For the dynamic mode, the resonant frequency shift was measured in air before and after the bimolecular detection event and in the presence of the analyte. In the static mode, the bending of the cantilever was measured in solution before and after the bimolecular event and then in the presence of the analyte. Static measurements in solution demonstrated the DNA hybridization on the chitosan-bound complementary probe. The dynamic measurements in air revealed that the surface density of oligonucleotides was two orders of magnitude larger than the comparable results obtained by probes tethered to SAMs. This was a result of the higher probe concentration in the 3D hydrogel network structure in comparison to the 2D self-assembly monolayer.

The detection of oligonucleotides can also be performed via very simple methods like bioactive papers. Biomolecule-modified papers are used for the detection of biomolecules with a simple mechanism. On account of their inexpensive, sensitive, and robust structure, they are used for detection assays that do not require any instrumentation. A simple bioactive paper-based detection of DNA was reported by Su and colleagues.[166] They used paper stripes printed with carboxylic PNIPAm microgels modified by either an antibody or DNA aptamer. The modification of PNIPAm microgels with vinyl acetic acid groups makes them possible candidates for bioconjugation. Therefore, DNA aptamers were coupled with the carboxylic groups by bioconjugation and then immobilized on the bioactive papers without losing biorecognition activity. The immobilized microgels were used as biosensing elements to detect the target molecule. The working principle of the proposed technique is illustrated in Figure 12.

Another method, used for the detection of adenosine triphosphate (ATP), utilized a structure-switching fluorescent DNA aptamer. The selectivity of the method has been proved by a higher fluorescence level for ATP compared to that of guanosine triphosphate (GTP). The simplicity of the system makes it attractive for a wide range of sensing applications. A novel methodology was developed for the detection of fluorometric DNA hybridizations and was based on noncovalent coupling of DNA to a water-soluble zwitterionic polythiophene derivative.[167] Therefore, 3-[(*S*)-5-amino-5-carboxyl-

3-oxapentyl]-2,5-thiophenylene hydrochloride (POWT) hydrogel has been cross-linked with cross-linker ssDNA on a polystyrene surface. POWT is the first polyampholytic conjugated polythiophene example, used for the detection of biospecific interactions.[168–171] The zwitteronic side chain of polythiophene forms a complex with polyelectrolytes like DNA via hydrogen bridges exhibiting the anionic or cationic behavior upon pH. In this method, the incorporation of complementary ssDNA fragments resulted in a planar polymer and an aggregation of the polymer chains. This induced a decrease in intensity and a red-shift of the fluoresecence. The proposed method can detect a single-base mismatch in five minutes by means of fluorescence without any denaturation step. The schematic illustration of the POWT/dsDNA complex formation and fluorescence picture of POWT/DNA complex are illustrated in Figure 13. This method has a lower detection limit for DNA hybridization of 10^{-11} M.

DNA microarrays, integrated into optofluidic hybridization systems, are widely used in the field of DNA detection. In one case, a DNA hybridization construct was designed based on microchannels in combination with UV-cross-linked hydrogels and photolithography-defined weirs.[172] ssDNA probes modified microbeads were immobilized in the microchambers and used to capture the complementary target sequences. The transport of complementary DNA target solution was provided by an electrophoretic transport (hydrogel switch open). Subsequently, hybridized DNA targets could be isolated via the weirs using pump-driven pressure (hydrogel switch

closed). Biotin-labeled ssDNA probes were immobilized on the microbeads and coated with strepavidin. Hybridization reactions were conducted by moving the targets across the array of probe-containing microchambers by electrophoresis. The hybridization of flourescein-labeled ssDNA targets to complementary probes was observed by fluorescence microscopy. In 1 min, 90% of the DNA were captured and could sequentially be released and recovered. A different approach in which encoded hydrogel particles were used to detect DNA hybridization has been studied.[173] Encoded particles, consisting of a semi-interpenetrating PEG network with tunable porosity, were prepared by UV cross-linking. The particles were fabricated using flow lithography and then immersed into a solution containing oligonucleotides at unknown concentrations. The dispersion was scanned for fluorescence in a flow-through device and the corresponding fluorescent targets were quantified. Meiring and colleagues used a sensor array platform to detect DNA hybridization.[154] The proposed method was based on a multianalyte sensor array platform which consisted of analyte-specific features that were indexed by shape. The array has been fabricated by soft-lithography using a PEG acrylate hydrogel. Fluorescently tagged methacrylamide-modified oligonucleotides were copolymerized into the hydrogel matrix. The covalent attachment of the ssDNA probes to the matrix was verified by two different DNAs, with and without a polymerizable methaacrylamide group. Each target sequence was dyed with a different fluorophore and retained the ability to hybridize selectively to the designated targets because of the nonadhesive nature of the PEG. Each hydrogel array contained different DNA probes and was incubated in the solution of three-different target sequence mix. After the hybridization, the hydrogels were rinsed with buffer to remove the unbound samples. One bright field and three fluorescence micrographs were captured; each micrograph was obtained using a specific optical filter set for one of the three-different target fluorophores (**Figure 14**).

By using surface-immobilized DNA structures with appropriate redox labels, it is possible to monitor the target-induced structural switching of DNA or aptamer-specific small molecule probes. This is done by measuring electrochemical currents which are directly associated to the distance between the redox label and the electrode.[146] In one case, an enzyme-amplified amperometric DNA hybridization was performed by Hajdukiewicz and colleagues.[174] The proposed method is based on solution-phase ferrocemethanol mediation of glucose oxidase. The carboxlymethylated dextran layer, containing ssDNA probes, was attached to the surface via amine groups. Using a ferrocenemethanol electron mediator, the hybridization of ssDNA probes to biotinylated-ssDNA and addition of glucose oxidase–avidinD conjugate led to a signal current. To analyze the signal current, the group used cyclic voltammetry and achieved a detection limit of 0.2 nmol in a 500-µl sample utilizing a graphite electrode. Most hydrogel-based electrochemical DNA sensors are based on nanoscale interactions between targets in solution, the recognition unit, and a hydrogel-coated electrode surface.

DNA sensors can also be used to detect gene mutations. One example for this application is the highly sensitive detection of a K-ras point mutation in codon 12, pancreatic cancer, based on DNA-carrying hydrogel microspheres.[175] The G–G mismatch in codon 12 of the *K-ras* gene leads to a mutation and seems to be a reason for pancreatic cancer. Hence, the detection of a single mismatch has crucial importance for early diagnosis of genetic disorders. The detection of this single mismatch was performed using hydrogel microspheres, which provided a high flexibility to DNA fragments. The hydrogel microspheres were synthesized by precipitation polymerization. To detect the mutation in the sequence, a hydrogel-enhanced sandwich method of a SPR assay was used. The use of the DNA-carrying microspheres enhanced the SPR response as a result of an increased dielectric constant.

3.329.3.1.4. Other binding mechanisms

3.329.3.1.4.1. Biotin–streptavidin

Responsive hydrogel-based microlenses can change their optical properties upon volume phase transitions in the presence of stimuli. They can be easily constructed in simple and rapid fashion with high sensitivity.[176] In hydrogel microlenses, the stimulus induced phase transition changes the focal lengths that causes a focusing or defocusing of the projected image.[177] Most studies in the literature concerning hydrogel microlenses

for biosensing have been performed by Lyon and coworkers. In one case, a bioresponsive hydrogel construct was developed to investigate the specific and nonspecific adsorption.[178] Poly(*N*-isopropylacrylamide-*co*-acrylic acid) (PNIPAM-*co*-AAc)-based bioresponsive microgels were prepared by incorporation of both biotin and aminobenzophenone (ABP) as a photoaffinity label via carboimide chemistry. Functionalization with ABP allows for photochemical tethering of antibiotin after it is associated to the microlens through native antibody–antigen association. Hydrogel microlenses were generated by electrostatic assembly of anionic microgels on positively charged, silane-modified glass substrates. Two different routes were used for determination of the specific and unspecific binding. In the first route, the hydrogel microparticles were functionalized with biotin with EDC coupling, whereas in the second route, these particles were functionalized with biotin-ABP via EDC and DCC coupling. With a secondary IgG exposure, specific/ancillary binding effects were investigated via bright-field and fluorescence microscopy. Biotin and polyclonal anti-biotin-sensitive hydrogel microlenses were constructed using the same microlens approach as shown in Figure 15.[176]

First, PNIPAm-*co*-AAc hydrogel particles were prepared by the free-radical precipitation polymerization method (Figure 15(a)). Then, biotin was incorporated into hydrogel particles via EDC coupling (Figure 15(b)), followed by formation of cross-links in the hydrogel by multivalent binding of avidin to biotin and antibiotin to biotin provided on the hydrogel microlenses (Figure 15(c) and 15(d)), respectively). Multivalent binding of both avidin and polyclonal antibiotin was determined by monitoring the optical properties via a bright-field optical microscopy. The same group developed a new method, label-free biosensing by combining antibody–antigen cross-linked hydrogel microlenses, to use for the detection of small molecules with a tunable sensitivity.[179]

Piezoelectric biosensors have widely been used for affinity interaction.[180] In one case, hydrogel-coated streptavidin piezochips were used for the physical and chemical immobilization of streptavidin molecules. Subsequent biosensing of biotinylated bovin serum albumin (BSA) revealed a higher binding capacity for the covalently immobilized streptavidin. Another PZ sensor was used for the detection of poly His-tagged proteins using nitrilotriacetic (NTA) captured oxidized dextran hydrogel layer.[181] The binding of chelating ions, Co^{2+}, Cu^{2+}, and Ni^{2+} was investigated with regard to binding to poly His-tag proteins. Ni^{2+} exhibited the highest binding capability to detect poly His-tag-gel proteins.

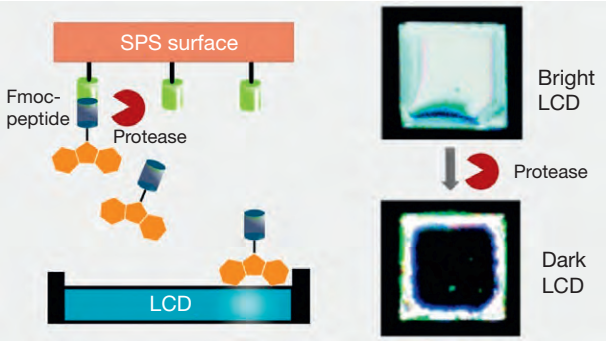

Figure 16 Schematic representation of the sensor chamber in combined SPS–LCD protease. Redrawn from Birchall, L. S.; Ulijn, R. V.; Webb, S. J. *Chem. Commun.* **2008**, 2861–2863, with permission from The Royal Society of Chemistry.

A hydrogel-based sensor for monitoring protease activity has been constructed by combining a versatile solid-phase synthesis (SPS) with the simplicity of liquid crystal display (LCD).[182] In this study, PEG acrylamide (PEGA) was used as SPS support for immobilization of peptide sequences that are specifically recognized and cleaved by proteases. In the presence of proteases, the respective peptides were cleaved with high specificity, resulting in their release from the hydrogel and interaction with the LC surface. This leads to a realignment in the liquid crystalline layer and thus to optical changes from bright to dark. Hence, this method offers the screening of protease specificity by the eye without the need for any special complex instrumentation (Figure 16).

Lee *et al.* created a micropattern on the PEG hydrogels through graft polymerization and photolithography for the

detection of strepavidin binding to an avidin-modified hydrogel layer.[183] Surface modification of the antiadhesive PEG hydrogel layer was performed by grating PAA via photoinduced surface-initiated polymerization with benzophenone as photoinitiator. Biotinyl-3,6,9-dioxaoctanediamine (biotin–NH_2) was coupled to the PAA micropattern via EDC/NHS-coupling. Specific binding between biotin and streptavidin was used for evaluation of new PAA-modified PEG surface.

3.329.3.1.4.2. Calmodulin-based sensing

Daunert and coworkers reported a new hydrogel microlens system that can change optical properties via ligand exchange.[184] Protein calmodulin (CaM) was used as a model hinge-motion binding protein for the chemical tunability of the microlenses. CaM was chemically bound to the hydrogel network as well as its low-affinity ligand phenothiazine. The recognition between CaM and phenothiazine led to a further increase in cross-linking density. However, in the presence of a high-affinity CaM ligand like chlorpromazine (CPZ), an exchange between phenothiazine ligand and CPZ occurs and thus leads to a decrease in cross-linking. In consequence, the hydrogel is swelling and the refractive index decreases. This ability of volume change in response to a (bio)chemical stimulus allows its uses as chemically tunable microlenses.

3.329.3.1.4.3. Carbohydrate recognition by boronic acids

Besides the already mentioned enzyme receptors, synthetic glucose receptors like phenylboronic acids have also been intensively studied for glucose sensing.[185–188] The sensing effect of phenylboronic acid is based on the fact that the molecule becomes negatively charged upon sugar binding, which then can generate an osmotic pressure due to the resulting Donnan potential.[189] This results in a swelling of the hydrogel that can be easily sensed. Asher's group worked intensively on this field and did some pioneering work by applying a crystalline colloidal readout between glucose and phenylboronic acid.[186,190] When an analyte selectively binds to the hydrogel matrix, the binding will result in a change in the osmotic pressure and by that in the swelling of the gel. On account of the swelling, the separation between the colloidal spheres increases and the Bragg peak of the diffracted light will be shifted to longer wavelengths (**Figure 17**).

Ben-Moshe *et al.*, from Asher's group, for example, developed a fast responsive crystalline colloidal array photonic crystal glucose sensor based on hydrogels that embed an array of ~100-nm-diameter monodisperse polystyrene colloids that Bragg diffract light in the visible spectral region.[191] The hydrogels changed volume as the glucose concentration varies. The changes in the lattice spacing changed the wavelength of the diffracted light. The sensor had a full response rate within 90 s to the average glucose concentrations found in blood (5 mM) and within 300 s to the average glucose concentrations found in tear fluid (0.15 mM). They demonstrated that the sensor is responsive to ~0.15 mM glucose concentrations in artificial tear fluid solution.

Another sensing method based on phenylboronic acid was presented by Worsley *et al.*[192] in their work about continuous blood glucose monitoring using a thin-film optical sensor. The sensor is based on holography and made of an acrylamide

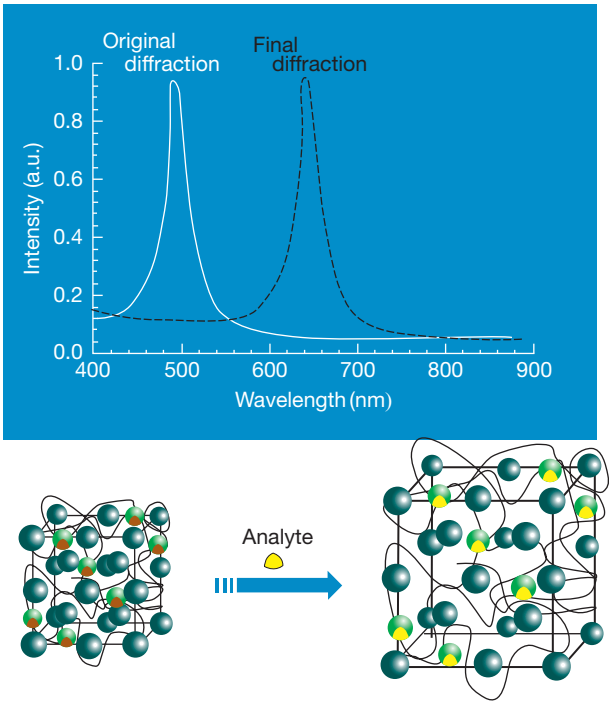

Figure 17 Typical diffraction from intelligent polymerized crystalline colloidal array particle dispersions. Redrawn from Asher, S. A.; Alexeev, V. L.; Goponenko, A. V.; *et al. J. Am. Chem. Soc.* **2003**, *125*(11), 3322–3329, with permission from American Chemical Society.

hydrogel thin-film containing phenylboronic acid receptors. Utilizing the sensor, it was possible to measure glucose in human blood plasma *in vitro*.

Lapeyre *et al.*[193] reported the synthesis of monodispersed PNIPAm submicrometric microgels, modified with a phenylboronic acid (PBA) derivative. The particles were glucose-responsive at a pH close to the pK_a of the PBA derivative, with a swelling degree proportional to the concentration of glucose. Owing to their characteristics, the particles might serve as building blocks for the design of colorimetric sensors based on the light diffraction of colloidal crystals.

3.329.3.1.4.4. Fluorescence-based glucose sensing

Here, we make a short digression for fluorescence-based glucose sensing in combination with hydrogel systems. In this context, three terms need to be mentioned because they are the main components of many fluorescence-based glucose sensors: the fluorescence (or Förster) resonance energy transfer (FRET), Concanavalin A, and dextran labeled with fluorescein isothiocyanate (FITC). FRET involves the nonradiative (i.e., no photons are passed) energy transfer from a fluorescent donor molecule to an acceptor molecule in close proximity (which needs not be fluorescent), and is usually brought about by dipole–dipole interactions. The signal in FRET is a decrease in fluorescence intensity and lifetime of the donor. Concanavalin A (Con A) is a plant lectin, extracted from the jack bean, which has four binding sites for glucose per molecule of the protein. Finally, dextran is a complex, branched glucan (polysaccharide), in this case, labeled with fluorescein isocyanate, a fluorescence dye. These are the three ingredients needed to form a

fluorescence-based glucose sensor involving Con A. Such sensors are based on the competitive binding to the lectin of either glucose or a labeled carbohydrate derivative such as dextran. At this point, we do not want to go more into detail and would like to advise the reader to have a closer look at the review of Pickup *et al.*[194] about fluorescence-based glucose sensors. This review gives the most important background information about the topic, as well as the use of PEG-based hydrogels to improve the biocompatibility of implanted sensors. One example for a hydrogel biosensor based on these three ingredients is the work of Chaudhary *et al.*[195] The group investigated the feasibility of dissolved-core alginate-templated fluorescent microspheres as glucose biosensors in simulated interstitial fluid (SIF). The sensor worked on the principle of competitive binding and fluorescence resonance energy transfer and consisted of multilayer thin film-coated alginate microspheres incorporating dye-labeled glucose receptor and competing ligand within the partially dissolved alginate core. Further, it was possible to combine the visible sensing assay (FITC-dextran-TRITC-Con A/FITC-dextran-TRITC-apo-GOx) with a near infrared sensing assay (AF-647-dextran amino-QSY-21-apo-GOx), co-encapsulated inside polymeric hydrogel microspheres. The incorporation of long wavelength NIR dyes enables more efficient excitation through scattering tissue, which effectively improves the odds of successful use *in vivo*. The system exhibited a maximum response time of 120 s and a sensitivity of 0.94% mM^{-1} glucose with a response in the range of 0–50 mM glucose.

3.329.3.1.4.5. Peptide-modified hydrogels for toxin screening

In comparison to 2D surfaces, the 3D network of hydrogels offers a variety of benefits if used for biosensing applications where the immobilization of receptor molecules, for example, antibody or enzyme, is an important factor. If such a kind of biomolecule is immobilized on a 2D surface, it can denature and lose activity and affinity to antigens.[196–198] The explanation for this is easy: If the molecule binds to a 2D limited surface, it will undergo structural deformations in the binding region or even in the protein structure itself, which will have a negative impact on the activity, binding kinetics, or even inhibit the complete binding process. A 3D hydrogel network, swollen to its equilibrium water content, on the other hand, can preserve the protein structure and simulate a solution-phase environment while also granting multidirectional access for ligand binding.[199] Further, the hydrogel structure allows an easy penetration of large biomolecules and therefore an access to the active binding sites.

Charles *et al.* made use of these benefits that 3D hydrogels offer when they developed a galactose polyacrylate-based hydrogel scaffold for the detection of cholera toxin (CT) and staphylococcal B (SEB) in a sandwich immunoassay format.[199] On account of the galactose polyacrylate backbone and a selected binding chemistry, they succeeded in creating a hydrogel system that provided enhanced sensitivity with low nonspecific binding characteristics. By utilizing a PDMS microchannel template, they patterned arrays of the immobilized antibodies for the development of a sandwich immunoassay (**Figure 18**).

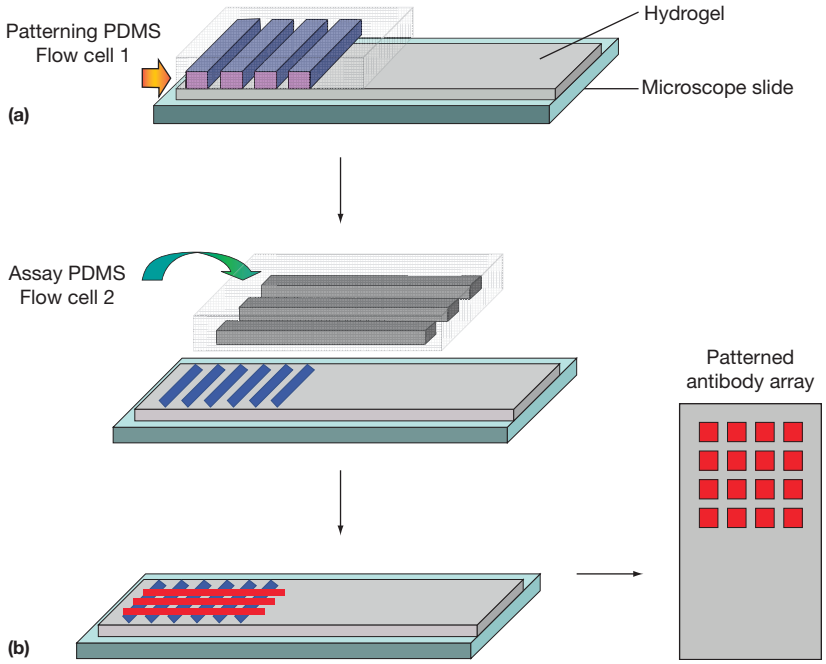

Figure 18 Array patterning template for the immobilization of capture antibodies and application of assay reagents. (a) The poly(dimethylsiloxane) (PDMS) patterning module, containing six channels for fluid flow that run in a perpendicular direction of the slide. When placed in contact with hydrogel, cross-linkers and capture antibodies are applied into each lane and allowed to incubate. Repetitive cycles of cross-linkers and antibodies were performed to optimize immobilization of the biomolecule. (b) Assay template for application of toxin (i.e., cholera or staphylococcal enterotoxin B (SEB)) and tracer antibody (Cy3-anti-SEB or Cy3-anti-CT). The PDMS assay module contains six channels which are placed parallel to the patterned capture antibodies on the hydrogel slide forming the patterned array. Different concentrations of antigen can be applied to each lane to determine detection limits. Reproduced from Charles, P. T.; Velez, F.; Soto, C. M.; *et al*. *Anal. Chim. Acta* **2006**, *578*(1), 2–10, with permission from Elsevier.

Fluorescence and 3D imaging by confocal microscopy and laser scanning confocal microscopy of Cy3-labeled anti-CT and/or Cy3-anti-SEB tracer molecules provided qualitative and quantitative measurements on the efficiency of protein immobilization, detection sensitivity, and signal-to-noise ratios. With the established system, they were able to achieve low limits of detection for SEB and cholera toxins ($1.0\ ng\ ml^{-1}$).

Besides the integration of active biomolecules, it is also possible to create hydrogels that are cross-linked by peptides, which dissolve in the presence of certain stimuli, like reducing agents or enzymes.[200,201] The cross-linking system can be designed in such a way that the hydrogel can act as a self-sacrificing biosensor for enzymatic active analytes. This 'sacrificing' hydrogel can be used for sensing toxins that possess enzymatic activity, such as botulinum neurotoxin type A. A hydrogel system utilizing this system was described by Frisk *et al.*[202] They created peptide-modified hydrogels for sensing the enzymatic activity of botulinum neurotoxin type A (BoNT/A). Using so-called SNAP (synaptosome-associated protein)-modified hydrogels in combination with microfluidics, they were able to generate autonomous sensors that simply required a visual readout (Figure 19). Using microfluidics, they were able to simply introduce ~20 µl of toxin-laden solution and observe degradation without the need for detectors, pumps, or valves, thus making microfluidic-based biosensors promising as toxin-screening vehicles.

3.329.3.2. Living Sensors

This section gives an overview of the combination of hydrogels with living cells and microorganisms to form living cell–polymer composites for biosensing applications. The use of microorganisms and cells as biological sensing elements in biosensors is well established, and microorganisms offer advantages of ability to detect a wide range of chemical substances, amenability to genetic modification, and broad operating pH and temperature range, making them ideal as biological sensing materials. They have been integrated with a variety of transducers such as amperometric, potentiometric, calorimetric, conductimetric, colorimetric, luminescence and fluorescence to construct biosensor devices. Here, we do not want to cite paper over paper and would just like to draw the reader's attention to the short but comprehensive reviews about 'Microbial biosensors' and 'Whole cell biosensors' published by Lei *et al.*[203] and Luc Bousse.[204] The review of Lei *et al.* concentrates on the advantages of using microorganisms as biosensing elements, the immobilization of microorganisms, electrochemical, amperometric, potentiometric, conductimetric, optical, bioluminescence, fluorescence, and colorimetric microbial biosensors as well as microbial fuel cell type biosensors, fluorescent protein-based biosensors, and O_2-sensitive fluorescent material-based biosensors. Luc Bousse also concentrates on the field of biosensors in which the biological component consists of living cells and points out some of the most important reasons for using living cells, that is, to obtain functional information about the effects of a stimuli on a living system.

Our focus should be the use of living cell biosensors utilizing hydrogel networks for biosensing applications. The immobilization of cells in different hydrogel types for biosensing applications is reported: polyacrylamide[205,206] polyurethane-based hydrogels,[207] photo-cross-linkable resins[207,208] and polyvinyl alcohol,[209–213] polyacrylonitrile membranes[214] and PEG hydrogel,[215] alginate,[216–218] carrageenan,[206] low-melting agarose,[219] chitosan[220] and proteinic matrix.[221]

One of the main benefits hydrogels have is their high water content and the 3D polymer network, which allows a high gas exchange rate and transport of nutrients to cells immobilized in the polymer network. These characteristics, in combination with their biocompatibility, make it possible to even cultivate cells or bacteria inside of hydrogels and to use the cell–polymer composites for biosensing applications.

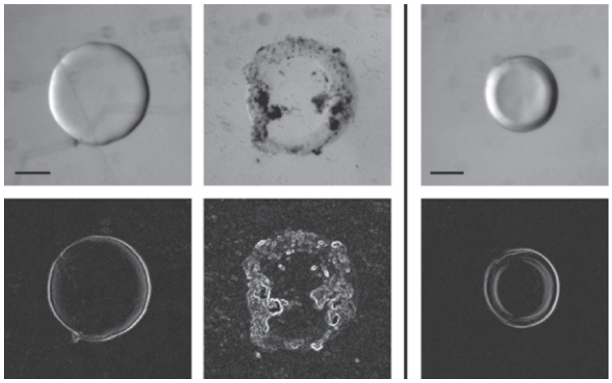

Figure 19 Fifteen micrograms per milliliter BoNT/A degrades posts in cream. (a) Initial 425 µm synaptosome-associated protein peptide post in 1× PBS, $t = 0$ h; (b) after 48 h exposure to BoNT/A in cream; (c) 325 µm control post with BoNT/A-insensitive cross-linker after 48 h toxin exposure. H.; Lin, G.; Johnson, E. A.; Beebe, D. J. *Chem. Mater.* **2007**, *19*(24), 5842–5844, with permission from American Chemical Society.

3.329.3.2.1. Bacteria

Utilizing the mentioned cell-supporting characteristics, it is possible to create biosensors that use bacterial cells as biological recognition elements. One example for this sensor type is a biosensor for the rapid determination of the concentration of biodegradable pollutants in wastewater, developed by Renneberg *et al.*[222] The sensor consisted of salt-tolerant yeast *Arxula adeninivorans* LS3 cells immobilized in a poly(carbamoyl)sulfonate (PCS) hydrogel, on a Clark-type oxygen electrode. The group claimed that the sensor made it possible to get comparable results for the so-called standard 5-day biochemical oxygen demand (BOD5) method, employed as a pollution index, in just 5 min (Figure 20).

Another example for yeast cells in a hydrogel matrix are the fiber-optic biosensors based on luminescent yeast cells entrapped in calcium alginate, or polyvinyl alcohol (PVA) hydrogels, constructed by Fine *et al.*[223] The entrapped genetically modified *Saccharomyces cerevisiae* cells contained the estrogen receptor α-mediated expression of the *luc* reporter gene and enabled a novel approach for estrogenic endocrine disrupting chemical (EDC) biodetection. Owing to the protective hydrogel matrix that formed a protective environment for the entrapped cells, it was possible to operate even under

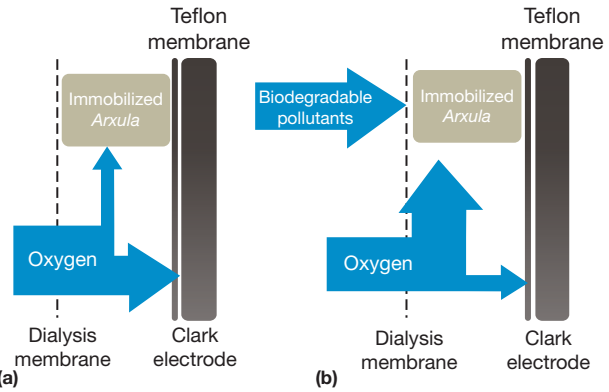

Figure 20 Schematic diagram of the *Arxula adeninivorans* LS3 microbial sensor. It illustrates the microbial consumption of dissolved oxygen (a) before and (b) after the addition of biodegradable pollutants. Redrawn from Renneberg, T.; Kwan, R. C. H.; Chan, C.; Kunze, G.; Renneberg, R. *Microchim. Acta* **2004**, *148*(3–4), 235–240, with permission from Springer.

nonsterile conditions. Further, Martinez *et al.* described a fast method to study cell metabolic characteristics immobilizing yeast cells (*S. cerevisiae*) in a microbial biosensor-like device.[224] Main components of the sensor where *S. cerevisiae*, for example, entrapped in a poly(carbamoylsulfonate) hydrogel membrane, and a carbon dioxide electrode. The sensor device allowed the calculation of Michaelis–Menten parameters related to the kinetics of transport and degradation of several carbohydrates (i.e., glucose, fructose, galactose, sucrose, and xylose, with $K_{m(app)}$ of 6.0, 5.8, 0.9, 2.0, and 147 mM, respectively), and the study of the kinetics of expression of nonconstitutive proteins related to the transport and degradation of galactose.

Köster *et al.* made use of an immobilized *Staphylococcus* type to create an amperometric, microbial respiration-based microbiosensors for the quantification of available dissolved organic carbon (ADOC) instantaneously respired by microorganisms.[225] Therefore, they immobilized aerobic seawater microorganisms, closely related to *Staphylococcus warneri*, in a polyurethane hydrogel sensing membrane. The group focused on biochemical and physiological properties of respiration-based ADOC microbiosensors that measure all of the dissolved organic carbon compounds that are instantaneously respired by the immobilized cells. The sensor had a detection limit equivalent to about 6–10 μM glucose and a 90% response time of 1–5 min. The shelf lives of individual sensors were up to 2 weeks.

With *E. coli*, Fresenko *et al.* used one of the most popular bacteria strains for their hydrogel microchip. They developed a cell–hydrogel system for biosensing and monitoring of cell populations using a polyacrylamide-based hydrogel bacterial microchip (HBMChip).[226] The microchip represented an array of hemispherical gel elements that contained live immobilized *E. coli* cells. They were able to measure and monitor intracellular metabolism using vital fluorescent stains, engineered constructs encoding bioluminescent or fluorescent reporters. It was possible to monitor the dynamics of nucleic acids in growing *E. coli* cells using vital fluorescent stain SYTO 9. Further, they made use of the biosensing opportunities the cell-chip offered and illustrated the detection of antibiotics and sodium meta-arsenite by quantitative analysis.

3.329.3.2.2. Cells

The same characteristics that make hydrogels preferable candidates for bacterial biosensors count as well for cell-based biosensors. Besides the already mentioned biocompatibility and the high diffusion rate for nutrients, gas, etc., hydrogels have a structural similarity to the macromolecular-based components in the human body, which offers applications *in vivo* and *in vitro*. To get a better overview of human cell–hydrogel composites, we advise the reader to have a closer look at the review 'Hydrogels for tissue engineering' written by Lee and Mooney.[227] Further, Hynd *et al.* published a comprehensive review about hydrogels in applications for neural cell engineering.[228] The review gives a overview of acrylate-based polymers and their derivatives, used in biomedical applications, including drug delivery, tissue engineering, cell encapsulation, and as templates for directed cell growth, attachment, and proliferation. In the following sections, we focus on hydrogels used in the field of cell-based biosensors.

3.329.3.2.2.1. Hydrogel coatings and influence of the third dimension

In the field of cell-based biosensors, hydrogels preferably are used in two different shapes: either as coating material for recognition elements like electrodes, implantable sensors etc., or as a 3D-Matrix for cells that are utilized as biological recognition element themselves. Hydrogels that are used as sensor coatings in most cases play a passive role; they, for example, support gas transportation, ion-exchange etc., or make it possible to immobilize cells on sensor surfaces. An example for the immobilization of cells on a sensor surface is the work of Ding *et al.*[229] They prepared a nanocomposite by neutralizing a solution of chitosan encapsulated gold nanoparticles formed by reducing *in situ* tetrachloroauric acid in chitosan. The gel was designed for immobilization and electrochemical study of cells, monitoring their adhesion, proliferation, and apoptosis on electrodes. The nanocomposites gel showed improved immobilization capacity for K562 leukemia cells, as a model cell line, and good biocompatibility for preserving their activity on glassy carbon electrodes. Another example came from the same group when Hao *et al.* combined the biocompatibility of chitosan (CS) and conductivity of carbon nanofiber (CNF).[230] By an electrodeposition of soluble CNF-doped CS colloidal solution, they were able to form a robust CNF-CS nanocomposite film with good biocompatibility for the immobilization and cytosensing of K562 cells on an electrode.

The biocompatibility of hydrogels can be increased by modifying them with certain biomolecules that support the immobilization of cells or decrease the inflammation of tissue in case the sensor is implanted. Norton *et al.* examined the release of vascular endothelial growth factor (VEGF) and dexamethasone (DX) from nonfouling hydrogel-based sensor coatings and their effect on the foreign body response.[231] The hydrogels were prepared from 2-hydroxyethyl methacrylate, *N*-vinyl pyrrolidinone, and PEG. The study revealed that VEGF-releasing hydrogel-coated fibers increased vascularity and inflammation in the surrounding tissue after 2 weeks

of implantation compared to hydrogel-coated fibers. DX-releasing hydrogel-coated fibers reduced inflammation compared to hydrogel-coated fibers and had reduced capsule vascularity compared to VEGF-releasing hydrogel-coated fibers. Owing to the fact that after 6 weeks there were no detectable differences between drug-releasing hydrogel-coated fibers and control fibers, it could be concluded that the drug depot was exhausted.

Apart from immobilizing cells on hydrogel coatings, they can be embedded in the coating as well. In this case, the hydrogel has a passive but important role because it supports the cells by forming a cell-friendly 3D environment and cells can be cultivated as close as possible to the sensor surface. Klueh *et al.*, for example, reported the uses of tissue-interactive biohydrogels, such as fibrin, to enhance gene delivery at sites of sensor implantation.[232] Therefore, cells genetically engineered to overexpress the angiogenic factor (AF) vascular endothelial cell growth factor (VEGF) were incorporated into an *ex ova* chicken embryo chorioallantoic membrane (CAM)-glucose sensor model. The VEGF-producing cells were delivered to sites of glucose sensor implantation on the CAM using a tissue-interactive fibrin biohydrogel as a cell support and activation matrix. This VEGF–cell–fibrin system induced significant neovascularization surrounding the implanted sensor and significantly enhanced the glucose sensor function *in vivo*.

Desai *et al.* demonstrated different behavior of cells cultured on a 2D coating or in a 3D network.[233] When they used SH-SY5Y human neuroblastoma cells, cultured in 3D collagen hydrogel, confocal microscopy, and immunofluorescence staining, to assess the merit of the system as a functional, cell-based biosensor, they were able to show the depolarization-induced differences in intracellular calcium release when cultured using a 2D versus a 3D matrix. Similar results regarding the difference in 2D or in 3D substrates could be shown by Wu *et al.*[234] They fabricated a packed Cytodex 3 microbead array as a simple 3D cell-based biosensing format. Resting membrane potentials and voltage-gated calcium channel (VGCC) function of SH-SY5Y human neuroblastoma cells cultured on the microbead array versus collagen-coated flat (2D) substrates were evaluated by confocal microscopy with a potentiometric dye and a calcium fluorescent indicator. The exaggerated 2D cell calcium dynamics, in comparison with those of 3D cells, were consistent with previous 2D/3D comparative studies. The study established the rationale and feasibility of the microbead array format for 3D cell-based biosensing.

3.329.3.2.2.2. Cell preservation in 3D hydrogels

As a next step, we highlight some results regarding the influence of entrapping cells into hydrogels and possibilities to preserve them over longer times in *in vitro*. Here, we would like to draw the reader's attention to the short but interesting review about preservation methods to keep biosensor microorganisms alive and active, published by Bjerketorp *et al.*[235] That cells can survive the entrapment into hydrogels is known from literature and was already mentioned in the introduction. That it is even possible to immobilize cells in a hydrogel matrix, by photopolymerization, without a loss of activity has been shown by Zguris *et al.*[236] They demonstrated the ability to entrap human microsomes in PEG hydrogel microstructures without loss of activity, during the photopolymerization process, by reference to the activity of cytochrome P450. Further, they developed two photopolymerization methods for the fabrication of heterogeneous PEG hydrogel structures containing multiple phenotypes of mammalian cells.[237] Besides a two-step photoreaction injection molding process, they described a novel method for one-step fabrications of stacked hydrogel microstructures using a microfluidic mold. In addition to hydrogels containing fluorescent dyes, they were able to create differing extracellular matrixes, unmodified or modified with the cell adhesion promoter RGD, within one hydrogel microstructure and to generate patterns of hydrogels containing multiple phenotypes. The studies revealed new promising opportunities for cell-based hydrogel biosensors.

