA was linked to commercial streptavidin-coated QDs, the dye-labeled Rev peptide was added to the system and peptide–RNA interactions were monitored at the single-molecule level using FRET analyses. The authors demonstrated that the stoichiometry of Rev peptide binding to RRE could be accurately determined using the single-QD-based system. This system could sensitively quantify the inhibitory efficacy of proflavin (an anti-HIV drug) on Rev peptide–RRE binding, even in the presence of substantial levels of fluorescence interference from high concentrations of proflavin.

Hybridization is one of the most frequently used techniques to study biomolecular interactions. Both genome and proteome researchers use hybridization as a tool, and both protein–protein and DNA–DNA interaction assays have now been developed to the high throughput level. Many microarray products based on hybridization technology are available to study gene variation or protein expression levels *in vitro*. The signal read-out from the microarrays often suffers from photobleaching, low brightness, and background fluorescence. Fluorescent nanoparticles may prove to be an alternative to organic dyes that are used in microarray experiments.

Wu *et al.* have reported a microarray technology, based on RuDS dye-encapsulated silica nanoparticle labeling, to sensitively immuno-detect interleukin-6 (IL-6) protein *in vitro*.[139] The protein-modified nanoparticles with high fluorescence intensity, photostability, and biocompatibility were highly specific for IL-6, even in the presence of a range of cytokines or proteins, thus showing interesting promise for clinical diagnosis.

QDs have also been used in the microarray experiments. Ghazani *et al.*[140] used QDs to immuno-stain the membrane epidermal growth factor receptor (EGFR), pan cytokeratin, and E-cadherin on the tissue microarray. They found the quantitative analysis of tissue microarray using the QD-based immunoprofiling of proteins enabled accurate measurements of the tumor-derived antigen and delineated expression profiles of archival cancer tissue specimen. Goldman *et al.*[141] utilized streptavidin-coated QDs to visualize the protein toxins, which were immobilized in a galactoside polyacrylate hydrogel in a microarray format. And myriad examples have demonstrated that QDs are excellent candidates to increase the sensitivity of microarrays.[142–146]

3.324.3.4. Fluorescent Nanoparticles as a Biosensor

In the field of biosensing, fluorescence-based detection is one of the most common methods used because of its high sensitivity, simplicity, and diversity. Very recently, fluorescent nanoparticles have begun to replace traditional organic dyes as the sensing component in biosensor design. Fluorescent nanoparticles offer superior optical properties, such as brighter fluorescence, wider selections of excitation and emission wavelengths, higher photostability, and size- or shape-controlled optical characteristics.

Most fluorescent nanoparticle biosensors are based on FRET and the fluorescent nanoparticles usually serve as either the donor or acceptor, or both. In a typical sensor, the fluorescent nanoparticle is linked to biomolecules (protein, peptide, DNA, or RNA) and is quenched by another dye or particle. When the sensor meets its target, the target will interact with the biomolecules, break the link between the fluorescent nanoparticle and its quencher, thus releasing the fluorescent nanoparticle, which recovers its strong fluorescent signal.

Shi *et al.*[147] have developed a QD-based FRET probe which could be used to quantitatively sense trypsin and enable screening of trypsin inhibitors. This FRET-based probe used QDs as a donor and rhodamine as an acceptor; the rhodamine dye was immobilized onto the QD surface through peptide linkers. When trypsin was present in the solution, the probe would light up due to the enzymatic cleavage of the peptides and release of the rhodamine dye molecules from the surface of the QDs. Zhang *et al.*[148] have developed another single-QD-based aptameric sensor that was capable of detecting the presence of cocaine using both signal-off and signal-on modes. They functionalized the surface of QDs with aptamers, which could recognize cocaine. The FRET between 605QD and Cy5 and Iowa Black RQ sensed the binding of the cocaine to the aptamer and enabled detection of cocaine.

QDs of different colors can be simultaneously excited by one wavelength. This property allows multiple QD-mounted biosensors to be used to simultaneously and independently sense different targets in the same sample. Suzuki *et al.* have described a FRET-based QD bioprobe which was able to detect the actions of a protease, a deoxyribonuclease, a DNA polymerase, or changes in pH. Such QD bioprobes allow multiplex detection of the action of trypsin in the presence of a deoxyribonuclease[149] (**Figure 5**).

Ramadurai *et al.*[150] have also developed a nanosensor based on FRET between fluorescent QDs and organic quencher molecules, which could be used for the multiplex detection of biological antigens in solution. This multiplex detection could be accomplished by using several different sizes of QDs, with each QD of a given size labeled with an antibody for a different antigen. Their results demonstrated that QD-based nanosensors could detect several antigens simultaneously with high specificity and sensitivity almost in real time.

The dye-doped silica nanoparticles are also good candidate biosensors for bioanalyses. Tapec *et al.*[151] have made different kinds of biosensors using dye-doped silica nanoparticles. For example, avidin-coated nanoparticles were used to determine biotinylated bovine serum albumin, and glutamate dehydrogenase-coated nanoparticles were used as biosensors to measure glutamate.

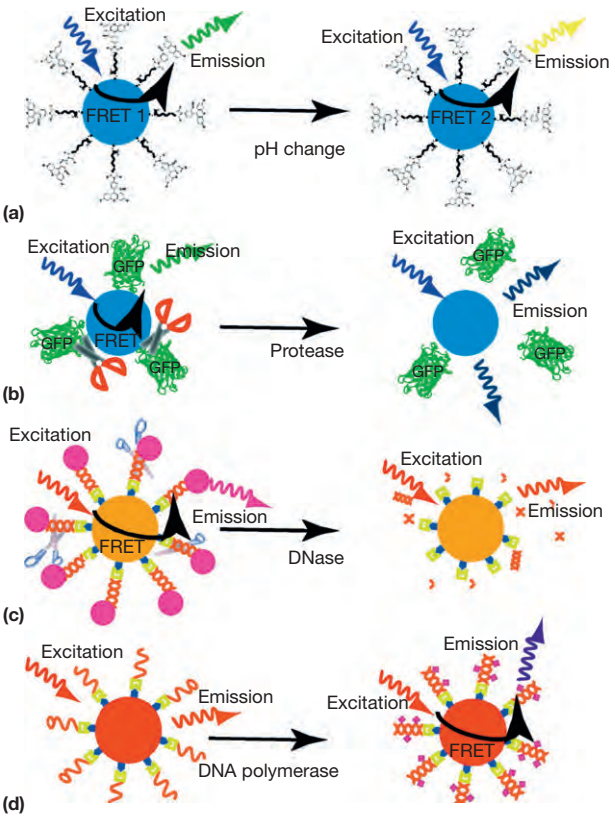

Figure 5 Forster resonance energy transfer (FRET)-based quantum dot (QD) bioprobes designed to give FRET changes upon (from top to bottom): (a) pH change via pH-sensing dyes attached to a QD; (b) cleavage of a green fluorescent protein (GFP) variant with an inserted sequence recognized by a protease (e.g., trypsin) to release GFP from the QD surface; (c) digestion of dsDNA by DNase (labeled with fluorescent dUTP) bound to a QD; (d) incorporation of fluorescently labeled dUTPs into ssDNA on a QD by extension with DNA polymerase. Reprinted from Suzuki, M.; Husimi, Y.; Komatsu, H.; Suzuki, K.; Douglas, K. T. *J. Am. Chem. Soc.* **2008**, *130*, 5720–5725, with permission from American Chemical Society.

Peng *et al.*[152] have made a pH sensor based on two-fluorophore-doped nanoparticles for noninvasive monitoring of intracellular pH changes induced by drug stimulation. This pH sensor contains a pH-sensitive indicator (fluorescein isothiocyanate, FITC) and a reference dye (tris(2,2′-bipyridyl) dichlororuthenium(II) hexahydrate, RuBPY). This sensor was used to monitor pH changes in living HeLa cells upon drug stimulation and was found to have excellent quantification, with high stability and excellent reversibility in the intracellular pH measurements. Doussineau *et al.*[153] have also used two-dye-doped silica nanoparticles for ratiometric pH measurements in the biologically relevant pH range. However, their sensors used a rhodamine derivative embedded in a silica core as the reference dye and a pH-sensitive naphthalimide dye immobilized on the amino-functionalized core as the sensing element.

Hong *et al.*[154] have developed some sensors for cardiac markers using nano-metallic fluorescent particles. In selected biocompatible solvents, the sensitivity of the nano-metallic fluorescent particles was improved because of enhancement

effects. Using those fluorescence enhancing nano-metallic particle reagents, they simultaneously quantified four cardiac markers in plasma with a very high signal-to-noise ratio.

3.324.4. Fluorescent Nanoparticles: *In Vivo* Applications

3.324.4.1. *In Vivo* Tumor Imaging

Tumor imaging is one of the hottest areas in bioimaging. Tumor cells have a lot of surface antigens, which are different from the normal cells and these serve as the targets in tumor imaging. Imaging tumor cells *in vivo* requires labeling the sensing agents such as dyes and nanoparticles with biomolecules that can specifically bind the tumor targets, thus detecting the tumor site effectively. Many different methods can be used to image live tumor cells such as X-ray imaging, positron emission tomography (PET), magnetic resonance imaging (MRI), and fluorescence imaging. With the development of highly fluorescent nanoparticles, *in vivo* fluorescent imaging of tumor cells has become easy, and some multifunctional fluorescent nanoparticles can even be used in multimodal imaging. For example, the metal fluorescent nanoparticles can be used for both MRI and fluorescent imaging.[155]

Due to their excellent optical and electronic properties, QDs are the most popular probes used in tumor imaging. Gao *et al.*[68] designed an ABC triblock copolymer-coated QD for *in vivo* imaging of growing human prostate cancer cells in nude mice. They conjugated the QDs with monoclonal antibody against the prostate-specific membrane antigen (PSMA). By injecting these QD-tagged cancer cells or antibody-QD probes into a live animal, they have achieved sensitive and multicolor fluorescent imaging of cancer cells *in vivo*.

Smith *et al.* have reported the use of peptide-conjugated QDs for noninvasive imaging of tumor vasculature markers in small animal models. The arginine–glycine–aspartic acid (RGD) peptides, which specifically bind to the newly formed/forming blood vessels in tumor tissues, were used as the target group to functionalize QDs in their experiments. Using intravital microscopy, they obtained a subcellular-resolution image of the tumor blood vessels in living subjects.[156] Cai *et al.*[157] have also used the RGD peptide-labeled QDs to image tumor blood vessels *in vivo*. The QDs used were QD705-RGD, a near-infraredQD. Their experiments showed that QD705-RGD had great potential as a universal NIR probe for detecting tumor vasculature in most cancer types *in vivo*. In another paper, they described the detailed procedure for the preparation of such peptide-conjugated QDs using commercially available PEG-coated QDs and RGD peptides.[158]

The use of polymer fluorescent nanoparticles is another newly developed area in tumor imaging. Hun *et al.*[159] have reported the use of polymer fluorescent nanoparticles (PFNPs), which were synthesized by precipitation polymerization using methacrylic acid (MAA) as the monomer, trimethylolpropane trimethacrylate (Trim) as the cross-linker, azobisisobutyronitrile (AIBN) as the radical initiator, and butyl rhodamine B (BTRB) as the fluorescent dye. These PFNPs were functionalized with anti-Her-2 monoclonal antibody and were used to detect ovarian cancer cells by fluorescence microscopy imaging *in vivo*. Their results demonstrated that the anti-Her-2 monoclonal antibody-conjugated PFNPs could effectively recognize ovarian cancer cells and that they exhibit good sensitivity and exceptional photostability.

Dye-doped silica nanoparticles can also be used in tumor imaging. Qian *et al.*[160] have synthesized a Nile Red-doped silica nanoparticle and conjugated it to apo-transferrin to target live HeLa cells. They further coconjugated the nanoparticles with PEG, which would improve the long *in vivo* circulation of these nanoparticles.

3.324.4.2. *In Vivo* Tracking of Cell Migration in Living Animal

In live animals, some cells will not stick to one place; instead they move around to execute their biological functions. Imaging such cells requires a strong and highly stable signaling tag. The recently developed fluorescent nanoparticles which are usually more stable and photobleach-resistant than organic dyes, are the latest tools used to track cell movements *in vivo*.

Noh *et al.*[161] have reported the use of near-infrared QDs for noninvasive, *in vivo*, tracking of DC migration into lymph nodes. DCs are phagocytic cells which play a key role in initiating the adaptive immune response. When DCs meet the antigen in circulation, they are activated and migrate to the lymph nodes where they present the antigen to the T cells. The ability to track their movements *in vivo* enables an exploration of their function and a better understanding of the immune system. Noh *et al.* found that labeling of the DCs with QDs had no effect on DC phenotype and migratory capacity, thus enabling the tracking of the QD-labeled DC movements, *in vivo*, using NIR fluorescence. Sen *et al.* have also used QDs to image DC behavior *in vitro* and *in vivo*. They found that when antigen-conjugated QDs were used, T cells formed stable clusters when in contact with DCs. Following subcutaneous injection of QDs in an adjuvant depot, DCs that had endocytosed QDs were visualized up to a depth of 400 μm within the draining lymph nodes.[162] Their results established the QDs as a versatile platform for immunoimaging of DCs and as an efficient nanoparticle-based antigen delivery system for priming an immune response.

During embryonic development, many cells migrate to new places to form different organs. The tracking and imaging of these cells are hot topics in development biology. Slotkin *et al.* have labeled the neural stem and progenitor cells (NSPCs) with QDs, and then monitored their behavior in early mammalian embryonic development.[163] Their results showed that the labeled NSPCs continued to develop in an apparently normal manner, implying that QDs could be effectively used to label mammalian NSPCs and to image their migration and differentiation during mammalian development *in vivo*.

Imaging the tumor cell migration may assist in the development of effective anti-cancer therapies. Labeling the tumor cells with fluorescent nanoparticles enables the observer to follow cells at high resolution in live animals. Voura *et al.*[164] have labeled tumor cells with QDs, intravenously injected the QDs into mice, and acquired images of QD migration into lung tissue. Their results showed that the behavior of QD-labeled tumor cells, *in vivo*, was indistinguishable from that of unlabeled cells, and that the QD fluorescent imaging allowed simultaneous identification of five different populations of cells using multiphoton laser excitation.

3.324.4.3. *In Vivo* Imaging of Cardiovascular and Lymphatic Systems

The cardiovascular and lymphatic systems are major components of the circulatory system in the human body. The cardiovascular system distributes blood while the lymphatic system distributes lymph. Both are hot topics in bioimaging research because they are very dynamic and are difficult to monitor *in vivo*. Many human diseases are related to cardiovascular and lymphatic systems. Cardiovascular disease is one of the leading causes of death in the world, and early accurate diagnosis of cardiovascular disease is crucial in saving lives. There are many cardiac muscle-specific biomarkers in the blood that can be targeted by functionalized fluorescent nanoparticles. The optical imaging of those markers *in vivo* may help in making a more accurate diagnosis of cardiovascular disease.

Ravnic *et al.*[165] used fluorescent nanoparticles as intravascular tracers to image the intravascular flow field in blood circulation *in vivo*. They modified the surface of the fluorescent nanoparticles to maximize plasma half-life as well as to minimize interactions with other blood components. Subsequent intravital imaging of the microcirculation demonstrated that the fluorescence nanoparticles could provide an accurate description of the localized intravascular flow field over time and space.

Jayagopal *et al.*[166] used QD-antibody bioconjugates (QD-mAb), which targeted to the cell adhesion molecules (CAMs) PECAM-1, ICAM-1, and VCAM-1 on the retinal endothelium, to image a rat model of diabetes *in vivo*. They incorporated PEG cross-linkers and Fc-shielding mAb fragments on to the surface of QDs to increase *in vivo* circulation times and targeting efficiency. They also imaged the circulating and adherent leukocyte subsets in live rats using QD-mAb targeted to RP-1 and CD45. After *in vivo* imaging, they examined the retinal whole mounts of the rat and confirmed the fluorescence patterns observed *in vivo*. Their results demonstrated that QDs are promising fluorescent tags that can specifically label vascular cells and be used to perform *in vivo* cardiovascular imaging.

The lymphatic system transports immune cells to and from the lymph nodes. In addition, the presence of lymph node metastases is an important prognostic marker in many types of tumors. Hence imaging lymphatic system *in vivo* can help in understanding the mechanisms of metastases and developing early diagnostic methods for cancer detection.

Soltesz *et al.*[167] used NIR fluorescent QDs as optimal lymphotrophic optical probes to image draining lymphatic channels and nodes in large animals, *in vivo*. They injected NIR QDs into the lobar parenchyma of 12 Yorkshire pigs (mean weight 35 kg) to get accurate maps of lymphatic drainage and sentinel lymph nodes (SLN). Their results showed that all SLNs were strongly fluorescent and could be easily visualized within 5 minutes of injection. Histological analyses confirmed that the fluorescent QDs and nodal tissue coexist, demonstrating that QDs were good noninvasive imaging tools, which provided real-time visual feedback for image-guided localization and resection.

Kobayashi *et al.*[168] used five QDs with similar physical sizes but different emission spectra to perform multicolor imaging of lymphatic system via direct interstitial injection. They simultaneously injected different QDs intracutaneously into five different sites in a mouse and monitored lymphatic drainages in the neck and in the upper trunk, *in vivo*. Their results showed that all major drainage trunks of the lymphatics in the upper body of the mouse could be depicted separately on five color images, indicating that such simultaneous visualization using nanoparticle-based technology could be very useful in predicting the route of cancer metastasis into the lymph nodes (**Figure 6**).

More recently, some multifunction polymer fluorescent nanoparticles, based on the dendrimer platform, were also used to image the lymphatic system *in vivo*. Mounzer *et al.* have developed a bimodal (fluorescence and MR) nanoparticulate composed of a polyamidoamine dendrimer core conjugated to paramagnetic contrast agents and fluorescent probes. They used this new bimodal nanoparticle to image the lymphatic vessels and lymph nodes by both fluorescence imaging and MRI.[169] The new bimodal nanoparticles provided much higher resolution and a clearer delineation of both lymph nodes and lymphatic vessels compared to traditional visualization methods. In another paper, Kobayashi *et al.* have also synthesized multimodal and multicolor nanoparticles based on the polyamidoamine dendrimer platform which are linked to both radionuclides and optical probes.[170] They used these nanoparticles to image the lymphatic system and obtained a dual-modality scintigraphic and spectrally resolved five-color NIR optical image via multiple excitation.

3.324.5. Future Perspective

Fluorescent nanoparticles are becoming the probes of choice for both *in vitro* and *in vivo* bioimaging. As fluorescent nanoparticles have strong signal strength, are resistant to photobleaching, and can be conjugated to biomolecules, they are being used more and more frequently to replace the traditional organic dyes. However, many issues still have to be addressed before these particles can be used to their full potential in practical biomedical and clinical diagnosis applications. In our opinion, further efforts should be focused on several key issues in the future. First of all, nanoprobes with smaller size are more suitable for labeling and detection of subcellular components or intracellular measurements, and for tagging a particular protein or studies on a group of proteins in an assembly. Thus, developing methods for constructing fluorescent nanoparticles with smaller sizes deserves special attention. Secondly, design and development of biocompatible fluorescent nanoparticles to overcome nonspecific binding and to facilitate their subsequent attachment to biological targets is highly desirable. Therefore, further efforts are needed to develop nanoprobes with 'smart' surfaces highly specific to target tissue that can interact minimally with the surrounding tissue. In addition, optimizing the size, shape, and surface chemistry of fluorescent nanoparticles is needed so that future nanoparticles can avoid nonspecific organ uptake or scavenging in the reticuloendothelial system in live animals. Thirdly, fluorescent nanoparticles with multiple signaling features are also desirable for highly accurate detection of complicated targets. Combinations of multiple modalities can yield complementary information and offer synergistic advantages over a single modality nanoparticles. For example, a single

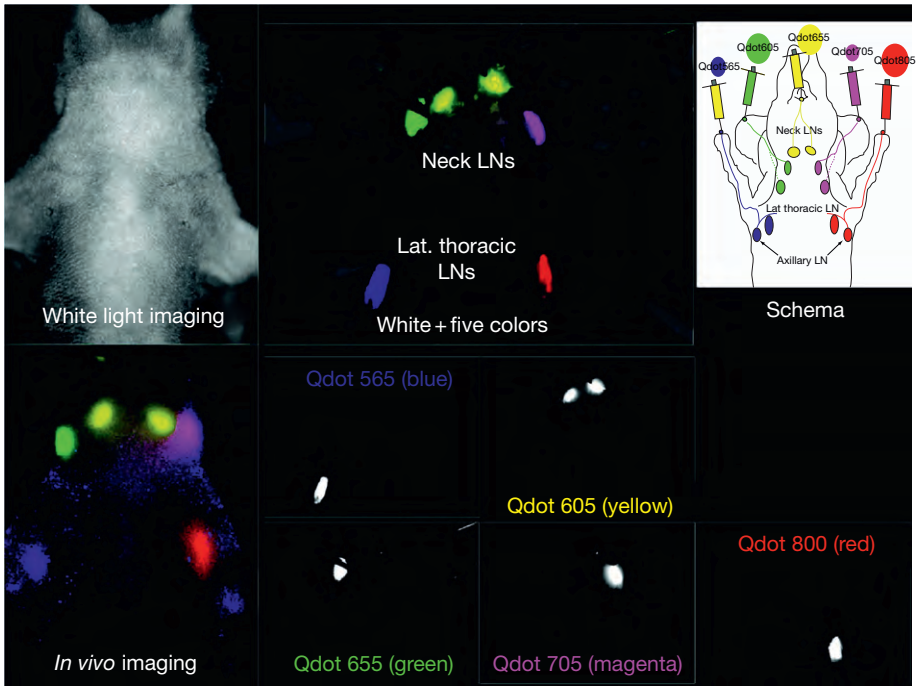

Figure 6 *In vivo* and intrasurgical spectral fluorescence imaging of a mouse injected with five carboxyl quantum dots (565, blue; 605, green; 655, yellow; 705, magenta; 800, red) intracutaneously into the middle digits of the bilateral upper extremities, the bilateral ears, and at the median chin. Five primary draining lymph nodes were simultaneously visualized with different colors through the skin in the *in vivo* image. Reprinted from Kobayashi, H.; Hama, Y.; Koyama, Y.; *et al. Nano Lett.* **2007**, *7*, 1711–1716, with permission from American Chemical Society.

nanoprobe possessing both fluorescence and magnetic properties will be a more powerful practical application because these two signal modes will complement each other, even though individually, each has its own strengths and weaknesses.[171] In summary, nanoparticles appear to have a bright future in imaging applications in both laboratory and clinical use.

Glossary

Annulus fibrosus The outer segment of the spinal disc.
Compact bone The inner segment of the spinal disc.
Nucleus pulposus The inner segment of the spinal disc.
Trabecular bone The porous inner region of the bone.

Abbreviations

BMD	Bone mineral density
CSI	Chemical shift imaging
CT	X-ray computed tomography
DCE	Dynamic contrast-enhanced
DDD	Degenerative disc disease
DQF, MQF, TQF	Double, multiple, triple quantum filtered
DWI	Diffusion-weighted imaging
EFG	Electric field gradient
HAp	Hydroxyapatite
MR	Magnetic resonance
MRI	Magnetic resonance imaging
MRS	Magnetic resonance spectroscopy
NMR	Nuclear magnetic resonance
SE	Spin echo
SNR	Signal-to-noise ratio
SQ, DQ, TQ	Single, double, triple quantum
SSNMR	Solid-state nuclear magnetic resonance
TWI	Tensor-weighted imaging

Symbols

B_0	External magnetic field
B_1	Applied magnetic field
d	Dipolar coupling constant
D	Diffusion constant
e	Electronic charge
G_x, G_y, G_z	Magnetic field gradients along the x, y, and z axes
h	Planck constant
$\hbar$	Planck constant divided by 2π
$\hat{H}_\sigma$	Magnetic shielding Hamiltonian
$\hat{H}_{DD}$	Direct dipole Hamiltonian
$\hat{H}_J$	Indirect spin–spin Hamiltonian
$\hat{H}_Q$	Quadrupolar Hamiltonian
$\hat{H}_{RF}$	Applied RF Hamiltonian
$\hat{H}_Z$	Zeeman Hamiltonian
I	Nuclear spin quantum number
I, S	Nuclear spin operator
I_Z	Azimuthal spin-angular momentum operator
J_{IS}	Isotropic spin–spin coupling constant
k	Reciprocal space vector
M_0	Initial magnetization
m_I	Magnetic quantum number
M_{xy}	Magnetization in the xy-plane of the laboratory frame
M_z	Magnetization along the z-axis of the laboratory frame
Q	Nuclear quadrupole moment
r_{IS}	Distance between spin I and S
t	Time
T_1	Longitudinal relaxation time
$T_{1\rho}$	Longitudinal relaxation time in the rotating frame
T_2	Transverse relaxation time
$T_{2\rho}$	Transverse relaxation time in the rotating frame
T_E	Echo time
T_R	Repetition time
V	Electric field gradient tensor
x, y, z	Cartesian coordinates
Δ	Time between two gradient pulses in a diffusion experiment
Θ	Angles that relate the direction of B_0 with respect to the principal axis system of the shielding tensor
γ	Magnetogyric ratio
δ_{iso}	Isotropic chemical shift
δ	Duration of the gradient pulses in a diffusion experiment
μ_0	Permeability of vacuum
ν_L	Larmor frequency
$\rho(r)$	Spin density as a function of position
σ_{iso}	Isotropic magnetic shielding
σ_{zz}	zz component of the shielding tensor
τ	Mixing time
τ_{max}	Time at which signal intensity in the DQF experiment is maximum

3.326.1. Introduction

Modern materials are changing the world of medicine. Metal, ceramic, polymer, hydrogel, and nanocomposite materials are all finding new applications to treat injuries and diseases. As these materials are developed and used, it is important to employ characterization techniques that probe the chemical changes that occur because of disease and the use of biomaterials in treatment. Magnetic resonance (MR) techniques, both nuclear magnetic resonance (NMR) spectroscopy and magnetic resonance imaging (MRI), are powerful methods for studying molecular level properties and therefore have the potential to be useful probes of the biochemical interactions between the body and biomaterials. Many MR phenomena have already found utility in clinical medicine. In particular, ^{1}H MRI techniques can provide contrast related to spin density, relaxation parameters (e.g., T_1- and T_2-weighted images), susceptibility changes (e.g., blood-oxygen-level-dependent contrast in functional MRI), flow, and diffusion. However, to fully exploit the potential of MR in novel and more specific ways, it is vital that researchers developing new techniques have a familiarity with the selection of biological markers that can be used for diagnosis, treatment, and monitoring a patient's response to treatment.[1]

The first important task when applying existing or developing new MR methods is to select the biological molecules that best characterize the changes caused by disease or treatment. Important criteria for selecting appropriate biological molecules are the presence of an element with an isotope that is amenable to MR studies and a molecule that is in high enough concentration that it can be detected with MR techniques. In conventional medical MRI, water is studied due to the ideal NMR properties of ^{1}H in water; however, other nuclei such as ^{23}Na or ^{31}P can be used as they also have favorable NMR properties. Finally, MR provides researchers a plethora of experimental methodologies that can be employed to measure a range of magnetic and chemical properties. In conventional ^{1}H MRI experiments that rely on water to provide the MR signal, proton density, and T_1 and T_2 relaxation properties are commonly probed. When developing new methods, other relaxation mechanisms (e.g., in the rotating frame), or nuclear spin interactions such as magnetic shielding (i.e., chemical shifts) or quadrupolar couplings, may provide more meaningful information, even for water.

The goal of this chapter is to illustrate how a deeper understanding of the fundamentals of MR, biochemistry, and biomaterial science can open up new methods for elucidating the biochemical implications of disease and biomaterial treatments. In this chapter, we define a biological marker as the molecule, the nuclear isotope used in the MR experiment, and the NMR property being probed, which in combination can be correlated to a disease, injury, or treatment response. By broadening the definition to include experimental techniques in addition to the molecules, the same molecule can be used as a biological marker to probe different biochemistries. The focus is on markers present in the body and not on those introduced specifically for imaging purposes such as contrast agents or MR tags. This chapter initially describes the basic concepts of MR and the properties that can be measured using NMR spectroscopy and imaging. Different biological markers will then be highlighted to illustrate how the choice of molecule, nucleus, and experiment is an important aspect of selecting the marker. Finally, we focus on two disease case studies where biomaterials are playing increasingly important roles and demonstrate how different biological markers are being used in imaging and diagnosis.

3.326.2. Principles of MR and the Implications for Imaging and Diagnosis

This section introduces basic concepts in MR, including fundamental theory, measurable interactions, pulse sequences, and experimental methodologies based on MR. Applications of these concepts to imaging and diagnosis of biomarkers are outlined.

3.326.2.1. The MR Interactions

NMR is a very sensitive probe of local molecular and electronic environment. In addition to the fundamental Zeeman interaction, the resonance frequencies, the shape of the resonance, and the relaxation times of an MR signal are related to the interaction of nuclear spins with each other, local and applied magnetic fields, electric field gradients (EFGs), and coupling to the surroundings. The energies of interaction for a spin system determine the resonance frequencies, and the total energy can be described by a Hamiltonian, $\hat{H}$:

$$\hat{H} = \hat{H}_Z + \hat{H}_Q + \hat{H}_{RF} + \hat{H}_{DD} + \hat{H}_\sigma + \hat{H}_J \qquad [1]$$

where the Zeeman interaction $\hat{H}_Z$ is the largest (MHz), followed by the quadrupole interaction $\hat{H}_Q$ (kHz to MHz), $\hat{H}_{RF}$ (kHz) which describes the coupling of the spins to the external applied radiofrequency (RF) field, the direct dipole–dipole coupling $\hat{H}_{DD}$ (kHz), the magnetic shielding $\hat{H}_\sigma$ (Hz to kHz), and the indirect dipole–dipole coupling $\hat{H}_J$ (Hz). Exploiting these interactions, NMR spectroscopy has long been recognized as a powerful tool for identification of molecular species and elucidation of molecular structure.[2] Herein, we describe briefly key information that can be obtained via characterization of each interaction, and the reader is referred to the literature for a complete description of the interaction Hamiltonians.[3–6]

3.326.2.1.1. The Zeeman interaction

The MR response relies on the fundamental interaction of a magnetic field with the magnetic dipole moment associated with the orbital angular momentum of a nucleus.[7] Many atomic nuclei possess half-integer or integer spin-angular momentum, $\mathbf{I}\hbar$, colinear with a magnetic dipole moment, $\mu = \gamma\mathbf{I}\hbar$, where γ is the magnetogyric ratio and $\hbar$ is the Planck constant h divided by 2π. As shown in eqn [2], the Zeeman Hamiltonian describes the energy of interaction of $\mathbf{I}\hbar$, with an external magnetic field, $\mathbf{B}_0$,

$$\hat{H}_Z = -\gamma\mathbf{I}\hbar\mathbf{B}_0 \qquad [2]$$

Typically, only the largest component of the $\mathbf{B}_0$ column vector (B_x, B_y, B_z) is considered, which defines the z-axis of the laboratory frame of reference, $\mathbf{B}_0 = (0, 0, B_0)$.

A proton (^{1}H) possesses a magnetic dipole moment and has a half-integer nuclear spin, $I = 1/2$. In the presence of an external magnetic field, the magnetic dipole moment aligns either parallel or antiparallel to the direction of B_0. As shown in Figure 1(a), different energies are obtained for the two possible projections with respect to the applied magnetic field, and correspond to the nondegenerate nuclear spin eigenstates: $m_I = 1/2$ (parallel) and $m_I = -1/2$ (antiparallel). The diagrams in Figure 1(b) and 1(c) illustrate the Zeeman splitting that results for a species with $I = 1$ (e.g., ^{2}H) and with $I = 3/2$ (e.g., ^{23}Na), respectively. Tables of nuclear spin properties are available.[8] The frequency corresponding to the difference in energy between adjacent states, ΔE, is defined by the Larmor equation:

$$\nu_L = \frac{|\gamma|B_0}{2\pi} = \frac{\Delta E}{h} \qquad [3]$$

where ν_L is referred to as the Larmor frequency. Transitions between energy levels with a change in magnetic quantum number equal to one (i.e., $m_I = 1/2 \rightarrow m_I = -1/2$) are called single-quantum (SQ) coherences, and are directly observable. Also, as shown in Figure 1(b) and 1(c), for nuclei with $I > 1/2$, coherences exist at multiples of the resonance frequency and are labeled on the basis of the order of the coherence, for example, double quantum (DQ), triple quantum (TQ), and so on. Both eqns [2] and [3] show the magnetic-field-dependent nature of the NMR frequency. The Larmor frequencies of nuclei in commercial superconducting MR magnets are on the order of 10^8 Hz, or in the RF range.

3.326.2.1.2. Quadrupole interaction

An NMR active nucleus with $I > 1/2$ possesses an asymmetric charge distribution, which gives rise to a quadrupole moment, Q. The quadrupole moment couples to the surrounding EFG, and therefore, the resultant interaction can provide valuable insight regarding electronic structure in the region around the nucleus. Rapid isotropic motion (e.g., solutes in solution, or liquids) leads to an averaging of the quadrupole coupling tensor to a value of 0; the EFG is properly described by a traceless second-rank tensor. When the Zeeman interaction dominates the total interaction Hamiltonian, the quadrupolar Hamiltonian can be written as shown in eqn [4]:

$$\hat{H}_Q = \frac{eQ}{6I(2I-1)\hbar}\mathbf{IVI} \qquad [4]$$

where e is the elementary charge and $\mathbf{V}$ is the traceless EFG tensor. The most common quadrupolar nuclei used for biological applications are ^{2}H ($I = 1$) and ^{23}Na ($I = 3/2$) (see Section 3.326.3).

3.326.2.1.3. Interaction with an applied RF field

Pulsed RF fields are used to apply an oscillating magnetic field, B_1, at the Larmor frequency and perpendicular to B_0. The net magnetization vector, M, of a sample is subject to a torque due to B_1, which causes M to rotate about the axis along which B_1 is applied. The angle of rotation of M is determined by the amplitude and duration of B_1. The amplitude of B_1 (on the order of kHz) typically dominates other interactions except for the Zeeman and quadrupole interactions. RF fields can be used to access information regarding slower NMR relaxation process (i.e., on the order of kHz rather than MHz) due to processes such as molecular tumbling and exchange (see Section 3.326.2.3.2). The interaction Hamiltonian for B_1 is analogous to that shown in eqn [2] for the Zeeman interaction.

3.326.2.1.4. Direct dipole–dipole interaction

One of the large interactions between nuclei is the mutual through-space coupling of their magnetic dipole moments. In solution, the dipole–dipole interaction is averaged to zero. In the absence of isotropic molecular tumbling, the perturbation of the energy levels, on the order of tens to hundreds of kilohertz, can impart a significant and measurable influence on the NMR signal, and is typically the dominating mechanism for relaxation. The magnitude of the interaction is given by the dipolar coupling constant, d, as shown in eqn [5]:

$$d = -\left(\frac{\mu_0}{4\pi}\right)\frac{\gamma_I\gamma_S\hbar}{r_{IS}^3} \qquad [5]$$

where r is the distance between the point-magnetic dipoles. The manifestation of the dipole–dipole coupling in the NMR signal is orientation-dependent, related to the angle between B_0 and the vector joining the coupled spins.

3.326.2.1.5. Magnetic shielding interaction

The ubiquity of NMR spectroscopy for molecular species identification and structural characterization finds its origin in the sensitivity of the measured frequency to chemical environment. The magnetic shielding interaction gives rise to perturbations of the energy levels which yield frequency shifts related to

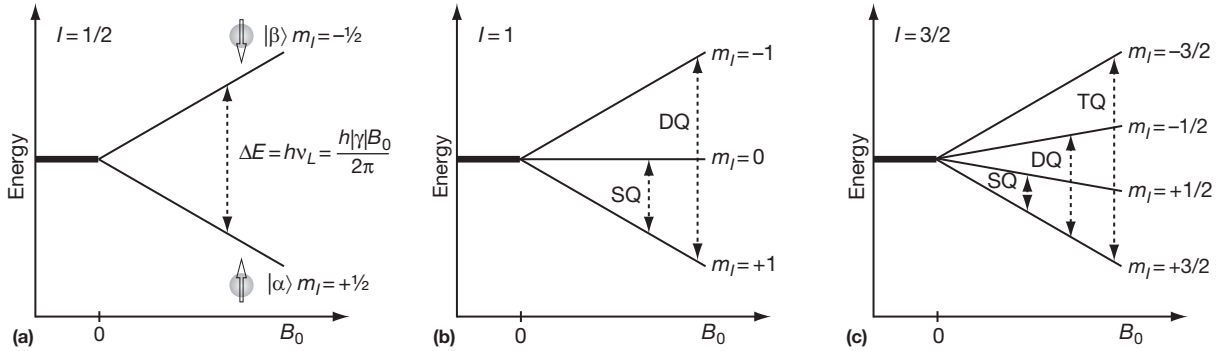

Figure 1 Zeeman energy levels demonstrating the separation of the nondegenerate nuclear spin eigenstates as a function of applied magnetic field, B_0 for (a) a nucleus with $I = 1/2$, (b) $I = 1$, and (c) $I = 3/2$, where SQ, DQ, and TQ are single, double, and triple quantum transitions, respectively.

the specific electronic (and chemical) environment of a nucleus. The interaction Hamiltonian for a spin I in the laboratory frame is described by eqn [6]:

$$\hat{H}_\sigma = -\gamma\hbar B_0\sigma_{iso}\hat{I}_z - \frac{1}{2}\left(3\cos^2\Theta - 1\right)(\sigma_{zz} - \sigma_{iso})\gamma\hbar B_0\hat{I}_z \quad [6]$$

where σ_{iso} is the isotropic shielding value, equal to one-third the trace of the second-rank magnetic shielding tensor, $(\sigma_{zz} - \sigma_{iso})$ is the anisotropic shielding value, and Θ is the angle between B_0 and the principal axis system of the shielding tensor. The angular dependence can be removed by setting Θ to the so-called magic angle ($\sim$54.7°) such that $3\cos^2\Theta = 1$. This technique is often employed in solid-state NMR where samples are spun rapidly (i.e., on the order of kHz) at the magic angle to reduce line-broadening caused by the anisotropic magnetic shielding, quadrupolar, and direct dipolar interactions. In solution, molecular tumbling eliminates the second term in eqn [6] leaving the isotropic shielding value. In practice, magnetic shielding is normalized by measuring the difference in frequency between the sample and a reference Larmor frequency for that nucleus, creating a so-called chemical shift scale which is reported in parts per million and is independent of the applied magnetic field.

3.326.2.1.6. Indirect spin–spin coupling

The indirect spin–spin coupling (also known as scalar or J-coupling) is an interaction between nuclear moments mediated by electrons participating in chemical bonds between the nuclei. The energy of interaction results in small perturbations to the frequency on the order of hertz, ranging from 1 to 10 Hz for homonuclear ^{1}H couplings to hundreds or thousands of hertz for heteronuclear cases involving heavy atoms. Unlike the direct dipolar interaction, J-coupling does not average to zero under conditions of molecular tumbling. This results in a perturbation of the NMR spectrum which is independent of molecular orientation. For an isotropic liquid, the interaction Hamiltonian (in units of Hz) is given by eqn [7]:

$$\hat{H}_J = 2\pi J_{IS}\mathbf{IS} \quad [7]$$

where J_{IS} is the isotropic spin–spin coupling constant, equal to one-third the trace of the J-coupling tensor. For NMR of dilute solutions, J-coupling can provide critical information for analyzing molecular structure, confirmation, and connectivity.

3.326.2.2. Basics of MR Pulse Sequences

3.326.2.2.1. Creating and detecting the MR response

The MR signal generated by an ensemble of nuclei is governed by Boltzmann statistics, which determines the relative populations of the nuclear spin eigenstates. In thermal equilibrium, the net magnetization vector of a sample under study is oriented with the external applied magnetic field and is often denoted M_0. To detect an MR signal, M_0 must be reoriented from the large external applied field. An oscillating magnetic field, B_1, is applied transverse to the z-axis, with frequency that matches ν_L, generally termed an RF pulse. The duration and amplitude of the B_1 field together determine the extent to which the net magnetization vector rotates about the B_1 field away from the z-axis. **Figure 2** shows a schematic of a spin-echo (SE) sequence where the first pulse rotates M_0 by 90°. This orients the magnetization vector along the plane transverse to the external applied field and is often denoted $M_{x,y}$. $M_{x,y}$ continues to precess at the Larmor frequency, creating a detectable signal, called the free-induction decay (FID), the amplitude and phase of which are measured as a function of time. This is the MR signal.

3.326.2.3. Relaxation in MR

NMR relaxation is a general term that is used to describe the phenomena of either the recovery of M_0 or the decay of $M_{x,y}$. The time that is required for the magnetic moments of an ensemble of spins in random orientation to align with an applied magnetic field depends on many variables including material density and molecular motion (e.g., solid, liquid, mobile), and applied field strength. Similarly, the components of $M_{x,y}$ 'dephase' or lose coherence, and the detectable response decays.

3.326.2.3.1. Longitudinal and transverse relaxation

At thermal equilibrium, M_0 is in the direction of B_0 along the z-axis. Application of an RF pulse that rotates the magnetization away from the z-axis and into the x,y plane disturbs the

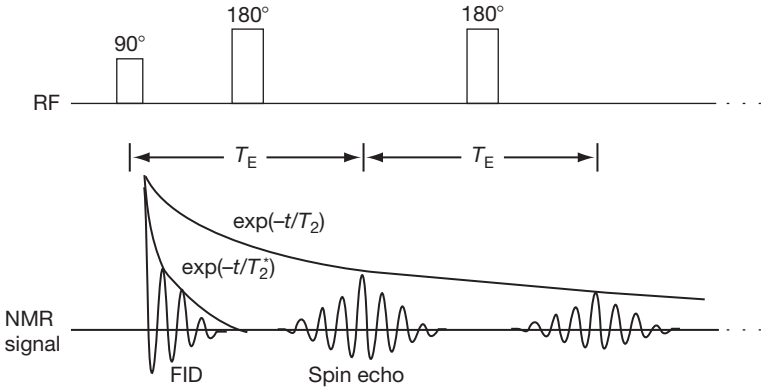

Figure 2 An example of a basic multi spin-echo sequence. The decay of the free-induction decay (FID) can be described as a monoexponential function of characteristic time T_2^*, and the decay of the spin-echo envelop by the spin–spin relaxation time, T_2. The echo time, T_E, is the time between the RF pulse and the peak of the spin-echo.

equilibrium of the spin system. Over time, the equilibrium will be restored, and the magnetization along the z-axis at time t, $M_z(t)$ can be described using the classical equation of motion derived by Bloch, eqn [8][9]:

$$M_z(t) - M_0 = [M_z(0) - M_0] \exp\left(-\frac{t}{T_1}\right) \qquad [8]$$

where $M_z(0)$ is the magnetization remaining along the z-axis after the RF pulse and T_1 is the first-order time constant that describes the recovery of M_0 after the RF pulse. This time constant is generally referred to as the spin-lattice or longitudinal relaxation time. As described by the monoexponential dependence, during a period T_1, approximately 63% of the original equilibrium magnetization recovers, after $3T_1$ approximately 95% recovers, and essentially complete relaxation occurs after $5T_1$. Thus, the number of times that M_z can be tipped (e.g., to signal average) in a particular time period (often called the repetition time, T_R) without saturating the signal is related to T_1 (i.e., a delay of several seconds may be required to reach $M_z = M_0$).

Once the magnetization vector is rotated away from B_0, and into the transverse plane (i.e., $M_z \rightarrow M_{x,y}$), $M_{x,y}$ will decay due to inhomogeneous and random homogeneous interactions and result in no net transverse magnetization. The decay of the FID can typically be described by a monoexponential function with a characteristic time constant $T_2{}^*$ (see **Figure 2**). For molecules in solution, this relaxation process and the transverse magnetization at time t, $M_{x,y}(t)$, can generally be treated using the theory of Bloembergen, Purcell, and Pound[10] and described by eqn [9]:

$$M_{x,y}(t) = M_{x,y}(0) \exp\left(-\frac{t}{T_2}\right) \qquad [9]$$

where $M_{x,y}(0)$ is the transverse magnetization immediately following the RF pulse and T_2 is the spin–spin or transverse relaxation time. In general, $T_2 \leq T_1$. Aqueous or semisolid systems containing water with a homogeneous composition, in the absence of paramagnetic materials, tend to exhibit ^{1}H T_2 values on the order of 10^{-1} s or longer.

In the presence of static magnetic field inhomogeneity, SE-based techniques are often used. After the initial RF pulse to tip the magnetization into the transverse plane, a RF refocusing pulse can be applied to flip $M_{x,y}$ in the transverse plane (i.e., rotate by 180°). This rotation of the magnetization reverses the direction of inhomogeneous dephasing, and results in the formation of an SE. A train of appropriate RF refocusing pulses will yield a series of SEs, the decay envelope of which can be described by a monoexponential function of T_2 (**Figure 2**). This method, referred to as the Carr–Purcell–Meiboom–Gill (CPMG) experiment, is often used to measure T_2.[11,12]

3.326.2.3.2. Rotating frame relaxation

The NMR relaxation processes discussed above require magnetic field fluctuations on the order of megahertz, which often correlates well with molecular tumbling. As originally described by Ailion and Slichter, slower relaxation processes can be probed by measuring the relaxation of the magnetization vector in the transverse plane during application of the B_1 field, which is typically on the order of kilohertz.[13] After an initial 90° RF pulse is applied to place the magnetization in the transverse plane, the phase of the RF pulse is changed so that it is aligned with the transverse magnetization. This technique is called a spin-lock; the transverse magnetization is unable to precess away from this axis for the duration of the spin-lock pulse, and the magnetization decays approximately exponentially. Repeating the procedure for several values of the spin-locking time provides a series of FIDs with a characteristic decay time, denoted $T_{1\rho}$, the spin-lattice relaxation time constant in the rotating frame. In practice, the spin-lock is implemented as a composite pulse termed a rotary-echo to compensate for B_1 inhomogeneity.[14]

Recent developments in spectrometer hardware have facilitated the implementation and application of amplitude and phase-modulated pulses in modern imaging and spectroscopy techniques.[15] Much research has been completed to understand relaxation processes that occur during the application of adiabatic pulses,[16] and to obtain novel contrast in MRI related to tissue pathology.[17,18] Application of an adiabatic full passage (AFP) RF pulse with appropriate parameters such that the sample magnetization vector remains aligned with the applied field will provide $T_{1\rho}$ relaxation contrast. $T_{1\rho}$ contrast is sensitive to water–protein interactions, and research shows that this may be an indicator of neuronal loss in some neurological disorders and of cartilage degeneration.[19,20] If the magnetization vector is placed in the transverse plane prior to application of the AFP RF pulse, the magnetization remains approximately perpendicular to the applied field. This yields contrast related to transverse relaxation in the rotating frame, $T_{2\rho}$. $T_{2\rho}$ contrast has been shown to be sensitive to diffusion and to exchange of water protons in environments with different local magnetic susceptibilities, which is postulated to reflect local iron content.[21]

3.326.2.4. Diffusion in MR

In the presence of a magnetic field gradient, $M_{x,y}$ will dephase in a predicable manner, and can be refocused with an equal gradient of opposite sign. However, if the ensemble of spins is subject to diffusion, the two magnetic fields experienced by the spins will be of different magnitude, and an attenuation of the transverse magnetization will result. Stejskal and Tanner demonstrated that this principle could be applied to obtain the bulk rate of diffusion, D, of the molecular species giving rise to the NMR signal.[22] In the absence of other relaxation mechanisms (i.e., T_2), the attenuated transverse magnetization due to unrestricted translational diffusion, as measured by a pulsed field gradient SE experiment, can be expressed by eqn [10][23,24]:

$$M_{x,y}(t) = M_{x,y}(0) \exp\left[-\gamma^2 G^2 D \delta^2 \left(\Delta - \frac{\delta}{3}\right)\right] \qquad [10]$$

where G is the strength of the applied gradient, δ is the duration of the gradient pulse, and Δ is the time between application of the two gradient pulses.

3.326.2.5. Magnetic Resonance Imaging

3.326.2.5.1. Magnetic field gradients

According to the Larmor equation (eqn [2]), the NMR frequency of a nucleus is related directly to the magnitude of the external applied magnetic field. The application of

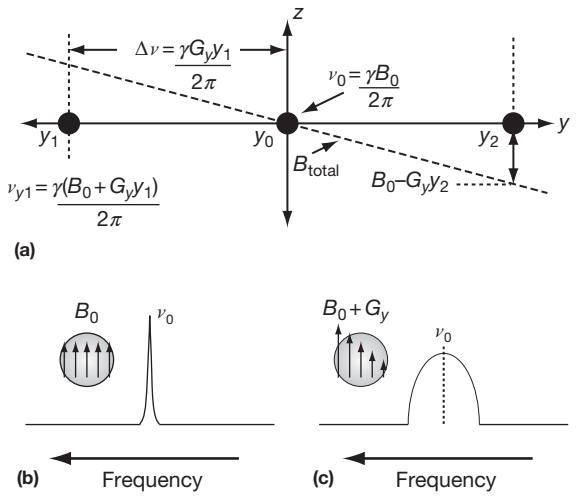

Figure 3 (a) A magnetic field gradient along the *y*-axis, G_y, modulates the magnitude of the total applied magnetic field along the *z*-axis, B_{total}. The change in magnetic field is related to the strength of the gradient and the distance from the origin of the axis along which the gradient is applied such that $B_{total} = B_0 + G_y y$. The resulting resonance frequency, ν_y, can be related to position in space with respect to the gradient axis. (b) A sample placed in a uniform B_0 will exhibit a single peak with frequency centered at ν_0. (c) Application of G_y across the sample introduces a spatial dependence of the frequency, and results in a peak shape representative of the projection of the sample profile.

well-defined and controlled pulsed magnetic field gradients can make the frequency and phase of the NMR signal vary as a function of space. Figure 3(a) shows the relation between a magnetic field gradient along the *y*-axis, G_y, applied onto B_0, and the resulting well-defined spatial dependence of frequency. Note that the magnetic field created is in the *z*-direction, the subscript *y* denotes the axis along which the magnitude of the field varies. The corresponding change in resonance frequency, $\Delta\nu$, can be described as a function of the applied field gradient and therefore of position in space, *y*, by $\Delta\nu(y) = \gamma G_y y / 2\pi$. For example, Figure 3(b) shows a sample experiencing a uniform magnetic field B_0, which results in a single peak at frequency ν_0. In comparison, if a magnetic field gradient, G_y, is applied across the sample as shown in Figure 3(c), the total magnetic field experienced by nuclei varies with respect to their position within the applied gradient.

3.326.2.5.2. NMR signal and k-space

The amplitude of the NMR signal is acquired as a function of time and is denoted $S(t)$. In MRI, the frequency of the signal from a volume of spins at position **r**, that is, the spin density, $\rho(\mathbf{r})$, is a function of the position with respect to the magnetic field gradient vector, **G**. The signal integrated over volume has the form of a Fourier transform (FT) and assuming mixing with a reference frequency, can be expressed as[23]:

$$S(t) = \iiint \rho(\mathbf{r}) \exp[i\gamma \mathbf{G} \mathbf{r} t] d\mathbf{r} \qquad [11]$$

Mansfield introduced the concept of a reciprocal space vector, **k**[25–27]:

$$\mathbf{k} = \frac{\gamma \mathbf{G} t}{2\pi} \qquad [12]$$

which shows that **k**-space can be traversed by gradient magnitude or by time. Shown in eqns [13] and [14] is the fundamental relationship of MRI, that is, the signal, $S(\mathbf{k})$, and $\rho(\mathbf{r})$ are an FT pair:

$$S(\mathbf{k}) = \iiint \rho(\mathbf{r}) \exp[i2\pi \mathbf{k} \mathbf{r}] d\mathbf{r} \qquad [13]$$

$$\rho(\mathbf{r}) = \iiint S(\mathbf{k}) \exp[-i2\pi \mathbf{k} \mathbf{r}] d\mathbf{k} \qquad [14]$$

Subjecting **k**-space to a multidimensional FT converts the data into an image, that is, a map of signal intensity as a function of frequency, and therefore physical space.

3.326.2.5.3. Image contrast

The contrast of an MR image is related to numerous factors including the volume and spin density of the sample, relaxation mechanisms, and local magnetic field variations. To obtain an image with contrast that represents only one of the factors, the data must be collected in a manner to isolate the contribution, or corrected with knowledge of the other parameters. For example, T_1-weighted contrast can be obtained by acquiring images with varied T_R values ($<5T_1$). This results in different amounts of magnetization saturation. To obtain an image with T_2-weighted contrast only, T_1 weighting is removed by adjusting the T_R value to prevent saturation of the magnetization (i.e., $T_R > 5T_1$). Images with contrast related to T_2 can be obtained by acquiring images at a series of different echo times (see Figure 2). This is generally facilitated using multi-echo experiments.

3.326.2.5.4. Example of MRI sequence

An example of a typical slice-selective SE MRI sequence is shown in Figure 4. Slice selection can be performed to obtain an image from a defined region by simultaneous application of an appropriate RF pulse shaped in the time domain (such that the frequency profile is approximately square) and a magnetic field gradient, G_x, in the direction of the slice thickness. The echo time, T_E, is the period between the first RF pulse applied to perturb the magnetization vector, and the peak of the SE that results from application of a refocusing pulse. To allow for T_1 relaxation processes, a delay, referred to as the repeat time, T_R, is implemented between applications of subsequent excitation pulses. One dimension of an image is often encoded by applying a magnetic field gradient, G_y, during acquisition of the signal, a process called frequency encoding. Higher-order dimensions are obtained in a series of experiments by imparting a phase shift in the signal prior to acquisition by incrementing a magnetic field gradient, G_z, that is applied for a fixed time period, in a process called phase encoding. If phase encoding is used to select a defined region and a gradient is not applied during the acquisition time (i.e., no frequency encoding), the FID recorded can be flourier transformed to yield an NMR spectrum corresponding to the selected region; this is referred to as magnetic resonance spectroscopy (MRS). As indicated in Figure 4, multiple refocusing RF pulses can be implemented following a single excitation pulse. The echoes can be phase encoded differently to cover **k**-space more quickly, summed to increase the SNR, or used to create a series of images that have contrast related to T_2 relaxation. In addition, by appropriately changing the T_R and T_E values, contrast with good specificity to tissue pathology can often be obtained.

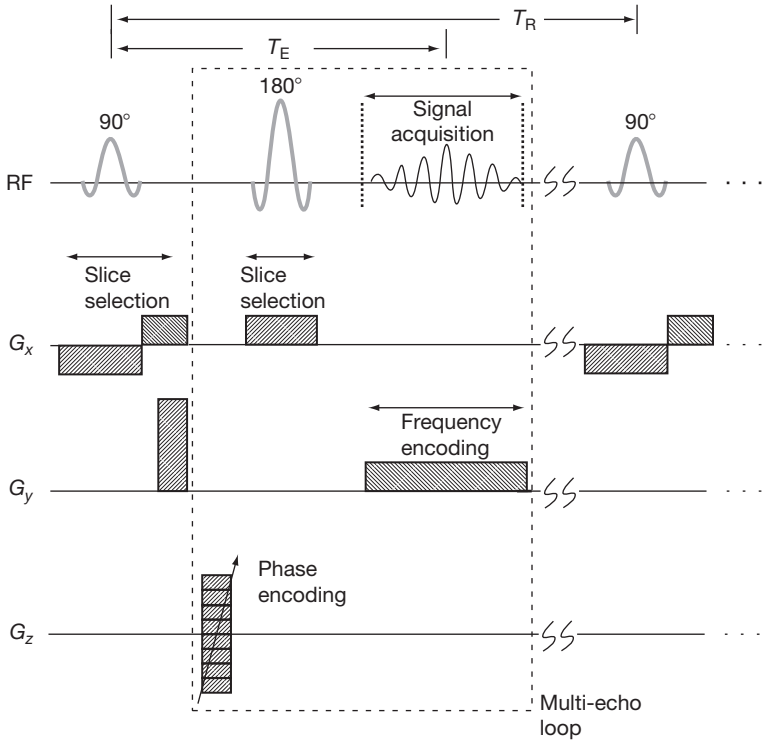

Figure 4 (a) An example of a two-dimensional (2D) spin-echo imaging sequence with slice-selective 90° and 180° radio frequency (RF) pulses along the *x*-axis, followed by frequency encoding along *y*, and phase encoding implemented along the *z*-axis. T_R is the repetition time between 90° RF pulses that perturb the magnetization along *z*.

3.326.2.6. Application to Imaging and Diagnosis of Biological Markers

The multitude of magnetic-field-perturbing NMR interactions enables nuclei to be very sensitive to their local and long-range environment. In solution, the identification of various molecular species relies predominantly on the magnetic shielding and indirect spin–spin coupling interactions, which under rapid molecular tumbling average to isotropic values. Solution NMR techniques are used extensively for *ex vivo* identification and quantification of biological markers.[28–31] MRI exploits the direct dependence of the NMR frequency on applied magnetic field to obtain spatially resolved information. Identification of biological markers with MRI relies on variation in tissue properties to impart contrast related to parameters including NMR relaxation characteristics, susceptibility changes, restricted motion, and diffusion. In the absence of rapid rotational molecular motion (i.e., in solids), the orientational dependence of NMR interactions is evident, which may reveal significant information about the local and long-range molecular environment. Solid-state NMR techniques are often applied on *ex vivo* samples, but *in vivo*, the presence of orientation-dependent interactions (e.g., quadrupolar, direct dipolar) can provide valuable information.

3.326.2.7. Summary

This section introduces the fundamental interactions and concepts of NMR which, over the decades, have facilitated the development and application of diverse and robust MR-based techniques. The various interactions by which MR-active nuclei can be perturbed enable sensitive and specific information to be obtained from appropriate experiments. Recognizing and understanding the influence of the NMR parameters can facilitate development, implementation, and use of MR-based techniques for imaging and diagnosis of biological markers.

3.326.3. Viable Molecules, Nuclei, and Experiments for MR Studies

Of all the biological molecules that can serve as markers for disease, only some can feasibly be studied using MR techniques. The molecules chosen must be in sufficient concentration to yield a strong MR signal; the typical concentration of detectable solutes ranges from 1 to 1000 mmol, depending on the nucleus being studied. This is particularly important for imaging experiments where the signal is spread out over a wide range of frequencies to create the spatially resolved images; MRI requires much higher concentrations to attain images in reasonable amounts of time. For this reason, *ex vivo* studies using NMR spectroscopy or microimaging are often the first step in developing new techniques and often can provide useful diagnostic tools because the number of molecules and nuclei that can be studied is much larger.[32,33]

Each NMR active isotope has unique properties that affect the feasibility of MR studies including the Larmor frequency, the natural abundance, and the nuclear spin number. The receptivity of a nucleus is an important factor when considering which biological markers to use. Of the top 10 occurring

Table 1 NMR properties of the most commonly used nuclei for MR imaging and diagnosis[8]

	Frequency 2.35 T (MHz)	*Natural abundance (%)*	*Receptivity with respect to proton*
^{1}H ($I = 1/2$)	100	99.9	100
^{13}C ($I = 1/2$)	25.14	1.07	0.017
^{23}Na ($I = 3/2$)	26.45	100	9.27
^{31}P ($I = 1/2$)	40.48	100	6.65

elements in the human body, only three have NMR properties that make them amenable to MRI studies (Table 1); while challenging, particularly for *in vivo* studies, ^{13}C can be used in certain cases. This section briefly reviews the nuclei that have found use for MR studies of different classes of biological markers.

3.326.3.1. ^{1}H Magnetic Resonance

Protons are the most commonly used nuclei for imaging and diagnosis. Current medical MRI is based on the fact that the human body is 80% water by mass and ^{1}H is the most receptive nucleus for MR studies. Water is therefore the biological molecule in most routine MRI scans and many reviews and books can be found on MRI methodology and application in medicine.[34–36] Here, we will focus on some of the unconventional methods of harnessing the MR properties of protons to employ different biomarkers.