Preservation of cells for certain time periods in a hydrogel matrix has been shown by Itle *et al.* when they entrapped cells into PEG hydrogel microstructures for biosensing applications.[238] In their work on 'Hepatocyte viability and protein expression within hydrogel microstructures,' they reported the entrapment of mammalian hepatocytes in hydrogels of varying PEG compositions. They were able to maintain cell viability for 7 days in free structures and in structures contained in microfluidic channels. The production of protein by cells in hydrogels decreased with increasing PEG concentration, suggesting mass transfer limitations in hydrogels with higher PEG compositions. Following up on this topic, they reported the fabrication of mammalian cell-containing PEG hydrogel microarrays by a 'stage-down' freezing process for potential applications in drug screening and pathogen detection.[239] The work revealed possibilities of fabricating cell-containing microdevices and cryopreserving them for later use. Their work resulted in the fabrication of whole mammalian cell biosensors for the optical monitoring of cell viability and response to two model chemotoxins: sodium hypochlorite and sodium azide, and one model biotoxin, concanavalin A.[240] Therefore, the cells were entrapped either in PEG microspheres or in array format. It was possible to detect sodium azide in micromolar quantities in fewer than 30 min.

3.329.3.2.2.3. Pathogen

On account of their big impact on the human health system, we briefly highlight a few results regarding pathogen detection with hydrogel biosensors. One example is the work of Kim *et al.* who examined the potential of a sensing strategy based on live T cell–B cell interactions in a biosensor chip format which could be used in pathogen detection.[241] They developed an approach to fabricate patterned PEG dimethacrylate (PEGDMA) hydrogel microwells functionalized at their bases with antibodies to promote specific immobilization of lymphocytes. The microwells were used to array single T cells in a regular pattern on a substrate. A sensing platform was created by overlaying arrayed T cells with a confluent layer of antigen-capturing B cells. Utilizing the hydrogel/lymphocyte sensing chip, it was possible to detect a model peptide analyte within minutes, with dose-dependent linear signals over the concentration range 0.05–5 μM (**Figure 21**).

Another example for the detection of pathogens was published by Banerjee *et al.*[242] They developed a multiwell plate-based biosensor containing B cell hybridoma, Ped-2E9,

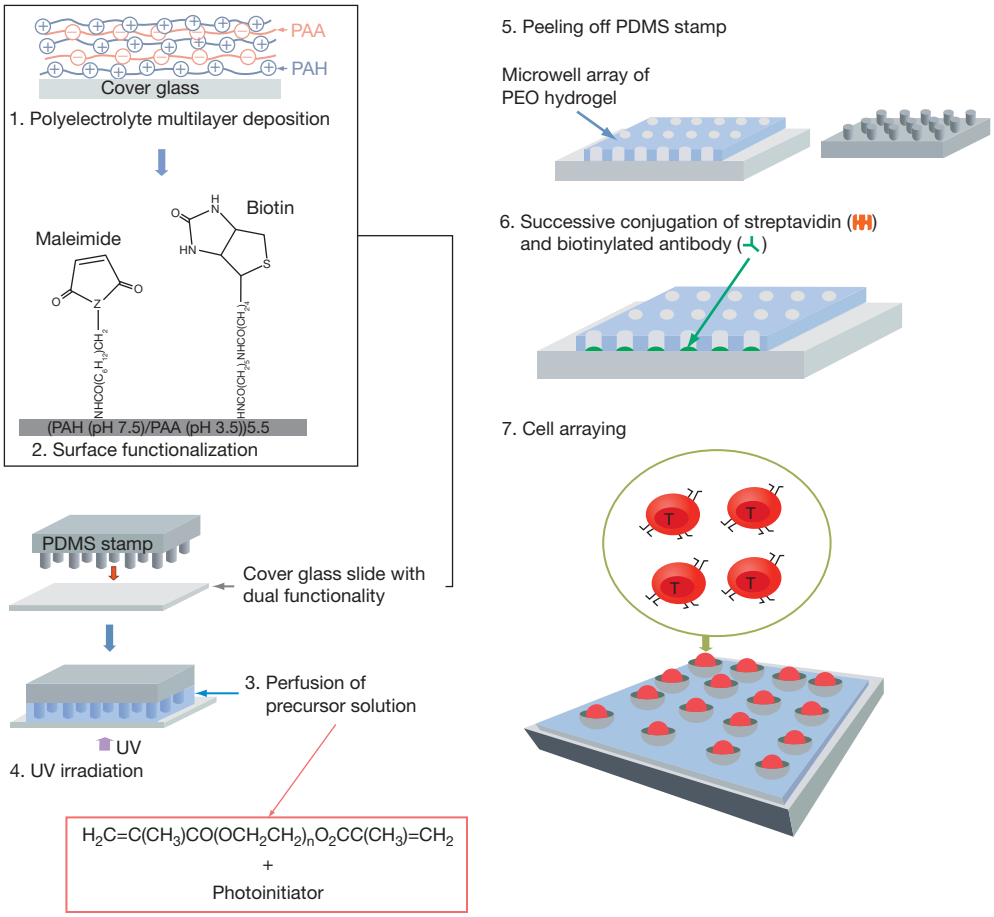

Figure 21 Schematic illustration of poly(ethylene glycol) dimethacrylate (PEGDMA) hydrogel microwell array fabrication and T cell arraying. PAH, poly(allylamine hydrochloride); PAA, poly(acrylic acid); PEO, poly(ethylene oxide). Reproduced from Kim, H.; Cohen, R. E.; Hammond, P. T.; Irvine, D. J. *Adv. Funct. Mater.* **2006**, *16*(10), 1313–1323, with permission from Wiley.

encapsulated in type I collagen matrix, was developed for rapid detection of viable cells of pathogenic *Listeria*, the toxin listeriolysin O, and the enterotoxin from *Bacillus* species. This sensor measured the alkaline phosphatase release from infected Ped-2E9 cells colorimetrically and gave an example of a cell-based sensing system using collagen-encapsulated mammalian cells for rapid detection of pathogenic bacteria or toxin.

3.329.3.2.2.4. Nitric oxide/glutamate

Another interesting field for hydrogel biosensors is the detection of nitric oxide and/or glutamate. Castillo *et al.* presented the simultaneous detection of nitric oxide and glutamate using an array of individually addressable electrodes, which were modified with a sensitive nitric oxide sensing chemistry and a glutamate oxidase/redox hydrogel-based glutamate biosensor.[243] The first working electrode was covered with a positively charged Ni porphyrin, entrapped into a negatively charged electrodeposition paint, and the second working electrode by a bienzyme sensor architecture based on cross-linked redox PEG diglycidyl ether (PEGDGE) hydrogels with entrapped peroxidase and glutamate oxidase. Adherently growing C6-glioma cells were grown on membrane inserts and placed in close distance to the modified sensor surfaces. The current responses recorded at each electrode after stimulation of glutamate and NO release by means of K^+ and bradykinin demonstrated the ability of the individual electrodes in the array to detect the analyte without interference from the neighboring electrode or other analytes present in the test mixture (Figure 22).

From the same group, Wartelle *et al.* reported test results from a compact, biocompatible, hydrogel-based, electrochemical sensing device for the detection of nitric oxide released from C6 glioma cells.[244] Owing to the use of an ionically conducting κ-carrageenan hydrogel membrane, in combination with the integrated electrode setup, used by Castillo *et al.* as well, it was possible to create a living cell-based device for NO detection.

3.329.4. Summary

This chapter gave an overview of the use of hydrogels in biosensing. As highlighted in the introduction, many intrinsic properties of hydrogels predetermine their use in this field of application. The most important points are their high water content that renders them biocompatible and allows diffusion of water-soluble compound through the polymer network as well as their chemical diversity and the ability to tune their

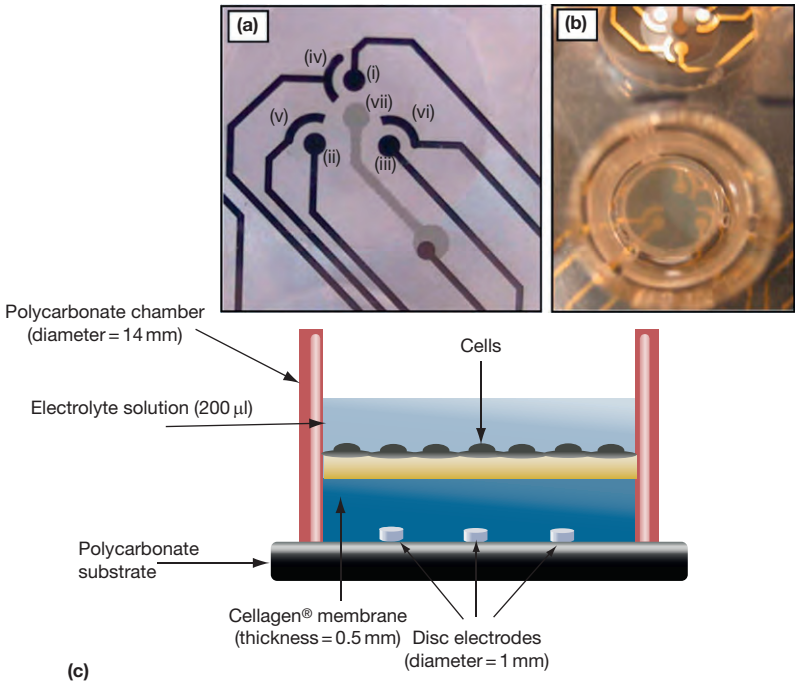

Figure 22 (a) Representation of the array of electrode employed in this study: i, ii, and iii are working electrodes; iv, v, and vi are counter electrodes; and vii is the reference electrode. (b) Photograph and (c) schematic representation of the well plate with and without the membrane insert positioned over the integrated electrodes on the bottom. Redrawn from Castillo, J.; Isik, S.; Bloechl, A.; *et al*. *Biosens. Bioelectron*. **2005**, *20*(8), 1559–1565, with permission from Elsevier.

properties both regarding the chemical nature of the polymer backbone and the introduction of (functional) side groups. This allows the generation and design of stimuli-sensitive hydrogels that may act as sensors themselves, for example, by introduction of hydrophobic groups for temperature sensitivity or protic groups for pH sensitivity. It also enables functionalization of the hydrogel with moieties that act as sensors. The range of molecules that can be and has been used for this purpose is very broad and comprises (fluorescence) dyes, luminescent compounds, enzymes, biochemical recognition sites such as oligonucleotides, antibodies, lectins, and very specific recognition mechanisms.

Hydrogels may be prepared in aqueous solutions through a variety of mechanisms. Most prominently, either UV- or temperature-initiated radical polymerization techniques are used. The gelation from low viscous solutions to gels allows application-specific preparation of the gels in desired geometries and is compatible with miniaturization and microfluidic applications. Moreover, hydrogels can be prepared by preparation methods that are compatible with living cells or bacteria so that these can be encapsulated and may serve as sensors in the hydrogel network.

Recently, especially multifunctionalization of the gels, the combination of hydrogels and other intelligent materials and advances in sensor design has led to advances. Examples are combinations of responsive hydrogels that react with volume changes to stimuli and piezoelectric readout. Also, optical readout through microsphere arrays embedded in a responsive hydrogel matrix is an elegant approach. Double modification of hydrogels with enzymes such as peroxidase and glucose oxidase allows sequential bienzymatic reactions in the hydrogel. Aside of application-specific sensor design, microfabrication techniques are more commonly used to miniaturize and parallelize sensing. The versatile nature of hydrogels, their compatibility with biomolecules, and preservation of their specific activity together with the possibility to tailor the hydrogel preparation process according to application-specific demands make them ideal materials for biosensing.

Glossary

Atomic Force Microscopy (AFM) A microscope that uses a tiny probe mounted on a cantilever to scan the surface of an object. The probe is extremely close to, but does not touch the surface. As the probe traverses the surface, attractive and repulsive forces arising between it and the atoms on the surface induce forces on the probe that bend the cantilever. The amount of bending is measured and recorded, providing a surface map with near atomic detail.

Carbon nanotubes (CNTs) Carbon nanotubes are allotropes of carbon with a cylindrical nanostructure.

Chemical Vapor Deposition (CVD) CVD is a chemical reaction which transforms gaseous molecules, called precursors, into a solid material in the form of thin film or powder on the surface of a substrate.

Field-effect Transistor (FET) A transistor in which the voltage on one terminal (the gate) creates a field that allows or disallows conduction between the other two terminals (the source and drain).

3.330.1. Introduction

In the first two decades since their discovery, carbon nanotubes (CNTs) and their derivatives have proven to be one of the most versatile nanostructures in engineering, science, and medicine. Carbon-based nanomaterials have made broad and significant societal impacts, from providing unique material composites and enabling nanoscale electronics to facilitating effective treatments for disease and the development of novel biological probes. The properties of CNTs are what make them attractive and versatile for many applications: CNTs are nanoscopic in size, have high length-to-width aspect ratio, have a high surface-to-volume ratio, have hollow geometry, are chemically inert but can be easily modified to possess different surface chemistry, are mechanically robust, have conducting or semiconducting properties, and have unique optical properties.

In terms of sensing, combinations of these properties have been attractive for a variety of sensing platforms, including optical, electrical, thermal, mechanical, and so on. For example, the high surface-to-volume ratio and electrical conductivity of CNTs have been used to enhance electrode surfaces and improve sensitivity for electrochemical detection applications. The nanoscopic size, high aspect ratio, hollow geometry, and mechanical robustness have been attractive for probing single living cells. Independent of the desired combination of properties, carbon-based nanomaterials have been widely studied and utilized for a wide range of sensing applications. In this chapter, we discuss the development of CNT-based sensors and their utilization in various biological sensing applications.

3.330.2. CNTs and Related Carbon-Based Nanostructures

Over the past century, carbon fiber research has progressed from carbon fibers and filaments to carbon nanofibers (CNFs) and nanotubes.[1] On the smaller side of things, the field has progressed from hollow graphitic nanofibers to

the higher-ordered structure of CNTs. In the first decade after the discovery of multiwalled CNTs (MWCNTs) in 1991,[2] the majority of research focused on the fabrication, characterization, and determination of properties for CNTs and related structures. In the twenty-first century, one of the main focuses has been on applying their unique qualities as sensors. This section briefly introduces CNTs and related carbon-based nanostructures and, in the context of sensors, describes how these nanostructures are fabricated and explains their distinct properties.

To simplify our discussion of a broad field, we adopt earlier proposed nomenclature[3] to describe all hollow tube-like carbon structures with at least one dimension of 100 nm or less as CNTs. Likewise, we will describe all solid fiber-like carbon structures with at least one dimension of 100 nm or less as CNFs. However, the reader should note where indicated that distinct differences in CNT structure give distinguishing properties.

3.330.2.1. Brief Perspective

One of the first CNTs discovered was produced in vapor-growth carbon fiber processes.[4] These nanotubes, termed graphitic CNTs, had nanoscopic diameters on the order of 10 nm. In 1991, similar structures were observed with a much higher degree of structural perfection,[2] later referred to as MWCNTs. These resemble graphene sheets seamlessly rolled into concentric cylinders spaced apart at distance slightly larger than the interlayer distance in single-crystal graphite (0.34 nm as opposed to 0.335 nm). Although each sheet is highly ordered, the layers are rotationally disordered with respect to one another. The diameters of MWCNTs are typically in the range of 2–25 nm. In 1993, single-walled CNTs (SWCNTs) were discovered.[5,6] Similar to MWCNTs, SWCNTs are also made from a single sheet of graphene seamlessly rolled into a cylinder having a uniform diameter (1–2 nm). SWCNTs and MWCNTs form a distinct class of nanotubes called fullerene CNTs.

Continued carbon fiber research throughout the 1990s led to the development of template-synthesized CNTs[7,8] and CNFs.[9,10] Although the structures of template-synthesized CNTs and CNFs are typically disordered, these carbon nanostructures can be annealed to increase the degree of order and can be formed in a wide range of tube sizes (tens of nanometers to tens of micrometers), geometries (cylinders and cones), and unique material compositions (pristine, nanoparticle-embedded, and so on).

Although all CNTs and CNFs are made of carbon, they have distinguishing characteristics, properties, and capabilities that differentiate them from one another. These distinctions have been reviewed in detail.[11] The first major distinction is the differences in structure. Fullerene CNTs have a known and uniform molecular structure throughout each CNT and between CNTs, which enables near-precise theoretical predictions to be made about their behavior and properties. In contrast, CNTs synthesized from templates or traditional carbon fiber methods (e.g., extrusion, vapor deposition) have nonuniform molecular morphology and structure throughout each CNT and between CNTs. These structural variations hinder precise theoretical predictions of their behaviors and result in large deviations in experimentally determined property values.

The second major distinction is the differences in manufacturing. Fullerene CNTs of various diameters and chirality can be produced in mass by electric arc discharge and laser ablation. The CNTs produced need to be filtered and separated from the highly impure raw material that results from such processes. Decomposing hydrocarbon gases onto catalyzed surfaces can, instead, produce fullerene CNTs. These chemical vapor deposition (CVD) processes produce CNTs of higher purity with narrowed dimensions. In contrast, CNTs synthesized from templates are manufactured in high yield and purity to desired configurations. Template synthesis allows one to manufacture CNTs with prescribed outer diameters, wall thicknesses, and lengths, and even customize the nanostructures with embedded objects or unique geometries and shapes.

3.330.2.2. Fabrication

CNTs of various diameters, lengths, and structure can be fabricated using different methods, including electric arc discharge,[5,12–14] laser ablation,[15,16] catalytic CVD (C-CVD),[17] catalytic plasma-enhanced CVD,[18] and template-based CVD.[7,8,19] Electric arc discharge and laser ablation are very efficient methods for producing high-quality SWCNTs and MWCNTs in large quantities. Useful nanotubes are obtained by removing unwanted carbon particles and other material through complex purification and filtering processes. CNTs made in this fashion are free to be suspended and utilized in random dispersions. CNTs are also produced in quantity by CVD methods. In general, CVD involves the decomposition of hydrocarbon gases to controllably synthesize CNTs and CNFs. In C-CVD, the size of catalyst particle controls the uniform diameter of the carbon products. Catalyst particles can be prefabricated into patterned arrays to produce well-aligned CNT assemblies.[20,21] The location, alignment, geometry, and structure of CNTs and CNFs can be controlled during synthesis with C-PECVD.

As an extension of CVD processing, CNTs and CNFs can be produced by depositing carbon inside porous substrates like alumina membranes and glass capillaries. The template is removed to get aligned arrays,[19,22] individual nanotubes, or single integrated nanostructures.[23–25] Template-synthesis processing allows CNTs to be produced in various dimensions, geometries, and shapes, as well as produce customized nanotubes with wall-embedded nanoparticles[26] or nanoparticle-filled inner bores.[27]

3.330.2.3. Properties

The unique mechanical, electrical, chemical, thermal, and optical properties of CNTs and CNFs are well reviewed[11,18,19] and will not be discussed here in great detail. In addition to these properties, CNTs and CNFs have extremely large length-to-diameter aspect ratios and high surface-to-volume ratios. Their characteristics depend primarily on their structure and can vary significantly between the type and the origin of the carbon material.

CNTs exhibit high tensile strength, stiffness, and ductility. For instance, SWCNTs have tensile strengths as high as 100 times that of steel, making them the strongest known material.[28] CNTs also behave elastically. When pushed against a

hard surface, CNTs bend and buckle without fracture and return to their original shape when force is removed.[24,29] CNTs and related structures exhibit a wide range of electrical characteristics. For example, SWCNTs can be metallic and semiconducting depending on their helicity, whereas MWCNTs exhibit a range of electronic behavior (metallic, semiconducting, and semimetallic).[11] CNTs with defect sites, such as those grown using template-based synthesis methods, are good electrical conductors yet can be annealed to further improve conductivity.[30] Additionally, the reactivity of carbon surfaces varies greatly with surface microstructure, cleanliness, and functional groups.[31] Thus, carbon nanostructures provide a diverse platform to attach biomolecules for a variety of sensing applications.

3.330.3. Manufacturing Devices from Carbon Nanostructures

CNT-based sensors come in many configurations depending on the desired transduction and application. Configurations include electrodes with nanotubes, randomly dispersed nanotubes on their surfaces, substrates, or electrodes consisting of aligned nanotube arrays or forests, probes tipped with individual or bundled nanotubes, transistors made up of a single nanotube or networks of nanotubes, or even three-dimensional nanotube-based electromechanical devices.[32] This section will highlight the variety of CNT-based devices and sensing platforms available.

3.330.3.1. Devices with Randomly Oriented CNTs

Several sensor configurations are manufactured from randomly oriented CNTs, from conductive CNT films and CNT-coated electrode surfaces to transistor-based sensors. CNT films and composites are well suited for macro- and microscale sensing platforms, such as smart wearable fabrics[33] and lab-on-chip devices,[34] where concentrations of analytes are above μM. Smaller electrodes, with tips ranging from hundreds of nanometers to hundreds of micrometers, have been coated with CNTs to enhance their sensitivity.

SWCNTs (**Figure 1(a)**) were coated onto flame-etched carbon fiber nanoelectrodes and utilized as electrochemical sensors (**Figure 1(b)**).[35] The CNT-modified electrode, with tips ranging from 100 to 300 nm, exhibited overall detection capabilities in the nanomolar range, an order of magnitude lower than conventional carbon fiber electrodes of similar geometry. These small electrodes would be well suited for electrochemical applications in ultralow fluid volumes or biological systems such as tissue or cells.

The size and high sensitivity of CNT-based field-effect transistor (FET) sensors make them well suited to detect trace analytes in restricted spaces. FETs, first developed in 1998,[36,37] have been made either by depositing or by growing SWCNTs onto a SiO_2/Si substrate, then patterning connective electrodes or, in reverse order, patterning electrodes and depositing SWCNTs over top. The former is the more common method and has been used extensively by a few research groups. In this method, semiconducting SWCNTs are grown on SiO_2/Si substrates by CVD from catalyst particles or islands.

The result produces randomly oriented nanotubes across the substrate. Electrical contacts are then patterned over the nanotube dispersion using shadow mask evaporation or electron beam or photolithographic processes. The resulting sensor can consist of either single[38,39] or networked[40] CNT-based FET sensors. The latter method has been used to create larger interdigitated electrode (**Figure 1(c)**) with reproducible performance, where, as shown in **Figure 1(d)**, networks of randomly dispersed nanotubes lay on the electrodes to bridge the fingers.

3.330.3.2. Devices from Vertically Aligned CNTs and CNFs

Sensing devices have been made from vertically aligned (normal to the substrate) CNT and CNF forests and patterned arrays. The multiple detection sites of vertically aligned CNT arrays improve the signal-to-noise ratios and temporal responses orders of magnitude better than conventional flat electrodes of similar size and material.[41] When grown in patterns, vertically aligned arrays enable deterministic spatial resolution for a variety of sensing applications, for example, plated living cells.

Although different substrates and growth methods are used, vertically aligned CNT or CNF devices are manufactured using a similar strategy, as shown in **Figure 2**. The device occasionally utilizes nonconducting substrates such as SiO_2/Si but

typically utilizes a conducting substrate, either in the form of a metal wire, sheet, or plate or a substrate with a deposited metal film (Figure 2(a)). Catalysts such as Fe or Ni films or nanoparticles are then deposited on the substrate (Figure 2(b)). For deterministic arrays, the catalyst films are patterned. PECVD is used to grow the CNTs or CNFs from the catalyst and vertically orient the tubes on the substrate (Figure 2(c)). These devices can be used as is so that the substrate and nanotubes act as the sensor (Figure 2(d)) or embedded in an insulating film to only expose the ends of the nanotubes. In the latter, the insulating layer can be applied such that the nanotube tips protrude (Figure 2(e)) or polished so the tips are flush (Figure 2(f)).

Methods were developed to grow vertically aligned CNTs from Fe nanoparticles embedded into the pores of mesoporous silica[20] and CNFs from Ni films sputtered onto glass.[42] These methods produced large-scale, well-aligned vertical carbon nanostructures that were isolated from one another. Methods were developed to grow vertically aligned CNTs and CNFs arrays at predetermined locations by patterning the catalyst on substrates (Figure 3(a)).[43,44] These methods have since been utilized to produce an assortment of vertically aligned carbon nanostrucutures using PECVD for applications ranging from nanoelectrode ensembles for biosensing to needle arrays for the parallel delivery of reagents to multiple single cells.

As shown in Figure 3(b), arrays of conically shaped CNFs (200 nm tip diameter, 6–20 µm long, deterministic nanofiber separation) were produced from Ni catalyst dots deterministically patterned on Si substrates.[45] The planar arrangement, vertical alignment, and small dimensions of the CNFs made them well suited to penetrate multiple cells simultaneously and deliver surface-adsorbed DNA into the cells.[46] A similar technique was later utilized to produce a nanoelectrode array of CNFs (30–160 nm diameter, ~5 µm long, deterministic nanofiber separation) from patterned Ni catalyst dots on Cr-coated Si wafer.[41]

CNT electrode ensembles consisting of a dense array of CNTs (15–80 nm diameter, 30–100 µm long, 100–200 nm nanotube separation) were produced from an ion-sputtered Fe catalyst film on an Al-coated Si wafer.[47] As depicted in Figure 2(d), the CNTs and the conducting substrate act as the electrode and increase the electroactive surface area. Nanoelectrodes were made from carbon nanopipettes (CNPs) (10–15 nm tip diameter, several micrometers long) on Pt substrates[48] and low-density arrays of vertically aligned CNTs (50–80 nm diameter, 10–12 µm long, >5 µm nanotube separation) from electrodeposited Ni nanoparticles on a Cr-coated Si substrate.[49] To limit the electroactive area to the tips of the CNTs or CNFs, these arrays can be coated with an epoxy to insulate the conductive substrate to expose needle-like tips or surface-polished to expose only the ends of the nanotubes.

3.330.3.3. Carbon Nanostructure-Tipped Devices

In contrast to CNT arrays, devices tipped with a single CNT or bundle of CNTs can deterministically interrogate a single feature on a substrate or a region of interest such as a single cell or intracellular location, with high spatial resolution. Carbon nanostructure-tipped devices have been utilized in several applications including scanning probe microscopy (SPM), nanoscale electrochemistry, and cellular and intracellular studies. Their utilizations differ from other CNT-based devices in that they provide remote manipulation with nanoscale resolution and precise positioning of the sensor.

MWCNTs have been attached to the tips of atomic force microscope (AFM) cantilevers to take advantage of the

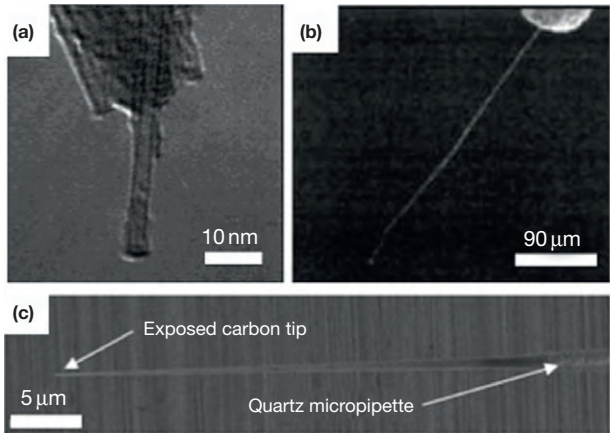

Figure 4 Probes tipped with carbon nanostructures. (a) Carbon nanotube (CNT)-tipped atomic force microscopic probe. Adapted from Hafner, J. H.; Cheung, C. L.; Oosterkamp, T. H.; Lieber, C. M. *J. precise manipulation capabilities of the AFM (Figure 4(a)). By bringing the tip into contact with an adhesive and then a bundle of tubes dispersed on a surface, CNTs can be adhered onto the surface of the tip.[29] These devices, tipped with CNTs ranging from 5 to 200 nm diameters, were used for SPM of surfaces[50–54] and probing and delivering cargo to cells.[55,56] CNTs have also been grown directly onto the tips of AFM cantilevers.[57] Although CNT-tipped AFM probes are relatively easy to use and have high spatial resolution due to the AFM, they are limited by fabrication, equipment, sensing, and delivery capabilities.

Instead of AFM tips, CNTs have been attached to the tips of thin wires using similar contact assembly methods. One of the earliest examples of such a probe was made by bringing the tip of a micron-sized Pt wire, coated with Ag-conducting epoxy, into contact with aligned MWCNTs (Figure 4(b)).[58] The conductive surfaces were insulated with polyphenol. Afterward, a 1 V negative potential in electrolyte was applied to expose only the CNT tip of the probe. It was demonstrated that these MWCNT bundle-tipped probes could be used as electrochemical nanoelectrodes.

AC electric fields were used to capture bundles of CNTs at the tips of tungsten microelectrodes to form nanoprobes with a macroscopic handle.[59] Two tungsten microelectrodes were submerged in aqueous solutions containing either SWCNT or MWCNTs, so that their tips opposed each other. By applying an AC field across the two electrodes, CNTs were attracted to the regions with high field intensity to form narrow bundles at the electrode tip. Instead of AC fields, magnetic forces have been employed to position ferromagnetic CNTs at the tips of glass micropipettes.[60] Magnetic CNTs placed inside a glass micropipette were driven to its tip by magnetic fields, upon where the protruding CNT was fixed in place by epoxy.

Glass micropipettes have also been used as templates for forming CNPs. Using CVD, a carbon film was deposited onto all the surfaces of the glass micropipettes[23] or preferentially on the inner surfaces with catalyst[24] and CVD process controls.[25] After the glass was selectively removed from the pipette tip, an integrated CNT-like structure remained at the tip of the larger glass micropipette (Figure 4(c)). Diameters as small as 10 nm have been achieved with this technique.

3.330.3.4. Enhancement and Selectivity

Several strategies have been developed to enhance the sensing capabilities of carbon nanostructures. Their surfaces can be functionalized, modified, and customized to selectively detect molecules, chemicals, and biological materials in liquid or gas phases. Noncovalent attachment can be utilized to preserve the structure of CNTs by adsorbing material onto their surface. Covalent attachment needs the surface of CNTs to have defect sites, often requiring the surface to be chemically activated in order to bind molecules to their surface. Alternatively, CNTs can be embedded or filled with material.

Surfaces of CNTs can be modified by noncovalent attachment. A simple method is to deposit material onto CNTs through incubation or drying steps. For example, CNT-coated glassy carbon electrodes were incubated in a combination of proteins and surfactants to enhance interfacial electron transfer[61], while single-stranded DNA were deposited and left to dry on top of CNT-based FETs in order to detect vapors.[62]

A more elegant method is to use adsorption of aromatic compounds. In general, this strategy involves first attaching linker molecules to hydrophobic surfaces of CNTs via pi–pi stacking. Subsequently, nanoparticles, molecules, or proteins are then attached to linker molecule. For example, this method was used to selectively bind to streptavidin.[63] The surfactant poly(ethylene glycol) (PEG) was used to bind to hydrophobic CNTs to prevent the nonspecific binding of proteins to their surface. However, when CNTs were coated with diamino-PEG, amine-reactive protein reagents (in their case, amine-reactive biotin) could be bound to the CNTs. This gave the CNT selectivity by only permitting selective binding to high-affinity molecules, in this case streptavidin. These methods were used with several different linker molecules and selective reagents (proteins, receptors, and even chemicals) to enhance the selectivity of FETs and chemical sensors.[34,38,64]

Covalent functionalization is accomplished by chemically attaching molecules to the CNT surface and is reviewed in detail.[65] In general, CNTs that lack defect sites need to undergo processes, such as sonication, acid treatment, electrochemical oxidation, or plasma treatment to activate their surface and provide hydrophilic surface functional groups for covalent attachment. CNTs and CNFs that have defect sites, such as those grown from template-based synthesis methods, will have binding sites but often still require a degree of surface activation.

A common approach is to use two linker molecules to covalently attach biomolecules to the surface of CNTs. CNTs are first activated by acid, electrochemistry, or other means to produce carboxyl functional groups on their surface. CNTs are then incubated in standard coupling agents, such as 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and derivatives of *N*-hydroxysuccinimide (NHS) or 2(*N*-morpholina)ethane sulfonic acid (MES). The combination of the linker molecules allows biomolecules to bind to

the CNT surface by forming linkages between the biomolecule amine groups and CNT carboxyl groups. This functionalization method has been successful in many applications, for instance, attaching peptide nucleic acid to CNTs to preferentially bind to DNA sequences,[66] attaching DNA to the surface of magnetic CNTs for intracellular delivery,[67] and binding glucose oxidase to CNTs for the electrochemical detection of glucose.[68]

Several methods have been developed to make CNT-nanoparticle hybrids. The tips of CNT-based nanoelectrodes were coated with Au, Fe, and Ag nanoparticles using short-pulse, nonthermal corona discharge in liquids containing metal-salt solutions.[69] Metal nanoparticles can also be attached to CNT surfaces through electrostatic interactions. A positively charged polyelectrolyte was used to attach negatively charged Au nanoparticles to the negatively charged surface of acid-treated nitrogen-doped MWCNTs.[70]

Besides attachment to CNT surfaces, nanoparticles can be embedded into CNTs or filled inside. For instance, CNTs grown by C-PECVD contain ferromagnetic nanoparticles enclosed in their tips. It was demonstrated how vertically aligned CNTs grown from Ni could be manipulated by external magnetic forces and be directed to spear cells.[67] Similar capabilities were demonstrated by embedding iron oxide nanoparticles into the walls of CNTs[26] or filling them with magnetic nanoparticles[27] during template-based CNT synthesis processes.

3.330.4. Sensing Applications of Carbon Nanostructures

The unique properties of CNTs and other carbon nanostrucutures make them well suited for a broad range of sensing applications. For example, the mechanical properties of CNTs enable them to be used, among other things, as strain gauges,[71,72] pressure transducers,[73–75] torsional sensors,[76,77] textile-based sensors,[78] atomic mass sensors,[79] fluid flow sensors,[80] and displacement sensors.[81] The thermal responses of CNTs can be used as thermometers,[82,83] environmental monitors,[84,85] and infrared sensors,[86] while their optical properties have found uses as strain gauges,[87] pressure gauges,[88] and photodetectors.[89] This section mainly focuses on the biological sensing applications of CNTs and other carbon-based nanostructures. Reviews of additional CNT-based biological sensors can be found in literature.[90–92]

3.330.4.1. Electrochemical Sensors

Whether randomly dispersed or grown onto conductive surfaces, the electrical properties and modifiable surfaces of CNTs enable them to be used as electrochemical sensors. Compared to conventional electrodes, CNT-based electrochemical sensors offer higher surface area-to-volume ratio that increases the signal-to-noise ratio for sensitive detection. CNT-based electrodes can be further modified by surface activation to enhance interfacial electron transfer, selectively detect analytes, or attach reagents that prevent nonspecific binding but allow specific binding of analytes. Additional information on chemical sensing with other nanostructured materials is available.[93]

Randomly dispersed CNT films can be used as electrochemical sensors. For instance, ferrocene was noncovalently attached to acid-treated SWCNT films to detect glutamate.[34] The combination of SWCNTs and ferrocene provided enhanced surface area, direct electron transfer, and catalytic effect. Electrodes can also be coated with CNTs to enhance the performance. As described in a previous section, CNT-coated carbon nanoelectrodes outperformed conventional carbon fiber electrodes of similar geometry.[35]

CNT coating with CNTs can also enhance other electrodes, such as glassy carbon and Pt microelectrodes. It was found that CNT-coated glassy carbon electrodes offered superior performance to noncoated electrodes.[94] The same group later showed that direct electrochemistry of microperoxidase immobilized on the surface of CNT-coated Pt microelectrodes catalyzed the reduction of O_2 and H_2O_2.[95]

CNT arrays, as depicted in **Figure 2(e)** and **2(f)**, can be used directly as electrochemical sensors. The Ren group developed an electrochemical sensor (similar to **Figure 2(f)**) from an array of CNTs (50–80 nm diameter, 10–12 μm long) grown from electrodeposited Ni nanoparticle catalyst on a Cr-coated Si substrate.[49] The low-density array exhibited sigmoidal behavior during cyclic voltammetry and provided high signal-to-noise ratio. The electrochemical sensor was used to detect glucose (as well as ascorbic acid, uric acid, and acetaminophen) by attaching glucose oxidase to the CNT surface through the EDC/sulfo-NHS linker moiety.[68] The sensor was later used to detect lead in low-electrolyte conditions[96] and trace cadmium (II) and lead (II) at sub-ppb level (detection limit of 0.04 $\mu g l^{-1}$).[97]

Electrochemical sensors have also been developed from arrays of CNTs that protrude an insulating surface, as depicted in **Figure 2(e)**. Starting with CNPs grown on a Pt-wire substrate (**Figure 3(c)**),[98] a nanoelectrode array with protruding conical carbon tips (**Figure 3(d)**) was produced that exhibited sigmoidal electrochemical behavior.[48] By oxidizing the protruding nanoscopic tips, the sensor was able to electrochemically distinguish between ascorbic acid (oxidation-shifted peak) and dopamine. Electrochemical sensors of a similar configuration using PECVD-grown CNT arrays have also been reported.[99]

3.330.4.2. Detection of Gases and Vapors

The conductance of SWCNT- and MWCNT-based FETs is significantly affected by changes on or near their surface and as such provides attractive sensors for detecting gases and vapors with high sensitivity. Although manufactured in various ways as described previously in this chapter, CNT-based FETs consist of a nanotube or network of nanotubes that bridge the gap between two electrodes (**Figure 5**). Semiconducting CNTs are

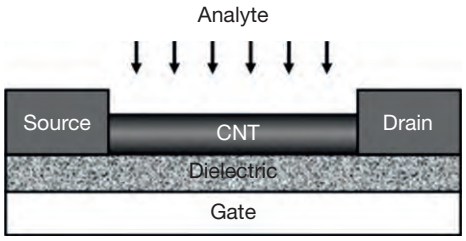

Figure 5 Configuration of a typical carbon nanotube-based field-effect transistor.

attractive for FET applications as their conductance is highly sensitive to the environment and varies significantly with changes in electrostatic charges and surface adsorption of molecules.