3.326.3.1.1. Water

Water is abundant in biological systems, and dominates the ^{1}H MR signal. Thus, using water as a specific biological marker can be difficult if the condition of interest is responsible for only a small fraction of the water signal. For example, trying to monitor water tightly bound to large biological molecules such as collagen using basic techniques is all but impossible because of the massive signal from liquid water in most tissues. One way to overcome these challenges is to harness the dipolar interaction to differentiate between water molecules in the body that experience different degrees of restricted motion. The dipolar coupling is an anisotropic interaction, which means that its magnitude is orientationally dependent, Section 3.326.2.1.4. When water is free to move isotropically, the dipolar interaction averages to zero; however, if the water is not moving freely, the dipolar coupling may not completely average. This leads to a nonzero coupling between the two protons, called the residual dipolar coupling, which has a magnitude that can be related to the degree of motional restriction. By employing specific NMR pulse sequences, one can collect spectra that differentiate the water protons with different residual dipolar couplings.[37]

Another way that water can be used as a more specific biological marker is to use MR relaxation times that are sensitive to dynamics on different orders of magnitude than the T_1 and T_2 relaxation mechanisms. An example of this is the use of $T_{1\rho}$ imaging of cartilage where the $T_{1\rho}$ of water is affected by motional frequencies appropriate for studying the interaction of water with large molecules such as collagen and proteoglycan (PG).[38,39]

MR techniques are an ideal way of measuring the bulk diffusion of liquids. In a biological context, this means measuring the diffusion of water in different tissues. Using magnetic field gradients, one can obtain diffusion coefficients (either average values or full diffusion tensors) for each pixel or voxel of an image. Diffusion-weighted imaging (DWI) is particularly useful for identifying areas of increased or irregular blood flow, while tensor-weighted imaging (TWI) has been used to map neuronal tracts. DWI has been applied to the detection of many different cancers and brain injuries and diseases.[40–43]

3.326.3.1.2. Fats

Fats are primarily formed from long hydrocarbons and are amenable to study by ^{1}H MR techniques. Fats also have proton chemical shifts that are well separated from water protons. This has led to the development of fat or water suppression techniques.[44] When applied to imaging, water suppressed techniques provide fat density images that can be used to complement water density images. The separation in chemical shifts has also led to the use of ^{1}H MRS, where ^{1}H NMR spectra are acquired for each pixel or voxel in an image to determine the relative amounts of water and fat on the basis of the NMR peak intensity. As examples, ^{1}H MRI has been used to probe fatty tissue, and fat deposits on arteries and in the liver.[45]

3.326.3.1.3. Direct detection of small molecule metabolites

The use of MR in the field of metabolomics is a rapidly expanding area of research. Studies are clearly showing the relationship between many metabolites in the human body and disease, and that NMR can provide a robust way of analyzing metabolite samples. *Ex vivo* MR studies of blood, stool, and urine are proving to be powerful diagnostic tools.[30,46–48]

The main drawback to using small molecules as markers for imaging is that their concentrations are often low. In the case of ^{1}H MRS, further complexity results because of the relatively small chemical shift range of protons. Complicated spectra of metabolites with many overlapping peaks are common in MR metabolomics and most researchers use high magnetic field strengths ($B_0 > 14.1$ T) to obtain the higher resolution. ^{1}H MRS can be used to monitor metabolites in specific regions but resolution and experimental time constraints can make this challenging. Continued developments in MRS imaging software and hardware bode well for eventual clinical integration of the methodology.[49,50] Chemical shift imaging (CSI) of specific molecules can sometimes be performed if a marker molecule is in high enough concentration and has unique proton chemical shift that can be used as a marker peak; this is analogous to fat imaging discussed in Section 3.326.3.1.2.

3.326.3.2. ^{31}P MR

The MR properties of ^{31}P make phosphorous MR relatively easy to perform. ^{31}P NMR spectroscopy is a well-developed field and much is known about the relationship between the ^{31}P NMR parameters and the local environment around the P nucleus. For diagnosis, this means that *ex vivo* studies can yield a great deal of information. ^{31}P is also used extensively by materials researchers to characterize the molecular structure of phosphorous containing biomaterials.

The primary challenge when employing ^{31}P NMR spectroscopy on a biological marker is that many of the phosphorous containing molecules in the body are chemically very similar; that is, they are phosphates (Table 2). Therefore, despite the fact that ^{31}P has a chemical shift range greater than 1800 ppm, most of the important biological markers have ^{31}P chemical shifts between −25 and 10 ppm. Another challenge when using phosphorous MR imaging is that many interesting phosphorous containing small molecules have low concentrations. The larger phosphorous containing molecules, phospholipids, polynucleotides, and hydroxyapatite (HAp) are more abundant, but generally yield broad lines due to their lack of motion. This makes them difficult to observe using standard imaging sequences; examples of using ^{31}P MR to study bones are discussed in Section 3.326.5.

Due to the general low occurrence of phosphorus (i.e., compared to protons), *in vivo* ^{31}P MR studies typically focus on targeted regions for MRS. Using MRS, it is possible to obtain spectra from specific voxels to reveal information regarding the presence and relative quantities of phosphorous-containing molecules. These molecules can be classified into energy-related molecules and molecules used in the synthesis of phospholipids. Studies have investigated the concentrations of these molecules in healthy tissues as well as different diseases.[52,53] For example, the phosphorous biological markers that are related to phospholipid synthesis provide measures of cell health in a tissue or organ. These can be useful markers for studying cancer, genetic diseases, neurological diseases, and infectious diseases.[52] Typically, the energy-related biological markers are used to determine if a muscle is functioning properly. Figure 5 shows an example of ^{31}P MRS spectra acquired of two human hearts, a healthy patient on the left and a patient who has had heart failure on the right. The ratios of ATP and phosphocreatine can be used to assess the loss of function due to the heart failure.[54] These same biological markers can be used to study brain activity.[55]

Table 2 Commonly used phosphorous containing biological markers

Biological molecule	*Primary function*	*Approximate ^{31}P chemical shift*[a] *(ppm)*
Phosphomonoesters	Phospholipid synthesis	3.5–4.2[b]
Phosphodiesters	Phospholipid synthesis	0.3–1.2[c]
Phosphoethanolamine	Phospholipid synthesis	3.7[b]
Phosphocholine	Phospholipid synthesis	3.2[b]
Glycerophosphoethanolamine	Phospholipid synthesis	0.4[b]
Glycerophosphocholine	Phospholipid synthesis	−0.1[b]
Nucleotide triphosphates	Energy storage and regulation	$\alpha = -9.7$ to -12.7[c] $\beta = 20.7$ to -21.3[c] $\gamma = -5.3$ to -6.0[c]
Phosphocreatine	Energy storage and regulation	−3.3
Inorganic phosphate		1.5

[a]Chemical shifts are referenced to 85% H_3PO_4. Many researchers reference their spectra to phosphocreatine. Others do not state their reference compound. Additionally, chemical shifts are pH and temperature dependent.
[b]Henderson *et al.*[51]
[c]Arias-Mendoza and Brown.[52]

3.326.3.3. ^{23}Na Magnetic Resonance

Sodium ion concentrations throughout the body are relatively high compared to other metal ion species and the favorable NMR properties make ^{23}Na imaging feasible.[56] In general, the sodium concentration is ten times higher in the extracellular matrix than in the cells. However, this can change depending on the health of the tissue.[57] While the measurement of ^{23}Na MR in physiological samples is decades old,[58] the application of ^{23}Na imaging in medicine using medical imagers is relatively recent. In the past 5 years, the number of studies employing ^{23}Na imaging for diagnosis of disease or for the study of molecular level changes has increased significantly. ^{23}Na MR can be harnessed in two ways, concentration imaging and imaging based on specific MR parameters.

3.326.3.3.1. Na^+ concentration for diagnosis

The concentration of Na^+ in different tissues can be measured simply on the basis of the intensity of the MR signal. Sodium ion concentration can be used as a probe of cell health and cellular energy metabolism in many tissues in the body. It is important to be aware that ^{23}Na concentration imaging can be complicated by the quadrupolar spin dynamics of ^{23}Na.[58,59] ^{23}Na is a spin $I = 3/2$ quadrupolar nucleus and therefore, there are three different SQ transitions ($\Delta m_I = \pm 3/2 \leftrightarrow \pm 1/2$ and $\Delta m_I = 1/2 \leftrightarrow -1/2$; see Figure 1(c)). When measuring concentrations using MR signal intensity, variations in relaxation between sodium ions that are in the fast exchange versus the slow exchange regimes must be accounted for. In the fast exchange regime, $\omega_0\tau_c \ll 1$ (ω_0 = the Larmor frequency in radians per second and τ_c is the characteristic correlation time), all the sodium signal intensity is contained in a sharp peak with a monoexponential relaxation rate. However, in the slow exchange regime, $\omega_0\tau_c \geq 1$, the relaxation becomes biexponential for sodium ions that experience a single chemical environment; one rate for the $\Delta m_I = \pm 3/2 \leftrightarrow \pm 1/2$ transitions, for example T_{2f}, and one for the $\Delta m_I = 1/2 \leftrightarrow -1/2$ transition, for example T_{2s}. If there are multiple chemical environments that are not exchange-averaged, then multiexponential relaxation will be observed. This can complicate the interpretation of Na^+ concentration images.[59,60]

Sodium concentrations have been shown to correlate to many aspects of disease. Sodium ions are an important part of maintaining the ionic gradient between the extra and intra cellular matrices. In healthy tissue, the concentration can vary by as much as an order of magnitude across the cell membrane. In diseased cells, the gradient often decreases and the ratio of sodium inside and outside of the cell changes. These changes can result in either an increase or a decrease in the total amount of sodium in the tissue which can be detected using ^{23}Na MRI. Recently ^{23}Na imaging studies have been performed on the heart,[61,62] kidneys,[63] muscle,[57] and cartilage[64–67] while the diseases that have been investigated include different cancers[68] and Alzheimer's.[60]

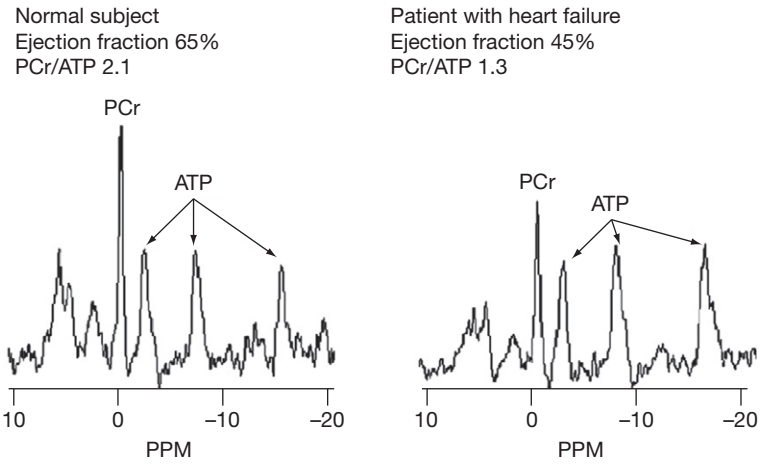

Figure 5 An example of two ^{31}P magnetic resonance spectra of the heart for a normal subject (left) and a subject that has experienced heart failure. It is clear that the phosphocreatin (PCr) levels have dropped in the patient with heart failure. Reproduced from Holloway, C.; Clarke, K. *Heart Lung Circ*. **2010**, *19*, 154–160.

3.326.3.3.2. ^{23}Na NMR parameters as biological markers for diagnosis

A second way that ^{23}Na MR can be used as a specific biological marker is to take advantage of the NMR properties that are sensitive to the local chemical environment that the sodium ions are found in. Using MR techniques that are sensitive to molecular structure can often provide valuable information about the biochemistry that is occurring during disease or as a result of treatment. As mentioned above, the relaxation can be multiexponential. If the different relaxation parameters can be extracted, either using a multiexponential fitting routine or by performing experiments that allow multisite fits of the experimental data, valuable information on the differences in intra- and extracellular volume or sodium coordination to large molecules can be obtained. For example, changes in the charge balance across the cell membrane or changes in the extra- and intracellular volumes can dramatically affect the average relaxation rates observed. This can complement the basic concentration data discussed in Section 3.326.3.3.1. Relaxation-based techniques have been used in many of the studies cited in Section 3.326.3.3.1.[69]

Another parameter that can probe the molecular level changes caused by disease or treatment is the quadrupolar coupling of the sodium. Because sodium is a spin $I = 3/2$ nucleus, there is a quadrupolar coupling between the nucleus and any external EFGs. While rapid motion of sodium in fluid environments often averages this parameter to a small, undetectable value, in some cases residual quadrupolar couplings can be detected. By measuring these couplings, analyzing them with respect to relaxation rates and concentrations, and understanding the biochemistry of the tissue, correlations between the parameters, biochemistry, and disease state can be made.[64,70,71]

3.326.3.4. ^{13}C Magnetic Resonance

The primary role of ^{13}C NMR in biological imaging and spectroscopy is as a probe of metabolites and larger biological molecules such as collagen. While NMR or MRS studies of these types of molecules are often more easily performed using ^{1}H NMR spectroscopy, ^{13}C NMR can sometimes be a more useful technique. One key advantage to ^{13}C NMR over ^{1}H NMR is the larger chemical shift range of ^{13}C. With a chemical shift range around 200 ppm, ^{13}C spectra are often much less crowded than ^{1}H spectra which can aid the identification of peaks specific to the biological molecule of choice. ^{13}C NMR spectroscopy is a well-developed field and *ex vivo* studies have become routine for solution and solid samples, as well as microimaging applications. The main problem with ^{13}C MR for imaging or MRS studies is the low natural abundance of ^{13}C, and therefore the low signal intensity.[72] Recent advances in using hyperpolarized ^{13}C MR of small molecules as contrast agents may greatly increase the utility of ^{13}C for imaging and diagnosis.[73,74]

3.326.3.5. Other Nuclei

Nearly every element on the periodic table has an NMR active isotope. While most are not relevant from a biochemical perspective, the potential to develop techniques to study other biologically important ions and molecules does exist and researchers continually work on applying the knowledge developed in chemical NMR to imaging and diagnostics.

^{2}H is an NMR active isotope of hydrogen that is quadrupolar with a nuclear spin $I = 1$. While the natural abundance of ^{2}H is low, it is relatively inexpensive to obtain isotopically labeled D_2O for *ex vivo* studies. The addition of the quadrupolar interaction and quadrupolar-induced relaxation mechanism can add an additional level of information about local structure to the data obtained from H_2O measurements.[37,75]

Inert gases such as ^{3}He and ^{129}Xe, although not biological species, can be used in imaging experiments. These gasses have been used to image the void space in lungs to detect lung diseases.[76] Xe, which can pass through the blood brain barrier, has also been used for brain imaging.[77] Experiments with ^{3}He and ^{129}Xe are often conducted using hyperpolarized gasses which yield MR signal enhancements on the order of 10 000 compared to standard experiments. Xe has also been proposed

as a biosensor by trapping Xe in cage molecules such as cryptophanes, and then functionalizing the cryptophan to target specific physiological receptors or binding sites.[78,79] Binding of these sensors affects the ^{129}Xe chemical shift and can be detected using MR techniques.[80]

The primary isotope of nitrogen is ^{14}N which is a spin $I = 1$ quadrupole nucleus that has a relatively large quadrupole moment. This makes using ^{14}N very difficult in biological systems. Typically ^{14}N is avoided by labeling molecules with ^{15}N, which is a spin $I = 1/2$ nucleus. While this is practical in synthetic chemistry and biology it is impractical from a diagnostic and imaging perspective. Similarly, ^{17}O is the potentially useful isotope of oxygen for MR experiments but has a very low natural abundance; ^{16}O is not NMR active. As these nuclei are often on organic molecules with hydrogen and carbon atoms, the ^{1}H and ^{13}C MR techniques provide similar information. However, the potential development of these isotopes for imaging and diagnostics may increase as signal enhancement techniques and higher magnetic fields are developed.

3.326.3.6. Summary

To date, MR of protons is the most developed and widely used technique for diagnosis and imaging. The ability to perform a wide range of experiments on conventional MR scanners means that the potential exists for researchers to test new imaging and diagnosis methods without purchasing or building new hardware. The future of ^{1}H imaging will involve using the NMR parameters of ^{1}H, such as chemical shifts and $T_{1\rho}$ relaxation rates, to develop more specific diagnostic tools. ^{23}Na has entered a phase where *in vivo* diagnosis and imaging are possible. While this requires modification of conventional MRI scanners, the ability to use a very simple species, Na^{+}, as a diagnostic marker is very attractive and could greatly compliment ^{1}H imaging of water. Finally the use of ^{31}P and ^{13}C has been limited to NMR and MRS studies. While these show a great deal of promise for understanding the chemistry and biochemistry of different molecules, wide scale applicability to diagnosis and imaging has not been well established. Despite this, the use of these nuclei, particularly ^{31}P, should be studied further as the information they can reveal about cell metabolism could be extremely powerful from a diagnostic perspective.

3.326.4. Case Study: Biological Markers for the Diagnosis of DDD

Degenerative disc disease (DDD) is a leading cause of back pain. Degeneration occurs when the molecular structure of the spinal disc changes with age leading to disc compression and greater structural rigidity. Severe degeneration can cause a loss of mobility and pain for patients.[81] MRI techniques have been used extensively to diagnose spinal disc injuries. The majority of these techniques have employed T_1 and T_2 relaxation methods to diagnose injuries such as herniated discs. These acute injuries can be readily diagnosed because they involve changes in the size or shape of the disc which can be imaged on the basis of the location and concentration of water. However, in cases where the damage does not significantly affect the dimensions of the disc, standard MRI techniques have been unreliable for assessing the stage of DDD.[82–85]

The degeneration caused by DDD is slow, beginning as early as the mid-teens in some patients, and in many cases may be asymptomatic in the early stages.[85] Patients often do not report discomfort until the disease is in its latter stages when treatment options are limited and often invasive. An ideal diagnostic technique for DDD should identify biochemical changes in the disc that are associated with early disc degeneration, thus providing patients with the greatest variety of surgical and nonsurgical treatment options. The same technique would also help monitor the spinal disc tissue after treatment. For example, one potential treatment method currently being explored is the injection of hydrogels into the disc tissue.[86] Currently, this methodology is used after discectomy to replace extracted tissue.[87–89] Recent efforts have focused on matching the chemistry of these hydrogels to the biochemistry of the disc tissue.[88,89] These types of studies and the resulting treatment methods require imaging and diagnostic techniques that can properly report on the biochemical changes within the disc upon treatment. The first step in developing reliable MRI-based diagnostic tools is to determine biological molecules and MR techniques that can be used as markers of DDD (See also **Chapter 5.524, Biomaterials for Replacement and Repair of the Meniscus and Annulus Fibrosus**; **Chapter 6.615, Intervertebral Disc**; **Chapter 6.612, Biomaterials for Intervertebral Disc Regeneration**; and **Chapter 6.613, Nucleus Replacement**).

3.326.4.1. Molecular Changes During DDD

The spinal disc is composed of two regions: the outer annulus fibrosus which provides the structural rigidity of the disc tissue, and the spongy inner nucleus pulposus, which exhibits the greatest changes due to DDD. Both regions primarily contain water, collagen, and PG which compose between 70 and 80% of the disc mass.[85] The primary molecular level change during DDD is the loss of PG. PG contains a protein core to which negatively charged sulfated glycosaminoglycan chains are attached. The negative charge of the PG is balanced by a high concentration of sodium ions in the disc tissue, up to 0.3 M.[85] The loss and degradation of the aggrecan are accompanied by a loss of sodium ions and, due to osmotic forces, the loss of water in the disc tissue.[81,90] PG, sodium ions, and water are all potential biological markers that can be used as probes of DDD (See also **Chapter 2.216, Collagen–GAG Materials**).

The challenges for conventional T_1- and T_2-based MRI experiments relate to the nature of water in disc tissue. The local environments of water vary depending on the biomolecules that the water interacts with during the MRI experiment.[75] As a result, different water molecules can experience different NMR relaxation rates, leading to multiexponential relaxation behavior which can be difficult to analyze. Significantly, the water molecules that would provide the highest degree of diagnostic sensitivity would be those that interact most with PG. These molecules will be a small fraction of the total water in the disc and will have the shortest relaxation times, making them difficult to observe. This is likely one of the reasons that relaxation-based MRI techniques have had difficulties detecting DDD, particularly in the early stages of the disease.

3.326.4.2. ^{2}H Double Quantum Filtered NMR Studies

As discussed in Section 3.326.2, there are many ways that the MR experiment can be employed to measure different interactions and relaxation rates. To provide a robust diagnostic technique, an experiment and molecule must be chosen that can provide information about the specific problem. In the case of DDD the changes in PG, sodium ion and water concentration at a molecular level. One option is to probe the way different molecules interact with each other as the disease progresses. This can be monitored by measuring the dipolar or quadrupolar interactions that are sensitive to the local geometry and not specifically dependent on changes in chemical bonding.

In solution, where water molecules tumble isotropically, the dipolar and quadrupolar interactions are averaged to their isotropic values of zero; these interactions do not affect the NMR frequencies but do cause relaxation. If the water molecules experience restricted motion due to interaction with large biological molecules, the interactions will not average to zero but to some residual value, the size of which will depend on the local structure and exchange dynamics of the water. Typically, these residual interactions are small and can be difficult to detect using standard SQ pulse sequences. In fact, the residual dipolar couplings for water in spinal disc tissues are so small that even experimental techniques designed to detect small couplings have difficulty measuring them.[75]

To harness the quadrupolar interaction to diagnose disc degeneration, the H_2O in the disc must be substituted for D_2O; using the residual ^{2}H quadrupolar interaction in water is an *ex vivo* diagnostic technique. To measure the small quadrupolar interaction, a double quantum filtered (DQF) NMR experiment can be performed that is sensitive to D_2O molecules that are experiencing restricted motion; water molecules that are moving freely are not measured in the DQF experiment.[91] Using this experimental approach, D_2O can be used as a biological marker to monitor the variations in hydration caused by molecular level changes in the collagen and PG. This application of ^{2}H DQF as a biological marker was demonstrated in joint cartilage by numerous groups,[37,92–95] and was recently applied to spinal disc tissue.[75]

The ^{2}H DQF line shapes observed in the spinal disc tissue experiments demonstrated a trend of increasing line width as degeneration occurred.[75] The line width in the DQF spectra is dominated by the magnitude of the residual quadrupolar coupling and therefore is a probe of the motional restriction of the water molecules. At high degeneration, the disc tissue is significantly dehydrated compared to a young healthy tissue and the water molecules interact more with the PG and collagen molecules leading to the larger residual quadrupolar couplings and larger ^{2}H DQF line widths.[75,81]

A simple analysis of the DQF build up curves revealed a correlation between the degree of degeneration and the time of maximum DQF signal intensity, denoted τ_{max}.[75] This parameter is affected by the magnitude of the residual quadrupolar interaction and the T_2 relaxation of the water molecules that experience restricted motion. The correlation was particularly sensitive at low levels of disc degeneration and therefore could be used to develop a diagnostic technique for early stages of disc degeneration.[75]

3.326.4.3. ^{1}H $T_{1\rho}$ Studies of Water to Assess DDD

Another way to use the power of MR for diagnosis and imaging of DDD is to take advantage of relaxation measurements other than T_1 and T_2. One such promising technique is to measure the ^{1}H spin-locked relaxation times, $T_{1\rho}$, of water in the spinal disc tissue.[38,39,96] As mentioned in Section 3.326.2.3.2, $T_{1\rho}$ is sensitive to low-frequency interactions and thus can be used to measure the exchange of water between different environments in the disc tissue.[39] This result is complementary to the data measured using ^{2}H DQF techniques.

Studies using $T_{1\rho}$ have been performed on a wide range of cartilage tissues and have shown a remarkable ability to measure changes in the biochemistry of such tissues.[38,39,96–99] The same properties that affected the ^{2}H DQF spectra also play a role in the $T_{1\rho}$ studies; water molecules that interact differently with the large biological molecules yield different $T_{1\rho}$ values. It has been shown that PG in particular plays a large role in determining the $T_{1\rho}$ values of water in cartilage.[100] Therefore, water $T_{1\rho}$ measurements act as an indirect biological marker for the amount and quality of the PG molecules and by extension the amount of degeneration. *In vivo* $T_{1\rho}$ weighted images of spine sections have been performed and have demonstrated that the measured $T_{1\rho}$ relaxation values correlated reasonably to the degenerative grade of the spinal discs.

3.326.4.4. Na^{+} Concentration Studies to Assess DDD

As mentioned in Section 3.326.4.1, another important species that changes in concentration as a result of DDD is sodium ions. The concentration of Na^{+} in the spinal disc tissue is high, ~0.3 M, in order to balance the negative charge of the PG and maintain high tissue hydration through osmotic forces. During degeneration of the disc, PGs degrade and the concentration decreases resulting in a loss of sodium ions. As outlined in Section 3.326.3.3, the ^{23}Na nucleus is well-suited for NMR and MRI experiments. ^{23}Na NMR of sodium ions holds potential for use in diagnosis and imaging of DDD.

There have been a number of researchers working on sodium MRI of various cartilage tissues. While most have been *ex vivo*, there have been *in vivo* studies of porcine osteoarthritis,[101] and human wrist cartilage.[101] Since the feasibility of ^{23}Na spinal disc imaging was demonstrated,[102] it has been shown that the concentration of Na^{+} as measured by ^{23}Na MRI is strongly correlated to the amount of PG determined by standard methods.[103] Using these correlations, researchers showed that low Na^{+} concentrations could be detected *in vivo* in a young symptomatic subject.

3.326.4.5. ^{23}Na Multiple Quantum Filtered NMR Studies

The same principles outlined for ^{2}H DQF NMR of D_2O in spinal disc tissues can be applied to sodium; the experiment must be modified to account for the fact that sodium is a spin $I = 3/2$ quadrupolar nucleus.[104–106] Using multiple quantum filtered (MQF) NMR experiments, signal can be selected from only those sodium atoms that do not undergo isotropic motion. It is expected that these sodium ions primarily interact with PG and therefore the ^{23}Na DQF signal can act as a specific probe of changes in the PG content and structure of the disc.

^{23}Na MQF experiments have been performed extensively on cartilage tissue.[104,106–109] Other examples of ^{23}Na MQF studies include the analysis of blood cells,[110] brain imaging,[111] and, more recently, spinal disc tissue affected by DDD.[71] The application of ^{23}Na MQF to spinal disc tissue combined two different multiple quantum techniques to measure all the water in the spinal disc samples and then fit the data to a multisite model using analytical expressions. The results clearly show that multiple sodium environments can be observed in the same sample and that the experimentally measured parameters, residual quadrupolar couplings and T_{2f} and T_{2s} relaxation times can be correlated to the hydration level of the specimen. Experiments on healthy disc tissue, which has a higher hydration, produced smaller residual quadrupolar coupling constants as well as longer T_2 relaxation times, whereas degraded samples showed larger couplings and shorter relaxation times. The differences were most clearly seen in the nucleus pulposus where disc degeneration has its greatest effect on molecular and mechanical properties.

The signal intensity of the ^{23}Na MQF experiments as a function of the experimentally controlled mixing time, τ, could be used as a probe of hydration. Signal intensities reach a maximum at shorter τ values for less hydrated tissue and at longer τ values for more hydrated tissues. This characteristic was harnessed to prove that ^{23}Na MQF could be used as an imaging technique for spinal disc tissue.[112] One-dimensional, spatially resolved ^{23}Na images were recorded as a function of τ and revealed contrast could be obtained using a triple quantum filter (TQF) which provides greater signal than a DQF (Figure 6). The τ-maps showed the ability to differentiate the annulus fibrosus and the nucleus pulposus on the basis of their different hydration levels using the TQ signal behavior.

3.326.4.6. Conclusions

The development of new MR-based diagnosis and imaging techniques for studying DDD is being advanced by the combined understanding of the biochemistry, fundamental principles of NMR, and the ability to design MR experiments that can probe the properties of different biological molecules. While this section has focused on diagnosing spinal disc degeneration, the same principles apply to monitoring the interaction of tissues with biomaterials and to monitoring the efficacy of biomaterial treatments.[89] The development of techniques for probing specific biological markers will aid biomaterial researchers as they continue to develop new materials for medical applications.

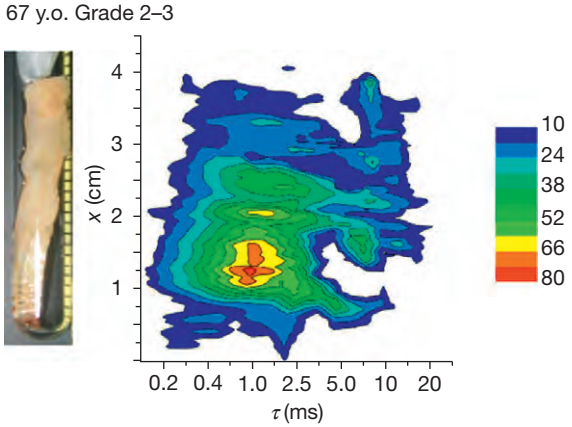

Figure 6 A ^{23}Na triple quantum filtered (TQF) τ-map. The signal intensity in the annulus fibrosus, the lower half of the sample, builds up faster and has a higher maximum signal intensity due to lower hydration. The nucleus pulposus, top half of the sample, shows the opposite trend, longer signal buildup times and lower maximum intensities. Reproduced from Ooms, K. J.; Cannella, M.; Vega, A. J.; Marcolongo, M.; Polenova, T. *J. Magn. Reson.* **2008**, *195*, 112–115.

3.326.5. Case Study: MR for Diagnosing Bone Disease and Treatment

Recent evidence demonstrates that orthopedic conditions, such as osteoporosis, osteoarthritis, and bone tumors are increasingly prevalent. As a result of bone weakening, these orthopedic conditions often result in increased susceptibility to bone fractures and breaks. Sources within Canada, the United States, and Europe cite dramatic increases in bone-related surgeries as well as the hospitalization costs associated with these orthopedic conditions and treatments.[113,114] As a result of the growing patient numbers affected by bone-related disease, there is a need for innovative treatments that strengthen existing bone in degenerated regions and promote the regrowth of bone tissue.

Throughout all stages of diagnosis and treatment of orthopedic conditions, MR techniques are proving to be an effective characterization tool. There are a variety of MR detectable biological markers within the bone that can be correlated with bone health. By understanding changes in bone due to disease, MR techniques can be implemented for diagnostic purposes. MR techniques have also been critical for characterizing synthetic biomaterials. Finally, biomaterial-based treatments can be monitored and studied using MR techniques and provide insights into the functionality and biocompatibility of the new materials. In this section, different biological molecules are identified for studying different parts of bone and MR techniques being used to study these molecules are discussed.

3.326.5.1. Bone Structure and Markers of Disease

Bone is a complex endoskeletal organ that is constantly remodeled and organized through a dynamic process of absorption and resorption which allows for flexibility and bone growth. A variety of bone cells play a role in this process: osteoblasts produce bone collagen and are involved in bone mineralization; osteoclasts are responsible for bone resorption into the circulatory system; and osteocytes, the primary bone cells, are involved in waste exchange, nutrient exchange, and other aspects of bone metabolism.[115] These cellular components all work to maintain the appropriate balance of molecules in the bone (See also Chapter 2.210, Bone as a Material).

The key to employing MR-based imaging and diagnostic techniques lies in determining what molecules serve as biological markers for the bone diseases. There are several components of bone which can be studied: inorganic mineralized portions of bone, organic collagenous tissue, marrow, water

within cortical bone pores, and several other components.[116] With a clear understanding of these components of bone and the changes that occur as a result of disease and treatment, novel MR techniques can provide unique information about the bone.

The solid phase of the bone is a hybrid material composed of an organic component, collagen I, and an inorganic component, calcium HAp that provides the structural rigidity and strength required for proper bone function. The densest region of the solid phase is in the outer portion of the bone which is referred to as the compact bone while the inner part of the bone, the trabecular bone, is much more porous. The inorganic portion of the bone matrix results from the biomineralization of calcium and phosphate by osteoblasts to form HAp nanocrystals. These nanocrystals form among the bone collagen creating a hybrid material that gives bone its strength. Aging is accompanied by a loss of bone mass as the fraction of compact bone decreases. Many bone diseases, such as osteoporosis, result in an increased loss of collagen and HAp, leading to unusually low bone density and the loss of mechanical stability. It has been shown that the chemical structure of both the inorganic and organic components of the solid bone experience changes due to disease; these changes are detectable and significant.

Within the pore spaces of the trabecular bone are the marrow and blood vessels. The marrow is found in two forms, yellow and red. Yellow marrow is primarily adipose and hence has a high lipid content. Red marrow contains primarily hemopoietic tissue, the body's chief site of blood cell production, and blood vessels. Red marrow therefore has a higher amount of water, with the water in the blood vessels being far more mobile than that in the cellular components. As the marrow fills the inner space of bone, and often fills growing porous space within the bone, irregular patterns of marrow development can be used to indicate changing porous space in the bone. As changing and increasing porous space is associated with bone loss, analysis of marrow for irregular changes or growth can be correlated to degenerative bone disease. This provides an indirect, yet vital probe that complements direct measurements of collagen and HAp.

3.326.5.2. Diagnosis of Bone Disease Using MR Techniques

As musculoskeletal conditions are one of the leading causes of disability, technologies for early diagnosis are essential in preventing additional health difficulties.[117] As a result of the relationship between orthopedic conditions and resulting susceptibility to further bone damage, it is essential that innovative techniques, such as MR, are employed to accurately characterize bone tissue and indicate potential for damage. A further prevalent bone condition is cancer, most commonly occurring within the bone as a result of metastasis from cancers in other areas of the body. Conventional bone cancer diagnosis, X-ray imaging, is limited in detecting early bone tumors, as it often cannot detect them until they are 1 cm in size.[118] As a rapid, noninvasive technique, requiring no pretreatment or ionizing radiation, MR is an appealing method for bone analysis. Four main biological markers have been used for studying bone degeneration: collagen and HAp in the solid phases of the bone, and fat and water in the porous regions of the bone.

3.326.5.2.1. Collagen imaging

While conventional methods of diagnosing bone degeneration analyze the density of mineralized bone using X-ray radiation, recent research indicates that a more effective method of diagnosing bone degeneration also involves analysis of collagen in bone.[116,119] MR techniques can potentially detect the presence and density of collagen; however, the use of MR to study solids is complicated by the lack of rapid molecular motion. In the solid, anisotropic NMR interactions can cause broadening of the signal leading to low signal intensities and challenges in image reconstruction. Molecules in the solid state also tend to have much shorter T_2 relaxation times than molecules in liquid phases making complex multipulse experiments challenging. While short T_2s can lead to technical challenges when acquiring spectra of collagen, they can also be used as a contrast mechanism. ^{1}H NMR signal from the bone with fast relaxation times can be separated from the more fluidic components which have longer T_2 relaxation times. Since collagen is the primary source of proton signal in the solid phase, an experiment that can differentiate ^{1}H signal based on T_2 can be used to select only protons from the collagen, leading to an image based on collagen density.[116,119,120] Using these types of techniques, researchers have shown that proton images from the collagen in the bone can be observed and be useful for quantifying bone density.[116]

3.326.5.2.2. Studies of HAp

The chemical formula of synthetic HAp is $Ca_{10}(OH)_2(PO_4)_6$. While natural HAp in bones is similar in structure to synthetic HAp it is not a pure structural phase, existing in a nonstoichiometric, disordered, nanocrystalline state.[121] For example, it has been shown that carbonates substitute for phosphate ions in natural bone so that between 5 and 8 wt% carbonate is achieved. While MR studies of calcium and oxygen are extremely difficult, ^{31}P MR provides an ideal probe for using the phosphate component as a biological marker to measure the density of HAp and its chemical structure.[122]

Solid-state ^{31}P NMR has been used for identifying different HAp phases and stoichiometric compositions. Because the ^{31}P isotropic chemical shifts are similar for the different structural phases of HAp,[123] typically yielding a single or overlapping ^{31}P NMR peak, the anisotropy in the chemical shift has been employed in many studies by analyzing the spinning sideband patterns observed under magic angle spinning conditions.[124,125] ^{1}H–^{31}P cross-polarization and two-dimensional correlation experiments have also been used to study the structure of different HAp phases[122] Another key study was performed to identify the presence of hydroxyl radicals in HAp; the presence of hydroxyl ions in HAp had been the focus of a decades-old controversy.[121] All these studies have been important steps to understanding the structure of HAp and illustrate how NMR spectroscopy is sensitive to the chemical structure of the different HAp phases. These differences could provide valuable tools for development of future diagnostic techniques that monitor the health of solid bone. From a materials perspective, it is vital to develop an understanding of the different structural forms of HAp present in bone so that new biomaterials can be designed with higher degrees of biocompatibility (See also **Chapter 1.112, Calcium Phosphate Coatings**).

Bone density is controlled by the balance between bone production and bone degradation, and therefore studies have been undertaken using ^{31}P NMR to understand mechanisms and structures involved in the formation and decomposition of HAp. The transformation of octacalciumphosphate, a HAp precursor, into synthetic HAp, has been studied using ^{31}P MR, revealing a possible mechanism of HAp formation.[126,127] Complementing these formation studies have been studies that look at the degradation of HAp; for example, ^{31}P NMR spectroscopic signatures have been identified for calcium deficient HAp[128] (See also **Chapter 3.323, Magnetic Resonance of Bone Microstructure and Chemistry**).

Bone mineral density (BMD) tests are performed using X-ray radiation. The feasibility of using ^{31}P MR to measure biological bone mineral densities in conjunction with collagen imaging has recently been demonstrated *ex vivo*.[120] Along with *ex vivo* NMR analysis, simple imaging studies using ^{31}P have been performed.[129,130] Despite these initial studies, very few other ^{31}P imagings have been done on bone. However, as imaging instrumentation is developed for multinuclear studies, the application of ^{31}P MRI may become a valuable tool for the diagnosis of bone conditions.

3.326.5.2.3. MRS of marrow fat

While direct measurements of bone density, either through BMD or potentially through MR measurements of collagen and HAp, are important for diagnosing bone degeneration diseases, recent studies have demonstrated that osteoporosis bone depletion is also connected to factors such as marrow quality, trabecular architecture, and trabecular connectivity. As bone degrades a greater percent of the total bone becomes porous. The new porous regions become filled mostly with yellow marrow; the ratio of yellow and red marrow changes as bone degradation occurs during normal aging or as a result of bone degeneration diseases. As mentioned above, the yellow marrow is full of lipids, while the red marrow contains a higher volume of water. The amount of fat in the bone marrow can be quantified using ^{1}H MRS, where spectra are acquired for specific regions of the bone and the intensity of the ^{1}H water peak is compared to the ^{1}H aliphatic (CH_2, CH_3) peak to determine relative water/lipid ratios.[131–134] It has been shown, for example, that people with osteoporosis have a higher amount of fat in their bones than normal patients based on the ^{1}H MRS.[134] Using MRS measurements of fatty marrow content, researchers have estimated that increases in marrow fat from 0% to 100% correspond to a BMD decrease of $0.16\,g\,cm^{-2}$ in men and $0.14\,g\,cm^{-2}$ in women.[135] This quantitative measure of bone changes due to osteoporosis has been viewed as a more accurate measure of bone density and degradation than BMD measurements.[134]

3.326.5.2.4. Diffusion imaging of water in marrow

As aging and bone degradation occur, the amount of yellow marrow increases and the amount of red marrow decreases. As the red marrow has a far greater degree of vascularization, changes in the amounts of red and yellow marrow will affect the overall vascularization of the marrow in the porous regions of the bone. Researchers speculate that degraded portions of bone, affected by osteoporosis, are filled with adipose tissue and thus have low degrees of vascularization. As a result, the degree of marrow vascularization in some regions of the bone may drop with age or disease.

This change in vascularization has a significant effect on the average mobility of water in the marrow, which can be characterized on the basis of the diffusion coefficient, see **Section 3.326.2.4**. Water in blood vessels will diffuse faster and over longer distances than water in the adipose tissue. MR techniques have been developed that provide image contrast related to the diffusion of water (i.e., DWI) or that aim to measure the magnitude and direction of diffusion (i.e., diffusion tensor imaging, DTI). These MR techniques have significant potential for improving and opening new possibilities in bone diagnostics.[136–140] In recent studies, diffusion techniques have been combined with MRS of water and fats to obtain a more complete picture of the structure of the marrow.[131–134] Investigating changes due to disease with complimentary techniques that rely on unique biomarkers (e.g., diffusion of water and MRS of fat) can provide corroborative information that may lead to more robust diagnosis and a better understanding of specific biochemical changes.

Changes in the porous regions of the bone marrow can also be a useful probe of bone cancer. Bone cancer most commonly occurs when cancer located elsewhere in the body metastasizes to the bone. Bone metastases, observed in higher rates with cancer of the thryroid, breast, lung, and prostate, may result in bone tumors as the cancerous tumor cells clump when traveling through bone via the Haversian canals.[141,142] Identifying metastatic disease can be difficult as bone X-ray computed tomography (CT) scans lack the specificity necessary for definite early stage diagnoses. MR imaging is a far more favorable approach than other techniques for diagnosis, as cancerous cells are detectable with MRI prior to visibility using CT scans.[143] Just as DWI can be used to study the biochemical changes in the marrow due to degenerative disease, it can also report the location of bone cancer tumors. Cancers are far more likely to occur in regions of the bone with high concentrations of red marrow and can lead to regions of even higher vascularization than normal. This elevated vascularization can be detected as an increase in the diffusion of water as measured by DWI.

Other important MR techniques used in the analysis of bone tumors are *in vivo* dynamic contrast-enhanced (DCE) MRI and *in vivo* ^{1}H MRS of metabolites.[144] DCE MRI can assess regions of blood vessel development within bone and as a result can demonstrate even slight changes in tissue vascularization related to tumor development. In the context of bone tumor diagnosis, MRS is also effective; specific metabolic markers such as choline, a constituent of the phospholipid cell membrane, can be identified using MRS and used to determine the changing biochemistry of tumor cells.[145] Using ^{1}H MRS, benign and malignant bone tumors can be distinguished with 89% accuracy, in a noninvasive way.[145] MR techniques have demonstrated a great deal about the nature of bone metastases diagnosis and research.[146]

3.326.5.3. Developing and Assessing Biomaterial Treatments

The strength of healthy bone tissue is essential to human wellness considering the enormous forces that act on bones

even in daily activities. As a result, there is great need for biomaterials that are capable of providing powerful reinforcement for weakened, diseased, or fractured bone tissue. Understanding the structure and chemical characteristics of biomaterials is essential as these properties determine the interaction of a material with bone tissue. In many of the same ways that MR is used to study healthy and diseased bone tissue, it can be used to assess the efficacy of different material implants and their incorporation into the bone (See also **Chapter 6.610, Trends in Materials for Spine Surgery** and **Chapter 1.120, Synthetic Bone Grafts: Clinical Use**).

3.326.5.3.1. Bioinert and resorbable bone materials

In cases of severe bone injury or degradation, synthetic bone implants may be necessary to replace the damaged region. Bioinert materials, those that minimally interact with surrounding tissue, are effective in providing mechanical support and bone retention. These materials are typically magnesium alloys, titanium alloys, or stainless steel. Commonly used to provide weight-bearing support in regions such as the spine; these materials act as replacements for damaged bones while allowing surrounding bone growth to continue.[147] Other forms of bioinert materials include metal bone screws, used to secure damaged joints, such as knee or ankle joints.[148] These forms of bone implants are effective in providing musculoskeletal support and allowing bone fusion.

In general, these implants cannot be imaged directly using MR because of their metallic components. Differences in magnetic susceptibility between materials used in implants and surrounding biological tissue result in dramatic MR frequency shifts and rapid MR signal relaxation (i.e., on the order of microseconds). Conductive materials also effectively attenuate RFs, which prevents both perturbation of the magnetization vector with an applied B_1 field and detection of the MR signal. In addition, the pulsed RF and magnetic field gradients can induce high voltages and eddy currents in conductive components. These factors can either prevent acquisition of MR images, or at the least, impart significant artifacts.[147]

Because MR is such a valuable technique, alternatives to metallic implants have been sought. Researchers have demonstrated the effectiveness of carbon-fiber-reinforced polymers that do not cause image artifacts in the surrounding tissue. Structural support or bone fixation can also be provided by biosorbable biomaterials.[148] These resorbable materials are commonly made up of compounds such as polyglycolic acid (PGA), poly-L-lactic acid (PLLA), poly-D-lactic acid (PDLLA), and polyparadioxanone (PDS) and can be imaged using MR without the interference seen with metal implants. Following the implantation of these biomaterials, *in vivo* MRI can be used to demonstrate the level of biocompatibility between the implant and surrounding tissues.[148] Most studies have used ^{1}H NMR of water; for example, the absorption of bioabsorbable screws has been monitored after implantation using T_1 and T_2 weighted images of water surrounding the implant.[148,149] In addition to monitoring the dimensions of the screws, the surrounding tissue could be monitored for damage caused when implanting the screws. Osteolysis could be detected using imaging techniques that could not be detected using CT methods.[148]

3.326.5.3.2. Bioactive bone implants

The development of bone substitutes with osteoconductive and biologically active properties has played a large role in the effectiveness of bone biomaterials. The central feature of these bioactive materials is their biomimetic properties that ideally result in their full integration with natural bone tissue.[150] Additionally, these biomaterials are intended to promote healthy bone metabolism, bone regrowth, and the development of osteoblast-induced bone mineralization.[151] These materials are often composed of nanophase particles.[152] Several forms of bioactive materials that are used in orthopedic treatments include polymers, glasses, synthetic HAp crystals, and bioactive bone cements.[150,153] Calcium phosphate ceramics, in particular, have been widely used since the 1980s due to their similarity to natural compact bone HAp crystals.[151]

The study of the effects of bioactive materials on osteoformation involves several types of MR analysis. *In vivo* DCE MRI has been effective in clinical studies in demonstrating the development of blood vessels and bone growth following biomaterial use.[154] In research settings, ^{31}P solid-state NMR of biomaterial implants is routinely used to determine the rate of HAp formation and the structure of the new HAp along the tissue implant interface.[155] The feasibility of ^{31}P MRI to differentiate between natural and synthetic HAp has also been demonstrated.[130]

Proton NMR is similarly vital in demonstrating the interaction of surrounding fluids with the gradually forming HAp structures on the material. An additional method of analyzing the effectiveness of bioactive bone substitutes is ^{13}C solid-state NMR, which is useful in demonstrating the production of extracellular matrix in biomaterials.[156] With the ability to demonstrate molecular level characteristics of the resulting HAp crystal and surrounding tissue, MR is invaluable in the development of safe and effectual bioactive biomaterials.

3.326.5.3.3. Hybrid bone biomaterials

In cases of orthopedic damage where bone tissue integration along with strong mechanical support is required, hybrid bone materials are most effective. These synthetic bone analogs involve both structural support, typically using a metal implant coated with bioactive material which promotes attachment, and interaction of the implant with surrounding tissue.[150] MR studies are important for the development and medical application of these novel materials.

HAp coatings on metal implants, such as titanium alloys, chromium cobalt alloys, and stainless steel, significantly improve their biocompability and enhance ingrowth of regenerated bone. Specifically, nanophase HAp coatings are effective as they promote the precise growth of mineralized bone regions with strength similar to that of natural bone.[151] In a recent example, HAp nanoparticles derived from a water-based sol–gel process using triethyl phosphate and a variety of calcium precursors were used as bioactive coatings on 316L stainless steel implants.[151] ^{31}P NMR analysis was essential in characterizing the molecular structure of the HAp as it formed during the sol–gel synthesis.[151]

Following successful implantation of hybrid biomaterials, it is essential that materials are monitored to determine their interaction with natural tissue and their promotion of bone regrowth. The integration of resorbable porous β-tricalcium

phosphate (β-TCP) cylindrical scaffolds containing osteogenically differentiated mesencymal stem cells 3 months following implantation in rabbits has been analyzed using ^{31}P and ^{13}C NMR spectroscopy. Results demonstrated that new bone was formed and that NMR could quantitatively detect both the inorganic calcium HAp and the collagen of the new bone on the implants.[156]

3.326.5.4. Conclusions

This section has described the current need for innovative orthopedic treatments and the necessity of clear diagnostic methods. MR is a technique with a wide range of applications in orthopedics, as it is capable of characterizing healthy bone tissue, diagnosing areas of bone degeneration and weakness, demonstrating structural characteristics of bone biomaterials, and testing the biocompatibility of implanted materials. As MRI hardware improves and multinuclear capabilities become available on medical scanners, the application of novel biological marker imaging techniques will greatly aid doctors and researchers in the diagnosis and treatment of bone diseases. These developments will be greatly facilitated by stronger interdisciplinary research between medical researchers, materials scientists, and MR specialists.

3.326.6. Summary and Future of Imaging and Diagnosis of Biological Markers

This chapter has focused on providing a broad overview of the ideas and considerations behind the use of MR techniques for imaging and diagnosis of biological markers. The two case studies highlighted are meant to provide a framework that demonstrates that by using multiple biological molecules, nuclei, and MR experiments, information about biological markers can be gained. MR techniques are some of the most powerful and noninvasive diagnostic and characterization techniques modern science has at its disposal. The past decade has seen an incredible advance in the implementation of MR for imaging and diagnosis. In many ways, the current clinical applications are akin to the chemists' use of proton NMR; while extremely powerful, it represents only a small part of the potential of MR. While newer techniques such as diffusion-weighted imaging, MRS of ^{1}H, ^{13}C, and ^{31}P containing molecules, and ^{23}Na imaging are proving useful in research, they are only slowly penetrating the diagnostic community. The need for new diagnostic techniques will only increase as biomaterials researchers seek to tailor materials for specific functions to treat disease and injury. To meet these future needs research must be done with an understanding of the biochemistry of disease, the chemistry of novel biomaterials and their interaction with the body, and the fundamental NMR theory that makes the development of novel MR techniques feasible. If approached as a multidisciplinary project between medical, materials, and MR specialists, the future of MR for diagnosis and imaging is extremely bright.

Glossary

Absorbance Units used to measure the amount of infrared radiation absorbed by a sample; it is linearly proportional to concentration of the component giving rise to the molecular vibration.

Attenuated total reflectance (ATR) An infrared sampling technique, where a sample contacts a crystal with a high refractive index. The infrared radiation undergoes internal reflection, but makes at least one pass through the sample surface along the crystal via an evanescent waveform and gives rise to an infrared spectrum.

CCD detector A charge-coupled device detector used to detect Raman scattering.

Diffuse reflectance Occurs when infrared radiation reflects off a rough surface. The light is scattered and reflected by the surface. The light approaches the surface from one direction, but leaves the surface in all directions.

Interferogram The fundamental measurement obtained by an FTIR spectrometer, which is essentially a plot of infrared detector response versus optical path difference. Interferograms are Fourier transformed to convert to infrared spectra.

Laser Acronym for 'light amplification by stimulated emission of radiation'; a device that produces an intense monochromatic beam of coherent light.

MCT detector A mercury cadmium telluride photoconductive infrared detector that requires liquid nitrogen cooling.

Raman intensity A measure of the amount of Raman scattering; intensity is usually displayed in arbitrary units.

Raman scattering The inelastic scattering of photons at frequencies different from that of the incident photon. The energy, and hence the frequency, of the incident light shifts due to the vibrational energy that is gained or lost in the molecule.

Spatial resolution A measure of the ability of the spectrometer to distinguish the spatial separation (distance) of two points.

Transmission sampling A sampling method where the infrared beam passes through the sample prior to detection.

Wavenumber The commonly used units of frequency for infrared and Raman spectra. The units of wavenumbers are cm^{-1} (1/wavelength), where $2.5\,\mu m = 4000\,cm^{-1}$.

Abbreviations

ATR	Attenuated total reflectance
CCD	Charge-coupled device
FPA	Focal plane array
FTIR	Fourier transform infrared
He–Ne	Helium–neon
MCT	Mercury cadmium telluride
Nd:YAG	Neodymium:yttrium–aluminum–garnet

3.322.1. Introduction

Vibrational spectroscopy has been utilized for the characterization of polymers and other materials since the 1940s[1–3] and soon thereafter was applied to the characterization of biological tissues and their components.[4–12] Variations in the environment of molecular components of materials and tissues are reflected in shifts in absorbance band intensities and positions in vibrational spectra. The spectrum of a material therefore provides insight into the chemical composition of a substance and how it might be altered during processing, or as a result of *in vivo* implantation. The most common vibrational spectroscopic techniques utilized for assessment of biomaterials are mid-infrared (mid-IR) and Raman spectroscopy. Both techniques have been widely applied to evaluate polymers, biomaterials, and tissues, with the choice of technique dependent on the particular problem under investigation. In general, IR techniques require specific sample preparations but have excellent signal-to-noise capabilities, and Raman techniques require minimal sample preparation but with somewhat lower signal to noise.

3.322.1.1. Principles of Vibrational Spectroscopy

3.322.1.1.1. Mid-IR spectroscopy

Molecules absorb radiation in the mid-IR spectral range, 4000–400 cm^{-1} (cm^{-1} is the unit of frequency) and it is converted into energy of molecular vibrations and rotations. The frequency of the vibrations is characteristic of the specific bonds involved and therefore can be utilized to identify chemical species. There are two general types of vibrations, stretching and bending, and a change in overall dipole moment must occur during the vibration for a molecule to absorb IR radiation.

3.322.1.1.2. Raman scattering

When light encounters a molecule or atom, most photons are elastically scattered, also known as Rayleigh scattering. The scattered photons have the same energy (wavelength) as the incident photons. A small proportion of the photons are scattered inelastically at frequencies different from that of incident photon. This is called Raman scattering where the energy, and hence the frequency, of the incident light shifts due to the vibrational energy that is gained or lost in the molecule.[13] The Raman scattering process from the ground vibrational state leads to absorption of energy by the molecule and its promotion to a higher energy state, called Stokes scattering (**Figure 1**). However, some molecules may be present in an excited state. Scattering from these states to the ground state is called anti-Stokes, which is a very weak scattering that involves transfer of energy to the scattered photon. Raman scattering occurs with a change in vibrational, rotational, or electronic energy of a molecule and is presented as the Stokes spectrum.

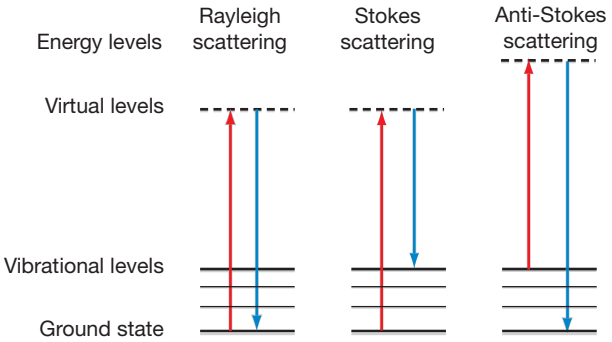

Figure 1 Schematic representation of Raman and Rayleigh scattering. Raman scattering occurs upon inelastic scattering of light and Rayleigh scattering occurs upon elastic scattering of light.

This is given as a shift in energy from the energy of the laser beam and is obtained by subtracting the scattered energy from the laser energy.[13,14] The frequency shift (cm^{-1}) due to the Raman scattering is recorded with respect to the intensity of the light. Therefore, individual peaks at different frequencies provide information on the vibrational states of molecules and ions. Any parameter altering the scattering process can result in a change in the position, intensity, and shape of the Raman bands.

3.322.1.1.2.1. IR spectroscopy versus Raman scattering

The question often arises as to which spectroscopic technique is better for evaluation of a specific sample. Molecular species can have vibrations that are only IR active and/or only Raman active. In contrast to IR, if a molecular vibration does not have an overall change in dipole moment it will be Raman active. Interference from the large water absorbances in the IR spectral regions can be a significant issue to overcome with IR analyses, while with Raman, fluorescence can be a problem. An organic sample, or impurities in the sample, can absorb laser light and reemit a strong fluorescence band that masks the Raman spectra.[13] Therefore, the use of both techniques in a complementary fashion is sometimes required to get the complete vibrational spectrum of a substance.

3.322.1.2. Mapping and Imaging

A major advance in spectroscopic analysis occurred with the coupling of a light microscope to an IR spectrometer,[15] a technology which was first applied to biological tissues with a Fourier transform IR (FTIR) microscope in the 1980s.[16] The coupling of a Raman spectrometer to a microscope was first demonstrated in 1975,[17] followed by biological applications in the 1980s,[18–20] and development of systems capable of single-point analysis and imaging. These techniques enabled

point-by-point mapping of samples and allowed investigators to assess the spatial location of different chemical species at high spatial resolution, on the order of microns.[19,21,22] Data collection by microscopic mapping requires the sample to be moved a specified distance for each point analyzed until the entire region of interest has been mapped. A further advance in these techniques was the coupling of an FTIR microscope with an array detector, FTIR imaging, or 'hyperspectral imaging' which was a true paradigm shift for data collection and processing. With FTIR imaging technology, an image of the sample is focused onto an array detector, and the intensity of radiation passing through the sample is measured at each pixel simultaneously. Thus, entire millimeter sections of tissue samples can be scanned and analyzed at ~6.25 μm pixel resolution in relatively short periods of time.[23,24] Similarly, Raman imaging can be performed with a Raman spectrometer coupled to a charged-coupled device (CCD) detector,[25] with many CCD–Raman spectrometers having the major advantage of a confocal design as well.[26]

3.322.2. Instrumentation, Sampling, and Data Processing

3.322.2.1. IR Microscopy Instrumentation

IR microscopy combines identification of chemical components by vibrational spectroscopy with high spatial resolution microscopy. The use of FTIR microscopes has grown considerably over the past 20 years, with several different models now commercially available. The two most common modes of sampling are transmission and reflectance, and most models are able to interchange between the two quite easily. The most widespread IR source is a globar, an incandescent silicon carbide rod with black-body radiation characteristics. The IR radiation originates from the globar spectrometer source and is directed to the microscope stage through a series of mirrors and lenses. In transmission mode, the radiation passes from beneath the stage through the sample to the detector. In reflectance mode, the radiation passes from above the sample, penetrates the sample and either reflects back to the detector, or scatters inside the sample (diffuse reflectance) and then reflects back toward the detector. The sampling size is controlled through an adjustable microscope aperture that typically spans 5–200 μm. In general, the smaller the aperture size, the less energy is passed through the sample. Further, the radiation that passes through the aperture is diffraction limited, so the minimum practical aperture is on the order of ~10 μm. Spectral resolution is user-defined and generally ranges between 2 and 16 cm^{-1}, dependent on the specific sample parameters. Another sampling mode available on FTIR microscopes is attenuated total reflectance (ATR). In ATR mode, a crystal with a high refractive index, such as germanium, contacts the sample surface and IR radiation passes through the sample surface along the crystal via an evanescent waveform. Sampling resolution is enhanced in ATR mode such that data can be collected at ~1.5–3 μm pixel resolution.[27] With respect to detectors, most laboratory-grade FTIR spectrometers are equipped with deuterated triglycine sulfate (DTGS) detectors that operate at room temperature. However, DTGS detectors are not sensitive enough for microscopy data and therefore,1 FTIR microscopes are generally equipped with the more sensitive mercury cadmium telluride (MCT) detector that requires liquid nitrogen cooling.

3.322.2.2. IR Imaging Instrumentation

IR imaging spectrometers enable acquisition of spatially resolved component maps of biomaterials and tissues over regions millimeters to centimeters in size with relatively short scan times. Hyperspectral images are produced where the *x*- and *y*-axes are the spatial coordinates of the material being imaged, and the *z*-axis is the parameter measured, such as intensity at a specific frequency. There are two types of instrumentation, those equipped with a focal plane array (FPA) detector such as the Varian 620-IR, and those equipped with a linear array detector, such as the Perkin Elmer Spotlight 400. An FTIR imaging spectrometer with an FPA detector will have a defined maximum number of detector elements and a defined maximum field of view for imaging, on the order of 128 × 128 elements with ~5 × 5 mm total imaging field. The Perkin Elmer Spotlight 400 equipped with a linear array detector (**Figure 2**), permits imaging of somewhat larger sample regions and more flexible sample sizes due to its data collection configuration. Both types of imaging spectrometers support ATR attachments that enable high spatial resolution data collection, on the order of 1.5 μm, and larger pixel sizes for data collection in transmittance and reflectance, from 6.25 to 50 μm. In general, larger pixels for sampling are utilized when large regions of tissues or materials are being evaluated. The IR sources used can be the same as those utilized for IR microscopy, typically globars, and MCT detector elements are very common in imaging spectrometers as well.

3.322.2.3. FTIR Microscopy and Imaging Sampling

Preparation of samples for FTIR microscopy and imaging is similar and is determined based on the mode of data acquisition. For data collection in transmittance, flat, thin sections on the order of 2–10 μm thick, similar to those utilized for histological assessments, are required. The specific method of thin sample preparation is dependent on the sample. Mineralized materials typically need to be embedded in a plastic such as polymethyl methacrylate, Epon or Spurr to facilitate sectioning.[28] Soft biomaterial samples and tissues can either be cryosectioned, or embedded in paraffin and then sectioned.[29] It is important to note that most embedding materials also absorb in the IR and can interfere with the component spectrum of interest. It is possible to chemically remove the media from the thin section prior to data collection to alleviate the interference problem, or alternatively, one can spectrally subtract the contribution of the embedding media during the data processing step.[29]

Until very recently, most tissues and materials were sectioned onto salt windows that are IR transmissive, such as KBr, CaF_2, and BaF_2. However, a lower cost substrate is now available, a low-e IR reflective slide by Kevley Technologies. The 'MirrIR' slide is optically transmissive but has a coating that reflects IR radiation. Thin tissue sections are prepared for sectioning onto these slides in a similar fashion as for the salt substrates, but the data is collected in reflectance mode. Use of

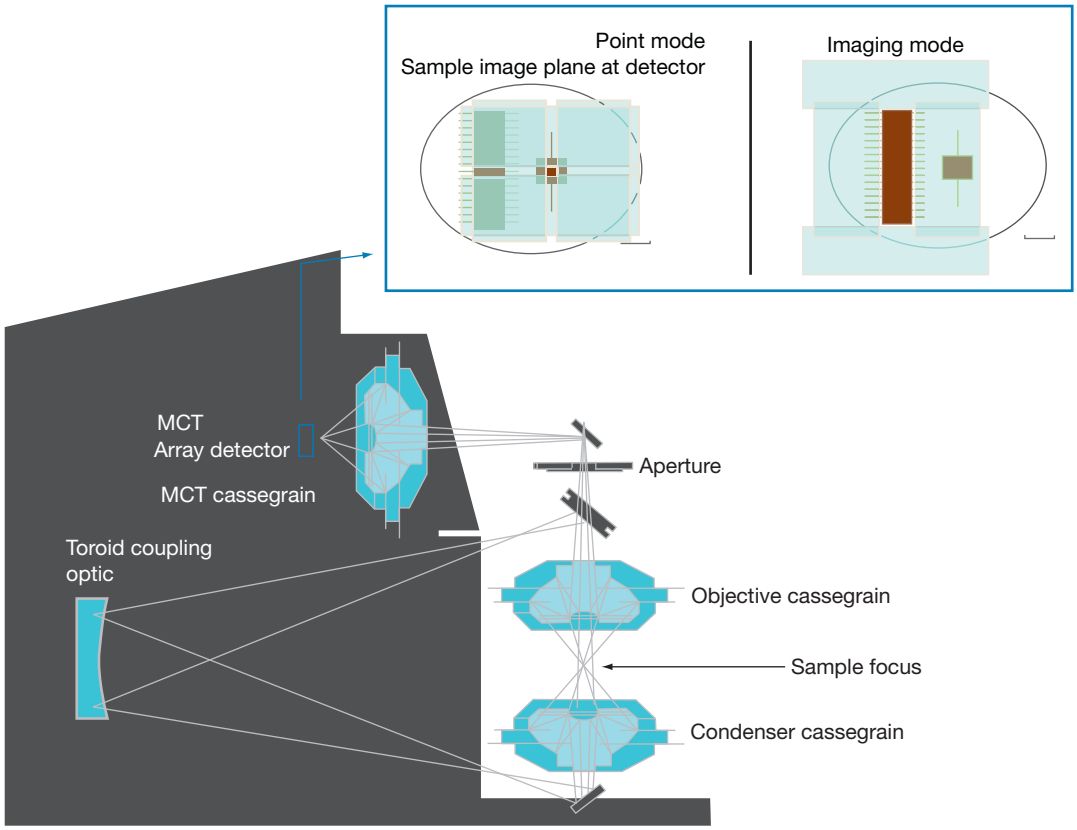

Figure 2 The Perkin Elmer Spotlight 400 with Cassegrain optics. The infrared beam is focused onto the sample which sits on a motorized stage. The transmitted light is collected by the objective, goes through a switched 4× magnifier, passes through a set of motorized aperture blades and gets refocused onto the MCT detector. There is no optical beam switching to alternate between the array detector and the point detector, as the sample image falls across the entire detector plane. Adapted with permission from Perkin Elmer.

these slides permits histological assessments on the same sample utilized for IR data collection. Another substrate has recently been described that permits culture, differentiation and fixing of cells followed by IR imaging on the same substrate, an inexpensive Si_3N_4 membrane.[30] The authors report strong adherence of the cells to the membranes, and visually normal proliferative and phenotypic cell growth. It is also possible to collect data in reflectance from intact or polished samples, such as from the surface of metal implants or from bone.[31] However, scattering artifacts can occur at times, a challenge for data interpretation.