The resistance of semiconducting SWCNT-based FETs operating at room temperature dramatically changes when exposed to gaseous molecules such as nitrogen dioxide, ammonia, and oxygen.[39] Due to their sensitivity, SWCNT-based FETs had an order of magnitude faster response than solid-state sensors. Similar SWCNT-based FETs were later used to detect butylamine and 3′-(aminopropyl)-triethoxysilane in vapor phase.[100] The work was extended to detect low levels of NO_2 (44 ppb) and nitrotoluene (262 ppb) using a network of semiconducting SWCNTs connecting interdigitated electrodes (**Figure 1(c)** and **(d)**).[40]

CNT-based FETs were used as 'electronic noses' to detect odors.[62] Metal electrodes were patterned over CVD-grown CNTs on an SiO_2/Si substrate with e-beam lithography to form the FET. To enhance the detection and provide selectivity, single-stranded DNA was deposited and dried on the device (**Figure 6(a)**). The sensor was used to detect and distinguish between methonal and propionic acid, as shown in **Figure 6(b)**, as well as other odors such as trimethylamine, dinitrotoluene, and dimethyl methylphosphonate.

Gas ionization sensors were developed from vertically aligned MWCNTs arrays to overcome argued limitations of CNT-based FETs, such as poor diffusion kinetics, inability to identify gases with low adsorption energies, low capacity to distinguish between gases and gas mixtures, and high susceptibility to changes in moisture, temperature, and gas-flow velocity.[101] These sensors utilized differences in breakdown voltage to distinguish between mocromolar concentrations of distinct gases, measurements that were unaffected by moisture, temperature, and gas-flow.

Acoustic and optical gas sensors, respectively, were developed by coating CNTs onto quartz crystal microbalances (QCMs) and silica optical fibers (SOFs).[102] As shown in **Figure 6(c)**, CNT-coated QCMs were roughly one to two orders of magnitude more sensitive than uncoated QCMs. It was demonstrated that CNT-coated SOFs had similar low limits of detection and enhanced sensitivity.

3.330.4.3. Detection of Biomolecules

CNT-based sensors are attractive for detecting biomolecules commonly found in aqueous environments. For instance, researchers at the NASA Ames Research Center utilized vertically aligned CNT arrays[47] to bind DNA to the surface of CNTs,[103] detected RNA, DNA, and DNA PCR amplicons in solution,[41,104,105] and even delivered DNA plasmids into cells.[46] For the detection applications, CNT-based devices similar to those depicted in **Figure 2(f)** were manufactured and DNA probes were covalently attached to the ends of CNTs using the EDC/sulfo-NHS method. When combined with the $Ru(bpy)_3^{2+}$-mediated guanine oxidation method, the CNT-based sensor was capable of detecting less than a few

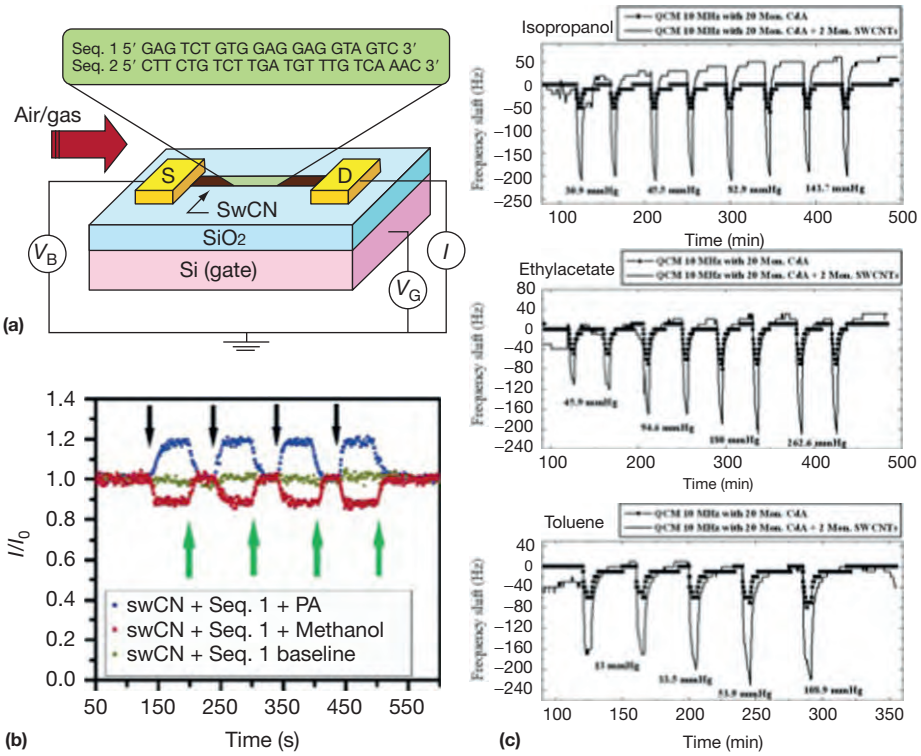

Figure 6 Carbon nanotube-based gas and vapor sensing. (a, b) Odor sensing with field-effect transistor. Adapted from Staii, C.; Johnson, A. T.; Chen, M.; Gelperin, A. *Nano Lett*. **2005**, *5*, 1774–1778, with permission. (c) Gas sensing by microbalance. attomoles of oligonucleotide targets, showing orders of magnitude improvement in sensitivity over other electrochemical detection of DNA immobilization,[105] as well as detecting low number of PCR amplicon targets comparable to fluorescence-based DNA microarray techniques.[104] These detection capabilities were later summarized.[41] The electronic platform facilitates DNA and RNA detection and makes it possible to be integrated into handheld microfluidic lab-on-chip devices.

Although their sensing capabilities were first demonstrated with the detection of gases and vapors, CNT-based FETs were soon utilized in electrolytes[106] to detect chemicals and biomolecules in aqueous environments. The development of such SWCNT-based FETs with the selective binding and recognition of target proteins was reported.[38] FETs were manufactured by dispersing a network of polyethylene oxide (PEO)-functionalized SWCNTs between two electrodes. The PEO coating, noncovalently bound to the CNT surface by pi–pi stacking, strongly prevented nonspecific binding. However, when its hydroxyl termini were activated, the receptors of specific targets could be conjugated to the PEO-coated CNTs to enable selective binding of target proteins. CNT-based FETs conjugated with staphylococcal protein A (SpA) were extremely sensitive to the addition of a protein that has a high affinity to SpA (i.e., IgG protein) but showed negligible response to others. Additional sensors were developed for streptavidin–biotin and U1A-mAbs 10E3 to demonstrate their usefulness in disease detection and proteomics.

The Strano group developed SWCNT-based near-infrared sensors to detect biomolecules *in situ*. These optical sensors detect the presence of specific targets by monitoring the fluorescence of functionalized SWCNTs at wavelengths that are transparent to biological tissue (900–1600 nm). In one application, a porous vessel containing glucose oxidase-coated SWCNTs was implanted beneath a human epidermal tissue sample.[107] The implanted sensor was capable of distinguishing between slight variations in local glucose concentration within the range of blood glucose. In contrast to flux-measuring electrochemical glucose sensors, concentration-measuring optical sensors were less prone to biofouling and significantly more stable over longer periods.[108] The group later reported detecting DNA hybridization and conformational polymorphism in cells with similar sensors.[109,110]

3.330.4.4. Single-Cell Probes and Sensors

CNT-tipped probes offer the ability to probe small aqueous environments, such as ultralow volumes of liquids or single living cells. In contrast to CNT arrays or planar configurations, CNT-tipped probes are needle-like configurations, like those shown in **Figures 1(b)** and 4, things as fluid droplets, single cells, or living tissue.

As discussed earlier, CNT-tipped AFM cantilevers were some of the first CNT-tipped probes to be developed.[29] With high spatial resolution and precise manipulation, CNT-tipped AFM cantilevers were used in SPM applications[50–54] and were able to probe and deliver surface-bound cargo to cells.[55,56] Despite their relatively easy use and high spatial resolution, these CNT-tipped probes were limited by laborious fabrication and inadequately suited for fluid delivery to and electrical sensing of discrete fluid volumes. In contrast, the development of CNT-tipped pencil-shaped probes and their utilization in biological sensing have progressed more rapidly. This is mostly due to their ability to readily fit standard cell physiology equipment such as optical microscopes, micromanipulators, cell injection systems, and electrophysiology amplifiers.

One of the earliest CNT-tipped biological sensors reported was an SWCNT-coated carbon fiber nanoelectrode (100–300 nm tip diameter, as shown in **Figure 1(b)**).[35] Using cyclic voltammetry, the CNT-tipped electrode could detect dopamine, epinephrine, and norepinephrine at concentrations of an order of magnitude lower than that of noncoated probes. The demonstration was significant because the dimensions of the CNT-tipped probe would make it possible to study the functions of living cells and tissue with minimal intrusion. Additionally, the pencil-like shape of the probe readily fit standard cell physiology equipment and facilitated its use.

Several pencil-shaped probes tipped with a single or bundle of CNTs were developed afterwards. Of note, it was reported that a probe tipped with a bundle of MWCNTs could be used as an electrochemical sensor.[58] This demonstration helped inspire the development of CNT-based probes to measure intracellular signals.[111] Referred to earlier as CNPs, these CNT-tipped probes were used to penetrate the membrane of single living cells and electrically measure changes in their transmembrane potential upon extracellular chemical and pharmacological stimuli. It was later shown that a CNT-tipped probe was capable of electrically stimulating and measuring intracellular and extracellular responses more efficiently than the electrolyte-filled glass micropipettes typically used in cell electrophysiology.[112]

3.330.5. Future Opportunities

As illustrated in this chapter, the diversity in size, shape, structure, and configuration of carbon nanostructures enables a broad range of capabilities for biological sensing. Over the past two decades, research related to CNTs and carbon nanostructures has grown from discovery, fabrication, and characterization to utilization and application. However, the later is still in its infancy. Over the next few decades, the applications of CNTs and carbon nanostructures, especially sensing applications, should be expected to grow exponentially into industrial applications, clinical usage, and consumer products.

Abbreviation

AuNP	Gold nanoparticles
BSA	Bovine serum albumin
BSE	Biological sensing element
CNT	Carbon nanotubes
CP	Conjugated polymer
dsDNA	Double-stranded DNA
DNA	Deoxyribonucleic acid
EDC	1-ethyl-3-(3-dimethylaminopropyl) carbodiimide
ELISA	Enzyme-linked immune sorbent assay
EP	Electropolymerization
FRET	Förster resonance energy transfer
GOx	Glucose oxidase
HRP	Horseradish peroxidase
LbL	Layer-by-layer
LOD	Limit of detection
MBP	Maltose-binding protein
MV-B	Methylviologen-labeled biotin
NTA	Nitrilotriacetic acid
PANI	Polyanline
PDA	Polydiacetylene
PPO	Polyphenol oxidase
PPY	Polypyrrole
PSA	Prostate-specific antigen
PTP	Polythiophene
QCM	Quartz crystal microbalance
RNA	Ribonucleic acid
SPR	Surface plasmon resonance
ssDNA	Single-stranded DNA
ssPNA	Single-stranded peptide nucleic acid
SEM	Scanning electron microscopy

3.331.1. Conjugated Polymers (CPs): History and Perspectives

3.331.1.1. Introduction

Biosensors based on conjugated polymers (CPs) have attracted much attention from the research community during the last 20 years. The definition of biosensors can be summarized from a discussion on biosensors published by IUPAC.[1,2] In reference to these publications, biosensors are a subclass of chemical sensors and devices that recognize selective and reversible chemical substances or ions and produce a concentration dependent continuous signal. Further refinements of this definition and definition of terms are in accordance with the standard article on chemical and biochemical sensors by Renneberg and coworkers published as part of *Ullmann's Encyclopedia of Industrial Chemistry*.[3] The signal that is generated can be in principle electric, calorimetric, or optical. This definition might be extended by the assumption that either the analyte that is to be detected by the sensor or the principle of detector–analyte interaction is derived from biological systems (Figure 1).

This definition appears to be a good measure for technologies that can be easily applied in research or in medicine. In addition, stability, selectivity, shelf life, and cost must be considered for a widely used tool in R&D and medicine. Applying this strict definition for biosensors, sensoric systems based on CPs and biorecognition molecules, described in a major part of the literature, cannot be regarded as biosensors, because they lack the direct contact of the biorecognition component with the transducer, reversibility, selectivity, a continuous signal, or a combination of those.[4] However, even though the definition of a biosensor is not met, it does not mean that the sensoric system cannot be used for analytical purposes. But the technology is rather to be described as a bioassay in analogy to the terms dosimeter or indicator in the field of chemosensors.[5] This chapter aims to give an overview of technologies based on CPs that are used to detect selectively specific analytes and to explain the principles of detection behind these technologies. The focus lies on sensoric systems that meet the definition of a biosensor, though bioassays are important as analytical tools and can sometimes be converted into a biosensor by changing the design and are therefore not, in principle, excluded from this chapter. The selectivity of a sensoric system is further defined by the accuracy of the result in terms of the interference by other substances to the measurement. In detail, selectivity is the ratio of the sensitivity of an interfering substance to the sensitivity measured for the analyte. The sensitivity of a biosensor or a bioassay is the slope of the calibration curve of the analyte and is expressed in signal units per concentration. Sensitivity is the change in signal observed with a change in analyte concentration and should not be confused with the limit of detection (LOD) which expresses the smallest detectable concentration of the analyte. Especially for biosensors that reversibly detect analytes, stability is a very important parameter. Stability describes the variation of the signal with time and often decreases toward the end of the lifetime of a sensor system. To create a biosensor or a bioassay, based on CPs that achieves good properties within the above specifications, the CP, and the sensor or assay design need to be fine-tuned for the employed detection mechanism and the analyte that is to be detected. To see the possibilities and to understand the challenges for tailoring the CPs and sensor and bioassay designs, a short introduction to the properties of CPs will be given, followed by an introduction to electrochemical and optical detection systems. Electrochemical biosensors and optical biosensors and bioassays employing CPs, detecting deoxyribonucleic acid (DNA), small biomolecules, and proteins, will be discussed. Biosensor and bioassays employing CPs is a relatively new discipline that emerged from two different research areas, biosensor/bioassay research and the discovery of specific properties of conductive polymers. It is noteworthy that both research areas needed many decades to advance and to produce such sophisticated materials, methods, and devices that will be discussed in this chapter. Bioassay research dates back to at least the middle of the nineteenth century when Fehling[6] published his method to detect glucose in the urine of diabetic patients in 1848. Biosensors in terms of the definition made above had their dawn in 1962 when Clark reported on an 'electrode' that can continuously and reversibly measure glucose concentration in blood during cardiovascular

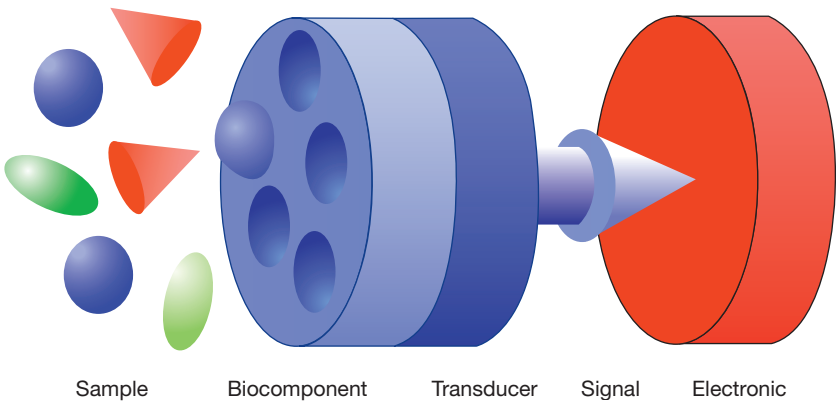

Figure 1 A generalized schematic of a biosensor. The sample contains the analyte that interacts with the biocomponent, which leads to a physical or chemical change that is 'transduced' by the transducer into a signal. This signal is finally detected by the electronic component and displayed or recorded. Reprint with permission from Trau D. Thesis, 2004.

surgery.[7] Since then, biosensors and bioassays have advanced much, and detection of drugs, metabolites, toxins, small molecules, ions DNAs, ribonucleic acids (RNAs), proteins, and polysaccharides is possible nowadays.[8,9] The development of biosensors can be described in three stages, the first, second, and third generation of biosensors.[10–13] In the first generation of biosensors, as, for example, the Clark electrode to detect glucose, the naturally occurring product of the enzymatic reaction diffuses to the transducer and generates the electrical response.[10–12] Biosensors of the second generation use a mediator interacting with the reaction product and the electrode to generate an improved response.[10–12] Biosensors of the third generation, however, do not rely on the diffusion process of reaction products or mediators.[10–12] The enzymes are immobilized together with the mediator very close to the electrode surface, and sometimes there may even be direct electrical contact between the electrode and the enzyme.[14–16] Many of today's biosensors relying on electrochemical transduction mechanism fall into the second or third generation category and can detect various analytes.[11,12,17] In today's biosensor and bioassay research, the major challenges are to create multiplex systems with high selectivity and sensitivity and good LOD without false positive or negative analytical readings. Selectivity of a biosensor or bioassay is especially challenging when real samples such as tissue homogenates, blood, urine, saliva, or sweat are to be analyzed.[4,17] Furthermore, the LOD and the ability to distinguish different concentrations are challenging in real samples. Bioassays that fulfill the above criteria and are commercially available and widely employed in research and medicine are for example: enzyme-linked immune sorbent assays (ELISA), lateral flow assays such as pregnancy tests or CardioDetect® – a bioassay to detect heart attacks in patients. Biosensors that fulfill the above definition and are commercially available are reviewed in the literature[18,19]; the most prominent ones are glucose biosensors in medicine and surface plasmon resonance (SPR), and quartz crystal microbalance (QCM) biosensors as research instruments. CPs are promising candidates to facilitate a new generation of biosensors and bioassays with ultra low limits of detection and high sensitivity due to their signal amplifying properties.[5,20] Research on CPs is ongoing for more than 130 years as extensively pointed out by Gyorgy Inzelt in his book *Conjugated Polymers – Historical Background* (or: There is nothing new under the sun).[21] In fact, the first report about polyacetylene by Adolf von Baeyer entitled *On Polyacetylene Compounds*.[22] dates back to 1885. Reports on polyaniline (PANI) produced by electrochemical oxidation are even older[23] and is unlike the polyacetylenes at that time, very similar to our today's PANI that is frequently used in biosensors.[21] CPs that are frequently used for biosensor and bioassay application are depicted in **Figure 2**.

CPs can serve two major purposes in biosensor devices. They are used either as passive supporting and structuring material on which the sensory biomolecule system can be easily immobilized or as an active component.[8] CPs are able to combine the properties of the very high conductivity of metals with chemical modifiability and properties of polymers.[24] They are therefore also referred to as synthetic metals.[25] Due to the diversity of CPs, many possibilities are available to couple analyte receptor interactions to convert them into an

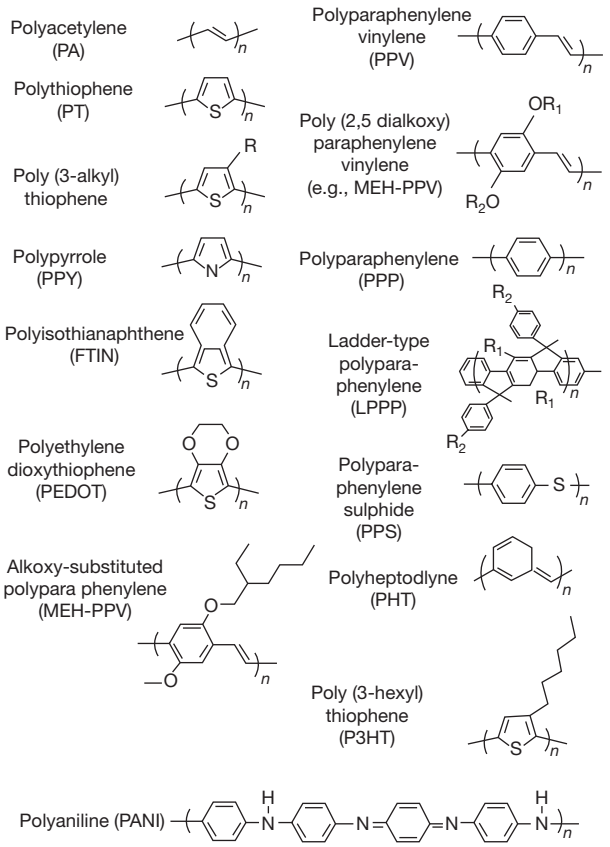

Figure 2 A selection of conjugated polymers that are frequently used for biosensor and bioassay applications. Noteworthy is the occurrence of conjugated double bounds within the polymer backbones, creating a conjugated π-electron system that equips the conjugated polymer with its 'electric conductive' property. observable signal. In cases where CPs are used as active component, they often serve as the transducer, mediating the signal upon analyte interaction. One of the main advantages of the use of CPs in biosensor devices over simple small molecule sensor elements is the signal amplifying property of CPs.[5] In biosensor devices using CPs, the sensory system is very sensitive to minor perturbations upon analyte interaction which leads to a dramatic improvement of the LOD compared to biosensors using small molecule sensor elements.[20] For biosensor devices employing CPs, two general classes of transducible signals can be generated: (1) electrical signals, which could be a change in resistivity, in electrical current, or in potential[19,26] and (2) optical signals, manifested in a change of fluorescence wavelength or intensity, in quenching of fluorescence, or change in color or intensity in nonfluorescent systems.[27–29] The signal amplifying properties of CPs are mainly due to their charge and 'signal transport' properties. The backbone of the CP, which consists of a conjugated π-electron system, allows a fast migration of 'signals.' Those signals are electrical charges or energy states that are also responsible for the CPs' high conductivity.[30] It needs to be noted that those energy states and charges create the electrical conductivity unlike in classical semiconductors such as silicon where electrons or holes are transported.

3.331.1.2. Synthetic Strategies and Processability of CPs

The methods to synthesize CPs are extremely versatile and there is often more than one way that leads to the same CP.[31,32] However, the plasticity and processability of the polymer can change dramatically with the procedure that is used for synthesis.[32] Processability is one of the most important properties of CPs when it comes to fabrication of a biosensor device, and the most suitable way of polymerization must be chosen for the desired application. In general, synthetic strategies for the polymerization might be chosen from classical polymer chemistry methods such as coordination polymerization on specific catalysts,[33] common polymer organic chemistry methods,[34,35] or electrochemistry methods.[23,36]

It should be pointed out that most non-modified CPs are insoluble in water and most organic solvents, and often cannot be melted without degradation, and thus, to obtain solubility in organic solvents or water, further processing is necessary.[32] To obtain solubility, side chain modifications of CPs are conducted. Different functionalities can be introduced depending on desired properties.[37] To obtain water solubility, either hydrophilic oligomers such as polyethylene glycols or charged groups such as acid or amine functions, which render the polymer a water-soluble polyelectrolyte, can be introduced. To obtain good solubility in organic solvents, aliphatic or other hydrocarbon chains are introduced.[32] Furthermore, special side chains can be introduced to allow specific interactions or binding with analytes or biomolecules to bring the sensoric system close to the polymer backbone.[28,29,38] In some cases and especially for electrochemical biosensors, the CP is polymerized directly on the surface of the electrode while simultaneously physically entrapping the biomolecular detection system (e.g., enzymes). In this case, the biomolecule is present with polymer monomers in aqueous solution when a certain potential is applied at the electrode on which the CP shall be precipitated (usually by an oxidation reaction). Electrochemical polymerization can, in general, be done by three different methods: (1) the current between the electrodes can be held constant to obtain polymerization under galvanostatic conditions, (2) the potential between the electrodes can be held constant to allow polymerization under potentiostatic conditions, or (3) the scanning or sweeping of the potential can be used to alter the polymer properties obtained during polymerization.[34,36] To polymerize the polymers directly on an electrode surface, usually a divided cell containing a working electrode, a counter electrode, and a reference electrode is used. This method works with most conducting electrode materials and is thus a widely employable method for various biosensor designs. The obtained polymer does not need to be solution processible, but side chain modification can dramatically increase the sensing ability or facilitate polymerization under mild conditions.[39] Special attention is attributed to heterocyclic CPs such as polypyrroles (PPYs), polythiophenes (PTPs), and PANIs because of their importance for biosensor and bioassay systems. PPYs and PTPs can be polymerized by electrochemical oxidation direct on an electrode surface, by oxidizing chemicals, or by other synthetic strategies.[34,35] PANIs are mostly polymerized by direct oxidation on an electrode. For heterocyclic CPs such as PTPs, a side chain modification is necessary to render them water or solvent soluble. Due to the nonsymetric nature of thiophene molecules, four different couplings are possible as depicted in **Figure 3(a)**.

The properties of CPs change significantly from one regioisomer to another, and hence the correct method for synthesis needs to be chosen (**Figure 3(b)**).[31] The chemistry for PPYs is partially similar to that of PTPs, and care must be taken to choose the correct polymerization method.[36,40–42] PANI in its neutral form can exist in different oxidation states (**Figure 4(a)** to **Figure 4(d)**), the least oxidized form called leucoemeraldine base, the semioxidized form called emeraldine base, and the most oxidized form called pernigraniline base.[25] The most practical way to synthesize PANI in its different states is to synthesize the emeraldine base, which is the only form stable at room temperature and air and to reduce or oxidize it to the other forms. The emeraldine base can be obtained by oxidation of aniline in aqueous media by oxidizing agents such as $(NH_4)_2S_2O_8$, KJO_3, $K_2Cr_2O_7$, and others or by electrochemical oxidation in acidified solutions by sulfuric or hydrochloric acid (**Figure 4**).[23]

Chem.* **2001**, *40*, 2581–2590.

Excellent reviews describing synthetic strategies for PTPs,[31,35] poly(pyrroles),[41,42] poly(anilines),[23] other CPs suitable for biosensors[43–45] as well as processability of CPs[32] are available and therefore are not further reviewed in this chapter.

3.331.1.3. Doping Reactions to Facilitate Conductivity and Specific Tasks

CPs are usually stated to be 'semiconductors with a wide band gap' in their pristine (not doped) state and exhibit low conductivity properties. However, CPs can be made electrically conductive by doping. The term doping in the chemistry of CPs originates from semiconductor physics. In semiconductor physics, atoms of a material framework are replaced to generate free electrons (e.g., phosphorus atoms in a silicon framework) or electron holes (e.g., boron atoms in a silicon framework), which is referred to as n-type doping and p-type doping, respectively. In CPs, the doping process, however, refers to oxidation (p-doping) or reduction (n-doping) of the σ-electronic structure of the polymer backbone. This fundamental discovery,[46] mainly made by Alan G. MacDiarmid, Hideki Shirakawa, and Alan J. Heeger during their research on the partial oxidation of polyacetylene, earned them the Nobel prize in Chemistry in 2000.

Doping of CPs can be divided into mainly four methods, chemical doping, electrochemical doping, photochemical doping, and interfacial doping.[25,47] One of the most studied chemical doping mechanisms is the doping of PANI by acid base chemistry. The doping of PANI is depicted in **Figure 5**. The emeraldine base is converted into the emeraldine salt upon addition of acid. This mechanism leads to one unpaired spin per repeat unit; however, the electron number per repeat unit does not change.

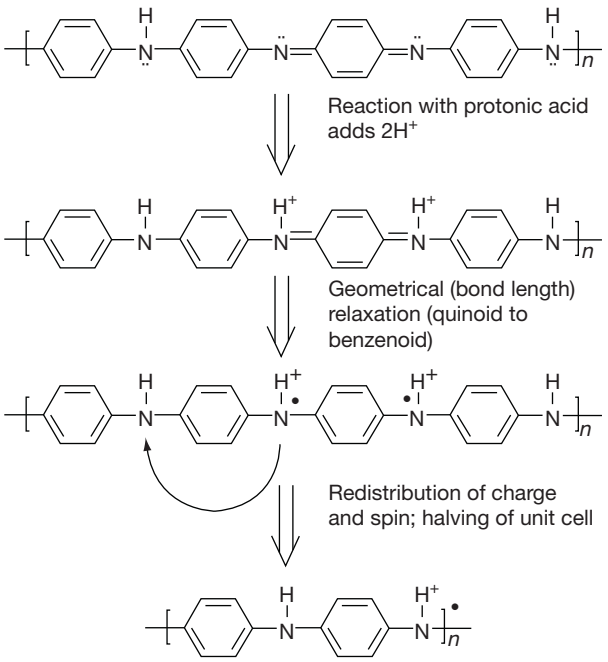

Figure 5 Doping of polyaniline by acid base chemistry changes the properties from insulating to electric conductive without changing the number of electrons in the backbone. Reprinted with permission from Heeger, A. J. *Angew. Chem.* **2001**, *40*, 2591–2611.

A more generalized mechanism for chemical doping is that of charge transfer redox doping in which CPs are either oxidized (p-type doping) or reduced (n-type doping). Oxidation of CPs is often accomplished by exposure of the polymer to halogens such as iodine, bromine, or chlorine leading to partial oxidation of the backbone.[46] Reduction of CPs can be achieved by compounds with a strong reduction potential such as sodium organic compounds.[25] The principle of electrochemical doping is essentially the same as that of chemical doping, except that the redox potential is supplied by an electrode. The extent to which the CP is doped directly depends on the potential and can thus be precisely controlled. The charges that are created during this process are compensated from counter ions from the surrounding electrolyte solution.[36] Electrochemical doping is the most widely used doping mechanism for CPs in biosensor devices and is depicted in **Figure 6**.

During photodoping, the CP becomes locally oxidized and reduced, which creates a charge separation and thereby induces conductivity.[48,49] Interfacial doping of CPs is mainly reported by charge injection at a metal–CP interface.[50] Electrons and holes can be injected from a metallic contact into the π^* and π gaps of the polymer. In this process, electrons are either removed from the band gap (oxidized polymer) or electrons are added into the band gap (reduced polymer). This process is fundamentally different from that of chemical doping because of the fact that no counter ions are present to those charges.[47] The polymerization of pyrrole or thiophene by electrochemical oxidation leads to their doped (oxidized) state.[32,40]

Heterocyclic CPs differ significantly in their properties when they are not doped. PPY is highly reactive and reacts with the smallest amounts of oxygen whereas neutral PTP is stable under ambient conditions.[32]

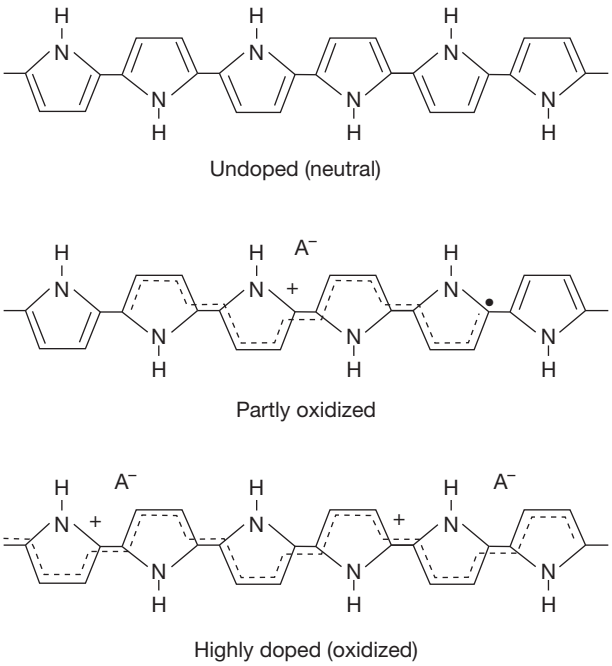

Figure 6 Electronic structure of polypyrrole after electrochemical or chemical oxidation. The charges created are compensated by counterions from the surrounding environment. Reprinted with permission from Smela, E. *Adv. Mater.* **2003**, *15*(6), 481–494.

3.331.1.4. Properties of CPs

3.331.1.4.1. Electric conductivity

During the doping procedure in which the CP is oxidized or reduced, local charge carriers are generated. Those carriers can exist in different variations such as anion, anion radical, dianion or cation, cation radical, and dication.[51] Due to the conjugated π-electron system in the backbone of the polymer, those charge carriers are not isolated and immobile. The surrounding environment is able to interact directly with the charge carriers, which allows relaxation in close proximity to the charge carriers. The result of this relaxation is distortions of different species such as solitons, polarons, and bipolarons. Those distortions are able to migrate through the polymer and thereby mediate electrical conductivity. The electrical conductivity can be best imagined as migration of energy waves through the polymers instead of jumping electrodes in classical conductors. Additionally, the interpolymer chain migrations of electric charges is another very important factor for the very high electric conductivity, especially for films of CPs. The above description is only a very condensed summary of relatively complex physical phenomenons for which excellent reviews are available.[34,52,53]

3.331.1.4.2. UV/VIS absorption and fluorescence

Analogous to molecular spectroscopy, the π-electrons can be excited by an ambient wavelength.[54,55] The relaxation of the electron to its ground state can generally occur by two different mechanisms, by radiative recombination in which the energy difference between the higher state and the ground state is released as light (luminescence or fluorescence) or by a nonradiative mechanism. In general, the assumption can be made that more polarizable polymers in which the π-electrons are more delocalized, such as polyacetylene or PTPs, will exhibit a very weak luminescence, whereas other classes of CPs, for example, poly(phenylenevinylene) or poly(paraphenylene) exhibit a very high luminescence quantum efficiency.[47] For the design of biosensor devices, only the final property of the CP is of importance. Though, detailed theoretical explanations to group CPs in classes of good luminescence and in classes of poor luminescence as well as band gap engineering are available[56], these properties of CPs have direct influence on the design of a biosensor device. If a biosensor or a bioassay is to be designed which uses fluorescence superquenching as detection approach, soluble poly(phenylenevinylene) or poly(paraphenylene) derivatives are often used,[28,29] whereas if an electrochemical transducer principle is employed, soluble PTP, PANI, or PPY derivatives are often used.[26]

3.331.1.4.3. Signal amplifying properties

The surrounding environment can induce hypsochromic or bathochromic effects as well as hypochromic or hyperchromic effects. In the typical case in molecular spectroscopy, however, the surrounding environment interacts with only one separated fluorescent molecule. The signal that can be obtained from one molecule is relatively low, and many interactions need to occur at the same time in order to obtain a measurable signal. This means the concentration of an interacting molecule (e.g., the analyte) needs to be high to be detected. In the case of CPs, one environmental molecule interacts with many monomer units of the CP due to the conjugated π-system. Therefore, in the case of CPs, the concentration of interacting molecules (e.g., analyte) in the environment can be very low and still lead to a large signal. This phenomenon is referred to as signal amplification in CP-based biosensor devices using optical transducer systems.[5,9,20]

3.331.1.5. Electrochemical Biosensors

3.331.1.5.1. Amperometric biosensors

Amperometric biosensors measure the current flow between electrodes when a redox reaction takes place. The most investigated amperometric biosensor system is probably the glucose biosensor. In this system, glucose oxidase (GOx) catalysis the reaction of glucose with oxygen to gluconolacton and hydrogen peroxide. The signal is usually depicted as current (ampere) against concentration of glucose caused by a redox reaction of a mediator or hydrogen peroxide at the working electrode. Noteworthily, most CP-based amperometric biosensors are biosensors of the third generation where the enzyme and the mediator are directly immobilized on the transducer. Thus, the detection of the signal does not rely on the diffusion of reaction products or the mediator. An excellent review of PPY-based biosensors and general electron transfer principles was published by Singh *et al.*[11,12] and Habermüller *et al.*,[57] respectively (**Figure 7**).

3.331.1.5.2. Potentiometric biosensors

In potentiometric biosensors, the CP is immobilized on a measurement electrode, and the electrochemical potential relative to a reference electrode (without a current flow) is

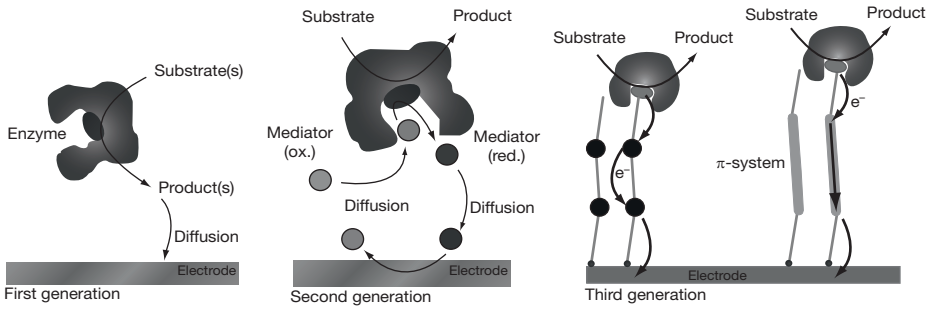

Figure 7 Different principles of amperometric redox enzyme-based biosensors. Left: direct measurement of the current generated by the redox reaction (first generation biosensor). Middle: using a mediator that transfers the signal from the enzyme to the electrode by diffusion (second generation biosensor). Right: transfer of the electron from the enzyme to the electrode by a conjugated π-system or "molecular wire" (third generation biosensor). Adapted with permission from Habermüller, K.; Mosbach, M. *Fresenius J. Anal. Chem.* **2000**, *366*, 560–568.

measured.[16] The mechanism behind those biosensors is the change of the electrochemical potential of the electrode coating materials.[58] The electrode coating can only comprise either the CP or the CP with specific biomolecules.[59] The analyte might bind to the biomolecule that is bound to the CP and thereby change the electrochemical potential of the CP, or the CP might be sensitive to reaction products of the analyte with a bound enzyme (e.g., pH).[60]

3.331.1.5.3. Conductometric biosensor

Biosensor devices based on CP can be designed in such a way that the signal is displayed by a change in electrical conductivity. This can be done relatively easily by connecting a 'source' and 'drain' electrode with a film of CPs.[61,62] The conductivity or resistivity is then measured against the analyte concentration. In general, the applied potential can be either constant or sweeping during this measurement. As the nature of the CPs is to obtain high conductivity only when the polymer is charged, those measurements are very sensitive to processes in which a change of the doping state occurs.[63,64] This needs to be especially considered when the pH affects the doping status. Furthermore, the charges that are created within the backbone of the CP are able to interact with the surrounding environment and thus change the conductivity of the CP.

3.331.1.6. Optical Biosensors and Bioassays

3.331.1.6.1. Colorimetric, fluorescence, and superquenching-based biosensors

Biosensors of the strict definition made above based on optical transducer systems mainly employ SPR or other evanescent wave-based technologies.[65] So far the possibilities of creating optical biosensors using evanescent wave technologies together with CPs have been poorly investigated. Most reports on CP-based optical biosensing focus on homogeneous or surface-immobilized bioassays that are often not reversible.[28,29,66]

The difference between optical transducer systems based on colorimetric change or change of fluorescence is that a colorimetric change refers to a change in absorption wavelength and fluorescence refers to changes in emitted light. Analogous to the principles of molecular spectroscopy, the absorption and emission characteristics of CPs depend on the local electronic structure and the environment. An excellent review of the fluorescence phenomena, fluorescence spectroscopy, and Förster resonance energy transfer (FRET) can be found in 'Principles of fluorescence spectroscopy' by Lakowicz.[67] Transduction principles in optical bioassays based on CPs rely mostly on the following mechanism: quenching (FRET) or main chain conformational perturbation of the CP.[38,68] The fluorescence of CPs can be quenched by FRET. Many CPs exhibit a very high-fluorescence quantum yield attributed to many repeating conjugated monomer units. A single analyte molecule can cause a significant reduction of fluorescence because, in theory, one quencher molecule is able to quench the fluorescence of a whole polymer molecule. This signal amplification by CPs can be in the magnitude of millionfold compared to corresponding molecular excited states.[27] Bioassays based on quenching principles can be based, in general, on increased fluorescence by removing the quencher from the polymer upon analyte interaction or by decreasing fluorescence, bringing the analyte close to the polymer and causing quenching. Both mechanisms are depicted in **Figure 8** on the example of DNA sensing.

In addition to quenching or FRET-based bioassay systems, other mechanisms that generate readable optical signals are used. One possibility is to use CPs that are able to undergo backbone conformational changes upon interaction with the analyte as depicted in **Figure 8(b)**. Suitable polymers (such as PTP derivatives) for this mechanism usually exhibit a relatively low π-electron delocalization while in twisted conformation. As described earlier, the more the π-electrons are delocalized, the weaker is the fluorescence of a CP. In this type of assay, the negatively charged DNA probes interact with the cationic CP to form a duplex in which the polymer has a planar conformation. When the target DNA interacts with the DNA probe, which is attached to the CP, a triplex is formed in which the CP has a twisted conformation. The interaction of the target DNA with the probe-CP duplex restores thereby the initial fluorescence. Bioassays using optical readout signals based on CPs have been introduced for DNA, protein, and polysaccharide sensing.[4,69–71] Bioassays with extremely low LOD (zeptomolar) for DNA and very good selectivity (e.g., single nucleotide mismatch in DNA) have been described ideal samples (solutions of analyte in buffer). However, when it comes to real samples such as cell lysates, body fluids, or cell culture media, those assays often lack specificity and reversibility in general.

3.331.2. Using CPs for Electrochemical Biosensor Devices

3.331.2.1. Introduction

After the establishment of the first electrochemical glucose biosensor, the immobilization techniques of biological sensing elements (BSEs) onto electrodes for subsequent electrochemical biosensors began to evolve as a means to improve the sensitivity and detection limits of these biosensors. Electrochemical biosensors began to utilize associations of these elements, with the electrodes (transducers), through various methods such as direct adsorption, cross-linking, covalent bonding, and gel entrapment. The direct interaction of BSEs with the electrodes, rather than using a dialysis membrane, effectively reduced proximity-related issues and resulted in a better exchange of electrochemical signals and electroanalytical response between these two entities. However, the mentioned approaches were not ideal as there were possibilities of immobilized BSEs getting detached (binding forces are susceptible to changes in pH, temperature, or ionic strength), limiting available surface area for the immobilization of BSEs, and the use of covalent cross-linking chemicals might be too harsh for the BSEs.

Immobilization of BSEs onto electrodes fortunately took a revolutionary transformation after the initial demonstration that stable CPs layers can be deposited onto electrodes with strong adhesion properties.[72] By simply adopting an electropolymerization procedure, which can be performed under mild conditions, with good reproducibility, and onto electrodes of any geometry, BSEs such as DNA,[73] enzymes,[74,75] antibodies,[76,77] and cells[78,79] can be immobilized within the electropolymerized CPs and be in close proximity to the electrodes. In addition, these BSEs can retain their bio-functionality. Electrochemical biosensors were thus revolutionized and two possible CP-based electrochemical biosensor configurations have since been realized. Most works have retained the original Clark and Lyons configuration (Figure 9(a)) for biosensing applications while an alternative miniaturized bioelectrochemical transistor configuration had also been demonstrated (Figure 9(b)).

Currently, the most applied configuration for CP-based electrochemical biosensors is the Clark and Lyons configuration (Figure 9(a)), where the BSEs and CPs are deposited onto the working electrode and various electroanalytical methods, such as amperometric and impedimetric, have been adopted for the detection of the respective analytes. In this setup, the CPs serve as excellent electronic conduits that convey biophysical or biochemical reactions occurring at the biosensing interface as electrical information to the underlying electrodes. Examples include the interaction of antibodies and antigens or an enzymatic reaction that induces a change in the CPs' electronic properties. In contrast, CP-based electrochemical biosensors using the miniaturized bioelectrochemical transistor configuration involves the switching 'on' or 'off' of the conductivity of the deposited CPs (between two electrodes: a 'source' and a 'drain') as depicted in Figure 9(b). For example, at a given source-drain voltage and using GOx as the BSE, introduction of glucose has resulted in a corresponding increase of drain current (i.e., the CP is converted into a better conducting state as a result of chemical interaction of GOx with glucose).[61,62,80,81] On the other hand, the use of horseradish peroxidase (HRP) as BSE caused a decrease in drain current when hydrogen peroxide was introduced (i.e., the CP was

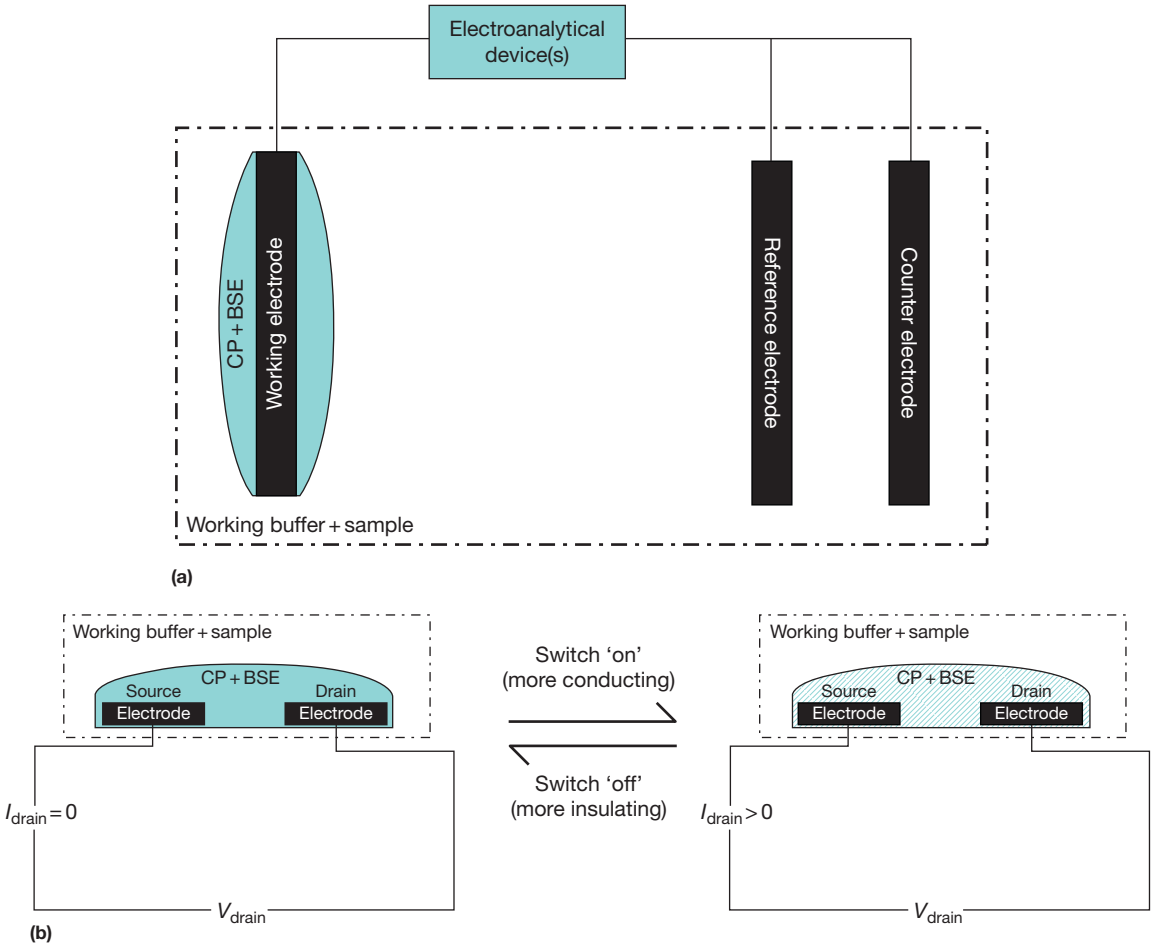

Figure 9 (a) Simplified conjugated polymer-based 'Clark and Lyons' configuration electrochemical biosensors and (b) simplified CP-based miniaturized bioelectrochemical transistor configuration electrochemical biosensors.

converted into a more insulating state).[63,64] Current progress in this area encompasses the use of CP nanowires[82,83] or microtubules[84] as bridges between the 'source' and 'drain' electrodes (**Figure 10**) rather than CP films as the high surface-to-volume ratio of these structures can create strong electrochemical signals in the presence of low analyte concentrations.[85] Advantages of using CPs in these electrochemical biosensors include possible controlled localization of biological materials within defined CP film layers on working electrodes,[86] immobilization of different enzymes onto closely spaced working electrodes through manipulation of the applied potentials,[87] and chemical flexibility in modification of the CPs for association with BSEs[88–90] or redox mediators.[57,91,92] In view of focus to the discussion of CP-based electrochemical biosensors and due to the uncertainties clouding the exact mechanisms, the various biosensing mechanisms via CP-based electrochemical means will not be discussed. Also, subsequent sections will discuss only CP-based biosensors designed through the Clark and Lyons biosensor configuration.

Deposition of CP layers on electrodes is mainly performed either through potentiostatic or galvanostatic techniques, and the thickness of the film can be tuned[93,94] by varying either the potential or current with time. Thicker films have been reported to exhibit electrochemical responses of increasing magnitude with increment of CP layer thickness[95] whilst thinner films, although with lesser sensing elements, produce biosensors with higher sensitivities[58,93,94] and faster response times[96,97] as diffusion of analytes within these thinner films

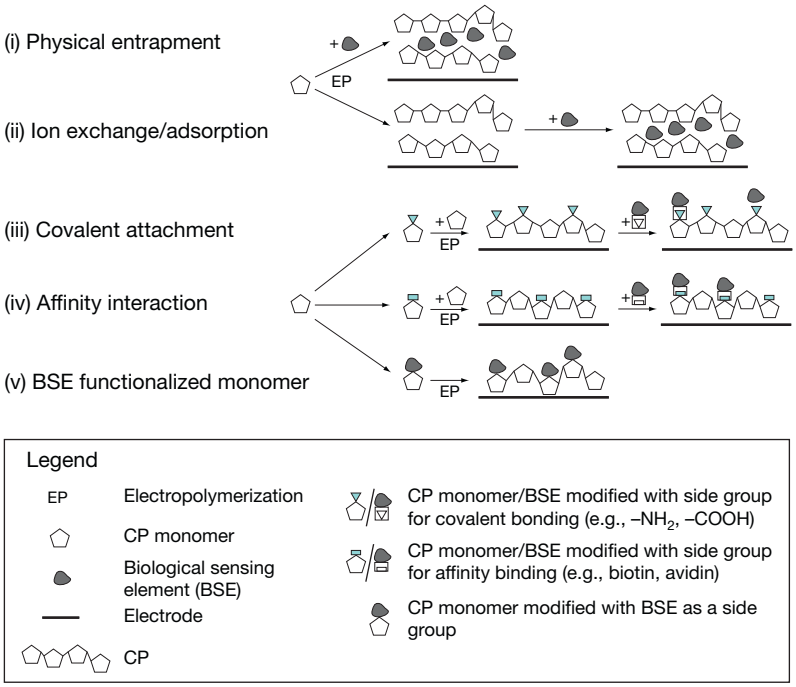

Figure 11 Schematic representation of five general approaches adopted for immobilization of BSEs with conjugated polymer electrochemical biosensors: (i) physical entrapment, (ii) ion exchange or physical adsorption, (iii) covalent attachment, (iv) affinity interaction, and (v) BSE-functionalized CP monomer. It is worth noting that (ii), (iii), and (iv) are post-EP immobilization strategies.

are easier. Supporting electrolytes are usually included during the electropolymerization process as a means to increase the electroconductivity of the CP monomer solution and to compensate the charge of the growing CP layers. Unfortunately, these electrolytes also tend to compete with the BSEs for the polymer doping sites, in the case of physical entrapment technique, and thus reduce the quantity of BSEs incorporated. Therefore, BSEs, such as GOx,[59] α-human serum albumin,[76] and single-stranded DNA (ssDNA),[73] have been substituted as counterions during the growth of the CP layers to allow for more efficient entrapment. Interestingly, deposition of CPs has been demonstrated to be possible via the layer-by-layer (LbL) technique as well.[98,99] In the next section, the incorporation of BSEs during the fabrication phase of electrochemical CP-based biosensors will be described.

3.331.2.2. Immobilization Strategies for Biological Sensing Elements (BSEs) onto CP-Coated Electrodes

PPY is currently one of the most extensively used CPs in the fabrication of CP electrochemical biosensors, as compared to the other CPs such as PANI and PTP. The popularity of PPY stems from the mild conditions required for the one-step simultaneous electropolymerization of pyrrole monomers and entrapment of BSEs. Only mildly oxidative conditions and an aqueous neutral medium are necessary for its electropolymerization onto an electrode, thereby resulting in minimal disturbance to the native properties of the many BSEs that are to be entrapped during the electropolymerization process.[11,12,100] PANI and PTP, on the other hand, require acidic conditions and extreme oxidation potential, respectively, during the electropolymerization process to yield highly conducting CPs, and both conditions are not favorable to many BSEs that are to be entrapped within the CP layers during the electropolymerization process.[11,12,100] Therefore, BSE immobilization strategies involving PANI and PTP, are in general, approached by post-electropolymerization (EP) immobilization strategies. Figure 11 categorizes the five general approaches adopted for immobilization of BSE in CP-based electrochemical biosensors: (1) physical entrapment, (2) ion exchange or physical adsorption, (3) covalent attachment, (4) affinity interaction, and (5) BSE-functionalized CP monomer. (NB: (2), (3), and (4) are post-EP immobilization strategies). In the following section, only brief details of the immobilization protocols are given. Readers are referred to excellent reviews in Table 1 for further elaborations and Table 2 for immobilization examples.

3.331.2.2.1. Physical entrapment

By far, this is the most straightforward BSE immobilization strategy for CP-based electrochemical biosensors and can be achieved in a single step. Physical entrapment of enzymes,[74,75] antibodies,[76,77], DNA,[73] and cells[78,79] has been achieved during the electropolymerization of CP monomers onto electrodes. A solution of CP monomers and BSEs is first prepared and the monomers are subsequently subjected to electrochemical oxidation to create a matrix of CP strongly adhered to the surface of the electrodes that also encapsulates nearby BSE within the matrix. Advantages of this strategy include the possibility of controlling the amount of entrapped biomolecules simply by controlling the thickness of the CP layer that is being polymerized and the ability to entrap different enzymes simultaneously[145] or in a layered fashion.[86] Unfortunately, physical entrapment of BSEs via direct electropolymerization requires a high concentration of monomer and BSEs, which might not be especially suitable for costly BSEs.

3.331.2.2.2. Ion exchange/physical adsorption

An alternative measure for immobilization of BSEs within CP layers can be achieved via a postpolymerization approach as depicted in Figure 11(ii). Such a method is especially suitable when using CPs, such as PANI or PTP, where the polymerization conditions for fabrication of the CP layers are not favorable to maintain the biofunctionality of BSEs. Immobilization of BSEs by physical adsorption is simply performed through the interactions of oppositely charged BSEs and CPs. An ion exchange step can be first performed through manipulation of the redox states of the CPs to realize physical adsorption of BSEs. Depending on the redox states, CPs can exist in the charged or uncharged state, thus affecting the mobility of dopant ions into and out of the polymerized CP layers. By electrochemically changing the CPs into the uncharged state, ions can be expelled from the CP layer and recovery of the charged state will attract and cause oppositely charge BSEs to be adsorbed onto the polymerized CP layers. For example, GOx (pI = 4.2) was successfully adsorbed onto PANI-polyisoprene layers that had been prepared on platinum electrode. Adsorption was achieved through reduction (using a negative potential) of the PANI copolymer layer to remove dopant anions followed by reoxidation (using a positive potential) of the CP layer and immersion of the electrode into a GOx solution (pH = 6.5).[106]

3.331.2.2.3. Covalent attachments

Although immobilization via physical entrapment and absorption are simple procedures, there are also certain drawbacks. Physically adsorbed BSEs are susceptible to desorption should changes in the environment arise (e.g., pH or ionic strength), and biosensors fabricated with entrapped BSEs are likely to experience problems associated with inaccessibility of the embedded BSEs and diffusion hurdles for the analyte (e.g., antigens). To improve the stability and efficiency of interaction between BSEs and CP layers, these BSEs can be covalently attached to the working electrode by a postpolymerization immobilization strategy (Figure 11(iii)). Interfacial localization of these BSEs allows ease of interaction with their respective analytes, especially when considering analytes of large molecular weight. Covalent immobilization of BSEs is commonly carried out by initial preparation of functionalized monomers such as carboxylated pyrrole,[94] carboxylated thiophene monomer[110,111,124] or pyrrole monomers with an amino side group.[113] Electro-oxidative polymerization of these functionalized monomers is subsequently carried out to fabricate CP layers with interfacial attachable side groups. These attachable groups can then be covalently bounded to BSEs containing the corresponding groups (e.g., CP–COOH with NH_2-BSE) through the use of cross-linkers if necessary (e.g., 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide, EDC). PANI, on the other hand, requires no prefunctionalization as the secondary amino groups present within the CP skeletal backbone can be utilized for covalent attachment of BSEs. This can be performed through bifunctional cross-linkers such as gluteraldehyde with BSEs containing an amino side group.[109,112] However, harsh conditions associated with the use of covalent cross-linkers have provided an impetus for researchers to synthesize functionalized monomers containing easy leaving groups such as *N*-hydroxyphthalimide[93,138] which do not require the use of cross-linkers. Work has also been presented that demonstrated the use of benzophenone-functionalized pyrrole monomers that, after polymerization, can be covalently attached to GOx through the use of light irradiation.[90]

3.331.2.2.4. Affinity interactions

Affinity binding systems, such as biotin/avidin, have been employed for immobilization of BSEs onto CP layers as well. Currently, the biotin/avidin affinity pair is the most frequently utilized affinity system in immobilization of BSEs onto CP layers, and stems from the commercial availability of biotinylated enzymes, ssDNA probes, and antibodies. Other possible systems utilized are the nitrilotriacetic acid (NTA)-cation/histidine pair,[116] pyridine/maltose binding protein (MBP) pair,[117] and adamantane/β-cyclodextrin pair.[146] In the biotin/avidin system, the general immobilization approach consists of creating either a biotinylated CP interface (e.g., polymerization of pyrrole-biotin monomer[88,89,125]) or an avidin-CP interface (e.g., postmodification of PANI layer with avidin[11,12]) first. CP layer formation with biotinylated pyrrole monomers unfortunately requires a copolymerization process with unmodified pyrrole monomers due to the poor electropolymerization ability of these biotin derivatives.[89] It follows that if the interface had been biotinylated, the subsequent binding of avidin-modified BSEs (e.g., avidin–alkaline phosphatase[88]) or biotinylated BSEs (e.g., biotin-GOx,[88,89] biotin–antibody[125]), through an avidin bridge, can take place on these biotinylated CP layers. If the interface consists of avidin, following binding of biotinylated BSEs can take place. For the NTA-cation/histidine and pyridine/MBP pair, addition of histidine or MBP tags onto either the C′ or N′ end of proteins was required and performed via mutagenesis to allow binding to their respective binding partners, where these partners had already been modified onto the CP layers. In the last system, GOx and pyrrole monomer were covalently bonded to β-cyclodextrin and adamantane respectively for the fabrication of a glucose electrochemical biosensor. Unlike covalent bonding, affinity interactions can provide the same strong and stable interactions while allowing only a single linkage, through regioselective modification of the BSEs, between the BSEs and CP layer. Multiple linkages are undesirable as

the active site for analyte interaction might become sterically hindered and thus affect the response of the biosensor.

3.331.2.2.5. BSE-functionalized CP monomer

A last and novel approach for the fabrication of CP electrochemical biosensors involves the prefunctionalization of the CP monomer with the desired BSE prior to polymerization. This was first demonstrated with GOx covalent attached to pyrrole monomers in 1992.[118] Polymerization of the GOx-modified pyrrole resulted in a CP layer that demonstrated good stability of the modified enzymes and was used to generate a glucose-sensitive biosensor. This was performed in the presence of the unmodified monomers due to steric problems associated with the dimerization of the GOx-functionalized PPY monomer. Subsequently, only a handful of similar works utilizing this same approach was demonstrated and used for the immobilization of peptides[142,147] and ssDNA[148,149] onto CP films; however, the electrochemical approach for detection of their respective bioanalytes was not used in most works.

3.331.2.3. Choice of Entrapment Approach

As has been described, the immobilization of BSEs will result in two spatial possibilities: either within the CP layers or at the surface of the CP layers. The choice of immobilization approach is dependent on the type of BSE in consideration and the size of the analyte to be detected. For example, immobilization of oxidoreductases (e.g., GOx) is preferentially done via entrapment within the CP layers due to the ease of electron transfer from the enzyme's redox centre to the bulk of the surrounding CP or due to rapid redox reaction of electroactive species (e.g., H_2O_2) resulting from the enzymatic catalysis. In addition, the enzymatic analytes (e.g., glucose) are usually small and are able to diffuse easily within the CP. On the other hand, antibodies and ssDNA are preferentially immobilized on the exterior surface of the CP layers due to the ease of access between these BSEs and their respective target of interest. This was exemplified by the immobilization of antibodies for prostate-specific antigen (PSA) within PANI layers via physical entrapment and onto the exterior surface using the biotin–avidin affinity system. Upon introduction of PSA, the latter affinity biosensor exhibited detection limits that were ~1000 times lower than that of PSA biosensors fabricated using the physical entrapment approach.[126,150]

3.331.2.4. Current Research Directions of Electrochemical CP-based Biosensors

The discovery and application of CPs as an underlying matrix support and conduit for BSEs in electrochemical biosensors has indisputably enhanced the performance and reliability of electrochemical biosensors since its introduction in 1979. Unfortunately, although many significant improvements have been reported, the application of CPs for electrochemical biosensors is still plagued with certain compatibility issues. One issue pertains to the hydrophobic nature of CPs, which provides an unfavorable environment for entrapped BSEs and thus results in biosensors with reduced analytical responses.[120,151] Various methods can be employed to counterbalance this hydrophobic nature of the organic CP and include the use of laponite clay,[151] hydrogels (poly (2-hydroxyethyl methacrylate)[97,152] and alginate[134,153,154]), and hydrophilic pendant groups[120] within the CP layers. Incorporation of hydrophilic functionality within CP layers is likely to improve swelling and thereby increase the percentile of aqueous content within the CP layer. This permits a more efficient diffusion of water-soluble analytes and reaction end-products within the CP layer, and also provides a more favorable environment for the entrapped BSEs.

Gold nanoparticles (AuNPs)[109,123,155] and carbon nanotubes (CNTs)[98,145,156–158] have been utilized in the design of CP-based electrochemical biosensors as a means to enhance the electroconductivity and electroproperties of these biosensors. Incorporation of AuNP has been demonstrated through aqueous electropolymerization of pyrrole monomers in the presence of chloroauric acid[159] (where the chloroauric acid oxidizes into AuNP) or via direct physical entrapment of AuNPs within polypyrrole–pyrrolepropulic acid layers.[160] In both these examples, AuNPs within the CP layers resulted in biosensors of improved sensitivity during analyte detection. Another advantage of utilizing AuNP is the conversion of PANI, where the native form is only electroactive in acidic conditions, to an electroactive form at neutral pH,[123,155] thus extending the range of BSEs that can be incorporated into PANI-based biosensors. Inclusion of CNTs within the CP-based electrochemical biosensor can be achieved using CNT surface-modified electrodes,[145,156] alternate deposition of CP and CNT via the LbL technique[98] or electropolymerization of CP with CNT.[157,158] CNT surface-modified electrodes have been demonstrated to possess higher surface area due to the introduced nanometer-sized CNT and hence allowing an increased quantity of CPs and ssDNA probes to be deposited onto the electrode.[156] Electropolymerization of PPY with CNT was demonstrated to result in biosensors of improved sensitivity[145,157,158] and response times.[157] Lastly, the oxidation potential utilized for glucose detection, through the incorporation of CNTs, could be performed at potentials lower than 0.7 V,[98,158] thereby avoiding possible noise signals from common interfering substances such as ascorbate, urate, acetaminophen.

A final approach pertains to the formation of CP nanostructures rather than using films of CP onto the electrodes. Such nanostructures include nanoparticles,[107,110,124,161] nanofibers,[136] and nanoelectrode arrays.[140,162–166] With a bigger surface area to volume ratio, as opposed to a planar CP film, this allows for a higher capacity of BSEs loading via surface immobilization and an improved diffusion of target analyte to the immobilized BSEs. PANI nanoparticles, doped with dodecylbenzenesulfonic acid, have been fabricated via polymerization and electrodeposited onto the surface of glassy carbon working electrodes.[107] Adsorption of HRP onto these deposited PANI nanoparticles via an ion exchange process resulted in a hydrogen peroxide electrochemical biosensor with improved signal-to-background ratio and an improved response time. Alternatively, CP nanoparticles can be directly synthesized onto electrodes as reported with the use of a thiophene-derivative monomer.[110,124] An advantage of these thiophene nanoparticles, as reported, is the use of a reduced oxidative potential for the sensing of H_2O_2.[110,111] PPY nanofibers have been fabricated onto platinum electrodes through the introduction of a series of potential pulses, and subsequent physical absorption of double-stranded DNA

(dsDNA) resulted in an electrochemical biosensor that can detect a wide linear range of spermidine and with improved LOD.[136] CP-based nanoelectrode arrays can be fabricated either through direct polymerization of CPs onto the exterior of existing nanoelectrodes[162,166] or within the pores of a membrane template.[140,163–165] For example, CP-based nanoelectrode glucose electrochemical biosensors have been fabricated through either the electropolymerization of PPY and GOx onto carbon postmicroarray or physical absorption of GOx within the pores of PPY nanotubes that had been prepared with a porous membrane, and both works demonstrated the fabrication of a glucose biosensor of improved sensitivity.

3.331.3. Using CPs for Optical Biosensor Devices

3.331.3.1. Introduction

In the following section, the optical biosensing of DNAs, proteins, and small organic biomolecules with the use of CPs will be described. Many excellent reviews describing the optical detection of DNAs, protein, and small organic biomolecules with the use of CPs are available[9,28,38,167–172]; and this chapter is different in that the focus will underline 'biosensor' applications and the general detection mechanisms (performed through the use of CPs as transducers) involved in the identification of these different groups of bioanalytes. CPs have also been exploited for the detection of metal ions, but most of the reported works describes the use of CPs as chemosensors rather than biosensors.[8,9] The optical biosensing of metal ions using CPs also appears to be limited (potassium ions using ssDNA/CP liposomes[173,174] and mercury ions using papain/CP complexes,[175] sugar modified CPs[176] or aptamer/CP liposomes)[177] and hence will not be discussed. In addition, experimental specifics will be brief (e.g., synthesis or the exact structure of CPs used, temperature, buffer system, and sequence of DNA used in analysis are intentionally left out) so as to not to 'overload' the readers with information. By providing these general mechanisms, it is hoped that readers will gain insightful information and knowledge regarding the use of CPs in optical biodetection and further apply them for use in biosensor devices.

The exploitation of CPs, for the optical biosensing of biological targets has seen remarkable progress after its proof-of-concept demonstration in the early 1990s.[178] In 1993, a blue colored Langmuir–Blodgett film consisting of ultraviolet polymerized bilayer assembly of polydiacetylene (PDA) functionalized with an analog of sialic acid was prepared for the biosensing of influenza virus.[179] Sialic acid serves as a recognition ligand for the influenza virus hemagglutinin, and the subsequent introduction of target virus resulted in a blue to red color change of the PDA film. Liposomes fabricated from the same functionalized PDA also demonstrated the same colorimetric changes upon incubation with the influenza virus.[180] Two possible mechanisms for the observed colorimetric changes have been suggested.[181] Firstly, the binding of the large multivalent virus is likely to have caused a significant conformational change in the polymer side chains, which progressively affected the main conformational shape of the conjugated backbone, thus resulting in the colorimetric change. The colorimetric change has also been attributed to a possible virus insertion into the bilayer film followed by a disruption of the initial conformational shape of the CPs.

After its initial demonstration, biosensing based on CPs has been further advanced by many researchers and is classified into three subclasses in this section for ease of references for the readers: (1) the use of liposomal CPs functionalized with BSE, (2) the use of BSE/CP complexes, and (3) CP covalently modified with BSE.

3.331.3.2. BSE-Functionalized Liposome CPs

Liposomes, lipid-based microcapsules, are an interesting class of vesicles that have been commonly used for gene or drug delivery therapeutics as they share common properties with cellular membranes. Interestingly, liposomes can be fabricated with CPs (Figure 12) as well and have been utilized for biosensing applications. It is worth noting that functionalizing of liposomal CPs with BSEs for biosensing applications is a critical component of the biological sensing ability and can be carried out by various approaches. For example, the probes can be either initially covalently modified onto the CP monomers prior to assembly into liposomes[179,180,182] or postmodified onto the surface architecture of the liposomes. Postmodification can be carried out covalently[183–185] or by physical insertion into the bilayer assembly.[74,186]

Generally, the biosensing of target species through the use of liposome CPs functionalized with biological probes employs a common transduction mechanism that produces a colorimetric response and can be used to identify the presence of the target of interest. Upon interaction of the probe and target of interest, regardless of whether the interaction is a chemical or physical reaction, the conformational shape of the CP backbone is disturbed and results in a colorimetric response. For example, the interfacial catalysis of phospholipids by phospholipases[187,188] results in hydrolysis products that do not retain within but leave the liposome membrane. The loss of these phospholipids results in pits and cracks within the membrane[187] and perturbs the CPs conformational backbone. Table 3 summarizes a nonexhaustive list of the different types of target and corresponding probes that have been detected with the use of liposomal CPs.

However, for the development of CP-based optical biosensor devices, it is preferred that the demonstration of target detection is performed on a solid support as stable and repeatable analyte monitoring in solution phase (susceptible to concentration variations caused by evaporation) is very unlikely to be achievable. Using solid-support biosensing has an additional advantage of allowing multiplex detection of desired targets. Solid-support liposomal CPs have been demonstrated and this was achieved either by trapping the liposomal CPs in hybrid sol–gel materials[196] or via covalent attachment onto a surface-modified planar substrate.[173,174,177,197] By associating different antibodies with liposomal CPs, solid-support arrays of these differently modified lipsosomal CPs have been fabricated and were shown to be capable of multiplexed detection of proteins[196] or bacteria.[197]

3.331.3.3. BSE/CP Complexes

Aside from optical biosensing via the use of liposomal CPs, optical biosensing of desired targets can also be achieved

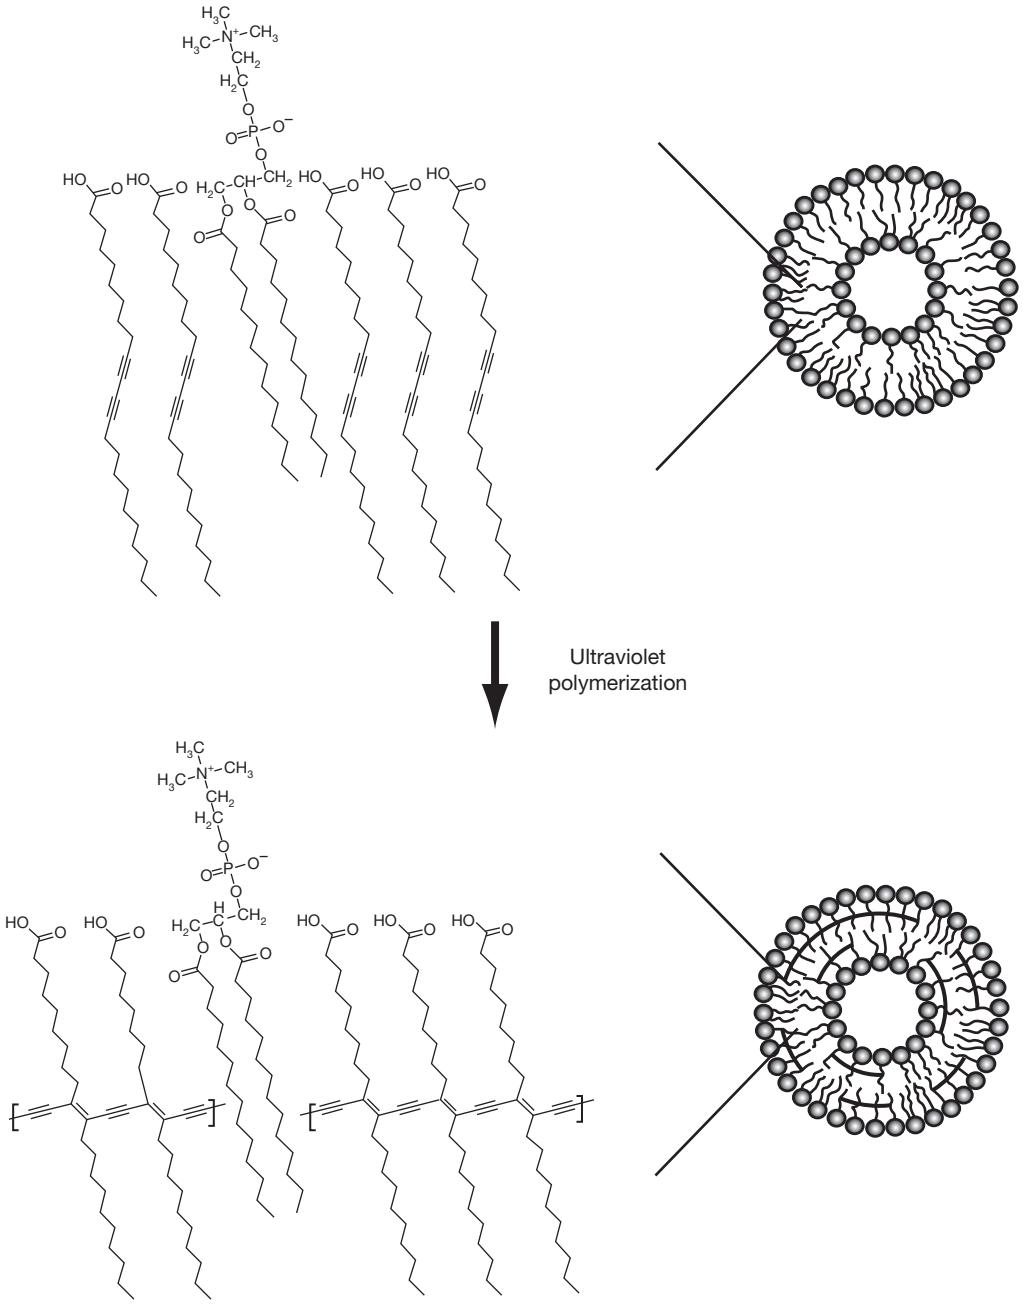

Figure 12 Schematic representation of a typical approach for the fabrication of lipid(dimyristoylphosphatidylcholine in this case)/polydiacetylene liposomes. Reproduced from Okada, S. Y.; Jelinek, R.; Charych, D. *Angew. Chem. Int. Ed.* **1999**, *38*, 655–659.

through the use of BSE/CP complexes. For example, biodetection of ssDNA and enzymes can be achieved through the use of ssDNA probe/CP and enzymatic substrate/CP complexes, respectively. For simplification of target detection, the following section will be split into (1) DNA and (2) protein optical biosensing through the use of BSE/CP complexes.