With ATR imaging, contact between the sample and the ATR crystal is critical. For polymer samples, this can mean that high pressure is exerted onto the material to obtain optimal contact. ATR data can be obtained from an intact sample provided that the morphology of the material fits the geometric constraints of the ATR sampling fixture. For biological tissues, they are generally required to be hydrated to obtain good contact with the crystal. If adequately hydrated, the contact pressure can be minimized so that negligible damage to the tissue occurs.

3.322.2.4. Raman Microscopy Instrumentation

Micro-Raman spectroscopy or Raman microscopy, the most extensively utilized type of Raman spectroscopy, involves the pairing of an optical microscope with a Raman spectrometer. This coupling provides enormous power in sampling regions with high spatial resolution, on the order of 1 μm.[14] **Figure 3** shows a Raman microscopy setup, where the laser beam passes through a high numerical aperture microscope objective and focuses on the sample. Types of lasers include continuous wave (CW), such as argon (351.1–514.5 nm), krypton (337.4–676.4 nm), and He–Ne (632.8 nm). More recently diode lasers operating at 785, 810, or 830 nm, and also pulsed lasers such as Nd:YAG (1064 nm) have been used. The scattered light from the sample is then passed through the monochromator that is used to disperse the collected radiation onto multichannel detector. Among the detectors, intensified diode arrays or CCD are the most common type that allow simultaneous detection of a large spectral range.[32]

3.322.2.5. Confocal Raman Microscopy

Traditional Raman microscopes suffer from limited resolution along the optical axis due to the conventional microscope coupling. Improvement in resolution has been achieved with integration of a confocal-designed microscope with a Raman spectrometer. In confocal microscopy, an adjustable pinhole is applied to obstruct the out-of-focus signals from above and below the focal plane. This also reduces the background signals

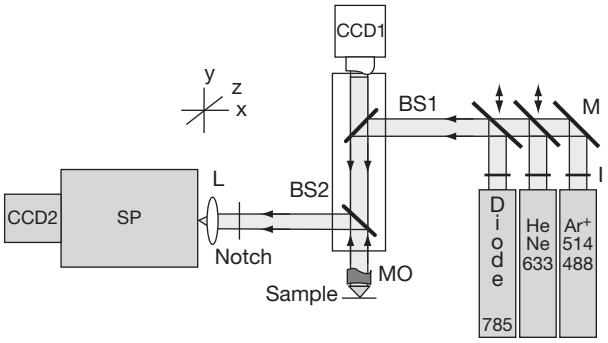

Figure 3 Schematic of a micro-Raman setup featuring different types of laser for the excitation; I, interference filter; M, mirror; BS1 and BS2, beam splitters; MO, microscope objective; CCD1, camera for sample observation; L, lens; SP, spectrometer; OMA, optical multichannel array; CCD2, Peltier-cooled camera for recording of the spectra. Reproduced from Petry, R.; Schmitt, M.; Popp, J. *ChemPhysChem* **2003**, *4*, 14–30, with permission from John Wiley & Sons.

significantly, and a fluorescence-free spectrum with sharper images can be obtained.[32,33] The *z*-axis resolution for confocal Raman is on the order of 1 μm.

3.322.2.6. FT-Raman Microscopy

The FT-Raman technique is the coupling of a Raman accessory with an FTIR instrument that contains an interferometer. The Raman effect is measured by a Nd:YAG laser (emission wavelength of 1064 nm). The scattered light is collected and passed to an interferometer head before focusing onto a liquid nitrogen cooled detector. The most important advantage of this technique is the reduction of the fluorescence effect as a result of working in a near-IR (NIR) higher frequency region. This is particularly important in the application of Raman spectroscopy in medicine and biology. Another advantage is that a higher spectral resolution can be obtained with excellent wavelength accuracy compared to conventional Raman spectroscopy. Further, unlike conventional Raman spectroscopy, FT-Raman simultaneously measures the intensity of light at many frequencies. There are still drawbacks to this technique, however. In particular, sampling at elevated temperatures could be problematic since dark samples strongly absorb and may heat-up considerably, even to the point of degrading the sample. Above 250 °C black-body emission could also occur and mask the Raman signal.[34]

3.322.2.7. Raman Mapping and Imaging

Chemical maps and images of samples are produced by combining Raman microspectroscopy with automated focusing and automated *xyz* movement of the stage. These techniques have been widely applied in the investigation of nonhomogenous samples, especially in the field of biomaterials where the investigation of the distribution of various components is essential. There are several different modes of data acquisition for Raman microscopes. In point mode, a laser is focused on a single point chosen under the microscope and the spectrum is measured by a single channel detector system. A second mode is an imaging technique where the sample is illuminated with a line focus (line-imaging). This system requires a monochromator and a multichannel detector. The scattered light is first split into different frequencies by the monochromator and then focused as a line on the CCD where individual frequencies are detected along each point of line. Another mode is the global illumination (wide-field imaging) mode where a two-dimensional CCD detector is used to measure the spectrum of an entire area under illumination. As the image of the sample is focused onto an array detector, the beam passing through each region is measured at each pixel.[35,36]

3.322.2.7.1. Mapping

During mapping, the laser is focused on the point of interest of the sample and the spectrum of a single point is then dispersed across the CCD. The sample is moved under the focused beam and spectrum is acquired at each point until the whole region is scanned. If the sample is moved in one direction (x or y) it is termed line mapping. If the sample is moved in both x and y directions the data is similar to that obtained while imaging, and the same methodology is applied during the analysis.[36] Regardless of the specific method, each pixel on the image represents a spectrum measured at each spatial location on the sample.

Both Raman mapping and imaging require the use of CCD array detectors. Mapping is a slower process since measurement of spectroscopic data is done point by point, or pixel by pixel. The advantage of mapping is that the entire spectrum is recorded and better spatial resolution can be obtained. Imaging, on the other hand, can be much faster since it uses a multichannel detector to collect data from different spatial regions simultaneously.[14] However, it is limited to the collection of one spectral frequency at a time per image.

3.322.2.8. Raman Microscopy and Imaging Sample Preparation

One of the major advantages of both Raman and FT-Raman microscopy is the minimal sample preparation required. Data can be acquired from samples in the form of solids, liquids, polymers, or vapor. In the visible excitation range glass sample holders or substances dissolved in water can be used since water and glass exhibit only very weak Raman signals. In the UV excitation range quartz sample holders can be used. Crystalline samples can sometimes exhibit orientation effects that arise from the angle of samples with respect to the scattered beam. However, sample rotation can average out orientation-related effects. Another common problem that could arise as previously mentioned is sample degradation, or burning, due to high energy absorbance. Reducing data collection time or moistening the sample when possible can minimize this undesirable effect. A final consideration with respect to sample preparation is penetration depth. The spatial resolution of a Raman microscope depends upon the optics of the system, and the penetration depth will also depend on the laser and specific sample being evaluated. Thus, penetration depth has to be evaluated experimentally, and has traditionally been done using polished Si wafer samples as standards.[37]

3.322.2.9. Spectral Data Processing

Both IR and Raman spectral data are amenable to processing with similar methods and software. Integrated areas and/or peak heights of IR absorbance bands or Raman intensities are generally proportional to the quantity of a specific component present. These univariate analyses often require preprocessing of the spectra, such as baseline correction, but can yield significant information about a sample with minimal computation required. Concomitant with the advances in mapping and imaging instrumentation is the requirement for more efficient analysis of the vast data files generated; thus, multivariate data processing methods are increasingly utilized. Application of these methods to spectral imaging data sets are reviewed in Wang and Mizaikoff.[38]

3.322.3. Applications to Biomaterials

IR and Raman microscopy and imaging are increasingly utilized in biomedical, pharmaceutical, and biomaterials applications to provide information on the quantity, distribution, and quality of sample components at the molecular level. The techniques are sensitive to organic and mineral components, can be applied to intact samples with little preparation, or to samples prepared for histologic evaluation. An overview and examples of applications in the biomaterials field are presented below.

3.322.3.1. IR Microscopy Applications

IR microscopy has been applied to a multitude of interesting and challenging problems in biomaterials, including assessment of polymer composition and degradation, evaluation of composition of tissue-engineered constructs and dental materials, and characterization of drug delivery systems.[39–64] These studies are either performed to assess small quantities of components that can't be detected using FTIR of bulk samples, or to evaluate composition at specific microscopic locations.

Ultra-high-molecular-weight polyethylene (UHMWPE), a material commonly used in orthopedic implants, has been evaluated by several investigators using FTIR microscopy. These studies typically involve assessment of microtomed slices of implants retrieved from surgeries to evaluate oxidation, crystallinity, transvinylene index (TVI),[45,58,59] or in one case, assessment of organic components diffused into the material.[44] The use of FTIR to assess UHMWPE oxidation, based on the area of the carbonyl peak centered near 1720 cm^{-1}, and to assess the amount of unsaturation (trans-vinyls, TVI) based on the area of the peak near 965 cm^{-1} are in fact ASTM methods widely utilized in the orthopedic community.[58]

Shibata and Tomita[60] utilized FTIR microscopy to evaluate whether α-tocopherol, an antioxidant added to UHMWPE, would improve oxidative resistance and crystallinity in γ-irradiated implants. Fifty micron thick slices were obtained from γ-irradiated implants with and without the addition of α-tocopherol, and FTIR microscopy was data acquired over a 50×10 mm region using a 50×50 μm aperture. Oxidation was significantly lower, and crystallinity (based on absorbances related to the crystalline and amorphous UHMWPE phases at 1897 and 1305 cm^{-1}, respectively) significantly higher, in the α-tocopherol samples compared to control γ-irradiated implants. These data also correlated with improved fatigue resistance in the α-tocopherol samples. Thus, the FTIR microscopy studies enabled elucidation of the molecular and structural changes that correlated with changes in material properties of the UHMWPE.

FTIR microscopy characterization of polymers fabricated for novel biomaterial applications continues to be widely applied. Ekblad *et al.*[46] fabricated charged polymer gradients and characterized protein adsorption behavior using FTIR microscopy. In these experiments, they prepared a bilayer of polymers having opposing charges using UV-initiated free-radical polymerization. A 12×12 mm^2 glass slide was coated with a 45 nm thick gold layer as the substrate. First cationic poly (2-aminoethyl methacrylate hydrochloride) was laid down followed by a layer of anionic poly(2-carboxyethyl acrylate). Adsorption from protein solutions and human blood plasma was investigated by FTIR microscopy. FTIR microscopy data were collected in reflectance using a 150 μm aperture along the polymer gradient (*x*-axis). In **Figure 4**, it can clearly be seen that protein adsorption based on the amide bond vibrations, specifically amide I, the carbonyl stretching frequency centered near 1660 cm^{-1}, and amide II, a combination stretching–bending vibration centered near 1560 cm^{-1}, was found in regions where one of the polymers dominated the composition, and that a minimum of protein absorption was found at the interface of the two oppositely charged proteins, where the charge was neutral. These data show the feasibility of creating a protein-resistant surface by balanced material charges.

3.322.3.2. IR Imaging Applications

Applications of IR imaging to assess materials, cells, and tissues have grown considerably over the last decade.[29,65–78] The ability to obtain images of molecular environments has provided insight into spatial variation of material structure and correlates with other properties, such as mechanical strength.[74] Researchers have utilized FTIR imaging to evaluate the composition of engineered tissues such as bone and cartilage,[29,70,72] and degradation, dissolution, and phase separation of biomaterials.[66,71,76]

One challenge in the biomaterials field is the development of polymer blends with a range of properties such as mechanical, biological, degradation, and drug permeability, and the ability to tailor these to specific applications. Malheiro *et al.*[74] utilized FTIR imaging to evaluate a new synthesis method for poly(ε-caprolactone)/chitosan fiber blends (PCL/CHT). The goal of the study was to develop fibers that combined the superior biological properties of chitosan, including CHT being biodegradable, nontoxic, hydrophilic, and having a high protein affinity, with improved mechanical performance provided by the PCL. Fibers were prepared by wet spinning from blend solutions, using a formic acid/acetone 70:30 vol% mixture as common solvent and methanol as coagulant. Varying amounts of PCL and CHT were added to the solvent mixture in order to obtain 0, 25, 50, 75, and 100 wt% CHT in the PCL/CHT blends. FTIR imaging was performed on 10 μm slices of pure components (**Figure 5**) and fiber blends embedded in epoxy resin. The integrated area of the CHT amide I absorbance centered at 1650 cm^{-1} was utilized to map

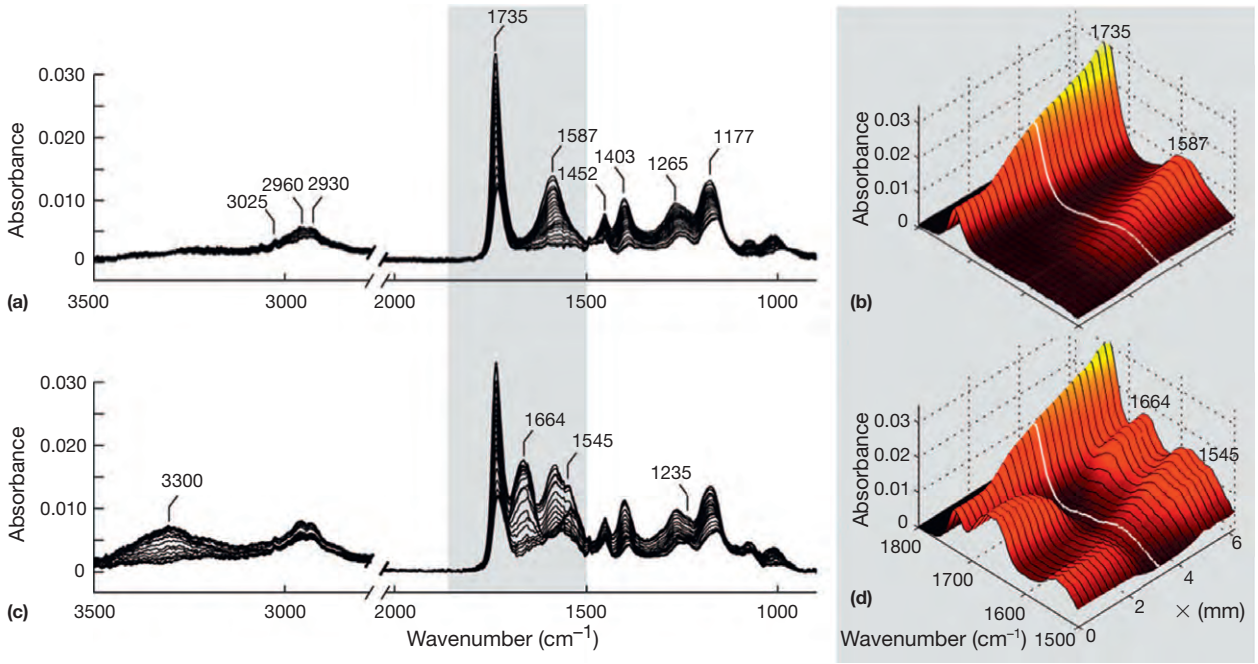

Figure 4 Stacked IR spectra measured along the same line of a gradient surface before (a and b) and after (c and d) incubation in lysozyme/pepsin mixture (0.5 mg ml^{-1} of both in HBS-N, pH 7.4). These spectra are, respectively, plotted against position along the gradient (x) in the 1800–1500 cm^{-1} region in (b) and (d). Note the gradually increasing carbonyl peak at 1735 cm^{-1} and the COO− peak at 1587 cm^{-1} (from the polymer). After protein incubation, two new peaks appeared at 1664 and 1545 cm^{-1}, respectively, both typical for vibrations in the amide bond of proteins. Reproduced from Ekblad, T.; Andersson, O.; Tai, F. I.; Ederth, T.; Liedberg, B. *Langmuir* **2009**, *25*, 3755–3762, with permission from American Chemical Society.

the CHT distribution, and the integrated area of the PCL carbonyl stretching absorption at 1730 cm^{-1} was use to map the PCL distribution (Figure 6). The IR images visualized the even distribution of the two components in the mixtures at all three blend concentrations. Further, FTIR spectra did not display frequency shifts of the signature functional groups of PCL and CHT, indicative of no chemical reaction occurring between the two components in the blends. Dynamic mechanical analysis found that the storage modulus of the blends correlated with component concentration, and also that some interaction exists between the fibers. Together, these data demonstrated the potential for tailoring the properties of PCL/CHT fiber blends for specific tissue engineering applications.

Discussion of a final application of FTIR imaging concerns the assessment of a polymer coated, drug eluting metallic coronary stent.[73] The drug delivery characteristics and stability of coatings are of prime interest for these clinical applications. In the Lewis study, the stent was coated with a phosphorylcholine (PC)-based polymer that either contained the cell migration inhibitor batimastat (loaded) or was unloaded. Stents were implanted in a porcine coronary artery model, removed after 6 months, ATR spectroscopy applied to assess the chemical nature of the stent coating, and FTIR reflectance imaging applied to assess the uniformity of distribution of the PC coating. Figure 7 shows characteristic ATR spectra that arise from the unloaded PC coating (a), the loaded PC coating (b), and from a harvested loaded stent (c). The most prominent absorbance from the PC coating is the carbonyl stretching absorbance at ~1730 cm^{-1}. This absorbance is present in all three spectra. An additional absorbance from the batimastat can be seen in (b) at ~1628 cm^{-1}. The spectrum from the loaded stent harvested after 6 months of *in vivo* implantation is very similar to the unloaded PC-coated, with no evidence of the batimastat absorbance band. This was expected, as drug delivery had previously been shown to occur over the first month of implantation.

Next, IR images of the explanted loaded stent were acquired in reflectance, and the PC carbonyl stretch at 1730 cm^{-1} utilized to image the distribution of the coating (Figure 8). The high intensity spot in the image (Figure 8(d)) corresponds to a pit in the stent surface (Figure 8(c)), and indicates a pooling of the PC solution during the dip-coating process. Overall, the nonuniformity of the coating can be visualized. Although not demonstrated in this study, an advantage of the noninvasive IR reflectance imaging technique is the potential for comparison of coating distribution on the same stent before and after implantation.

3.322.3.3. Raman Microscopy and Imaging Applications

Biomaterial applications of Raman microspectroscopy and imaging have focused on surface wear of synthetic biomaterials, failure analysis of artificial joints (mainly ceramic oxides), dental implants, joint implants, drug delivery systems, tissue engineering, surface engineering, and biocompatibility of biologically inspired materials. There is also an increasing amount of research on medical and clinical applications which include diagnostic applications such as atherosclerosis, breast cancer,

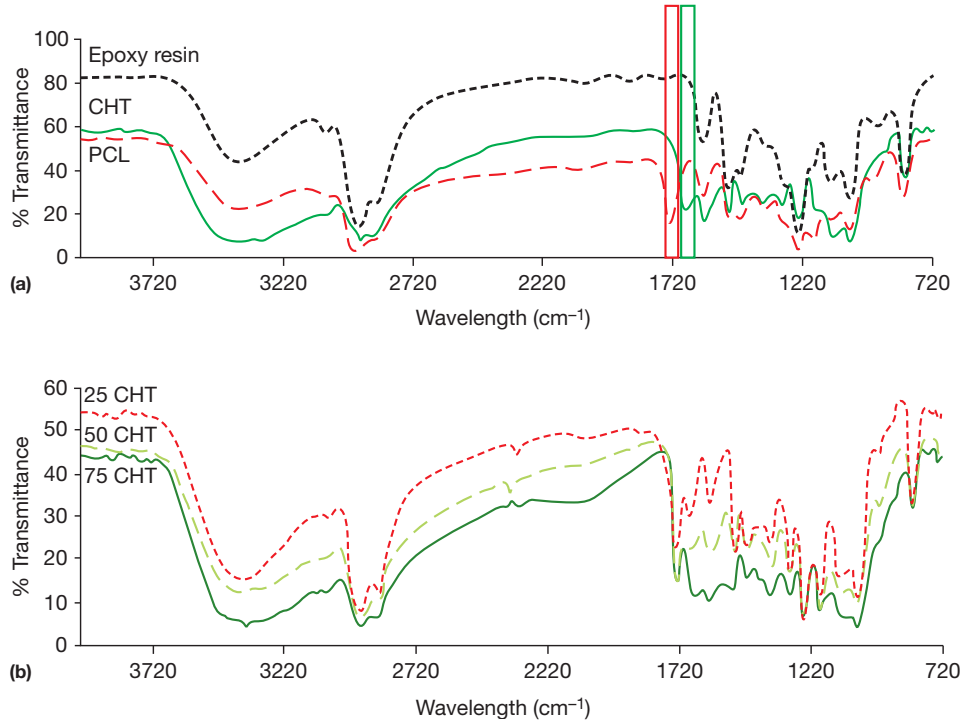

Figure 5 FTIR spectra of the pure PCL (dashed lines), CHT (solid lines), and epoxy-based resin (dotted lines) (a) and of the blend fibers (b). The colored bands identify the regions that have been selected for the integration procedure used to obtain the images of **Figure 6** (red for PCL, green for CHT). Reproduced from Malheiro, V. N.; Caridade, S. G.; Alves, N. L. M.; Mano, J. O. F. *Acta Biomater.* **2010**, *6*, 428, with permission from Elsevier.

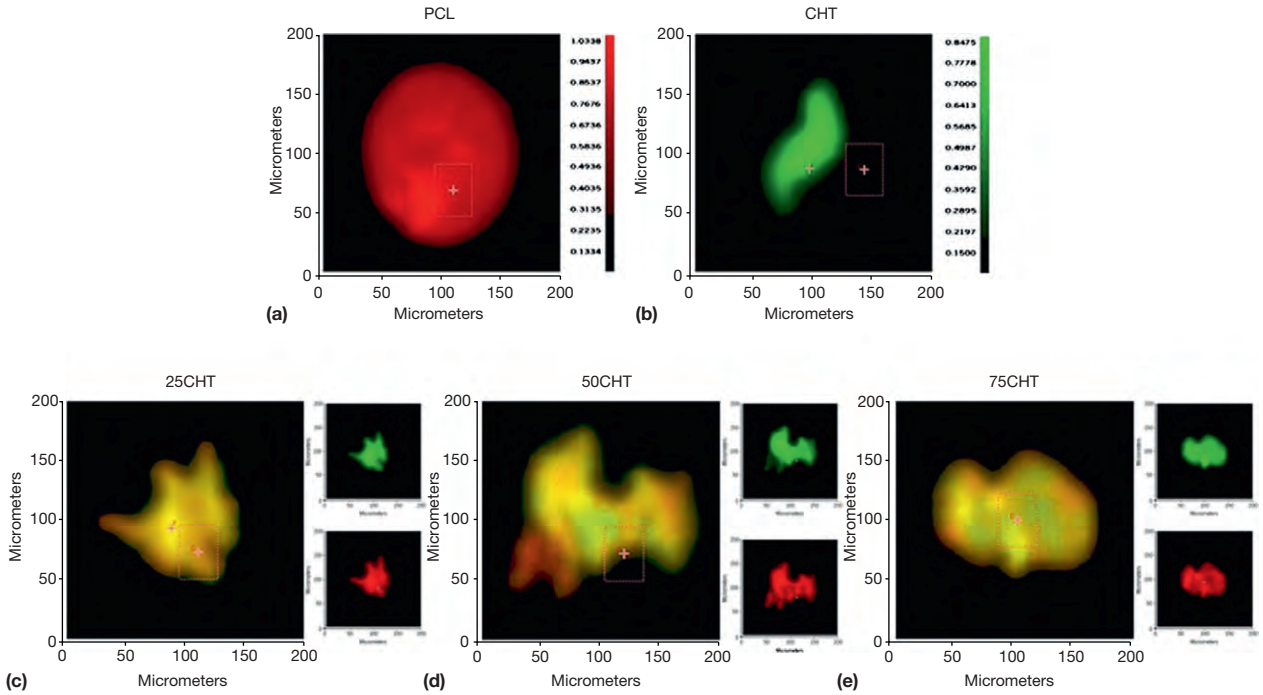

Figure 6 Chemical maps of five discrete compositions of the fiber cross-sections. Note that the existence of regions in the cross-sections with different intensities can be an indication of differences in thickness. For the chemical map, red indicates the presence of PCL, green the presence of CHT, and black corresponds to the epoxy resin. The inset images individualize the presence of the pure polymers in the blends. Reproduced from Malheiro, V. N.; Caridade, S. G.; Alves, N. L. M.; Mano, J. O. F. *Acta Biomater.* **2010**, *6*, 428, with permission from Elsevier.

Alzheimer's disease, blood analyses, skin studies, and identification of pathogenic microorganisms.[32,79–95] Some recent applications to biomaterials are discussed below.

3.322.3.3.1. Raman microscopy

Synthetic hydroxyapatites (HA) and other calcium phosphates are used as bone implants and prostheses in the medical and dental fields, and characteristics of the coatings of the implant are especially important in terms of biocompatibility. Surface characterization, composition, and mineralization of implant coatings such as HA, bioactive glass, ceramic materials, carbons, and bone cement have been investigated with Raman microscopy.[80,96] Comparison of the Raman vibrational bands of pure components can be utilized to assess whether a chemical reaction between the components took place. These analyses also provide information on the crystallinity and identify of different phases in the coating.[97,98]

Dippel *et al.*[99] investigated the integration of bone into a HA-coated implant via FT-Raman microscopy.[99] They assessed canine and human specimens with hip or knee joint prosthesis (uncoated and HA coated) where the samples were removed 6 and 18 months after implantation. The specimens were then dehydrated, embedded in PMMA and cut into 200 µm slices followed by polishing down to 50 µm. Raman measurements were conducted using a NIR FT-Raman spectrometer coupled to an inverted microscope with a Nd:YAG laser ($\lambda = 1064$ nm). After 18 months of implantation with an HA-coated implant, the canine samples showed that the HA coating was separated from the prosthesis forming a gap which was filled with bone ingrowth (**Figure 9**).

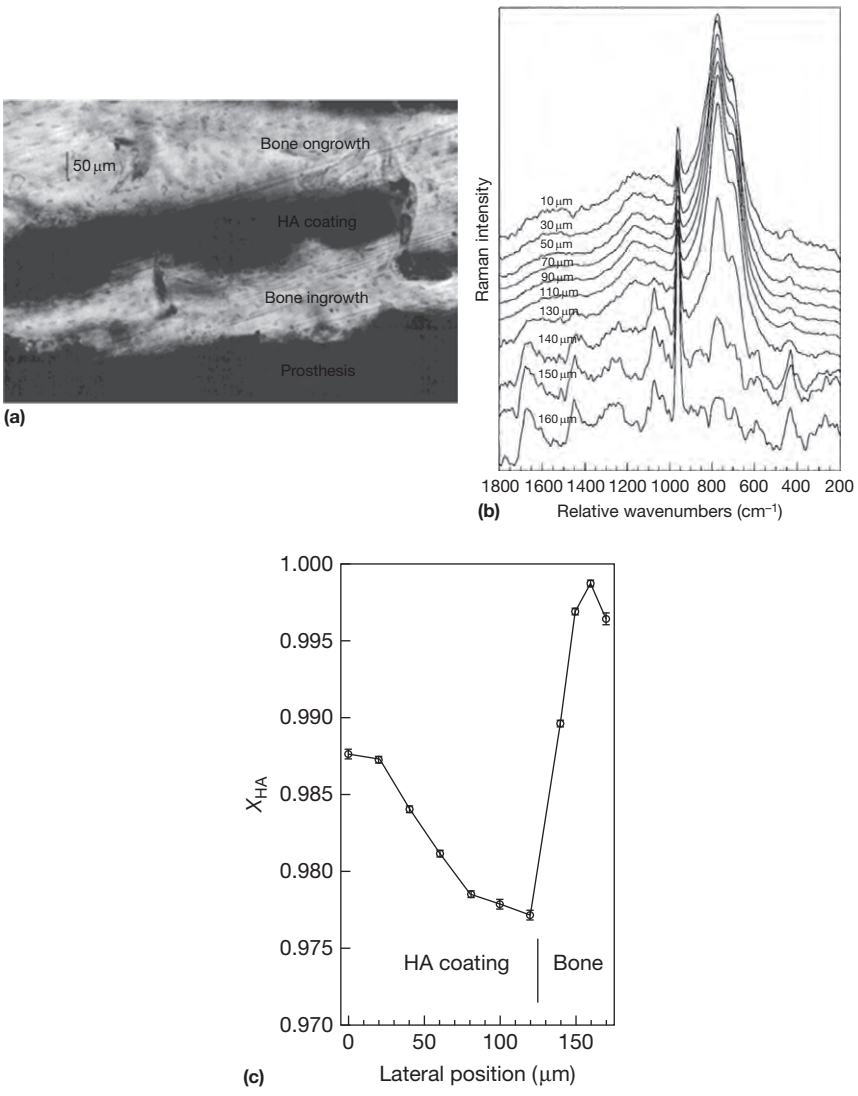

Figure 9 (a) Canine microscopic section 18 months after implantation of a coated implant. The HA coating was separated from the prosthesis. The resulting gap was filled with bone (bone ingrowth). Additionally, bony integration of the HA coating (bone ongrowth) is observed. (b) Series of Raman spectra showing the progression from implant coating (top) to ongrown bone (bottom). (c) HA content (*x*HA) at different lateral positions from the prosthesis. Reproduced form Dippel, B.; Mueller, R. T.; Pingsmann, A.; Schrader, B. *Biospectroscopy* **1998**, *4*, 403–412, with permission from John Wiley & Sons.

They also observed a bony integration (bone ongrowth) with direct contact to the HA coating. A series of Raman measurements were taken from different locations along the coating to the ongrown bone at ~10 μm increments (Figure 9(b)). Figure 9(b) shows that the spectra from the implant HA coating, in addition to the characteristic HA PO-symmetric stretching absorbance at 962 cm^{-1}, have additional dominating bands at 695 and 773 cm^{-1}, probably from POP vibrations of calcium polyphosphates. After the lateral position of 130 μm, the intensities of the organic matrix bands (amide I at 1660 cm^{-1}, and the δ(CH) vibrations at 1445 cm^{-1}), increase, indicative of mineralized protein containing tissue, while the 695 and 773 cm^{-1} bands decrease. This indicates the HA of bone starts to dominate while the calcium polyphosphates decrease. This was quantified by calculation of a mineralization factor, X_{HA}, based on the ratio of the HA and collagen Raman intensities at different lateral positions. Figure 9(c) indicates that the HA which is in direct contact to the implant decreased in mineralization from 98.5% to 97.7% toward the periphery of the coating and increased to 100% at the site of the ongrown bone. Together, the results of this study indicate that FT-Raman spectroscopy can be useful in analysis of compositional changes in HA coatings, along with assessment of the integration of the implant coating with surrounding tissue.

There are a number of Raman studies relevant to dental research including the analysis of synthetic minerals, enamel, dental calculus,[93] dental adhesive resins, and dental implants.[100] Lemor *et al.*[101] utilized Raman microspectroscopy to assess whether chemical reactions were taking place at the surfaces of the dental-amalgam interface that might contribute to adhesion failure, and Miyazaki *et al.*[102] applied Raman microscopy to investigate the chemical composition and demineralization at a dentin–resin interface. In that study, an adhesive system was prepared with a self-etching primer system, Mac Bond II/Palfique Estelite, and a one-bottle adhesive system, Single Bond/Z100. The adhesives were prepared and applied to bovine tooth surfaces, the specimens were sectioned parallel to dentinal tubules and polished. Raman measurements were conducted with a He–Ne laser (wavelength = 632.8 nm) Raman microscope coupled with a CCD camera. The spatial resolution was 0.6–0.8 μm, and spectra were obtained across the dentin–adhesive interface with a 0.2 μm step size.

Figure 10(a) shows the Raman spectrum of bovine dentin without resin. The peak at 960 cm^{-1} arises from the P–O stretching vibration in the mineral component and the bands at 1242, 1450, and 1669 cm^{-1} are associated with the organic phase of dentin. The Raman spectrum of the adhesive is shown in Figure 10(b), where peaks at 640 cm^{-1} (aromatic ring group of Bis-GMA) and 1450 cm^{-1} (C–H alkyl group) were chosen as a measure of resin adhesive. The intensities of selected bands associated with the mineral, aromatic ring, and organic components were plotted across the dentin–resin interface for the different adhesive systems (Figure 11). Transitional changes in the HA and resin were clearly observed at the interface. These changes in the intensity of the Raman peaks suggested that the depth of dentin demineralization was 1.8–2.2 μm for Mac Bond II, and that penetration of Bis-GMA through the entire depth of demineralized dentin occurred.

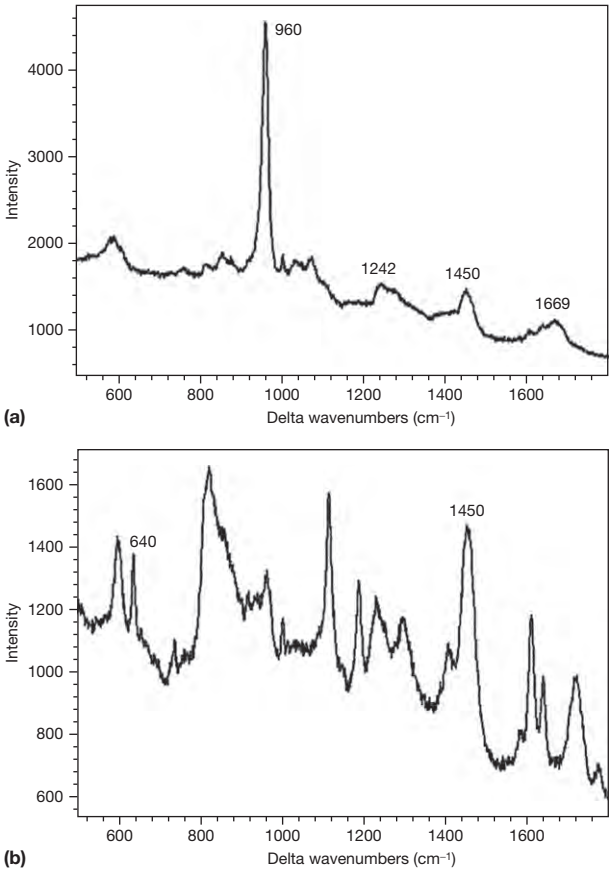

Figure 10 The Raman spectrum of bovine dentin (a) and Single Bond adhesive (b) in the region of 500–1800 cm^{-1}. Reproduced from Miyazaki, M.; Onose, H.; Moore, B. K. *Dent. Mater.* **2002**, *18*, 576–580, with permission from Elsevier.

3.322.3.3.2. Raman imaging

Raman imaging has been employed to monitoring the growth of human cells on scaffolds, to investigate autologous cell culture systems and to evaluate stem cell biology. Several recent studies used this technique to observe real-time cellular interactions with bioactive materials[103] and to detect changes or variation among the cells.[89,104,105] Raman imaging data have been successfully collected from live cells in a nondestructive and noninvasive manner, and different types of cells used in tissue engineering have been recognized based on spectral features.

Applications of Raman imaging in the pharmaceutical industry to characterize drug formulations and kinetics of drug delivery systems have increased in recent years.[83,85,106–108] Information on the degradation of nanoparticulate drug carriers

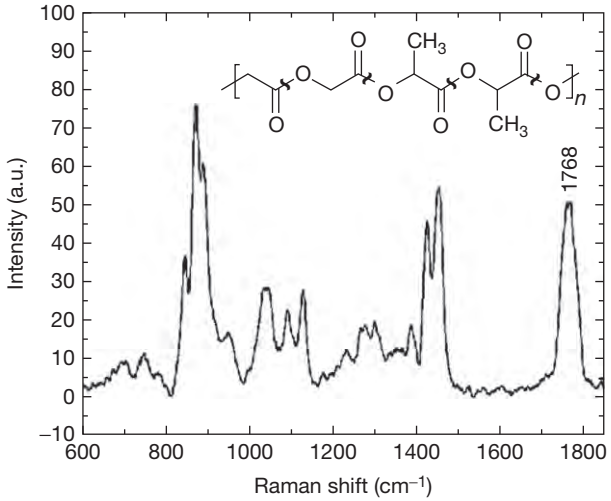

Figure 12 Raman spectrum and chemical structure of PLGA. In the structure, two glycolic acid units are shown on the left, whereas lactic acid units are displayed on the right. The ester bonds (marked '∼'), which are hydrolyzed upon degradation, are characterized by a carbonyl stretching vibration at 1768 cm^{-1}. Reproduced from Van Apeldoorn, A. A.; Van Manen, H. J.; Bezemer, J. M.; De Bruijn, J. D.; Van Blitterswijk, C. A.; Otto, C. *J. Am. Chem. Soc.* **2004**, *126*, 13226–13227, with permission from American Chemical Society.

such as poly(ε-caprolactone) (PCL) and poly(lactic-*co*-glycolic acid) (PLGA) have been assessed based on the decrease of the characteristic spectral peaks of PCL and PLGA. In one recent study, it was found that as the particles integrated into the cell body, shifts in Raman peak heights and ratios occurred that could be indicative of the physical processes that occurred.[83]

Raman imaging also provides information on the degradation of drug carriers *in vivo* and *in vitro*. Van Apeldoorn *et al.*[94] used both confocal Raman microscopy and Raman imaging to assess the degradation of PLGA microspheres inside macrophages *in vitro*. The microspheres were prepared by a salting-out procedure and added to a macrophage cell line. The cells were then cultured on poly-L-lysine coated CaF_2 slides and Raman imaging conducted on samples in PBS. An intracellular area of $7.5 \times 7.5\,\mu m^2$ was scanned with a 647.1 nm laser excitation.

Figure 12 is the Raman spectrum of the pure PLGA, and Figure 13 shows the light microscopy and Raman imaging results of macrophages containing phagocytosed beads. Figure 13(a) reveals a cavity-like structure in the center of the microspheres indicating the degradation of PLGA, as confirmed by Raman imaging as well. Raman images were created using the 1768 cm^{-1} band that is associated with the ester group of PLGA (Figure 13(b)). The image reveals a lower intensity at the center of particles, which means the loss of PLGA ester bonds from these regions. The image also shows a collapsed microsphere in the top right corner.

In another recent study, carbon nanotubes (CNTs) used in drug delivery systems were explored via Raman imaging in order to assess their tumor targeting ability.[109] Single-walled nanotubes (SWNT) have a few strong, distinctive Raman peaks that do not get affected by the fluorescence background and are therefore suitable for Raman imaging. It was shown that isotopically modified SWNTs present shifted G-band (tangential mode) peaks. This feature of SWNTs enables them to be used as color contrast agents in Raman imaging.[110] Figure 14 shows the multicolor confocal Raman imaging of cancer cells that were labeled with three different isotopes of 'colored' SWNT's conjugated with different targeting ligands such as Herceptin (anti-Her2), Erbitux (anti-Her1), and an RGD peptide. These results demonstrate the potential of using SWNT's for biological detection and imaging.

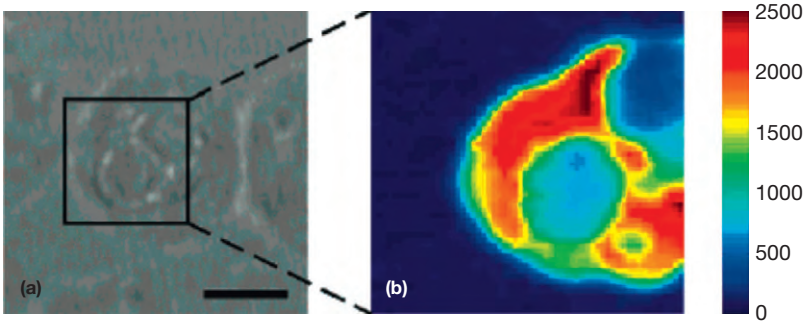

Figure 13 (a) Light micrographs of macrophages containing phagocytosed beads cultured for 1 week (scale bar 5 μm). The Raman image of these beads is shown in (b). The scale in (b) shows the relative intensity of the 1768 cm^{-1} band used for imaging (specific for PLGA ester bonds). Reproduced from Van Apeldoorn, A. A.; Van Manen, H. J.; Bezemer, J. M.; De Bruijn, J. D.; Van Blitterswijk, C. A.; Otto, C. *J. Am. Chem. Soc.* **2004**, *126*, 13226–13227, with permission from American Chemical Society.

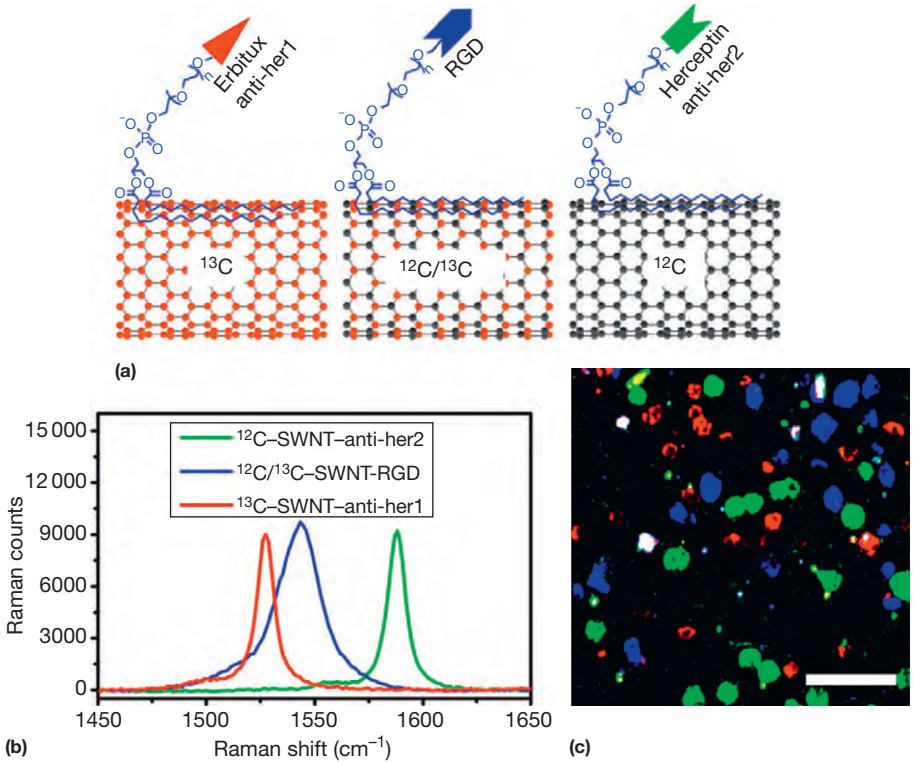

Figure 14 Multicolor Raman imaging with isotopically modified SWNTs. (a) Schematic illustration of SWNTs with three different isotope compositions (13C-SWNT, 12C12/13C-SWNT, 12C-SWNT) conjugated with different targeting ligands. (b) Solution phase Raman spectra of the three SWNT conjugates under 785 nm laser excitation. Different G-band peak positions were observed. (c) A deconvoluted confocal Raman spectroscopy image of a mixture of three cell lines with different receptor expressions incubated with the three-color SWNT mixture. Scale bar = 100 μm. Reproduced from Liu, Z.; Li, X.; Tabakman, S. M.; Jiang, K.; Fan, S.; Dai, H. *J. Am. Chem. Soc.* **2008**, *130*, 13540–13541, with permission from American Chemical Society.

3.322.4. Conclusions

The spatially heterogeneous nature of many biomaterials makes the use of imaging modalities an essential component of analyses, and vibrational spectroscopic techniques can provide a substantial amount of information. Applications of IR and Raman microscopy and imaging to assess biomaterials have greatly increased in recent years, and the field is still maturing. In particular, we anticipate that applications to evaluate cell phenotype and cellular interactions with biomaterials will become essential tools in characterization of the biocompatibility of materials. The ability to obtain images of molecular environments utilizing these methods will greatly enhance correlations of composition with mechanical strength and cell interactions, with the ultimate goal of optimization of *in vivo* material properties.

3.328.1. Introduction

Sol–gel processing technique, first reported by Ebelman in the mid-eighteenth century, historically used for fabricating decorative and constructional materials, was extensively developed in the last century for applications such as glasses, ceramics, catalysts, coatings, composites, and fibers.[1] In general, the sol–gel process involves the transition of a system from a liquid 'sol' (mostly colloidal) into a solid 'gel' phase. Because of the special properties of sol–gel materials (e.g., optical transparency, porosity and high surface area, chemical inertness), sol–gel technology has been gradually extended to the encapsulation of specific biorecognition elements, such as enzymes, antibodies, oligonucleotides, or even whole cells and tissues.[2,3] The immobilized biological recognizing elements in sol–gel matrix exhibit structural integrity, very often full biological functions and also significant stability to resist chemical and thermal deactivation.[4,5] Moreover, the sol–gel matrix provides the advantages of good biocompatibility and large immobilization capacity.[3,6] As a result, sol–gel materials offer a suitable and versatile platform for the fabrication of biosensors.[7–9]

A biosensor is a device capable of providing selective quantitative or semiquantitative analytical information using a biological recognition element, by converting a biochemical event into a detectable signal via a transducer and a processor.[8–10] Typically, the biosensor is a self-contained analytical device capable of detecting an analyte which consists of a selective biorecognition element (bioreceptor) and a transducer which converts the changes in the physicochemical properties during the detection of an analyte into a suitable

analytical signal. Biosensors can be classified according to the transduction element (e.g., electrochemical, optical, piezoelectrical, thermometric, or magnetic biosensor) or the biorecognition principle (e.g., enzymatic, immunoaffinity recognition, or whole-cell biosensor). Since the first introduction of the word 'biosensor' by Clark and Lyons,[11] numerous exciting biosensor designs have been proposed in several reports during the past few decades. Nevertheless, simple, low cost, and reliable methods for bioreceptor immobilization are still required for the further development of biosensors, as immobilization is the key step in the fabrication of biosensors.

Several excellent book chapters[9,12] and reviews[7,8] on the applications of sol–gel process for the development of various biosensors for a wide range of applications have been published. Through an exhaustive survey of literatures, it has been shown that a significant number of recent papers clearly illustrate the growing interest on the sol–gel process to develop biosensors.

This chapter, therefore, summarizes a variety of currently available biosensors based on sol–gel-derived materials. Section 3.328.2 gives an overview of current developments in the various sol–gel bioencapsulation techniques, classified according to the immobilized biorecognition elements, stability of biorecognition elements, and interactions between sol–gel matrix and analytes; Section 3.328.3 describes the different classes of sol–gel biosensors, including electrochemical biosensors, optical biosensors, and biosensors based on other transducing principles in detail; and Section 3.328.4 outlines the concluding remarks, challenges, and future prospects of biosensors based on sol–gel-derived materials.

3.328.2. Sol–Gel Bioencapsulation

Sol–gel processing is a soft-chemistry method and high purity method to obtain functionalized materials at low temperature and mild chemical conditions. These materials' hosting and recognition properties, as well as their flexible chemical structures containing many easily accessible active sites, make them particularly attractive for analytical purposes.

Immobilization of biological recognizing elements (e.g., proteins, enzymes, antibodies, DNA, and whole cells) by entrapment in the sol–gel materials has become a research area of intense interest.[2,4,8,13,14] Braun *et al.*[15] first reported that a purified enzyme, alkaline phosphatase (ALP), can maintain some of its biological activity while being entrapped in a tetramethoxysilane (TMOS)-derived sol–gel matrix. Later, Ellerby *et al.*[16] modified this approach to improve on the stability of biomolecules during encapsulation. Bioencapsulation in sol–gel matrices typically involves hydrolysis of tetraalkoxysilanes in an acidic or alkaline medium followed by the addition of biomolecules in the presence of a buffer (pH 7), which initiates condensation of the hydrolyzed precursors around the biomolecules that become physically entrapped in an active form within the porous silicate network.

Since these pioneering studies, many enzymes and proteins have been immobilized in a functional state, and quite a few of them have been protected against degradation by the sol–gel network and have exhibited better activity and longer lifetime than free soluble enzymes. By entrapment in (surfactant modified) silica sol–gel matrices, ALP, naturally with an optimum pH of 9.5, was kept active at extreme acidic environment as low as pH 0.9 and acid phosphatase, naturally with an optimum activity at pH 4.5, was kept functioning at extreme alkaline environment up to pH 13.0. It was found that the protection of the enzymes against harsh pH conditions is dependent on the nature of the surfactant in the sol–gel matrix.[17] Recently, researchers have attempted to optimize this process by controlling the porosity of bioencapsulates and chemical environment of trapped species to avoid the too constrained motions of encapsulated proteins, and to obtain the necessary conformational changes for binding and release of substrates. Investigators have also proposed alternative synthetic routes to avoid enzyme denaturation due to release of alcohol during the hydrolysis and condensation of the tetraalkoxysilanes in a typical sol–gel process. Notably, avoiding denaturation requires the use of biocompatible silane precursors, aqueous silicate starting materials, protein-stabilizing additives, such as charged polymers, or sugars and amino acids.[17,18]

Bioencapsulation via sol–gel processing enables the conversion of labile biological materials into reusable and physicochemically robust (nano)composites that can be interfaced with spectroscopic and electrochemical platforms to generate different analytical useable biosensing devices.[19] The porous structure of the silica matrix ensures an effective biomolecule entrapment while enabling analytes to access the bioactive centers and the diffusion of product(s) from the reaction site. To ensure that the biosensor can achieve the best possible performance, one must provide suitable transduction of the biological recognition event into a measurable physical signal, and one must enhance both the accessibility of the analytes to entrapped biorecognition elements and the mass-transfer rates to improve the biosensor sensitivity.

3.328.2.1. Sol–Gel Immobilized Biorecognition Elements

3.328.2.1.1. Enzymes

Since the emerging report of sol–gel bioencapsulation, enzymes have been widely studied due to their well-known biochemical mechanisms, commercial availability in good purity, wide applications, good solubility in water, good stability, and simple molecules compared with animal, plant, or microorganisms. Dickery[20] demonstrated for the first time bioencapsulation with partial activity of urease and catalase in the sol–gel matrix, but muscle adenylic acid deaminase completely lost its activity. After three decades, considerable attention has resurfaced toward the bioencapsulation using sol–gel glasses. Braun *et al.*[15] successfully encapsulated ALP in silica gel, which retained its activity up to 2 months with improved thermal stability. Furthermore, Shtelzer *et al.*[21] sequestered trypsin within a binary sol–gel-derived composite using tetraethoxysilane (TEOS) and polyethylene glycol (PEG). Ellerby *et al.*[16] also entrapped other proteins, cytochrome *c* (cyt *c*) and myoglobin (Mb), in TEOS sol–gel. Later studies on bioencapsulation were well recorded by other groups, and several proteins, such as Mb, hemoglobin (Hb), cyt *c*, lactate oxidase, glucose oxidase (GOx), ALP, Cu–Zn superoxide dimutase, urease, bacteriorhodopsin (bR), horseradish peroxidase (HRP), and acetylcholinesterase (AchE) were immobilized into various sol–gel matrices. Other studies have included the

various aspects of sol–gel entrapped biomolecules in various properties, such as conformation, dynamics, accessibility, reaction kinetics, activity, and stability.

3.328.2.1.2. Antibodies

The specificity and sensitivity of antigen recognition by antibodies or enzyme-labeled antibodies immobilized in sol–gel materials have been exploited to design affinity biosensors and immunoassays.[22] An acid-labile temperature-responsive sol–gel reversible polymer for enhanced gene delivery to the myocardium and skeletal muscle cells was reported; multiblock copolymers (MBCPs) synthesized from pluronic (R) and di-(ethylene glycol) divinyl ether were used as a delivery vehicle for controlled and sustained release of plasmid DNA (pDNA) in *in vitro* as well as *in vivo* experiments. The nonionic MBCP/pDNA complex showed remarkable transfection efficiencies against the myocardium cells as well as muscle cells *in vivo*, which is otherwise very difficult to achieve by using cationic polymers. In *in vitro* experimental settings, this intelligent stimuli-responsive polymer was shown to improve the transfection efficiency of branched polyethylenimine (BPEI)/pDNA complex when used together. The rapid sol–gel transition of MBCP under thermal stimuli with concomitant release of pDNA under acidic stimulation has potential for site specific, efficient, and controlled transfection of therapeutic gene.[23] The schematic was shown in Figure 1.

In addition to the obvious applications of these designs, namely determining biologically relevant species and detecting diseases, they have also been used for environmental monitoring, for example, detecting contaminants that alter the biosensor response.[24] Although some optical detectors have been reported (e.g., on the basis of antifluorescein antibodies), the key transduction method has mostly involved electrochemical methods, namely potentiometry, amperometry, and conductometry. Sol–gel-derived electrochemical immunosensors based on enzyme-labeled antibodies have experienced advances similar to those described in Section 3.328.2.1.1 and Section 3.328.2.1.2, including improvements in charge-transfer reactions, mass transport of analytes, and the durable immobilization of all components onto the electrode surface. Aptamers are oligonucleic acid or peptide molecules that bind to a specific target molecule, usually created by selecting them from a large random sequence pool, and have been developed to specifically capture the toxic target molecules.[25] Notably, these improvements have allowed us to take advantage of the chemistry of organosilane reagents to enhance the analytical performance and operational stability of the devices[26] and to use nanoparticles assembled in three-dimensional sol–gel networks to enhance the sensitivity of amperometric immunosensors.[27]

3.328.2.1.3. Whole cells

Whole cells (e.g., *Escherichia coli*) have been encapsulated in sol–gel materials in a way that blocks their proliferation and prevents bacterial death upon entrapment,[18,28] which are necessary prerequisites for biosensor development. Most biosensors based on sol–gel entrapment of whole cells employ optical detection modes that exploit the excellent transparency of the silica matrix. Recent examples include fluorescence detection of herbicides with immobilized *Chlorella vulgaris*[29] and naphthalene determination from the bioluminescence response of the bacterial bioreporter *Pseudomonas fluorescens* HK44.[30] Liu *et al.*[31] reported on an organic–inorganic hybrid material, which consisted of silica and copolymer of poly (vinyl alcohol)-grafted-poly(4-vinylpyridine) (PVA-*g*-PVP), and employed to immobilize *Trichosporon cutaneum* strain 2.570 cells. It revealed that arthroconidia produced in the

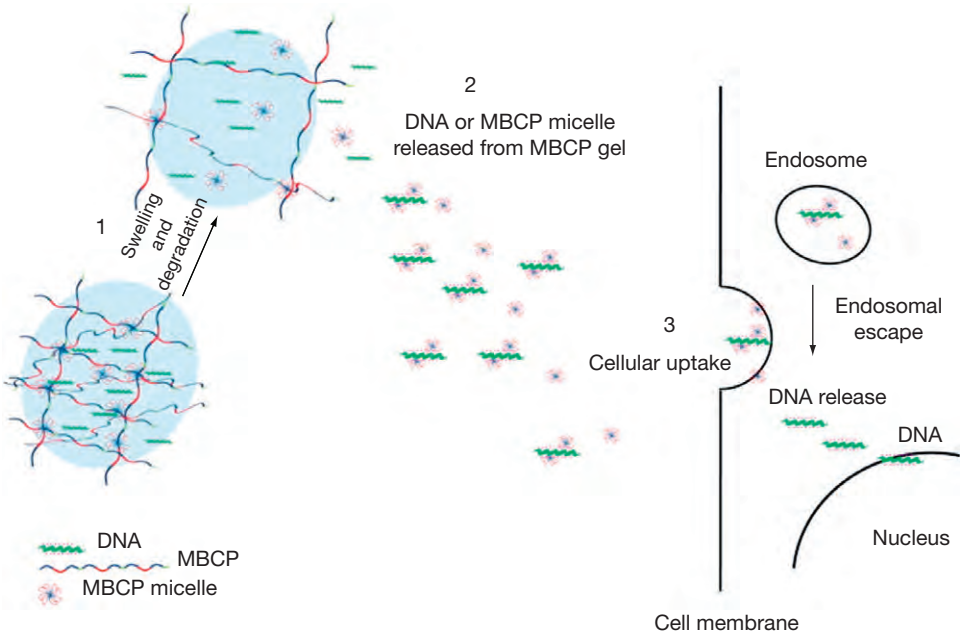

Figure 1 Schematic diagram of MBCP-mediated gene delivery. By swelling and degradation of MBCP gel (1), DNA or MBCP micelles are released into the medium and form complex (2), finally complexes enter into the cells by endocytosis (3). Adapted from Namgung, R.; Nam, S.; Kim, S. K.; *et al. Biomaterials* **2009**, *30*, 5225–5233, with permission.

extracellular material played an important role in keeping the long-term viability of the immobilized microorganism. Other detection methods are based on piezoelectric or surface plasmon resonance measurements. In addition to bacteria, other microorganisms can be used for biosensing applications.[32]

3.328.2.2. Stability of Biorecognition Elements in Sol–Gel Matrix

Leaching of biorecognizing elements from the sol–gel matrix is one of the problems of the immobilization method and this is due to the porosity of the matrix. The decrease in concentration of entrapped species can be observed because these entrapped species are able to migrate out of the matrix resulting in contamination of the media and degradation performance of the biosensor. Direct bonding of molecules to inorganic network is difficult due to relative inertness of the surface, for example, silica matrix has only siloxane and silanol groups.[33] However, such materials can be activated via surface modification, that is, via functional group immobilization which allows the formation of covalent bond. Unfortunately, covalent immobilization may alter the structural and optical properties of the sensing reagent leading to a loss of biosensing properties. In some applications, increasing the hydrophobicity of the network can also prevent leaching. In this case, hydrophobicity allows the increase of sensitivity because water, which decreases the gas permeability, cannot penetrate into the matrix. Another opportunity to increase the chemical stability of the biosensor is preparation of organic–inorganic copolymer using, for instance, using poly(vinyl alcohol) and silica.[34]

The conformational structures of entrapped proteins have been examined. Conformational studies have indicated that proteins tend to retain a native conformation immediately upon entrapment, although some proteins, such as Mb, may undergo substantial conformational changes during entrapment.[35] Aging of the sol–gel matrix can induce significant structural changes in the entrapped proteins. For example, fluorescence measurements for the acrylodan-labeled proteins were consistent with partial unfolding of a fraction of the entrapped protein as aging continued. These structural changes resulted from the changes in internal solvent composition (owing to loss of water and solvent molecules) and subsequent protein–silica interactions, which lead to undesirable changes in the protein conformation. Studies have indicated that the conformational motions of large proteins, such as bovine serum albumin, can be substantially restricted in the sol–gel media, and that in certain cases inactive conformations may end up 'trapped' in the sol–gel matrix.[36] On the other hand, small proteins, such as cyt *c* and parvalbumin, appear to retain their full conformational flexibility upon entrapment and are only moderately affected by aging of the matrix. The inability of larger proteins to fully unfold within the silica-based glasses indicates that the small pore sizes provide insufficient free volume to accommodate the fully unfolded protein as typical pore diameters in aged silicates are 5–20 nm.

Denaturation studies have also indicated that the entrapment of proteins often leads to the need for higher temperatures or denaturant levels to induce protein unfolding.[37,38] Entrapment can also stabilize proteins against other denaturing forces, for example, in the case of catalase, the silica gel stabilises the encapsulated enzyme to higher methanol concentrations. Oxidation of either HRP or Mb by peroxide can also be minimized by immobilization of the proteins in the silicate matrix. The enhanced stability of entrapped proteins has been related to a 'molecular confinement' process, wherein the protein is restricted in its ability to undergo conformational changes and therefore requires a higher energy input before it can unfold. Studies have suggested that increased thermal stability may in fact be transient and that continued aging of the matrix can result in slow denaturation of the protein and loss of conformational integrity. These studies have also indicated that the unfolding of entrapped proteins in most cases is irreversible, predominantly owing to adsorption of the unfolded protein onto the solvent–silica interface. However, reversible denaturation has been reported in the case of the anionic Ca(II)-binding protein oncomodulin,[39] likely owing to unfavorable electrostatic interactions between the protein and the silicate surface.

3.328.2.3. Interactions Between Sol–Gel Matrix and Analytes

The interactions between sol–gel matrices and analytes include electrostatic, hydrogen bonding, and hydrophobic interactions.[40,41] They play key roles in the accessibility of analytes to the entrapped biomolecules even though the pore sizes are large enough for the analytes to pass though the matrices and are important in determining the accessibility of analytes to entrapped proteins. For cases in which repulsive or attractive interactions exist between the glass and analytes, the sol–gel matrices take up the analytes either partially or excessively.[19,42] The study of these interactions is very important because they affect the diffusional properties significantly. Collinson[43] revealed that diffusion is governed by interactions between the entrapped cationic guest and the negatively charged walls of the sol–gel host. Specifically, negatively charged molecules reside in the center of the fluid-filled pore and move at rates similar to the rates at which they move in solution. Positively charged molecules, however, electrostatically interact with the walls of the matrix (silica has a p*I* of −2 and therefore the walls are negatively charged under these conditions) and do not move as rapidly. Diffusional rates slow down as the gel dries and shrinks because the entrapped reagents are closer to the pore walls. The results were supported by strategically modifying the walls of the silica host with organoalkoxysilanes. The most convincing evidence comes from hybrid gels prepared using *N*-trimethoxysilylpropyl-*N*,*N*,*N*-trimethyl trimethylammonium chloride or a polyamine (N^+) polymer. In these gels, it was shown that $Co(bpy)_3^{2+}$, a large positively charged ion, diffused at the same rate as it did in the sol and maintained that rate during a 3-week drying period. In contrast, $Fe(CN)_6^{3-}$ showed an order of magnitude drop in its apparent diffusion coefficient during a few days of drying period. In either case, internal and external concentrations of the ion are unequal even after equilibrium is reached.[44] The protein entrapped in TEOS gels completely showed accessibility to the neutral quenchers, perhaps partial accessibility or repulsion in case of negatively charged quenchers.[45]

3.328.3. Applications of Sol–Gel Biosensors

By far, the most widespread applications of biological recognizing elements doped sol–gel materials have been the development of biosensors. A number of review articles have been published in the general field of sol–gel-based biosensing.[8,14,42,46–48] Such biosensors rely on the intimate interfacing of a biorecognition element to a physical transducer that converts the biological reaction into a measurable signal. Typical transduction schemes in biosensors include electrochemical, optical, piezoelectrical, thermometric, and magnetic methods. However, most sol–gel-based biosensors have relied on electrochemical and optical transduction schemes, for example, amperometric, potentiometric, fluorescent, and absorbent modes.

In the case of biosensors, the key attributes that can be optimized include response time, initial and long-term biological activity, analytical range, sensitivity, selectivity, detection limit, and reproducibility. To a certain extent, many of these parameters are determined by the biorecognition element itself on the basis of its binding constant to the analyte of interest and by the specific detection method employed. Substantial changes in analytical performance can, therefore, be derived from changes in these parameters. A great effort has been made to understand short- and long-term interactions between the biorecognition elements and the evolving sol–gel matrix.[7,49,50] Typically, reduced accessibility or activity leads to poorer sensitivity and detection limits and may alter the analytical range. Furthermore, analyte–matrix interactions can lead to an expanded analytical range, but lower sensitivity, although this can be controlled to some degree by the addition of charged polymers. Other advantages include the ability to make the matrices either electrochemically active or optically transparent, the ability to achieve high protein loading, to tune the polarity and porosity of the matrix to selectively modulate enzyme activity, the potential to modulate the material composition to maximize the biocompatibility of the matrix, and the reduced leaching of biomolecules.

While sol–gel-based biosensors have several advantages, they also suffer from a number of disadvantages. For example, it is generally difficult to predict the final properties of the sol–gel matrix. Aging of sol–gel materials is also a problem, as this process can take up to several months. As the matrix ages, the analytical parameters of merit also change; hence, there is a need for continual recalibration of the biosensor. Denaturation of entrapped biorecognition elements with time can also lead to problems with calibration, and may even result in a loss of biosensor function overtime. Furthermore, pore diameters must be carefully controlled to allow facile transport of analytes into the matrix and diffusion of products away from the reaction site, while preventing leaching of entrapped biorecognition elements. Finally, cracking and shrinkage of the matrix during aging can lead to serious problems with biosensor responses and, in some extreme cases, can lead to removal of the bioreceptor from the biosensor surface.

Sol–gel bioencapsulation has been widely used to immobilize enzymes onto the surface of an electrode or an optical biosensor. The development of biological-based rapid glucose assays has centered on the development of glucose biosensors.[51] Many of the sol–gel-based biosensors typically focus on glucose biosensing as a test case, mainly due to the inherent stability of GOx, the diversity of sensing parameters for glucose, and the clinical importance of this analyte. Glucose biosensors rely on entrapment of GOx, which catalyzes the oxidation of glucose to gluconic acid, and the simultaneous generation of hydrogen peroxide (H_2O_2). The GOx enzyme has been entrapped into a wide variety of sol–gel-derived materials, including silica, metallosilicates, ormosils, and composites which have been formed as monoliths, fibers, layers, thin films, or microarrays. Detection strategies for glucose have relied on the measurement of oxygen levels, H_2O_2 concentration, pH, or changes in the emission properties of the flavin moiety of GOx using electrochemical, absorbent, or fluorescent transduction schemes. Such methods typically provide sensitivity over the physiologically relevant range, rapid response times, and good stability.

In addition to GOx and HRP, biomolecules such as urease, AchE (for pesticide detection), cholesterol oxidase (ChOx), lactate oxidase and lactate dehydrogenase, monoamine oxidase, tyrosinase, catalase, and other oxidoreductases and even whole cells have been developed based on sol–gel-derived biosensors. Bienzymatic immobilization has also been applied to improve the performance of such biosensors.[52] These include substrates, cofactors, effectors, and inhibitors of enzymes, antigens, and haptens that bind to antibodies and gaseous molecules such as O_2, CO, and NO that bind to heme-containing transport proteins. The majority of biosensors fabricated by the sol–gel method have demonstrated reasonable performance with good detection limits, useful analytical ranges, and in many cases excellent long-term stability.

3.328.3.1. Electrochemical Biosensors

Sol–gel-derived materials have attracted the attention of many electrochemists because they provide a versatile way to prepare modified electrodes.[7,8,19,42,53,54] One of the major advantages that sol–gel technology offers to the electrochemical biosensor is that the composition of sol–gel hybrid materials can be easily varied to develop electrodes with different configurations. The slow diffusion of the electroactive species within the sol–gel matrix causes a long response time, hence for the improvement of conductivity, it is possible to prepare electrodes that contain conducting species, organosilanes or polymer additives, redox mediators, and several enzymes, each of which can be used to finetune the properties of the electrode. Typical conducting species including graphite, gold, palladium, iridium, ormosils, and polymers are generally used to modulate enzyme activity. For example, it has been demonstrated that the incorporation of polycationic polymers into the sol–gel materials could improve the performance of flavoproteins,[55,56] while Wang *et al.*[57] demonstrated that the incorporation of copolymers into silica-based glasses can improve the activity of entrapped GOx for amperometric detection of glucose. Gavalas *et al.*[58] have doped carbon nanotubes (CNTs) as conductive materials into alkoxysilane sol–gels, and L-amino oxidase was encapsulated into CNT sol–gel through and an aqueous sol–gel process. The added particles improved

morphology of the composite surface and electrochemical response characteristics.

Most sol–gel-derived electrochemical biosensors reported to date have mainly relied on one of the two basic configurations: conductive ceramic composites and thin sol–gel film coating on the electrode surface. Since the pioneering work of Glezer and Lev,[59] sol–gel-derived composite carbon electrodes have been widely used to develop all kinds of amperometric biosensors.[60–62] The first configuration utilizes a bulky monolith that is doped with conducting materials to create a conducting bioceramic. This is typically achieved by dispersion of carbon or metal powders or colloids (the conductor) together with biomolecules and mediators (when necessary) into the sol before gelation occurs.[63–65] This protocol yields rigid, porous, conducting biocomposites that can be molded in glass tubes to obtain a disk electrode. In particular, this type of biocomposites is suitable for microfabrication. The second configuration involves formation of thin films by spin or dip coating or simply spreading of a sol containing biomolecules and mediators on top of the conventional electrode surfaces.[66–71] This configuration usually avoids the need for dispersion of a conductive component, and is most useful for electrochemical biosensors because of its short diffusion pathway. Three main approaches for the electrodes dependent on the convenience, stability, and response are as follows: single-layer, bilayer, and sandwich configurations (Figure 2). Along with entrapment inside the sol–gel matrix, a few studies have been carried out by covalently linking the active biomolecules on the surface of the sol–gel functionalized matrices.[72,73] Another important factor in developing biosensors is the thickness of gel film. In most cases, thin films exhibit quicker response than the thick layers due to the good diffusion properties.[74–76] With increasing gel thickness, the signal decays and diffusion of analytes to a biomolecule active site becomes slow; eventually these factors lead to poor response. Homogeneous distribution of enzymes is possible in sol–gel films compared with regular carbon paste electrodes; hence, it allows the homogeneous electron transfer and larger current response in amperometric sensing.

Figure 2 illustrates the three most commonly used thin film configurations employed in sol–gel-derived electrochemical biosensors. In the single-layer configuration, the bioreceptor-doped sol–gel film is directly deposited onto the electrode surface. For mediated electrochemical biosensors, mediators can be entrapped together with the bioreceptor in the sol–gel film or may be present in the solution phase, if it is soluble. In the bilayer configuration, initial sol–gel layer is first deposited on the electrode surface and the bioreceptor is then attached either by simple adsorption or by covalent binding via functional groups such as thiol or amine groups present on the sol–gel surface. In this case, the bioreceptor solution can be directly deposited on the surface of an electrode such as a carbon paste electrode, after which a sol–gel film is deposited as a protective layer to prevent the leaching of bioreceptor. For mediated biosensing, the mediator layer is first deposited on the electrode surface and a layer of a bioreceptor-doped sol–gel film is then deposited on top of the mediator layer. For the deposition of the mediator layer, the mediator can be dissolved in an organic solvent or added in the sol before application on the top of the electrode surface.

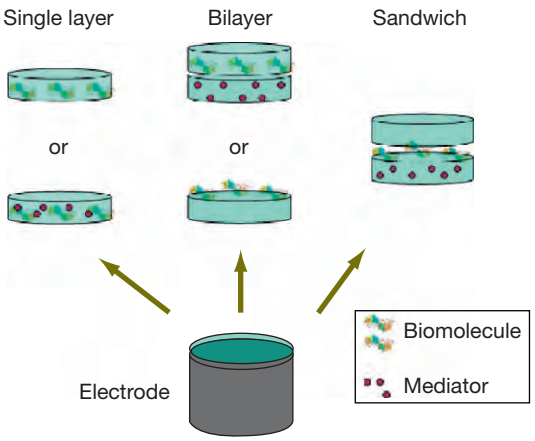

Figure 2 Configurations used to interface sol–gel-derived thin films to electrochemical biosensors.

In the sandwich configuration,[77,78] the mediator-doped sol–gel layer is first deposited on the electrode surface. The bioreceptor layer can be formed by spreading either an enzyme solution or an enzyme containing sol on top of the mediator layer. Another layer of sol–gel-derived material is then added as a protective layer, which prevents bioreceptor leaching and microbial attack. The key advantage of the sandwich configuration is that the methods used to form the first layer and second layer, and the thicknesses, polarity, and porosity of these layers can be different, permitting some control over the final properties of the sandwich films. The two sol–gel layers have great influence on the performance of the glucose biosensor.[63] This configuration provides good sensitivity, low detection limits, and fast response times compared to the use of a bulky monolith for electrochemical measurements. Pauliukaite *et al.*[78] reported protective polymer coatings used to enhance the retention of enzymes in sol–gel films. Carbon film electrodes were electrochemically modified with poly (neutral red). These electrodes were coated with sol–gel films incorporating GOx and an outer coating of carboxylated poly(vinyl chloride) or polyurethane (PU) with and without Aliquat-336 or isopropyl myristate plasticizer. The membranes without plasticizer extend the lifetime of the biosensor to more than 2 months, when PU is used as an outer membrane.

The typical electrochemical biosensors based on sol–gel matrices are listed in Table 1. As shown in Table 1, among the numerous enzymes studied, GOx and HRP have been widely used in sol–gel entrapment studies. The sol–gel immobilized GOx exhibits high thermal stability in terms of half-life mainly due to the favorable local polymer–protein interaction between the positive charges on the GOx and the negatively charged silicate matrix. Tatsu *et al.*[163] prepared TEOS-derived silica gel doped with GOx and responded to glucose of physiological concentration in a flow-injection analytical system. Metal alkoxides are more attractive matrices because they provide good conductivity and the possibility of manipulation of polarity, rigidity, pore size and distribution, and electronic conductivity. Taking into consideration the advantages of metal alkoxides, Glezer and Lev[59] prepared platinum electrodes coated with vanadium pentoxide sol–gel film doped with GOx. Wang *et al.*[71] reported a glucose biosensor based on immobilization

Table 1 Typical electrochemical biosensors based on bioreceptors encapsulated in sol–gel matrices

Biorecognition element(s)	*Analyte(s)*	*Sol–gel precursors*	*Principle of detection*	*Linear range/detection limit*	*References*
Acetylcholinesterase	Paraoxon	ZnO	Amperometry	0.035–1.38 ppm	65
Acetylcholinesterase	Chlorpyriphos-ethyl-oxon	Al_2O_3	Amperometry	2.5×10^{-10} M	79
Alcohol dehydrogenase	Alcohol	Pd–Ormosil	Amperometry	0.04 mM	80
Alcohol dehydrogenase	Alcohol	CNT–Ti_2O_3	Amperometry	1.0×10^{-5} M/3.0×10^{-3} M	81
Aldehyde dehydrogenase	Acetaldehyde	MTMOS/Meldola's blue	Amperometry	10–260 μM	82
L-Amino acid oxidase	L-Phenylalanine	Ormosil	Electrochemical method		60
L-Amino acid oxidase	L-phenylalanine	PTMOS/sodium silicate/carbon nanotubes	Cyclic voltammetry	0.02–10 mM/0.02 mM	58
Catalase	H_2O_2	TMOS	Voltammetry	1–30 μM/0.4 μM	83

of enzyme in alumina (aluminum isopropoxide) sol–gel films on a platinized glassy carbon electrode. At the GOx/sol–gel/platinized glassy carbon electrode, glucose response started at +0.20 V and approached a maximum value at +0.60 V. The low operating potential greatly reduced the interference from coexisting electroactive species. Liu *et al.*[164] immobilized HRP in the ZrO_2 sol–gel matrix to develop a biosensor for the H_2O_2 determination. A simple vapor-deposition method was introduced to immobilize HRP, GOx, and other biomolecules in titania sol–gel, which retained their catalytic activity and exhibited good response on electrode surface.[111,165,166] The uniform porous structure of the titania sol–gel matrix has very low mass transport barrier, a high catalytic activity, and a fast response. The advantages of room temperature (or lower) processing conditions, chemical inertness, negligible swelling effects, tuneable porosity, and the high purity of sol–gel-derived glasses make them ideal for many types of biosensing applications. Narang *et al.*[167] developed a glucose biosensor by immobilizing GOx between two sol–gel layers (sandwich). GOx was immobilized in/on a thin TEOS sol–gel film using physisorption, microencapsulation, and a new sol–gel: GOx:sol–gel sandwich configuration for amperometric detection of glucose. The results clearly demonstrate that the sandwich configuration exhibits a fast response and high enzyme loading.

Mediated biosensors have gained wide attention for probing redox enzyme catalyzed reactions. The participation of redox mediator in signal transduction leads to the development of second generation biosensors. Mediators such as ferrocene and its derivatives, osmium complexes, quinone salts, and ruthenium complexes have been employed in biosensors. Biosensors in which the mediator is coimmobilized with enzyme on electrode will not require the addition of the former to the test solution, thereby eliminating many practical challenges. The immobilized mediator catalyzes the redox reactions of biomolecules and shuttles the electrons more efficiently between enzyme and electrode to greatly enhance the sensing performance, and operating potential of the biosensor is typically lowered. On the other hand, the inclusion of electrocatalytically active graphite-supported palladium, platinum, and ruthenium or gold nanocrystals allows the construction of mediator-free electrodes that are highly sensitive, selective, and stable. However, the incorporation of a redox mediator within sol–gel network may provide strongly diminished electrochemistry in dried xerogel samples due to the restricted mobility in a dried sol–gel structure. Mediatorless amperometric biosensors have been reported by coupling GOx with HRP or soybean peroxidases, which mediate the reduction of H_2O_2.

The fundamental problem arising in the construction of an amperometric glucose biosensor is the selectivity of the substrate detection. The often-used detection approach is electrochemical oxidation of the liberated H_2O_2 through the enzymatic reaction, and requires a relatively high working potential. At such a potential, endogenous or exogenous compounds present in biological samples (e.g., urate, ascorbate, or paracetamol) can be electrochemically oxidized, leading to a high level of interference and false results in the quantification of glucose concentration. To overcome this limitation, Wang *et al.*,[168] and Sampath and Lev[169] took advantage of the catalytic

properties of palladium-modified carbon particles to detect glucose at lower potentials (+0.30, +0.50 V) via a screen-printing process or by molding the porous organically modified silica in a glass capillary. A type of sol–gel-derived, inert metal-modified, composite, amperometric biosensor is developed. The electrodes are composed of a dispersion of biochemically and chemically modified graphite powder in a porous, organically modified silicate (ormosil) network. The percolating carbon dispersion provides electrical conductivity; oxidoreductase enzymes are used for biocatalysis, metallic palladium is used for electrocatalysis of the biochemical reaction product; and the porous organically modified silica provides a rigid skeleton.

The hydrophobicity of this composite material guarantees that only a limited section of the electrode is wetted by the aqueous analyte, thus providing a controlled-thickness reactive layer. Coche-Guerente *et al.*[170] reported a mediatorless amperometric bienzymatic glucose biosensor. This mediatorless sensor was made by the simultaneous immobilization of graphite microparticles and two enzymes (HRP and GOx) in a silica gel matrix. The amperometric detection of glucose was assayed by applying a potential of 0 V versus SCE in order to reduce the catalytically generated H_2O_2. The active graphite particles evenly dispersed within the silica gel matrix establish an efficient electrical communication between the electrode surface and the HRP active center. By taking advantage of the direct electrochemistry of HRP, reagentless immunosensors have been developed for the detection of carcinoma antigen 125 and HCG. These kinds of reagentless immunosensors are quite useful for medical applications because the use of fewer reagents in clinical assays leads to less interference and more accuracy, especially in the analysis of real biological samples. Abad *et al.*[171] presented a strategy for establishing electrical contact to the metal center of a redox metalloenzyme, galactose oxidase (GO), by coordination of a linker attached to a monolayer-protected gold cluster. The cluster–enzyme hybrid system was prepared in solution, and the electrochemical communication between a gold electrode and GO was achieved by first modifying the electrode surface with a biphenyl dithiol self-assembled monolayer followed by reaction with gold clusters capped with thioctic acid. GO was then immobilized by replacement of the water molecule at exogenous site by coordination of a carboxylate-terminated gold cluster. This chemical attachment ensures the electrical contact between the redox center and the electrode, leading to direct mediatorless electron transfer to the protein.

Exploiting the encapsulation ability of sol–gel, many other nanomaterials were immobilized onto the electrode surface, such as CNTs,[172–174] carbon nanofibers,[175] and graphene[176] demonstrating that sol–gel nanocomposites can provide new capabilities for the development of nanobased materials for electrochemical biosensors. Arvinte *et al.*[172] prepared a meldola blue (MB)-single-walled carbon nanotubes (SWNT)-sol–gel nanocomposite material by the sol–gel process incorporating a redox mediator and CNTs. The electrocatalytic properties of the nanomaterial-based biosensor toward nicotinamide adenine dinucleotide (NADH) oxidation were studied. Significant enhancement of oxidation current is obtained at electrodes modified by MB-SWNT-sol–gel in comparison with the analogous carbon black and/or graphite composite modified electrode. Analytical parameters of D-lactate biosensors with and without SWNT in the hybrid film were compared demonstrating that performance of the biosensor was significantly improved when SWNT was incorporated. Zhu *et al.*[177] fabricated surface renewable and mechanical rigid CNT ceramic composite electrodes (CCEs) by dispersion of multiwall CNTs in sol–gel solution. Nanotube CCEs provide better reversibility with substantial decreased over working potential, better defined peak shape, and higher sensitivity compared with carbon (graphite) CCEs. In addition, CNTs and graphite ceramic electrodes were employed as H_2O_2 and NADH probes. Watcharotone *et al.*[176] fabricated transparent and electrically conductive composite silica films on glass and hydrophilic SiOx/silicon substrates by incorporation of individual graphene oxide sheets into silica sols followed by spin-coating, chemical reduction, and thermal curing.

To improve on the hydrophilic nature and to reduce the cracking and swelling problems of silica matrix, Tsionsky *et al.*[178] reported some composite ceramic–carbon materials with incorporated surfactants. Modified porous composite carbon–silica electrodes can exhibit hydrophobic or hydrophilic surface characteristics and can serve as an indicator (inert) electrode, as a potentiometric (selective or reference) electrode, and in amperometric sensing and biosensing. The electrodes offer higher stability than carbon paste electrodes, and they are more amenable to chemical modification than monolithic and (organic) composite carbon electrodes. And grafting copolymer, PVA-*g*-PVP has been incorporated into the sol–gel (i.e., TEOS) and entrapped GOx to improve the hydrophilic nature. It prevents the cracking of conventional sol–gel-derived glasses and eliminates the swelling of the hydrogel. The biosensor exhibited a series of good properties of high sensitivity (600 nA $mmol^{-1}\,l^{-1}$), short response time (11 s), and remarkable long-term stability (at least 5 months). PVA-*g*-PVP polymer provides hydrophilic–hydrophobic properties and large amount of hydrogen bonds within the sol–gel matrix, hence the enzyme retains its active conformation.[105] The composite material merged the best properties of the inorganic species, titanium oxide, and the organic copolymer, PVA-*g*-PVP. The GOx entrapped in the composite matrix retained its bioactivity. The response time of the biosensor was less than 20 s. In hybrid sol–gel matrices, organic components contribute to the formation of defect-free inorganic membranes and make it less brittle, and an inorganic phase can improve the chemical and temperature stability of organic membranes.[179] Similarly, to obtain improved properties, pure silica sol–gels have been doped with natural polymers such as chitosan. Miao and Tan[127] fabricated silica sol–gel/organic hybrid composite material consisting of sol–gel and chitosan for amperometric H_2O_2 biosensor. The composite film was used to immobilize HRP on a carbon paste electrode. Hexacyanoferrate (II) was present in the solution as an electron donor. The biosensor had a fast response of less than 10 s. In another study, chitosan was cross-linked with (3-aryloxypropyl) dimethoxymethylsilane, in which HRP was sequestered for the construction of H_2O_2 biosensor. Chen *et al.*[180] fabricated a glucose biosensor by encapsulating the GOx in MTMOS and natural polymer chitosan composite matrix, and using ferrocene as a mediator. All the cases of biomolecules encapsulated in sol–gel hybrid materials showed improved stability and good analytical response due to the improved characteristics of sol–gel matrix. Solanki *et al.*[86] immobilized cholesterol esterase and ChOx onto

sol–gel-derived silica (SiO_2)/chitosan/multiwalled CNTs-based nanobiocomposite film, which is shown in **Figure 3** and which shows the response time of 10 s and shelf-life of about 10 weeks.

Sampath and Lev[169] reported a renewable GOx entrapped glucose biosensor by the addition of hydrophilic PEG into the hydrophobic ormosil (present on the electrode surface). Li *et al.*[100] reported a renewable glucose biosensor based on a sol–gel-derived carbon composite material. GOx and mediator vinylferrocene were immobilized within the porous, rigid, and organically modified silicate network in the composite material. The organic group in the silicate network controls the hydrophobicity of the electrode surface and thus limits the wettability of the electrode surface. The glucose biosensor can be renewed easily in a reproducible manner by a simple polishing step and has a long operational lifetime. Thionin was covalently immobilized to construct a bulk modified, leak-free composite electrode. This renewable composite electrode provides stable immobilization matrix for thionin via glutaraldehyde cross-linking. In the electrode composition, the sol–gel precursor 3-aminopropyltrimethoxy silane serves as the host for immobilization of thionin, thereby preventing its leakage. An additional precursor methyl trimethoxy silane provided the hydrophobicity and limits the wetting section of electrode.[181] Low-cost, screen-printed materials are often used as disposable biosensors.[182] The renewable or screen-printed sensors were highly convenient for application and low cost. In order to circumvent limitations such as microbial adhesion and growth on the surface, recently nitric oxide (NO)-releasing sol–gel particles have been reported;[106] the hybrid sol–gel/PU glucose biosensor consisted of a platinum electrode coated with four polymeric membranes including the following: (1) sol–gel with immobilized GOx; (2) PU to protect the enzyme; (3) NO donormodified sol–gel particle-doped PU; and (4) PU. For the hybrid sol–gel/PU biosensor, sol–gel particles were first modified with the NO donor and then incorporated into a PU layer that was coated onto the preimmobilized GOx electrode. In that manner, the GOx layer was not exposed to the harsh conditions necessary to impart NO release ability to the biosensor. Nitric oxide is a potential antimicrobial agent,[183] if it is released slowly from the matrix adhesion and the growth of microbes can be controlled. NO-releasing glucose biosensors prepared by doping diazeniumdiolate-modified sol–gel particles in a PU membrane exhibit high sensitivity, reproducibility, and fast response. To reduce both enzyme inactivation by NO (by minimizing NO exposure) and sol–gel particle leaching, PU membranes are coated as a layer.

A major advantage of sol–gel-based electrochemical sensors is that they are not limited to the use of silica as the metal center since the films do not need to be optically clear. Hence, sol–gel coatings can be fabricated from alumina, aluminosilicate, vanadium, or titanium to alter both the electrical and material properties and to improve chemical inertness. This also leads to the ability to perform measurements in turbid or opaque samples, as is often the case for *in vivo* sensing. Another advantage of sol–gel composite electrodes

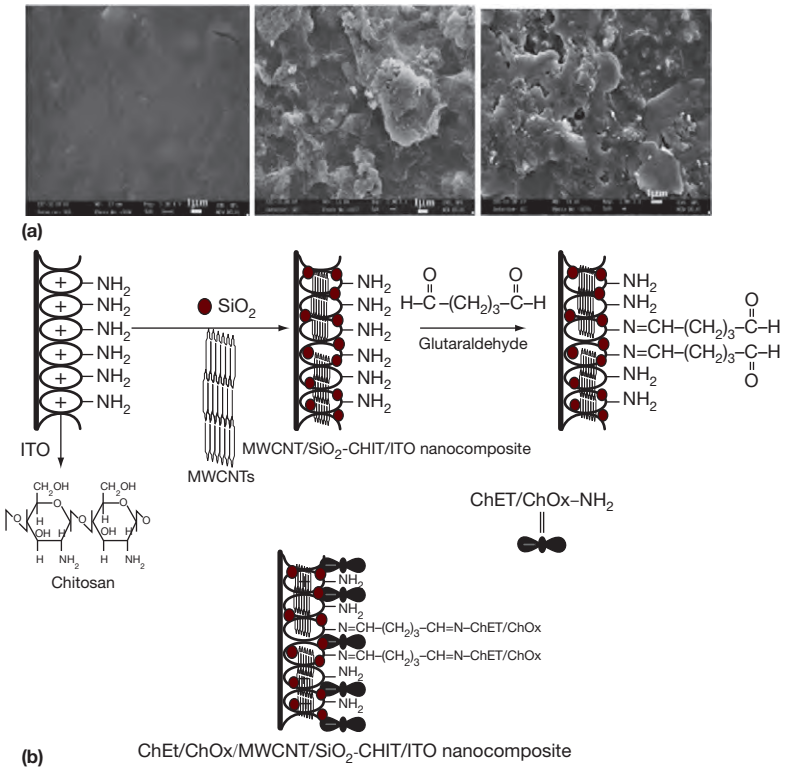

Figure 3 (a) SEM image of chitosan/indium–tin–oxide (ITO) electrode multiwalled carbon nanotubes (MWCNT)/SiO_2–chitosan/ITO electrode and cholesterol esterase (ChEt)–cholesterol oxidase (ChOx)/MWCNT/SiO_2–chitosan/ITO bioelectrode, respectively. is that they tend to be more homogeneous than regular carbon paste electrodes, leading to homogeneous electron transfer kinetics and larger current responses in amperometric sensing. Of course, the ultimate sensitivity of the electrode is determined by background noise, but it is relatively easy to prepare shielded electrodes to improve on sensitivity and detection limits.

3.328.3.2. Optical Biosensors

The good sol–gel optical transparency with diverse chemistries and configurations for the entrapment of many biorecognition elements enables the development of various optical biosensors.[7,184] Rather than measuring current response as in the case of electrochemical biosensors, optical biosensors normally measure the photons. More specifically, optical biosensors operate based on the measurement of absorbance, reflectance, or fluorescence emissions that occur in the ultraviolet, visible, or near-infrared. Fluorescence spectroscopy is by far the method most widely applied and comes in a variety of schemes.[10] Fluorescence is considered as the ideal technique to monitor sol–gel hybrid systems as it can address both the host matrix and the guest biomolecule and enables the visualization of molecular diffusion down to single-molecule level.[185]

Similar to electrochemical biosensors, the bioreceptor used for recognition is normally immobilized on the surface of optical biosensors as a single-layer, double-layer, and sandwich configurations.[8,10,186] Three different configurations of oxygen transducer and sol–gel immobilized GOx have been investigated by Wolfbeis *et al.*[187]. In the first configuration, GOx was sandwiched between a sol–gel layer doped with Ru(II)-tris(4,7-diphenyl-1,10-phenanthroline) ($Ru(dpp)_3$) and a second pure sol–gel layer. Such configuration provided the highest enzyme activity and the widest dynamic range (0.1–15 mM) but suffered from a distinct decrease in sensitivity upon prolonged use. Secondly, a sol–gel layer doped with $Ru(dpp)_3$ was covered with sol–gel-entrapped GOx, which provided the fastest response time (>50 s). In the third configuration, both the oxygen-sensitive sol–gel powder and the sol–gel powder containing GOx were incorporated into a single sol–gel phase, which provided the best operational lifetime. Three types of immobilization modes (i.e., physisorption, microencapsulation, and sol–gel sandwich) have also been compared in terms of their response profiles to glucose by Narang *et al.*[167] The results indicated that the sandwich configuration (sol–gel:GOx:sol–gel) was most promising for future biosensor operation. Since the diffusion of the analyte proceeded through the sol–gel top layer, its thickness was adjusted to 0.10 μm in order to obtain the shortest response time (30 s).

There has been widespread and growing interest in recent years in the development of optical biosensors for a wide variety of analytes.[188–190] Recent advances in the design and application of optical biosensors assays were extensively reviewed.[10,12,184,191–193] Available data of typical optical biosensors based on sol–gel matrices have been reported and summarized in **Table 2**. In most cases, the optical biosensors are sensitive, robust, rapid in response, cheap, and easily miniaturized.

As shown in **Table 2**, the most frequently used precursors in optical biosensors are based on TMOS and TEOS sol–gel matrices. The sensing material is generally obtained by controlled hydrolytic polycondensation of TEOS to give a fairly inert inorganic glassy matrix, in which porosity and size of pore network can be varied by polymerization conditions.[214] The tailor ability was demonstrated for oxygen-sensitive sol–gel films doped with the $Ru(dpp)_3$ complex and were fabricated using different ratios of TEOS and methyltriethoxysilane precursors.[215] Furthermore, hydroxyethyl carboxymethyl cellulose and TEOS hybrid polymer could improve on the stability of entrapped GOx (up to 3 years).[216]

Generally, optical biosensors can be divided into two main categories based on their bioactivity: biocatalysts (e.g., enzymes and cells) and bioaffinity molecules (e.g., antibodies, receptors, and nucleic acids).[217] Like electrochemical biosensors, most works on sol–gel optical biosensor development have focused on the immobilization of enzymes. Besides their unique biocatalytic properties and specificity for a substrate or a group of substrates, enzymes allow a wide range of analyte recognition processes by using different combinations of enzymes or enzyme-transducer systems. Changes in absorbance and fluorescence of the colored or luminescent substances for enzymatic reactions enable the direct detection using an optical biosensor. If the enzymatic reaction does not involve such substances, optochemical transduction is obligatory for indirect detection.[218] Actually, as most enzymes do not have intrinsic optical properties that undergo a change when they interact with the analyte(s), most of these biosensors rely on the use of a chemical transducer and its analytical signal which can be related to the concentration of the analyte of interest.[184] Following the first report for the successful encapsulation of a purified enzyme (i.e., ALP) in a TMOS-based sol–gel material,[15] a wide variety of enzymes have been immobilized in sol–gel-based optical biosensors which have been employed for the monitoring of pesticides, pharmaceuticals, hydrogen peroxide, sugars, lactate, urea, cholesterol, nitrates, nitrites, etc. (**Table 2**).

Among the various enzymes, the most well-studied enzyme in the sol–gel context biosensors is GOx, which mediates the air oxidation of glucose with generation of H_2O_2. Different biosensing schemes based on sol–gel doped with GOx have been proposed. For instant, de Marcos *et al.*[204] immobilized GOx, firstly covalently bonded to a fluorescein derivative, in a TMOS-based sol–gel film, as the basis of an optical biosensor. During the enzymatic reaction, glucose reacts with the labeled GOx. When the oxygen dissolved in the solution is consumed, an increase in fluorescence intensity is recorded.

Besides GOx, there are many papers reporting the immobilization of other enzymes within sol–gel matrices. Biosensors based on AchE and cholinesterase inhibition have been proposed for screening of organophosphates and carbamates, two major classes of pesticides with widespread uses in agriculture activities. A pH-sensitive fluorescent biosensor was reported for the detection of acetylcholine and praoxon, in which fluorescene isothiocyanate (FITC)-dextran conjugate and AChE were coimmobilized in TMOS sol–gel.[219] A portable optical fiber biosensor for the detection of the pesticides carbaryl and dichlorvos was developed on the basis of a three-layer sandwich scheme. The enzyme cholinesterase was immobilized on the outer layer, a hydrophilic modified polyvinylidenefluoride membrane, which was in contact with a sol–gel film doped

Table 2 Typical optical biosensors based on bioreceptors encapsulated in sol–gel matrices

Biorecognition element(s)	*Analyte(s)*	*Sol–gel precursors*	*Principle of detection*	*Linear range/detection limit*	*References*
AChE and bromothymol blue	Chlorpyrifos	TEOS	Absorption	0.05–2.0 mg l^{-1}/0.04 mg l^{-1}	189
AChE (+FITC-dextran)	Paraoxon	TMOS	Fluorescence	152 ppb (30% inhibition)	218
AChE and a lipophilic chromoionophore	Dichlorvos	TEOS	Absorption	0.5–7 mg l^{-1}/0.5 mg l^{-1}	194
Bacillus licheniformis, *Dietzia maris*, *Marinobacter marinus*	BOD	TMOS + DiMe-DMOS (+PVA)	Fluorescence	0.2–40 mg l^{-1}/0.2 mg l^{-1}	195
Bacillus subtilis (+$Ru(dpp)_3$)	BOD	TMOS (+PVA-*g*-PVP)	Luminescence	0–25 mg l^{-1}	196
Carbonic anhydrase (+cresol red)	Acetazolamide	TMOS	Absorption	1.0–10.0 mM/0.2 mM	197
Cholesterol oxidase + HRP	Colesterol	TEOS	Absorption	2–10 mM	87
Cholinesterase (+bromocresol purple)	Carbaryl dichlorvos	TEOS + PTMOS	Absorption	0.11–0.8 ppm/108 ppb 5.0–30 ppm/5.2 ppb	198
Concanavalin-A labeled with FITC	Bacterial endotoxins	TEOS + APTES	Luminescence	–	199
Cytochrome *c*	NO and CO	TMOS	Absorption	–	200
Cytochrome *c*	NO	TMOS	Absorption	1–25 ppm/1 ppm	201
Cytochrome cd_1 nitrite reductase	NO_2^-	TMOS	Absorption	3.4–57 ppb/3.4 ppb	202
Escherichia coli (recombinant)	DDT, aldicarb, malathion	TMOS	Luminescence	–	18
GOx	Glucose	TEOS	Absorption	5–35 mM/0.2 mM	167
GOx	Glucose	1.0 ml of TMOS and 1.8 ml of DiMe-DMOS	Fluorescence	0.00–0.50 mM and 0.50–3.00 mM/ 3.6×10^{-6} M	203
GOx labeled with fluorescein	Glucose	TMOS	Fluorescence	0.55–55 mM	204
GOx (+$Ru(dpp)_3$)	Glucose	TMOS + PTMOS/ MTMOS	Fluorescence	0.1–15 mM[a]	187
GOx (+DPO)	Glucose	TEOS/ TEOS + APTES	Fluorescence	0.1–15 mM	205
Glutamate dehydrogenase	Glutamate	TiO_2, glycerol, and PVA	Fluorescence	0.04–10 mM/5.5 μM (water sample) 0.02–10 mM/6.7 μM (biological samples)	188
Glutathione *S*-transferase (+bromocresol green)	Atrazine	TEOS + PTMOS	Absorption	2.52–125 μM/0.84 μM	206
Hemoglobin	NO and CO	TMOS	Absorption	–	200
HRP	H_2O_2	TEOS	Chemiluminescence	8×10^{-3}–2 mM	207
HRP or HRP/GOx	H_2O_2 and glucose	TEOS/PDMS Ormosil	Luminescence	0.05–20 mM H_2O_2 and 0.5–20 mM glucose	208
Lactate dehydrogenase (+NADH)	L-Lactate	TMOS	Fluorescence	0.1–1.0 mM	209
Lactate dehydrogenase	Piruvate	TEOS	Absorption	0–1.5 mM/5×10^{-5} M	210
Myoglobin	NO and CO	TMOS	Absorption	–	200
Nitrate reductase	NO_3^-	TMOS	Absorption	0–1.5 μM/0.125 μM	201
Pseudomonas fluorescens	Naphthalene; salicylate	TMOS	Bioluminescence	1.2 mg l^{-1}/0.5 mg l^{-1}	30
SOD and SOD dismutase–peroxidase enzymes	Superoxide radical	TEOS	Fluorescence	0–1.2 μM/20 nM	211
Urease	Urea	TEOS	Absorption	0.05 mM	167,212
Urease	Cu(II), Cd(II), Zn(II), Ni(II), Pb(II), and Cr(III)	TMOS	Fluorescence	10–230 μM/10 μM for Cu(II) and Cd(II) Detection limit: 40 μM for Zn(II), 100 μM for Ni(II), 100 μM for Pb (II), and 300 μM for Cr (III)	213

with bromocresol purple, deposited on an inner glass disk.[198] Andreou and Clonis[206] also proposed the same biosensing scheme for the determination of the herbicide atrazine, using the enzyme gluthatione *S*-transferase and bromocresol green. After deterioration, the bioactive sandwich could be easily replaced on the terminal of the probe. **Figure 4** shows the experimental setup and electrode construction.

Carbonic anhydrase was employed in the enzyme sol–gel film for developing optical biosensor for determination of the antiglaucoma agent acetazolamide, suitable for diagnosis and pharmaceutical control purposes.[197] Ferretti *et al.*[202] encapsulated cytochrome *cd1* nitrite reductase between two sol–gel thin films, which enabled the determination of nitrite in environmental waters with detection limits below the levels established by the European Union and response times of 5 min. Sol–gel encapsulation of the enzyme lactate dehydrogenase in thin films was employed by Li *et al.*[209] and Ramanathan *et al.*[210] to develop optical biosensors for L-lactate and piruvate, respectively. Urease had also been entrapped in sol–gel films for the development of biosensors for urea detection.[212]

Multienzymatic entrapment in the same sol–gel matrix allows for sequential reactions to occur in a confined space and lead to high conversion efficiencies due to the proximity of analytes and intermediates to the enzymes' active sites.[19,190] Pastor *et al.*[211] developed a fluorescent biosensor to determine superoxide radical based on the coupled reaction of the enzymes superoxide dismutase (SOD) and HRP, together with the use of the probe *N*-acetyl-dihydroxyphenoxazine (Amplex red). Within this biosensor, SOD catalyzes the dismutation reaction of generated superoxide radical with the release of H_2O_2 which, in the presence of HRP, reacts stoichiometrically with the nonfluorescent Amplex red to generate the red-fluorescent oxidation product resorufine. An array-based optical biosensor for the simultaneous determination of urea, acetylcholine, and heavy metals has been reported.[220] Urease and AChE were coentrapped with FITC-dextran in the sol–gel matrix and fixed on a sensing probe. Coimmobilizion of three enzymes, xanthine oxidase (XO), SOD, and HRP, in a single sol–gel matrix was used to prepare a fluorescent biosensor for the accurate determination of xanthine.[190] In this case, the enzymatic system included XO which catalyzes the oxidation of xanthine to uric acid and superoxide radical. More recently, the ability of three sol–gel immobilized multienzymatic systems coupled with the indicator Amplex red to determine superoxide radical and evaluated the scavenging capacity of several antioxidant compounds was investigated.[221] In the first system, the enzymes SOD and HRP were immobilized in a single sol–gel slide, while in other systems, the enzyme XO was also immobilized either in the same slide (system 2) or in a different slide (system 3). Results indicated that the three systems could be used to quantify superoxide radical, but only systems 1 and 3 were able to detect scavenging capacity.

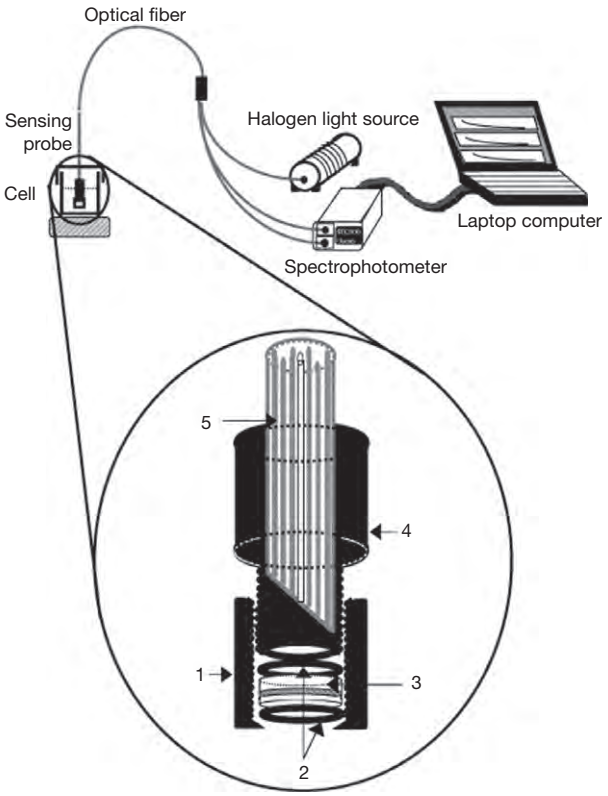

Figure 4 Experimental setup for atrazine analysis showing the optic fiber fitted with the probe at its end: (1) screwable terminal holding ring, (2) sealing 'O' rings, (3) biosensing sandwich (bottom to top: Durapore® membrane with immobilized enzyme, middle sol–gel/indicator layer, supporting glass disk), (4) probe tip, and (5) multielement (six illumination, one read) optical fiber. Another way of using enzymes is through whole cells rather than the purified enzymes, which has been successfully applied in sol–gel films-based optical biosensors for

biochemical oxygen demand (BOD) determination. Lin *et al.*[195] proposed a biosensing film consisting of an organically modified silicate film embedded with tri(4,7-diphenyl-1,10-phenantroline) ruthenium(II) perclorate and three kinds of seawater microorganisms (*Bacillus licheniformis*, *Dietzia maris*, *Marinobacter marinus*) immobilized on a polyvinyl alcohol sol–gel matrix. The coimmobilized microorganisms maintained their activity even if kept for 1 year at 4 °C, and the stored biosensing film could be employed for BOD measurement after 1 day's reactivation. Kwok *et al.*[196] constructed a biosensing device for parallel multisample determination of BOD by immobilizing activated sludge and *Bacillus subtillis* on oxygen-sensing films placed on the bottom of glass sample vials. The microorganisms were entrapped in a sol–gel-derived film of silica and PVA-*g*-PVP copolymer. The oxygen film contained $Ru(dpp)_3$ immobilized in a silicone rubber.

The most important factor in the construction of whole cells biosensors is the immobilization of living cells. Premkumar *et al.*[222] immobilized recombinant luminous bacteria into TEOS sol–gel to study the effect of sol–gel conditions on the cell response (luminescence). The entrapped and free cells showed almost the same intensity of luminescence (little lower), but the entrapped cells were more stable than the free cells (4 weeks at 4 °C). It revealed that the encapsulated recombinant bacteria maintained their physiological ability to synthesize a fully functional luciferase and sufficient substrate to generate luminescence.

Due to the biocompatibility and chemical inertness of sol–gel materials, it was also used for designing optical biosensors for monitoring biological species. For example, Kishen *et al.*[223] developed an evanescent wave biosensor for the monitoring of mutans *streptococci* in human saliva. This sensor employed bromophenol blue entrapped in a porous sol–gel film coated on the unclad portion of an optical fiber, which enabled real-time monitoring of pH variations in saliva produced by the reactivity of mutans *streptococci* with sucrose.

The optical biosensors have been incorporated in lab-on-a-chip (biochip) device.[10] A novel, miniature optical biosensor was developed by integrating the complementary metal oxide semiconductor (CMOS) photosensor, the sol–gel technique and the chemilumminescence detection method.[208] The detection area of chip is only 0.5 mm × 0.5 mm. This miniature CMOS-based optical biosensor not only exhibits high detection capability, short detection time and high reproducibility, but also requires only a small sample. With these characteristics, the miniature optical biosensor has great potential in the future development of a simple portable biosensing system for rapid screening and in-field/on-site monitoring. A more sophisticated, powerful, miniature optical biosensor system is expected to be easily fabricated for future biochip development.

3.328.3.3. Biosensors Based on Other Transducing Principles

Piezoelectricity is the ability of some materials (notably crystals and certain ceramics, including bone) to generate an electric field or electric potential[224] in response to applied mechanical stress. Piezoelectric sensors utilize crystals which undergo an elastic deformation when an electrical potential is applied to them. An alternating potential produces a standing wave in the crystal at a characteristic frequency. This frequency is highly dependent on the elastic properties of the crystal, such that if a crystal is coated with a biological recognition element, the binding of a (large) target analyte to a receptor will produce a change in the resonance frequency, which gives a binding signal. In a mode that uses surface acoustic waves, the sensitivity is greatly increased. This is a specialized application of the Quartz crystal microbalance as a biosensor.[225] Recently, microdiaphragm piezoelectric-based biosensors have been successfully applied as a biological diagnostic tool in air and liquid media.[226]

Thermometric- and magnetic-based sol–gel biosensors are seldom being reported and very few publications could be found in Web of Science. Ramanathan *et al.*[227] reported a sol–gel-based glucose biosensor using thermometric measurement. Enzymes such as GOx and catalase were entrapped on the surface of reticulated vitreous carbon cylinder using sol–gel as a binder. The cartridge was placed within the column of an enzyme thermistor device. Injection of various glucose concentrations resulted in changing the heat content of the circulating buffer, recorded as a thermometric peak by a sensitive thermistor. Wu *et al.*[228] reported a kinetic assay of trypsin with a wireless magnetoelastic sensor. A wireless magnetoelastic trypsin biosensor was fabricated by first coating a magnetoelastic ribbon-like sensor with a pH-sensitive polymer and then upon it a layer of trypsin. In response to an externally applied time-varying magnetic field, the magnetoelastic sensor mechanically vibrates at a characteristic frequency that is inversely dependent upon the mass of the attached film. As the magnetoelastic sensor is magnetostrictive, the mechanical vibrations of the sensor launch magnetic flux that can be detected remotely from the sensor using a pickup coil.

3.328.4. Conclusions and Future Trends

The development of novel biosensor devices is currently the subject of extensive research in areas such as clinical diagnosis, food technology, biomedical, defense science and environmental analysis.[10,229–231] Exciting biosensor designs have been proposed in several reports during the past few decades and numerous approaches for effective biosensor systems have also been demonstrated in laboratories.

The selection of appropriate (and stable) materials probably is the most challenging task in biosensor development.[10] The biocompatible and versatile sol–gel process offers a flexible approach for the fabrication of various biosensors with different configurations to suit different applications.[7–9] Typically, those sol–gel materials possess physical rigidity, chemical inertness, high photochemical biodegradation, and negligible swelling in aqueous and organic solutions.[232]

As previously stressed, the enormous versatility of the sol–gel chemistry enables the production of robust hybrids at low temperatures with remarkably new and improved material properties that can be used to enhance the stability of bioreceptors. Bioencapsulation in mineral/hybrid sol–gel hosts has been successfully attempted with a great variety of biological entities including numerous enzymes, antibodies, microorganisms, and even whole cells.[8,9] Another major reason for the popularity of sol–gels results from the fact that the activity of bioreceptors is retained over a long time.[10] As a result, the

investigation of sol–gel hybrid systems has progressed dramatically over the past two decades for biosensing proposes.

An emerging area for sol–gel biosensors is the incorporation of nanomaterials in the sol–gel matrix. In addition to the molecular inorganic–organic hybrid network, the physical, electronic, optical, or catalytic properties of nanomaterials resulting from the inorganic crystalline, glassy, or metallic properties also can be tailored to suit a particular application.[233–235] Nanomaterials exhibit a number of special properties relative to the bulk materials. Two of the major factors in the special properties are the increase in the ratio of surface area to volume, and the size of the particle moving into the realm where quantum effects predominate.

However, even though some other precursors have been introduced, sol–gel matrices are mainly prepared by TMOS or TEOS as precursor.[232] The poor water solubility of such precursors usually involves enzyme immobilization in organic cosolvents. Therefore, development of enzyme biosensors based on biocompatible silica sol–gel matrix has attracted increasing attention recently. Despite the effects of designing new precursors with improved water solubility and biocompatibility,[236,237] silica-based organic–inorganic hybrids are adopted as attractive materials for biosensor fabricating.[238,239] It is expected that the new hybrid sol–gel materials and/or methods could improve biocompatibility and activity, and also provide less brittle nature matrices.

Furthermore, despite the promising studies, only a few biosensors are commercially available.[240] Some critical issues still need to be considered and resolved, in order to make mass production and commercialization viable. A significant number of sensing devices reported exhibit one or more limitations that hinder their continuous use, and some of them (except when specified) were not applied to real samples or practical situations. Many of the works referred, although describing optimization and, sometimes, showing preliminary results, present insufficient data concerning analytical performance. It is desirable to fabricate sol–gel biosensors with high stability that can be used as everyday analytical tools.

As shown in the reports assembled in this chapter, rapid advances have been made in improving immobilization protocols and overcoming many hurdles of sol–gel technology in the recent years. Novel configurations, such as miniaturized devices and integrated sensors based on planar waveguides, are currently employed and provide high sensitivity, fast response and low costs, as well as an enlarged range of possible applications. It is also expected that microfabrication techniques, such as soft lithography and photo pattern ability, will enable the production of the new generation of microbiosensors.

3.325.1. Introduction

The functions of important organs, such as bone and teeth, are determined by the biomechanical properties of the mineralized tissues they are made of.[1,2] In addition, bone is the ion reservoir in our body, a central organ for calcium and phosphate homeostasis[3] and is considered to be an endocrine organ.[4] Its mineral content has a decisive influence on the mechanical properties,[5] and methods for a quantitative characterization of mineral content and characteristics are clearly needed. The difficulty is that virtually all biological materials, including mineralized tissues, are hierarchically structured, which means that they are inhomogeneous over many length scales.[6] Imaging using different techniques and covering many scales is, therefore, needed to fully characterize mineralized tissues.

In recent years, imaging methodologies have been developed on the basis of various probes, diffraction, and spectroscopy using photons or electrons, absorption imaging, as well as scanning probe microscopy techniques and more. For example, the use of synchrotron radiation has rapidly developed in recent years and allows insight into the nanoscale properties of mineralized tissue. The goal of the present chapter is to summarize the characterization possibilities offered by various approaches. This is preceded by a description of the hierarchical structure of mineralized tissues, and in particular of bone. A better understanding of the structure–function relation in mineralized tissues might lead to new strategies for treatment of patients with bone fragility. The systematic use of imaging techniques will thus help to improve our arsenal in fighting such diseases with high socioeconomic impact and influence on quality of life.

3.325.2. Structure of Mineralized Tissues

In vertebrates, several types of mineralized tissues can be found. In this article, we will focus on tissues which mineralize in normal physiologic conditions, such as bone, teeth, mineralized cartilage, and calcified tendon. Many of them have a complex structure and are hierarchically organized. It is important to study their normal occurrence for the understanding of their development. Deviations from their normal structure (for instance changes in osteoporosis) might give not only information on pathological processes occurring in specific diseases but also insights into normal tissue development. It should be mentioned that there are also many different forms of calcified deposits which develop from pathologic processes and occur in tissues which normally do not mineralize (mineralized valves, mineral deposits in muscles, renal or urinary stones, and so on). In many cases, imaging these deposits might give important information on the pathological processes and conditions of their history of formation. However, the description of this is beyond the scope of this chapter. Moreover, we will not touch other classes of mineralized tissues, for example, those based on silicate or calcium carbonates, as found in molluscs or sponges.

3.325.2.1. Bone

Bone is a living organ with outstanding mechanical properties. This is due to the complex structure and the material properties of bone, which is a composite of protein and mineral. In addition, one has to bear in mind that bone cells are actively remodeling it (replacing old and building new bone material) throughout the lifetime of an individual. Bone can grow, it can adapt to changing mechanical loading conditions, and it can heal.[1] Bone fulfils both mechanical and metabolic functions. Indeed, the skeleton enables locomotion and protects vital structures, but bone is also the site of hematopoiesis (blood synthesis) and acts as a calcium and phosphate reservoir for maintaining the required ionic levels in the serum. The amazing mechanical properties of bone are achieved by an adaptation at various levels: not only its form (shape of the bone) but also the material itself varies according to needs, leading to a complex, hierarchically organized structure; see **Figure 1**.[6–10]

Generally, bone is the umbrella term for many different types of materials found in various forms in vertebrates (including lamellar bone, parallel-fibered bone, woven bone).[1] All these variants of bone tissue are complex materials, which have in common their basic building block – the mineralized collagen fibril.[7]

3.325.2.1.1. Hierarchical structure of bone

Starting with the macroscopic visible bone structure (organ level, in **Figure 1**), that is, the shape of the bone, one can distinguish between long (such as in our limbs), short (such as the vertebra), and flat bones (such as the scapula). The optimization for mechanical loading at this macroscopic level is most obviously seen in the long bones. Their circular to ellipse-shaped cross-sections with the central canal of the bone marrow reveal a distribution of the bone material optimized for maximum bending properties at a minimum use of

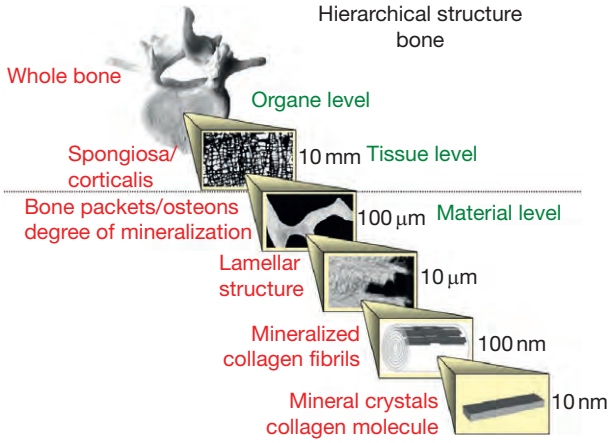

Figure 1 Hierarchical structure of bone shown in a human vertebra. The interior is a porous bony structure (spongiosa) within a dense cortical shell. Each of the struts (trabeculae) of the spongy structure consists of bone packets synthesized at different moments in time because of the permanent remodeling of the structure. At the micron level, bone tissue is lamellar, on the basis of mineralized collagen fibrils arranged in a plywood-like pattern. At the nanoscale, finally, the mineralized fibrils are on the basis of parallel collagen molecules reinforced with thin calcium phosphate mineral platelets.

bone material. As the fourth power of the outer radius is dominating the moment of inertia, the bending stiffness of long bones is highly dependent on the outer diameter of their cross-section.

At the next lower structural level (tissue level in Figure 1), most generally two types of bone architecture can be seen: an outer cortical compact bone is enclosing an inner cancellous (or trabecular) bone. The compact bone dominates in long bones, such as in the midshaft of the femur, for instance, where the cortex has a thickness of several millimeters. Looking closer at cortical bone, one sees that it has a porosity of only about 5–8%. The pores mainly contain blood vessels and nerves. In the human skeleton, about 80% of the total bone is compact bone while the remaining is cancellous (or trabecular) bone. Cancellous bone is found at the metaphyses of long bones, between the cortical plates of flat bones (iliac crest, for example) and essentially in the vertebrae. It exhibits porosity from 30 to 85%. Cancellous bone consists of struts (trabeculae) which are some hundreds of microns in size. Characteristic for cancellous bone is its highly organized trabecular network. Connectivity of the trabeculae is an important prerequisite for mechanical competence of cancellous bone.[11] More than a century ago Wolff compared the architecture in the femoral head with the architecture of a gothic cathedral, where the struts follow the principle load directions.[12] The architecture of the trabecular network is observed to be oriented according to mechanical demands.[13] In the vertebrae, which are mainly loaded in compression, the trabeculae are preferentially arranged in vertical and horizontal direction. During the development of the human lumbar spine vertebra, the structural changes at several size scales were observed.[14] The trabeculae were seen to change from an originally radial pattern in the fetus to a pattern with predominantly vertical and horizontal directions in the adult vertebra. Generally, rod- and plate-like structures can be identified in the trabecular network. With aging, specifically, the rod-like structures get thinned and finally vanish totally from the network[15] causing a significant decrease in mechanical competence (failure due to buckling) of the whole vertebra.

With the next lower hierarchical level, we reach the material level of bone which is divided further into four hierarchical sub levels (material level in Figure 1). We can find that the bone material is not homogenously formed, but composed of so-called bone structural units (BSUs) which are the bone packets in the trabecular and the osteons (here the bone packets have a cylindrical shape surrounding an haversian canal) in the cortical motifs. This BSU bone matrix is formed during remodeling by a bone multicellular unit (BMU) within 180 days involving all types of bone cells. Each of the BSUs has a certain mineral content corresponding to its tissue age[16] and they reveal a uniform lamellar arrangement of mineralized collagenous fibrils. Further they are connected among themselves via a noncollagenous mineralized surface layer (cement surfaces/lines). In that way, a remarkable heterogeneity is introduced into the bone material with respect to mineral content and orientation of bone lamellae.[17,18]

The arrangement of the fibrils can differ depending on the type of bone. Plywood-like and parallel organization can be found in lamellar bone (see Section 3.325.2.1.2) and a less ordered organization of the fibrils is seen in woven bone (see Section 3.325.2.1.3).

The mineralized collagen fibril itself has a diameter of about 0.1 μm.[19] It is the main building block of all types of bone and is composed of a collagenous scaffold into which the nanosized mineral (calcium phosphate) particles are embedded. The exact arrangement of the mineral particles has not been measured directly, and different forms of arrangements have been proposed with parallel[20] or staggered mineral plates.[21] The material at this level can be considered as a composite with the organic components being the elastic part which is stiffened by the calcium phosphate particles. The collagen (type I in bone) is deposited by the osteoblasts which are the bone forming cells. They excrete collagen molecules into the extracellular space, which subsequently assemble into fibrils. These fibrils have a characteristic pattern with adjacent molecules staggered along the axial direction by a specific distance of about 67 nm. This generates zones in which the molecules overlap and zones containing holes.[22,23] When the collagen becomes mineralized, the mineral particles grow in these holes and overlap zones.[24,25] The nucleation, growth, and the final size of these mineral particles are essentially controlled by the collagen[26] and by noncollagenous proteins.[27] The mineral particles are flat with a few nanometers in thickness[7,28] and elongated (nearly 100 nm in length).[25,29] As the mineralized collagen fibril is the basic building block of bone, the understanding of its mechanical function is of specific interest. In a mechanical model, it was demonstrated that under tensile loading, the mineral particles carry the load while the organic matrix transfers the load between the particles via shear.[21] The shape of mineral particles and their large aspect ratio were shown to compensate for the high elasticity of the organic component. An advantage of the small thickness of the particles is that at this size scales the particles become insensitive to flaws.[30] Generally, it can be expected that the amount of

the mineral platelets incorporated into the elastic collagen fiber tunes the stiffness and hardness of the whole structure. Increasing the mineral density will increase the stiffness but also brittleness of the material.[5,31] There are extensive attempts to elucidate the structure of the nanocomposite material (specifically the interface between the mineral particles with the collagen matrix) and to relate this structure to the mechanical properties, the deformation mechanism in mineralized tissues.[32–34]

The lowest level of structural hierarchy represents the components of the nanocomposite material. The collagen I molecule is a large protein consisting of a sequence of amino acids based on –Gly–X–Y– with Gly being glycine, and X and Y being often proline and hydroxyproline.[35,36] The bone mineral is a poorly crystalline hydroxyapatite ($Ca_5(PO_4)_3OH$) having a hexagonal crystal lattice with *a*, *b* being 9.432 Å and *c* being 6.881 Å.[37] However, the mineral is not a static moiety, and ion substitutions for both Ca and phosphate ions are abundant.[38]

3.325.2.1.2. Lamellar bone

The lamellar organization is the most frequent organization of mature bone tissue at the micron and submicron levels (Figure 2). The collagen fibrils are arranged in parallel bundles which are further organized to form a lamellar structure. Slightly different models of fibril arrangement have been suggested for the lamellar bone structure surrounding a blood vessel within cortical bone (osteon): a plywood-like pattern where parallel fibrils are arranged in layers with a rotation of fibril orientation in the direction perpendicular to the layers (similar to a cholesteric liquid crystal[39]) accompanied by a rotation of the fibrils around their own axis resulting in a rotated plywood structure.[40] Alternatively, the structure has been described as alternating dense and loosely packed fibrils which only give the impression of lamellae.[41] The helocoidal structure of the collagen fibrils arranged in a spiral around the blood vessel makes the osteons extensible and compressible during *in vivo* mechanical loading.[42]

Light-microscopy of bone sections or scanning electron microscopic images reveals small holes (10 μm in width) within the lamellar bone matrix. These represent osteocyte lacunae which are occupied by specific bone cells (osteocytes) in the living bone material and which are connected via canaliculi. These cells and their network are assumed to play an important role in the detection of the mechanical load and in transmitting this load signal to the other bone cells.