3.331.3.3.1. DNA biosensing using DNA probe/CP complexes

Intercalating dyes are a conventional and commonly used tool in the detection of dsDNA as these dyes increase in fluorescence quantum yield after intercalating between base pairs of dsDNA. Therefore, intercalating dyes can also serve as transducers for the detection of specific DNA sequences through intercalation of dsDNA that were hybridized from sample ssDNA and a probe ssDNA of predetermined sequence. Unfortunately, the detection efficiency of dsDNA using intercalating dyes has not been as desired but can be significantly enhanced[163,164,198–200] when combined with the use of CPs; where efficient FRET can occur from the excellent light-harvesting CP to the intercalating dyes. Recently, CPs have seen immense applications in the field of DNA sequence

Table 3 A nonexhaustive list of the different types of BSEs and corresponding targets that have been detected through the use of liposomal CPs

Target of interest (analyte)	*Biological sensing element (BSE)*	*Functionalization method*	*References*
Influenza virus	Sialic acid	Precovalent modification of CP monomer	180,181
Ions	Ionophores (valinomycin, monensin)	Physical insertion	189
Escherichia coli	Glycolipid (dioctadecyl glyceryl ether-β-glucosides)	Physical insertion	74
Antibody	Peptide antigen	Physical insertion	186
Streptavidin	Biotin	Precovalent modification of CP monomer	182
Potassium ions	G-Rich ssDNA	Postsurface modification of CP liposome	173,174
Mercury (II) ions	T-Rich aptamers	Postsurface modification of CP liposome	177
Cryptosporidium parvum	Antibody	Postsurface modification of CP liposome	183,184
Phospholipases	Phospholipid	Physical insertion	187,188
Human immunoglobulin	Antibody	Postsurface modification of CP liposome	185
Bacteria (*Escherichia coli*, *Pseudomonas aeruginosa*, *Salmonella enteriditis*, *Salmonella Minnesota*, and *Shigella flexneri*)	Typtophan and tyrosine	Precovalent modification of CP monomer	190
Catecholamines (noradrenaline and dopamine)	Specially designed synthetic receptors	Physical insertion	191
Pore forming toxins (streptolysin O)	Lipid constituents (glycine-terminated diacetylene monomer, 1,2-bis (10,12-tricosadiynoyl)-*sn*-glycero-3-phosphocoline and cholesterol)	Physical insertion and precovalent modification of CP monomer	192
ssDNA	ssDNA	Physical insertion	193
Sphingomyelinase/galactosidase	Sphingomyeline/cerebroside	Physical insertion	194
Cholera toxin	G_{m1} ganglioside	Precovalent modification of CP monomer	195
Antigens (α-fetoprotein, β-galactosidase, bovine serum albumin, and phosphatase)	Antibody	Postsurface modification of CP liposome	196
Bacteria (*Cryptosporidium parvum*, *Giardia lamblia*, *Escherichia coli*, *Salmonella typhimurium*, *Shigella flexneri*, *Encephalitozoon intestinalis*)	Antibody	Postsurface modification of CP liposome	197

optical detection[201–203] and have also been applied in single nucleotide polymorphisms (SNPs) detection,[169,170,204–207] DNA lesion detection,[208–211] and quadruplex-to-duplex transition of G-rich oligonucleotides.[212] RNA optical detection with the use of proteins and CP has been demonstrated[213] but will not be discussed here. An advantage that CP-based optical detection of DNA sequence holds over conventional laboratory methods of DNA detection is the likely elimination of a polymerase chain reaction (PCR) step as the excellent light-harvesting properties and efficient electron/energy transfer properties of CPs allows DNA to be detectable at the zeptomolar (10^{-21} M) range.[205,214] Similar to most DNA detection protocols, DNA sequence optical detection through the use of CPs emphasizes on the need of specific and stable Watson–Crick base pairing of nucleic acids. The sensitive biological elements responsible for specific DNA sequence detection are ssDNA or single-stranded peptide nucleic acid (ssPNA) probes. CPs do not partake in the detection (i.e., not the recognition element) but are exploited as transducers that emit a unique optical response upon interaction with double-stranded helixes.

Using the works of Ho *et al.*[205] as an example, a fluorescence-labeled ssDNA was utilized as a probe for a specific DNA sequence while a cationic PTP derivative was used as a light-harvesting tool to excite the fluorescence-labeled ssDNA via FRET. The use of neutral fluorescence-labeled PNA probes is also possible and has been demonstrated,[29,215,216] but this probe cannot be categorized as a biosensor due to lack of spatial contact between the PNA and CP. A cationic CP is necessary for this approach as the positively charged polymer serves as a counterion for, and allows duplex formation with, the negatively charged DNA to form supramolecular aggregates.[217] A solution of this labeled probe/CP complex gives a red color with an accompanying quenched fluorescence from the probe. However, a new higher-order triplex (dsDNA/CP) structure (**Figure 13**) that possesses fluorescence emission spectra overlapping with the excitation spectra of the labeled dye is established when this probe/CP complex is presented with its complementary ssDNA. This higher-order structure is a result of hybridization occurring between the ssDNA probe and complementary ssDNA. Therefore, fluorescence emission from the labeled probe (excited via FRET from the CP) can be observed in the presence of a complementary ssDNA while no fluorescence is observed at all upon addition of noncomplementary ssDNA. The minimum detection limit determined by this approach was 3 zM, and this approach could also distinguish sequences having two or even one mismatches. As described by the authors, the detection of ssDNA at such low concentrations through their approach is very likely to be attributed to both the large optical density of the polymer and a fast and efficient energy transfer from the CPs to many neighboring labeled probes (a process that was described as 'superlighting' or 'fluorescence chain reaction' (FCR)).

Instead of going through the hassle of labeling DNA probes or using an intercalating dye for DNA detection, DNA biosensing using cationic CPs only is possible. This was well demonstrated by the different colorimetric and fluorescence responses that a PTP derivative had with either ssDNA or

dsDNA (Figure 14)[218] and is attributed to the different conformations[219] adopted by the CPs when interacting with ssDNA or dsDNA. The CP adopts a random coil when in solitude and is highly fluorescent but adopts a highly conjugate, planar conformation upon formation of a duplex with ssDNA that is less fluorescent and with a red-shifted absorbance. In the presence of a complementary ssDNA, a triplex (CP/dsDNA) structure (less conjugated and in a nonplanar conformation) is formed, and the fluorescence is recovered with the absorbance maxima shifted back to the blue region. In summary, the different responses of cationic CPs with either ssDNA or dsDNA allows the possibility of CPs as suitable transducers in biosensor devices.

Many solid-support DNA sequence detection methods using CPs[173,174,183,184,209,220–222] have been demonstrated, but only works describing DNA biosensing by addition of only unlabeled DNA sample will be mentioned. Using a planar polystyrene platform, hydrogel spots of a PTP derivative (formed through cross-linking of the PTP derivative with an ssDNA solution) were created and could demonstrate different results when incubated with either noncomplementary ssDNA or complementary ssDNA.[223] The emitted fluorescence from a hydrogel spot incubated with noncomplementary ssDNA was observed to be more red-shifted compared to the spot incubated with complementary ssDNA (Figure 15). This difference in observed fluorescence is caused by a conformational transition of the polymer backbone when the CP/ssDNA binds with the complementary DNA. Interaction of the CP with cross-linking ssDNA forces the CP coil to become stretched, whereas interaction with dsDNA formed through hybridization with

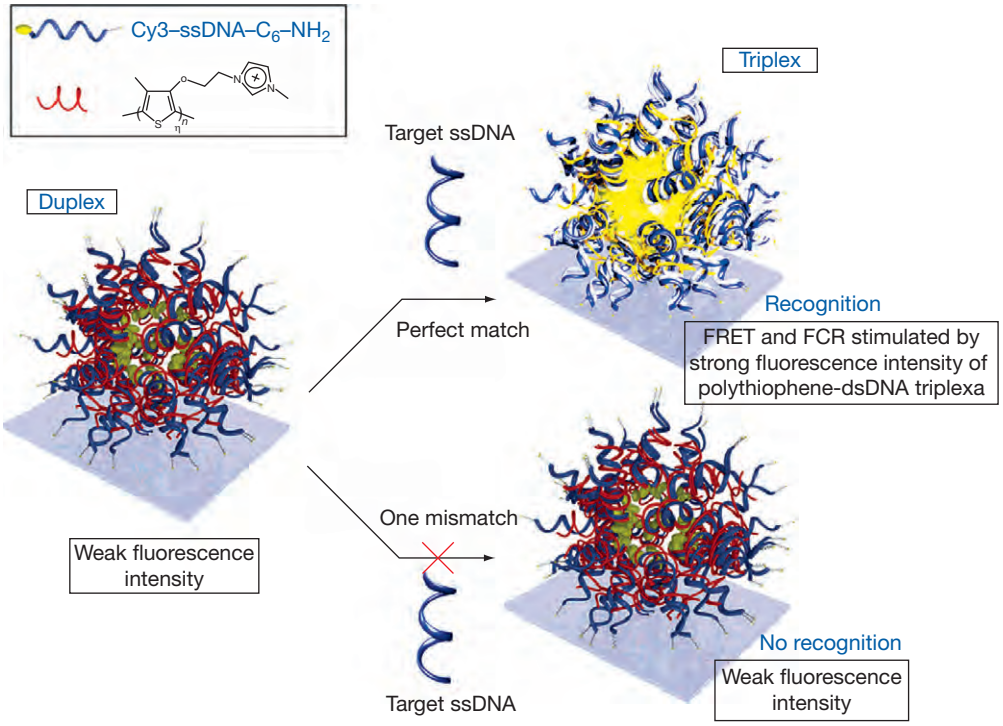

Figure 16 Schematic representation of the specific recognition of target single-stranded DNA by duplex aggregates onto glass slides and of the signal amplification mechanism based on a conformation change of the cationic conjugated polymer transducer and fast energy transfer within the micelle. FCR, fluorescence chain reaction. Reproduced from Najari, A.; Ho, H. A.; Gravel, J.; Nobert, P.; Boudreau, D.; Leclerc, M. *Anal. Chem.* **2006**, *78*, 7896–7899.

complementary ssDNA caused the CP to adopt a more helical conformation. The stretched form of the CP backbone is planar with an emission maximum occurring at longer wavelengths while the helical conformation is nonplanar with an emission maximum occurring at shorter wavelengths.[219]

Alternatively, arrays of labeled DNA capture probe/CP complexes could be created for the detection of DNA. The DNA probe could first be complexed with PTP and subsequently covalently attached unto a surface-treated glass slide.[224] In this model (Figure 16), the CP backbone is more planar with fluorescence intensity that is red-shifted as it has complexed with the Cy3-ssDNA probe. Therefore, no FRET can occur between and the CP and the Cy3 (whose excitation is in the blue wavelength region). Upon formation of the triplex with complementary ssDNA, the fluorescence emission of the CP becomes blue-shifted and will be able to excite (i.e., FRET can occur) the many neighboring Cy3-ssDNA probes (i.e., FCR can occur). This method has also been demonstrated to be capable of quantifying the DNA of interest and of differentiating samples with single nucleotide mismatches (Figure 17).

Chem.* **2006**, *78*, 7896–7899.

3.331.3.3.2. Protein biosensing using BSE/CP complexes

Detection of proteins through the use of CPs began in the late 1990s[27,188,195] and the number of works involving protein detection using CPs has grown tremendously in the last decade. Metalloproteins are, by a minimal definition, proteins that contain a metal ion cofactor and have been demonstrated to be capable of complex formation with and 'superquenching' of CPs.[225–228] The complex formation process is electrostatically driven between oppositely charged CPs and proteins, and complex formation is thereby highly dependent on the pH and pI of the buffer and protein used, respectively. This observed fluorescence 'superquenching' phenomenon of CPs by metalloproteins is a likely result of an electron transfer mechanism from the CPs to the proteins' metal ion cofactor[225,229] upon excitation of the CPs and is hence likely to be

applicable only for detection of metalloproteins. However, by using an array of 6 different CPs, individual signal signatures were obtained for 17 different proteins, thus providing the conceptualization of using CPs for specific identification of proteins.[230] Aside from detection of proteins, direct interactions between proteins and CPs have also been used for the detection of protein conformation changes (formation of fibrous protein amyloids[231] or negative CP[232] and conformational changes of calmodulin upon binding with calcium ions[233,234]). Although CPs have been demonstrated to be effective in detection or sensing of proteins and protein conformational changes, it is worth noting that no BSEs were employed during these sensing processes and therefore they cannot be categorized as biosensors, but may likely be applied or extended to biosensor devices with the introduction of suitable BSEs. Generally, the strategies of protein biosensing are different compared with those applied for the biosensing of DNA via probe/CP complexes; while DNA biosensing utilized only ssDNA as the BSE, protein biosensing uses various possible BSEs such as protein-specific aptamers[235] and oligonucleotides of random sequences.[236] In addition, it is worth noting that there has been no demonstration of amino acid mutation detection or of specific amino acid sequences within proteins.

Aptamers are DNA or RNA oligonucleotides (16–60 monomers) that bind to specific proteins and have also been utilized with CPs for the detection of proteins.[235,237,238] Being an oligonucleotide, aptamers are negatively charged (in physiological conditions) and therefore capable of forming higher-order complexes with cationic CPs, which exhibit different fluorescence characteristics. The aptamer also changes its conformational shape from an unfolded to a folded (G-quadruplex) structure in the presence of bound protein, and this conformational change likewise affects the conformational shape and optical properties of the closely associated cationic CPs (i.e., the backbone orientation of the CP transducer will differ depending on whether the aptamer is bound with the protein of interest). Fluorescence spectrum of the CPs will therefore be different in the absence (planar, red-shifted) or presence (nonplanar, blue-shifted) of the aptamer's corresponding binding protein. Nonspecific oligonucleotides too can be utilized

Table 4 Nonexhaustive list of works involving CPs used as bioanalytical assays and in biosensing of enzymes

Enzyme of interest	*Enzyme substrate*	*Mechanism*	*References*
Bioanalytical			
Trypsin	BSA	Product chelates CP fluorescence quencher (Cu^{2+})	239,241
Kinase (protein kinase A, protein kinase Cα, interleukin-I receptor-associated kinase 4)	Peptides (refer to reference for exact sequence), myelin basic protein, histone H1, phosphorylated heat- and acid-stable protein	Phosphorylated substrate binds to and quenches Ga^{3+} associated CP coated microspheres or quenches these microspheres via a competitive quenching strategy	248,252
β-Galactosidase	β-Galactopyranoside derivative	Conversion of substrate with another coupled enzyme into a CP fluorescence quencher	208–211
Nucleases (S1, B*am*HI, E*co*RI) and methyltransferases (E*co*RI methylase)	Fluorescently labeled ssDNA and dsDNA	Cleaving away of fluorescence dye from DNA substrates and resulting in reduced FRET or inhibition of cleaving mechanism by methyltransferases	245
Adenylate kinase	ATP	Conversion of substrate from a strong sequestering compound, of a CP fluorescence quencher (Cu^{2+}), into a weaker sequestering compound	251
Alkaline phosphatase	Pyrophosphate	Conversion of substrate from a strong sequestering compound, of a CP fluorescence quencher (Cu^{2+}), into a weaker sequestering compound	247
Bio-sensing			
Alkaline phosphatase/trypsin	ATP/Arg_6 peptide	CPs/substrate aggregates separation upon substrate cleavage by enzymes	246
Protease (trypsin, pepsin)	BSA	Enzymatic cleavage of surfactant substrate that results in CP aggregation	244
Proteases (enterokinase, caspases 3/7, β-secretase)	Peptides (refer to reference for exact sequence)	Cleaving away of quencher from peptide-quencher substrates attached to CP coated microspheres	240
Tyrosinase	Phenol derivative	Conversion of substrate into a CP fluorescence quencher	208–211
Proteases (papain, peptidase, thrombin)	Peptides (refer to reference for exact sequence)	Cleaving away of quencher from peptide-quencher substrates associated with CP or conversion of substrate associated with CP into a quencher	242
Acetylcholinesterase	Modified acetylcholine	Cleaving away of quencher from peptide-quencher substrates associated with CP	250
Endonucleases (HaeIII, Pvu II, EcoRV)	Fluorescence-labeled Y-DNA	Cleaving away of fluorescence dye from DNA substrates associated with CP and resulting in reduced FRET	208
Phospholipase C	1,2-Didecanoyl-*sn*-glycero-3-phosphocholine	Enzymatic cleavage of substrate associated with CP that results in CP aggregation	249
Trypsin	Peptides (refer to reference for exact sequence)	Cleaving away of quencher from peptide substrate covalently associated with CP	243

for the detection of specific proteins.[236] However, the differentiation of protein identity in this case requires the concerted use of a cationic CP along with ssDNA of different random sequence and length to generate a fingerprint identity of the proteins. By using five different ssDNA/CP complexes, it was successfully demonstrated that proteins (of different local hydrophobic and charged domains) could generate distinct and different fluorescence intensities from each of ssDNA/CP complex that, when combined and analyzed, would allow for fingerprinting of the detected proteins.

Another class of proteins that have been detected via the use of CPs are enzymes and include:

1. *Hydrolases* that cleave
   - peptide (proteases[239–244])
   - phosphodiester (nucleases[208,245])
   - phosphoester (phosphatases[246–248] and phospholipase C[249])
   - ester (acetylcholinesterase[250])
   - ether bonds (β-galactosidase[208–211])
2. *Kinases*[248,251,252]

Enzymes are a unique class of proteins as they possess the catalytic ability of converting substrates into a product. One example of such catalysis involves the cleaving of chemical bonds within the substrate to form smaller components of the original substrate (e.g., proteins into amino acids), and researchers have taken advantage of this particular property and coupled it with CPs for the detection of hydrolases. **Table 4** summarizes a nonexhaustive list of works involving CPs used in bioanalytical assays and biosensing of enzymes.

An example of enzyme biosensing using enzymatic substrate/CP complexes is depicted in **Figure 18** and involves (1) the cleaving off of a noncharged quencher from a positively charged peptide (closely interacting with a negatively charged CP) or (2) the conversion of the substrate into a quencher by proteases.[242] With reference to the former principle, the close proximity of the substrate quencher with the CP (prior to substrate cleavage) turns on the 'superquenching' effect of the CP but is rapidly turned off after the quencher has been cleaved off and separated away from the CP/peptide complex. Cleavable fluorescent dyes can also be utilized and result in reduced FRET from the CPs to the cleaved fluorescence dyes.[208] Alternatively, as depicted in the latter principle, an enzymatic substrate that is interacting closely with the CP can be converted into a quencher[208–211,242] in the presence of the enzyme and resulting in 'superquenching' of the CPs.

A third type of BSE/CP complexes are the ligand/CP complexes where the protein of interest would interact with the ligand (e.g., avidin/biotin[27,253] or antibody/antigen[254]) and cause a corresponding response from the closely associated CP. An important requirement of such a strategy is an ability of the ligand to interact closely with both the CP and protein of interest but with a higher affinity for the protein such that the ligand is sequestered. **Figure 19** illustrates the identification of avidin through interaction with a methylviologen-labeled biotin (MV-B)/CP complex. Prior to interaction, the fluorescence of the CP is 'superquenched' due to the close association with MV-B. However, this 'superquenching' effect is turned off upon introduction of avidin (having a higher affinity) which sequesters away the MV-B, resulting in a recovery of the strong fluorescence of the CP.

Conventionally, the specific detection of proteins on solid supports is achieved by the ELISA technique. However, although protein detection via ELISA is simple and requires easily accessible laboratory equipments, it is a time-consuming and material-wasting process. Sensitive and specific detection of proteins without the need of excessive washing is desired and has been demonstrated through the use of CPs/aptamers complexes immobilized onto a glass slide.[235] Duplexes of a PTP derivative/Cy3-ssDNA human α-thrombin aptamer were first prepared before being covalently attached onto surface-treated glass slides, where the duplexes exhibited weak FRET fluorescence (Figure 20). However, binding of human α-thrombin with the aptamers causes a subsequent conformation change of both aptamer and accompanying CP that transcends into strong FRET fluorescence exhibited by the duplexes. The weak FRET fluorescence initially observed (i.e., without human α-thrombin) is due to the formation of neutral rigid-rod moieties between the CPs and aptamers that further assembles into nanoaggregates, thus resulting in significant fluorescence quenching of the CP. The strong fluorescence of the PTP derivative after DNA aptamer–protein interaction was described to be due to the partial hindrance of aggregation and planarization of the CP due to the interaction with the protein of interest. In addition, this solid-support array approach also demonstrated the possible differentiation of different concentrations of human α-thrombin from different concentrations of bovine serum albumin (BSA) and immunoglobulin E (IgE) (Figure 21).

3.331.3.4. CP Covalently Modified with BSE

A third possible strategy of developing CP-based optical biosensors is via covalent attachment of the BSEs onto to the pendant chains of CPs, which results in a subsequent optical response when the corresponding target of interest interacts with these modified CPs. Hexokinases, as the BSE of a glucose sensing

Figure 22 Schematic representation of interaction of glucose with hexokinase on the polydiacetylene monolayer. It is not necessary for the enzyme to be consistently oriented in the same manner with respect to the polymer film since glucose will be able to bind to the enzyme in almost any orientation, and it is the conformational change that induces the color change. Reproduced from Cheng, Q.; Stevens, R. C. *Adv. Mater.* **1997**, *9*, 481–483.

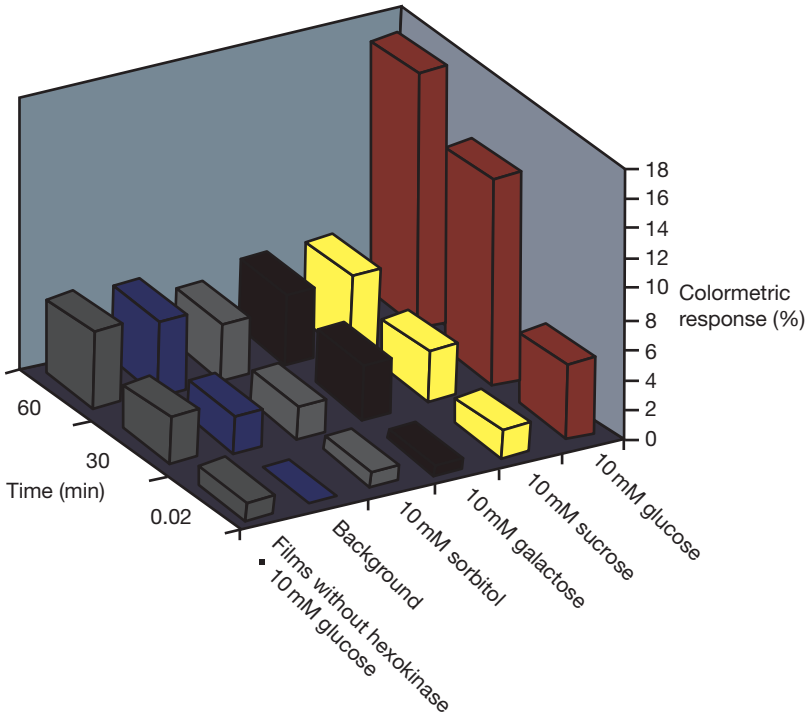

Figure 23 Colorimeric response of the hexokinase-immobilized polydiacetylene sensors for glucose and other compounds used as controls. The first column on the left represents the glucose agitation on the PDA monolayers without immobilized hexokinase. Reproduced from Cheng, Q.; Stevens, R. C. *Adv. Mater.* **1997**, *9*, 481–483.

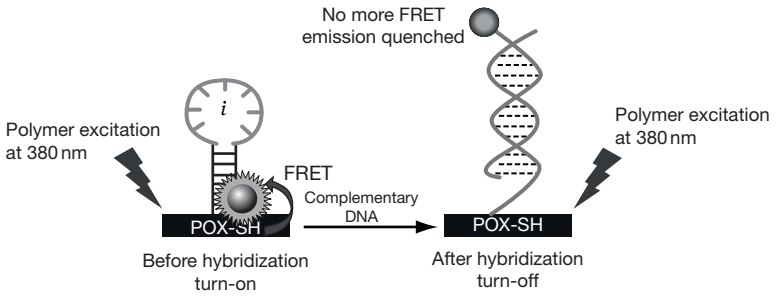

Figure 24 Schematic representation of the detection of DNA sequence by combining a fluorescent dye with a molecular beacon. CP used was POX-SH, a poly(oxadiazole) derivative. Reproduced from Lee, J.; Jun, H.; Kim, J. *Adv. Mater.* **2009**, *21*, 3674–3677.

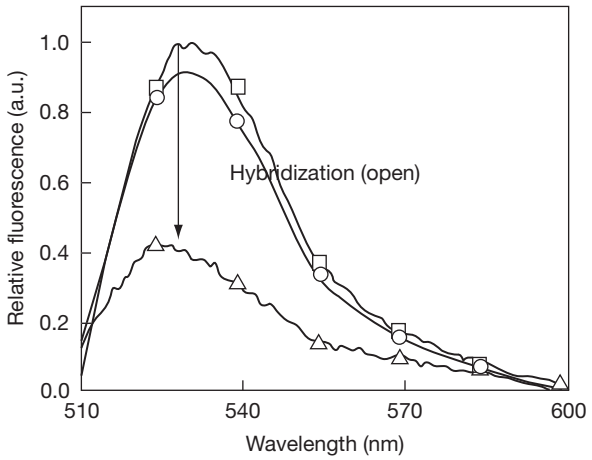

Figure 25 Fluorescence spectrum of POX-SH before (square) and after hybridization with the complementary DNA (triangle) and random noncomplementary DNA (circle). Reproduced from Lee, J.; Jun, H.; Kim, J. *Adv. Mater.* **2009**, *21*, 3674–3677.

platform, have been covalently attached to the side chains of a PDA Langmuir–Blodgett layer deposited on a solid support.[255] Upon binding to glucose, the hexokinases undergo a large conformational change and this creates a mechanical force that affects the conformational shape of the attached PDA layer as well (Figure 22). A concomitant colorimetric response (absorbance increase at 550 nm) over time was observed for this biosensing platform upon glucose incubation but not for sorbitol, galactose, or sucrose incubation (Figure 23). A key contribution of this physical transduction approach is the possibility of capitalizing and incorporation of other biological materials, which also undergo similar conformation changes, into CP-based biosensing devices of small biomolecules.

Using direct on-chip oligonucleotide synthesis methods, ssDNA probe were immobilized onto a layer of polyoxadiazole derivative (possessing amine group and thiol groups).[177] In this model (Figure 24), fluorescently (fluorescein or HEX) labeled synthesized ssDNA probe exists as the closed form in the absence of complementary ssDNA and causes the fluorescent dye to be located close to the POX-SH CP layer. The close proximity allows efficient FRET to occur from the immobilized layer of polyoxadiazole derivative and produces an amplified emission from the fluorescence-labeled dye (Figure 25). Selective hybridization of the ssDNA probes with complementary ssDNA opens up the closed structure of the probe and increases the distance between the fluorescence dye and CP, resulting in a decreased fluorescence emission from the dye as no efficient FRET can take place.

Table 5 Examples of CPs modified with BSEs and their respective target of interest

Target of interest (analyte)	*Biological sensing element (BSE)*	*References*
Avidin	Biotin	257–260
Escherichia coli	Mannose, galactose	261
Influenza virus/*Escherichia coli*	Sialic acid/mannose	262
Lectins (*Concanavalin A*, wheat germ agglutinin)	Glucose	256
ssDNA	Oligonucleotide probe	177
Glucose	Hexokinase	255

Aside from enzymes and ssDNA, glucose[256] and biotin[257–260] moieties have been covalently attached to CPs, and upon binding with lectins and avidin respectively, various types of optical response can be observed. Depending on the optical detection approach adopted, modified CPs were observed either to have a blue-shifted absorbance maxima corresponding to a nonplanar configuration of the CP backbone or an observation of FRET if the target was prelabeled with fluorescence. Further examples of CPs modified with BSEs and their respective target of interest can be found in Table 5.

Glossary

Arthroplasty Surgery to relieve pain and restore range of motion by realigning or reconstructing a joint.

Inflammation A complex biological response of vascular tissues to harmful stimuli, such as pathogens, damaged cells, dead tissue, foreign bodies, or other irritants.

Phagocytosis The cellular process of engulfing solid particles by the cell membrane to form an internal phagosome by phagocytes and protists.

4.401.1. Introduction

Biocompatibility is a condition met by a biomaterial or medical device usually based on the tissue response elicited by an implant in an animal model. If the material releases noxious agents or degrades biological molecules coming in contact with its surface, the response in the tissue is obvious – necrosis and persistent acute inflammation – and the material is clearly judged nonbiocompatible. Biocompatible materials include those which are chemically inert and 'bioactive' materials that present certain reactive chemical groups to the surrounding tissue or undergo changes in their chemical composition *in vivo*, often releasing certain agents to achieve a specific biological response. Nonabsorbable bioactive materials may selectively adsorb specific biological molecules or release select agents to favor a particular tissue response. Absorbable biomaterials (e.g., scaffolds for tissue engineering) are, in effect, bioactive materials whose action is temporary.

Determinants of the tissue response to biomaterials, and the subsequent assessment of biocompatibility, reside in the intrinsic wound-healing process in the particular tissue or organ (structure comprising two or more tissues) into which the biomaterial has been implanted. This wound-healing process, initiated by the surgical trauma of implantation, can be modified: by the physical presence of the device, and its porosity and modulus of elasticity; and the chemical composition of the material and agents released by the biomaterial. The tissue response to a biomaterial is, therefore, a characteristic of the host tissue's wound-healing process as well as being a characteristic of the biomaterial. There is often an implication that a biomaterial which displays a favorable (biocompatible) response in a particular test (i.e., tissue) has met the condition of biocompatibility for all applications in which it may be used. In light of the above, the tissue response to the same biomaterial might be quite different depending on the tissue in which it is implanted. Biocompatibility is not, therefore, an invariant property of a biomaterial.

The objectives of this chapter are to: provide a basis for interpreting the tissue response to implants in the context of biocompatibility, with specific attention to the roots of the tissue response in wound-healing processes; provide examples of the types of tissue responses elicited by select biomaterials in certain tissues; and describe specific features of the cellular make up and extracellular matrix composition of the tissue surrounding implants in the context of understanding to what degree the tissue response can be controlled therapeutically, postimplantation.

4.401.1.1. Criteria for Assessing Biocompatibility

The term 'biocompatible' is employed to describe a wide variety of (generally, *in vivo*) findings, from a benign tissue response to a biomaterial in an animal model to the successful clinical implementation of a medical device. Moreover, the

term is also often used to generally describe biomaterials which have met certain standards of safety and efficacy in select situations. While there is convenience in using the term biocompatibility to convey a general assessment of a biomaterial or medical device, its nonspecific use can be misleading. Its use should be qualified with respect to the specific conditions under which the biomaterial/device is being evaluated. The device should be considered biocompatible only in the context of the criteria used to assess the acceptability of the tissue response in relation to the required function of the device.

In this regard, each study involving the assessment of tissue compatibility should provide its own working definition of biocompatibility. For example, biomaterials and devices implanted into bone would be expected to become enveloped by the regenerating osseous tissue, and thus be considered compatible with bone regeneration. However, altered bone remodeling around a modulus-mismatched device due to its alteration of the strain distribution in the bone, with a net loss of bone mass (i.e., osteopenia), could lead to the assessment that a material or device is not compatible with normal bone remodeling.

In situations in which an implant is surrounded by fibrous tissue, macrophages on the surface of the material might be the expected response to the dead space produced by the physical presence of the implant. The cellular array of fibroblasts and macrophages resembles synovium which might then be considered an acceptable chronic response relative to the chemical compatibility of the material with tissue. Utilization of the thickness of the fibrous scar capsule around an implant alone as a measure of biocompatibility is problematic because the formation of scar tissue can be influenced by movement of the tissue at the site relative to the implant. Thicker fibrous capsules may not, therefore, reflect the degree to which a material displays biocompatibility.

4.401.1.2. Factors Affecting Biocompatibility

The biological processes comprising tissue response are affected by implant-related factors, including

1. the 'dead space' created by the presence of the implant;
2. soluble agents released by the implant (e.g., ions or molecular fragments);
3. insoluble particulate material released from the implant (e.g., wear debris);
4. chemical interactions of biological molecules with implant surface; and
5. alterations in the strain distribution in tissue due to the mismatch in modulus of elasticity between the implant and surrounding tissue, or the movement of the implant relative to adjacent tissue as a result of the absence of mechanical coupling.

There are, however, numerous examples of adverse responses to medical devices that have failed to perform properly due to factors unrelated to the biomaterial, including

1. the intrinsic capability of the tissue to heal by repair (scar) or regeneration;
2. problems associated with implantation of the device, including improper positioning and excessive surgical trauma; and
3. host disease.

4.401.1.3. Examples of Biocompatible and Adverse Tissue Responses

Nonbiocompatible responses to biomaterials and medical devices can include the following: persistent acute inflammatory responses and attendant pain; cytotoxicity and necrosis; and tissue changes that are incompatible with, and interfere, with the performance of the device. Examples of the first two of these nonbiocompatible responses to medical devices in human subjects are rare because of the extensive preclinical testing performed on the biomaterials and device before they are introduced into clinical use. Biomaterials and devices that elicit acute adverse biological responses can generally be readily detected in animal studies.

There are many cases of devices such as total joint replacement prostheses, which initially function successfully, relieving pain and restoring joint motion. However, due to premature breakdown of the materials (e.g., wear) particulate debris is generated, which elicits a cellular response (viz., macrophage phagocytic response) that results in the loss of surrounding tissue (e.g., osteolysis). There are other examples of tissue responses to devices that may be benign in some situations, but in other applications result in failure of the device. For example, a relatively benign fibrous capsule around a device in some applications is inconsequential, but for other devices such as a silicone breast implant can lead to scar contracture, pain, and loss of function of the implant to provide the desired effect.

4.401.2. Wound-Healing Responses Underlying Biocompatibility

4.401.2.1. Fundamental Stages of the Wound-Healing Response to Implantation Surgery: Acute Phase

The surgical trauma associated with the preparation of the implant site initiates a cascade of physiological processes which comprise wound healing (Figure 1). This healing process ensues in the gaps between the implant and surrounding, surviving tissue. In vascularized tissue, in which implants are most often placed, surgery initially induces a vascular response in intact vessels surrounding the implant site resulting in the leakage of fluid (edema) and blood proteins. Blood

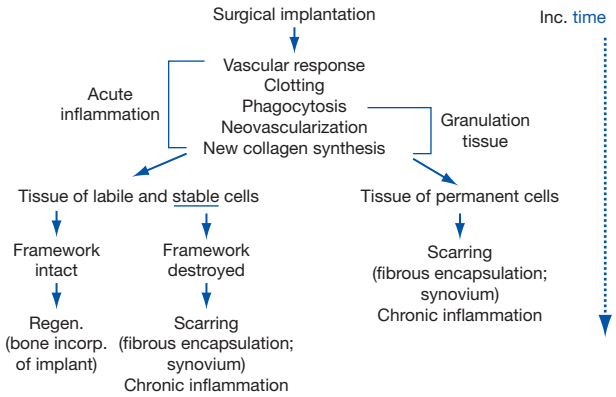

Figure 1 Sequence of physiological processes comprising wound healing.

elements from the cut vessels lead to the formation of a fibrin clot, which serves as a provisional scaffold into which cells can migrate. Phagocytic cells, polymorphonuclear neutrophils first and then macrophages, infiltrate into the surgical site and begin to ingest the cellular and extracellular matrix debris. Endothelial cell migration and the formation of new blood vessels follow. Fibroblasts invade the fibrin clot and synthesize more robust scaffolding made up of types I and III collagen. The tissue comprising phagocytic cells, newly forming blood vessels and fibroblasts, which forms within the first days (acute phase) of healing, is referred to as granulation tissue. Thereafter, the parenchymal cells of the surrounding tissue begin to infiltrate the newly forming stroma.

4.401.2.2. Repair Versus Regeneration

In order for tissue to regenerate in a defect it is necessary for the surrounding cells to divide and migrate into the wound site. The fundamental question, then, regarding the intrinsic capability of the tissue to heal through regeneration or repair with the formation of scar tissue is answered by the potential of the parenchymal cells to divide: Is the tissue made up of labile, stable, or permanent cells? Labile cells are those which are undergoing mitosis, albeit at a low rate, continually. Stable cells are those that can be stimulated to divide, and permanent cells are those which never undergo cell division. Prior dogma instructed that defects in tissues in which the parenchymal cells were incapable of division would never regenerate. However, we now know that many such tissues contain progenitor cells (viz., stem cells) that have the capability of proliferating in response to injury; migrating to the site of injury; and differentiating into the parenchymal cell type. Studies are also revealing the many antagonists that interfere with intrinsic progenitor/stem cell-driven regenerative processes.