The orientation of the lamellae is introducing anisotropy in the mechanical properties of the bone material.[43] Such a heterogeneity in material properties is advantageous for crack stopping, but might favor crack initiation too.[17,44] Generally, much higher energies are needed to force a crack perpendicular to the collagen orientation through the material[45,46] compared to parallel collagen orientation. The reason is that a crack propagating in a direction perpendicular to the lamellae has to follow a tortuous path (Figure 2). Furthermore, large variations in elasticity and hardness have been reported from nanoindentation experiments depending on the angle between indentation and the long axis of the mineralized collagen fibrils.[47,48]

3.325.2.1.3. Woven and plexiform bone

The term woven bone is commonly used for bone tissue, which clearly differs from lamellar bone in the organization of its collagen fibrils. It has no regular lamellar structure and the collagen fibrils lie irregularly,[7] not preferentially oriented as can be visualized by polarized light microscopy. Additionally, this tissue is characterized by a huge number of large irregular shaped osteocyte lacunae. It has been suggested[49] that this tissue type is the result of recruitment and activity of specific, not yet polarized osteoblasts synthesizing the extracellular matrix in all directions of free tissue space. Thus, these osteoblasts soon become entrapped in their matrix and become osteocytes living in large, irregularly shaped osteocyte lacunae. This woven bone forms the first scaffold in which regular bone matrix can be apposed by normal polarized 'surface' osteoblasts. This process is called direct or intramembranous ossification as found in the fetal and postnatal growth stage of flat bones (e.g., scull) and also during fracture healing and callus formation. The rapid growth is also characteristic of woven bone which is deposited during bone development enabling lamellar bone formation or during fracture healing (see Figure 3) when a rigid scaffold has to bridge the fracture region very rapidly.[50] In general, woven bone is subsequently remodeled into highly organized lamellar bone. Despite the

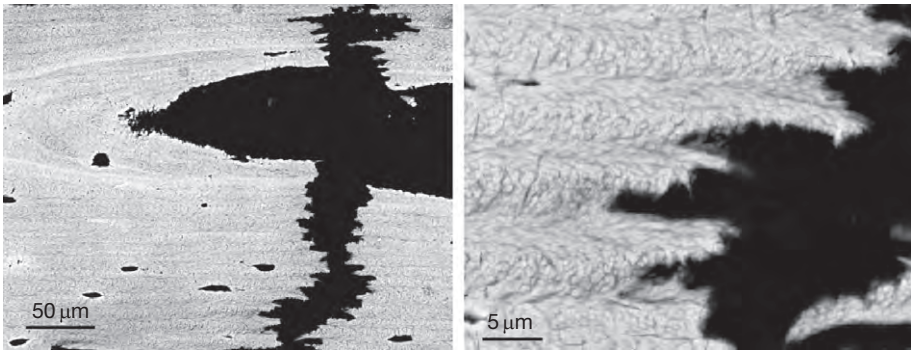

Figure 2 Lamellar bone – example of lamellar organization of mineralized fibrils surrounding a haversian canal (osteon) (backscattered electron image). A crack is propagating perpendicular to the bone lamellae performing a zigzag path because of the changing fibril orientation between the lamellae; right image shows an enlarged detail of the left. Reproduced from Peterlik, H.; Roschger, P.; Klaushofer, K.; Fratzl, P. *Int. J. Fract.* **2006**, *139*, 395–405.

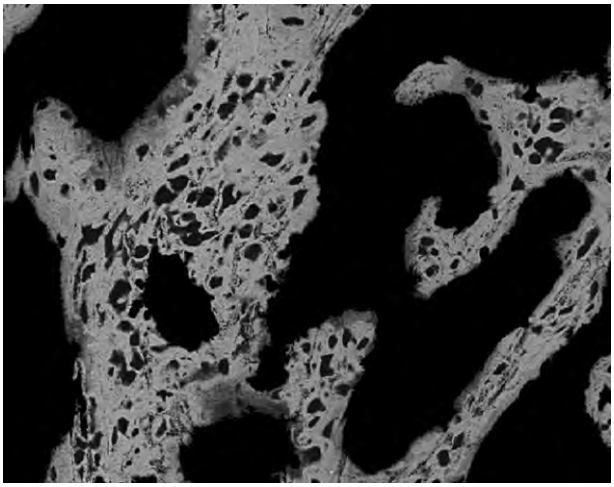

Figure 3 Woven bone – example of intramembranous ossification during bone healing (callus formation). Note the irregularly formed and enlarged osteocyte lacunae (backscattered electron image).

differences in collagen arrangement, transmission electron microscopy (TEM) has shown that the morphology of the mineral particles in woven bone is similar to that in lamellar bone.[51] The mineral particles were found associated with the collagen surface, distributed in extrafibrillar and intrafibrillar collagen regions. Remarkable is that this tissue, when it gets older mineralizes to a higher degree of mineral content than a regular lamellar bone.[52]

Plexiform bone can be found in fast growing animals (such as cows or sheep for instance), where the outer diameter of long bones have to grow rapidly to fulfill their mechanical function.[1] The rapid periosteal growth is accomplished by the repeated formation of a vascular network (plexus) around the bone surface with the generation of parallel buds of bone matrix (woven bone) between them, which provide a huge surface for further bone deposition. Consequently, the increase in bone volume and bone strength can occur more rapidly than in normal lamellar compact bone.[53] This type of bone contains plates of parallel-fibered bone with cores of woven bone.[1] The bone plates are subsequently interconnected in which lamellar bone circumference the blood vessels of the vascular plexus. The mineral particle sizes in these types of bone have been found to be in the same range as in lamellar bone.[29,54]

3.325.2.2. Tooth

Tooth is like bone a highly specialized tissue; however, the essential difference is that it is not remodeled once it has been formed and fully mineralized.[55,56] It consists mainly of dentin, which forms the body of the root and crown, while a thin layer of enamel covers the surface of the crown. Dentin is composed of a network of mineralized collagen I fibrils having hydroxyapatite particles with a thickness comparable to that of bone.[57] It can therefore be considered as one special type of bone.[58] In contrast, enamel is an extremely hard material containing mainly hydroxyapatite (98%) and only small amounts of proteins revealing a structure of huge columns of hydroxyapatite crystallites.

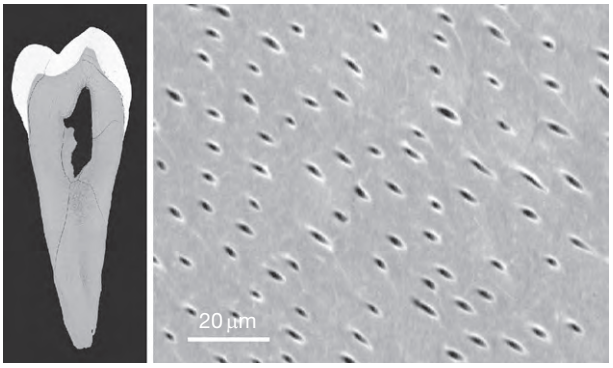

Figure 4 Tooth (overview + zoom-in) (backscattered electron image) obliquely cut tubuli – peritubular dentin lights up because of high mineral content.

Looking closer at dentin, one recognizes different zones: tubules surrounded by the peritubular dentin (PTD) (see Figure 4) and the intertubular dentin (ITD). However, the arrangement of these is variable within dentin from the dentin–enamel-junction towards the pulp which is likely associated with the tooth's mechanical properties.[59,60] Differences between the mineral content of PTD and ITD can be observed (see Figure 4), but the crystal organization in PTD is similar to that found in ITD and bone.[61]

Strong compressive and shear forces act on the tooth during chewing, thus making a specialized structure necessary.[62,63] The construction of a tough bulk material (dentin in the tooth) covered by a hard wear-resistant coating (enamel) is also known from engineering structures. However, one problem of such materials is that they are not resistant to fracture propagation. Once a fatigue crack is generated near to the surface it can propagate easily and catastrophically into the bulk material which is relatively softer than the surface layer. A strategy for reducing this problem is to design the bulk material to have a graded microstructure and mechanical properties (e.g., stiffness) near to the interface to the hard surface layer. This is exactly what is found in the tooth: while the thickness of the mineral crystals increased, the mineral content, hardness, and elastic modulus were found to decrease towards the dentin–enamel interface.[57]

3.325.2.3. Calcified Cartilage

Calcified cartilage plays an important role in the development and growth of long and short bones (e.g., femur, vertebra, etc.). For instance at the metaphyseal growth plate, growth cartilage becomes mineralized, forming the first scaffold for bone apposition by 'surface' osteoblasts. This process is called endochondral ossification. Subsequently, this combination of mineralized cartilage and primary bone apposition gets remodeled into highly organized lamellar bone. Its other prominent role is at the interface of cartilage and bone in joints.

Unlike bone, which contains collagen type I solely, cartilage is comprised of different types of collagen. Types II, IX, and XI are specific for cartilage where type II builds the basic framework for the cartilage material. Unmineralized articular cartilage contains collagens, proteoglycans, and a high amount

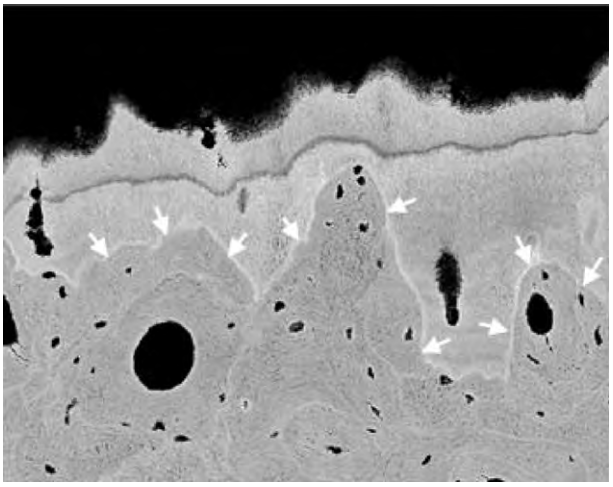

Figure 5 Backscattered electron image of calcified cartilage at the interface between bone (gray) and cartilage (black). Note the cement line which separates bone and calcified cartilage (white arrows). It is also interesting to see the negative gradient of mineral concentration towards the unmineralized cartilage.

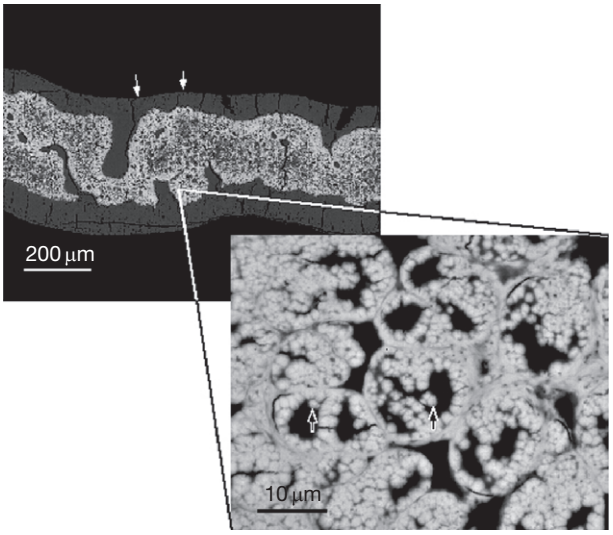

Figure 6 Mineralized turkey leg tendon cross-section (backscattered electron image). Note the heterogeneity of mineral deposition which is important for mechanical behavior.

of water (up to 75%). Structurally, zones of different fibril orientation can be distinguished from parallel to the articular surface in the superficial to a perpendicular orientation in the deep and calcified zones.[64] In the zone of mineralized cartilage in the joint (which is a rather small, about 200-μm-thick region between unmineralized cartilage and bone), the water is replaced by hydroxyapatite mineral particles. Anchoring of cartilage in bone by mineralized cartilage is mechanically important for the load transfer from unmineralized cartilage to the subchondral bone region. It was shown that the relationships between mineral and local mechanical properties such as stiffness and hardness were different in mineralized cartilage and bone. The subchondral bone requires less mineral content to gain the same stiffness and hardness than the mineralized cartilage. Generally, the calcified cartilage was found to be higher mineralized than subchondral bone[65] (see also **Figure 5**). An important aspect in view of microcrack propagation is the varying mechanical properties of the mineralized cartilage: alternating zones with lower and higher stiffness were observed lying parallel to the interface with bone.[66] Such structures of varying stiffness were shown to resist crack propagation and have also been found in other mineralized tissues (for instance in the tooth).

3.325.2.4. Calcified Tendon

In the human skeleton, tendons are normally not mineralized. Extensive tendon mineralization in humans occurs only in pathological conditions or after injury. However, in some species, some of the tendons mineralize also in normal physiologic conditions. Among these, the Achilles tendon of the turkey is the most prominent and an often studied model as it has a more simple structure than bone with parallel collagen fibrils in which the mineral particles are embedded (see **Figure 6**). The mineralized turkey leg tendon (MTLT) is a large, cylindrically shaped, thick tendon which is extending from the claws to the insertion points in two major hip muscles of the animal. Distally, it is a single segment, while proximally it bifurcates into two smaller and more flattened segments. Mineralization occurs near to this bifurcation and proceeds in a distal to proximal direction. As mineralization is rather slow in the tendon, it has been studied extensively.[67–69]

The morphology of the MTLT has some similarities to those of mineralized cartilage and bone. The tendon-forming cells, the tendonoblasts can be found arranged in columnar arrangements parallel to one another and to the long axis of the tendon. These cells synthesize and secrete the organic components of the tendon which is mainly collagen type I but consists also of collagen types V and XII and specific non-collagenous proteins. The collagen molecular packing in the tendon and its relation to mineralization and biomechanical function have been reported in detail.[70,71] *In situ* tensile tests and X-ray diffraction (XRD) experiments were used to measure the fibril deformation, with applied external strain giving evidence for an inhomogeneous elongation at larger strains in the MTLT.[72] Generally, the mineral particles were described to have a plate-like shape[73] and consist of poorly crystalline hydroxyapatite.[72] The reason that avian tendon, such as the long Achilles tendon in the turkey, gets partly mineralized is to reduce the elongation of the tendon and to increase tensile strength and stiffness. Mechanical models have been suggested for the estimation of the effect of the mineral on the energy storage in the tendon.[75] Tensile tests of samples with gradually increasing mineral content showed gradually increasing stiffness and yield strength together with gradually reduced plastic deformation.[31]

3.325.3. Heterogeneity of Mineral Content and the Need for Imaging Techniques

To study the trabecular architecture of bone, standard imaging tools (in particular light microscopy) have a sufficient resolution and, especially, micro computed X-ray tomography allows

a three-dimensional (3D) characterization and helps to estimate the fracture risk for the patient, sometimes in conjunction with finite element (FE) modeling.[76–80] However, imaging techniques are not only needed to study the bone architecture but also the material it is composed of. Most of the biological mineralized tissues are spatially inhomogeneous. Specifically, bone is not only a spatially but also temporally inhomogeneous tissue because of bone modeling and remodeling activities.[6] These are occurring throughout the lifetime of the individual and should maintain the bone mass, remove bone damage, and control the homeostasis of the phosphocalcic metabolism. For instance, a total of about 10% of bone mass is renewed per year in the human skeleton.[81] This percentage varies depending on the location (cancellous, intracortical, etc.). However, it means that the average lifetime of the BSUs is 10 years, resulting in a completely renewed bone tissue after this time period. Bone remodeling takes place at the bone multicellular units (BMUs) at the surfaces of trabecular bone or in the osteons of cortical bone involving all types of bone cells. During the remodeling cycle, preexisting bone packets are resorbed and replaced by new bone. This new bone is first deposited as collagen fibrils which get mineralized after a specific mineralization lag time. During the primary mineralization process, most of the mineral (about 70%) is deposited in the collagen matrix very rapidly (during a few days).[82] The remaining mineral (up to bone's final mineral content) is placed in the matrix during the subsequent secondary mineralization which lasts much longer, having a time scale of several months to years.[83,84] Therefore, the mineral content of the bone material is dependent on two processes, the bone turnover (how much of the bone is renewed in a specific time period) and the kinetics of mineralization of the newly formed bone. These two processes cause a distribution of bone areas having a specific tissue age,[85] being the reason why bone is not a homogeneously mineralized bulk material but has a characteristic pattern of bone mineralization. The deposition rate of newly mineralized bone matrix can be visualized and quantified by fluorescence labeling (see **Section 3.325.5.1**). Using this latter technique, the properties of the bone material of a specific tissue age or age range can be studied and compared between different individuals. Bone turnover is not constant during life but undergoes changes during growth or aging. Together with the speed of the mineralization of the newly formed collagen, it can be affected in diseases and/or by treatment. The pattern of mineral properties (including calcium concentration, mineral:matrix ratio, intensity of the phosphate bands, etc.) contains therefore important information on the present physiologic status of the individual, and on the history of eventual pathophysiological processes. Although average mineral properties are important (such as the bone mineral density (BMD) determined noninvasively and used frequently to estimate the fracture risk of an individual patient), diagnostic techniques with a higher spatial resolution are necessary if the mineral distribution within the bone material is to be assessed.

Moreover, for the evaluation of treatment effects imaging techniques are required. Generally, agents for treatment affect bone turnover (e.g., bisphosphonates reduce[86] and teriparatide increases bone turnover[87]) and some of these agents also become incorporated into the bone mineral (fluoride or strontium for instance[88–91]). Therefore, in many cases, the effect of the treatment can be seen in the new bone material formed during the treatment period.

3.325.4. Estimates of Total Bone Mineral Content

This section discusses techniques which measure the bone sample or the skeleton as a whole but do not provide any spatial information. It has to be mentioned that many of the imaging techniques which will be described in the following section were previously used (sometimes are still used) on powder samples which are also lacking any spatial information on the tissue studied. However, the latter will not be described further.

3.325.4.1. Ash Weight Analysis

Determination of the ratio ash weight to dry weight is a common method to assess the average mineral content of a mineralized tissue.[92] For this purpose, the bone tissue sample is defatted by chloroform and subsequently dried at 80 °C for 4 days and the weight of dried bone is determined. This dried bone sample is placed in crucibles and is heated to 550 °C for 24 h to remove the organic constituents. Subsequently the weight of the ashed bone is determined. The ash fraction is calculated by dividing the weight of the ashed bone by the weight of the dried bone.

The average elemental composition of the bone mineral is also measured by inductively coupled plasma optical emission spectrometry (ICPOES), which requires ashed whole bone tissue.[91]

3.325.4.2. Density Fractionation

Density fractionation separates particles of powdered bone into more homogenous fractions of various densities, thus providing some information on the heterogeneity of the mineralization in the sample. For this purpose bone is ground and sieved to a small particle size (<50 μm). The bone particles are then centrifuged in organic solvents to separate them by specific gravity. The higher the density, the higher is the mineral content in a given volume of organic matrix. The lower density represents the least mineralized fraction.[93]

3.325.4.3. Neutron Activation

If a sample is placed into a neutron beam, the elements within the sample will form radioactive isotopes. As the radioactive emission and the radioactive decay paths are well known in general, the emission spectra from the samples can be analyzed for the elements occurring in the samples (neutron activation analysis, NAA). NAA is a very accurate and nondestructive method for measuring the elemental composition of a mineralized tissue sample, although one disadvantage is that the samples become radioactive and a fairly large amount of material is needed. The method requires a nuclear reactor or another source of neutrons. An advantage of this method is that it is sensitive to the nuclei of the elements and is independent of the chemical compounds in which the elements are present in the sample (for instance ^{49}Ca counts representative for the amount of calcium[94]).Generally, the

γ-ray emission of the elements is collected using scintillation or semiconductor detectors. The parameters which can be varied in NAA are the energy of the neutrons (low energy or thermal neutrons versus high energy neutrons), and the time delay of spectrum acquisition (prompt gamma spectra or delayed gamma spectra).[94–96]

3.325.4.4. Bone Mineral Density

In the clinical routine, bone mineral density (BMD) is measured *in vivo* by absorption of X-rays and is used as an indictor of the patient's bone mass. During lifetime, the BMD is not constant but increases during early life, reaching a maximum value and decreasing in the later lifespan. In particular, BMD is used to diagnose osteoporosis and osteopenia as well as to monitor effects of osteoporosis treatment. However, it has to be emphasized that BMD is a surrogate parameter describing the apparent mineral density of bone at organ level which is dependent on the bone volume (bone volume per tissue volume) as well as the amount of mineral within the bone material (degree of mineralization) of the patient.[97] To distinguish between subtle changes occurring in bone volume and/or in mineralization, a second measurement is necessary, giving the degree of bone matrix mineralization at tissue level (for instance obtained from transiliac bone biopsy samples).[98] The BMD is also influenced by changes in mineral average atomic number, such as in patients treated with strontium ranelate, where strontium atoms are incorporated into the bone material and increase the attenuation of the X-rays, apart from having eventual effects on bone volume.[99]

For the measurement of areal BMD and volumetric BMD, dual X-ray absorptiometry (DXA) and computed tomography (CT), respectively, are widely used. The DXA method is on the basis of unidirectional transmission of the body with X-rays of two different energies and projection of an absorption image on a 2D-detector. Both X-ray energies are differentially absorbed by the different tissues, thus making the discrimination between bone and soft tissue possible. The resulting areal BMD is a 2D-variable (mainly given in grams per square millimeter) which makes several geometrical corrections necessary or is limited to comparison of bone features with similar 3D sizes. Typically, the areal BMD of a specific patient is compared to the maximum BMD of the healthy population and its deviation is given by the T-score (which is the number of standard deviations from the normal value) or it is compared to age-matched normal values and this deviation is given by the Z-score. T- and/or Z-scores are used as important indicators for fracture risk and diagnosis of bone diseases, and are important for treatment decisions.[100]

Volumetric BMD is on the basis of multidirectional transmission of the body with X-rays by CT-scans (quantitative CT, QCT). The attenuation of the X-rays by the sample results in voxels with different gray scales. To transform these into bone mineral equivalents (in grams per cubic centimeter) appropriate bone mineral phantoms have to be used. Generally, such mineral content measurements at organ level can be done *in vivo* (using whole body CT-scanners) or also in *in vitro* samples. Dedicated peripheral CT-scanners (pCT or pQCT) have been developed, which allow the measurement of bone mineral content (BMC) in radius or tibia, either in total or separately within trabecular and cortical compartments.[101] Moreover, high-resolution micro-CT-scanners have been developed for measuring bone microarchitecture in peripheral skeletal sites in humans and in animals (see **Section 3.325.5.4**). However, up to now, DXA is more commonly used than QCT, as it is faster and uses lower doses of ionizing radiation.[101]

3.325.5. Imaging of Mineralized Tissues

Generally, one can distinguish between techniques which produce a full field image of a specific structure such as transmission light or electron microscopy and those in which the specimen is imaged by scanning in a point-by-point mode. Depending on the scanning probe and the produced signal, a property map with a specific spatial resolution of the specimen is generated (for latter see **Section 3.325.6**). In both imaging and mapping, the result is a 2D image of the sample. In certain cases, tomographic techniques utilize 2D projections which are further mathematically processed for a 3D map or images of mineral properties.

For most of the 2D imaging techniques, tissue samples have to be taken and have to be embedded in plastic without decalcifying. Most commonly, polymethylmethacrylate (PMMA)[102] is used because it penetrates well into the tissue, and because of its low viscosity. Such embedding is necessary to perform thin tissue sections or bulk samples with plano-parallel flat surfaces. Additionally, for backscattered electron imaging, the embedded samples require electrical coating (carbon or gold) to avoid a build-up of charge at the surface. In contrast, CT, magnetic resonance imaging (MRI), micro-CT, Raman, scanning acoustic microscopy (SAM), atomic force microscopy (AFM), and nanoindentation can be applied using native samples.

3.325.5.1. Light Microscopy and Morphometry

Histochemical staining of bone and other mineralized tissues is used to generate a selective light absorption contrast. Von Kossa staining is often used to differentiate between soft and calcified tissue. This staining technique uses the chemical reaction between the calcium phosphate and the reagents of a silver nitrate solution. The mineralized tissue will then appear as a black to dark brown color. It can localize mineral in the tissue as well as in bone cell cultures, but it cannot provide additional information on other properties of the mineral such as amount of mineral within the collagen or mineral maturity.[103] As the Von Kossa stained sections reveal a high contrast between the mineralized and the unmineralized tissues, they offer the prerequisite for automated histomorphometrical analyses of the images. Another technique which provides also such a high contrast and therefore suitable for automated histomorphometry is backscattered electron imaging (see **Section 3.325.6.2**).

The analysis of the 2D morphometry of the mineralized tissues has been done for a long time and specifically transiliac bone biopsies from patients are used for clinical management to assess bone quality.[104] Among the variables of interest are the structural indices of trabecular compartment (bone

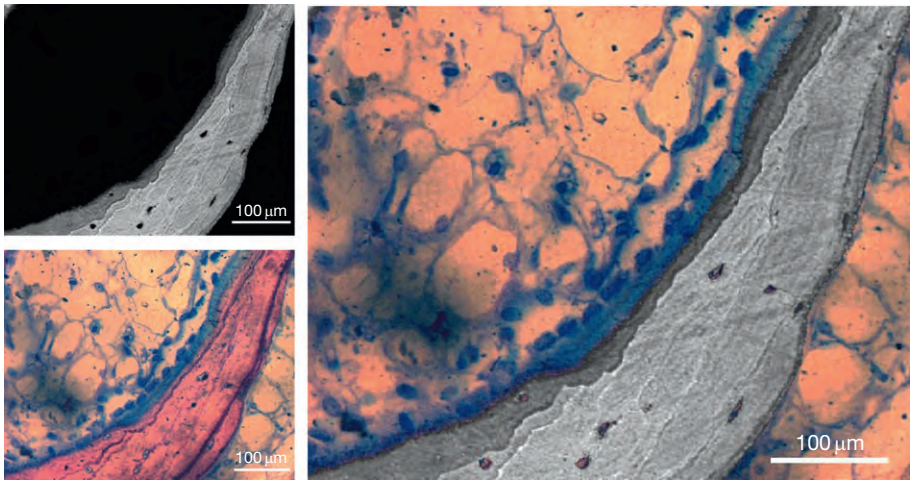

Figure 7 Surface stained (Giemsa) ground section of a trabecular feature combined with mineral map of the identical surface using backscattered electron imaging. Note that the osteoblasts are forming osteoid which starts to mineralize and form a new bone packet of lower mineral content compared to the adjacent old bone packet.

volume fraction, thickness, separation, and number and connectivity of trabeculae) as well as of cortical bone (width and porosity).[105] Further, variables of static bone formation and resorption like osteoid surface, volume and thickness, osteoblast and osteoclast surface as well as eroded surface are assessed. For these variables, staining techniques like trichrome Goldner or Giemsa are applied, to visualize the osteoid, mineralized bone and the cells (see **Figure 7**). Variables of dynamic bone formation like mineralizing surface and mineral apposition rate can be determined, if fluorescence labeling has been applied *in vivo* by administration of tetracyline in a certain time schedule (e.g., 3 days tetracycline, 12 days pause, 3 days tetracycline, and 5 days pause before bone biopsy). The tetracycline is incorporated selectively into the mineralizing front of forming bone packets and can be observed under UV-light. In general, histomorphometric data reveal quite large variations even for healthy individuals and therefore only relatively large deviation from normal can be identified in pathologically altered tissue. This circumstance is mainly caused by the high biological variability at the biopsy site[106] and because 2D histomorphometry using only few or even a single section is a poor representation of the 3D situation.

In the context of histomorphometrical analysis of bone sections, it should be mentioned that sometimes information on the collagen orientation is required[107] which can be obtained from polarized light microscopy.[108] The arrays of collagen fibrils have a highly anisotropic structure, thus causing birefringence of these structures in visible light. Consequently, linearly polarized light[109] and circularly polarized light[110] can be used for the determination of the collagen fibril orientations.

3.325.5.2. X-Ray Microradiography

Microradiography is a technique which utilizes unidirectional X-ray projection and absorption in thin slices of mineralized tissues for imaging and quantifying differently mineralized areas in the sample.[111] This method was developed in the 1950s for studying bone samples[112] and was the first to reveal the heterogeneous pattern of mineralization in bone.

In general, the local X-ray attenuation is measured by photographic films, which are directly in contact with the sample slice. The gray levels generated on the photographic film, which reflect the X-ray intensities transmitted through the bone slice, are evaluated by microdensitometric methods. Samples have to be prepared by embedding the undecalcified tissue into plastic (usually PMMA) which is nearly transparent for X-rays. The embedded samples are then cut into 150-µm-thick slices which are subsequently ground manually to the required thickness (about 100 µm for bone[113]).

As the volume for X-ray absorption within the samples is low, the X-ray energy for illumination has to be relatively low to receive a high contrast between differently mineralized areas in the sample. For bone, a wavelength of about 1.5 Å (nickel-filtered copper K-alpha radiation) is often used.[114] The X-rays penetrating the sample are then absorbed according to the atomic number of the constituents of the sample material. The intensity of the X-ray beam is decreased exponentially with sample depth and dependent on the mass absorption coefficient of the elements in the sample. Therefore, it is crucial that the thickness of the sample is uniform. Moreover, it is highly important that the bone area is illuminated by a homogeneous X-ray field.

For the quantification of the mineral content within the specific sample area, the differences in X-ray attenuation have to be related to the corresponding degrees of mineralization within the tissue. This is usually done using an aluminum step-wedge (thin foils of aluminum of known thickness) reference, which is imaged together with the bone slice. In consequence, the absorption of the sample can be expressed in terms of equivalent thickness of aluminum and can be further transformed to hydroxyapatite density values in grams per cubic centimeter.[114]

Microradiographic studies were extensively done on normal and diseased bone and were used for the detection of osteoporotic treatment effects on the bone material.[91,115]

A limitation of the microradiographic technique is the fact that it is a transmission technique which implies an averaging of the calcium content over the thickness of the sample (i.e., over 100 μm) which seriously limits the resolution of the technique. Indeed, features of mineralized tissues, such as a trabeculum might not be filling the whole thickness of the sample section, thus leading to an erroneous estimate of the mineral content in this particular trabeculum. Specifically, in cancellous bone, which has a relatively large internal surface area, this might lead to significant errors in the resulting mineral content.[16]

3.325.5.3. Phase-Contrast and Dark Field X-Ray Imaging

Conventional X-ray imaging is on the basis of the absorption contrast of the studied object and is limited to tissues which reveal differences in the absorption contrast of their components. In analogy to phase-contrast imaging in light microscopy, where the phase contrast is revealed by inserting a $\lambda/4$ plate into the diffraction plane, for X-ray imaging, a new technique with a grating interferometer has been introduced.[116] The experimental setup consists of a series of three gratings, a source grating placed near to the X-ray source (creating an array of coherent linear X-ray sources), and two other gratings, one being directly in front of the detector. Phase-contrast X-ray imaging is also possible using the coherent X-ray light from synchrotron sources.[117] The advantage is that this contrast may reveal features hardly visible in absorption contrast, particularly in soft tissue. The disadvantage is that it is difficult to evaluate quantitatively the contrast (which typically enhances at interfaces between features in the specimen). Finally, setups using diffraction gratings may also be used for phase-contrast dark field imaging of mineralized tissues.[118]

3.325.5.4. Microcomputed X-Ray Tomography and Synchrotron Radiation Microtomography

3.325.5.4.1. X-ray tomography for structural analysis

Similar to clinical CT-scanners, the microcomputed X-ray tomography (μCT) scanner measures the multidirectional attenuation of the X-ray beam by the sample and allows a structural 3D analysis of the mineralized tissue, but with a spatial resolution in the micrometer range.[119] The microfocus X-ray source illuminates the rotating sample in hundreds of different angles and the projection images are collected by a planar X-ray detector. Numerical algorithms are necessary to reconstruct 3D images from these data. Once the 3D images have been reconstructed, the sample can be viewed in arbitrary virtual cross-sections. The energy of the X-ray source is variable in most instruments (typically 20–100 kV) which enable the study not only of bone but also titanium implants in bone, to give just one example. The typical spatial resolutions for the micro-CT-scanners vary from 10 to 50 μm. Scans with better spatial resolution (down to 1 μm) are possible, but take much longer for the image reconstruction process if the specimen size is not reduced at the same time, and powerful computers are necessary for handling of large amounts of data.

Bone architecture has been investigated for a long time on the basis of histological staining (see Section 3.325.5.1). A big disadvantage of the approach is the use of 2D sections. 3D analysis of the sample not only provides unbiased measurement of architecture[120] but also keeps the sample intact for further (for instance, mechanical) investigation. During recent years, micro-CT has become a commonly used, powerful technique for the assessment of trabecular (see Figure 8) and/or cortical architecture[121] and for the evaluation of human bone biopsy samples after treatment.[122] Micro-CT data also provide the possibility of setting up FE models to estimate strength and stiffness of the whole bone sample, on the basis of its trabecular microarchitecture.[123,124]

High-resolution μCT cannot be applied *in vivo* because of the high dosage needed for obtaining useful images. However, the increasing sensitivity of CCD-cameras has now led to the development of the first *in vivo* CT-scanners. They are used for monitoring local changes in bone architecture with growth or treatment in animal models (typically, mice and rats).[125–127]

Generally, beam hardening, noise, and partial volume effects are challenging problems. Beam hardening can be reduced by using physical filters during scanning and by corrective algorithms during reconstruction. Another option is to work with monochromatic X-ray radiation, as available at synchrotron sources. Similarly, noise can be reduced by applying filters. A crucial parameter in the evaluation of micro-CT images is the segmentation of the raw images – that is, the decision whether a voxel corresponds to bone or to marrow.[128] When the voxel size is not much smaller than the typical feature size (e.g., trabeculae in cancellous bone), this segmentation has a large influence on the outcome of morphometric analyses. Indeed, voxels only partially filled with bone may lead to an over- or underestimation of the bone volume. A simple geometrical consideration shows that imaging rod-like trabecular motifs (of a diameter of 200 μm) using a voxel size of 10 μm will result in 20% of voxels showing a wrong gray level due to the partial volume effect.[16] Global thresholding with a single gray level (selected visually or by analyzing the histogram of μCT bins) is most widely used, but may result in

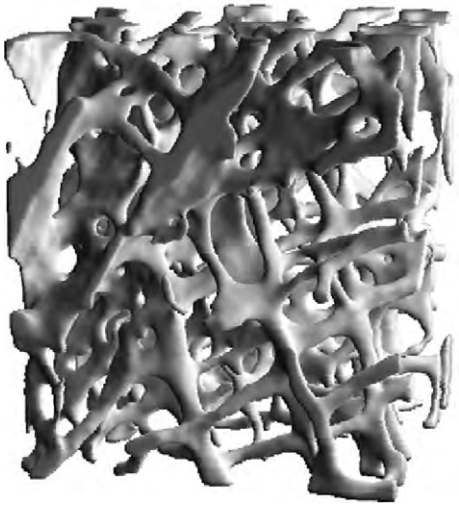

Figure 8 Cancellous bone structure obtained from microcomputed tomography imaging. Reproduced from van Lenthe, G. H.; Hagenmüller, H.; Bohner, M.; Hollister, S. J.; Meinel, L.; Müller, R. *Biomaterials* **2007**, *28*, 2479–2490.

the loss of thin trabeculae or in an overestimation of thicker ones. Segmentation is also very important for extracting cortical from trabecular bone. If the real volume of a sample is known by previous Archimedes testing[124] the binary data set can be forced to have the same volume as determined experimentally. To overcome the errors occurring with global thresholds, more than one threshold value may be used,[129,130] or use of local[131] thresholding algorithms based on the analysis of the histogram of the local neighborhood of a voxel is a possible approach. However, the efficacy of these methods is limited by lower scan resolution and the heterogeneity of the studied materials.

3.325.5.4.2. X-ray tomography for quantitative analysis of the mineral content

A recently developed technique for the quantification of the mineral content of a mineralized tissue at the bone packet level is synchrotron radiation microtomography (SRμCT)[132,133] based on the multidirectional projection and absorption of a focused, monochromatic X-ray beam. The aforementioned difficulties with the segmentation also apply to the SRμCT analysis, but their effect is smaller, because of the generally better spatial resolution of the technique and the higher X-ray beam intensity which improves the signal to noise ratio.

SRμCT can be used with a voxel size of 5 μm or even better and is well suited for the investigation of single trabeculae. The information obtained from the 3D measuring technique is combined with an imaging processing method that derives bone mineralization density distribution (BMDD) from analysis of voxels which are representing the mineral content in units of grams per cubic centimeter. Because of the long time needed for data acquisition and the huge amount of data to be handled, the analyzed volume is usually in the range of few cubic millimeters at the most. This method is rather new and still in development. One difficulty in this method is to avoid artifacts in the 3D reconstruction, but there is rapid progress in this field.[134]

There are also attempts to use normal (laboratory) μCT techniques to record mineral content at tissue level. However, X-ray fluxes in laboratory sources are low which makes the use of a polychromatic beam necessary, resulting in beam hardening effects, which are difficult to correct. Furthermore, the signal to noise ratio is lower than that at the synchrotron, thus reducing the capability to resolve differences in mineral contents. Additionally, it was shown that the effects of varying imaging parameters, such as tube voltage, current, integration time, object to X-ray source distance, projection number, detector array size, and imaging media (surrounding the specimen) have a strong influence on the relationship between equivalent tissue density and its linear attenuation coefficient.[135]

3.325.5.5. Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) techniques are highly sophisticated methods which make use of the magnetic properties of atomic nuclei (spin relaxation time) in a magnetic field irradiated with a radio frequency (RF) pulse. MRI is a noninvasive method which measures the structure of mineralized bone tissue indirectly *in vivo* or *in vitro*. The outcome of MRI is an image of the distribution and state of protons bound in water and fat in the different body tissues. As bone has a relatively low water content, the surrounding bone marrow is visualized while the mineralized bone appears dark in the MRI.

The hardware of an MRI instrument consists of the imaging magnet (which generates the static magnetic field), three weak magnets (providing the gradient magnetic fields for the *xyz*-localization of the signal), transmitter, and receiver RF coils (which transfer energy to the sample and detect the MR signals). In conventional MRI the spatial resolution is too low for the imaging trabecular features; however, there have been attempts to image trabecular bone architecture using high-resolution MR instruments (with a static magnetic field of about 1.5 T for clinical use). Spatial resolutions of about $100 \times 100 \times 300$ μm have been achieved and MR-deduced histomorphometric parameters have been shown to be more or less correlated (depending on the type of studied bone) with those obtained from other methods.[136] MRI has the advantage that it does not need ionizing radiation; however, spatial resolution is still far below that of CT imaging.

3.325.5.6. Transmission Electron Microscopy

TEM provides high-resolution imaging and is used for studying small areas or even single mineral platelets selectively. The TEM can be operated at different electron energies (often 100 keV for conventional TEM and 1 MeV for high-resolution imaging). The contrast of the TEM images is dependent on several factors, mainly on the difference in electron density of the structures in the sample (difference in organic matrix and mineral electron density), the thickness and the density of the sample, the diameter of the objective aperture, and on the energy of the electrons. Another parameter which can be varied is the usage of either bright or dark field imaging. The advantages of dark field imaging in TEM applied to mineral crystals have been discussed.[137]

For viewing the material with TEM, ultrathin sections of the plastic (mainly Spurr's resin or Epon) embedded samples of about 70–100 nm[54,138] have to be prepared. Sections can be left unstained or enhanced by contrast with uranyl acetate and lead citrate.[138] Another preparation technique is cryo-sectioning.[139]

TEM has mainly been used for the characterization of the lamellar structure[39,140] and for studying the arrangement of the mineral particles in the collagen matrix of normal and diseased bone,[141] dentin,[142] enamel,[143] and MTLT.[144,145] One specific interest was also the shape (needle- or plate-like) of the single mineral particle.[73,146]

Although transmission electron tomography is a rather exotic technique for studying bone, it should be mentioned here that TEM analysis can be also used for 3D information. For this purpose, the sample has to be viewed in many directions. In the literature 2° tilt series over a minimum range of $\pm 60°$ is described. The volume of mineralized tissues studied by TEM tomography is rather small. Generally, it is used for viewing the interface between the collagen fibrils and the mineral or for the shape of single mineral particles.[145,147]

The TEM instrument can also be used for the observation of the diffraction pattern of a mineralized tissue sample. One of the specific features here is the selected area electron diffraction (SAD or SAED). Application of lenses enables to image the

diffraction pattern of a very small area (micron to submicron range). This can be used for studying the crystal properties of single bone mineral particles.[148]

3.325.6. Property Mapping in Mineralized Tissues

3.325.6.1. Vibrational Spectroscopy

The molecular bonds of any mineralized material are not stationary but undergo twisting, bending, rotation, and vibration. When irradiated with light, there is absorption and/or inelastic scattering at specific wavelengths, which can be attributed to specific structures and environments of the molecules. Vibrational spectroscopy (infrared and Raman spectroscopy) give access to the basic components of mineralized tissues. The utility of vibrational spectroscopy has been accelerated by the development of optic fibers and by the extension of the previous microprobe technique to spectroscopic imaging.[149–151] The strength of vibrational spectroscopy in the context of mineralized tissues is that it allows the simultaneous mapping of properties of the mineral and of the organic matrix. For instance, collagen cross-link ratios are one of the matrix properties which are clinically relevant, because of their implication for the mechanical performance of bone.[152–155]

3.325.6.1.1. Fourier transform infrared imaging

Infrared radiation (IR) is absorbed at specific wavelengths depending on the molecular bonds and their modes of vibration. Absorbance spectra can be obtained in reflection mode or in transmission mode. The former has the advantage that the surface of a bulk bone sample can be studied, but this is generally more difficult. This makes the combination with other imaging techniques done on the same surface of the bulk sample material easier and more convenient.[57] Attenuated total reflection (ATR) is another possible reflection mode which has been developed recently[156] and is used for studying spectra from aqueous solutions[157] for instance.

For the IR-transmission mode, the common setup consists of a broadband radiation source, a microscope, an automated translation stage for scanning the regions of interest and an Fourier transform infrared (FTIR) spectrometer interfaced to single-channel or a focal plane array detector. The typical spatial resolution of FTIR imaging (FTIRI) is about 10 μm with the laboratory instrument and better (down to 1.3 μm) at the synchrotron.[158] The typical spectral resolution is 8 cm^{-1}.[155] For calcified tissues such as bone, 2–4-μm-thick sections from resin (PMMA) embedded mineralized tissue have to be prepared. Consequently, the spectral contribution of the resin has to be subtracted from each individual spectrum. This is most crucial for poorly mineralized tissues where resin penetration is extensive and less crucial for higher mineralized samples (such as older bone areas) where the resin penetration is much lower.[158]

The infrared absorption spectrum of bone reveals broad absorbance peaks, which are the sum of many smaller subbands. They mirror the collagen (amide bands and cross-links) and the carbonated hydroxyapatite crystals (phosphate and carbonate groups) of the bone mineral. For fast automated evaluations of IR spectra (especially in area scans), the intensities at the wavelength of the band maximum of interest are determined. For more accurate analysis (e.g., in line scans) the broad IR-bands can be deconvoluted into subbands, the contributions of which (peak height) are evaluated by curve fitting. The integrated area under the individual subbands reflects the relative amount of this chemical bond in the sampled volume (voxel). To minimize errors due to heterogeneity in sample thickness (absorbance volume) and surface topography (reflection), FTIR absorbance values are generally given in peak ratios and not in absolute values: mineral to matrix, phosphate to carbonate and, as a measure of cross-link maturity, the pyridinium (an older, trivalent collagen cross-link) to dehydrodihydroxylysinonorleucine (a younger, divalent, and freshly synthesized collagen cross-link) ratio. For a correct interpretation of these variables, it has to be noted that changes in both the numerator and denominator have an influence on changes of the ratio. It was shown that FTIRI mineral to matrix ratios correlated well with ash weight measurements.[159] Mineral to matrix ratios have been extensively studied in normal[160,161] and diseased bone, and have proven to be a powerful tool in monitoring treatment effects.[150] Their usage has been reviewed for the examination of biological tissues in general[157] and for mineralized tissues in particular.[158,162] The collagen cross-link ratios, which reflect collagen maturity or aging and play a pivotal role in mechanical properties of the collagen scaffold, have also been successfully studied,[163–165] to give just some examples).

3.325.6.1.2. Raman spectroscopy

In Raman spectroscopy, the sample is irradiated by monochromatic laser light and the inelastically scattered light from the specimen is measured. While the IR technique has usually a superior signal to noise ratio, Raman spectroscopy has other advantages, such as its easy use in reflectance mode and its higher spatial resolution in 1 μm range. Furthermore, the obtained vibrational bands are very sharp in many cases and, therefore, even small band-shifts can be detected.

The Raman spectrometer consists of a laser which acts as an intense and monochromatic polarized light source, a device that separates the elastically scattered light from the inelastic Raman scattering, a spectrograph, and a detector. A challenging feature with the typically used laser wavelength of 532 nm is the high autofluorescence of the biological samples. One method to avoid this problem is photobleaching prior to Raman imaging[166] or the usage of near infrared laserlight[151] or of UV-laser light which, however, bears the risk of inducing photodegradation damage in the sample.[157] Laser light in the deep UV (about 200 nm wavelength) can also be used to enhance the vibrational intensities of specific parts of the proteins of the organic component in the studied tissue.[167] Moreover, Raman spectroscopy was shown to be compatible with commonly used staining techniques.[168] Fluorescence bands from labeled bone specimens for instance can be identified easily giving access to the tissue age of the studied bone packets in the sample. Minimal or even no sample preparation is necessary for Raman microspectroscopy. Native or embedded samples can be used.[169] If Raman spectroscopy is used in reflectance mode on polished samples, it can be easily combined with other techniques visualizing the same sample surface.

The most prominent band for minerals is the ν1 phosphate band at 961 cm^{-1}. Carbonate substitution in the apatite mineral can be seen at the 1075 cm^{-1} band. Amide collagen bands are

visible at higher frequencies.[151] A characteristic feature of Raman microscopy is that the intensity of the Raman light is strongly dependent on the relative orientation between the polarization plane of the laser light and the bond axis of the molecular group. Thus, Raman intensities have to be interpreted with caution, because they can be due to compositional as well as to orientational contrast. It was shown that the bands have different polarization behavior, which makes some band intensities dependent on the longitudinal axis of the collagen fibrils and/or the apatite crystal *c*-axis orientation in bone (**Figure 9**). For example, using the polarization information one can obtain information on fibril orientation and composition simultaneously.

The high spatial resolution of about 0.5–1 μm makes Raman spectroscopy a powerful tool for dental research,[170] or for the investigation of small sized features in bone, such as the lamellar structure of osteons in cortical bone.[171,172] In disease-related alterations[173] and changes due to mechanical deformation, the breakage of collagen cross-links have been identified using Raman microspectroscopy.[174] Raman microspectroscopy can be used in confocal geometry, thus making information from a specific depth in the sample available[175] (for instance, reviewed by Gamsjäger *et al.*[151]).

3.325.6.2. Secondary Electron and Back-Scattered Electron Imaging

In the scanning electron microscope (SEM), the interaction of the beam electrons with the target material leads to the emission of secondary electrons (SE) with low energy and backscattered electrons (BE) with high energy. In general, the SE and BE signal intensities are highly influenced by the topography of the sample surface. Especially the SE electrons, which are emitted from only a few nanometer thick surface layer, are used for studying topographic features of bone surfaces.[40,176,177] Specific techniques including low voltage imaging and high-resolution imaging have been developed and described in detail.[178,179]

The intensity of the BE signal coming from below the sample surface up to a depth of about 1.5 μm,[180] is related to the average atomic number of the target material. Hence, in bone tissue calcium is dominating the material contrast because of its relatively high atomic number ($Z = 20$), provided that any topographic contrast is excluded by plane surface preparation. This can be done by grinding and polishing or by micromilling of PMMA embedded samples. The pixel gray levels of the BE images, therefore, provide information on the local variation of the mineral content throughout the bone tissue.[181,182] The general rule is that the brighter the gray level of a pixel is, the higher is the concentration of calcium. Thus, soft tissue and PMMA exhibit the lowest gray level in the image. After proper calibration of the gray levels, they can be transferred to calcium concentration values to quantify the local calcium content in the sample (quantitative backscattered electron imaging, qBEI).[16,183] From such calibrated BE images, the frequency distribution of calcium concentration (histogram) can be deduced and is usually referred to as the BMDD. A bin width resolution of 0.17 wt% Ca has been described for qBEI by Roschger *et al.*[16] For statistical analyses and comparison of the different BMDDs, five parameters have been introduced[16]: the average calcium content in the bone volume of investigation (Ca_{MEAN}), the most frequent calcium content (the peak position of the BMDD, Ca_{PEAK}), the width of the calcium content distribution (Ca_{WIDTH}), the amount of low mineralized bone areas (Ca_{LOW}), and the amount of highly mineralized bone areas (Ca_{HIGH}) (see **Figure 10**). These parameters were found to be an effective way of quantifying differences between BMDD curves. Another approach of BMDD evaluation consists in reducing the histogram to only a few bins by including multiple gray levels in one bin.

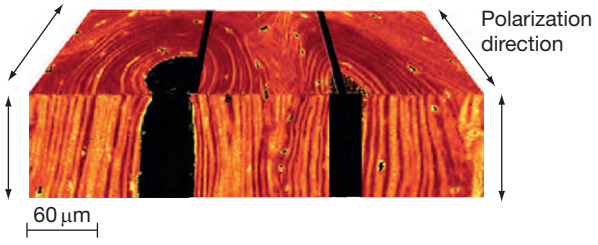

Figure 9 Raman imaging of two orthogonal planes within cortical bone using the intensity ratios of the ν_1 PO_4/amide I vibrations. Same lamellae show different contrast, depending on polarization direction of the beam in panel. Reproduced from Kazanci, M.; Wagner, H. D.; Manjubala, N. I.; *et al*. *Bone* **2007**, *41*, 456–461.

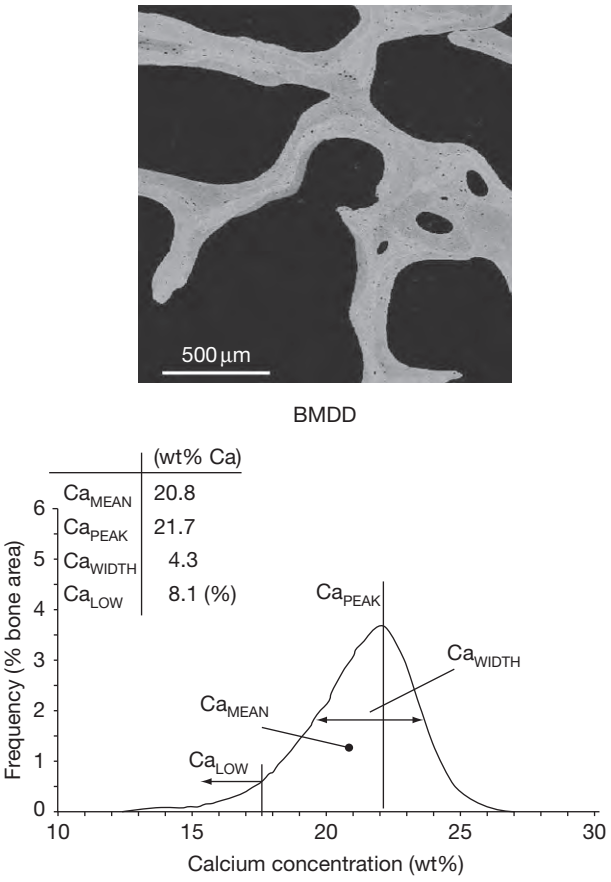

Figure 10 Quantitative backscattered electron imaging revealing trabecular bone mineralization density distribution (BMDD) and corresponding BMDD variables. Reproduced from Roschger, P.; Paschalis, E. P.; Fratzl, P.; Klaushofer, K. *Bone* **2008**, *42*, 456–466.

This allows comparison of BMDD curves on a bin-to-bin basis, by introducing bins with very low, low, intermediate, high, and very high mineral content.[184]

The sensitivity and quality of the BMDD analysis are crucially dependent on the reproducibility of the BMDD acquisition and its resolution in mineral content. For qBEI, an inter-assay variance of 0.3% CV (coefficient of variance) for the mean Ca-content was achieved.[183] The stability of the instrument, especially constant beam intensities, calibration procedures using suitable reference materials, and minimizing the beam damage effects are required to maximize the resolution of differences in the Ca-content. An important parameter which generally limits the resolution is the signal to noise ratio influencing the counting statistics of the detection of the BE signal. A peak broadening of only 5% could be achieved.[16,183] In contrast to other techniques, such as microradiography, for instance, the partially filled volume effect is not a problem in qBEI, as the penetration distance of the electrons is very small. The typical lateral resolution is in the range of 1–4 μm and, thus much smaller than the thickness of a bone trabecula, for example.[16] Caution in interpretation of BE-gray levels is necessary, when the composition of bone mineral is expected to deviate strongly from normal, as it is the case in patients treated with strontium (Sr) ranelate. In this case, one can not differentiate between true changes in the mineralization density and the incorporation of Sr into the bone mineral.[89]

The shape of the BMDD histograms reflects two processes, the mineralization kinetics of formed bone packets and the bone turnover rate.[85] For normal human adult trabecular bone, the BMDD was found to have a specific shape with relatively minor variations. Hence, even small deviations from this normal BMDD in diseased bone were shown to have a biological meaning and, thus, provide an interesting tool for differential diagnosis.[16]

3.325.6.3. Scanning Small Angle X-Ray Scattering and Diffraction

When an X-ray beam hits a target, various processes of interaction of the X-ray electromagnetic wave with the sample electrons, atoms, crystal lattice, and structural components take place. In the present section, the scattered intensities are of interest. These can give information on the crystal lattice and/or on small structures of differing electron densities within the sample. In bone, the difference in electron density between the mineral and organic phase of the composite material produces small angle X-ray scattering (SAXS) and provides information on the collagen-mineral composite material.[28]

In scanning-SAXS, the scattered X-ray intensities within angles not larger 1° with respect to the direction of the incident beam are measured and evaluated. They correspond to scattering vectors of 0.1–5 nm^{-1} and, thus, objects between 1 and 50 nm size can be detected within the sample. The diameter of the primary X-ray beam is about 200–100 μm at laboratory X-Ray sources and down to the submicron range at undulator synchrotron sources, such as the European Synchrotron Radiation Facility (ESRF). During the measurement, the sample is moved in *xy*-directions perpendicular to the primary beam. For each measurement position, the 2D scattering pattern is collected by a 2D X-ray detector. The scattering intensities are analyzed for parameters such as the mineral particle thickness, the predominant orientation of the mineral particles, and their degree of orientation.[185]

These parameters were shown to be a powerful tool for the characterization of healthy bone and for the detection of deviations from normal. The shape of the mineral platelets was studied in human bone[186] and bone from different species.[28,187–189] The thickness of the mineral particles was shown to increase rapidly within the first 5 years, to subsequently reach a plateau level,[16] and to be in the range of 2.5–4 nm in the normal adult human trabecular bone.[186] Scanning SAXS was also used for the evaluation of the effect on the collagen-mineral composite in the most commonly used osteoporosis treatments.[88] In addition, mineral particle characteristics were also measured in teeth, in mineralized cartilage, and in the MTLT.[185]

The usage of a microfocus beamline at the synchrotron provides high photon flux and high brilliance, and enables higher spatial resolution compared to a laboratory device. Scanning-SAXS studies at the synchrotron have been done for characterizing archaeological bone samples,[190] for studying the interface of articular cartilage and subchondral bone,[191,192] for the structure of the mineral particles in the MTLT,[193] for investigation of the lamellar fibril arrangement in osteons,[194] and for examination of the bone mineral particle characteristics after strontium ranelate treatment.

In contrast to SAXS, scanning X-ray diffraction (XRD) measures the scattered X-ray intensities under wide angles (typically larger than 5°) with respect to the direction of the incident beam. This gives information about the crystal structure of the mineral particles, as well as the lattice parameter. The intensity and width of the Bragg reflections also give useful information on the crystallinity and on the crystal dimensions, respectively. Generally, a strong reflection (002 reflection) comes from the longest (the *c*-axis) of the hydroxyapatite crystals. As the hydroxyapatite c-axis is parallel to the collagen fibril axis (as also known from SAXS and TEM analysis), this reflection can also be used for imaging the collagen fibril orientation in mineralized tissues and has been used for the pole figure analysis of the crystal texture. For this purpose, a rotation of the sample is necessary to obtain the 3D-information about the orientation of the crystal axis. Such pole figure analyses for texture were done on femoral bovine bone[195] and on single trabeculae[196] (using X-rays from laboratory sources) and on human osteonal bone with a 1 μm beam at the ESRF.[194] The width of the 002 reflection can additionally be used for the analysis of the longer dimensions of the mineral particles.[197]

Texture analysis of normal bone,[198] disease-related deviations from normal apatite crystal characteristics,[199] and changes in the crystal lattice parameters in the presence of therapeutic agents like strontium ranelate[90,200] were reported. Strontium, for instance, was found to be incorporated into the hydroxyapatite lattice, thus increasing the crystal lattice constant correspondingly. Recent developments in high-resolution area detectors make the simultaneous detection of XRD (wide angle X-ray scattering, WAXS) and the SAXS intensities with one single detector possible (see **Figure 11**). Applications of this combination of methods in mineralized tissues have been reviewed recently.[201] Limitations of the XRD as well as of SAXS technique are generated by beam damage effects which have not yet been systematically studied.

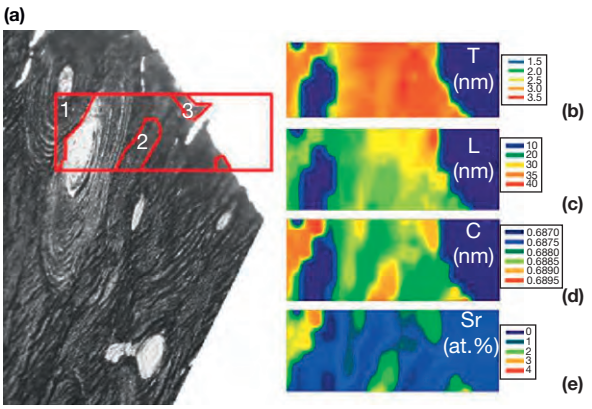

Figure 11 Mapping of bone mineral characteristics in a bone biopsy section of a patient treated with strontium ranelate: (a) light microscopic image of a 10 μm thin bone section with indicated regions of interest, (b) corresponding mapping of mineral thickness parameter (*T*) as obtained by SAXS, (c) mineral crystal length (*L*) using XRD signal, (d) crystal lattice distance (*c*) in *c*-axis direction using XRD signal, and (e) incorporation of atomic percentage of Sr into the cyrstal deduced by the increase of *c*. Regions 1, 2, and 3 indicate newly formed bone under strontium ranelate treatment. Reproduced from Li, C.; Paris, O.; Siegel, S.; Roschger, P.; Paschalis, EP.; Klaushofer, K.; Fratzl, P. *J. Bone Miner. Res.* **2010**, *25*(5), 968–975.

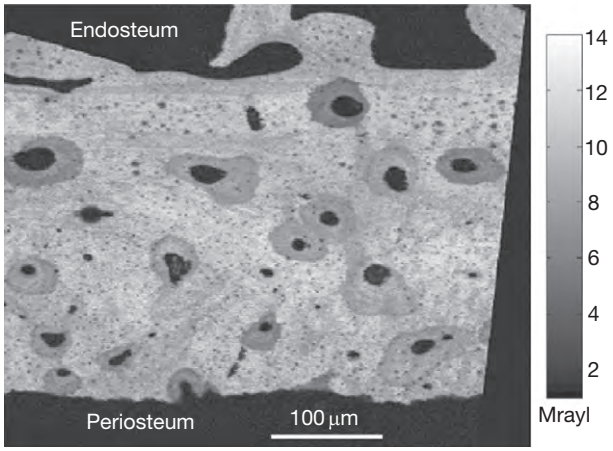

Figure 12 Calibrated acoustic impedance image of osteonal bone from the cross-section of the distal part of the human radius using a 200 MHz acoustic lens. Interstitial bone (high mineral content) has brighter gray levels than secondary osteons (low mineral content) indicating the relationship between mineral content and acoustic/mechanical properties. 3.325.6.4. Mapping of Elastic Properties

3.325.6.4.1. Scanning acoustic microscopy

In scanning acoustic microscopy (SAM), the inherent contrast mechanism arises from the elastic interaction of high-frequency acoustic waves with the target material. SAM is based on generation and focusing of high-frequency acoustic waves (longitudinal/compressional waves) to a target followed by the detection of the echo signals. The amplitude and the timing of the echo pulses allow mapping local mechanical (elastic) properties of the specimen with spatial resolution up to 1 μm (see **Figure 12**).[202–205]

Three different approaches can be used for assessing elastic properties of bone.[205] (1) Time of flight measurements of pulse echoes from the frontal and backside sample surface in thin tissue sections. If the section thickness is known, the compressional wave velocity can be determined. (2) Measurement of the confocal reflection amplitude in thick sections; the acoustic impedance can be derived. (3) Generation of surface acoustic waves in thick sections by a series of increasing negative defocus of the sound field and detection of the resulting amplitude of the pulse echoes; surface acoustic wave velocities can be derived.

In general, the acoustic lens of the SAM is a piezo-based transducer mounted on a sapphire rod, which has a concave depression on the front side for focusing the emitted sound waves. This lens is scanned mechanically over the specimen using distilled water as the coupling medium between lens and sample surface. The same lens is used to detect the incoming echoes with the transducer working in detection mode. The resolution and pixel of the image depends on the working frequency of the transducer.[206] Frequencies of 400 MHz and 1 GHz are commonly used, providing a resolution of 3–1 μm.[202,207] The frequency of 2 GHz (2000 MHz), being the highest practical frequency available, results in a resolution of about 0.4 μm. For sample preparation, it is crucial that the surface roughness is smaller than the wave length of the acoustic probe, because scratches and local inclination will change the propagation of the incident waves. Further, the reflected amplitude is a maximum, when the focus of the sound beam is coinciding with the sample surface. Thus, the distance between acoustic lens and sample surface should be constant. Native and plastic embedded tissue can be used. Micromilling and grinding following polishing are the methods to manufacture suitable sample surfaces.

Previous studies using frequencies between 50 MHz and 1 GHz revealed new insights into the microstructural and anisotropic elastic properties at various hierarchical levels of the bone structure.[205] A strong correlation was obtained between acoustic impedance and nanoidentation modulus.[207] The strength of SAM is to enable a microelastic imaging of mineralized tissue. However, for interpreting the acoustic contrast properly, SAM has to be combined with other methods providing complementary information like qBEI, SAXS, Raman, etc.

3.325.6.4.2. Nanoindentation

The atomic force microscope (AFM) can be operated at different modes (see **Section 3.325.6.6**). In one of these, the tip of the AFM can be used as a nanosized indenter for measuring the local elastic response of the sample in the submicron range. In a controlled deformation experiment, a diamond tip (in most cases a three-sided pyramid Berkovich tip) is pushed into the sample (block or thick section) and the load displacement curve is recorded, from which the indentation modulus as well as the hardness can be derived.[208]

Nanoindentation is done under wet, dry, and resin-embedded conditions of the mineralized tissue. It has to be emphasized, that under hydrated (physiological) conditions, the values of the indentation outcomes are remarkably lower than under dry conditions.[209] To control the reliability of the

indentation experiments, the formed indents can be imaged directly by AFM in the tapping mode or by SEM. Indents too close to cracks and to edges of bone surface, haversian canals, and osteocytes lacunae can be excluded in this way. To calibrate the instrument, a fused silica sample with a known elastic modulus is commonly used.[210] Typically, the complete loading and unloading cycle of the indenter tip consists of five steps: (1) loading to the maximum force, (2) followed by a holding period, (3) subsequent decrease of the load, and (4) a second holding period, before (5) final unloading. Elastic modulus and hardness are extracted from the first unloading curve, using the Oliver and Pharr method.[210] By measuring the load, the indentation depth, and the projected indentation area (contact area) and by using an empirical indenter shape factor, the reduced elastic modulus can be evaluated, which is the combination of the elastic modulus and Poisson ratio of both the indenter and the sample. The commercially available add-on nanoindentation devices have an instrumental force and displacement resolution of respectively 100 nN and 0.2 nm. Indents are done in a quasi load-controlled mode (i.e., without feed-back control for the loading force).

In nanoindentation studies of bone, a general correlation of the elastic modulus and hardness with the mineral content has been observed; however, the nanoindentation values show quite large variation at a specific mineral content[47] and reveal a high anisotropy of the bone material depending on the direction of the lamellar structure.[211] The latter gives evidence for a relatively strong influence of the organic component (orientation and composition) on the elastic properties of bone which might be a limitation of nanoindentation in characterizing the mineral of the material. Commonly, nanoindentation studies are performed in combination with other spatially resolved techniques which measure for instance the amount of mineral[48,57,66] (see **Figure 13**) and/or the properties of the organic matrix[212,213] at the indentation site.

3.325.6.5. Mapping of Elemental Composition

3.325.6.5.1. X-ray fluorescence

Excitation of characteristic X-ray fluorescence lines in a target material can be done by an electron beam in the SEM (electron induced roentgen fluorescence, ERF) or by an X-ray beam (X-ray induced roentgen fluorescence, XRF). The emitted X-ray spectra, which are specific for each element, are analyzed by an energy dispersive X-ray (EDX) or a wavelength dispersive X-ray (WDX) detection method. The former works with a semiconductor (e.g., germanium detector) sensitive to the energy of the incoming X-ray photons and the latter with crystal Bragg reflections for wave length analysis of the X-rays prior detection. In general, XRF mapping is done on thin or bulk sections in reflection mode.

For the elemental analysis of biological tissue such as bone in the SEM, the beam current of the electron beam has to be carefully chosen to provide sufficient counting statistics for the spectral analysis on one hand, and also to avoid beam damage to the sample on the other hand. Beam damage is the crucial limiting factor for quantifying and mapping elements of low concentration by SEM. As the WDX method needs relatively large XRF signals, it cannot be used in many cases. Studies on dentin[214] and bone[215] can be found in the literature. However, the need for high electron beam intensities makes this technique prone to beam damage. For studying bone with EDX, a 20 keV beam energy, a probe current of 0.220 nA and a data acquisition time of 500 s for small area scans (10 μm × 10 μm) have proven to be successful in quantifying the elemental composition of single bone packets.[89,183] It has to be emphasized that elemental mapping of large areas will require acquisition times of many hours under these conditions because of the low X-ray count rates achieved by this method. Special correction methods for elemental quantification have to be applied for block samples as used in the SEM. For instance, the ZAF method corrects for effects of atomic number (Z), absorption (A) and X-ray fluorescence (F) within the material on the emitted X-ray intensities. Prior to analysis, reference standards with known composition have to be measured which are near or similar to the mineralized tissue of interest.[89,216] The ERF detection method is limited to element concentration of about 0.1–0.5 wt%.[95]

In contrast, XRF in the laboratory or at the synchrotron enables a much more sensitive detection of elements in bone tissue. Trace elements in concentration down to the femtogram range can be detected.[217,218] This is due to the much higher

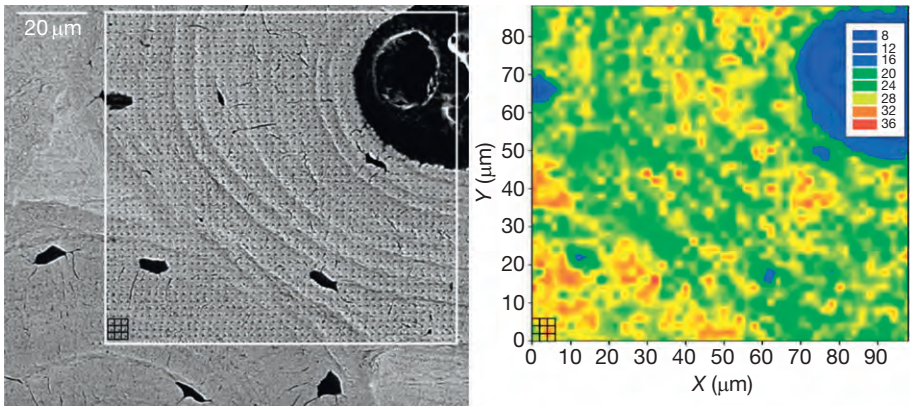

Figure 13 Indentation modulus mapping around a quadrant of an osteon. Left: scanning electron microsopic image with the region of interest after indentation; Right: 2D interpolated color plot of the reduced indentation modulus, showing a clear modulation along the lines of the lamellae inside an osteon. Reproduced from Gupta, H. S.; Stachewicz, U.; Wagermaier, W.; Roschger, P.; Wagner, H. D.; Fratzl, P. *J. Mater. Res.* **2006**, *21*, 1913–1921.

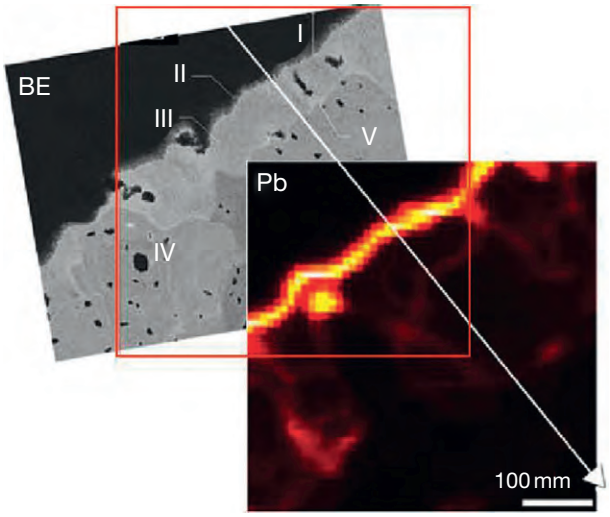

Figure 14 Elemental mapping of Pb concentration using SR μXRF: (BE) Backscattered electron image from a chondral/subchondral region of a patella; Noncalcifed cartilage (I), tidemark (II) calcifed cartilage (III), subchondral bone (IV), and cement-lines (V) can be clearly identifed. (Pb) Pb signal intensity maps of the corresponding region revealing a high accumulation of Pb in the tide mark (II). Modified after Zoeger, N.; Roschger, P.; Hoefstaetter, J. G.; *et al*. *OsteoArth. Carti*. **2006**, *14*, 906–913.

efficiency of the X-ray in exciting elemental X-ray fluorescence compared to electrons. The depth to which the element- and matrix-specific information can be obtained varies with the energy and self absorption of the induced X-rays of the different elements ranging from 40 μm for calcium to 600 μm for strontium.[217]

Synchrotron radiation-induced micro-XRF (SR-μXRF) has the advantage of a higher photon flux, natural collimation, polarization, and tuneable primary photon energy compared to convential XRF. Furthermore, high spatial resolution of typically $10 \times 10 \times 10\ \mu m^3$ can be achieved in bulk samples by a confocal experimental setup[217] (see **Figure 14**). This was used, for example, to study the accumulation of the element Pb in the tide mark of articular cartilage or the local distribution of the element zinc.[219] Strontium could be detected in young bone packets of strontium ranelate-treated patients and experimental animals.[220]

3.325.6.5.2. Secondary ion mass spectrometry

Another powerful technique for microanalytical and -structural analysis of mineralized tissues is secondary ion mass spectrometry (SIMS) which provides a high sensitivity of elemental/isotopic detection combined with a high spatial resolution. SIMS is on the basis of the (1) sputtering (gradual erosion) of the superficial atomic layers of a sample with primary ions, (2) the generated secondary ions from the sample are then separated according to their mass-to-charge ratios and are (3) subsequently collected as mass-spectra, as in-depth or along-surface concentration profiles, or as element distribution images of the studied sample surface.[221,222]

The SIMS technique requires ultra-high vacuum, because the collision of the high energy primary ions is needed to generate and detect the secondary ions from the sample surface. Therefore, the mineralized tissue has to be embedded in plastic. The sensitivity of elemental detection of the SIMS instruments is dependent on the ionization rate of the atoms in the sample and on the transmission of the system, which is the ratio between the number of ions formed and the number of ions detected. The maximum spatial resolution achieved in the instruments today is dependent on the type of the primary ions used and is about 50 nm for Cs and 150 nm for oxygen in the commercially available instruments.[222]

Advantages of SIMS are that the analysis is fast and also sensitive to most elements, including also the light ones. SIMS can be used with a very high mass resolution which however reduces the sensitivity. Nowadays, up to five ion images can be collected in parallel from the same sample volume.[222] As the lateral resolution of SIMS is far behind that of TEM, complementary information can be obtained as done on hydroxyapatite agglomerates during mineralization from the combination of both.[222]

3.325.6.6. Scanning Surface Topography with AFM

In AFM, a sharp tip attached to a small cantilever is used to scan the sample surface. Various surface tip-interactions, such as mechanical contact, atomic-scale friction, and magnetic and electric field sensing, can be used for imaging. The imaging of the surface topography coupled with its usage for nanoindentation has been the main application of AFM in mineralized tissues.[223]

For this purpose, the AFM instrument is operated in the constant-force mode, where the contact force between the tip and the sample is held constant or in the tapping mode, where the cantilever is oscillating closer to the sample than in contact mode, so that it intermittently taps the sample surface. The tapping mode has the advantage that the shear forces can be reduced compared to contact mode. The axial movement of the tip is a direct function of the surface height and is used to visualize for mapping the topography of the sample.

AFM imaging of bone has been done on native samples, as well as on dried and/or embedded specimens for viewing the mineral particles which have been observed to have a plate-like shape,[69,224] for the arrangement of the mineralized collagen fibrils in dentin,[225] and for viewing the Haversian systems in osteonal bone. By using AFM, evidence for the glue-like phase in the nanocomposite material of bone was reported.[226] There have also been attempts to increase the scanning speed of AFM.[227]

3.325.7. Conclusions

Biological mineralized tissues are heterogeneous materials and require imaging techniques which give information on structural and compositional properties on different hierarchical size levels. During recent years, new techniques have emerged (e.g., nanoindentation, Raman spectroscopy, SAM) and already established techniques have been modified to improve spatial resolution to the submicron range (such as SAXS, XRD, XRF, μCT at the synchrotron sources). When bone is investigated, most of the imaging techniques cannot be used *in vivo* but require biopsies (or necropsies). Future developments will increase the feasibility of *in vivo* imaging.

Micro-CT is already used for monitoring the time course of changes in trabecular architecture during treatment and there is promising progress in noninvasive Raman imaging. Phase-contrast imaging with X-rays is not limited to use at synchrotron sources and might become a common setup to improve clinical radiography. Future directions will also include tomographic viewing at high spatial resolution, for instance at the synchrotron. Finally, there is advancement in the combination of techniques providing complementary information from identical sample features. Thus, for example, mechanical/elastic properties combined with the measurements of the mineral components and of the properties of the collagenous and noncollagenous proteins will provide the basis for a better understanding of the structure–function relation of the mineralized tissue at the micron or submicron range. This will lead to a better prediction of fracture risk – a prerequisite for prevalence and treatment of bone fragility.

3.327.1. Introduction

As research in cell biology, neuroscience, and immunology has progressed from purely structural characterization of cells toward understanding dynamic processes, such as signaling, excitability, growth, and metabolic transport, studies have evolved to include new methodologies applicable to living cells. Organisms comprise a diversity of cells, and these, in turn, contain an enormous variety of biomolecules. The concentrations, chemical modifications, and interactions of these molecules are generally precisely controlled, both spatially and temporally. Deciphering this complex system of interacting molecules inside and among cells is one of the long-term goals of biology. To this end, it is highly valuable to rely on methods that probe the behavior of molecules of interest, and *in vivo* characterization of protein activity, key metabolite expression, or any other important biological functionality has become one of the central quests in molecular cell biology.

The development and application of biomaterials, that is, materials science-based tools, that allow visualization of events in living cells is a highly active and interdisciplinary area of research. Understanding of biological systems is increasingly dependent on the ability to visualize and quantify signaling molecules and events with high spatial and temporal resolution in a cellular context. This represents true biomaterials science, it is state-of-the-art materials science at the interface with biology.

In this chapter, we will review some unique optical techniques for intracellular sensing. We will review fluorescence-based intracellular probes with a brief description of fluorescence phenomena and measurement techniques, and we will describe the use of conventional fluorescent dye molecules for intracellular imaging. Considering the potentially enormous impact of nanomaterials in this field, we will discuss the nanoplatform-based fluorescent probes. In the last section, we will also review optical label-free nanoprobes which can be detected by conventional optical instruments.

3.327.2. Fluorescence-Based Intracellular Probes

3.327.2.1. Introduction

Fluorescence is a widely used optical method for biosensing due to its selectivity and sensitivity. A fluorescence-based device monitors the frequency change of electromagnetic radiation emission stimulated by previous absorption of radiation and subsequent generation of an excited state that only exists for a very short duration of time. Single molecules can be repeatedly excited and detected to produce a bright signal that is easily measured even at the single cell level.

Subsequent to discussing the physical principles, we will describe the most salient applications: (a) Fluorescent molecules for intracellular probing; (b) Fluorescence resonance energy transfer (FRET)-based sensing; and (c) Nanoplatforms-based fluorescent probes. Although there are still other applications, the descriptions of these three fluorescence-based techniques provide an extensive overview of the breadth of options available. All of these probes include the same basic components: biological recognition molecules, a source of excitation light, and an optical readout device capable of discriminating excitation light from emitted fluorescence.

3.327.2.2. Physical Principles

Fluorescence is emission of light from singlet-excited states, in which the electron in the excited orbital is paired (of opposite sign) to the second electron in the ground-state orbital. Return to the ground state is spin-allowed and occurs rapidly by emission of a photon. This emission rate of fluorescence is typically 10^{-8} s, so that a typical fluorescence lifetime is near 10 ns. Fluorescence spectral data are generally presented as emission spectra. Emission spectra vary widely and are dependent upon the chemical structure of the fluorophore and the solvent in which it is dissolved. In this chapter, we will focus on single photon excitation processes, although the analytical use of multiphoton excitation is also an important and vibrant field.[1]

Fluorescence is a quantum mechanical phenomenon and can be best explained by the Jablonsky diagram (Figure 1).

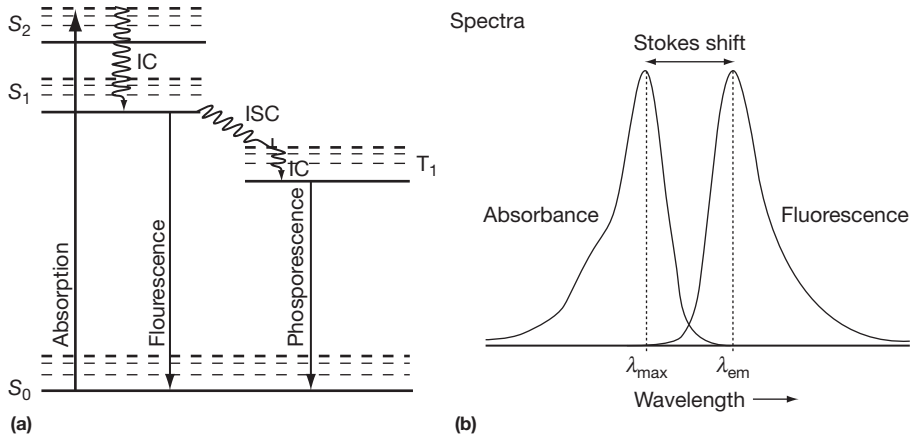

Figure 1 (a) Jablonski diagram of single-photon excitation. The electronic energy levels and their vibrational substructure are shown with horizontal lines, and the physical processes that cause transitions between these levels are depicted by vertical arrows. The singlet ground, first, and second electronic states are labeled S0, S1, and S2, respectively, and the first triplet state is labeled T1. For each of these electronic states, the molecule can exist in a multitude of vibronic states indicated by the dashed lines. (b) Schematic drawing of the absorption and fluorescence emission spectra of a fluorophore. Spectra are normalized to peak absorption and emission, respectively.

For absorption to occur, the energy of the exciting photon has to approximately match the energy difference between the excited state and the ground state (Figure 1). At room temperature, absorption of a photon takes place from the vibrational ground state S0 within $\sim 10^{-18}$ s. Photon absorption excites the molecule to the singlet state S2 from which it undergoes a radiation-less loss of energy by internal conversion to reach S1.

From S1, there are several possible fates. The decay of the excited state can occur with photon emission (i.e., fluorescence) or in a nonradiative (NR) fashion. This 'NR quenching' of the fluorophore excited state can occur through one of a variety of processes, including bond rotation or vibration, molecular collision,[2] and photoinduced electron transfer (PeT).[3] From S1, another possible fate is to emit a phosphorescent photon. In this case, the excited electron undergoes intersystem crossing (ISC) to attain the triplet state, before it exits to the ground state. The lifetime of the excited state in phosphorescence is significantly longer than that in fluorescence and it is in the order of $\sim 10^{-4}$ s to minutes or even hours. The drop to the ground state is accompanied by emission of a photon, also of lower energy than the exciting photon.[4] Another important pathway for decay of the singlet excited state involves FRET to an acceptor molecule. This process is distance-dependent and can be used as a 'spectroscopic ruler' to measure the proximity of labeled entities.[5]

Taking in to account the probabilities of each of these processes, a quantum yield quantifies the relative importance of a given decay pathway. For example, the fluorescence quantum yield gives the efficiency of the fluorescence process. It is defined as the ratio of the number of photons emitted to the number of photons absorbed. The parameters that characterize a molecule's capacity for light absorption and fluorescence emission are the molar extinction ε (measured at peak absorption per mole and cm of optical path-length) and absorption spectrum and the fluorescence quantum yield φ (dimensionless) and emission spectrum, respectively (Figure 1(c)). The brightness of a fluorophore is hence determined by the product $\varepsilon\varphi$.

3.327.2.3. Fluorescent Molecules for Intracellular Probing

When cells are going through physiological activation processes or pathological stresses, their response can be quite heterogeneous in time and space. Conventional physiological and biochemical methods often fail to analyze or describe these parameters in bulk (such as in tissue or cellular suspension), and can often fail to resolve discrete differences in the kinetics and magnitudes of the responses between cells, as well as complex intracellular and subcellular dynamical processes, critical to understanding how cells actually work. Small fluorescent molecules are indispensable tools for these purposes, can be used as biomolecular labels, enzyme substrates, environmental indicators, and cellular stains.[6–17] Given the fact that there are countless fluorescent molecules available either commercially[18] or by modification of existing ones, selection of a suitable fluorophore to visualize a biochemical or biological process can be daunting. Fortunately, the plethora of fluorescent probes has an intrinsic flexibility toward modulation. Attachment of various reactive groups, substrate moieties, chelating components, and other chemical entities to a small number of 'core' fluorophores gives rise to the archive of probes. Overall, these core fluorophores are well-established[14,19] and consist of molecules with excellent spectral characteristics, high chemical stabilities, and facile syntheses. Probe selection and design can, therefore, be simplified by understanding the properties of these core fluorescent compounds. In this regard, some excellent review articles have already appeared in the literature.[20–26]

3.327.2.3.1. Design criteria

In order to apply fluorescent probes to live cells, their design criteria is of utmost importance. In general, four sets of criteria must be kept in mind while designing efficient florescent probes: (i) the physiological and structural integrity of the cells should remain intact during the delivery of the probe; (ii) the probe must be selectively targeted toward ion, molecule, organelle, or other structure; (iii) the spectroscopic characteristics of the probe must be compatible with the instrumentation that is to be used for detection, that is, the fluorescence output of the probe must be sufficient to permit the detection of the target at natural abundance levels; and (iv) probes and target interaction must be detectable through spectroscopic responses such as spatial distribution of fluorescent image or change in fluorescent intensity or a spectral shift.

The specific chemical properties (e.g., reactivity, lipophilicity, pK_a, stability) and photophysical properties (e.g., λ_{max}, λ_{em}, ε, φ, τ) determine the application of a particular fluorophore. For the comparison of spectroscopic properties of different fluorescent molecules we can rely on two parameters, that is, the extinction coefficient (ε) and the quantum yield (φ) and product of them ($\varepsilon\varphi$). A plot of $\varepsilon\varphi$ versus λ_{max} for the major classes of biologically significant fluorescent dyes is shown in Figure 2. Some of those molecules are discussed below in details.

3.327.2.3.2. Fluorescent dyes

Quinine (**1**) was the first naturally occurring fluorescent compound discovered. Subsequently, many other natural compounds were found which exhibit measurable fluorescence.[27] The aromatic amino acids have fluorescence properties that were first described by Weber.[28] While phenylalanine (**2**) and tyrosine (**3**) exhibit weak fluorescence under UV excitation, tryptophan (**4**) is the strongest fluorescent natural amino acid, with a λ_{max} of 280 nm, λ_{em} of 348 nm, extinction coefficient of 6.3×10^3 $M^{-1}\,cm^{-1}$, and a quantum yield of 0.13.[27] Among other naturally occurring fluorophores, reduced nicotinamide cofactors (e.g., nicotinamide adenine dinucleotide; **5**) and Flavin (flavin mononucleotide; **6**) show measurable fluorescence under UV excitation.[27,29,30]

Polycyclic aromatic compounds give a wide variety of useful probes by substitution on its abundant open valencies. A classic example in this category is the naphthalene family. These include the amine-reactive 5-(dimethylamino)naphthalene-1-sulfonyl (dansyl) chloride[31] and other associated fluorophores.[32,33] Another important related naphthalene derivative is 5-((2-aminoethyl)amino)naphthalene-1-sulfonic acid (EDANS). Derivatives of this fluorophore, such as compound (**7**), exhibit a λ_{max} of 336 nm, λ_{em} of 520 nm, extinction coefficient of 6.1×10^3 $M^{-1}\,cm^{-1}$, and a quantum yield of 0.27 in water.[34]

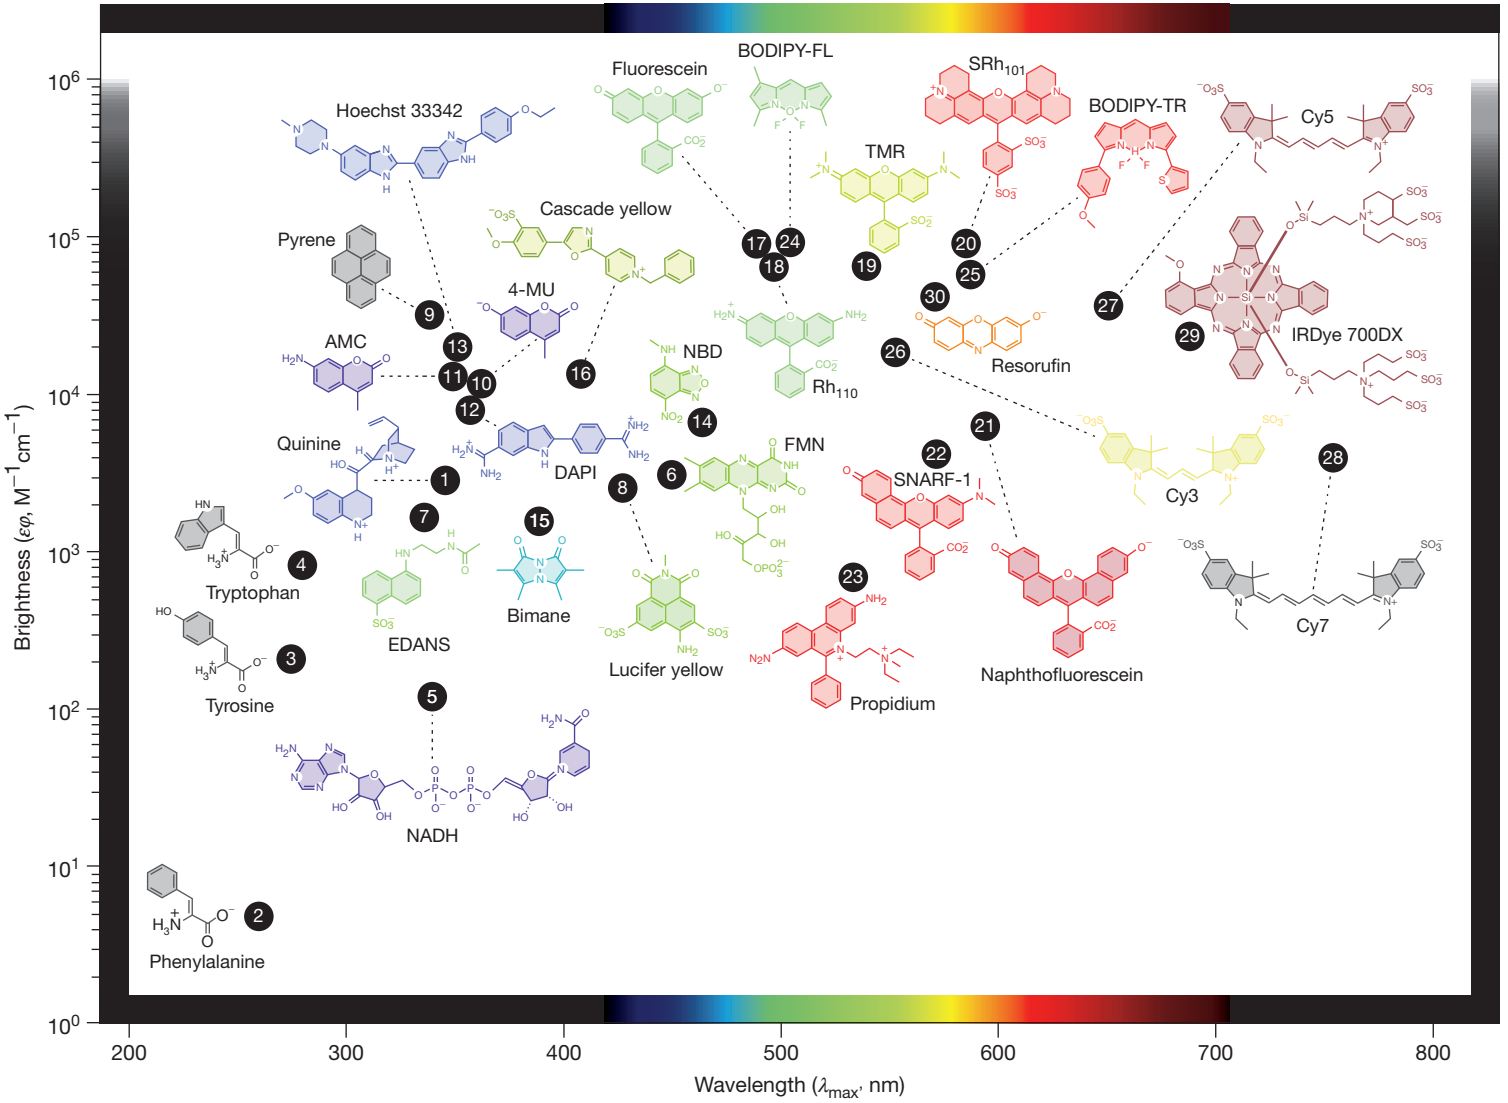

Figure 2 Plot of fluorophore brightness ($\varepsilon\varphi$) versus the wavelength of maximum absorption (λ_{max}) for the major classes of fluorophores. The color of the structure indicates its wavelength of maximum emission (λ_{em}). For clarity, only the fluorophoric moiety of some molecules is shown. Reproduced from Lavis, L. D.; Raines, R. T. *ACS Chem. Biol.* **2008**, *3*, 142–155, with permission from ACS Publications.

Another polycyclic aromatic compound is pyrene. Derivatives of pyrene (**9**) show $\lambda_{max}/\lambda_{em}$ of 340/376 nm, $\varepsilon = 4.3 \times 10^4\ M^{-1}\ cm^{-1}$, and $\varphi = 0.75$.[18,35] It has been shown that environmental sensitivity of this fluorophore can be used to detect the RNA folding.[36] Other polycyclic aromatic molecules such as anthracene, pyrelene, and their derivatives are also used to construct useful fluorescent tools both in water and organic solvent.[37–39]

The naturally occurring compound derivatives of coumarins represent a broad class of fluorophores. A common example is 7-hydroxy-4-methylcoumarin (i.e., 4-methylumbelliferone; 4-MU; **10**), which is derived by heteroatom substitution at position 7 of coumarin.

Other examples include the phenolate form of 4-MU, 7-amino-4-methylcoumarin (AMC; **11**), which exhibits fluorescence under basin condition (>pH 5).[18,40] On of the advantages of coumarins is its versatility due to the possibility of different substitution reactions, which offer to synthesize coumarin dyes with desirable chemical properties, such as higher solubility in aqueous solution and lower sensitivity to pH.[18,40–42] Coumarins are also useful for assembling enzyme substrates. Various derivatives of 7-hydroxycoumarin can be used to assay an assortment of hydrolases[43,44] and dealkylases.[45] Peptidyl derivatives of AMC are widely used to measure protease activity.[46]

Beyond the well-known tryptophan, the derivatives indole fluorophore Indo-1[47] is used as calcium indicator and another notable derivative 4′,6-diamidino-2- phenylindole (DAPI; **12**) is used for staining intracellular DNA.[48] Hoechst AG developed a dye Hoechst 33342 (**13**) very similar to DAPI and it is cell permeable and can be used in live cell for staining DNA.[49,50]

Fluorescein (**17**), the most widely utilized fluorophore in modern biochemical, biological, and medicinal research, is a heterocyclic compound and was first synthesized by Baeyer in 1871.[51] Fluorescein can exist in seven prototropic forms, the most fluorescent and biological relevant form of fluorescein is the dianion form with a λ_{max} of 490 nm, λ_{em} of 514 nm, extinction coefficient of $9.3 \times 10^4\ M^{-1}\ cm^{-1}$, and a quantum yield of 0.95.[15,18] The monoanion form is also used for biological purposes.[52]

The structure of fluorescein can be modified to tune the acid dissociation constant or pK_a values and to increase its photostability. One such example is 2′,7′-difluorofluorescein (i.e., Oregon green), it has fluorescein-like wavelengths, less basic (pK_a 4.6) than fluorescein, and has better photostability relative to fluorescein.[53]

Because of the pH-sensitive fluorescent properties, fluorescein was used as a pH sensor[54] and also used as an index to report on the status of fluorescein-labeled biomolecules.[52]

Another widely used fluorophore is Rhodamine, which is an isologue of fluorescein. Main advantages of this dye are its low pH sensitivity, better photostability, and tunable spectroscopic properties. Different N-alkyl substitution patterns on the rhodamine core can modify spectral characteristics. The most commonly used members in this family are rhodamine 110 (Rh110; **18**; λ_{max}= 496 nm, λ_{em}=517 nm, ε=$7.4 \times 10^4\ M^{-1}\ cm^{-1}$, and φ=0.92 in aqueous solution) and tetramethylrhodamine (TMR; **19**; $\lambda_{max}/\lambda_{em}$ of 540/565 nm, but a lower quantum yield $\varphi = 0.68$).[8,55,56] Rhodamine labels are very useful for FRET-based experiments along with fluorescein derivatives due to efficient energy transfer between these xanthene compounds.[18]

Some important features such as the insensitivity of the spectral properties to the environment, the small Stokes shift, and the overall lipophilicity make the boron difluoride dipyrromethene (BODIPY) dye and its derivatives very useful fluorescent labels and other probes.[18,57,58] The base-sensitive core structure of BODIPY is the main drawback of this dye for its application particularly in solid phase peptide synthesis.[59] The mostly used form BODIPY **24** shows fluorescein-like parameters with $\lambda_{max} = 505$ nm, $\lambda_{em} = 511$ nm, $\varepsilon = 9.1 \times 10^4\ M^{-1}\ cm^{-1}$, and $\varphi = 0.94$ and is commonly called BODIPY-FL.[8,18]

Here we have discussed some of the important small molecule fluorescent dyes and there are also some other important dyes such as cyanine, phthalocyanine, and oxazine dye families which also have important applications in biology. These well known small-molecule fluorophores have a wide range of spectral and chemical properties. Elaboration of these core structures has provided numerous probes for assaying biological systems. Nonetheless, extraordinary opportunities remain, because to deliver deeper insight into complex biochemical and biological phenomena will require ever more sophisticated and tailored probes.

3.327.2.4. FRET-Based Sensing

3.327.2.4.1. Introduction

The applications of Förster or fluorescence resonance energy transfer (FRET) have been extensively studied in the last 25 years,[60–69] but only with recent technical advances has it become feasible to apply FRET to biomedical research.[70–83] In this section, we describe the general principles of FRET microscopy and provide a brief overview of its potential application in the biomedical field. There are various excellent reviews about FRET that can be suggested for further readings; these reviews also provide many of the earlier references.[61,66,67,69,84–94]

FRET is unique in generating fluorescence signals sensitive to molecular conformation, association, and separation in the 1−10 nm range. Thus, FRET is capable of resolving molecular interactions and conformations with a spatial resolution far exceeding the inherent diffraction limit (~λ/2) of conventional optical microscopy, yet is also compatible with super-resolution techniques.

The FRET mechanism involves a donor fluorophore in an excited electronic state, which may transfer its excitation energy to a nearby acceptor chromophore in a nonradiative fashion through long-range dipole–dipole interactions. The theory supporting energy transfer is based on the concept of treating an excited fluorophore as an oscillating dipole that can undergo an energy exchange with a second dipole having a similar resonance frequency. In this regard, resonance energy transfer is analogous to the behavior of coupled oscillators, such as a pair of tuning forks vibrating at the same frequency. In contrast, radiative energy transfer requires emission and reabsorption of a photon and depends on the physical dimensions and optical properties of the specimen, as well as the geometry of the container and the wavefront pathways. Unlike radiative mechanisms, resonance energy transfer can yield a significant amount of structural information concerning the donor–acceptor pair.

3.327.2.4.2. Principle of FRET

In the process of FRET, initially a donor fluorophore absorbs the energy due to the excitation by incident light and transfer the excitation energy to a nearby chromophore, the acceptor.

$$D + h\upsilon \rightarrow D^*$$

$$D^* + A \rightarrow D + A^*[D \rightarrow \text{donor}, A \rightarrow \text{Acceptor}]$$

$$A^* \rightarrow A + h\upsilon'$$

Energy transfer results in decrease or quenching of the donor fluorescence and a reduction of excited state lifetime accompanied also by an increase in acceptor fluorescence intensity.

FRET is a quantum mechanical process in which direct radiationless transfer of energy from a donor (D) to an acceptor (A) molecule occurs.

For FRET to occur between a donor and acceptor, the following four conditions must be fulfilled: (i) there must be an overlap between fluorescence emission spectrum of the donor molecule and the absorption or excitation spectrum of the acceptor chromophore (Figure 3). The degree of overlap is expressed by overlap integral (J). (ii) In order to fulfill the above condition the two fluorophore molecules (donor and acceptor) must be in the close proximity to one another (typically 1–10 nm). (iii) The donor emission dipole moment and the acceptor absorption dipole moment must be approximately parallel to each other. (iv) The fluorescence lifetime of the donor molecule must be of sufficient duration to allow the FRET to occur.

The extent of resonance energy transfer is determined by the distance between the donor and acceptor and the extent of spectral overlap. For convenience the spectral overlap is described as in terms of the Förster distance, R_0, which is defined as the distance at which the resonance energy transfer (RET) is 50% efficient (Figure 4). The rate of energy transfer between the donor–acceptor pair, $k_T(r)$ is given by:

$$k_T(r) = \frac{1}{\tau_D}\left(\frac{R_0}{r}\right)^6$$

where r is the distance between the donor and the acceptor, and τ_D is the lifetime of the donor in the absence of energy transfer. Hence the rate of transfer is equal to the decay rate of the donor in the absence of the acceptor. At the Förster distance, the donor emission would be decreased to one-half of its intensity in the absence of acceptor. The efficiency of energy transfer for a single donor–acceptor pair at a fixed distance is

$$E = R_0^6/\left(R_0^6 + r^6\right)$$

The Förster radius (R_0) depends on the fluorescence quantum yield of the donor in the absence of acceptor (f_d), the refractive index of the solution (η), the dipole angular orientation of each molecule (K_2), and the spectral overlap integral of the donor–acceptor pair (J) and is given by

$$R_0 = 9.78 \times 10^3\left(\eta^{-4} f_d J\right)^{1/6} A^0$$

In summary, the FRET rate depends upon the extent of spectral overlap between the donor–acceptor pair, the quantum yield of the donor, the relative orientation of the donor–acceptor transition dipole moments, and the distance separating the donor–acceptor chromophore. Any event or process that affects the distance between the donor–acceptor pair will affect the FRET rate, consequently allowing the phenomenon to be quantified, provided that the artifacts can be controlled or eliminated. As a result, FRET is often referred to as a 'spectroscopic/molecular ruler,' for example, to measure the distance between two active sites on a protein that have been labeled with suitable donor–acceptor chromophores, and therefore to monitor the conformational changes through the amount of FRET between the fluorophores.

3.327.2.4.3. Detection

The detection and quantitation of FRET can be made in a number of different ways. Simply the phenomenon can be

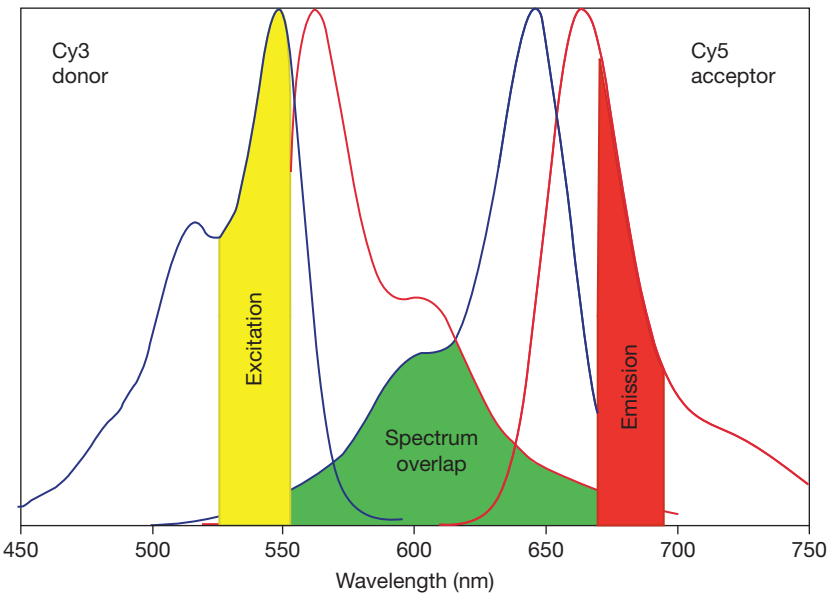

Figure 3 Schematic representation of the spectral overlap integral.

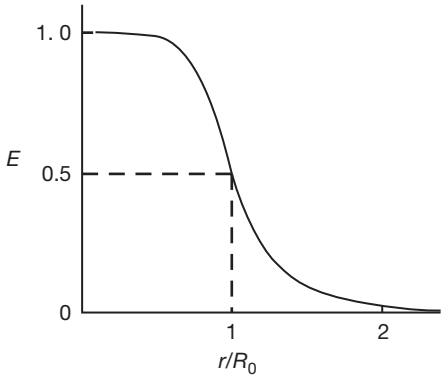

Figure 4 The dependence of the efficiency of energy transfer as a function of distance between fluorophores.

observed by exciting a specimen containing both the donor and acceptor molecules with light emitted at wavelengths centered near the emission maximum of the acceptor. Because FRET can result in both a decrease in fluorescence of the donor molecule as well as an increase in fluorescence of the acceptor, a ratio metric determination of the two signals can be made.

These ratiometric approaches give the true FRET efficiency, which quantifies the fraction of excited donor molecules whose energy is transferred to an acceptor molecule via resonance. The advantage of this method is that a measure of interaction can be made that is independent of the absolute concentration of the sensor. Because not all acceptor moieties are fluorescent, they can be used as a means to quench fluorescence. In these instances, those interactions that result in a fluorescent donor molecule coming in close proximity to such a molecule would result in a loss of signal. Inversely, reactions that remove the proximity of a fluorescent donor to a quencher molecule would result in an increase in fluorescence. One such example involves protease assays. These assays usually involve a fluorescent moiety on one terminus and a quenching molecule on the other terminus separated by a peptide containing the protease cleavage sequence.

3.327.2.4.4. Applications of FRET

The strong distance-dependence of the FRET efficiency has been widely utilized in studying the structure and dynamics of proteins and nucleic acids, in the detection and visualization of intermolecular association, and in the development of intermolecular binding assays.[95]

FRET is a particularly useful tool in molecular biology as the fraction, or efficiency, of energy that is transferred can be measured[94] and depends on the distance between the two fluorophores. The distance over which energy can be transferred is dependent on the spectral characteristics of the fluorophores, but is generally in the range 10–100 nm. Thus, if fluorophores can be attached to known sites within molecules, measurement of the efficiency of energy transfer provides an ideal probe of inter- or intramolecular distances over macromolecular length scales. Indeed, fluorophores used for this purpose are often called 'probes.' Techniques for measuring FRET are becoming more sophisticated and accurate, making them suitable for a range of applications.[94] FRET has been used for measuring the structure,[96–98] conformational changes,[99] and interactions between molecules,[100,101] and as a powerful indicator of biochemical events.[102] Further applications can be found in the reviews of Van der Meer *et al.*,[66] Lakowicz,[62] or Selvin.[103] Although the challenges of labeling molecules with fluorophores and making accurate measurements of the fluorescence emitted by them are being overcome, a number of difficulties still remain when examining real-life systems.

3.327.2.4.5. Problems associated with FRET

When designing FRET experiments, there are a number of issues that need to be considered. The most obvious and important issue is the matter of close proximity of donor and acceptor molecules. Depending on the assay design, close proximity will either be established or removed during the assay, resulting in a change in signal that can be measured. Appropriate donor–acceptor pairs need to be selected. There should be enough spectral overlap for pairs in order to ensure efficient energy transfer along with enough difference in spectra as to be distinguishable from one another. The most common problem is the detection of spectral overlap of donor spectral bleed-through signal in the acceptor channel. The spectral bleed-through results from a combination of both the acceptor fluorophore excited by the donor excitation light, plus the donor emission detected in the acceptor channel. As a result, one would get a high and variable background signal from which a weak FRET-based acceptor emission must be extracted. In addition, it is important to implement correction for the concentration or expression level of the fluorophore labeled to the proteins. These corrective measures would improve the accuracy in the calculation of the distance between the proteins involved in energy transfer. Moreover, there are other problems encountered in FRET microscopy imaging such as autofluorescence, detector, and optical noise, photobleaching, and spectral bleed-through signal. It is important to implement the correction in order to quantitate the FRET signal or in calculating the distance between the two proteins.[81,104]

3.327.2.5. Nanoplatforms-Based Fluorescent Probes

3.327.2.5.1. Introduction

There is a growing interest in the development of optochemical sensing devices that sense down to the submicron scale. This interest arises because in order to decrease typical response time down to the millisecond time scale, miniaturization of the sensors to nano-dimensions is the only option. With nanometer dimensions, the penetration volume is reduced to a few cubic micrometers and the sensors exhibit a spatial resolution at the nanometer scale. Nanoparticle sensors have been successfully applied to noninvasive real-time measurements of analytes, fields in cells and in rodents, with excellent spatial, temporal, physical, and chemical resolution.

This section covers major developments in the area of fluorescence-based nanosensors over the last decade; here we will only describe the fabrication and application of particle-based nanosensors for intracellular analysis. Nanoparticles-based sensors encompass a vast area of research, as a result of which we limit ourselves to two well-defined concepts that clearly illustrate the principles involved. Thus, we will describe probes encapsulated by biologically localized embedding (PEBBLE), and molecular beacons (MBs).

3.327.2.5.2. Probe embedded by biologically localized encapsulation

Fluorescent molecular probes have played a major role in intracellular sensing and imaging.[18,105–107] The fast response time, intense signal against relatively low background noise, and relatively simple instrumentation have made the molecular-probe-based fluorescence technique an ideal platform for real-time measurements in cells. Still, molecular probes suffer from several limitations that affect the reliability of the intracellular measurements.[108,109] The cell impermeability of probe molecules often requires proper derivatization of the molecules whereby their function might be affected. Other common problems are the cytotoxicity of available dyes or the chemical interference of the molecules with the cell's internal processes. Intracellular measurements are often skewed by sequestration to specific organelles inside the cell or by nonspecific binding to proteins and other cell components. Furthermore, the dye is usually not ratiometric (i.e., it has only a single spectral peak), which requires technologically more demanding techniques, such as picoseconds lifetime resolution and phase-sensitive detection, to be implemented. We have to keep in mind that merely loading a separate reference dye into the cell for ratiometric measurements will not solve the above problem because of the aforementioned sequestration and nonspecific binding.

The aforementioned drawbacks become more severe in the case of *in vivo* applications. Only a very few of the molecular probes can reach a specific location of interest within the body, which is also a challenge for other systems such as drug delivery. This is also true for crossing biological barriers, such as the blood–brain barrier. Moreover, for *in vivo* optical methods, photons can only penetrate tissue to a limited depth. For deep-tissue imaging (millimeters to centimeters), one must use near-infrared (NIR) light in the spectral range of 650–900 nm, which is separated from the major absorption peaks of blood and water.[110–112] The biggest advantage of NIR region is that it is free from autofluorescence of cellular components and therefore can be used for intracellular measurements. Note that most of the currently available molecular probes have visible absorption/emission wavelengths. Nanoparticle probes can be easily tailored for the NIR spectral range.

Advances in nanotechnology have made many types of nanoparticles available as platforms for constructing new types of bioanalytical sensors. The nanoparticles range from 1 to 1000 nm in size, thus causing minimal physical interference to cells. For example, a single spherical nanoparticle measuring 500 nm in diameter is at least four orders of magnitude smaller in volume than is a typical mammalian cell,[113] and a 20-nm particle is eight orders of magnitude smaller. Because of the nontoxic properties of most of the nanoparticle matrices the nanoparticles do not cause chemical interference to cells. Moreover, the nanoparticles can be delivered into cells or animals via standard delivery methods.

3.327.2.5.2.1. Design and synthesis

PEBBLE is a generic term to describe nanofabrication techniques that utilize biologically inert polymers to manufacture nanometer-sized spherical optical sensing devices capable of *in vitro* measurements. PEBBLEs are specifically designed to be minimally invasive, facilitating analyte monitoring in viable single cells or cell cultures without perturbing normal cellular functions. PEBBLEs use the same highly selective fluorescent probes normally used in biological monitoring.

For example, probes such as the Alexa Fluor® series of dyes or Oregon Green are often used as reference dyes, paired with an active fluorescent probe for analyte recognition such as fluo-4 for calcium or Ru[dpp($SO_3Na)_2$]$_3$[ruthenium(II) tris (4,7-diphenyl-1,10-phenanthroline disulfonic acid) disodium salt] for oxygen. The paired probes are encased in a permeable biologically inert matrix, which can be thought of as a sensing platform. The reference fluorophore is chosen specifically to complement the analyte-sensitive probe to ensure that ratiometric analysis can be achieved in either the excitation or emission modes.

The sensing mechanism involves two important steps: permeation of analytes into the nanoparticle matrix; the selective interaction of analytes with sensing components, which results in signal changes. The important properties of sensors, such as sensitivity, dynamic range, selectivity, reversibility, and stability, depend mostly on the incorporated sensing components. However, the nanoparticle matrix also plays an important role: The properties of the matrix, such as pore size, hydrophobicity, and charge, determine the permeability and solubility of the analytes as well as the loading efficiency of the sensing probes.[109] For example, polyacrylamide (PAA) nanoparticles have served as good matrices for ion sensors[114–118] due to their neutral and hydrophilic nature, whereas hydrophobic nanoparticle matrices are better suited for oxygen sensors.[119–121] A wide variety of nanoparticle matrices have been used as sensor platforms, including polymer nanoparticles made of organic, inorganic, or organic–inorganic hybrid materials; polymer-capped liposomes or micelles; semiconductor nanoparticles; and metallic (metal or metal-shell) nanoparticles. The pores of the nanoparticle matrix are sufficiently large to allow diffusion of the smaller analyte ions or molecules (so that the matrix can bind with the molecular probes located inside the nanoparticle), but the pores are still small enough to exclude the diffusion of larger proteins into the core matrix. This exclusion of macromolecules is quite significant because many 'naked-molecule' dyes change their fluorescence properties in the presence of proteins. However, the nanoparticle sensors containing these same dyes are not affected by the presence of proteins.[114,116,120,122]

The sensing components of a nanoparticle typically include indicator and reference dyes or a combination of reporter dyes and analyte-specific ligands/biological receptors. Loading of the sensing components into the nanoparticles is performed either during synthesis or after the formation of the nanoparticles by encapsulation, covalent linkage, bioaffinity interaction such as that between streptavidin and biotin, or physical adsorption through charge–charge or hydrophobic interaction. The covalent linkage is typically made via simple coupling reactions between the nanoparticle functionalized with amine, carboxyl, or thiol groups and the molecules containing similar functional groups. Biological molecules such as antibodies, DNAs, and peptides have been used as receptors because of their highly selective biological interactions. These biomolecular receptors have also been utilized as targeting moieties, enabling nanoparticles to perform real-time tracking of target biomolecules in cells[123] as well as tumor-targeted delivery of drugs or

image-contrast agents in rodents.[124,125] If targeting moieties are added to nanoparticle sensors, the sensors can even detect specific analytes in a spatially localized target area.[126]

3.327.2.5.2.2. Biological applications

3.327.2.5.2.2.1. Ion sensors Most of the nanoparticle sensors in this category are polymer-based PEBBLEs sensors. Nanoparticle sensors based on this design comprise the fluorescent indicator and reference dyes are loaded into the polymeric nanoparticle core or its surface-coated layer, and there is no interaction between the dyes (**Figure 5(a)**). For example, Almdal *et al.* and Brown *et al.* synthesize a pH nanoparticle sensor using a PAA nanoparticle with covalent linked dyes,[127] and a K^+ nanoparticle sensor was made by loading the sensing dye into the surface-coated layer polyelectrolytes instead of into the nanoparticle itself.[128] PEBBLE sensors have also made successful intracellular measurements for pH, Mg^{2+}, and Ca^{2+}.[114,115,129,130]

3.327.2.5.2.2.2. Dissolved oxygen sensors The first nanoparticle sensor for dissolved oxygen was the silica-based PEBBLE sensor, which was prepared by embedding $[Ru(dpp)3]^{2+}$ (a ruthenium oxygen indicator dye) and reference dyes into silica nanoparticles.[121] The sensor successfully imaged intracellular oxygen in live C6 glioma cells. Oxygen PEBBLE sensors with enhanced sensitivity and dynamic range were developed embedding the more sensitive platinum-based oxygen dyes, as well as reference dyes, into a hydrophobic matrix such as organically modified silica (ormosil)[119] or polydecylmethacrylate (PDMA).[120] Oxygen sensors have also been created by embedding ruthenium dyes into the polyelectrolyte layers on commercial fluorescent nanoparticle surfaces[131] or into polymerized phospholipid vesicles (liposomes).[132] However, the sensitivities of these sensors were only 60% for polyelectrolyte-coated nanoparticle sensors and 76% for polymerized liposome sensors. The different types of sensors used for dissolved oxygen species are summarized in **Table 1**.

3.327.2.5.2.2.3. Reactive oxygen species sensors Ratiometric PEBBLE sensors were developed for reactive oxygen species (ROS), singlet oxygen, H_2O_2, and hydroxyl radical using irreversible molecular probes. A singlet oxygen PEBBLE sensor was prepared by incorporating the singlet oxygen-sensitive 9,10-dimethyl anthracene or the singlet oxygen-insensitive octaethylporphine into ormosil nanoparticles.[133] The nanoparticle matrix enhances the selectivity of the indicator dye to singlet oxygen by blocking the entry of short-lived polar ROS such as OH and superoxide radicals. These nanoprobes have been used to monitor the singlet oxygen produced by dynamic nanoplatforms, which were developed for photodynamic therapy (PDT).[124] Another singlet oxygen PEBBLE sensor was constructed with ormosil nanoparticles incorporating 1,3-diphenylisobenzofuran (DPIBF). The intracellular concentration of singlet oxygen within C6 glioma cells during PDT was measured with the DPIBF sensors.[134] A PEBBLE sensor for H_2O_2 was prepared by embedding 2′,7′-dichlorofluorescin diacetate into ormosil nanoparticles. The PEBBLE sensors successfully detected H_2O_2 within a macrophage at a low-nanomolar concentration.[134,135]

A PEBBLE sensor for detecting the OH radical was created by covalently attaching the hydroxyl indicator dye, coumarin-3-carboxylic acid, onto the PAA nanoparticle surface while encapsulating the reference dye deep within the sensor.[136]

This design circumvents two potential problems posed by the hydroxyl radical, the most reactive ROS: (a) its inability to penetrate significantly into any matrix without being destroyed and (b) its ability to oxidize (and photobleach) most potential reference dyes. This nanoprobe demonstrated a proof of principle of a ratiometric hydroxyl radical probe and showed good sensitivity and reversibility.

3.327.2.5.2.2.4. Electric field sensors The E-PEBBLE, a nanosensor designed to measure electric fields, was fabricated by encasing the fast-response, voltage-sensitive fluorescent dye di-4-ANEPPS inside silane-capped (polymerized) micelles.[137] The hydrophobic core of the micelle provides a uniform environment for the molecules and thus allows for universal calibration. It also allows for fast orientation of these dye molecules, which shortens the response time. The E-PEBBLEs were introduced into immortalized astrocyte cells (DITNC) by endocytosis, and – for the first time – enabled complete three-dimensional electric-field profiling throughout the entire volume of living cells (not merely inside membranes)

3.327.2.5.2.2.5. Chemiluminescence sensors Chemiluminescence has been utilized to design sensors for H_2O_2 (**Figure 5(c)**).[138] Such sensors are made of peroxalate ester nanoparticles and encapsulated fluorescent dyes. The sensing mechanism occurs as follows: H_2O_2 reacts with the peroxalate ester groups, generating a high-energy dioxetanedione that then chemically excites encapsulated fluorescent dyes, leading to chemiluminescence. These sensors have nanomolar sensitivity and excellent specificity (over other ROS) for H_2O_2. The chemiluminescence wavelength can be tuned by changing the encapsulated fluorescent dyes. In one study,[138] peroxalate particles containing perylene, rubrene, and pentacene emitted light at wavelengths of 460, 560, and 630 nm, respectively. The nanoparticle sensors with encapsulated pentacene were applied for *in vivo* imaging of H_2O_2 and were externally injected as well as endogenously produced in the peritoneal cavity of mice during lipopolysaccharide-induced inflammatory response.[138]

3.327.2.5.2.2.6. Sensors with encapsulated proteins Two types of nanosensors operating on different sensing mechanisms have been developed using an encapsulated-protein design (**Figure 5(d)**). The first type incorporates an encapsulated protein that behaves as a fluorescent molecular probe. Nanoparticle sensors for copper and phosphate ions are two examples. The $Cu^{+/2+}$ sensor was constructed by incorporating DsRed, red fluorescent protein, and a reference dye into PAA nanoparticles.[117] The detection range for Cu^{+} and Cu^{2+} was 0.2–5 μM. The phosphate sensor was made of PAA nanoparticles and embedded fluorescent phosphate-sensing proteins and had a micromolar detection range.[139] In the second type of sensor, the encapsulated protein is an enzyme that catalyzes the reaction involved with analytes. The enzymatic reaction leads to a change in fluorescence, either by fluorescence product or by coembedded fluorescent indicator dye for depleted reactant. Examples include a glucose sensor and two H_2O_2 sensors.[140–142]

PEBBLE technology is defining a new type of ionic nanoprobe designed specifically for intracellular applications. Single-cell analysis can diagnose disease at an early stage, when tissue-level changes are not yet evident but chemical changes within cells are observable.[143] Obtaining chemical or physical information from a single cell or a specific location within a single cell is an important future application of nanoparticle sensors. The PEBBLE sensors are reversible and dye leaching is limited for the relevant experimental time scales, that is, the lifetime of a cell on a microscope stage. Several PEBBLEs have been optimized for ionic measurements, including PEBBLEs optimized for hydrogen, calcium, potassium, sodium, magnesium, zinc, copper, and chloride ions. By marrying emerging technologies with ion-sensing PEBBLEs (i.e., MOONs, optical tweezing, and targeting), one can enhance signal and/or direct placement of the PEBBLE within the cell for localized ion sensing.

3.327.2.5.3. Molecular beacons

With the continued advances in gene and protein function studies, the need for high-sensitivity, high-affinity molecular biological probes for qualitative and quantitative detection, is increasingly pressing. The methods available for genetic analysis have expanded enormously, mainly because the genetic data thus generated is being utilized not only by biologists but also by the scientific communities such as statisticians (to explore the population genomics) and computational chemists. Over the last decade, there is increasing evidence to suggest that RNA molecules have a wide range of functions in living cells, from physically conveying and interpreting genetic information through essential catalytic roles and providing structural support for molecular machines to gene silencing. These functions are realized through control of their expression level, turnover rates, and through their spatial distribution.

The ability to image specific RNAs in living cells in real-time promises to provide information on RNA synthesis, processing, transport, and localization; this information should offer new opportunities for advancement in molecular biology, disease pathogenesis, drug discovery, and medical diagnostics.

Accurately imaging endogenous or nonengineered RNA in live cells is not an easy task. In the early days, fluorescent methods of DNA analysis were highly dependent on fluorescent dyes that could complex the duplex DNA by means of noncovalent forces. Then, nucleoside building blocks containing different kinds of fluorophores (covalently linked) were used exclusively. Later on, especially in the post-genomic era, sequence-specific complementary binding of short synthetic oligonucleotides containing fluorescent tags have been used in DNA analysis.