There are conditions that can interfere with regeneration, even in tissues with the intrinsic capability to do so, such as bone. Fractures normally heal by bony union of the bone ends, through the process of endochondral and intramembranous ossification in the fracture gap. However, movement of the bone ends and excessive strain in the gap of unstable fractures result in a fibrous (scar) union. An analogous process occurs in the tissue around implants in bone. As expected in a regenerative tissue, bone forms up to the surface of implants (osseointegration) which are mechanically stable. In contrast, fibrous tissue is found encapsulating unstable implants which undergo movement in the bony bed. Explanations for the roles of excessive strains in interfering with bone formation include (1) destruction of the stroma necessary for osteoprogenitor cell migration into the gap, but permissive of opportunistic fibroblasts and (2) induction of differentiation of progenitor cells into fibroblasts instead of osteoblasts.

4.401.2.3. The Chronic Response: Macrophages and Fibroblasts – Synovium

The macrophages that initially invade the gaps between the implant and surrounding tissue to ingest debris can be found to remain indefinitely on the surface of implants in soft tissues. The very presence of the implant provides a dead space in tissue that attracts macrophages to the implant–tissue interface.[1] These macrophages, along with fibroblasts of the scar, often form a definable layer of cells that surrounds the implant. The tissue displays the characteristics of synovium,[2] and can be considered the chronic response to implants (unless the device is directly apposed to osseous tissue, i.e., osseointegrated). This process is often termed 'fibrous encapsulation,'[3,4] highlighting the fibrous tissue component. It is, however, the presence of regulatory cells such as macrophages at the implant–tissue interface that can profoundly influence the host response to a device because these cells have the potential to release proinflammatory mediators[5] if they are irritated by the movement of the device or substances released from the biomaterial. The inflammatory response of the tissue around implants is comparable to the inflammation that can occur in the synovium lining any bursa (e.g., bursitis); hence, the response to implants has also been termed 'implant bursitis.'[2]

While macrophages may be expected to remain on the surface of the implants in soft tissue, even after long periods of implantation, studies investigating the tissue response around devices may not find such cells. One explanation for this could relate to the methodology employed for the experimental studies. Because of the difficulty in sectioning implants, the devices are often removed prior to the histological processing of the resected samples. Macrophages adherent to the device would thus not be revealed in the histological sections.

For implants in bone which have become osseointegrated, there are no macrophages found on the surface of the device. Because macrophages were likely present at the implant site earlier in the healing process, the question arises as to why they did not persist on the surface of the biomaterial. The answer may relate to the inability of the nonmitotic macrophages to recruit monocytes from the circulation. This may be due to the inability of chemoattractants released from the macrophages to penetrate the mineralized matrix, and/or the inability of monocytes to migrate through the osseous tissue.

4.401.2.4. Historical Perspective on Observations on the Tissue Response to Implants

That the macrophage plays a central role in the tissue response to implants focuses attention on the early studies of Ilya (Elie) Metchnikoff (1845–1916),[6,7] a noted Russian zoologist, pathologist, and infection biologist. Metchnikoff spent most of his professional life focusing on his 'phagocytosis theory.' In one of his experiments in 1882, Metchnikoff inserted a splinter into the transparent body of the starfish larva. He observed amoeboid-appearing cells attempting to ingest the splinter. The small ones he referred to as 'microphages' and the large ones 'macrophages,' using as the suffix the Greek term, phage, meaning to ingest. We now refer to microphages as polymorphonuclear neutrophils, while macrophage remains the name of the same cell type. While Metchnikoff's interest was in revealing mechanisms underlying the host defense to invading organisms, he inadvertently made a discovery that should serve as the foundation of the tissue response to implants: the persistence of macrophages around a foreign body. In 1908, Metchnikoff shared the Nobel Prize in Physiology or Medicine with Paul Ehrlich.

A few decades later in 1923 in Boston, Marius Nygaard Smith-Peterson, an orthopedic surgeon, attended to one of his patients who presented with a shard of glass in the fleshy part of the back. By the time the patient had come to see Smith-Peterson the glass shard had been embedded in the tissue for 1 year. When Smith-Peterson resected the shard of glass, he found that it was surrounded by a glistening synovial sac, which contained a few drops of clear yellow fluid. Smith-Peterson reasoned that the glass must have induced the formation of synovium which secreted synovial fluid. He then set out to produce glass cups to fit over the femoral head of his patients with arthritis (in a procedure that came to be known as cup arthroplasty). His supposition was that the glass would induce the formation of a new synovial capsule in the hip joint of his arthritic patients. While the mechanical properties of glass proved unsuccessful for this application, Smith-Peterson's observation is important in the context of that of Metchnikoff. Synovium is a tissue comprising macrophage-like cells ('type A' cells) and fibroblast-like cells ('type B' cells). Smith-Peterson's findings parallel those of Metchnikoff in that macrophages were found on the surface of a foreign body after a long time period (i.e., a chronic response).

Additional insights into the presence of macrophages at the leading edge of wounds and around implants can be found in the work of several investigators employing the rabbit ear chamber model, dating from the late 1930s.[8–10] In the more recent of these studies, Ian A. Silver, a British researcher, studied wound healing in holes punched in the ears of rabbits.[11] The chamber is constructed over the hole in order to observe microscopically the healing of the injuries. Silver found that the leading edge of the tissue filling in the hole was always lined by macrophages, supporting prior findings.[8] In a related work, Silver employed a microelectrode to measure the oxygen tension within the hole and in the surrounding tissue. He found, as expected, low oxygen tension within the 'dead space' of the hole, and an increasing gradient of oxygen proceeding into the vascularized tissue surrounding the hole. Silver reasoned that the macrophages were attracted by the hypoxic environment of the dead space, and so migrated to the leading edge of the hole along the oxygen gradient. Once at the leading edge of the hole, they remained. Silver followed up this work with an experiment in which he placed a plastic coupon into the hole thus demonstrating more directly that macrophages persist at the surface of implants, likely due to the hypoxic environment.

There is much yet to be learned about the behavior of the 'implant macrophage.' The heterogeneity of the macrophage has long been recognized, with macrophages in different tissues displaying dramatically different properties.[12–14] While there is general agreement that marrow-derived cells in the circulation (viz., monocytes) are the source of the tissue macrophage, the specific characteristics of macrophages in different conditions remain in question with respect to their function, longevity, and turnover. While the results of some investigations indicated that the macrophage in chronic inflammatory conditions may persist for only 1–2 weeks,[14] other studies provided evidence that macrophages may persist in granulomatous tissue for up to 3 months without dividing, dying, or being replaced.[15] In general the supposition is that macrophages cannot divide, but there are data that demonstrate the capability of macrophages to undergo mitosis.[16] The indefinite (chronic) persistence of macrophages at an implant surface is generally understood to be the result of the influx of monocytes from peripheral blood into the tissue.

4.401.3. Characteristic Features of Tissue Around Implants: Emerging Insights

Recent studies have revealed characteristic features of the synovium-like layer and the underlying fibrous tissue that comprise the chronic response to implants. These features have been found in the tissue surrounding implants in soft tissue, and also in the tissue that forms around devices in bone which have loosened.

4.401.3.1. Fibroblasts: Expression of α-Smooth Muscle Actin

Generally the focus on the ubiquitous fibrous tissue capsule that surrounds implants is on its thickness which has been considered a reflection of the degree of biocompatibility, but which was noted above to be potentially erroneous. Recent studies have demonstrated that fibroblasts within the fibrous capsule around implants in soft tissue[17] and around prostheses in bone[18] which have loosened, express the gene for the contractile actin isoform, α-smooth muscle actin (α-SMA). These fibroblasts, which have the characteristic of myofibroblasts, resemble the cells seen in contracting skin wounds. Contraction of skin wounds may be beneficial in facilitating closure of the wound, but its adverse effect is in creating a dysfunctional and disfiguring scar. Contracture of fibrous capsules around prostheses, such as silicone breast implants, may result in pain and disfigurement. Contraction of SMA-expressing fibroblasts around orthopedic prostheses may contribute to densification of the fibrous tissue, making it more resistant to remodeling.

4.401.3.2. Presence of Lubricin in the Tissue Around Loose Orthopedic Prostheses

Given that synovial tissue can be found around devices, reflecting the chronic response to implants, the question arises as to the behavior of the synovial cells in the context of the normal physiological function of synovium (viz., in diarthrodial joints). Recent studies have found that the tissue around loose orthopedic prostheses which had previously been described as synovium contains lubricin, which forms a discrete layer on the surfaces of folds in the fibrous tissue comprising the capsule.[18]

Lubricin, a molecule discovered in joint fluid,[19,20] and later found to be synthesized by synovial cells,[21,22] has been shown to play an important role in joint lubrication.[23,24] Later work found that a protein synthesized by superficial zone chondrocytes,[25] superficial zone protein, was homologous to megakaryocyte stimulating factor[26] and to lubricin,[20] both protein products of the megakaryocyte stimulating factor gene (*msf*).[20] Proteoglycan 4 (PRG4) is the name collectively given to these homologous glycoproteins encoded by 12 exons of the gene, which is also known as *Prg4*.[27]

A recent study[28] employing cDNA array technology to screen periprosthetic tissue from five total knee arthroplasty

patients for the expression of over 800 immunologically relevant genes found that the strongest overexpression in aseptic cases (three patients) of all genes was for *msf*. The potential importance of identifying lubricin in periprosthetic tissue is that it may interfere with cell adhesion[29] and integrative repair processes[27] vital to the remodeling and ultimate resorption of periprosthetic tissue.

A single theory could explain the presence of both α-SMA and lubricin in periprosthetic tissue, and help to explain why they are ubiquitous findings. The micromovement of a prosthesis, which is not fixed by bone apposition or ingrowth, stimulates the expression of α-SMA and lubricin directly in the capsule as a result of mechanical stimulation of selected cells, and indirectly by inducing elevated levels of transforming growth factor (TGF-β) which is known to stimulate expression of α-SMA[30] and lubricin.[31] Moreover, of importance is a recent study that demonstrated that myofibroblast (i.e., α-SMA-expressing fibroblast) contraction activates latent TGF-β1 from extracellular matrix.[32] Particulate debris further acts to increase α-SMA and lubricin levels by promoting a cytokine cascade that also results in the upregulation of TGF-β and other molecules that stimulate α-SMA and lubricin synthesis. α-SMA and lubricin could synergistically serve to interfere with reparative and remodeling processes that restore the integrity of the implant–bone interface tissue. According to this theory, it would be expected that some degree of α-SMA and lubricin expression would be found in all periprosthetic tissue.

α-SMA and lubricin may contribute to prosthetic failure by interfering with processes that would result in the reduction of periprosthetic tissue, and this would allow for an ever-widening radiolucent zone around the unstable implant. Human studies to demonstrate such an association would require periprosthetic tissues from arthroplasties displaying varying degrees of loosening and radiolucent zone thickness. Moreover, the finding of α-SMA and lubricin in periprosthetic tissue 6 months postimplantation in one patient raises the question of the time course of expression of these proteins, in order to separate expression related to the response to surgery from the prosthetic loosening process, further complicating the procurement of control tissues. Another issue to be dealt with is that α-SMA expression is known to be transient,[33–35] and lubricin expression may prove to be the same. Therefore, accounting for all the α-SMA and lubricin associated with a periprosthetic tissue of measured thickness may prove to be impossible. Animal studies to prove cause (α-SMA and lubricin) and effect (increasing width of the periprosthetic tissue zone) would require an animal model for a loose prosthesis, which has been reported, and agents which can be administered to selectively downregulate the expression of these proteins in the periprosthetic tissue, which have not yet been developed. Alternative *in vivo* approaches using mice in which α-SMA or lubricin has been knocked out would be interesting to consider, but interpretation of the results would likely be confounded by the multiple critical physiological roles that these two proteins play. *In vitro* models which could be employed to study the relationships between α-SMA and lubricin and the development and persistence of prosthetic tissue and loosening have not yet been developed and would be challenged to account for the many factors, including the mechanical environment, that contribute to the problem.

The direct association between α-SMA and lubricin expression and prosthetic performance (viz., implant-related pain) is unclear. It is possible that α-SMA-enabled contracture of periprosthetic tissue may be related to pain in the same way that contractures of fibrotic lesions in other organs are related to painful conditions. The role of lubricin in pain mechanisms has not yet been studied.

4.401.4. Summary and Considerations for the Future

Despite the fact that the tissue response to implants has been investigated for decades there is much yet to learn the etiology of the response; its effects on device performance; and therapeutic approaches which will enable its regulation. That the response to implants and determinations of biocompatibility are tissue-specific raises questions about the roles of various cells (viz., resident progenitor/stem cells) in the intrinsic wound-healing response that is a principal determinant of the assessment of biocompatibility.

4.402.1. Introduction

In identifying the biocompatibility of a biomaterial, medical device, or prosthesis, numerous approaches may be taken. The approach presented in this chapter is a practical one, based on regulatory requirements and standards to a great extent. The goal of this chapter is to provide a practical pathway or roadmap for the identification of the fundamental biological requirements, that is, biological response evaluation, for biomaterials, medical devices, or prostheses. Therefore, the chapter is compartmentalized into eight sections: biocompatibility; materials for medical devices; *in vitro* tests for biocompatibility; *in vivo* tests for biocompatibility; inflammation, wound healing, and the foreign-body reaction; hemocompatibility; immune responses; and summary. Perspectives are presented throughout the chapter to provide insight into the ways in which regulatory agencies may view certain aspects and issues regarding the various topic areas. Numerous caveats are presented to provide a perspective on the ways in which the fundamental biological requirements of a biomaterial, medical device, or prosthesis might be viewed by regulatory agencies.

As the intended use of a biomaterial, either alone or in combination with other biomaterials in medical devices or prostheses, is to assist in maintaining or improving the health and welfare of humans, governmental regulation of the biomaterial or medical device is required to ensure appropriate and adequate safety and efficacy of the biomaterial or medical device. In this regard, it is noteworthy that the Food and Drug Administration (FDA) does not regulate biomaterials, but rather regulates the 'as-used' medical device or product intended for clinical application in humans. It is important to understand that the FDA does not regulate nor approves biomaterials, but rather, the FDA regulates the use of biomaterials in the end-stage 'as-used' medical device, that is, product.

In considering the fundamental biological requirements of a biomaterial for clinical application, it must be remembered that the biological requirements in one application may be different from those required in another application, even if the same biomaterial is being used. From this perspective, the intended application of the biomaterial or medical device dictates the biological requirements necessary to ensure safety and efficacy of the medical device or product. In turn, the biological requirements or biological design criteria dictate the types of tests required to determine biocompatibility.

4.402.2. Biocompatibility

The most commonly used term to describe the appropriate biological requirements of a biomaterial or biomaterials used in a medical device is 'biocompatibility.' A simple definition of biocompatibility of materials is 'the quality of not creating any adverse tissue reactions.' A more helpful definition of biocompatibility is 'the ability of a material to perform with an appropriate host response in a specific application.'[1,2] This definition is helpful in linking material properties or characteristics with performance, that is, biological requirements, with a specific application, a specific medical device, or biomaterial used as a medical device. The 'appropriate host response' implies identification and characterization of tissue reactions and responses that could prove harmful to the host and/or lead to ultimate failure of the biomaterial, medical device, or prosthesis through biological mechanisms. Viewed from another perspective, the 'appropriate host response' implies identification and characterization of the tissue reactions and responses critical to the successful use of the biomaterial or medical device. Biocompatibility assessment is considered to be a measure of the magnitude and duration of the adverse alterations in homeostatic mechanisms that determine the host response.[3] Safety assessment of a biomaterial or medical device is generally considered to be synonymous with its biocompatibility assessment.

4.402.3. Materials for Medical Devices

In the selection of biomaterials to be used in device design and manufacture, the first consideration must be the fitness for purpose with regard to characteristics and properties of the biomaterial(s). These include chemical, toxicological, physical, electrical, morphological, and mechanical properties. Relevant to the overall *in vivo* assessment of tissue compatibility of a biomaterial or medical device is knowledge of the chemical composition of the materials, including the conditions of tissue exposure as well as the nature, degree, frequency, and duration of exposure of the device and its constituents to the intended tissues in which it will be used. Table 1 presents a list of biomaterial components and characteristics that may affect the overall biological response of the medical device. Knowledge of the presence and quantity of these components in the medical device, that is, final product, is necessary. The range of potential biological hazards is broad and may include short-term effects, long-term effects, or specific toxic effects, which should be considered for every material and medical device. However, this does not imply that testing for all potential hazards will be necessary or practical.

Table 1 Biomaterials and components

The material(s) of manufacture
Intended additives, process contaminants, and residues
Leachable substances
Degradation products
Other components and their interactions in the final product
The properties and characteristics of the final product

Although the biomaterials and components listed in Table 1 are only superficially, if at all, considered in the research and development of new biomaterials, they become exceedingly important as the biomaterial moves from the R&D stage to the product stage of development. The components of biomaterials may play unexpected roles in the biocompatibility of the material or materials under consideration for a given medical device. Low molecular weight materials such as intended additives, process contaminants, residues, leachable substances, and degradation products may migrate and diffuse from the material and coat the surface of the material, potentially leading to different biological interactions than that intended with the original material. Examples of this phenomenon that have been identified in the past include processing aids that have coated the metal components of heart valves and wax extrusion aids that have ultimately coated the surfaces of polyurethane pacemaker leads. These examples illustrate how the material surfaces at the tissue–implant interfaces were of different chemistry than that intended by the manufacturer. Thus, the knowledge of the components and the composition of the materials of manufacture are important in predicting biological responses, both intended and unintended responses. There is also a possibility that these low molecular weight components, having diffused to the surface of the material in contact with tissue, may ultimately be released into the tissue, leading to modified or undesirable tissue reactions. Short-term biological assessment of the biomaterial may not identify these possibilities as the diffusion from the bulk of a material to its surface requires time. Therefore, long-term *in vivo* assessment and accelerated *in vitro* procedures to identify these possibilities may be necessary.

As final product or 'as-used' medical devices are generally made available in the sterilized state, the effect of sterilization and sterilization technique must be considered. Steam sterilization, radiation sterilization, or ethylene oxide sterilization may lead to modifications in the surface and bulk properties of the material and this may have a potential impact on biocompatibility. Radiation sterilization may crosslink or degrade polymers, leading to property changes. Ethylene oxide residuals are known to have an adverse reaction on *in vitro* toxicity tests. For these reasons, characterization of the final product following sterilization is necessary.

As stated earlier, testing for all potential hazards may not be necessary or practical. If a material and its components are well known and its manufacturing, processing, and sterilization procedures have been characterized with regard to potential changes in the material or biocompatibility, testing may not be necessary.

4.402.4. *In Vitro* Tests for Biocompatibility

The most common type of biocompatibility assay is the use of cell culture systems to identify cytotoxicity, cell adhesion, cell activation, or cell death. Cell culture assays are used extensively in biocompatibility studies of new biomaterials and are being required in biocompatibility assessment programs for products, that is, biomaterials, medical devices, and prostheses[4–6] (Table 2).

Table 2 *In vitro* cytotoxicity tests

Tests on extracts
– L929 elution test
– Neutral red uptake test
– Colony formation test
– MTT and related tests
Direct contact test
Indirect contact test
– Agar diffusion test
– Filter diffusion

Three types of cell culture assays are commonly used for evaluating biocompatibility. These are extract dilution, direct contact, and agar diffusion. Direct contact cell culture is most commonly used by investigators studying the biocompatibility of new biomaterials. In this type of assay, the investigator can use the cell type for which the biomaterial under investigation is intended for clinical use. For example, biomaterials intended for devices such as prosthetic heart valves, vascular grafts, and other cardiovascular devices will use human or animal endothelial cells to investigate biocompatibility as well as to investigate the capability of this cell type to proliferate and present the appropriate endothelial cell phenotype when in contact with the biomaterial. Studies involving inflammation and the foreign-body response use primary cells from blood or macrophage cell lines available through biological suppliers or cell banks. Materials intended for hard tissue or orthopedic application are commonly studied with osteoblasts or osteoblast cell lines. This type of assay permits the investigator to use the specific cell type in investigating the cell interaction and biocompatibility of the biomaterial for an intended application in an organ or tissue. This is a distinct advantage of this type of assay. Using appropriate negative and positive control materials as well as other biomaterials intended for similar application, new biomaterials can be assayed for a wide variety of types of cell interactions using this assay system.

The extract dilution type of cell culture assay requires a solvent extraction of the biomaterial under consideration and testing of this extract, most commonly at various dilutions, for evidence of cytotoxicity and cellular interaction. This type of cell culture assay finds its most common use in providing information for regulatory compliance. As identified in the preceding Materials for Medical Devices section and in Table 1, small molecular weight extractables are of concern regarding biocompatibility. The extraction assay, carried out with a series of solvents that are hydrophilic and hydrophobic, permits examination of the potential cytotoxicity of extracts and the identification of materials within a biomaterial that may be cytotoxic. These types of assays ultimately permit identification and characterization of cytotoxic materials within biomaterials or the lack of cytotoxicity, providing correlation with *in vivo* assays such as sensitization, irritation, intracutaneous (intradermal) reactivity, and other tests where the *in vivo* injection of extracts is required.

For regulatory purposes, the direct contact test commonly involves the development of a near-confluent monolayer of L-929 mammalian fibroblast cells on a culture plate. Biomaterial specimens under investigation are carefully placed on

these cell layers with fresh culture medium and incubated for 24 h at 37 °C. The culture medium and specimens are removed and the cells are fixed and stained with appropriate histological stains. Light microscopic evaluation is then used to identify cells adherent to the culture plate. Other cellular morphological characteristics can also be identified using this technique. Unlike that used for research purposes, regulatory cell culture assays most commonly use established cell lines. The use of established cell lines such as the L-929 mammalian fibroblast cell line offers the advantage of less assay repeatability, reproducibility, and efficiency. In addition, cell lines are more commonly available than are primary cells. For research, the most common practice is to culture cells directly on the new biomaterial surface.

In vitro cytotoxicity assays are the initial biocompatibility screening tests for a wide variety of biomaterials used in medical devices and prostheses. After the cytotoxicity profile of a candidate biomaterial has been determined, more application-specific tests may be performed to assess the biocompatibility of the biomaterial under end-use conditions. In general, biomaterials identified as nontoxic in *in vitro* assays will be nontoxic in *in vivo* assays. Biomaterials identified as toxic in *in vitro* assays must be further investigated for clinical acceptability. There are examples in which low levels of toxicity are present with biomaterials but this does not preclude or obviate their use in medical devices. An excellent example of this is glutaraldehyde-fixed porcine valves that produce adverse effects *in vitro* because of low residues of glutaraldehyde. In spite of the negative *in vitro* findings, this material is still used in the development of prosthetic heart valves for clinical use. This is an example of where the risk of low levels of toxicity is outweighed by the clinical advantage of the use of this material.

Two common problems may occur in *in vitro* cytotoxicity tests. The first problem occurs when the test cell culture is of too short a duration, that is, hours to a few days. In this case, sufficient time may not have been allowed to determine cell proliferation adequately, an important parameter, or cell death by necrosis, apoptosis, or anoikis (surface detachment). The second problem lies in the choice of cell type for the test. Commonly, immortalized cell lines derived from rodent or human tumors are used with virtually no understanding of the positive or negative attributes of phenotype expression by the respective immortalized cell line when compared to the primary cell intended for biological response and cytotoxicity evaluation. For example, primary macrophages derived from human blood-borne monocytes should be utilized to evaluate biomaterial-dependent cytotoxicity and macrophage activation. However, for macrophages, the more commonly used cell lines are HL-60 (human promyelocytic leukemia), U937 (human histiocytic lymphoma), RAW and RAW264.7 (mouse transformed lymphoma), and J774 (mouse histiocytic lymphoma). Rarely is any justification other than convenience given for the use of these tumor-derived cell lines.

4.402.5. *In Vivo* Tests for Biocompatibility

From a practical perspective, the *in vivo* assessment of the biocompatibility of biomaterials and medical devices is carried out to determine that the device performs as intended, that is, designed, and presents no significant harm to the patient or user (Table 3). Thus, the goal of the *in vivo* assessment of biocompatibility is to predict whether a medical device presents potential harm to the patient or user by evaluation under conditions simulating clinical use.

Recently, extensive efforts have been made by government agencies, that is, FDA, and regulatory bodies, that is, ASTM, ISO, and USP, to provide procedures, protocols, guidelines, and standards (Tables 4 and 5) that may be used in the *in vivo* assessment of the tissue compatibility of medical devices.[7–12] This chapter draws heavily on the ISO 10993 standard, Biological Evaluation of Medical Devices (Table 4), in presenting a systematic approach to the *in vivo* assessment of tissue compatibility of medical devices.

In vivo tests for the assessment of biocompatibility are chosen to simulate end-use applications. To facilitate the selection of appropriate tests, medical devices with their component biomaterials can be categorized by the nature of body contact of the medical device and by the duration of contact of the medical device. Table 6 presents medical device categorization by body contact and contact duration. The tissue contact categories and subcategories as well as the contact duration categories have been derived from standards, protocols, and guidelines utilized in the past for safety evaluation of medical devices. Certain devices may fall into more than one category, in which case testing appropriate to each category should be considered.

Two perspectives may be considered in the *in vivo* assessment of the biocompatibility of biomaterials and medical devices. The first perspective involves the utilization of *in vivo* tests to determine the general biocompatibility of newly developed biomaterials for which some knowledge of the tissue compatibility is necessary for further research and development. In this type of situation, manufacturing and other processes necessary for the development of a final product, that is, medical device, have not been carried out. However, the *in vivo* assessment of biocompatibility at this early stage of development can be used to evaluate the general tissue responses of the biomaterial as well as provide additional information relating to the proposed design criteria in the production of a medical device. While it is generally recommended that the identification and quantification of extractable chemical entities of a medical device should precede biological evaluation, it is quite common to carry out preliminary *in vivo* assessments to determine whether there are unknown chemical entities that produce adverse biological reactions. Utilized in this fashion, early *in vivo* assessment of a biomaterial may provide insight

Table 6 Medical device categorization by tissue contact and contact duration

Prolonged, $>$24 h and $<$30 days
Permanent, $>$30 days

into the biocompatibility of a material and may facilitate further development of a biomaterial into a medical device. Obviously, adverse reactions observed at this stage of development for a biomaterial would require further efforts to improve the biocompatibility of the biomaterial and identify the agents responsible for the adverse reactions.

The second perspective regarding the *in vivo* assessment of medical devices focuses on the biocompatibility of the final product, that is, the medical device and its component materials in the condition in which it is implanted. While medical devices in their final form and condition are commonly implanted in carefully selected animal models to determine function as well as biocompatibility, it may not be appropriate to carry out all of the recommended tests necessary for regulatory approval on the final device. In these situations, some tests may be carried out on biomaterial components of devices that have been prepared under manufacturing and sterilizing conditions and other processes utilized in the final product development.

In this section, brief perspectives on the general types of *in vivo* tests (Table 3) are presented. Details regarding these tests are found in the references. The ultimate selection of tests for *in vivo* biocompatibility assessment is based on the characteristics and end-use application of the device or biomaterial under consideration. Table 4 provides a list of types of tests to be considered for biological response evaluation under ISO 10993 and Table 5 provides a list of ASTM standards that can be used for biocompatibility evaluation.

4.402.5.1. Sensitization, Irritation, and Intracutaneous (Intradermal) Reactivity

Exposure to or contact with even minute amounts of potential leachables in medical devices or biomaterials can result in allergic or sensitization reactions. Sensitization tests estimate the potential for contact sensitization of medical devices, materials, and/or their extracts; are usually carried out in guinea pigs; and should reflect the intended route (skin, eye, mucosa) and nature, degree, frequency, duration, and conditions of exposure of the biomaterial in its intended clinical use. Emphasis is placed on utilizing extracts of the biomaterials to determine the irritant effects of potential leachables. Intracutaneous (intradermal) reactivity tests determine the localized reaction of tissue to extracts of medical devices, biomaterials, or prostheses in the final product form. Irritation and intracutaneous tests may be applicable where determination of irritation by dermal or mucosal irritation tests is not appropriate – albino rabbits are most commonly used.

Since these tests focus on determining the biological response of leachables that may be present in biomaterials, their extracts in various solvents are utilized to prepare the injection solutions. Critical to the conduct of these tests is the preparation of the test material and/or extract solution and the choice of solvents that must have physiological relevance.

4.402.5.2. Systemic Toxicity (Acute Toxicity) and Subacute and Subchronic Toxicity

Systemic toxicity tests estimate the potential harmful effects of either single or multiple exposures, during a period of <24 h, to medical devices, biomaterials, and/or their extracts. These tests evaluate the systemic toxicity potential of medical devices that release constituents into the body. These tests also include pyrogenicity testing.

In these tests, the form and area of the material, the thickness, and the surface area to extraction vehicle volume are critical considerations in the testing protocol. Appropriate extraction vehicles, that is, solvents, should be used to yield a maximum extraction of leachable materials to conduct the testing. Mice, rats, or rabbits are the usual animals of choice for these tests, and depending on the intended application of the biomaterial, oral, dermal, inhalation, intravenous, intraperitoneal, or subcutaneous application of the test substance may be used. Acute toxicity is considered to be the adverse effect that occurs after administration of a single dose or multiple doses of a test sample within 24 h. Subacute toxicity (repeat dose toxicity) focuses on adverse effects occurring after administration of a single dose or multiple doses of a test sample per day for a period of 14–28 days. Subchronic toxicity is considered to be the adverse effect occurring after the administration of a single dose or multiple doses of a test sample per day during a part of the lifespan, usually 90 days but not exceeding 10% of the lifespan of the animal.

Pyrogenicity (fever producing) tests are also included in the systemic toxicity category to detect material-mediated pyrogenic reactions of extracts of medical devices or materials. It is noteworthy that no single test can differentiate pyrogenic reactions that are material-mediated from those due to endotoxin contamination.

4.402.5.3. Genotoxicity

In vivo genotoxicity tests are carried out (Table 7) if potential genotoxicity is indicated by the chemistry and/or composition of the biomaterial (see Table 1) or by *in vitro* test results. Initially, at least three *in vitro* assays should be carried out and two of these assays should utilize mammalian cells. The initial *in vitro* assays should cover the three levels of genotoxic effects: DNA effects, gene mutations, and chromosomal aberrations. *In vivo* genotoxicity tests include the micronucleus test, the *in vivo* mammalian bone marrow cytogenetic tests – chromosomal analysis, the rodent dominant lethal tests, the mammalian germ cell cytogenetic assay, the mouse spot test, and the mouse heritable translocation assay. Not all of the *in vivo* genotoxicity tests need to be performed and the most common test is the rodent micronucleus test. Genotoxicity

Table 7 Tests for genotoxicity, carcinogenicity, and reproductive toxicity

Genotoxicity
– Bacterial reverse mutation assay
– *In vitro* mouse lymphoma tk assay
– Chromosomal aberation in mammalian cells
Carcinogenicity
– Syrian hamster embryo (SHE) cell transformation assays
– Balb/c 3T3 focus transformation assay
– rasH-2 mouse model
Reproductive toxicity
– Embryonic stem cell test

tests are performed with appropriate extracts or dissolved materials using appropriate media as suggested by the known composition of the biomaterial.

4.402.5.4. Implantation

Implantation tests assess the local pathological effects on living tissue of a sample of a material or final product that is surgically implanted or placed into an implant site or tissue appropriate to the intended application of the biomaterial or medical device. Evaluation of the local pathological effects is carried out at both the gross level and the microscopic level. Histological (microscopic) evaluation is utilized to characterize various biological response parameters. For short-term implantation evaluation of about 12 weeks, mice, rats, guinea pigs, or rabbits are the usual animals utilized in these studies. For longer-term testing in subcutaneous tissue, muscle, or bone, animals such as rats, guinea pigs, rabbits, dogs, sheep, goats, pigs, and other animals with relatively long-life expectancy are suitable. If a medical device is to be evaluated, larger species may be utilized. For example, substitute heart valves are usually tested in sheep, while calves are usually the animal of choice for ventricular assist devices and total artificial hearts.

Implant retrieval and evaluation plays a significant role in determining biocompatibility, factors and mechanisms of medical device failure or success, and new biological design criteria for next-generation devices.[13,14]

4.402.5.5. Chronic Toxicity

Chronic toxicity tests determine the effects of either single or multiple exposures to medical devices, materials, and/or their extracts during a period of at least 10% of the lifespan of the test animal, for example, over 90 days in rats. Chronic toxicity tests may be considered an extension of subchronic (subacute) toxicity testing and both may be evaluated in an appropriate experimental protocol or study.

4.402.5.6. Carcinogenicity

Carcinogenicity tests determine the tumorigenic potential of medical devices, materials, and/or their extracts from either single or multiple exposures or contacts over a period of the major portion of the lifespan of the test animal (Table 7). A new carcinogenicity test using a transgenic mouse assay is currently under investigation.[15] This assay is less time-consuming and less expensive than the two animal life-time assays. Carcinogenicity tests should be conducted only if data from other sources suggest a tendency for tumor induction. In addition, both carcinogenicity (tumorigenicity) and chronic toxicity may be studied in a single experimental study. With biomaterials, carcinogenicity studies focus on the potential for solid-state carcinogenicity, that is, the Oppenheimer effect. In carcinogenicity testing, controls of a comparable form and shape should be included; polyethylene implants are a commonly used control material. The use of appropriate controls is imperative as animals may spontaneously develop tumors and statistical comparison of the test biomaterial/device and the controls is necessary.

4.402.5.7. Reproductive and Developmental Toxicity

These tests evaluate the potential effects of medical devices, materials, and/or their extracts on reproductive function, embryonic development (teratogenicity), and prenatal and early postnatal development (Table 7). The application site of the device must be considered and tests and/or bioassays should only be conducted when the device has a potential impact on the reproductive potential of the subject.

4.402.5.8. Biodegradation

Biodegradation tests determine the effects of a biodegradable material and its biodegradation products on the tissue response. They focus on the amount of degradation during a given period of time (the kinetics of biodegradation), the nature of the degradation products, the origin of the degradation products (impurities, additives, corrosion products, bulk polymer, etc.), and the qualitative and quantitative assessment of degradation products and leachables in adjacent tissues and in distant organs. The biodegradation of biomaterials may occur through a wide variety of mechanisms, which in part are biomaterial-dependent, and all pertinent mechanisms related to the device and the end-use application of the device must be considered.[16–18] Test materials comparable to degradation products may be prepared and studied to determine the biological response of degradation products anticipated in long-term implants. An example of this approach is the study of metallic and polymeric wear particles that may be present with long-term orthopedic joint prostheses.

4.402.6. Inflammation, Wound Healing, and the Foreign-Body Response

Inflammation, wound healing, and foreign-body reaction are generally considered as parts of the tissue or cellular host responses to injury.[19] Table 8 lists the sequence/continuum of these events following injury. Overlap and simultaneous occurrence of these events should be considered; for example, the foreign-body reaction at the implant interface may be initiated with the onset of acute and chronic inflammation. From a biomaterials perspective, placing a biomaterial in the *in vivo* environment requires injection, insertion, or surgical implantation, all of which injure the tissues or organs involved.

The placement procedure initiates a response to injury by the tissue, organ, or body and mechanisms are activated to maintain homeostasis. The degrees to which the homeostatic mechanisms are perturbed and the extent to which

Table 8 Sequence/continuum of host reactions following implantation of medical devices

Chronic inflammation
Granulation tissue
Foreign-body reaction
Fibrosis/fibrous capsule development

pathophysiologic conditions are created and undergo resolution are a measure of the host reactions to the biomaterial and may ultimately determine its biocompatibility. Although it is convenient to differentiate homeostatic mechanisms as blood–material or tissue–material interactions, it must be remembered that the various components or mechanisms involved in homeostasis are present in both blood and tissue and are a part of the physiologic continuum. Furthermore, it must be noted that host reactions may be tissue-dependent, organ-dependent, and species-dependent. Obviously, the severity of injury varies with the implantation procedure.

4.402.6.1. Overview

Inflammation is generally defined as the reaction of vascularized living tissue to local injury. Inflammation serves to contain, neutralize, dilute, or wall off the injurious agent or process.[20] In addition, it sets into motion a series of events that may heal and reconstitute the implant site through the replacement of the injured tissue by regeneration of native parenchymal cells, formation of fibroblastic scar tissue, or a combination of these two processes.

Immediately following injury, there are changes in vascular flow, caliber, and permeability. Fluid, proteins, and blood cells escape from the vascular system into the injured tissue in a process called exudation. Following changes in the vascular system, which also include changes induced in blood and its components, cellular events occur and characterize the inflammatory response. The effect of the injury and/or biomaterial *in situ* on plasma or cells can produce chemical factors that mediate many of the vascular and cellular responses of inflammation.

Blood–material interactions and the inflammatory response are intimately linked, and in fact, early responses to injury involve mainly blood and vasculature. Regardless of the tissue or organ into which a biomaterial is implanted, the initial inflammatory response is activated by injury to vascularized connective tissue (Table 9). Since blood and its components are involved in the initial inflammatory responses, blood clot formation and/or thrombosis also occur. Blood coagulation and thrombosis are generally considered humoral responses and may be influenced by other homeostatic mechanisms such as the extrinsic and intrinsic coagulation systems, the complement system, the fibrinolytic system, the kinin-generating system, and platelets. Thrombus or blood clot formation on the surface of a biomaterial is related to the well-known Vroman effect, in which a hierarchical and dynamic series of collision, absorption, and exchange processes, determined by protein mobility and concentration, regulate early time-dependent changes in blood protein adsorption. From a wound-healing perspective, blood protein deposition on a biomaterial surface is described as provisional matrix formation. Blood interactions with biomaterials are generally considered under the category of hematocompatibility.