MB technology is set up based on FRET and the complementary pairing principles. These fluorescent molecular probes, which are very highly specific and sensitive, have now become one important tool in medical and biological researches. In this section, we will discuss the MB's structure, principle and its application in imaging RNA inside living cells. For additional reading on yet other aspects of MBs, one can consult various other publications.[144–148]

3.327.2.5.3.1. Structure and principle of operation

MB is a fluorescent-labeled oligonucleotide chain, typically has 25–35 nucleotides, and is constructed by three parts: the loop portion, the stem portion, and the fluorescence groups.[149] The loop is generally constructed by 15–30 nucleotides and specifically binds with target molecules. The stem portion comprises 5–8 base pairs. During the binding process of the MBs with target molecules, this portion is reversibly dissociated. Thermodynamic analysis of hybridization of linear and stem-loop (MB) DNA probes demonstrated significantly higher specificity than the conventional linear probe. Finally, the fluorescence groups connected to 5′ end and quenching groups in 3′ end (Figure 6).

Fluorophore/quencher pairs, the signaling elements, produce the on/off signals depending on the conformational state of MBs. When a donor fluorophore is in its excited state, the energy is transferred via a nonradiative long-range dipole–dipole coupling mechanism to an acceptor quencher in close proximity (typically <10 nm), known as FRET, which we have already discussed in detail. On the contrary, the fluorescence signal is freely produced when the quencher is in far distance. Stems made of four to seven base pairs function as lockers to maintain the closed hairpin structures and bring a quencher nearby a fluorophore in a few nanometers' distance without hybridization to the complementary targets. Thus, the quencher turns off fluorescence with high quenching efficiency via FRET. Loops are recognizing elements that, upon hybridization to their complementary targets, induce a conformational change in MBs. This change increases the physical distance between the fluorophore and the quencher, resulting in fluorescence. The unique on/off signal mechanism has been very useful in the field of detecting DNA and RNA targets.

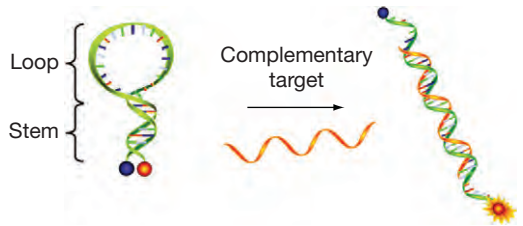

Figure 6 Diagram of an MB in a hybridized and unhybridized state. While the MB remains in free form without its target, it forms hairpin structure with quenched fluorescence. Once it binds to its target, the fluorophore restores the fluorescence signal due to the far distance from the quencher. Adapted from Kim, Y.; Sohn, D.; Tan, W. *Int. J. Clin. Exp. Pathol.* **2008**, *1*, 105–116, with permission from IJCEP.

The conventional MB, which was first designed and developed by Tyagi and coworkers, produces fluorescence without having to separate probe–target hybrids from excess probes in hybridization assays.[149,150] The unique hairpin structure and signaling mechanism endow the MBs with several advantages. First of all, the light-up signaling mechanism allows MBs to perform highly sensitive detection and monitoring of nucleic acids in real time. The unbound MBs stay with quenched fluorescence. Only hybridized MBs, whose amount is proportional to that of the target can produce a high fluorescence signal. Such a detection-without-separation property is particularly useful in situations where it is either impossible or undesirable to extract the probe–target hybrids from an excess of the unbound probes. Another advantage of MBs is their relatively high signal-to-background ratio, providing higher sensitivity of detection. Upon hybridization to its target, a well-designed MB can generate as high as 200-fold fluorescence enhancement under optimal conditions.[150] This provides the MBs with a significant advantage over other fluorescent probes in ultra-sensitive analysis. In addition to its sensitivity, MBs offer excellent selectivity. They are extraordinarily target-specific, and are able to differentiate as low as single-mismatched base pair sequences. The selectivity of MBs is a direct result of their hairpin conformation, as the stem hybrid acts as an activation energy barrier to the loop–target hybrid. The remarkable selectivity provided by the hairpin conformations has been demonstrated in a variety of biological environments where a number of different nucleic acid sequences and enormous amount of non-targets are present.

Due to these unique features in sensitivity and selectivity, the applications of MBs have been explored in many research fields since they were first created in 1996. The conventional MB introduced in the mid 1990s was modified by a number of research groups to improve its function, resulting in a range of modified MBs with varied designs, fluorophores, and quenchers. Some of the important changes are depicted in Figure 7. The functions considered for improvement include eliminating false signals, increasing specificity of the MB toward the target, and enhanced detection limit. It is reported that the background fluorescence intensity could be reduced significantly by using super quenchers (SQs) in place of normal quenchers (**2**; Figure 7).[151] An array of three quencher molecules is assembled at molecular level to produce SQs with a quenching efficiency of 99.7% and the signal to background ratio is also enhanced significantly. It has been shown that the original design constraint of a nucleobasepaired stem is not compulsory. Such 'stemless beacons' (**3**; Figure 7) possess sufficient signal-to-noise (S/N) ratio for some *in vivo* applications.[152]

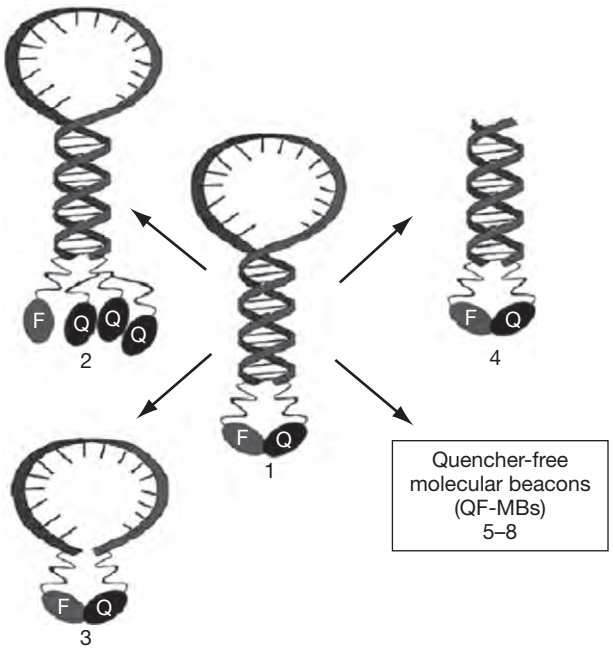

Figure 7 Modification of conventional MB. Adapted from Venkatesan N.; Seo, Y. J.; Kim, B. H. *Chem. Soc. Rev.* **2008**, *37*, 648–663, with permission from Royal Society of Chemistry.

Similar to conventional MB, the quenching of fluorophore in stemless beacon occurs through FRET. Hence, for better activity, the fluorophore and quencher should be chosen in such a way that there is maximum spectral overlap.[153]

3.327.2.5.3.2. Biomedical application

In recent years, real-time intracellular monitoring of gene expression has been developed rapidly. Many scientists used MB technology to detect gene, and achieved some initial results, such as detecting liquid phase hybridization,[154] effectively reducing cross-contamination of nucleic acids[155] and real-time nuclear acid detection.[156,157] Because of the high specificity and sensitivity,[158] it has been increasingly applied in large-scale automated detection[159] and even dynamic detection of nucleic acid *in vivo*.[160]

One of the initial applications of MB technology was to analyze concentration of target by real-time quantitative PCR.[161] On the basis of conventional PCR, corresponding MB probes were added. In every cycle of the PCR process, MBs combined with amplified products, fluorescence, and quenching groups separated and fired fluorescent, but it did not affect the accumulation of PCR products index. Only the DNA template which can combine with MBs can produce fluorescence signal during amplification. Therefore, the fluorescence intensity is proportional to the amount of specific amplification products, and it is the direct markers of template amplified by PCR. Compared with conventional methods, containing of the operation effectively eliminated the cross-contamination of DNA. It is real-time, quantitative, highly sensitive, and highly specific.

Currently, there are many methods used for the detection of mutation, SNP, allele, and multiple ingredients, but only those methods based on the real-time PCR are very effective. Compared with the linear oligonucleotide probes, stem-loop structure MBs have higher specificity. Even a single-base mismatch of target sequences or insertion mutations can be detected. Hence the real-time PCR system along with multicolor MB provides accurate determination of gene mutation, SNP, allele, multiple ingredients.[159,162–164]

Unlike RNA, DNA is the double helix structure and it is very difficult to detect with conventional methods. Peptide nucleic acid (PNA) combines double-stranded DNA complementarily and noncomplementary strand can be replaced and dissociated into single-chain, known as P-loop structure.[165] Dissociated double-stranded DNA can combine with the MBs to give fluorescence. Because of the advantages of MB for the analysis of nucleic acid, it can be used as the DNA probe as biochips and biosensors. This has been achieved with MBs marked with different fluorescent molecules in the form of bioepiderm and fixed to the surface of silicon wafers and used as the MB chips. Typical advantages of MB chips over the other types of DNA chips are low fluorescence background, obligated to remove redundant probes, and can be used multiple times.[166]

One of the marked achievements of MB technology is the dynamic analysis of the process of biological macromolecules metabolism *in vivo*. MBs are successfully employed for dynamic analysis of mRNA transcription process and other changes inside the cells. Perlette *et al*. designed and synthesized an MB specific for β-actin mRNA and microinjected it into the cytoplasm of single living kangaroo rat kidney cells (PtK2 cells). The results showed that MBs can be used for effective and real-time detection of RNA in living cells and understanding the process of RNA/DNA hybridization.[167] Matsuo studied intracellular bFGFmRNA metabolism with MBs.[168] They designed and synthesized MBs of complementary analyte target mRNA sequence and control MBs, respectively, and intake by the cells with liposomes. Using laser scanning confocal microscope or fluorescence microscopy, the results showed that the fluorescence of experimental group cells was much higher than that of control cells. Extended incubation time, fluorescence of the control group would be gradually enhanced. MBs can be hydrolyzed by nucleases and thus emit fluorescence. PNA MBs can effectively avoid being hydrolyzed by DNA enzyme, so that the fluorescence intensity can accurately reflect the metabolism of mRNA *in vivo*.

With the completion of the human genome project, the research interest has shifted focus on utilizing the genetic information for prediction and discovery. Since its inception, because of the high specificity and sensitivity characteristics, MB technology has been quickly adopted in biology, basic medicine, clinical medicine, and other related researches. Their unique property of detection without separation makes them even more attractive in the research areas where the purification step is almost impossible to perform or a major cause of low signal to background ratio. Their great sensitivity due to the excellent quenching efficiency is always advantageous. As a result, a number of nucleic acid-probing systems with close resemblance to the MBs are being reported from time to time. Used with nanotechnology, laser scanning confocal technology and other advanced technology, it will certainly promote the MB technology amendment. With the

development of MB technology and emergence of new MBs, MBs will definitely be applied in gene diagnosis, gene therapy, and new drug researches wider and wider.

3.327.3. Optical-Label-Free Intracellular Probes

3.327.3.1. Surface Plasmon Resonance-Based Probes

One of the main advantages in using optical microscopy for biological imaging is that optical microscopes allow us to observe a sample in living conditions. Another advantage of optical microscopy is that the spectrum of the signal light provides a multitude of information regarding the material in the sample. This allows us to investigate biological molecules in cells and tissues without chemical labeling. The concept of surface plasmons (SPs) traces back to the 1960s and observable phenomena have been known since the beginning of the twentieth century. An SP is a charge density oscillation (transverse magnetic electromagnetic wave) that can exist at the interface between a free electron metal and a dielectric layer.[169–172] Surface plasmon resonance (SPR) is a label-free detection method capable of high sensitivity, monitoring the biointeractions at molecular levels real-time.

Initial application of SPR-based biosensors mainly comprise extracellular measurement.[173–185] The enormous development of nanoparticle synthesis and its surface functionalization procedure along with the development of Raman scattering instrumentation give SPR-based probes a huge boost for using it intracellularly. In this section, we will briefly discuss the principle and application of surface-enhanced Raman scattering tools as intracellular probe. Comprehensive review papers have already appeared in the literatures containing detailed overviews on this topic.[186–191]

3.327.3.1.1. Working principle

The most common technique for studying the intracellular behavior of nanocarriers is to encapsulate a fluorophore or a fluorophore-labeled drug derivative and subsequently image the system using fluorescence microscopy. The information provided from this analysis, however, is limited due to the potential of the fluorophore to leak out of the system and the extent of its interference with the biochemical behavior of the labeled molecule. Furthermore, this method does not provide information regarding nanocarrier/payload association and dissociation patterns, which is the ultimate purpose for the carrier system and a crucial issue in nanotechnology. Low contrast, autofluorescence, and photobleaching also confound fluorescent microscopy, compromising the continuous monitoring of the same sample. Raman spectroscopy in combination with optical microscopy provides a novel noninvasive and a label-free method to assess image-cellular processes based on their biochemical changes.[192–194]

In principle, spectroscopic techniques that deliver sensitive molecular structural information, such as Raman spectroscopy, have the potential to address this issue. Since more than a decade ago it has repeatedly been proven that the fingerprint-like information in Raman microspectra can add to our understanding of the biochemical background of various regular, induced, or pathological changes in eukaryotic cells.[195]

Raman spectroscopy is a highly specific technique used to detect and identify molecules on the basis of their unique vibrational energy levels and corresponding Raman fingerprints. In Raman scattering, photons are scattered inelastically, either losing energy (Stokes shift) or gaining energy (anti-Stokes shift) equal to the molecular vibration of the probed material. Figure 8 illustrates the Raman scattering process in a molecular-level scheme; for a general overview on Raman scattering see Kneipp *et al.*[196] Depending on whether photons interact with a molecule in its vibrational ground or first excited vibrational state, the scattering signals appear at the low-energy side (Stokes: $h\nu_S = h\nu_L - h\nu_M$) or high-energy side (anti-Stokes: $h\nu_{aS} = h\nu_L + h\nu_M$) of the excitation laser. The scattering signal power PRS of a Raman line depends on excitation intensity I_L and the Raman cross-section σ_R, where σ_R is determined by the polarizability derivative of the molecular vibration. In general, anti-Stokes Raman scattering results in much lower scattering signals as compared with Stokes scattering, because only a small fraction of molecules, as determined by the Boltzmann population, is in an excited vibrational state and can contribute to anti-Stokes Raman scattering.

When molecules adsorb onto a plasmonic nanoparticle or move to within a few nanometres of its surface, the local electromagnetic fields around the nanoparticle can enhance the Raman scattering by a factor of 10^6–10^8 for an ensemble of molecules,[197,198] and by as much as 10^{14}–10^{15} for single molecules.[199–201] This phenomenon, known as surface-enhanced Raman scattering (SERS), results in a highly specific and sensitive method for molecular identification.[202] Figure 9 shows a schematic of SERS, where molecules are in the close vicinity of a metal nanostructure. In the schematic, this nanostructure is a small aggregate built from spherical gold nanoparticles.

Two effects might be operative in SERS: (1) An electromagnetic enhancement factor arises because LSPR modes in the metal nanoparticles focus the incident light energy at the nanoparticle surface and also increase the density of states at Stokes-shifted wavelengths. The electromagnetic enhancement factor is typically 10^5–10^8 for nanoprisms, but simulations indicate

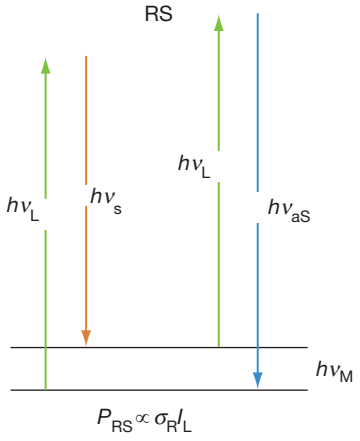

Figure 8 Raman (RS) in a molecular level scheme. Adapted from Kneipp, J.; Kneipp, H.; Kneipp, K. *Chem. Soc. Rev.* **2008**, *37*, 1052–1060, with permission from Royal Society of Chemistry.

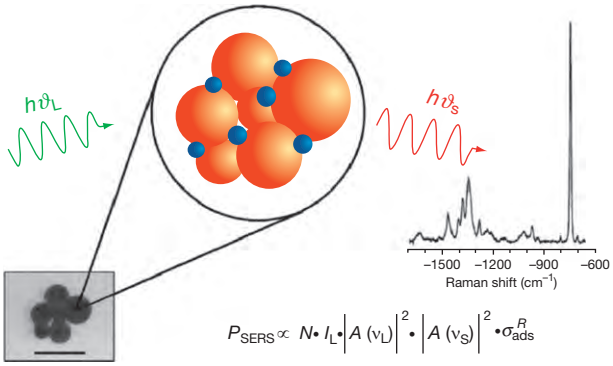

Figure 9 Schematic of surface-enhanced Raman scattering (SERS). Molecules (blue dots) are attached to silver or gold nanoparticles (orange balls). For comparison, the transmission electron micrograph shows SERS-active gold nanoaggregate. Adapted from Kneipp, J.; Kneipp, H.; Kneipp, K. *Chem. Soc. Rev.* **2008**, *37*, 1052–1060, with permission from Royal Society of Chemistry.

that it can be as large as 10^{13} for structures such as arrays of nanoprism dimmers.[203] (2) Chemical enhancement factors arise from changes in the molecular electronic state or resonant enhancements from either existing molecular excitations or newly formed charge transfer states. When molecules are excited by light resonant with an electronic absorbance, an additional enhancement factor of $\sim 10^1$–10^3 is observed in comparison with nonresonant excitation.

3.327.3.1.2. SERS nanosensor

The nanostructures which can provide a high level of electromagnetic field enhancement are the essential component for designing the hybrid SERS nanosensors for biological applications.[204–206] This is the mandatory property of the reporter for exhibiting an intense and stable spectroscopic signature but also for an efficient and sensitive Raman probe of the cellular environment. Moreover, the nanostructures should be small enough to cross cell membranes, and they should allow probing of cells without inducing any perturbation or toxicity.[204] Thus far, silver and gold have been the metals that provide the highest enhancement observed in SERS experiments. Even though silver shows a much better enhancement than gold using visible excitation, aggregates of both metals show comparably good SERS enhancement with NIR excitation, yielding enhancement factors up to 14 orders of magnitude.[207] Reporter molecules permit detection and imaging of the sensor based on their specific SERS spectrum. Potential reporters should be biocompatible molecules showing a strong and specific SERS spectrum.

3.327.3.1.2.1. Intracellular chemical probing

The first key to any successful intracellular SERS experiment is to introduce metal nanoparticles into the cellular matrix. The most common approach is through cellular uptake of fully formed nanoparticles in an external solution; however, as we shall see, there are several examples in which the cell can directly synthesize the nanoparticles *in vivo*. When considering cellular uptake, there are several issues of note: (1) size of the nanoparticle relative to the entry pathways of the cell; (2) mechanism of uptake by the cell; and (3) toxicity. Toxicity of nanoparticles, in particular, is a field of active research and ranges from studies on single cell viability for laboratory-based experiments to the environmental impact of nanoparticles on living tissue.[208–211] Gold nanoparticles have been tools of the trade in cell biology because of their favorable physical and chemical properties and biocompatibility. Once silver or gold nanoparticles are internalized within the cell, the next step is to measure the SERS spectrum that originates from molecules that are in close proximity to the enhanced electromagnetic field at the nanoparticle surface. Many different biological molecules offer strong Raman scattering signatures.[190]

Until now the study of the chemical composition of endosomes has involved fractionation and purification (i.e., *in vitro* approaches). Gold nanoparticles can serve as biocompatible mobile nanosensors and deliver chemical information by providing the enhanced Raman spectra of intrinsic cellular molecules in their vicinity eliminating the need of fractionation and purification steps.[204,205,212–216]

In one of the earliest examples of SERS spectroscopy within cells, the interaction of doxorubicin (DOX) with cancer cells was monitored as a function of cell location SERS for probing internal cellular structure and dynamics.[217] In this case, the SERS spectrum of free DOX and DNA-bound DOX was characterized *in vitro*, and specific bands were identified as being associated with different conformations of the molecule. Cells were then incubated with DOX followed by silver nanoparticles, or in solutions where DOX was preadsorbed onto the silver nanoparticles. In the former case, the drug was largely trafficked into the nucleus of the cell, where it was able to interact with DNA prior to the introduction of the nanoparticles, while in the latter case, the DOX–nanoparticle hybrid remained in the cytoplasm, unable to penetrate the nuclear membrane. Interestingly, the SERS spectra revealed distinct differences between the two scenarios: the DOX in the nuclei exhibited SERS spectra consistent with the drug bound to DNA, while the DOX–nanoparticle hybrid did not. Unlike studies of native biomolecules in cells, this work benefited from the introduction of a SERS-active analyte with a distinct spectrum that exhibited differences between two conformations, that is, DOX bound to DNA versus unbound.[217]

Another type of experiment involves the introduction of a chemical that can stimulate a specific response in the cell, and then using SERS to monitor changes in the environment of the nanoparticle. In one example, ionomycin (a drug that triggers Ca^{2+} release by the cell) was introduced to Chinese hamster ovary cells, and the changes in the SERS spectra from the CHO cell were monitored.[218] A new peak emerged at 1643 cm^{-1}, which is assigned to the amide I mode; this peak showed a fast rise in intensity, and then a steady fall over time. This result is qualitatively consistent with other studies in which Ca^{2+} is monitored via a fluorescent probe, although the two time scales appear to show some differences, with the SERS data showing a faster response to the drug than the fluorescence data.[218,219] In both experiments, Ca^{2+} flux is measured indirectly via a secondary reporter; however, in the SERS experiments, the reporter is a molecule that is native to the cell, providing additional insight into how the cell responds to the introduction of the ionomycin.

During recent years, it has been demonstrated that SERS labels offer exciting new capabilities, particularly also for applications in living cells.[214,215,220–224] Compared to fluorescence tags, SERS labels can provide several advantages. The optical

signature of a SERS label comprises several sharp Raman lines distributed over a spectral range comparable to the spectral width of a fluorescence dye. Because of this high specificity of a Raman spectrum, spectral overlap between different labels is very unlikely, even when their molecular structures are very similar. Spectral correlation techniques using different SERS lines can improve the contrast of an SERS label relative to the cellular background.[220] An important strategy for generating a specific response from nanoparticles internalized by the cell is to functionalize the nanoparticle surface directly with a molecule that has a known SERS spectrum. This can be used for simple location analysis of the nanoparticle aggregates, or can even be used for sensing within cells. In the former case, researchers have tagged nanoparticles with a variety of SERS active probes, each of which has its own unique spectroscopic signature.[220,223] This approach allows researchers to find exactly where the nanoparticles have localized in the cell without competition from non-surface-enhanced Raman bands.[220,223]

The final application of the use of functionalized nanoparticles as SERS probes is for intracellular pH measurements.[215,225] Determining intracellular pH with subcellular resolution is of particular importance for a better understanding of a broad range of physiological and metabolic processes. These include trafficking, recycling, and recruitment of intra- and extracellular molecules.[226–228] This goal can be addressed by using a 'pH sensitive' reporter. In this case, 4-mercaptobenzoic acid is attached to the nanoparticle surface. The protonated and deprotonated forms of this molecule have different relative intensities between the 1430 and 1590 cm^{-1} bands in their SERS spectra; as such, measuring the ratio between the two intensities is an excellent measure of pH.[215,225] 4-Mercaptobenzoic acid has a pK_a of around 5.8, which means that it should be most sensitive to pH changes in the range of 5–7, which is within the range of biological relevance. In the first study of this system, the pH surrounding the nanoparticles in the lysosome was measured to be less than 6, which is expected based on other reports.[225] The second study of this system mapped the pH of the entire cell and found that the pH varied by more than one pH unit depending on the location within the cell.[215] These studies provide unique insight into a particular property of the intracellular environment based on the SERS response of a functionalized probe.

To sum up, SERS represents an attractive technique, which advances hand in hand with nanoscience and nanotechnology, to offer solutions for a diverse array of biomedical applications. Nanomaterials can be engineered for individual and multimodal applications in SERS, including biomolecular recognition and characterization, ultrasensitive diagnosis and biodetection, and biomedical imaging. Although SERS has already been used for a wide range of applications both *in vitro* and *in vivo*, full realization of its potential requires addressing a number of open issues, including nanoparticle stability in biological fluids, single-event recognition detection, label-free analysis and classification, quantification of the analytes of interest, and acute and long-term health effects of nanomaterials.

3.327.3.2. Quantum Dots as Intracellular Probes

3.327.3.2.1. Introduction

Quantum dots (QDs) are semiconductor nanocrystals that have unique fluorescent properties (for review, see Alivisatos *et al.*,[229] Pinaud *et al.*,[230] and Michalet *et al.*[231]). Their photophysical properties are highly dependent on the chemical composition, shape, and size, all of which can be controlled during synthesis. The intrinsic photophysical properties of organic and genetically encoded fluorophores, which generally have broad absorption/emission profiles (**Figure 10(a)**) and low photobleaching thresholds, have limited their effectiveness in long-term imaging and 'multiplexing' (simultaneous detection of multiple signals) without complex instrumentation and processing. The seminal publications describing the first biological uses of QD-fluorophores foresaw that their unique properties could overcome these issues.[232,233] Compared with molecular dyes, two properties in particular stand out: the unparalleled ability to size-tune fluorescent emission as a function of core size (for binary semiconductor materials), and the broad excitation spectra, which allow excitation of mixed QD populations at a single wavelength far removed (>100 nm) from their respective emissions (**Figure 10(b)** and **10(c)**). In the past 10 years, the progress in synthesis and optimization of QDs for biological environments has opened the doors to an expanding variety of biological applications such as serving as specific markers for cellular structures and molecules, tracing cell lineage, monitoring physiological events in live cells, measuring cell motility, and tracking cells *in vivo*. In this section, we will briefly discuss the synthesis, surface bioconjugation, and intracellular applications. For a comprehensive review on this section, you should see the review papers that have appeared in the literature.[229,230,234–237]

3.327.3.2.2. Synthesis of QDs

The synthesis of monodisperse semiconductor nanocrystals, such as CdSe, CdS, or CdTe, can be achieved by injecting liquid precursors into hot (300 °C) coordinating organic solvent.[238,239] Adjusting the amount of precursors and crystal growth time generates QDs of specific sizes.[239] The quantum yield of the nanocrystal core synthesized as above is relatively low (<10%).[238,240] In order to overcome that problem CdSe core was over coated with a layer of wider band gap semiconductor such as ZnS and CdS.[241–243] The ZnS layer passivates the core surface, protects it from oxidation, prevents leeching of the Cd/Se into the surrounding solution and also produces a substantial improvement in the PL yield.[240,244] Even though thin ZnS (1–2 monolayers) shells often produce the highest PL yields, thicker ZnS shells (4–6 monolayers) provide more core protection against oxidation and the harsher conditions presented by biological media (e.g., acidic buffers and cellular organelles). Colloidal QDs made of ZnS, CdS, ZnSe, CdTe, and PbSe, emitting from the UV to the infrared have been prepared[238,240,243,245–257]; however, these are not as common in biological assays.

The real breakthrough in synthesizing high-quality colloidal QDs came when the Bawendi group reported[238] that the use of high-temperature growth solvents/ligands (mixture of trioctyl phosphine/trioctyl phosphine oxide, TOP/TOPO), combined with pyrolysis of organometallic precursors, yielded CdSe QDs with highly crystalline cores and size distributions of 8–11%. The same reaction combined with appropriate organometallic precursors was further used to overcoat the native CdSe core with a layer of wider-band gap semiconducting

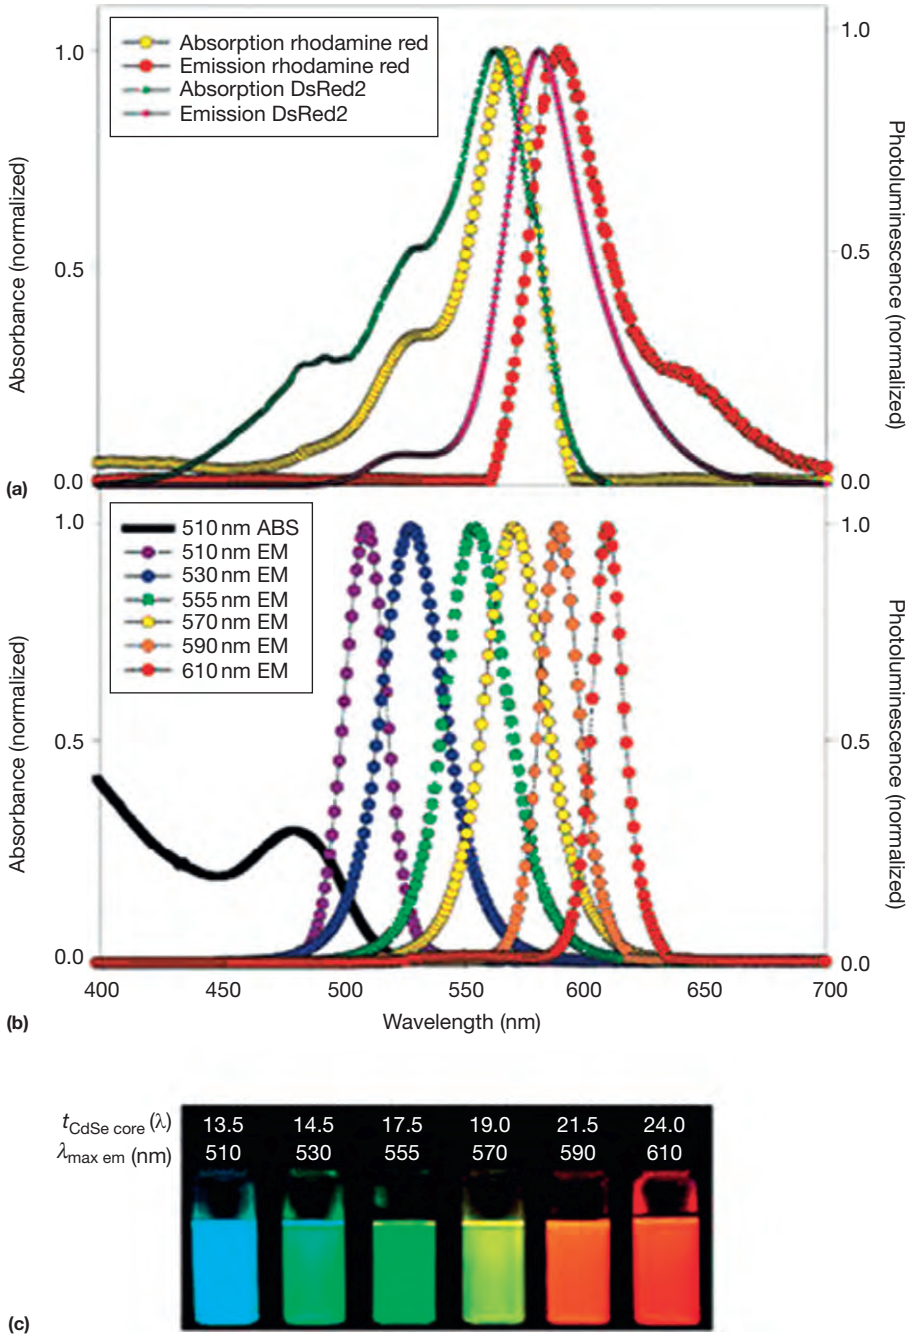

Figure 10 Comparison of rhodamine red/DsRed2 spectral properties to those of QDs highlighting how multiple narrow, symmetric QD emissions can be used in the same spectral window as that of an organic or genetically encoded dye. (a) Absorption (Abs) and emission (E_m) of rhodamine red, a common organic dye and genetically encoded DsRed2 protein. (b) Absorption and emission of six different QD dispersions. The black line shows the absorption of the 510-nm-emitting QDs. Note that at the wavelength of lowest absorption for the 510-nm QD, ~450 nm, the molar extinction coefficient is greater than that of rhodamine red at its absorption maxima (~150 000 vs. 129 000 M^{-1} cm^{-1}). (c) Photo demonstrating the size-tunable fluorescence properties and spectral range of the six QD dispersions plotted in b versus CdSe core size. All samples were excited at 365 nm with a UV source. For the 610-nm-emitting QDs, this translates into a Stokes shift of ~250 nm. Reproduced from Medintz, I. L.; Konnert, J. H.; Clapp, A. R.; *et al. Proc. Natl. Acad. Sci. USA* **2004**, *101*, 9612–9617. © National Academy of Sciences, USA.

material (e.g., ZnS and CdS).[240,243,244] Fine-tuning this synthetic scheme highlighted the importance of the high-temperature solvent/ligand mixtures, along with using less pyrophoric salt precursors (CdO and Cd-acetate), for preparing reproducible high-quality nanocrystals.[245,258]

3.327.3.2.3. Functionalization of QDs: Solubilization and bioconjugation

3.327.3.2.3.1. Solubilization

The core and core-shell QDs synthesized as described are only soluble in nonpolar solvents because of their hydrophobic

surface layer. For QDs to be useful probes for examination of biological specimens, the surface must be hydrophilic. They need to be biofunctionalized in order to meet four key requirements[62,259]:

(a) increased stability in water for long period,
(b) presence of sterically accessible functional groups for bioconjugation,
(c) biocompatibility and non immunogenicity in living systems,
(d) lack of interference with the nanoparticles native properties.

This problem has been solved by replacing the surfactant layer or by coating with an additional layer introducing either electric charge or hydrophilic polymers for mediating solubility in water. Coulomb repulsion between nanocrystals with surface charge of the same polarity prevents aggregation in water. The easiest approach is to exchange the hydrophobic surfactant molecules with bifunctional molecules, which are hydrophilic on one side and hydrophobic on the other side, which bind to the ZnS shell. Most often, thiols (–SH) are used as anchoring groups on the ZnS surface, and carboxyl (–COOH) groups are used as the hydrophilic ends. Many biological applications of QDs have been achieved by using mercaptohydrocarbonic acids (SH–. . .–COOH) to make QDs water soluble.[260–266] The long-term stability of the QDs depends on the bond between thiol and ZnS, which is not strong although it can be enhanced by using two thiol groups instead of one.[254,267] Therefore, the water solubility of the core–shell QDs capped in mercaptocarbonic acids is limited (**Figure 11**).

An alternative approach is based on the growth of a hydrophilic silica shell around the nanocrystals, through a process known as surface silanization.[268–274] A first step involves a ligand exchange to substitute the original hydrophobic surfactant covering the nanocrystal surface. This process involves exchanging the surface ligand with thiol-derived silane such as mercapto-trimethoxysilane (MPS). The trimethoxysilane groups can be cross-linked by the formation of siloxane bonds. In this way, the surfactant shell around the nanocrystal becomes cross-linked and has improved stability toward disintegration. To render the silica shell hydrophilic in the next step, molecules bearing methoxysilane groups at one and hydrophilic groups at the other end are incorporated in the shell again by the formation of siloxane bonds, resulting finally in a multilayer shell.

Recently other solubilization methods have been reported, one of which involves coating the surface with amphiphilic polymers.[275,276] Instead of exchanging the hydrophobic surfactant, the particles in this case are coated with a cross-linked amphiphilic polymer. In this approach the hydrophobic tails of the polymer intercalate the hydrophobic surfactant molecules on the nanocrystal surface and thus form an additional coating. The water solubility of polymer-coated nanocrystals is ensured by hydrophilic groups of the polymer which self-assemble on the outside of the polymer shell. In order to further stabilize the polymer shell around the nanocrystal, the individual polymer chains are cross-linked. Although this is a general method for nanocrystals grown in different organic solvents, the final size of the particles after coating is rather large. For CdSe/ZnS QDs, the diameter is between 19 and 25 nm,[276] which could place restrictions on many biological applications. Other approaches, such as coating the QDs with phospholipid micelles,[277] dithiothreitol,[278] organic dendron,[279,280] and oligomeric ligands,[281] have also been reported.

3.327.3.2.3.2. *Biomolecule conjugation*

In order to apply QDs in various biological systems, certain biological molecules need to be attached to the surface of these dots without any damage to the properties of the

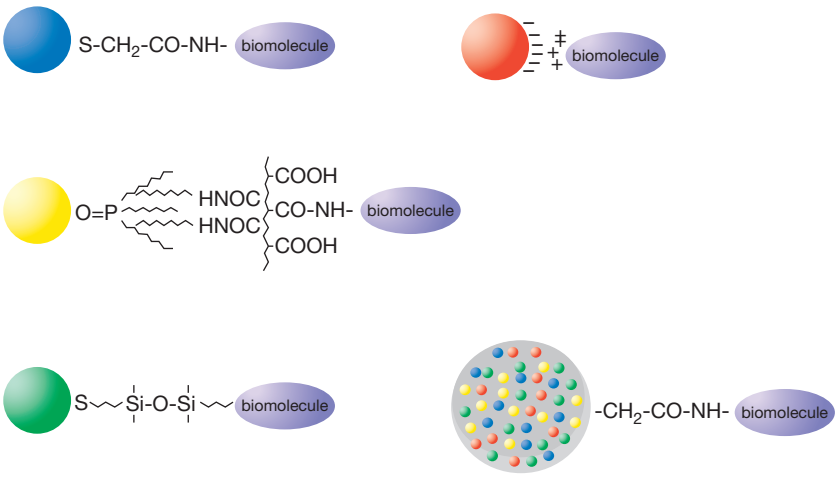

Figure 11 A schematic illustrating different approach of conjugation of QDs to biomolecules: (a) Use of a bifunctional ligand such as mercaptoacetic acid for linking QDs to biomolecules. (b) TOPO-capped QDs bound to a modified acrylic acid polymer by hydrophobic forces. (c) QD solubilisation and bioconjugation using a mercaptosilane compound. (d) Positively charged biomolecules linked to negatively charged QDs by electrostatic attraction. (e) Incorporation of QDs into microbeads and nanobeads. Reproduced from Chan, W. C. W.; Maxwell, D. J.; Gao, X. H.; Bailey, R. E.; Han, M. Y.; Nie, S. M. *Curr. Opin. Biotechnol*. **2002**, *13*, 40–46, with permission from ACS Publications.

molecules.[282] Owing to its finite size (comparable to or slightly larger than that of many proteins), a single QD can be conjugated to several proteins simultaneously. The QD thus acts as a nanoscaffold for attachment of several proteins, or other biomolecules, creating a multifunctional nanoparticle–biological hybrid.

Several successful approaches have been used to link biological molecules to QDs, including adsorption, electrostatic interaction, mercapto (–SH) exchange, and covalent linkage. It has been reported that simple small molecules, such as oligonucleotides[283,284] and various serum albumins,[285] are readily adsorbed to the surface of water-soluble QDs. This adsorption is nonspecific and depends on ionic strength, pH, temperature, and the surface charge of the molecule.

Mattoussi and coworkers presented a method of conjugating proteins to QD surfaces using electrostatic interactions. The protein of interest was engineered to fuse with a positively charged domain, which in turn interacted electrostatically with the negatively charged surface of the QD. The protein–QD conjugates prepared in this way were very stable and the fluorescence yield was even higher than that from the nonconjugated dots.[254,267]

Biological molecules containing thiol groups can be conjugated to the QD surface through a mercapto exchange process.[262,265,266,282,286,287] Unfortunately, the same problem of using thiol as anchoring group on a ZnS surface occurs because the bond between Zn and thiol is not very strong and is dynamic. As a result, biomolecules can readily detach from the surface, causing QDs to precipitate from the solution.

In an alternative method, biological molecules are covalently linked to the QD surface on their outer hydrophilic shell. Most simply, biological molecules can be adsorbed to the hydrophilic shell in a nonspecific way.[284,285] In a more specific way, molecules can be adsorbed to the hydrophilic shell by electrostatic interaction. Most colloidal QDs are negatively charged and therefore positively charged biological molecules stick to their surface. In the case of proteins, it is also possible to genetically engineer a positive zipper to one end of the protein, with which the protein then is electrostatically adsorbed to the QD surface.[267,288–290] Finally, biological molecules can also be covalently attached to the QDs by means of cross-linker molecules.[232,233,260,266,268,275,277,278,287,291,292] This requires hydrophilic surfactant shells with reactive groups, such as –COOH, $-NH_2$, or –SH. Since most biological molecules bear these functional groups or can be easily modified with them, a covalent linkage between functional groups on the QD surface and functional groups of the biological molecule can be formed. Typical procedures include carbodiimide activation of carboxylic acid groups on one entity followed by amide bond formation to amino groups on the other entity or the linkage of thiol and amino groups using bifunctional cross-linkers such as SMCC (4-(*N*-maleimidomethyl) cyclohexane-1-carboxylic acid *N*-hydroxysuccinimide ester).[293] A huge variety of suitable cross-linking reactions can be found in textbooks.[293]

3.327.3.2.3.3. *Toxicity/biocompatibility*

Since constituents of colloidal QDs such as cadmium[294] or selenium[295] are toxic to many cells, harmful effects can be expected, especially when the hydrophilic shell around the QDs is not stable they might dissolve under the release of toxic ions.

Cytotoxicity of QDs has been observed in a large number of *in vitro* studies,[235,271,296–299] affecting cell growth and viability.[300] The extent of cytotoxicity has been found to be dependent upon a number of factors including size, capping materials, color, dose of QDs, surface chemistry, coating bioactivity, and processing parameters.[299,301,302] Even if not inducing significant alterations in cell physiology, QDs can produce subtle alterations of function which may affect the quality of data derived from their use.[298,303,304]

A number of mechanisms have been postulated to be responsible for QD cytotoxicity. These include desorption of free Cd (QD core degradation),[235,271] free radical formation, and interaction of QDs with intracellular components. Examination of QD toxicity in a hepatocyte culture model showed that exposure of core CdSe to an oxidative environment causes decomposition and desorption of Cd ions. Such exposure during synthesis and processing played an important role in subsequent toxicity.

However, when properly capped by both ZnS and hydrophilic shells, no acute and obvious CdSe QD toxicity has been detected in studies of cell proliferation and viability in live cells[270,271,287,288] and animal[282,305] models. The most sensitive environment in which to test QD toxicity is that of the live embryo because even slight cellular perturbances are manifested as measurable biological phenotypes. The toxicity of QDs was examined in *Xenopus* embryos,[277] where injection of low concentrations of QDs had no negative effects. Although some abnormalities were noted with increasing concentrations, it was not clear whether they resulted from the QDs or changes in the osmotic equilibrium of the cell. In another case, primary hepatocyte cultures were examined because the liver is the major target of cadmium injury.[271] Under standard conditions of synthesis and water solubilization, QDs were not toxic. However, cytotoxicity was observed when Cd^{2+} was released.[271] This happened when the QD surface coating was not stable, exposing the CdSe to oxidization by air or UV damage. Therefore, strategies to protect the QD surfaces from oxidative environments are critical for live cell and animal experiments. Coating the QD surface with ZnS eliminates toxicity owing to air exposure but provides only partial protection of the core from UV exposure. Larger molecules, such as bovine serum albumin (BSA) and polymer/streptavidin, further slow down the photooxidation process. However, the potential effect of Cd^{2+} release over time has not been examined. There remains a pressing need for further investigations into QD toxicity in live animals and safety for diagnostic applications.

3.327.3.2.4. Biological applications

3.327.3.2.4.1. *Immunolabeling:* In vitro

The use of QDs for sensitive and multicolor cellular imaging has seen major advances due to significant improvements in QD synthesis, surface chemistry, and conjugation. Fluorescence immunolabeling is widely used in cell biology for probing structure and locating signal-transduction-related molecules. Owing to their robust optical properties, QDs are ideal probes in this area. Their application is in principle very similar to that of organic fluorophores.

Biologically conjugated QDs have shown great promise as multiwavelength fluorescent labels for on-chip bioassays and eukaryotic cells. Since the first experiment by Alivisatos *et al.*,

where semiconductor CdSe/ZnS nanocrystals were used to stain F-actin in fixed cells,[232] investigators have performed a variety of experiments in which QDs have been used to localize molecules in cells and tissues, both in live and fixed specimens.

Nowadays high-quality images such as the dual-color labeling can be obtained with standardized procedures. If antibodies are used as ligands, typically a two-step reaction is used. First, a primary antibody is reacted with the target. Then QDs conjugated with a secondary antibody, which targets the primary antibody, are added.[275,292] Since more than one secondary antibody can bind to each primary antibody, such cascade reactions amplify the fluorescence signal. However, the direct conjugation of antibodies to QDs is laborious; often biotinylated secondary antibodies are used, which are finally labeled by streptavidin–QD conjugates via biotin–avidin interaction.[273,306] This strategy is advantageous, because it involves only one universal conjugation of QDs with streptavidin, and most antibodies are commercially available with an attached biotin group. Further signal amplification can be achieved with the so-called TSA enzyme amplification technique. Here the secondary antibody is conjugated with horseradish peroxidase (HRP) and QDs are conjugated to tyramide (e.g., via biotin–avidin interaction). Horseradish peroxidase converts tyramide to a very reactive oxidized intermediate, which rapidly binds to all proteins in close proximity. In this way, the whole local environment of the secondary antibody is labeled with fluorescent QDs.[306] QD labeling of inner and outer structures of fixed cells has been used for a variety of receptors.

All these studies show that QDs have moved beyond the demonstration stage and are excellent probes with enhanced signal-to-noise ratio, extremely high stability, and improved specificity suitable for studying important biological problems.

3.327.3.2.4.2. Within living cells

Because QDs are extremely bright and photostable, they can be used as cell markers for long-term studies such as cell–cell interactions, cell differentiation, and cell lineage tracking. Most experiments conducted to date have shown that QDs do not interfere with normal cell physiology and cell differentiation.[270,277,307]

The idea of using QDs as cell markers is started when the Nie group reported that QDs are incorporated by living cells.[233] QDs can be internalized by cells, by either receptor-mediated[233] or nonspecific endocytosis.[231,270,285,288] The exact pathway of incorporating QDs into cells under endocytosis is not understood. However, after QDs enter cells, they accumulate in vesicles in the perinuclear region.[270,285,288] Perinuclear vesicles filled with nanocrystals were first seen by multiphoton microscopy.[270] Later, with the use of an endosome-specific marker, such as fluorescein-labeled dextran[285] or pECFP,[288] it was confirmed that QDs were indeed accumulated in the endosomes or lysosomes and not coating them on the basis of colocalization of QDs and endosome markers. Once internalized, QDs divided with the daughter cells at cell division.[270,277,285]

Internalized QDs are powerful probes for long-term studies within live cells. By virtue of their optical properties, QDs can highlight cells and subcellular structures above the surrounding background; in other words, they add contrast to a material that otherwise provides little contrast under visible light observation; in yet other words, they can communicate to the observer an image of a biological structure of interest.

To demonstrate multicolor labeling of live cells, endocytic uptake and selective labeling of cell surface proteins were used with antibody conjugated QDs, and then QD emission was followed for over a week as cellular development was monitored, showing that cells tolerate QDs for extended periods of time.[277,288,308] By using antibody-linked QDs, both the Her2 breast cancer marker and specific intracellular proteins were labeled in both live and fixed cancer cells, demonstrating that QD-probes can cross into cells and specifically bind their intended intracellular targets.[275] QDs can also be useful markers for tracking cellular movement, differentiation, and fate.[277,288,308] Cancer cells seeded on top of QDs engulf them and leave behind a fluorescence-free phagokinetic trail.[308] Using several cell lines, the size and shape of trails were shown to correlate well with potential invasiveness, providing a novel assay for this property.[308] Micelle stabilized QDs injected into *Xenopus* embryos demonstrated cell lineage-tracing during the complex developmental process spanning the embryo–tadpole stage and equal transfer of QDs from mother to daughter cells, again showing long-term cellular compatibility even with $>10^9$ QDs per cell.[277] By exploiting QD photobleaching resistance, previously onerous cellular physiology questions have been investigated on the single-molecule level. These include tracking the diffusion dynamics of individual glycine receptors in neuronal cells over long periods of time (min), which provided unique information on single-protein movement, and interestingly, the authors used blinking to identify single QDs and differentiate them from aggregates.[309] Additionally, the specific erbB/HER cellular receptor-mediated fusion and internalization process has been observed in single cells.[310] These publications mark the transition from 'proof-of-concept' to a useful tool as these complex cellular processes could not be tracked continuously with photolabile organic fluorophores.

3.327.3.2.4.3. In vivo *applications*

Imaging tissue with far red/NIR excitation overcomes some problems due to indigenous tissue autofluorescence, and QD spectroscopic properties can be exploited here to achieve somewhat deeper penetration than the available NIR dyes.[286,311,312] This was demonstrated by synthesizing NIR emitting QDs (840–860 nm) and applying them to sentinel lymph-node mapping in cancer surgery of animals.[70] Using only 5 mW cm^{-2} excitation, they imaged lymph nodes 1 cm deep in tissue, where lymphatic vessels were clearly visualized draining QD solutions into the sentinel nodes.[312]

Colloidal semiconductor nanocrystals have a two-photon cross-section that is 2–3 orders of magnitude greater than organic dyes.[305] A two-photon process requires about twice the excitation wavelength of a single-photon excitation. Longer wavelengths, extending into the infrared region, can be utilized to excite chromophores in a single quantum event. Therefore, multiphoton microscopy enables the imaging of structures deep within biological tissues with minimum photobleaching and photodamage. The high two-photon cross-section of QDs allows for more efficient probing of thick specimens and *in vivo* imaging when using multiphoton excitation microscopy. This makes them suitable for *in vivo* deep-tissue imaging

using two-photon excitation at low intensities.[305,313] Using this technique to excite green-emitting QDs in the near infrared allowed imaging of mice capillaries hundreds of micrometres deep and subcellular resolution of mouse brain.[305,313]

Recently, Gao *et al.* reported *in vivo* cancer targeting and imaging using QDs.[314] They conjugated QDs to the antibody specific for the prostate cancer cell marker PSMA. After injection into mice that had been transplanted with human prostate cancer cells, the QD-tagged PSMA antibodies recognized and bound at the tumor site and were clearly imaged *in vivo*. Owing to the QDs' large absorption coefficient and long lifetime, *in vivo* imaging of QDs was much brighter and more sensitive than imaging with green fluorescence protein (GFP), which was totally buried in autofluorescence and background.

Most recently, self-illuminating QD was conjugated as new probes for *in vivo* imaging. Specific immunofluorescent probes were synthesized by linking QDs to α-fetoprotein AFP antibody for specific recognization of AFP, an important marker for hepatocarcinoma cell line HCCLM6. *In vivo*, active tumor targeting and sensitive spectroscopic hepatoma imaging was achieved with an integrated fluorescence imaging system. The inhomogeneous distribution of the QD probes in tumor by using a site by site measurement method was investigated to test their ability for distribution studies of cancer cells in tumor. These results demonstrate the potential of QD probes as attractive immunofluorescent probes for cancer detection (Figure 12).[315]

Summarizing the above, there is no doubt about the great potential of QDs as labels or contrast agents in life sciences and medical diagnostics. Will QDs replace fluorescent dyes? No, – rather they will complement dye deficiencies in particular applications such as *in vivo* imaging. Moreover, adapting QDs for biological use will teach us critical lessons about creating future inorganic–biological hybrids with direct relevance to many other materials. Future studies will have to characterize the dose–response relationships of QDs. Dose–response in this case means not only evaluating which minimal dose is needed to obtain the desired optical signal as a response but also which dose is acceptable in terms of undesired side effects, which are a type of response as well. The existing literature gives some hints that at least in short-term studies toxicity may not be a limiting problem. Medical application in humans will however require an unequivocal assessment of the potential long-term effects of administered QDs. Together with other interdisciplinary developments of modern science, the optimization and application of QDs in biology and medicine may revolutionize what we know and what we think about biological processes.

Opt.* **2007**, *12*, 014008, with permission from SPIE.

3.327.4. Conclusion

The successful development of new systems and techniques which enable monitoring of individual biological macromolecules or individual biological cells in their natural (aqueous) environment will lead to a better understanding of the microdynamics of living systems. Such systems would, for example, allow real-time monitoring of the functioning of fluorescently tagged drugs absorbed into individual biological cells or their substructures. Nanotechnology combined with optical science will allow the realization of optical-based nanosensors suitable for the tasks described above. So far, research conducted has demonstrated the viability of constructing optical-based sensors allowing intracellular sensing with submicron resolution. Nonetheless, extraordinary opportunities remain, because delivering deeper into biochemical and biological phenomena will require ever more sophisticated and tailored probes.

Glossary

Free radical polymerization A method of polymerization by which a polymer is formed from the successive addition of free radical building blocks.

Hydrogels Hydrogels are three-dimensionally cross-linked hydrophilic polymeric networks capable of imbibing considerable amounts of water or biological fluids without undergoing dissolution.

Photonic crystals Periodic optical nanostructures that are designed to affect the motion of photons in a similar way that periodicity of a semiconductor crystal affects the motion of electrons.

Quartz crystal microbalance (QCM) A quartz crystal microbalance measures a mass per unit area by measuring the change in frequency of a quartz crystal resonator.

3.329.1. Introduction

3.329.1.1. Sensors: General Definition and Classification

In general, the term sensor is derived from the Latin word *sensus*, which directly translated means *sense*, or to *sense something*. If one thinks about a *sense*, the first idea that comes up is the traditional five human senses: sight, hearing, taste, smell, and touch. The senses give the human body the ability to receive signals or stimuli from the environment and to react or respond to them. If a sense gives the ability to receive and to respond to a signal, we can transfer this to the technical level and define a sensor as follows:

A sensor is a device that receives and responds to signals and stimuli from the environment. Furthermore, the human senses give a first hint of how sensors can be classified. Sight, hearing, and touch have one thing in common, that is they sense physical stimuli, namely light, in the form of electromagnetic waves, acoustic waves, and pressure. Smell and taste respond to chemical stimuli, like odor and taste molecules. Accordingly, sensors can be divided into two big classes: physical and chemical sensors. In 1991, the IUPAC defined the terms physical and chemical sensor with the following definitions[1]:

> A physical sensor is a device that provides information about a physical property of the system.
>
> A chemical sensor is a device that transforms chemical information, ranging from the concentration of a specific sample component to total composition analysis, into an analytically useful signal.

Now that the term sensor is defined and a first classification, corresponding to the sensed stimulus, is made, a closer look at the general structure of sensors can be taken. Again,

the human senses lead the way to this structure: whenever receptor cells in the human body receive certain stimuli, for example, an electromagnetic wave hits a photoreceptor cell in the retina, a chemical reaction is triggered and then transduced, in the form of an electrical signal, to the brain. Deductive sensors consist of two basic parts, namely, a receptor and a transducer part. Technically speaking, the receptor part of a sensor receives a chemical or physical stimulus and transforms it into a form of energy. The transducer part is then capable of transducing this energy into a useful analytical signal, which can be processed and displayed. Figure 1 illustrates the general sensor structure.

At the technical level, there are many ways to classify sensors, for example, according to the measuring effect, given analyte, receptor principle, field of application, mode of application, and so on. The most established way is the one following the principles of signal transduction, committed by the IUPAC 1991 for chemical sensors[1]:

1. Optical sensors, based on absorbance, reflectance, luminescence, fluorescence, index of refraction, optothermal effect, and light-scattering effects.
2. Electrochemical sensors, based on voltammetric, including amperometric and potentiometric effects, chemically sensitized field effect transistors (CHEMFET), and potentiometric solid electrolyte gas sensors.
3. Electrical sensors, based on metal oxide semiconductors and organic semiconductors.
4. Mass-sensitive sensors, based on piezoelectric and surface acoustic wave effects.
5. Magnetic sensors, based on paramagnetic gas properties.
6. Thermometric sensors, based on heat effects of specific chemical reaction or adsorption.
7. Radiation-sensitive sensors, based on absorbance, or emission of X-, β-, or γ-radiation that is used for the determination of a chemical composition.

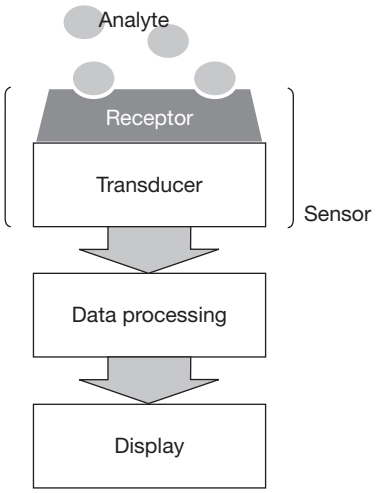

Figure 1 General sensor structure comprising a receptor that interacts with the analyte and a transducer. Beyond that core sensing unit, data processing and display are important parts of complete sensor systems.

As the classification shows, the IUPAC draws no clear line between chemical and physical sensors and counts physical sensors that measure, for example, a chemical state, reaction, or composition as chemical sensors. This shows that a general approach to classification is difficult, as chemical and physical sensing almost always go hand in hand. Hence, more generally, sensors can be defined as devices that determine selectively and reversibly the concentration of analyte molecules by amplifying the signal resulting from an interaction between the analyte and the receptor without the need for any other instrument and additional reagents.[2]

3.329.1.2. Biosensors

If a physical sensor is a device that provides information about the physical property of a system and a chemical sensor is a device that transforms chemical information into an analytically useful signal, a biosensor consequently must work in a similar way. Actually, the class of biosensors can be counted as a cross of both physical and chemical sensors. They can be devices that provide information about a biophysical property of a system and/or transform biochemical information into an analytically useful signal. What is more important is the fact that biosensors have a biological recognition element that enables the analysis of relevant biological information. This concept corresponds with the definition for biosensors given by the IUPAC in 1999[3]:

> A biosensor is an integrated receptor–transducer device, which is capable of providing selective quantitative or semi-quantitative analytical information using a biological recognition element.

A classification of biosensors can be done after one of the following principles:

1. Following the principle of signal transduction, for example, electrochemical, optical, mass sensitive, and so on.
2. Depending on the biological recognition element, for example, biological ionophores, enzymes, antigens/antibodies, whole cells, membrane receptors, plant and animal tissue, protein receptors and channels, oligonucleotides, specific ligands, etc.
3. Classified after the sensed analyte, for example, glucose, DNA, enzymes, toxins, certain drugs, and so on.

From the first biosensor invention filed by Leland C. Clark in 1962 that concerned a potentiometric enzyme electrode developed to measure concentration of glucose,[4] numerous biosensors with different specificities have been developed. During the last decade, much work was devoted to downsize the laboratory workspace toward small and versatile biosensor devices. However, indispensable requirements, including fast responsibility, reproducibility, reliability, and stability, remained the same. Crucial parameters in designing biosensors with high performance are (i) immobilization of biomolecules in their native conformation (ii) accessibility of receptors to the targets, and (iii) specific adsorption to the support.[5–7] Especially regarding these demands, hydrogels offer specific advantages for biosensors. As this chapter is dedicated to hydrogels in biosensing applications, the next paragraph gives a brief theoretical introduction into main properties and definitions.

3.329.1.3. Hydrogels: Definitions and Theoretical Aspects

Hydrogels are three-dimensionally cross-linked hydrophilic polymeric networks capable of imbibing considerable amounts of water or biological fluids without dissolving.[8] The cross-linking degree in hydrogel networks is described as the density of junctions joining the chains into a permanent form defining the mesh size.[9] The mesh size, ξ, is an important term used to define the distance between two adjacent cross-links and provides a measurable space available between the macromolecular chains for diffusion of particles[10] (**Figure 2**).

The swelling process of hydrogels with water consists of three main steps: first, diffusion of water molecule through the gel matrix, then relaxation of polymer chains via hydration, and lastly, expansion of the polymer network into surrounding bulk water upon relaxation.[11] The stretching of the polymer chains increases the elastic refractive force as a counteract for the network expansion. When balance between these two forces becomes equal, the network expansion due to swelling will stop and come to equilibrium volume. Several parameters like nature of the polymer and ionic groups[12,13] contribute to the swelling of the polymer network. For example, an increase of the ionic content inside the network results in an osmotic pressure between the gel matrix and its surrounding, thus exhibiting faster swelling and higher equilibrium degree of swelling.

One of the most widely used theories for swelling of neutral hydrogels is the equilibrium swelling theory of Flory and Rehner.[14,15] They modeled this theory as assuming Gaussian distribution of polymer chains. In this theory, the swelling of the polymer network is a function of elastic forces of the polymer chains and the thermodynamics compatibility of the polymer and water molecules. According to this theory, the free energy of a neutral hydrogel (ΔG) can be expressed as

$$\Delta G = \Delta G_{el} + \Delta G_{mix} \quad [1]$$

where ΔG_{el} represent the contribution of elastic refractive forces and ΔG_{mix} is the thermodynamic compatibility of the polymer and the swelling agent. The incorporation of ionic groups through the matrix will create the term, ΔG_{ionic}, which is the total free energy contribution of ionic groups in the network.

$$\Delta G = \Delta G_{el} + \Delta G_{mix} + \Delta G_{ionic} \quad [2]$$

This equation can be rewritten by means of chemical potentials, and the equilibrium conditions' total chemical potential (μ) will be equal to zero:

$$\mu = \mu_{el} + \mu_{mix} + \mu_{ionic} = 0 \quad [3]$$

In the absence of solvent, Flory and Rehner's theory leads to an expression for molecular weight between cross-links ($\bar{M}_C$) shown in eqn [4]:

$$\frac{1}{\bar{M}_C} = \frac{2}{\bar{M}_N} - \frac{(\bar{v}/V_1)\left[\ln(1-v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2\right]}{v_{2,s}^{1/3} - \frac{v_{2,s}}{2}} \quad [4]$$

where $\bar{M}_N$ is the average molecular weight of polymer chains prepared in the absence of a cross-linking agent. $\bar{v}$ and v_1 are the specific volume of water and the molar volume of the water, respectively. $v_{2,r}$ and $v_{2,s}$ refer to the polymer volume fraction in the relaxed, the state of the polymer immediately after cross-linking, and fully swollen states, respectively.