Injury to vascularized tissue in the implantation procedure leads to immediate development of the provisional matrix at the implant site. This provisional matrix consists of fibrin, produced by activation of the coagulation and thrombosis systems, and inflammatory products released by the complement system, activated platelets, inflammatory cells, and endothelial cells. These events occur early, within minutes to hours of implantation of a medical device. Components within or released from the provisional matrix, that is, fibrin network (thrombosis or clot), initiate the resolution, reorganization, and repair processes such as inflammatory cell and fibroblast recruitment. The provisional matrix appears to provide both structural and biochemical components to the process of wound healing. The complex three-dimensional structure of the fibrin network with attached adhesive proteins provides a substrate for cell adhesion and migration. The presence of mitogens, chemoattractants, cytokines, and growth factors within the provisional matrix provides for a rich milieu of activating and inhibiting substances for various cellular proliferative and synthetic processes. The provisional matrix may be viewed as a naturally derived, biodegradable, sustained release system in which mitogens, chemoattractants, cytokines, and growth factors are released to control subsequent wound-healing processes. In spite of the increase in our knowledge of the provisional matrix and its capabilities, our knowledge of the control of the formation of the provisional matrix and its effect on subsequent wound-healing events is poor. In part, this lack of knowledge is due to the fact that much of our knowledge regarding the provisional matrix has been derived from *in vitro* studies, and there is a paucity of *in vivo* studies that provide for a wider perspective. Little is known regarding the provisional matrix which forms at biomaterial and medical device interfaces *in vivo*, although attractive hypotheses have been presented regarding the presumed ability of materials and protein-adsorbed materials to modulate cellular interactions through their interactions with adhesive molecules and cells.

The predominant cell type involved in the inflammatory response varies with the age of the inflammatory injury (Figure 1). In general, neutrophils predominate during the first several days following injury and then are replaced by monocytes as the predominant cell type. Three factors account for this change in cell type: neutrophils are short-lived and disintegrate and disappear after 24–48 h; neutrophil

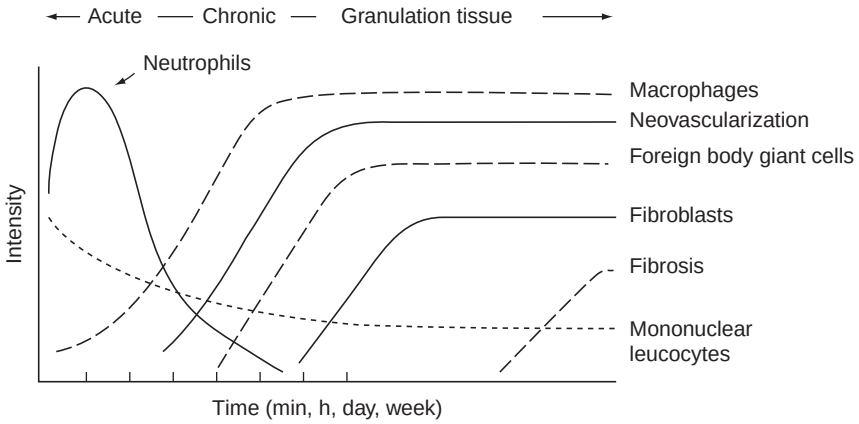

Figure 1 The temporal variation in the acute inflammatory response, chronic inflammatory response, granulation tissue development, and foreign-body reaction to implanted biomaterials. The intensity and time variables are dependent upon the severity of injury created in the implantation and the size, shape, topography, and chemical and physical properties of the biomaterial.

Table 10 Important chemical mediators of inflammation derived from plasma, cells, or injured tissue

Mediators	*Examples*
Vasoactive agents	Histamines, serotonin, adenosine, endothelial-derived relaxing factor (EDRF), prostacyclin, endothelin, thromboxane α_2
Plasma proteases	
Kinin system	Bradykinin, kallikrein
Complement system	C3a, C5a, C3b, C5b–C9
Coagulation/fibrinolytic system	Fibrin degradation products, activated Hageman factor (FXIIA), tissue plasminogen activator (tPA)
Leukotrienes	Leukotriene B_4 (LTB_4), hydroxyeicosatetranoic acid (HETE)
Lysosomal proteases	Collagenase, elastase
Oxygen-derived free radicals	H_2O_2, superoxide anion
Platelet activating factors	Cell membrane lipids
Cytokines	Interleukin 1 (IL-1), tumor necrosis factor (TNF)
Growth factors	Platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor (TGF-α or TGF-β), epithelial growth factor (EGF)

emigration from the vasculature to the tissues is of short duration; and chemotactic factors for neutrophil migration are activated early in the inflammatory response. Following emigration from the vasculature, monocytes differentiate into macrophages and these cells are very long-lived (up to months). Monocyte emigration may continue for day to weeks, depending on the severity of the injury and the type of the implanted biomaterial, and chemotactic factors for monocytes are activated over longer periods of time. In short-term (24 h) implants in humans, administration of both H1 and H2 histamine receptor antagonists greatly reduced the recruitment of macrophages/monocytes and neutrophils on polyethylene terephthalate surfaces.[21] These studies also demonstrated that plasma-coated implants accumulated significantly more phagocytes than did serum-coated implants.

The temporal sequence of events following implantation of a biomaterial is illustrated in Figure 1. The size, shape, and chemical and physical properties of the biomaterial may be responsible for variations in the intensity and duration of the inflammatory or wound-healing process. Thus, intensity and/or time duration of the inflammatory reaction may characterize the biocompatibility of a biomaterial.

While injury initiates the inflammatory response, the chemicals released from plasma, cells, or injured tissues mediate the inflammatory response. Important classes of chemical mediators of inflammation are presented in Table 10. Several points must be noted in order to understand the inflammatory response and how it relates to biomaterials. First, although chemical mediators are classified on a structural or functional basis, different mediator systems interact and provide a system of checks and balances regarding their respective activities and functions. Second, chemical mediators are quickly inactivated or destroyed, suggesting that their action is predominantly local (i.e., at the implant site). Third, generally the lysosomal proteases and the oxygen-derived free radicals produce the most significant damage or injury. These chemical mediators are also important in the degradation of biomaterials.[22]

4.402.6.2. Acute Inflammation

Acute inflammation is of a relatively short duration, lasting for minutes to days, depending on the severity of the injury. Its main characteristics are the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes

(predominantly neutrophils). Neutrophils (polymorphonuclear leukocytes, PMNs) and other motile white cells emigrate or move from the blood vessels to the perivascular tissues and the injury (implant) site. Leukocyte emigration is assisted by 'adhesion molecules' present on the leukocyte and endothelial surfaces. The surface expression of these adhesion molecules can be induced, enhanced, or altered by inflammatory agents and chemical mediators. White cell emigration is controlled, in part, by chemotaxis, which is the unidirectional migration of cells along a chemical gradient. A wide variety of exogenous and endogenous substances have been identified as chemotactic agents. Specific receptors for chemotactic agents on the cell membranes of leukocytes are important in the emigration or movement of leukocytes. These and other receptors also play a role in the transmigration of white cells across the endothelial lining of vessels and activation of leukocytes. Following localization of leukocytes at the injury (implant) site, phagocytosis and the release of enzymes occur following activation of neutrophils and macrophages. The major role of the neutrophil in acute inflammation is to phagocytose microorganisms and foreign materials. Phagocytosis is seen as a three-step process in which the injurious agent undergoes recognition and neutrophil attachment, engulfment, and killing or degradation. In regard to biomaterials, engulfment and degradation may or may not occur, depending on the properties of the biomaterial.

Although biomaterials are not generally phagocytosed by neutrophils or macrophages because of the disparity in size (i.e., the surface area of the biomaterial is greater than the size of the cell), certain events in phagocytosis may occur. The process of recognition and attachment is expedited when the injurious agent is coated by naturally occurring serum factors called 'opsonins.' The two major opsonins are immunoglobulin G (IgG) and the complement-activated fragment, C3b. Both of these plasma-derived proteins are known to adsorb to biomaterials, and neutrophils and macrophages have corresponding cell membrane receptors for these opsonization proteins. These receptors may also play a role in the activation of the attached neutrophil or macrophage. Other blood proteins such as fibrinogen, fibronectin, and vitronectin may also facilitate cell adhesion to biomaterial surfaces. Owing to the disparity in size between the biomaterial surface and the attached cell, frustrated phagocytosis may occur. This process does not involve engulfment of the biomaterial but does cause the extracellular release of leukocyte products in an attempt to degrade the biomaterial.

Henson has shown that neutrophils adherent to complement-coated and immunoglobulin-coated nonphagocytosable surfaces may release enzymes by direct extrusion or exocytosis from the cell.[23] The amount of enzyme released during this process depends on the size of the polymer particle, with larger particles inducing greater amounts of enzyme release. This suggests that the specific mode of cell activation in the inflammatory response in tissue depends upon the size of the implant and that a material in a phagocytosable form (i.e., powder, particulate, or nanomaterial) may provoke an inflammatory response of a degree different from that of the same material in a nonphagocytosable form (i.e., film). In general, materials >5 μm are not phagocytosed, while materials <5 μm, that is, nanomaterials, can be phagocytosed by inflammatory cells.

Acute inflammation normally resolves quickly, usually in <1 week, depending on the severity of the injury at the implant site. However, the presence of acute inflammation (i.e., PMNs) at the tissue–implant interface at time periods beyond 1 week (i.e., weeks, months, or years) suggests the presence of an infection.

4.402.6.3. Chronic Inflammation

Chronic inflammation is histologically less uniform than acute inflammation. In general, chronic inflammation is characterized by the presence of macrophages, monocytes, and lymphocytes, with the proliferation of blood vessels and connective tissue. Many factors can modify the course and histologic appearance of chronic inflammation.

Persistent inflammatory stimuli lead to chronic inflammation. While the chemical and physical properties of the biomaterial in themselves may lead to chronic inflammation, motion in the implant site by the biomaterial or infection may also produce chronic inflammation. The chronic inflammatory response to biomaterials is usually of a short duration and is confined to the implant site. The presence of mononuclear cells, including lymphocytes and plasma cells, is considered chronic inflammation, whereas the foreign-body reaction with the development of granulation tissue is considered the normal wound-healing response to implanted biomaterials (i.e., the normal foreign-body reaction). Chronic inflammation with the presence of collections of lymphocytes and monocytes at extended implant times (weeks, months, years) may also suggest the presence of a long-standing infection. The prolonged presence of acute and/or chronic inflammation also may be due to toxic leachables from a biomaterial.[24]

The following example illustrates this point. *In vivo* subcutaneous implantation studies were carried out in rats and rabbits with naltrexone sustained release preparations that included placebo (polymer-only) beads and naltrexone-containing beads.[18] Histopathological tissue reactions utilizing standard procedures and light microscopic evaluation to the respective preparations were determined at days 3, 7, 14, 21, and 28. The only significant histological finding in both rats and rabbits at any time period was the persistent chronic inflammation that occurred focally around the naltrexone-containing beads. The focal inflammatory cell density in both rats and rabbits was higher for the naltrexone beads than for the placebo beads at days 14, 21, and 28. This difference in inflammatory response between naltrexone beads and placebo beads increased with increasing time of implantation. Considering the resolution of the inflammatory response for the placebo beads with implantation time in both rats and rabbits, it is suggested that the naltrexone drug itself is identified as the causative agent of the focal chronic inflammation present surrounding the naltrexone beads in the implant sites.

The important lesson from this case study is the necessary use of appropriate control materials. If no negative control, that is, placebo polymer-only material, had been used, the polymer in the naltrexone-containing beads would have also been considered as a causative agent of the extended chronic inflammatory response. Similar chronic inflammatory responses have been identified with drugs, polymer plasticizers and other

additives, fabrication and manufacturing aids, and sterilization residuals. Each case presents its own unique factors in a risk assessment process necessary for determining safety (biocompatibility) and benefit versus risk in clinical application.

Lymphocytes and plasma cells are involved principally in immune reactions and are key mediators of antibody production and delayed hypersensitivity responses. Although they may be present at the sites of nonimmunologic injuries and inflammation, their roles in such circumstances are largely unknown.[25,26] Little is known regarding humoral immune responses and cell-mediated immunity to synthetic biomaterials. The role of macrophages must be considered in the possible development of immune responses to synthetic biomaterials. Macrophages and dendritic cells process and present the antigen to immunocompetent cells and thus are key mediators in the development of immune reactions.

Monocytes and macrophages belong to the mononuclear phagocytic system (MPS), also known as the reticuloendothelial system (RES). These systems consist of cells in the bone marrow, peripheral blood, and specialized tissues. **Table 11** lists the tissues that contain cells belonging to the MPS or RES. The specialized cells in these tissues may be responsible for systemic effects in organs or tissues secondary to the release of components or products from implants through various tissue–material interactions (e.g., corrosion products, wear debris, degradation products) or the presence of implants (e.g., microcapsule or nanoparticle drug-delivery systems).

The macrophage is probably the most important cell in chronic inflammation because of the great number of biologically active products it can produce. Important classes of products produced and secreted by macrophages include neutral proteases, chemotactic factors, arachidonic acid metabolites, reactive oxygen metabolites, complement components, coagulation factors, growth-promoting factors, cytokines, and acid. Phagolysosomes in macrophages can have acidity as low as a pH of 4 and direct microelectrode studies of this acid environment have determined pH levels as low as 3.5. Moreover, only several hours are necessary to achieve these acid levels following the adhesion of macrophages.[27–31]

Growth factors such as platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor-β (TGF-β), TGF-α/epidermal growth factor (EGF), and interleukin-1 (IL-1) or tumor necrosis factor (TNF-α) are important for the growth of fibroblasts and blood vessels and the regeneration of epithelial cells. Growth factors released by activated cells can stimulate production of a wide variety of cells; initiate cell migration, differentiation, and tissue remodeling; and may be involved in various stages of wound healing.

Table 11 Tissues and cells of MPS and RES

Tissues	*Cells*
Implant sites	Inflammatory macrophages
Liver	Kupffer cells
Lung	Alveolar macrophages
Connective tissue	Histiocytes
Bone marrow	Macrophages
Spleen and lymph nodes	Fixed and free macrophages
Serous cavities	Pleural and peritoneal macrophages
Nervous system	Microglial cells
Bone	Osteoclasts
Skin	Langerhans' cells
Lymphoid tissue	Dendritic cells

4.402.6.4. Granulation Tissue

Within 1 day following implantation of a biomaterial (i.e., injury), the healing response is initiated by the action of monocytes and macrophages. Fibroblasts and vascular endothelial cells in the implant site proliferate and begin to form granulation tissue, which is the specialized type of tissue that is the hallmark of healing inflammation. Granulation tissue derives its name from the pink, soft granular appearance on the surface of healing wounds, and its characteristic histologic features include the proliferation of new small blood vessels and fibroblasts. Depending on the severity of injury, granulation tissue may be seen as early as 3–5 days following implantation of a biomaterial.

The new small blood vessels are formed by budding or sprouting of preexisting vessels in a process known as neovascularization or angiogenesis.[32,33] This process involves proliferation, maturation, and organization of endothelial cells into capillary vessels. Fibroblasts also proliferate in developing granulation tissue and are active in synthesizing collagen and proteoglycans. In the early stages of granulation tissue development, proteoglycans predominate but later collagen, especially type III collagen, predominates and forms the fibrous capsule. Some fibroblasts in developing granulation tissue may have the features of smooth muscle cells, that is, actin microfilaments. These cells are called myofibroblasts and are considered to be responsible for the wound contraction seen during the development of granulation tissue. Macrophages are almost always present in granulation tissue. Other cells may also be present if chemotactic stimuli are generated.

The wound-healing response is generally dependent on the severity of injury or defect created by the implantation procedure[34–38]. Wound healing by primary union or first intention is the healing of clean, surgical incisions in which the wound edges have been approximated by surgical sutures. Healing under these conditions occurs without significant bacterial contamination and with a minimal loss of tissue. Wound healing by secondary union or second intention occurs when there is a large tissue defect that must be filled or there is extensive loss of cells and tissue. In wound healing by secondary intention, regeneration of parenchymal cells cannot completely reconstitute the original architecture and much larger amounts of granulation tissue are formed that result in larger areas of fibrosis or scar formation. Under these conditions, different regions of tissue may show different stages of the wound-healing process simultaneously.

Granulation tissue is distinctly different from granulomas, which are the small collections of modified macrophages called epithelioid cells. Langhans' or foreign-body-type giant cells may surround nonphagocytosable particulate materials in granulomas. Foreign-body giant cells (FBGCs) are formed by the fusion of monocytes and macrophages in an attempt to phagocytose the material.

4.402.6.5. Foreign-Body Reaction

The foreign-body reaction to biomaterials is composed of FBGCs and the components of granulation tissue (e.g., macrophages, fibroblasts, and capillaries in varying amounts, depending upon the form and topography of the implanted material[39]). Relatively flat and smooth surfaces such as that found on breast prostheses have a foreign-body reaction that is composed of a layer of macrophages of one to two cells in thickness. Relatively rough surfaces such as those found on the outer surfaces of expanded poly tetrafluoroethylene (ePTFE) or Dacron vascular prostheses have a foreign-body reaction composed of macrophages and FBGCs at the surface. Fabric materials generally have a surface response composed of macrophages and FBGCs, with varying degrees of granulation tissue subjacent to the surface response.

As previously discussed, the form and topography of the surface of the biomaterial determine the composition of the foreign-body reaction. With biocompatible materials, the composition of the foreign-body reaction in the implant site may be controlled by the surface properties of the biomaterial, the form of the implant, and the relationship between the surface area of the biomaterial and the volume of the implant. For example, high-surface-to-volume implants such as fabrics, porous materials, particulate, or microspheres will have higher ratios of macrophages and FBGCs in the implant site than smooth-surface implants, which will have fibrosis as a significant component of the implant site.[40–44]

The foreign-body reaction consisting mainly of macrophages and/or FBGCs may persist at the tissue–implant interface for the lifetime of the implant (Figure 1). Generally, fibrosis (i.e., fibrous encapsulation) surrounds the biomaterial or implant with its interfacial foreign-body reaction, isolating the implant and foreign-body reaction from the local tissue environment. Early in the inflammatory and wound-healing response, the macrophages are activated upon adherence to the material surface.[45]

Although it is generally considered that the chemical and physical properties of the biomaterial are responsible for macrophage activation, the subsequent events regarding the activity of macrophages at the surface are not clear. Tissue macrophages, derived from circulating blood monocytes, may coalesce to form multinucleated FBGCs. It is not uncommon to see very large FBGCs containing large numbers of nuclei on the surface of biomaterials. While these FBGCs may persist for the lifetime of the implant, it is not known whether they remain activated, releasing their lysosomal constituents, or become quiescent.[46]

Figure 2 demonstrates the progression from circulating blood monocyte to tissue macrophage to FBGCs development that is most commonly observed. Indicated in the figure are biological responses that are considered to play an important role in FBGC development. Material surface chemistry may control adherent macrophage apoptosis (i.e., programmed cell death) that renders potentially harmful macrophages nonfunctional, while the surrounding environment of the implant remains unaffected. The level of adherent macrophage apoptosis appears to be inversely related to the surface's ability to promote diffusion of macrophages into FBGCs, suggesting a mechanism for macrophages to escape apoptosis.

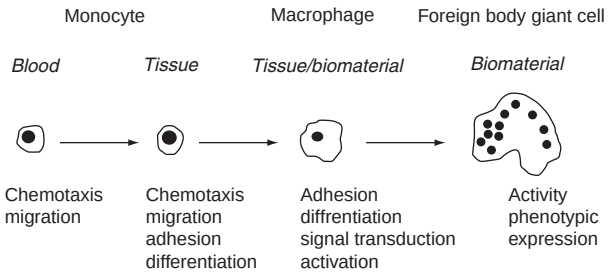

Figure 2 *In vivo* transition from blood-borne monocyte to biomaterial adherent monocyte/macrophage to foreign-body giant cell (FBGC) at the tissue–biomaterial interface. Little is known regarding the indicated biological responses, which are considered to play important roles in the transition to FBGC development.

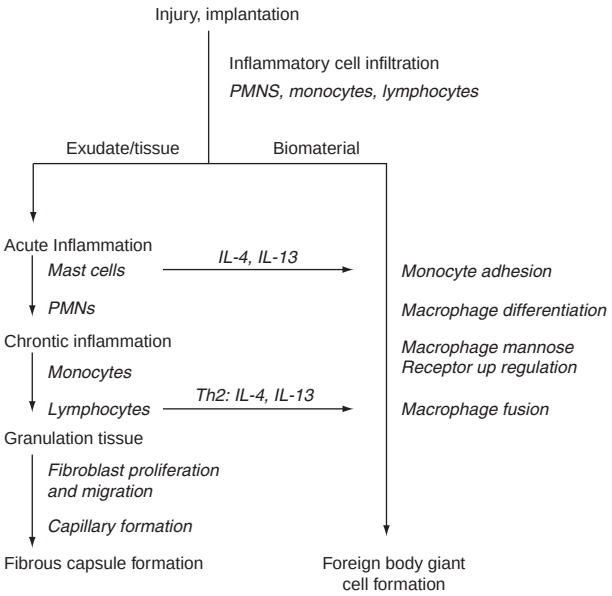

Figure 3 Sequence of events involved in inflammatory and wound-healing responses leading to foreign-body giant cell formation.

Figure 3 demonstrates the sequence of events involved in inflammation and wound healing when medical devices are implanted. In general, the PMN predominant acute inflammatory response and the lymphocyte/monocyte predominant chronic inflammatory response resolve quickly (i.e., within 2 weeks) depending on the type and location of the implant. Studies using IL-4 or IL-13 demonstrate the role for Th2 helper lymphocytes and/or mast cells, respectively, in the development of the foreign-body reaction at the tissue–material interface.[47,48] Integrin receptors of IL-4-induced FBGC are characterized by the early constitutive expression of $\alpha V\beta 1$ and the later induced expression of $\alpha 5\beta 1$ and $\alpha X\beta 2$, which indicate potential interactions with adsorbed complement C3, fibrin(ogen), fibronectin, Factor X, and vitronectin.[48–56] Interactions through indirect (paracrine) cytokine and chemokine signaling have shown a significant effect in enhancing adherent macrophage/FBGC activation at early times, whereas interactions via direct (juxtacrine)

cell–cell mechanisms dominate at later times.[57–59] Th2 helper lymphocytes have been described as 'antiinflammatory' based on their cytokine profile, of which IL-4 is a significant component.

4.402.6.6. Fibrosis/Fibrous Encapsulation

The end-stage healing response to biomaterials is generally fibrosis or fibrous encapsulation. However, there may be exceptions to this general statement (e.g., porous materials inoculated with parenchymal cells or porous materials implanted into bone). As previously stated, the tissue response to implants is in part dependent upon the severity of injury or defect created in the implantation procedure and the amount of provisional matrix.

The ultimate goal of tissue engineering and regenerative medicine is replacement of injured tissue by cells that reconstitute normal tissue and organ structures. Numerous approaches, including stem cells, scaffolds, growth factors, etc., are currently being investigated. However, the relatively rapid responses of inflammation, wound healing, and the foreign-body reaction, as well as other significant factors in tissue regeneration, present major challenges to the successful achievement of this goal.

Repair of implant sites can involve two distinct processes: regeneration, which is the replacement of injured tissue by parenchymal cells of the same type, or replacement by connective tissue that constitutes the fibrous capsule. These processes are generally controlled by either (1) the proliferative capacity of the cells in the tissue or organ receiving the implant and the severity of injury as it relates to the destruction, or (2) persistence of the tissue framework of the implant site.

The regenerative capacity of cells allows them to be classified into three groups: labile, stable (or expanding), and permanent (or static) cells. Labile cells continue to proliferate throughout life; stable cells retain this capacity but do not normally replicate; and permanent cells cannot reproduce themselves after birth. Perfect repair with restitution of normal structure can theoretically occur only in tissues consisting of stable and labile cells, whereas all injuries to tissues composed of permanent cells may give rise to fibrosis and fibrous capsule formation with very little restitution of the normal tissue or organ structure. Tissues composed of permanent cells (e.g., nerve cells and cardiac muscle cells) most commonly undergo an organization of the inflammatory exudate, leading to fibrosis. Tissues of stable cells (e.g., parenchymal cells of the liver, kidney, and pancreas); mesenchymal cells (e.g., fibroblasts, smooth muscle cells, osteoblasts, and chondroblasts); and vascular endothelial and labile cells (e.g., epithelial cells and lymphoid and hematopoietic cells) may also follow this pathway to fibrosis or may undergo resolution of the inflammatory exudate, leading to restitution of the normal tissue structure.

The condition of the underlying framework or supporting stroma of the parenchymal cells following an injury plays an important role in the restoration of normal tissue structure. Retention of the framework with injury may lead to restitution of the normal tissue structure, whereas destruction of the framework most commonly leads to fibrosis. It is important to consider the species-dependent nature of the regenerative capacity of cells. For example, cells from the same organ or tissue but from different species may exhibit different regenerative capacities and/or connective tissue repair.

Following injury, cells may undergo adaptations of growth and differentiation. Important cellular adaptations are atrophy (decrease in cell size or function), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (change in cell type). Other adaptations include a change by cells from producing one family of proteins to another (phenotypic change), or marked overproduction of protein. This may be the case in cells producing various types of collagens and extracellular matrix proteins in chronic inflammation and fibrosis. Causes of atrophy may include decreased workload (e.g., stress-shielding by implants), and diminished blood supply and inadequate nutrition (e.g., fibrous capsules surrounding implants).

Local and systemic factors may play a role in the wound-healing response to biomaterials or implants. Local factors include the site (tissue or organ) of implantation, the adequacy of blood supply, and the potential for infection. Systemic factors may include nutrition, hematologic derangements, glucocortical steroids, and preexisting diseases such as atherosclerosis, diabetes, and infection.

Finally, the implantation of biomaterials or medical devices may be best viewed at present from the perspective that the implant provides an impediment or hindrance to appropriate tissue or organ regeneration and healing. Given our current inability to control the sequence of events following injury in the implantation procedure, restitution of normal tissue structures with function is rare. Current studies directed toward gaining a better understanding of the modification of the inflammatory response, stimuli providing for appropriate proliferation of permanent and stable cells, and the appropriate application of growth factors may provide keys to the control of inflammation, wound healing, and fibrous encapsulation of biomaterials.

4.402.7. Hemocompatibility

Hemocompatibility tests evaluate effects on blood and/or blood components by blood-contacting medical devices or materials.[60,61] *In vivo* hemocompatibility tests are usually designed to simulate the geometry, contact conditions, and flow dynamics of the device or material in its clinical application. From the ISO standards perspective, five test categories are indicated for hemocompatibility evaluation: thrombosis, coagulation, platelets, hematology, and immunology (complement and leukocytes) (**Table 12**).

Several issues are important in the selection of tests for hemocompatibility of medical devices or biomaterials. *In vivo* testing in animals may be convenient; however, species differences in blood reactivity must be considered and these may limit the predictability of any given test in the human clinical situation. While species differences may complicate hemocompatibility evaluation, the utilization of animals in short- and long-term testing is considered to be appropriate for evaluating thrombosis and tissue interaction. European community law prohibits the use of nonhuman primates for blood compatibility and medical device testing even though blood values and reactivity between humans and nonhuman primates are very

similar. Hemocompatibility evaluation in animals is complicated by the lack of appropriate and adequate assay materials; for example, appropriate antibodies for immunoassays. Use of human blood in hemocompatibility evaluation implies *in vitro* testing, which usually requires the use of anticoagulants which are not usually present with the device in the clinical situation, except for perhaps the earliest implantation period. The use of anticoagulants or antithrombotics may complicate *in vitro* and *in vivo* hemocompatibility evaluation. For example, the calcium chelator EDTA is commonly used to anticoagulate whole blood but EDTA also inhibits activation of the complement system that, in turn, may reduce leukocyte adhesion to surfaces.

In vitro flow systems such as flow cells and recirculating flow tubes are usually of short duration, minutes to hours, and thus may not adequately assess blood component interactions with test materials. Flow is an important parameter that must be designed into each test model utilized for hematocompatibility. In additions, *in vitro, ex vivo,* and *in vivo* test systems must also consider and, if possible, evaluate the extent of thromboembolization that occurs. In the past, clean test surfaces have been considered blood compatible when, in fact, significant thrombus formation has occurred with thromboembolization under flow leading to the so-called 'clean' surface and interpretation of blood compatibility. Nonadherence of blood components does not necessarily imply hematocompatibility.

Table 12 Hemocompatibility: test methods for implant devices

Test category	*Evaluation method*
Thrombosis	Scanning electron microscopy (platelet adhesion and aggregation); platelet and leukocyte morphology; fibrin
	Percent occlusion
	Flow reduction
	Labeled antibodies to thrombotic components
	Autopsy of devices (gross and microscopic); histopathology
	Autopsy of distal organs (gross and microscopic); histopathology
Coagulation	Specific coagulation factor assay; FPA, D-dimer, F_{1+2}, PAC-1, S-12, TAT
	PTT (nonactivated), PT, TT; plasma fibrinogen; FDP
Platelets	PF-4, β-TG, thromboxane B2
	Platelet activation markers
	Platelet microparticles
	Gamma imaging of radiolabeled platelets, ^{111}In-labeled platelet survival
	Platelet function analysis
	Platelet count/adhesion
	Platelet aggregation
Hematology	Leukocyte count with or without differential
	Leukocyte activation
	Hemolysis
	Reticulocyte count; activation-specific release products of peripheral blood cells (i.e., granulocytes)
Complement system	C3a, C5a, TCC, Bb, iC3b, C4b, SC5b-9, CH 50, C3 convertase, C5 convertase

Low flow *in vivo* venous models have been suggested for hematocompatibility evaluation. However, these systems are not appropriately and adequately justified for use in assessing the long-term biocompatibility required for cardiac and cardiovascular implants.

4.402.8. Immune Responses

Immune response evaluation is not a component of the standards currently available for *in vivo* tissue compatibility assessment. However, ASTM, ISO, and the FDA currently have working groups developing guidance documents for immune response evaluation where pertinent and technical reports have been produced. The need for immune response evaluation is clearly understood in the case of modified natural tissue implants such as collagen, which has been utilized in a number of different types of implants. The Center for Devices and Radiological Health of the FDA has released a draft immunotoxicity testing guidance document, the purpose of which is to provide a systematic approach to evaluating potential adverse immunological effects of medical devices and constituent materials.[12] Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction. Adverse or immunotoxic effects occur when humoral or cellular immunity needed by the host to defend itself against infections or neoplastic disease (immunosuppression) or unnecessary tissue damage (chronic inflammation, hypersensitivity, or autoimmunity) is compromised.

With the advent of tissue engineering, the importance of immune response and immunotoxicity evaluation has increased significantly.[62–66] Immune response evaluation is an especially challenging area given the unique nature of the respective medial devices and the latency or time delay in the presentation of a response. Differences between animal and human immune responses provide additional complexity to this issue. The following presents an overview of and guidance to immune response evaluation.

The inflammatory (innate) and immune (adaptive) responses have common components. It is possible to have only inflammatory responses with no adaptive immune response. In this situation, both humoral and cellular components that are shared by both types of responses may only participate in the inflammatory response. Table 13 indicates the common components of the inflammatory (innate) and immune (adaptive) responses. Macrophages and dendritic cells are known as

Table 13 Common components in the inflammatory (innate) and immune (adaptive) responses

Components
Complement cascade components
Immunoglobulins
Cellular components
Macrophages
NK (natural killer) cells
Dendritic cells
Cells with dual phagocytic and antigen-presenting capabilities

professional antigen-presenting cells (APCs) responsible for the initiation of the adaptive immune response.

The acquired or adaptive immune system acts to protect the host from foreign agents or materials and is usually initiated through specific recognition mechanisms and the ability of humoral and cellular components to recognize the foreign agent or material as being 'nonself.'[67] Generally, the adaptive immune system may be considered as having two components: humoral or cellular. Humoral components include antibodies, complement components, cytokines, chemokines, growth factors, and other soluble mediators. These components are synthesized by cells of the immune response and, in turn, function to regulate the activity of these same cells and provide for communication between different cells in the cellular component of the adaptive immune response. Cells of the immune system arise from stem cells in the bone marrow (B lymphocytes) or the thymus (T lymphocytes) and differ from each other in morphology, function, and in the expression of cell surface antigens. They share the common features of maintaining cell surface receptors that assist in the recognition and/or elimination of foreign materials. Regarding tissue-engineered devices, the adaptive immune response may recognize the biological components, modifications of the biological components, or degradation products of the biological components, commonly known as antigens, and initiate immune response through humoral or cellular mechanisms.

Components of the humoral immune system play important roles in the inflammatory responses to foreign materials. Antibodies and complement components C3b and C3bi adhere to foreign materials, act as opsonins, and facilitate phagocytosis of the foreign materials by neutrophils and macrophages that have cell surface receptors for C3b. Complement component C5a is a chemotactic agent for neutrophils, monocytes, and other inflammatory cells and facilitates the immigration of these cells to the implant site. The complement system is composed of classic and alternative pathways that eventuate in a common pathway to produce the membrane attack complex (MAC), which is capable of lysing microbial agents. The complement system, that is, complement cascade, is closely controlled by protein inhibitors in the host cell membrane that may prevent damage to host cells. This inhibitory mechanism may not function when nonhost cells are used in tissue-engineered devices.

T (thymus-derived) lymphocytes are significant cells in the cell-mediated adaptive immune response and their cell adhesion molecules play a significant role in lymphocyte migration, activation, and effector function. The specific interaction of cell membrane adhesion molecules, sometimes also called ligands or antigens, with APCs produce specific types of lymphocytes with specific functions. Table 14 indicates cell types and function in the adaptive immune response. Obviously, the functions of these cells are more numerous than that indicated in Table 14, but the major function of these cells is provided to indicate similarities and differences in the interaction and responsiveness of these cells. Effector T cells (Table 15) are produced when their antigen-specific receptors and either the CD4 or the CD8 co-receptors bind to peptide–MHC (major histocompatibility complex) complexes. A second, co-stimulatory signal is also required, and this is provided by the interaction of the CD28 receptor on the T cell and the B7.1 and B7.2 glycoproteins of the immunoglobulin superfamily present on APCs. B lymphocytes bind soluble antigens through their cell surface immunoglobulin and thus can function as professional APCs by internalizing the soluble antigens and presenting peptide fragments of these antigens as MHC:peptide complexes. Once activated, T cells can synthesize the T cell growth factor interleukin-2 and its receptor. Thus, activated T cells secrete and respond to interleukin-2 to promote T cell growth in an autocrine fashion.

Cytokines are the messenger molecules of the immune system. Most cytokines have a wide spectrum of effects, reacting with many different cell types, and some are produced by several different cell types. Table 16 presents common categories of cytokines and lists some of their general properties. It should be noted that while cytokines can be subdivided into functional groups, many cytokines such as IL-1, TNF-α, and

Table 14 Cell types and function in the adaptive immune system

Cell type	*Function*
Macrophages (APC)	Process and present antigen to immunocompetent T cells Phagocytosis Activated by cytokines (i.e., IFN-γ) from other immune cells
T cells	Interact with APCs and are activated through two required cell membrane interactions Facilitate target cell apoptosis Participate in transplant rejection (type IV hypersensitivity)
B cells	Form plasma cells that secrete immunoglobulins (IgG, IgA, and IgE) Participate in antigen–antibody complex mediated tissue damage (type III hypersensitivity)
Dendritic cells (APC)	Process and present antigen to immunocompetent T cells Utilize Fc receptors for IgG to trap antigen–antibody complexes
NK cells (non-T, non-B lymphocytes)	Innate ability to lyse tumor, virus infected, and other cells without previous sensitization Mediates T and B cell function by secretion of IFN-γ

Table 15 Effector T lymphocytes in adaptive immunity

Th1 helper cells	CD4+ Proinflammatory Activation of macrophages Produces IL-2, interferon-γ (IFN-γ), IL-3, TNF-α, GM-CSF, macrophage chemotactic factor (MCF), migration inhibitor factor (MIF) Induce IgG2a
TH2 helper cells	CD4+ Antiinflammatory Activation of B cells to make antibodies Produces IL-4, IL-5, IL-6, IL-10, IL-3, GM-CSF, and IL-13 Induce IgG1
Cytotoxic T cells (CTL)	CD8+ Induce apoptosis of target cells Produce IFN-γ, TNF-β, and TNF-α Release cytotoxic proteins

Table 16 Selected cytokines and their effects

Cytokine	*Effect*
IL-1, TNF-α, INF-γ, IL-6	Mediate natural immunity
IL-1, TNF-α, IL-6	Initiate nonspecific inflammatory responses
IL-2, IL-4, IL-5, IL-12, IL-15, and TGF-β	Regulate lymphocyte growth, activation, and differentiation
IL-2 and IL-4	Promote lymphocyte growth and differentiation
IL-10 and TGF-β	Downregulate immune responses
IL-1, INF-γ, TNF-α, and MIF	Activate inflammatory cells
IL-8	Produced by activated macrophages and endothelial cells Chemoattractant for neutrophils
MCP-1, MIP-α, and RANTES	Chemoattractant for monocytes and lymphocytes
GM-CSF and G-CSF	Stimulate hematopoiesis
IL-4 and IL-13	Promote macrophage fusion and FBGC formation

Table 17 Potential immunological effects and responses

IFN-γ are pleotropic in their effects and regulate, mediate, and activate numerous responses by numerous cells.