Upon incorporation of ionic groups into the network, the swelling equilibrium of the swelling matrix becomes more complicated. The two new terms, ionic strength, I, and dissociations constants, K_a and K_b, have to be added to eqn [4]. The equivalent expression for anionic and cationic gels is shown in eqns [5] and [6], respectively.[16]

$$\frac{V_1}{4I}\left(\frac{v_{2,s}^2}{\bar{v}}\right)\left(\frac{K_a}{10^{-pH} - K_a}\right) = \left[\ln(1-v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2\right] + \left(\frac{V_1}{\bar{v}\bar{M}_C}\right)\left(1 - \frac{2\bar{M}_C}{\bar{M}_N}\right)v_{2,r}\left[\left(\frac{v_{2,s}}{v_{2,r}}\right)^{1/3} - \left(\frac{v_{2,s}}{2v_{2,r}}\right)\right] \quad [5]$$

$$\frac{V_1}{4I}\left(\frac{v_{2,s}^2}{\bar{v}}\right)\left(\frac{K_b}{10^{pH-14} - K_a}\right) = \left[\ln(1-v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2\right] + \left(\frac{V_1}{\bar{v}\bar{M}_C}\right)\left(1 - \frac{2\bar{M}_C}{\bar{M}_N}\right)v_{2,r}\left[\left(\frac{v_{2,s}}{v_{2,r}}\right)^{1/3} - \left(\frac{v_{2,s}}{2v_{2,r}}\right)\right] \quad [6]$$

Mesh size, ξ (i.e., correlation length) based on values for the cross-linking density or molecular weight between cross-links, can be described using the following equation:

$$\xi = v_{2,s}^{1/3}(\bar{r}_o^2)^{1/2} = Q^{1/3}(\bar{r}_o^2)^{1/2} \quad [7]$$

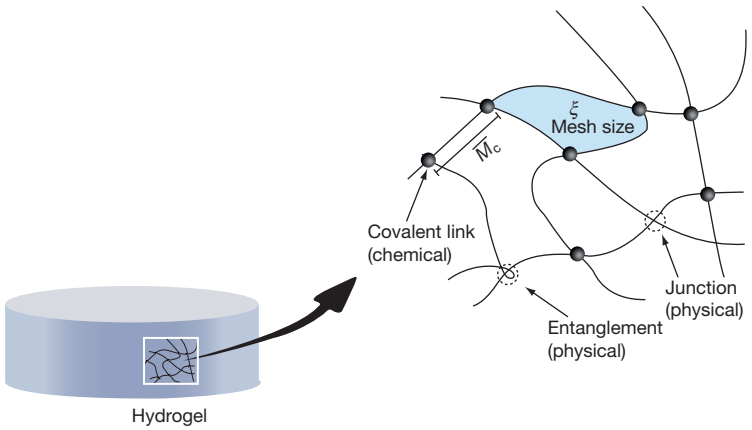

Figure 2 Scheme of a cross-linked hydrogel structure. ξ is the mesh size of the network and $\bar{M}_C$ is the molecular weight between two cross-linking points.

where α is the elongation of the polymer chains in any direction and $(\bar{r}_o^2)^{1/2}$ is the end-to-end distance of the polymer chains between cross-linking points in the unperturbed state. Assuming isotropic swelling of the gels, the end-to-end distance and the pore size of a swollen polymeric network can be calculated using the following equation:

$$\xi = \upsilon_{2,s}^{-1/3} \left(\frac{2\, C_N\, \bar{M}_C}{M_r} \right)^{1/2} \iota \qquad [8]$$

where ι is the length of the bond along the backbone chain and C_N and M_r are the Flory characteristic ratio (ratio of the square of the unperturbed distance to the square of the random flight end-to-end distance) and the molecular weight of the repeating units, respectively.

By changing such factors like mesh size or the molecular weight between cross-links, hydrogel with particular thermal, diffusive, or mechanic properties can be obtained.[17] Moreover, it becomes clear that analyte-induced changes in the characteristics of the network such as the cross-linking density, content of ionic species, or chemical nature of the polymer backbone will result in macroscopic effects such as altered swelling behavior. Such changes can result from physicochemical stimuli such as changes in temperature, pH, or ion strength, or they may originate from biochemical recognition events. Both effects are, among others, used in biosensing applications. The following paragraph gives a brief overview of the different applications of hydrogels in biosensing.

3.329.1.4. Hydrogels for Biosensors

The high water content and hydrophilic nature of hydrogel is similar to the void-filling component of the extracellular matrix and renders them intrinsically biocompatible. Hydrogels are thus used for a wide range of biomedical applications such as soft contact lenses[18] and controlled drug delivery systems.[19] Hence, a straightforward application of hydrogels in biosensors is a protection and coating function of sensor parts to prevent undesired interaction with biological molecules or cells. Their open porous structure and hydrophilic environment allows diffusion of analytes through the hydrogel. However, diffusion of larger molecules such as proteins may be prevented by an increased cross-linking density, and cells are usually not able to penetrate unless the gel structure is biodegradable.

Beyond simple protection, hydrogels can be used as an immobilization matrix for the biosensing elements. Hydrogels provide excellent environments for enzymes and other biomolecules to hold them in their thermodynamically stable form.[20] Also, cells are commonly immobilized in hydrogel matrices for various purposes.[21] Recognition in hydrogel-based sensors is provided by interaction between an analyte and sensing element by volume changes in response to target molecules. As a result of recognition, volumetric change creates a new kind of sensing system instead of the classical biosensor based on the electrochemical way. The prominent point in designing sensors with high selectivity and sensitivity mainly depends on receptors that have to be immobilized in their native conformation to be able to specifically interact with the analyte while support material should be resistant to unspecific adsorption. Furthermore, the quality of sensing mainly depends on accessibility and activity of the immobilized sensing molecules inside the hydrogel network, determining the sensitivity level. As hydrogels may easily be tailored in their properties, they form an ideal platform for this purpose, and extensive work has been carried out with a variety of analytes such as proteins, ions, carbohydrates, and nucleic acids.[22–24]

Hydrogels may also act as active sensing material. For this purpose, the so-called smart gels or stimuli-responsive gels are especially interesting. Such gels are sensitive to small changes in the environment and give the response to physical stimuli (temperature,[25] light,[26] pressure,[27] electric fields,[28] ionic strength,[29] and magnetic field[30]), chemical stimuli (pH,[31] ions[32]), or biological stimuli (glucose,[33] enzyme,[34] and antigen[35]) through volume changes. The response rate is dependent on the hydrogel composition, shape, and size and can be increased by several proposed techniques such as reducing the size,[36] decreasing the cross-linking density,[37] and increasing both ionic groups[38] and pore size.[39] In the presence of these stimuli, the hydrogels undergo phase transition by the sensing molecules and simultaneously translate this sense into a macroscopic event. In this way, the conversion of hydrogel swelling to an electrical output is possible with various techniques like light transmission measurement,[40] conductometry,[41] and pressure generated by the gel swelling.[42]

Hydrogels may be prepared in aqueous solutions by UV[43] or thermoinitiated radical polymerization,[44] addition reaction,[45] self-assembly of recognition motifs such as coiled-coils,[46,47] peptides,[48–50] hydrogen-bridges,[51] or DNA.[52–55] They can be formed by *in situ* gelation from low-viscosity solutions and thus be injected into small voids or complex fluidic and microfluidic devices. This predisposition to miniaturization and integration into the microsystem in desired geometry broadens their analytical applications. Hydrogels may thus be formed by *in situ* patterning on desired devices.[56]

3.329.1.5. Structure of the Chapter

In the last decade, remarkable efforts have been achieved to manifold sensitivity and selectivity of hydrogel-based biosensors. By using different gel combinations, various systems with different specificities have been prepared, leading to better sensor performance. This chapter gives an overview of the use of hydrogels in biosensors, not only actively acting as sensing material themselves but also used for immobilization of molecules that cause the sensing stimulus in the presence of the analyte. We have structured the following detailed discussion strictly according to the sensing mechanism. **Section 3.329.2** comprises examples for physicochemical sensing where the signal is generated as response to changes in parameters such as temperature, pH, ion strength, gas, and humidity. Importantly, no biochemical recognition process is involved in these sensing mechanisms. Studies where the sensing mechanism is based on such processes, either through molecular interaction or by reaction of bacteria or cells toward the analyte, are presented and discussed in **Section 3.329.3**. Molecular interactions may be based on enzyme–substrate interaction, where a chemical reaction is catalyzed and causes the effect that may be sensed, or on binding/debinding events caused by the presence of the analyte that causes changes in the hydrogel network. Antibody–analyte interaction, peptide–peptide bonding, or

streptavidin/biotin are examples for such selective binding systems with high analyte affinity. Also, chemical moieties that mimic biological ligand binding, such as the binding of glucose to phenylboronic acids, are included in Section 3.329.3.

3.329.2. Physicochemical Sensing Mechanisms

An excellent and detailed overview of stimulus-sensitive hydrogels used in sensor and actuators was published by van der Linden *et al.* in 2003.[57] Hence, this chapter presents the basic mechanisms that build the basis for sensing and focuses on the advances achieved in the last decade.

3.329.2.1. Temperature Sensitivity

Temperature sensing is significant in many fields of biotechnology.[58] Detection of temperature via sensors can be achieved in a variety of ways. One of the most convenient ways is the use of thermoresponsive polymers as sensing agents. These temperature-sensitive polymers respond to temperature by volume changes. Poly(*N*-isopropylacrylamide) (PNIPAm) is a widely used polymer for its temperature-induced reversible volume–phase transition behavior, showing between 20 and 40 °C.[59] The underlying sensing mechanism is based on the free energy of the network that comprises hydrophobic side groups. At lower temperatures, hydration of the polymer backbones is dominant. With rising temperature, the motion of the water molecules increases. At the critical solution temperature, the entropy gained by the release of the water molecules together with the energy gained by hydrophobic interaction and clustering of the hydrophobic moieties surpasses the free energy of the hydrated state. Hence, the network collapses. The swelling/shrinking of thermoresponsive-based hydrogel can be monitored by following the thickness and refractive index of the hydrogel layer via the spectroscopic ellipsometric technique in changing temperatures. For that aim, the hydrogel has to be immobilized on the solid support. In this context, also the patterning of PNIPAM-based hydrogels has been used by different groups.[60,61] In one case, a temperature sensor construct was fabricated from PNIPAM-*g*-PEG-based micropatterned hydrogel film by Schmaljohann and colleagues.[62] They used ellipsometry to monitor the changes in the layer of interest due to swelling of hydrogel as a function of temperature on a micrometer scale. PNIPAM-*g*-PEG-based hydrogel was immobilized and micropatterned using photolithography. After confirmation of patterning through imaging ellipsometry in dry state, detection of temperature was performed by changing the volume of the hydrogel in deionized water using the localized nulling node as well as the three-dimensional (3D) profiles of the thickness-sensitive ellipsometric angle.

Intelligent polymerized crystalline colloidal arrays (IPCCAs) are one of the alternative approaches for temperature sensing. IPCCAs consist of a crystal colloidal array of polymer spheres polymerized in a hydrogel matrix. The array of colloidal spheres acts similar to photonic crystal and diffracts the light, giving rise to intense color. With incorporation of a temperature-sensitive hydrogel, the IPCCA structure becomes an ideal candidate for temperature sensing. Upon temperature change, the volume transition of the hydrogel induces color changes by means of change in diffraction properties.[63] The diffraction through PCCA particles follows Bragg's law, which is formalized thus:[64]

$$m\lambda = 2nd\sin\theta \qquad [9]$$

where d is the diffraction order, λ is the wavelength of light in vacuum, and n and d refer to refractive index of system and diffracting phase spacing, respectively. θ is the Bragg glancing angle. Hence, when the hydrogel volume increases upon temperature change, the distance between the colloidal spheres increases and so, the Bragg peak of the diffracted light is shifted to longer wavelengths. In one case, a temperature sensing construct based on IPCCA particles was designed by cross-linking acrylamide (AAm) and *N*-isopropylacrylamide (NIPA) with bisacrylamide in the presence of the UV photoinitiator 2,2-diethoxyacetophenone (DEAP) around a face-centered cubic (fcc) array of monodisperse, ~100-μm diameter highly negatively charged polystyrene colloidal particles.[65] These particles diffract visible light because the (111) planes of the fcc polystyrene colloidal particle array have ~200-nm lattice constant. This NIPAM–IPCCA is swollen in cold water but collapses with increasing temperature, resulting in a blue shift of the diffraction. The change in diffraction wavelength is shown in Figure 3. The diffraction wavelength is monitored at a defined angle relative to the incident light.

A different methodology for sensing temperature was established by Borisov *et al.*[66] They use europium(III) complexes as luminescent temperature indicators within hydrogel-coated microbeads. These complexes exhibit strong brightness when excited at 405 nm. When the excitation is turned off, the luminescence decay time is temperature-dependent, so that an optical readout for temperature is possible. A similar temperature sensor with optical readout based on a PVA/borax hydrogel was reported by Lee *et al.*[67] They used 2-naphthol as a fluorescence indicator probe in the hydrogel with excitation at

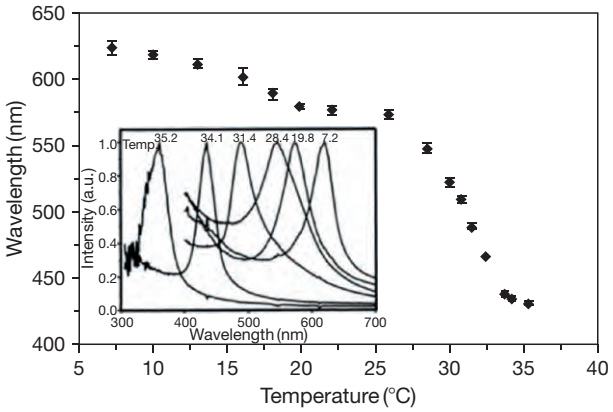

Figure 3 Temperature dependence of diffraction spectrum of *N*-isopropylacrylamide intelligent polymerized crystalline colloidal array particle dispersion. The diffraction is measured in back-scattering. As the temperature increases, the wavelength blue shifts. Reproduced from Reese, C. E.; Baltusavich, M. E.; Keim, J. P.; Asher, S. A. Anal. Chem. **2001**, *75*(21), 5038–5042, with permission from American Chemical Society.

365 nm and a maximum of the emission at 426 nm. Upon temperature increase, the fluorescence emission intensity of 2-naphthol increases linearly in the temperature range of 30–80 °C.

3.329.2.2. Ion Strength and pH

pH-sensitive hydrogels change their volume, mass, and elasticity reversibly in response to a change in the pH value.[68] The pH-sensitive character of hydrogels[69–76] makes them promising materials for a broad range of applications as microsensors[68–71] and microactuators in MEMS devices. The principles for swelling-dependent pH value detection can be various: changes of the holographic diffraction wavelength in optical Bragg grating sensors,[74] shifts of the resonance frequency of a quartz crystal microbalance in microgravimetric sensors,[75] a bending of micromechanical bilayer cantilevers,[76] as well as a deflection of silicon membranes in piezoresistive pressure sensors.[73,76] Before we give some detailed examples for pH sensors based on hydrogels, we advise the reader to have a closer look at the comprehensive review about hydrogel-based pH sensors and microsensors published by Richter *et al.* in 2008.[77] This review introduces the physical background of the special properties of pH-responsive hydrogels and gives a good overview of transducers, which are able to convert the changes of the physical properties of stimuli-responsive hydrogels into electrical signals.

An example for the use of pH-sensitive hydrogels based on an IPCCA was developed by Reese *et al.*[65] Through partial hydrolysis of the acrylamide hydrogel with NaOH, the hydrogel network was endowed with carboxylate groups. As described previously, this hydrogel was polymerized around a fcc array of monodisperse, ~100-μm diameter highly negatively charged polystyrene colloidal particles. Hence, change in pH induced swelling/deswelling of the hydrogel due to protonation/deprotonation of the particle surface and the hydrogel. The resulting color change was measured according to the temperature-sensitive IPCCA described earlier.

The group of Gerald Gerlach used the strong swelling ability of pH-responsive hydrogels[76] to develop a sensor which combines piezoresistive-responsive elements as mechanoelectrical transducers and the phase transition behavior of hydrogels as a chemomechanical transducer. They demonstrated the operational principle of chemical and pH sensors based on the swelling behavior of hydrogels.[78] For the realization of pH sensors, poly(vinyl alcohol)/poly(acrylic acid) (PAA/PVA) hydrogels with a pH value-dependent swelling behavior were used as chemomechanical transducers for a piezoresistive sensor setup. A similar setup but with PNIPAM has been applied and investigated for pH sensors as well. From the same group, Trinh *et al.* reported a simulation and design study of the system.[79] To optimize the sensor design, Sorber *et al.* investigated the swelling effect of the mentioned (PAA/PVA) hydrogel system by Fourier transform infrared (FT-IR) attenuated total reflection spectroscopic imaging under *in situ* conditions.[80] The results of the FT-IR spectroscopic images rendered an improved chemical sensor possible and demonstrated that *in situ* FT-IR imaging is a powerful method for the characterization of molecular processes within chemically sensitive materials.

Lee *et al.* observed the transformations of pH-sensitive hydrogel-based inverse opal photonic sensors from a fcc to a L11-like crystal structure.[81] By directly imaging a Rhodamine B (RhoB)-labeled inverse opal hydrogel, using two-photon laser scanning fluorescence microscopy, it was possible to characterize the mesostructure evolution of the pH-sensitive sensors during swelling. Along with the expected swelling normal to the substrate, they found that the template inverse opal structure undergoes a number of unique structural transformations upon swelling, including a transformation from fcc to an L11-like crystal structure.

An interesting optical sensing system utilizing the stimuli-responsive swelling character of a hydrogel lens system was published by Dong *et al.*[82] The central component of their lens system was a stimuli-responsive hydrogel integrated into a microfluidic system that served as the container for a liquid droplet (Figure 4). The hydrogel simultaneously sensed the presence of stimuli and actuated adjustments to the shape –

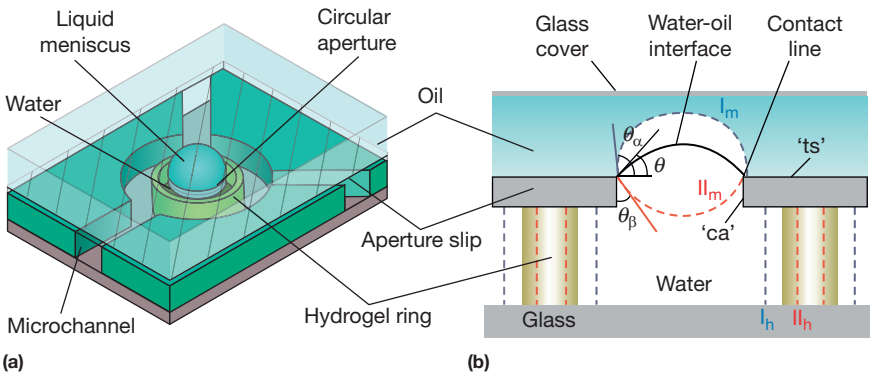

Figure 4 Smart microlens using a pinned liquid–liquid interface. (a) The water–oil interface forms the liquid microlens. The microchannels allow the flow of fluids to the microlens structure. (b) Smart variable-focus mechanism. The hydrophilic sidewall and bottom surface ('ca') and hydrophobic top surface ('ts') of the aperture pin the water–oil meniscus along the contact line 'ca–ts'. The expansion and contraction of the hydrogel regulates the shape of the liquid meniscus by changing the angle ν of the pinned water–oil interface. The blue dashed lines show the expanded state of the hydrogel ring ('Ih') and the corresponding divergent microlens ('Im') at $\theta = \theta_\alpha$. The red dashed lines show the contracted state of the hydrogel ring ('IIh') and the corresponding convergent microlens ('IIm') at $\theta = -(90^\circ - \theta_\beta)$. Reproduced from Dong, L.; Agarwal, A. K.; Beebe, D. J.; Jiang, H. *Nature* **2006**, *442*, 551–554, with permission from Nature Group.

and hence the focal length – of the droplet. The group demonstrated two systems: a pH-sensitive liquid microlens, using an acrylic acid-based hydrogel, and a temperature-sensitive liquid microlens, using a NIPA hydrogel.

An easy and biologically inspired method for sensing a pH value was presented by Kim *et al.*[83] The method is based on elastic instabilities of bipolymer swelling hydrogels: two different bipolymer gel stripes were fixed in such a way together that their differential response in swelling, induced by a designated stimulus, caused the strip to bend. On account of the fixation of the bipolymer gel stripes, the swelling energy released in an explosive elastic instability. One example was a setup with an acid-responsive dimethylaminoethyl methacrylate (DMAEMA)/hydroxyethyl methacrylate (HEMA)-based hydrogel on one side and an acrylic acid (AA)/HEMA-based hydrogel on the other side. In contact with a base or buffer, the bipolymer stripe delaminated in a rapid motion (**Figure 5**).

Sannino *et al.* used a quartz crystal microbalance (QCM) to recognize even very small changes in pH.[84] They established a spin coating method to coat QCM plates with cellulose-based superabsorbent hydrogels to obtain hydrogel-based fast sensors. The hydrogel network was obtained by cross-linking hydroxyethyl cellulose (HEC) and carboxymethyl cellulose (CMC) by the difunctional divinylsulfone (DVS). Owing to the polyelectrolyte CMC, the hydrogels displayed sensitivity to variations of ionic strength and pH of the water solution in which they were immersed. The change in mass resulted in a change of the oscillating frequency of the quartz plate with a fast response and a final accuracy on the weight variation of the order of nanograms.

A hydrogel-based method to recognize a local pH distribution by a change in color was developed by Maruyama *et al.*[85]

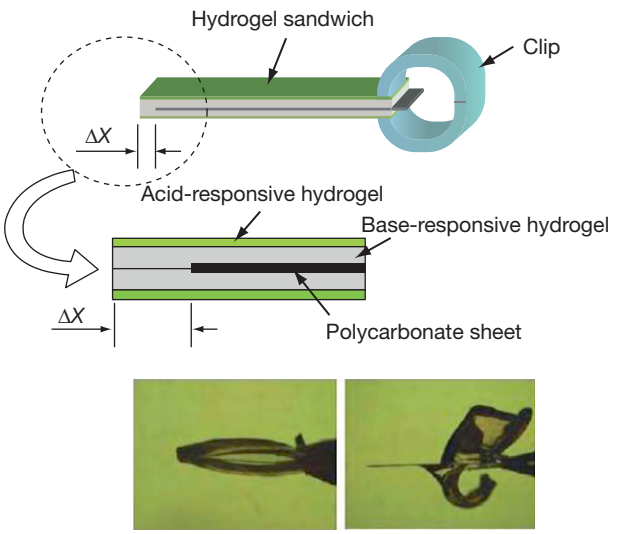

Figure 5 A hydrogel sandwich for explosive fracture motion. The hydrogel sandwich is composed of acid, and base-responsive hydrogels bond together in a certain way that an outward bending is created by stimuli like base and buffer. Once the elastic force overcomes the bonding force, the gels delaminate in a rapid motion. Reproduced from Kim, D.; Beebe, D. J. A sensing method based on elastic instabilities of swelling hydrogels. In *International Conference on Medical Biology*, Japan, 2006; pp 292–294.

They found a novel and easy technique to investigate local pH distribution on a chip using hydrogel films patterned by photolithography. To make the hydrogels sensitive to pH changes, they were functionalized with a pH-indicator, for example, Bromocresol Green (BCG). The local pH was measured from the color of the hydrogel impregnated with BCG based on the calibrated color information in YCrCb color space.

Ion-sensitive hydrogels generally work in a fashion similar to pH-sensitive systems. Guenther *et al.* proposed an online analytical system to monitor metal ions using gels as chemomechanical transducers.[86]

In this case, they improved the rheochemical sensor based on piezoresistive pressure sensor chips. This sensor was constructed from two piezoresistive sensor chips (chemical and viscosity sensors) mounted on a socket with an integrated capillary. A combination of these sensors makes it possible to obtain information about the investigated solutions. A piezoresistive Wheatstone bridge has been used as a mechanoelectrical transducer for the transformation of the plate deflection ω into electrical output signal U_{out}. Hydrogel is composed of a chemically cross-linked PNIPAAm, cross-linker BAA as well as photo-cross-linkable co- and terpolymer of NIPAAm, 2-(dimethyl maleimide)-*N*-ethylacrylamide (DMIAAm) as chromophore, and poly(2-vinylpyridine) (P2VP) (or *N*,*N*-dimethyl acrylamide (DMAAm), respectively), used as chemomechanical transducers. A thin layer of the photo-cross-linkable hydrogel has been deposited onto the back of the bending plate and irradiated with UV light. The aqueous solution has induced the volume change of hydrogel. These volumetric changes were monitored by integrated Wheatstone bridge inside a rectangular silicon plate. The plate deflection caused a stress state change inside the plate and therefore a resistivity change of the resistors affecting proportionally the output voltage of the sensor. An increase of this output voltage corresponded to the hydrogel swelling, whereas a reduction of electrical output voltage corresponded to the shrinkage of the gel.

As mentioned earlier, intelligent polymerized crystalline array (IPCCA)-based sensors can be used to detect pH changes. The same system can be modified for detection such as Pb^{2+} in high ionic-strength solution as well as in body fluids. Therefore, crown ether groups that chelate Pb^{2+} with high specificity were incorporated into the hydrogel network between the spheres, either by functionalization of the hydrogel with crown ether[87] or by direct copolymerization of vinyl-crown ether into the hydrogel matrix. When chelation of Pb^{2+} with crown ether occurred, the hydrogel started to swell driven by osmotic pressure. On account of this swelling, the distance between the spheres increased and red-shift of the diffracted light occurred proportional to the Pb^{2+} concentration. The detection limit of Pb^{2+} was lower than 0.5 $\mu mol\,l^{-1}$.

Also, hydrogel-modified microcantilevers have been used for ion sensing. They provide an excellent dynamic response even to small amounts of analyte by bending upon analyte adsorption on one side of the cantilever due to change in surface tension. CrO_4^{2-} ion can be sensed using microcantilever based on self-assembled monolayer (SAM) of a triethyl-12-mercaptododecylammonium.[88] The detection limit of this sensor is as low as 10^{-9} M; however, this sensor gradually loses its sensitivity over one week because of instability of the layer. Hence, a more stable coating is required for long-

time monitoring purposes. Hence, Zhang *et al.* used a hydrogel layer based on acrylamide and (3-acrylamidopropyl) triethyl ammonium chloride instead of SAM.[89] When this microcantilever is exposed to CrO_4^{2-} ions, deflection occurs as a function of CrO_4^{2-} concentration. This microcantilever shows higher specificity to CrO_4^{2-} compared to other ions like Br^-, HPO_4^{2-}, and NO_3^{2-} with a sensitivity as low as 10^{-11} M.

A different methodology was used to detect ionic strength and pH with hydrogel-based sensor arrays with perforated piezoresistive diaphragms.[90] The sensor was constructed with three components: the piezoelectric detectors, the pH-sensitive hydrogel sensor composed of hydroxypropyl methacrylate (HPMA), *N*,*N*-dimethylaminoethyl methacrylate (DMA), and the crosslinker tetraethylene glycol dimethacrylate (TEGMA), and a backing plate. Diffusion pores were comprised to allow analyte flow to the hydrogel. Alternatively, the backing plate was perforated. Swelling/deswelling of the hydrogel because of changes in ion strength induces pressure changes onto the piezoelectric sensors that are directly converted into electric signals.

3.329.2.3. Gas and Humidity

3.329.2.3.1. Gas

In the field of gas-sensing, hydrogels are mainly used for three purposes. Owing to their antiadhesive and protein-repellent character, hydrogels can be used just as a passive protection coating for a sensor/electrode.[91] Alternatively, hydrogels can be modified by gas-sensitive molecules, for example, special fluorescent dyes[92] which renders them sensitive for certain gases. Finally, the stimuli-responsive swelling character can be used for sensing, mainly for sensing carbon dioxide after the Severinghaus principle.[93,94] This strategy utilizes the pH change resulting from CO_2 diffusion into an electrolyte solution which can then be sensed by a pH-sensitive hydrogel.

One example for use as a protective layer is the internal hydrogel separation layer of the planar ultramicroelectrode nitric oxide (NO) sensor developed by Oh *et al.* to measure local NO surface concentrations.[95] The sensor array consists of a platinized working electrode and a silver paint reference electrode coated with a thin silicone rubber gas-permeable membrane. The working electrode and the gas-permeable membrane were separated by an internal hydrogel layer. They could demonstrate that the NO-selective ultramicroelectrode is an appropriate tool for determining accurate steady-state surface NO concentrations.

A hydrogel gas sensor from the second sub class was described by Zguris *et al.*[96] They developed a possible nitric oxide, hydrogel biosensor that utilized 4-amino-5-methylamino-2′,7′-difluorofluorescein (DAF-FM) entrapped in poly(ethylene glycol) (PEG) hydrogel microstructures. By utilizing the NO-sensitive fluorescence of the dye and bioinert character of the hydrogel matrix, it was possible to create a disposable biosensor that is applicable for nitric oxide production in certain mammalian cells. The sensor has a lower detection range of 0.5 μM of nitric oxide in solution. Owing to the irreversibility of the dye, it is a nondynamic system.

An example for a hydrogel sensor for the detection of carbon dioxide, based on the Severinghaus principle, was developed by Herber *et al.*[97] Therefore, a pH-sensitive hydroxyethyl methacrylate (HEMA)-*co*-dimethylaminoethyl methacrylate (DMAEMA) hydrogel disk, which swelled and deswelled in response to pH changes, was clamped between a silicon pressure sensor chip and a porous metal screen together with a bicarbonate solution. CO_2 reacts with the bicarbonate solution resulting in a pH change, which was converted into a pressure by the enclosed hydrogel. This pressure was a measure for the partial pressure of CO_2. A more sophisticated hydrogel biosensor based on the Severinghaus principle was described by Ter Steege *et al.*[98] They developed the prototype of a continuous hydrogel CO_2 sensor as an alternative and improvement to standard air tonometry. The work follows up on the previous work of Herber *et al.*[99] The sensor consisted of a pH-sensitive, dimethylaminoethyl methacrylate (DMAEMA) and comonomer 2-hydroxyethyl methacrylate (HEMA)-based hydrogel in a bicarbonate solution mounted on a catheter-tip pressure sensor. It is covered by a gas-permeable membrane (**Figure 6**). The swelling/shrinking of the hydrogel is dependent on the CO_2 concentration, which leads to a change in volume and pressure reflected by the pressure sensor.

The sensor enabled continuous measurement of luminal CO_2 and fast detection of sudden and gradual changes in pCO_2 in a clinical significant range. On account of the handmade assembly, the sensor lacked the temperature stability to meet clinical demands, but the authors gave a positive outlook for automated assembly system.

A crossover of the principles could be described in the work of Kocinova *et al.*[100] They presented an interesting method for noninvasive, simultaneous optical monitoring of oxygen and pH during bacterial cultivation in 24-well microplates by using an integrated dual sensor for dissolved oxygen and pH values. The dual sensor was based on oxygen-sensitive organosilica microparticles and pH-sensitive microbeads from a polymethacrylate derivative embedded into a polyurethane hydrogel. The readout was based on a phase-domain fluorescence lifetime. The sensor was used for monitoring the growth of *Pseudomonas putida* bacterial cultures (**Figure 7**).

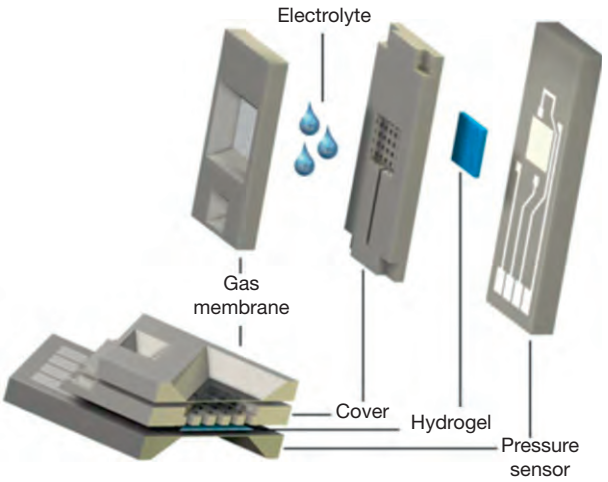

Figure 6 Exploded view of all parts and assembly drawing of the final hydrogel-based CO_2 sensor. Reproduced from ter Steege, R. W. F.; Herber, S.; Olthuis, W.; Bergveld, P.; van den Berg, A.; Kolkman, J. J. *J. Clin. Monit. Comput.* **2007**, *21*(2), 83–90, with permission from Springer.

3.329.2.3.2. Humidity

Humidity sensing is important in numerous industries such as food, petroleum, textiles, ceramics, and many others.[101] Optical-based detection via color change offers the most attractive way for detection of humidity without complex system configuration and tuning in comparison to other sensing mechanisms.[102] Photonic crystals fabricated by the colloidal method form a cubic close packed ordered structure. As the structure diffracts light, it exhibits a stop band in its transmission spectrum. Photonic crystal (PC) hydrogels are widely used in optical-based sensing devices due to the high sensitivity.[103–105] The color change feature of PC hydrogels to water endowed it as a promising candidate to act as a humidity sensor.

A humidity-sensitive PC hydrogel was prepared by infiltrating acrylamide (AAm) solution into a P(St–MMA–AA) PC template and subsequent photopolymerizing.[103] Owing to the intrinsic humidity-sensitive property of acrylamide, a broad range of humidity (from 20 to 100%) could be observed by obvious color changes. This was attributed to the humidity sensitivity of the sample's stopband. The color changes and optical properties were also investigated by UV–vis spectroscopy. The stopbands of the PC hydrogels shift to different values with regard to exposed humidity (Figure 8).

A different photonic crystal-based sensing system was reported by Kang and colleagues.[106] They prepared responsive photonic crystal hydrogel based on amphiphilic poly styrene-*b*-quaternized poly(2-vinyl pyridine) block-copolymers. This structure forms a single 1D periodic lamellar structure resulting in a responsive photonic crystal gel structure. The glassy hydrophobic layer forces expansion of the hydrophilic layer along the layer normal, yielding extremely large optical tunability through the changes in both layer thickness and index of refractions. The wavelength for this system was changed 575% (λ_{peak}= 350–1600 nm) in the position of the stopband.

Barry and coworkers reported the detection of humidity via polyacrylamide-based inverse opal hydrogels (IOH).[107] These smart materials have the capacity to respond to humidity changes by shifting its optical reflection peak noticeably within the visible wavelength range due to interlayer swelling and shrinking of the structures. With increasing humidity, equilibrium-swollen hydrogels absorb more water from air to restore equilibrium conditions. This volume change results in shifting the refractive spectrum. These IOH structures exhibited reflectance spectra with highly differentiable peaks due to their layered structure and Bragg reflection properties.

Galindo and coworkers reported another optical-based system for humidity detection.[108] They encapsulated fluorescent flavylium salts in a poly(2-hydroxylethyl methacrylate) (PHEMA) network matrix. Synthetic flavylium salts are a family of compounds possessing almost the same backbone as that

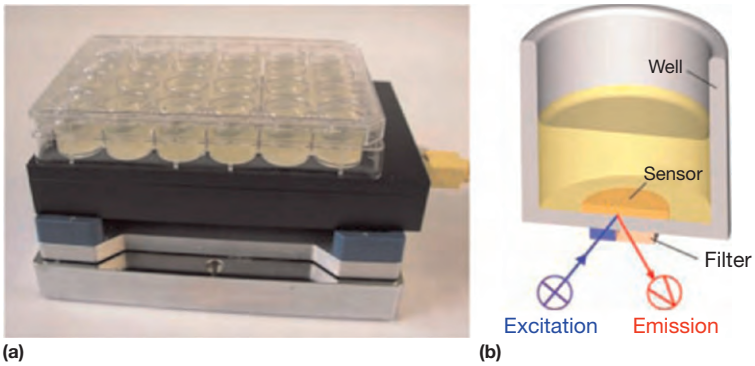

Figure 7 24-channel SensorDish® Reader on the shaker (a) and cross-section of a well of a microplate with included sensor at its bottom (b). of anthocyanin which is the pigment responsible for plant coloration. Flavylium salts are strongly colored and display a fluorescence emission that is quenched by water for synthetic flavylium salts possessing hydroxyl substituents. This is due to the presence of efficient intermolecular excited state proton transfer (ESPT) to water and opens the use of these molecules for humidity sensing. By this, swelling and deswelling of hydrogels at relative humidities between 7% and 100% could be measured by fluorescence decay times of the flavylium salts.

3.329.3. Biochemical Sensing Mechanisms

This paragraph concerns sensing based on biochemical mechanisms. At first, sensing based on molecular interactions is discussed, followed by a paragraph about 'living' sensors where bacteria or cells that are immobilized in or on hydrogels generate the signal that is used for sensing.

3.329.3.1. Molecular Interactions

3.329.3.1.1. Enzyme–substrate interaction

Enzymes are highly specific and efficient in their reaction with substrates. They act as catalysts by lowering the activation energy of chemical reactions. Therefore, in first approximation, the substrate is in a first step forming a complex with the enzyme by docking into the highly selective active pocket of the enzyme. This enzyme–substrate complex represents the reactive transition state of the reaction in which the substrate is activated. After the subsequent chemical reaction, the product is released and the enzyme is restored in its functional conformation. If the concentration of the substrate is sufficiently high, the catalyst is saturated with substrate and the reaction is only determined by the rate of conversion from the substrate to the product. This results in a pseudo-first-order kinetic of the reaction with regard to the concentration of the enzyme according to eqn [10] (Michaelis–Menton equation), where v is the rate of the reaction, k_{cat} the rate constant of the catalyzed reaction, K_m a constant that comprises k_{cat} and the rate constant for the enzyme–substrate complex formation, $[E_0]$ the starting concentration of the enzyme, and [S] is the concentration of the substrate.

$$v = \frac{k_{cat} \cdot [E_0] \cdot [S]}{K_m + [S]} \qquad [10]$$

In reality, often more complex reaction schemes such as multiple binding and allosteric rearrangements occur, in which the affinity and enzymatic activity is different for the consecutive binding events. However, the mathematical description of these processes is comparable. In any case, this brief introduction into enzyme activity and enzyme kinetic shows that enzymatic activity may be used for precise determination of analyte concentrations. In the following sections, a variety of different analytes that have been detected through enzyme substrate interaction in hydrogel matrices are presented and discussed.

3.329.3.1.1.1. Alcohol

Wu *et al.* developed an organic-phase alcohol biosensor by coentrapping alcohol oxidase and horseradish peroxidase within an ionotropic polymer hydrogel matrix fabricated from silica gel particles.[109] By entrapping the enzymes into the hydrogel matrix, it was possible to maintain a biocatalytic reaction at high and stable rates for an online detection of methanol in *n*-hexane under flow operation mode. The analytical working range of the sensor was 2.3–90 mM methanol in *n*-hexane with an operational biosensor-lifetime of more than 45 assays and a shelf lifetime longer than 2 weeks.

3.329.3.1.1.2. Amino acids

An L-glutamate sensor based on a bienzyme redox PVI19-dmeOs/poly(ethylene glycol)(400)diglycidyl ether (PEGDGE) hydrogel was developed by In Castillo *et al.*[110] The sensor was capable of detecting the release of this excitatory neurotransmitter from adherently growing HN10 and C6 cell cultures upon stimulation. Monitoring was utilized using an electrode modified with the bienzyme redox hydrogel at an applied potential of −50 mV versus the internal Ag reference electrode. The detection limit, 0.5 μM, and the response time of the sensor, 35 s, satisfied the experimental requirements of cell culture base experiments.

3.329.3.1.1.3. Ammonia

Kwan *et al.* constructed a bienzyme sensor for the amperometric determination of ammonium (NH_4^+) by immobilizing glutamate oxidase and glutamate dehydrogenase on a clark-type oxygen electrode.[111] To guarantee the catalytic activity, the enzymes were entrapped in a poly(carbamoyl) sulfonate hydrogel matrix. The sensor has fast response (2 s) and short recovery times (2 min), a linear detection range between 10 and 300 μM ammonium and a detection limit of 2.06 μM.

3.329.3.1.1.4. Glucose

On account of the increasing numbers of diabetes patients, the demand for smart glucose sensing systems has grown more and with this the effort to utilize hydrogels for glucose sensing applications. Before concentrating in more detail on hydrogel-biosensor systems that are used for glucose sensing, we would like to draw the reader's attention to the review 'Chemically controlled closed-loop insulin delivery' by Ravaine *et al.* published in 2008.[112] This review focuses on glucose-responsive hydrogels and gives a good overview of the hydrogel systems that are either modified, for example, by glucose oxidase, lectin, and phenylboronic acid moiety, release insulin, or swell/shrink in the presence of glucose. Thus, we want to focus on the major strategies for enzyme-based glucose sensing and on some recently published studies.

One of the most conventional methods to detect glucose levels is the use of enzyme systems like glucose oxidase (GOX)[113,114] or glucose dehydrogenase.[115] For example, when glucose oxidase is immobilized in a pH-sensitive hydrogel matrix, the oxidation reactions from glucose to gluconic acid will force the hydrogel to swell. The swelling of the hydrogel can then be sensed by mass-sensitive magnetoelastic sensors.[116] Kim *et al.* described a micropatterning technique to immobilize proteins on the surface of 3D PEG-based hydrogel microstructures that could be used for hydrogel-biosensor applications.[117] Therefore, hydrogel microstructures were fabricated by replica molding using a poly(dimethylsiloxane) (PDMS) replica as a molding insert and photolithography. Bovine serum albumin

(BSA), a model protein, was covalently immobilized to the otherwise protein-repellant surface of the hydrogel structures. The empty space inside hydrogel microstructures could be occupied by different proteins, and sequential bienzymatic reaction of glucose oxidase and peroxidase (POD) could be demonstrated in a hydrogel microstructure by immobilizing the GOX on the surface of the POD-entrapping hydrogel microstructure.

In 2009, Merchant *et al.* built a high-sensitivity reagentless amperometric biosensor based on ferrocene-modified linear poly(ethylenimine).[118] A double function biosensor for glucose and hydrogen peroxide has been built by immobilizing GOX and horseradish peroxidase (HRP) in cross-linked films of ferrocene-modified linear poly(ethylenimine). Ferrocene was involved as a mediator of electron transfer to the electrode surface. Current densities ~4 times higher than those obtained with other ferrocene-based redox polymers could be achieved. This sensor generated a limiting catalytic density of 1.2 mA cm^{-2} which is the highest known density ever reported for redox polymers with GOX at pH 7. Owing to the very high sensitivity (73 nA cm^{-2} μM^{-1}) of the system, it was possible to detect glucose concentrations in the micromolar range.

3.329.3.1.1.5. Hydrogen peroxide

Hydrogen peroxide is the product of reactions of oxidative metabolism catalyzed by oxidases and its detection is prominent in environmental, clinical, and biological studies due to its applications in many industrial processes as an oxidizing, bleaching, and sterilizing agent.[119] A lot of work has been done for the determination of hydrogen peroxide via different methods like titrimetry, electrochemistry, and UV spectrophotometry.[120] Peroxidases (POD) are generally used in these constructions to convert hydrogen peroxide into radicals. The sensitivity of the determination of hydrogen peroxide via peroxidase enzyme depends on the ability of the immobilizing matrix to retain the functional conformation of the enzyme for a long time. Through the last decade, an impressive number of inventive designs for hydrogen peroxide determination have appeared. Here, we focus on some illustrative example studies of hydrogel-based hydrogen peroxide detection, generally based on the electrochemical sensing system.

The detection of H_2O_2 is based on the intracellular optical sensor reported by Kim *et al.*[121] They established optical nanosensor based on PEG hydrogel spheres containing the enzyme horseradish peroxidase (HRP) for hydrogen peroxide detection. HRP was encapsulated in PEG hydrogel spheres by reverse emulsion photopolymerization without losing activity. Afterward, the fluorescence emission response of these hydrogel spheres changed as a function of H_2O_2 concentration in the presence of Amplex Red, and no leaching of HRP was observed from the spheres. The HRP-loaded hydrogel spheres were introduced via phagocytosis inside macrophages and were found to respond to both exogenous and endogenous sources of oxidative stress.

Varma and Mattiasson developed a simple amperometric biosensor for the detection of hydrogen peroxide in aqueous and organic solvents.[122] Therefore, they entrapped catalase in 30% polyacrylamide gels and created a two-electrode system. By studying the kinetics of the catalase-modified electrode by cyclic voltammetry (CV) and coupling it to a flow injection analysis (FIA) setup, it was possible to create a sensing system that could monitor a broad range of hydrogen peroxide concentrations (0.5–100 mM) in different solvents. As mentioned previously, amperometric detection of H_2O_2 has been achieved via immobilization of HRP in cross-linked films of ferrocene-modified linear poly(ethylenimine).[118] When a small amount of H_2O_2 was added to the solution, oxidation peaks disappeared and reduction peaks increased due to an increase in redox polymer mediation of the HRP-catalyzed reduction of H_2O_2.

A new-type sol–gel/hydrogel composite-based hydrogen peroxide biosensor based on silica sol and a graft copolymer of poly vinyl alcohol with 4-vinyl pyridine was fabricated by Wang *et al.*[123] The film was characterized by FT-IR spectroscopy and optimum analytical performance was obtained depending on the pH and electrochemical behavior of the biosensor using potassium hexacyanoferrate(II) as a mediator. This system exhibited high sensitivity (15 $\mu A\,mM^{-1}$) and a low detection limit of 5×10^{-7} M.

Optical-based local detection of H_2O_2 secreted by stimulated macrophages was performed using an enzyme-based biosensor by Yan *et al.*[124] Photolithographic patterning of hydrogel based on PEG with incorporation of horseradish peroxidase (HRP) applied to construct microstructures, use as sensing agent (**Figure 9**). They used a special organic molecule, called Amplex Red, which became fluorescent in the presence of H_2O_2 and HRP, and was either immobilized inside hydrogel elements alongside enzyme molecules or added into the cell culture media during cell activation. The production of H_2O_2 after mitogenic stimulation of macrophages resulted in the appearance of fluorescence in the HRP-containing hydrogel microstructures.

3.329.3.1.2. Antibody–antigen

Antibody–antigen-based sensors are affinity-based devices with a coupling of immunochemical reactions.[125] The general working principle of this sensor is based on the specific immunochemical recognition of antibodies (or antigens) immobilized on a transducer to antigen (or antibodies), which produce signals that depend on the centration of the analyte. Antibody–antigen-based detection of target molecules has gained attention in the last three decades due to its high specificity and low detection limit.[126] Antibody–antigen sensing has become an increasingly practical and useful tool in biotechnology.[127]

Detection in antibody–antigen sensing system can be performed in different ways. One of the widely used techniques is quartz crystal microgravimetry with dissipation (QCM-D) which provides real-time immunoassay capability. QCM is a detection method that quantifies the decrease of the resonant frequency of the crystal when the mass increases when antigen binds to immobilized antibodies. Dissipation measurement provides additional information about the viscoelasticity of the surface, which can increase with antigen binding. This technique is widely used in immunoassay applications because of high sensitivity. Tabrizian and coworkers prepared and used low-molecular-weight polyethylneimine (PEI) and carboxymethylcellulose (CMC), and covalently immobilized antibody by cross-linking between carboxymethyl groups of CMC and succinimide esters generated on the antibody.[128] This hydrogel-interface has been evaluated with detection of cytokines rhIL-1ra, rhIL-6, and rhiL-18BPa antigens. Increasing the

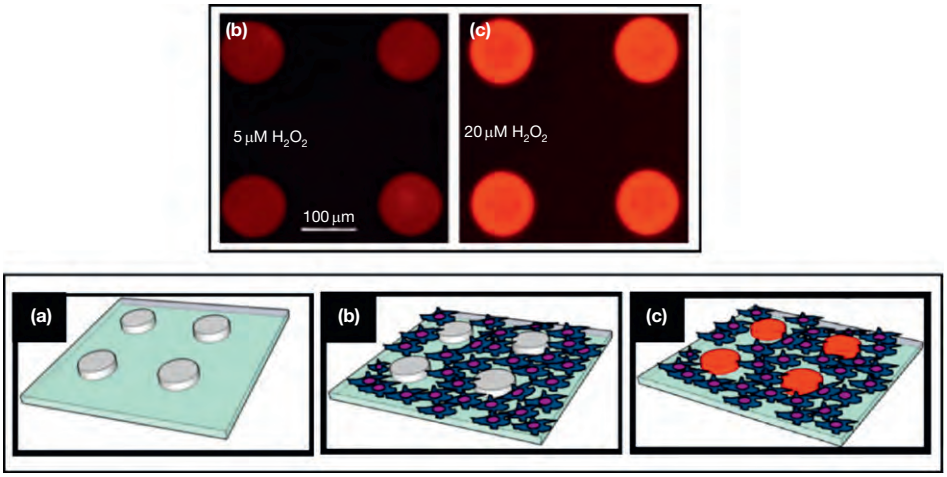

Figure 9 Top: Fluorescence images of hydrogel microstructures after 5 min incubation with 5 μM H_2O_2 (b) and 20 μM H_2O_2 (c) in the presence of Amplex Red. Bottom: Culturing cells with sensing hydrogel micropatterns. HRP-containing PEG hydrogel micropatterns are fabricated on glass substrate (a), encapsulation of enzyme molecules does not diminish cell-resistive properties of PEG hydrogel. When incubated with micropatterned substrates, macrophages attach next to sensing hydrogel structures (b) and macrophages release H_2O_2 upon mitogenic stimulation (c). Reproduced from Yan, J.; Sun, Y.; Zhu, H.; Marcu, L.; Revzin, A. *Biosens. Bioelectron.* **2009**, *24*(8), 2604–2610, with permission from Elsevier.

CMC concentration leads to higher antibody immobilization with decreasing nonspecific binding. At optimum conditions, this system gives a detection limit as low as 400 ng ml^{-1} for a 44 kDa antigen. Another study was performed by the same group using specific antibody capture ligands such as protein A, protein G, and anti-IgG Fc for oriented antibody immobilization and higher frequency QCM-D crystals to increase the detection limit.[129] In this case, the detection limit with the new technique increased to 25 ng ml^{-1} on 5 MHz crystals. Reduction of nonspecific adhesion for this method was shown with incorporation of PEG into this biointerface.[130] A different methodology used by Chen and colleagues is based on the periodate-oxidized dextran layer.[131] *Staphylococcus aureus* protein A (SpA) was immobilized on the poly-L-lysine-modified piezoelectric crystal surface to improve its stability, activity, and binding specificity with human immunoglobulin G (igG) in flow injection assays. The prepared sensing crystal shows best sensitivity and reusability at a flow rate of 140 μl min^{-1} with a detection limit as low as 0.2 nM with the proposed system.

Similar in function to QCM, surface plasmon resonance (SPR) is an established method for the label-free detection of biomacromolecular interactions. SPR uses evanescent waves to examine the surface. Analyte binding leads to a change in refractive index at the sensing surface influencing resonant angle and shifting to generate real-time signal.[132] SPR allows measurements in real time with high precision and repeatability and provides some advantages over other techniques. These are (i) The amount of complex at equilibrium is measured in the presence of unbound reactant without disturbing the reaction equilibrium, (ii) the stability of the immobilized ligand can be monitored by tracing the surface binding capacity and the baseline stability, and (iii) the low amount of material for analysis.[133] As for QCM, the surface of SPR sensors should be antiadhesive to unwanted compounds and interact specifically, and hydrogels have been used for this purpose.

Guidi and coworkers studied the detection of insulin-like growth factor-1 (IGF-1), a suspected carcinogen, in cow milk via SPR-based sensing system.[134] Hyperimmune polyclonal anti-IGF-1 antibodies were immobilized to detect IGF-1 due to its specific binding capacity. The amount of native IGF-1 in fresh raw milk was detected down to 4 ng ml^{-1} which is parallel to the study of Collier *et al.*[135] Another SPR-based sensing was used for the detection of prostate-specific antigen.[136] Anti--PSA antibodies were coupled covalently to the gel sensor disk that can detect PSA molecules with a concentration of 0.15 ng in 1 ml, which is a sufficient detection of physiological (<4 ng ml^{-1}) and clinical (4–10 ng ml^{-1}) PSA levels. A different study was reported for the detection of apolipoprotein B100 sensitivity to ten different monoclonal antibodies (mAbs, all IgG_1). Sensitivity was evaluated in terms of different structure recognition. The detection of recombinant human interferon-γ (IFN-γ) with SPR in plasma was reported by Stigter *et al.*[137] To test nonspecific adsorption of plasma components, numbers of SPR coatings were evaluated. Nonmodified dextran-coated SPR disks were the best candidates for the detection of IFN-γ in plasma with a lower detection limit of 150 ng ml^{-1}.

SPR-based sensors are also used for the detection of steroids. In a typical sensor, real-time detection of pair steroids, cortisol and cortisone, in saliva and urine was carried out using surface plasmon resonance-based immunosensor.[138] A polycarboxylate-based hydrogel layer was used for immobilization of the antibodies, anticortisol, and anticortisone. These antibodies are very specific for cortisol and cortisone and contribute to high specificity of the sensor without binding other steroids like testosterone, epitestosterone, and corticosterone. The layer exhibited a high degree of stability over time during repeated regenerations. Saliva and urine sources were selected due to the presence of a low amount of cortisol and cortisone in comparison to the 100-fold higher concentration in the blood. The detection limit of both steroids in saliva and urine samples was less than 10 μg l^{-1} which is sufficient sensitivity for both clinical and forensic use.

A novel immunosensing system for determination of human α-ferroprotein (AFP) was established using a

boronate immunoaffinity column via flow injection chemoluminescence. Sugar boronic acid was used to immobilize AFP antigen through the sepharose matrix. The mixture of the analyte AFP and horseradish peroxidase-labeled AFP antibody (HRP–anti-AFP) was injected into the column. The free HRP–anti-AFP was trapped by the immobilized antigen in the column and detected via chemoluminescence due to its sensitivity effects on the reaction of luminol and hydrogen peroxide.[139]

As a different method, 3D hydrogel thin films were used to protein binding (antigenicity) and antibody functionality in a microarray format.[140] Protein antigenicity was evaluated using the protein toxin, staphylococcal enterotoxin B (SEB). Cy3-labeled antimouse IgG (capture antibody) was microarrayed onto the hydrogel surfaces and interrogated with the corresponding Cy5-labeled mouse IgG (antigen). Lee *et al.* introduced an elastic and hydrophilic composite mold, which enables the transfer of hydrophilic polar ink such as polyelectrolyte multilayer.[141] The mold is composed of a urethane-related commercial polymer and PEG diacrylate (PEGDA), which forms a hydrogel upon its reaction with a photoinitiator. The group established a simple strategy for immobilizing antibodies exclusively inside the microreservoirs of the patterned composite mold, which made the system suitable for biosensing applications. A first try regarding the detection of *Escherichia coli* O157:H7 was explored.

Electrochemical-based sensing is also used in antibody–antigen sensors for the detection of IgG. In one case, a redox hydrogel-coated carbon electrode with avidin incorporated into the hydrogel was employed.[142] Avidin was conjugated with biotin-labeled antirabbit IgG. After exposure the tested solution to capture of IgG, the sandwich-assay was completed by conjugation of horseradish peroxidase (HRP)-labeled antilabeled IgG. Electrical contact between the HRP and the electrode-bound hydrogel resulted in formation of an electrocatalyst for the electroreduction of H_2O_2 to water. The detection limit with this method was as low as $3\,ng\,ml^{-1}$. The other electrochemical-based sensing was performed by using a 3D porous chitosan network as a matrix for hepatitis B surface antibody (HBsAb).[143] The porous network was prepared by electrodepositing a designer nanocomposite chitosan solution with an encapsulated silica nanoparticle as a hybrid film on an ITO electrode, followed by removal of the silica nanoparticles with HF solution. HBsAb was covalently immobilized to the hydrogel network for the detection of hepatitis B surface antigen. A novel label-free electrochemical detection method of ractomine was developed by Shen *et al.*[144] Ractopamine-bovine thyroglobulin antigen was incorporated into an agarose hydrogel film on a glassy carbon electrode. The $K_3Fe(CN)_6/K_4Fe(CN)_6$ redox probe system was used to translate the binding to an electrochemical signal with addition of the polyclonal antibody against ractopamine. Using a similar mechanism and a same hydrogel layer with a different antibody, the detection of the ferritin molecule was performed by immobilizing the ferritin antibody (FeAb) on the electrode.[145] CV and differential pulse voltammetry (DPV) were used for the conversion of signal to electrical output. The detection limit of ferritin with this method was $1.5 \times 10^{-5}\,g\,l^{-1}$ and the linear range was $5–50 \times 10^{-5}\,g\,l^{-1}$.

3.329.3.1.3. DNA and oligonucleotides

The detection of nucleic acids has become increasingly prominent in diagnostics systems due to its crucial role in a wide range of areas, including genetic diagnostics, monitoring of infectious bacteria, forensics, and basic research.[146] Besides simplicity, DNA-sensing systems require high selectivity to be able to detect single-nucleotide polymorphism (SNPs) and high sensitivity to enable sensing of only a few hybridization events of corresponding small amounts of target DNA fragments.[147,148]

Many groups dedicated their work on the detection of DNA via electro- or optical DNA sensors.[149–153] Generally, DNA-sensors work in three main steps: (i) immobilizing the oligonucleotide probes on the substrate, (ii) hybridizing with incorporation of target sequences through base-pairing interactions, and (iii) readout.[154,155] Fluorescence, electrochemical,[156,157] optical,[158] electrical,[159] and microgravimetric-based systems[158] are widely used for the detection of DNA concentrations down to 10^{-18} M. The key factor of high-throughput DNA analysis technologies, such as DNA microarrays, is the efficiency of the immobilization of nucleic acid fragments. This efficiency plays an important role in determining the accuracy and sensitivity of the detection. On account of their hydrophilic 3D nature and flexible structure, hydrogels can mimic the native environment of nucleic acid fragments and can keep them thermodynamically more stable. These characteristics offer important advantages for capturing probes in comparison to 2D rigid substrates and self-assembled monolayers. Here, we present the currently used hydrogel-based techniques for the detection of DNA and oligonucleotides by outlining some of the key studies. For general DNA-sensing methods including non-hydrogel-based systems, we would like to draw the reader's attention to the reviews 'Recent advances in DNA sensors' by Cosnier *et al.* in 2008,[160] 'Electrochemical DNA sensors' by Drummond *et al.* in 2003,[161] and 'Target-responsive structural switching for nucleic acid-based sensors' by Li *et al.* in 2010.[162]

Cantilevers are a widely used example for sensors that detect DNA with high sensitivity and selectivity. A cantilever is a small rectangular monocrystalline silicon tip of less than $1\,\mu m$ thickness.[163] By applying a thin hydrogel layer, it is possible to immobilize the sensing molecules for a long time without denaturing the structure as well as preventing nonspecific adhesion. These microstructure-based sensing systems can be used in various environmental conditions such as vacuum, liquid, and air having high sensitivity and direct transduction mechanism without the need for any labeling. The immobilization of target-selective receptors on the cantilever makes it possible to identify analyte molecules by means of changes in surface tension. The change in surface tension will lead to a bending of the cantilever and can be sensed by optical laser detection or capacitance changes.[164] This sensing method is widely used to detect DNA using hybridization assays with high sensitivity, as illustrated in **Figure 10**. Each cantilever is coated with an oligonucleotide-functionalized hydrogel layer. Subsequently, hybridization is performed by incorporation of complementary sequences, resulting in bending of the cantilever because of changes in surface tension. As a last step, after rinsing the oligonucleotides with an unbinding agent, the cantilever turns its first place and an optical detection system is used for detecting the bending of the cantilever.

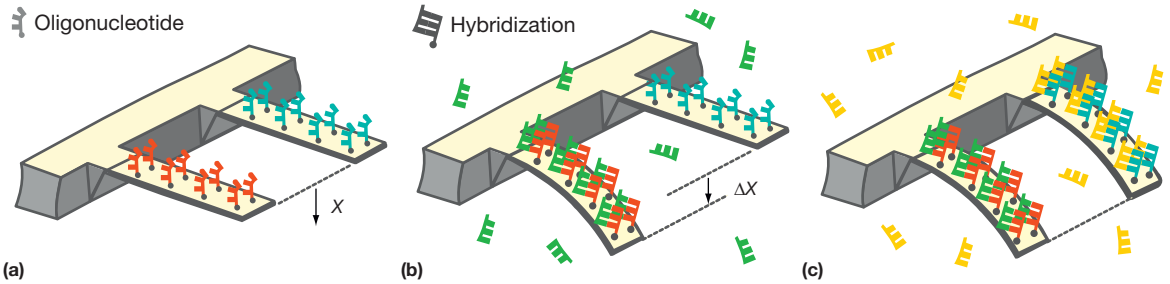

Figure 10 Scheme of the cantilever-array DNA sensor. (a) Refers to the immobilization of ssDNA probes to the cantilevers, (b) refers to hybridization of ssDNA probes with incorporation of the first complementary target strands, and (c) refers to injection of the second complementary oligonucleotide, respectively. In one case, chitosan film electrodepositing onto cantilever was reported for the detection of nucleic acid hybridization in solution (static) and air (dynamic).[165] Therefore, an electrodeposited chitosan film was biofunctionalized with oligonucleotides. These probes then detected target DNA hybridization by static mode (in solution) and dynamic mode (resonant frequency shift in air) on a cantilever construction, as illustrated in Figure 11.