Immunotoxicity is any adverse effect on the function or structure of the immune system or other systems as a result of an immune system dysfunction.[12] Adverse or immunotoxic effects occur when humoral or cellular immunity needed by the host to defend itself against infections or neoplastic disease (immunosuppression) or unnecessary tissue damage (chronic inflammation, hypersensitivity, or autoimmunity) is compromised. Potential immunological effects and responses that may be associated with one or more of these effects are presented in Table 17. Hypersensitivity responses are classified on the basis of the immunologic mechanism that mediates the response. There are four types: type I (anaphylactic), type II (cytotoxic), type III (immune complex), and type IV cell-mediated (delayed) hypersensitivity. Hypersensitivity is considered to be increased reactivity to an antigen to which a human or animal has been previously exposed, with an adverse rather than a protective effect.[68] Hypersensitivity is a synonym for allergy. Type I (anaphylactic) reactions and type IV (cell-mediated delayed hypersensitivity) reactions are the most common. Types II and III reactions are relatively rare and are less likely to occur with medical devices and biomaterials; however, with tissue-engineered devices containing potential antigens, that is, proteins, extracellular matrix (ECM) components, and/or cells, types II and III reactions must be considered in biological response evaluations.

Type I (anaphylactic) hypersensitivity reactions are mediated by IgE antibodies which are cytotropic and affect the immediate release of basoactive amines and other mediators from basophils and mast cells followed by recruitment of other inflammatory cells. Type IV cell-mediated (delayed) hypersensitivity responses involve sensitized T lymphocytes that release cytokines and other mediators that lead to cellular and tissue injury. Type IV hypersensitivity (cell-mediated) reactions are initiated by specifically sensitized T lymphocytes. This reaction includes the classic delayed-type hypersensitivity reaction initiated by CD4+ T cells and direct cell cytotoxicity mediated by CD8+ T cells. The less common type II (cytotoxic) hypersensitivity involves the formation and binding of IgG and/or IgM to antigens on target cell surfaces that facilitate phagocytosis of the target cell or lysis of the target cell by activated complement components. Type II hypersensitivity (cytotoxic) is mediated by antibodies directed toward antigens present on the surface of cells or other tissue components. Three different antibody-dependent mechanisms may be involved in this type of reaction: complement-dependent reactions, antibody-dependent cell-mediated cytotoxicity, or antibody-mediated cellular dysfunction. Type III immune complex hypersensitivity is present when circulating antigen–antibody complexes activate complement the components of which are chemotactic for neutrophils that release enzymes and other toxic moieties and mediators leading to cellular and tissue injury.

Immunological reactions that occur with organ transplant rejection also offer insight into potential immune responses to tissue-engineered devices. Mechanisms involved in organ transplant rejection include T cell-mediated reactions by direct and indirect pathways and antibody-mediated reactions. Immune responses may be avoided or diminished by using autologous or isogeneic cells in cell/polymer scaffold constructs. The use of allogeneic or xenogenic cells incorporated into the device requires prevention of immune rejection by immune suppression of the host, induction of tolerance in the host, or immunomodulation of the tissue-engineered construct. The development of tissue-engineered constructs by immunoisolation using polymer membranes and the use of nonhost cells have been compromised by immune responses. In this concept, a polymer membrane is used to encapsulate nonhost cells or tissues thus separating them from the host immune system. However, antigens shed by encapsulated cells were released from the device and initiated immune responses.[69–71]

Although exceptionally minimal and superficial in its presentation, the previously discussed humoral and cell-mediated immune responses demonstrate the possibility that any known tissue-engineered construct may undergo immunologic tissue

injury. To date, our understanding of immune mechanisms and their interactions with tissue-engineered constructs is markedly limited. One of the obvious problems is that preliminary studies are generally carried out with nonhuman tissues and immune reactions result when tissue-engineered constructs from one species are used in testing the device in another species. Ideally, tissue-engineered constructs would be prepared from cells and tissues of a given species and subsequently tested in that species. While this approach does not guarantee that immune responses will not be present, the probability of immune responses in this type of situation is markedly decreased.

The following examples provide insight into these issues. They further demonstrate in detail the approach that must be taken to appropriately and adequately evaluate tissue-engineered constructs or devices and their potential adverse responses.

The inflammatory response considered to be immunotoxic is persistent chronic inflammation. With biomaterials, controlled release systems, and tissue-engineered devices, potential antigens capable of stimulating the immune response may be present and these agents may facilitate a chronic inflammatory response that is of extended duration (weeks, months). Regarding immunotoxicity, it is this persistent chronic inflammation that is of concern as immune granuloma formation and other serious immunological reactions such as autoimmune disease may occur. Thus, in biological response evaluation, it is important to discriminate between the short-lived chronic inflammation that is a component of the normal inflammatory and healing responses versus long-term, persistent chronic inflammation that may indicate an adverse immunological response.

Immunosuppression may occur when antibody and T cell responses (adaptive immune response) are inhibited. Potentially significant consequences of this type of response are frequent and serious infections resulting from reduced host defense.

Immunostimulation may occur when unintended or inappropriate antigen-specific or nonspecific activation of the immune system is present. From a biomaterials and controlled release system perspective, antibody and/or cellular immune responses to a foreign protein may lead to unintended immmunogenicity. Enhancement of the immune response to an antigen by a biomaterial with which it is mixed ex vivo or in situ may lead to adjuvancy, which is a form of immunostimulation. This effect must be considered when biodegradable controlled release systems are designed and developed for use as vaccines.

Autoimmunity is the immune response to the body's own constituents, which are considered in this response to be autoantigens. An autoimmune response, indicated by the presence of autoantibodies or T lymphocytes that are reactive with host tissue or cellular antigens, may, but not necessarily, result in autoimmune disease with chronic, debilitating, and sometimes life-threatening tissue and organ injury.[72]

Representative tests for the evaluation of immune responses are given in Table 18. Table 18 is not all-inclusive and other tests may be applicable. The examples presented in Table 18 are only representative of the large number of tests that are currently available.[67] Table 18 is informative but incomplete as in the future direct and indirect markers of immune response may be validated and their predictive value documented thus providing new tests for immunotoxicity. Direct measures of immune system activity by functional assays are the most important types of test for immunotoxicity. Functional assays are generally more important than tests for soluble mediators, which are more important than phenotyping. Signs of illness may be important in *in vivo* experiments but symptoms may also have a significant role in studies of immune function in clinical trials and postmarket studies.

Table 18 Representative tests for the evaluation of immune responses

Functional assays	*Soluble mediators*
Skin testing	Antibodies
Immunoassays (e.g., ELISA)	Complement
Lymphocyte proliferation	Immune complexes
Plaque-forming cells	Cytokine patterns (T cell subsets)
Local lymph node assay (LLNA)	Cytokines (IL-1, IL-1ra, TNF-α, IL-6, TGF-β, IL-4, IL-13)
Mixed lymphocyte reaction	Chemokines
Tumor cytotoxicity	Basoactive amines
Antigen presentation	
Phagocytosis	
Degranulation	*Signs of illness*
Resistance to bacteria, viruses, and tumors	Allergy
	Skin rash
	Urticaria
Phenotyping	Edema
Cell surface markers	Lymphadenopathy
MHC markers	

As with any type of test for biological response evaluation, immunotoxicity tests should be valid and have been shown to provide accurate, reproducible results that are indicative of the effect being studied and are useful in a statistical analysis. This implies that appropriate control groups are also included in the study design.

Immunogenicity involving a specific immune response to a biomaterial is an important consideration as it may lead to serious adverse effects. For example, a foreign, nonhuman, protein may induce IgE antibodies that cause an anaphylactic (type I) hypersensitivity reaction. An example of this type of response is latex protein found in latex gloves. Low molecular weight compounds such as chemical accelerators used in the manufacture of latex gloves may also induce a T cell-mediated (type IV) reaction resulting in contact dermatitis. Tests for type I, for example, antigen-specific IgE, and type IV, for example, guinea pig maximization tests, hypersensitivity should be considered for materials with the potential to cause these allergic reactions. In addition to hypersensitivity reactions, a device may elicit autoimmune responses, that is, antibodies or T cells that react with the body's own constituents. An autoimmune response may lead to the pathological consequences of an autoimmune disease. For example, a foreign protein may induce IgG or IgM antibodies that cross-react with a human protein and cause tissue damage by activating the complement system. In a similar fashion, a biomaterial or controlled release system that has a gel or oil constituent may act as an adjuvant leading to the induction of an autoimmune response. Even if an autoimmune response (autoantibodies and/or autoreactive

T lymphocytes) is suggested in preclinical testing, it is difficult to obtain convincing evidence that a biomaterial or controlled release system causes autoimmune disease in animals. Therefore, routine testing for the induction of autoimmune disease in animal models is not recommended.

Babensee and coworkers have tested the hypothesis that the biomaterial component of a medical device, by promoting an inflammatory response, can recruit APCs (e.g., macrophages and dendritic cells) and induce their activation, thus acting as an adjuvant in the immune response to foreign antigens originating from the histological component of the device.[73–78] Utilizing polystyrene and poly(lactic–glycolic acid) microparticles and poly(lactic–glycolic) scaffolds together with their model antigen, ovalbumin, in a mouse model for 18 weeks, Babensee *et al.*, demonstrated that a persistent humoral immune response that was Th2 helper T cell dependent, as determined by the IgG1, was present. These findings indicated that the activation of CD4+ T cells and the proliferation and isotype switching of B cells had occurred. A Th1 immune response, characterized by the presence of IgG2a, was not identified. Moreover, the humoral immune responses for all three types of microparticles were similar indicating that the production of antigen-specific antibodies was not dependent on the chemistry of the material in this model. Babensee suggests that the presence of the biomaterial functions as an adjuvant for initiation and promotion of the immune response and augments the phagocytosis of the antigen with expression of MHC class II and co-stimulatory molecules on APCs with the presentation of antigen to CD4+ T cells.

Babensee and coworkers have identified differential levels of dendritic cell maturation on different biomaterials used in combination products.[79,80] The effect of biomaterials on dendritic cells maturation, and the associated adjuvant effect, is a novel biocompatibility selection and design criterion for biomaterials to be used in combination products in which immune consequences are potential complications or outcomes.

Badylak and colleagues have carried out extensive studies of the utilization of xenogeneic ECM as a scaffold for tissue reconstruction.[81,82] Use of the small intestinal submucosa (SIS) ECM in animals has indicated a restricted Th2-type immune response. The presence of natural antibodies to the terminal galactose-α-1,3-galactose (α-gal) epitope is considered to be a major barrier to xenotransplantation in humans. Cell membranes of all animals except those of the humans express this epitope and naturally occurring antibodies mediate hyperacute or delayed rejection of transplanted organs through complement fixation or antibody-dependent cell-mediated cytotoxicity. While ECM derived from porcine tissues, SIS, contain small amounts of the gal epitope, it appears that the quantity or distribution of this epitope and/or the subtype of immunoglobulin response to the epitope is such that complement activation does not occur.[83] In addition, the resorbable characteristics of this nonchemically cross-linked ECM scaffold demonstrate constructive tissue remodeling and deposition of new matrix, whereas chemically cross-linked ECM leads to active inflammation and eventually scar formation.

The role of Th1 and Th2 lymphocytes in cell-mediated immune responses to xenografts has been examined. Activation of the Th1 pathway leads to macrophage activation, stimulation of complement fixing antibody isotypes, and differentiation of CD8+ cells to a cytotoxic type phenotype that is associated with both allogeneic and xenogeneic transplant rejection. The Th2 lymphocyte response does not activate macrophages and leads to production of noncomplement fixing antibody isotypes and is usually associated with transplant acceptance.

The use of appropriate animal models is important in the safety evaluation of controlled release systems that may contain potential immunoreactive materials.[84–86] A recently published study involving the *in vivo* evaluation of recombinant human growth hormone in poly(lactic-*co*-glycolic acid) (PLGA) microspheres demonstrates the appropriate use of various animal models to evaluate biological responses and the potential for immunotoxicity. Utilizing biodegradable PLGA microspheres containing recombinant human growth hormone (rhGH), Cleland et al. used rhesus monkeys, transgenic mice expression rhGH, and normal control (Balb/C) mice in their *in vivo* studies.[87] Rhesus monkeys were utilized for serum assays in the pharmacokinetic study of rhGH release as well as tissue responses to the injected microcapsule formulation. Placebo injection sites were also utilized and a comparison of the injection sites from rhGH PLGA microspheres and placebo PLGA microspheres demonstrated a normal inflammatory and wound-healing response with a normal focal foreign-body reaction. To further examine the tissue response, transgenic mice were utilized to assess the immunogenicity of the rhGH PLGA formulation. Transgenic mice expressing a heterologous protein have been previously used for assessing the immunogenicity of sequence or structural mutant proteins.[88,89] With the transgenic animals, no detectable antibody response to rhGH was found. In contrast, the Balb/C control mice had a rapid onset of high titer antibody response to the rhGH PLGA formulation. This study points out the appropriate utilization of animal models to evaluate not only biological responses but also one type of immunotoxicity (immunogenicity) of controlled release systems.

4.402.9. Summary and Conclusion

The identification of the fundamental biological requirements of a biomaterial first requires the identification of how the biomaterial is to be used and in what type of implant, medical device, or prosthesis. After the identification of the intended application of the biomaterial, the identification of the tissues that will contact the biomaterial and the implant duration of the biomaterial, medical device, or prosthesis is necessary. Once these parameters have been defined, appropriate *in vitro* and *in vivo* assays can be selected to identify the success or failure of the biomaterial and its intended application. A broad perspective in the selection of *in vitro* and *in vivo* biocompatibility assays is necessary to not only identify adverse reactions but also to identify reactions that indicate the successful function of the biomaterial in its intended application. Adverse tissue responses do not necessarily reject a biomaterial from use in a medical device or prosthesis. Adverse tissue responses do require a risk assessment evaluation in which the risks are weighed against the benefits in the use of the biomaterial. A risk assessment program may involve additional biocompatibility testing in addition to the development

of a rationale and justification for continued use of a biomaterial that may present with adverse tissue reactions. Finally, it must be remembered that appropriate and adequate biocompatibility evaluation requires testing of the material, medical device, or prosthesis in its 'end-use' state, that is, as a product in which manufacturing processes and sterilization procedures have been considered.

This chapter presents biocompatibility evaluation in the context of current standards and guidelines. As such, it must be emphasized that standards and guidelines are constantly changing and evolving as new medical devices and prostheses, and biomaterials are developed for clinical application and new scientific information is obtained that provides new perspectives on the how and why of specific test procedures. The past decade has seen a virtual explosion in the areas of nanomaterials, tissue engineering, and combination products, each of which brings its own unique characteristics to biocompatibility testing and the development of tests that will ensure safety in clinical application. An example of new perspectives on biocompatibility testing is provided by recent efforts to move away from the use of animals and develop cell-culture-based alternative testing methods. Finally, it should be noted that this chapter presents biocompatibility testing from a so-called horizontal perspective, that is, the suggested test methods should be considered for all types of medical devices, prostheses, and biomaterials. Device-specific standards and guidelines, that is, vertical standards, available from ISO, ASTM, and the FDA have not been considered in this chapter.

Glossary

Acquired immune response A learned response by the immune system of nearly all living things that is developed after a primary exposure to a pathogen or irritant. The development of an acquired response by the immune system results in a more rapid and aggressive response to a repeated exposure by the same pathogen.

Adjuvant Any substance added to a vaccine that acts to accelerate, prolong, or enhance antigen-specific, adaptive immune responses.

Chemotaxis The process by which bodily cells, bacteria, and other single-cell or multicellular organisms direct their movements according to upregulation or downregulation of chemicals including cytokines in their environment.

Chronic inflammatory response Inflammatory response that is persistent and lasting over time.

Inflammasome A multiprotein complex consisting of caspase-1, PYCARD, a NALP, and sometimes caspase-5 or caspase-11. The exact composition of an inflammasome is dependent on the activator which initiates inflammasome assembly (e.g., dsRNA will trigger one inflammasome composition and asbestos will induce assembly a different variant). The inflammasome promotes maturation of inflammatory cytokines interleukin-1β and interleukin-18. The inflammasome is responsible for activation of inflammatory processes, and has been shown to induce cell pyroptosis, a process of programmed cell death distinct from apoptosis. http://en.wikipedia.org/wiki/Inflammasome – cite_note-2.

Inflammation Part of a complex biological response to harmful stimuli including pathogens, traumatic or surgical injury, disease, damaged cells, and irritants. Inflammation is a protective attempt by organisms to remove injurious stimuli and to initiate the healing process. Inflammation is a normal, beneficial response, and not considered adverse unless it becomes chronic and does not promote healing over time.

Innate immune response An intrinsic response of the immune system that is essential or inherent. It is the major response or host defense against pathogens in humans and nearly all other living things.

Passivation The process of making a biomaterial innert, usually by the deposition of a layer of oxide on its surface.

Phagocytosis The cellular process of engulfing solid particles by the cell membrane to form an internal phagosome by phagocytes such as macrophages.

Abbreviations

AR3	Aldehyde reductase
BMPs	Bone morphogenetic protein
C3, C4, C5	Complement proteins
C5a	Complement factor 5a
CoCr	Cobalt chromium
DC	Dendritic cells
dsRNA	Double-stranded RNA
GCs	Giant cells
GPIIb-IIIa	Glycoprotein IIb-IIIa
IgG	Immunoglobulin G
IL	Interleukin
INF-γ	Interferon gamma
NALP	Nacht domain-, leucine-rich repeat-, and PYD-containing protein 3
NK	Natural killer cells
NOD-like	Nucleotide-binding oligomerization domain-like
PEEK	Polyether ether ketone
PGA	Poly(gamma-glutamic acid)
PLA	Polylactic acid
PLGA	Polylactic-*co*-glycolic acid
PMNL	Polymorphonuclear leukocytes
PS	Polystyrene

PVA	Polyvinyl acetate	**TiAlV**	Titanium aluminum vanadium
PYCARD	PYRIN and caspase activation and recruitment domains	**TLRs**	Toll-like receptors
		UHMWPE	Ultrahigh molecular-weight polyethylene
SS	Stainless steel		

4.403.1. Introduction

Physical barriers, such as skin, nails, lips, and mucous membranes, are the first line of defense against pathogen invasion and irritants and are fairly effective in our day-to-day, minute-to-minute defense against exposure to microbes. However, the barriers can be compromised by disease or a physical breach (traumatic or surgical). Once they are breached, there are several strategies that can be used by the human body to respond to the presence of the foreign invader. Traditionally, these response methods have been segregated into *innate* (also called nonspecific) and *acquired* (also called adaptive or specific) immune responses.

The innate, or nonspecific immune response, is used against pathogens that have not been previously encountered and irritants that may or may not have been previously encountered. Unlike the acquired immune response, which adapts rapidly to a second or repeated invasion and therefore confers more long-term protection against pathogens, the innate response is more immediate, but generally takes longer to develop because a new strategy must be devised to deal effectively with the novel intruder or irritant. The major functions of the innate system are (1) inflammation with recruitment of immune cells to sites of infection through the production of cytokines; (2) activation of the complement cascade to identify bacteria, activate cells, and to promote clearance of dead cells or antibody complexes; (3) identification and removal of foreign substances present in organs, tissues, blood, and lymph by specialized white blood cells; and (4) activation of an adaptive immune response via antigen presentation. The major functions of the adaptive immune system are (1) rapid recognition of a returning invasive pathogen or antigen; (2) inflammation or recruitment of immune cells to sites of infection through the production of cytokines; (3) rapid production of antibodies specific to the pathogen; and (4) rapid removal of foreign substances present in organs, tissues, blood, and lymph by specialized white blood cells.

Although there are many differences between the two systems (Table 1), more recent investigations have provided evidence that there is considerable overlap. For example, T-lymphocytes may help macrophages to be more effective as phagocytes, whereas macrophages are needed to present antigens to T-lymphocytes to activate the acquired immunity pathways. Therefore, it is possible to view these systems as a continuum rather than as two separate systems, that is, the response to a pathogen begins with the innate response and macrophages phagocytosing the invader. Macrophages are activated to release cytokines. Other macrophages or precursor cells are then exposed to these cytokines. When recruited, macrophages ingest more particles, become antigen-presenting cells, and then play a role in the acquired immune system.

Irrespective of whether the immune system is viewed as a two-compartment or as an integrated system, the human body's defense against microbes and foreign bodies involves an interrelationship among mechanisms associated with wound healing, acute and chronic inflammation, and innate and acquired immunity. These defenses raised against the invader(s) produce a redundancy of feedback mechanisms that, when activated, serve to maintain homeostasis.

Medical devices used for structural repair and/or regeneration of tissues impact the immune system directly because all medical devices are composed of components that are considered foreign by the immune system whether they consist of nonautologous tissues or tissue components, metals, or polymers. Implantation of any biomaterial should therefore be considered a breach of the immune system. As such, the appropriate selection of a biomaterial or combination of biomaterials is critical to ensure a successful application as a reparative or regenerative device or as a drug-delivery vehicle/device. Selection of a biomaterial should be on the basis not only of engineering considerations but also of whether a material changes immediately after introduction into the body or with time as the implant wears or degrades. Chemical and/or physical temporal implant changes will dictate and drive the innate and adaptive responses to the biomaterials to advantage or disadvantage, depending on the biomaterial choice and the application for which it was chosen.

Table 1 Characterization of innate and adaptive immune responses

Parameter	*Innate*	*Adaptive*
Cells	Coordinated effort from many types of cells including eosinophils, neutrophils, macrophages, mast cells, and NK cells	Coordinated effort between antigen-presenting cells, T-cells, B-cells, and plasma cells
Response time	Rapid (<2 days)	Slower (>2 days)
Memory	None	Plasma cells
Circulating molecules	Complement	Antibodies
Effector molecules	Cytokines	Cytokines
Magnitude of the response	Moderate	Exponential

4.403.2. Biomaterial Changes

Upon implantation, immediate exposure of all implant types to bodily fluids can result in changes or modifications at the surface of the implant that will impact the immune response to the implant. These modifications may include physical changes to the implant surface (such as that which occur with passivation) or physical changes associated with preferential protein deposition on the surface of the implant.

Initially, metal, but not other types of implants, can undergo direct material changes, such as passivation or repassivation that can occur if a manufactured passivation layer intended to render the metal inactive to bodily fluids is scraped from the surface during implantation (e.g., implantation of a soft alloy such as a titanium, aluminum vanadium (TiAlV) total hip implant into bone). This type of change is usually rapid and, in and of itself, appears to have no long-term biological impact unless the process repeatedly occurs because of loosening and results in a large deposition of wear debris[1,2] (see a more detailed description of this phenomenon below).

Passivation can also be accomplished by the deposition of proteins that adhere to all implant surfaces, depending on the physical and chemical properties of the biomaterial. Although this type of passivation process has been harnessed to advantage for vascular implants (whereby the adsorbed proteins serve to passivate stent biomaterials), some investigators have shown that adsorbed protein(s) may undergo conformational changes (i.e., changes in tertiary structure) that could render the protein(s) foreign to the immune system.[3–5] This type of process could conceivably induce an autoimmune response whereby an overactive immune response targets self proteins. While there is no definitive evidence to prove that autoimmunity occurs with medical devices, there has been considerable debate over the evidence that suggests an association between specific implants and autoimmunity.[6] However, adsorbed proteins can be problematic, as has been shown with nonpassivated vascular implants that allow for deposition of proteins such as IgG, C3, fibrinogen, and factor XII (FXII), the effect of which is activation of the coagulation, contact, and complement systems that can ultimately lead to deposition of cells such as platelets, polymorphonuclear leukocytes (PMNL), and monocytes and subsequent thrombosis/stenosis.[7,8] Another example of problematic protein deposition occurs with silicone hydrogel contact lenses, in which deposition of proteins such as denatured lysozyme and albumin on the surface of the lenses can cause irritation.[9]

The immediate host response to implantation is therefore dictated, in part, by protein deposition, and may involve immediate self or nonself (i.e., foreign) recognition as the mechanisms directing acute inflammation and wound repair are activated and temporally contribute to the response to the implant. Assuming appropriate surgical placement, the manner in which healing then progresses is based on the configuration and the material composition of the implant (i.e., whether the materials are inert or biodegradable and whether they are present in appropriate configurations and/or concentrations), the site of implantation, and previous exposure of the host to the implant materials. All of these factors will dictate whether the implant is initially considered inert and therefore simply walled off, or is degraded or integrated with time via a dynamic removal and/or integration of the material(s).

Both inert and degradable biomaterials can change chemically and physically with time, producing chemical byproducts that induce a response that is similar to or different from the initial response to the bulk implant. The healing response can also be complicated by the presence of biomaterial particles (caused by physical or chemical breakdown of implants) that increase the surface area of the materials considerably and therefore increase the exposure of the body to the protein-bound surfaces of the materials or, for biodegradable materials, to increased amounts of chemical breakdown products. Inert materials may, with time, age and degrade *in vivo*, or they may be physically abraded against native tissues or other implant materials, resulting in the generation of particles. Therefore, the dynamic changes of both inert and biodegradable biomaterials will also affect the response to the medical device over time.

4.403.3. Inflammation and Biomaterials

Injection or surgical implantation of a medical device always results in a breach of the first lines of defense (i.e., skin and mucous membranes) and in inflammation, irrespective of whether the implant is composed of a metal, a polymer, a substance of biological origin (e.g., organ, tissue, or protein), or a combination of one or more biomaterials, with or without the addition of drugs. Acute inflammation is a necessary step for an appropriate wound-healing response, and therefore a normal and expected early response to biomaterials and medical devices. Steps in the inflammatory process that ultimately lead to functional incorporation of medical devices comprise the following[10,11]:

1. vasodilation and increased permeability of endothelium – release of circulating leukocytes and fluid, containing enzymes and other proteins, into the region of the insult;
2. decreased blood flow, sludging, clotting, and coagulation;
3. cellular invasion – margination, emigration (diapedesis);
4. chemotaxis – migration toward the site of injury or foreign body;
5. activation of phagocytic cells – synthesis and release of specific substances;
6. resolution with remodeling of tissues.

The immediate response to injection or implantation of a device is influenced by the nature (e.g., injection or surgery) and extent (number of tissues and total tissue mass affected) of tissue injury caused by the procedure as well as by the type of affected tissues (e.g., skin, muscle, nerve, and bone). One of the first responses is vasodilation and increased permeability of the blood vessels, which facilitates the release of fluids and circulating leukocytes into the injured area. Important modulators present in the released fluids include histamine, FXII (the Hageman factor), kinins, prostaglandins, leukotrienes, and kallikrein as well as antibacterial proteins such as properdin, lysozyme, β-lysins, immunoconglutinins, C-reactive protein, transferring, complement, and interferon.[11–13] The first cells to arrive at the site of the insult during the acute inflammatory response are neutrophils, followed by eosinophils

and monocytes.[14] Cells migrate within the circulatory system toward the inciting chemoattractant substances by a process called margination whereby phagocytes stick to lining of blood vessels, and then move into the surrounding tissue. In response to signals from the underlying tissue, there is an increase in specific molecules – for example, E-selectins – on the surface of the endothelial cells lining the blood vessels. A coordinated effort of upregulation and attachment between selectins (e.g., P- and E-selectins on endothelial cells; L-selectins on leukocytes) and their ligands results in margination of the cells with rolling of the phagocytes along the vessel wall.[15,16] Diapedesis (emigration) then occurs, whereby phagocytes squeeze between endothelial cells of blood vessels and enter the injured area.[15,17] The cells responding to the injury are directed to the site via chemotaxis. Several substances have been shown to be chemotactic, including the chemical or biochemical composition of the microbe or foreign body, factors released by most bacteria during growth, lymphokines, factors from the responding phagocytic cells, factors generated by the sequential activation of complement, local pH differences, and electrochemical factors.[11,13] Molecules that can coat the infectious agent or foreign body, called opsonins, can also be chemotactic and can enhance phagocytosis of the microbe or material. One example of an opsonin is the activated form of complement factor 5 (C5a).[11] The method in which chemotactic factors interact with leukocytes has been suggested to be via activation of esterases, including PI3 kinases on their surfaces.[13,18]

Once released at the site of injury, phagocytosis of dead cells and tissue components as well as other foreign implant debris ensues, along with activation of the effector mechanisms of the phagocytes. Neutrophils and eosinophils are the primary cells responsible for the removal of the foreign materials at wound sites because they work primarily through phagocytosis and degranulation, which result in the release of chemotactic factors necessary to recruit other cell types to the site. They are generally short-lived and play a primary role in acute inflammation within the first few days of exposure. However, the presence of extensive numbers of live neutrophils in tissue surrounding implants may, in the absence of infection, be interpreted as evidence of continued inflammatory challenge secondary to toxic or irritating breakdown products or particles caused by abrasion or breakdown of the implant.[11] Subsequently, once acute inflammation passes, chronic inflammation may develop if materials requiring phagocytosis are still present, mandating the continued presence of the cells of the mononuclear phagocyte system that include circulating monocytes and tissue-resident macrophage populations. The source of macrophages at sites of chronic inflammation may be local (because of recruitment and proliferation of tissue-resident macrophages) or distant (because of chemotaxis-driven migration of monocytes or macrophage precursors to the affected tissue).

The process of phagocytosis is dictated by chemotaxis and adherence of a microbe or implant particle to the surface of the phagocyte. To be taken up by a macrophage or some other white blood cell, particles must first bind to the phagocytic cell surface and activate one of a variety of surface receptors.[19] These receptors may recognize antibodies, opsonins (molecules that acts as a binding enhancer), or pattern recognition sites (molecular patterns present on a pathogen). When coated with opsonins, there is recognition of the opsonin through binding to an antigen-membrane receptor. The particle or microbe is then ingested via invagination and formation of a phagosome, which is produced as a portion of the cell membrane that surrounds the particle or microbe, thereby creating a host membrane-bound particle/microbe. This membrane-bound particle/microbe is called a secondary lysosome.[11] Fusion of the phagosome or secondary lysosome with a primary lysosome to form a phagolysosome then occurs and is followed by degranulation into the vacuole[11] and digestion (for biodegradable materials; e.g., cross-linked collagen or hyaluronic acid-based biomaterials) or attempted digestion (for inert materials; e.g., particles of polymethylmethacrylate or metals) by enzymes such as phagocytin, lysozyme, cathepsin, acid phosphatase, alkaline phosphatase, nucleosidase, ribonuclease, deoxyribonuclease, and β-glucuronidase[13] contained in the granules. This process is associated with a respiratory burst-producing hydrogen peroxide and superoxide anions that can also degrade materials and can be measured with *in vitro* assays.[20,21] A residual body then forms, containing indigestible material, and waste materials are discharged. Any residual undigested particles are released into the surrounding interstitial tissue, and the phagocytosis cycle begins again until the healing process and/or material removal process is ultimately complete, the endpoint of which is dictated by the functional requirements of the device. An alternative outcome is chronic inflammation that does not resolve and that adversely affects healing.

The inflammatory response to implants or injectable materials is quite variable, ranging from minimal to more extensive and resolves quickly or more slowly over time, depending on the physical and chemical biomaterial properties of the implant and the surrounding tissues and tissue fluids. The extent to which inflammation persists over time in a given biological environment depends on whether the implant is relatively inert, is resorbed or degraded over short or long periods of time, or results in the production of breakdown products or particulates over time. Inflammation does not necessarily constitute an adverse response to biomaterial implants unless the response is too prolonged and/or prevents appropriate healing, results in chronic inflammation or granulation tissue that occludes native tissue repair, is associated with infection of the injection or surgical site, or is associated with an immune response to the implant materials.

4.403.3.1. Infection

The initial breach of the skin or mucous membranes by needles or scalpels creates a portal for infectious agents to migrate into the biologic tissues surrounding the medical implant. The potential for infection is high for implanted medical devices, given that surgical approaches may involve cauterization, multiple incisions, and resection of tissues that may already be compromised by the trauma or diseases that produced the need for the medical device. Deep infection and unresolved superficial infections can have a major impact on the outcome of the surgical procedure and can ultimately cause failure of the device. Iatrogenic infection at an implant site that occurs because of the placement of a nonsterile implant may cause a large inflammatory response and failure of the implant,

particularly in bony sites where infection is associated with aggressive bone loss.[22] Once infected, bacteria can form biofilms that protect the bacteria from attack, making them extremely difficult to treat. In addition, endotoxins produced by the bacteria can also exacerbate the negative impact that bacteria can have on healing and/or implant stability.[23,24]

Infection has been reported as the cause of failure in some instances for most implant types, including total hip[25] and knee[26] replacements; spine fusion,[27] dental,[28] cranial–facial or maxilla–facial,[29] cardiovascular,[30,31] and optical devices[32]; and skin and bone graft substitutes.[33,34] Use of improved aseptic manufacturing and surgical techniques, and more recent improvements in minimally invasive surgical procedures have reduced the incidences of infection, thereby minimizing the adverse septic inflammatory responses that can result in implant failure. However, latent infection that has been attributed to secondary infections by pathogens such as *Staphylococcus aureus* present at sites other than the implant site has also been reported to result in implant failure many years after implantation.[35,36] Latent infection is associated primarily with metallic implants and is believed to be the result of the presence of a preferential environment at the tissue/implant surface.[14,37] It is not known if this process occurs regularly but is resolved in most instances. However, a large inflammatory response can be induced that can result in catastrophic failure of the implants, particularly those used for orthopedic[38,39] and dental[40] applications where infection is known to be associated with severe bone loss. In instances of infection, the inflammatory response is characterized by the presence of PMNL, lymphocytes, plasma cells, and (at bony sites) numerous osteoclasts at the surface of resorbing bone.

4.403.3.2. Persistent and Chronic Inflammatory Responses

In the absence of sepsis, inflammation caused by injection or by implantation of a successful medical device will generally diminish with time as the implant resorbs completely, or becomes incorporated at the implant site, leaving the implant directly apposed or juxtaposed to native tissue or encapsulated by a thin layer of fibrous tissue.[14,41,42] However, inflammation can persist and prolong the normal healing process or can occur at a later date secondary to the presence of breakdown products or mechanical loosening.

Persistent inflammation, characterized predominantly by the presence of macrophages and GCs, can be perceived as chronic and therefore problematic. However, this type of response is typical for resorbable materials and not considered adverse unless healing is prevented over time. Clearly, an undesirable response to an implant is one in which inflammation does not resolve over a relatively short period of time, becomes chronic, and prevents appropriate healing at the implantation site. This type of chronic inflammatory response can be associated with inert or nonresorbable implants as well as resorbable or degradable devices and can occur early or late in the life of an implant. Chronic inflammation usually occurs for a number of reasons, including instances where the implant (1) becomes dislodged, (2) abrades (resulting in the production of numerous particles that cannot be readily removed), (3) degrades or resorbs with deposition of breakdown products that are not readily eliminated, or (4) degrades or resorbs at a later time point (resulting in release of particles or breakdown products that are irritants or toxic). In these instances, the adverse response is often characterized by the presence of a large infiltrate of macrophages and may include other cell types, depending on the cause of the inflammation, that is, toxic breakdown products, particles, or an immunological component, all of which are discussed below in the context of degradable (i.e., implants intended to degrade over a short period of time) and nondegradable (i.e., implants intended to last many years or the lifetime of the patient) devices.

4.403.3.2.1. Nondegradable materials

Implants that are not expected to degrade quickly over time include a variety of metal alloys (such as stainless steel (SS), cobalt chrome (CoCr), TiAlV, and nitinol) and polymers (such as ultra-high-molecular-weight polyethylene (UHMWPE), delrin, and polyether ether ketone (PEEK)) that are used for a variety of orthopedic, dental, maxillofacial reconstructive, and cardiovascular indications. Although termed nondegradable for the purpose of this discussion, all implants age and degrade given sufficient time *in situ* and therefore have the potential to generate inflammatory responses after long-term implantation. Typically, a well fixed or integrated implant can be found directly apposed to native tissue or surrounded by a thin layer of fibrous tissue, with little evidence of any cells other than fibroblasts.

Corrosion and/or abrasion of total joint prostheses,[43–46] fixation devices,[47] pacemaker leads,[48] vascular stents,[49] and dental implants[50] have been documented extensively in the literature, and in all instances have been found to be associated with chronic inflammatory cells including macrophages, GCs, lymphocytes, and (in some instances) plasma cells and occasional PMNL. The macrophages and GCs present in periimplant tissues associated with these types of nondegradable implants often contain particles of implant material, which suggests a cause-and-effect relationship that has been well documented in the literature whereby loosening can cause the generation of wear debris. However, wear particles are not always present in tissue associated with loosened metal prostheses which suggests a role for metal ions in the loosening process. Metal ions released from implants have been shown to impact the behavior of circulating monocytes and tissue-resident macrophages.[51,52] Using a technique developed to examine phagocytosis in live cells, Graham *et al.* observed a significant effect on the phagocytic index of alveolar macrophages exposed to all concentrations of Ni_2^+.[52] Interestingly, Ni_2^+ had a minimal effect on alveolar macrophage viability or cellular lysis. Caicedo *et al.* noted an increase in the interleukin (IL)-1β secretion by human primary monocytes/macrophages exposed to soluble cobalt, chromium, and molybdenum but not nickel.[51] In addition to a potential effect on phagocytic function, metal ions may also stimulate fibrosis and the development of thickened fibrous tissue membranes around intact implants that may ultimately compromise the function of the implant – whether it be with mechanical loading of orthopedic or dental implants or with drug elution from cardiovascular implants.[3]

When particles are present in periprosthetic tissues, the chronic response is usually greater than responses associated with bulk materials, which strongly suggests that particles can

trigger the innate immune system more aggressively than bulk materials, leading to adverse inflammatory responses that impair healing if generated early on or cause and drive the loosening of well-fixed implants and tissue resorption processes. Although it is difficult to simulate the production of the same types of particles generated by corrosion and abrasion processes *in vivo*, many studies have attempted to determine the role particles play in the generation of innate immune responses.[53–60] Studies of human retrieval tissues containing large numbers of particles of nonresorbable materials have shown the presence of macrophages, GCs, lymphocytes, and (in some instances) lymphocytes and plasma cells as well as proinflammatory cytokines such as IL-1, tumor necrosis factor, and interferon-gamma (INF-γ).[59,61–65] One source of these proinflammatory cytokines is the macrophage. They can release cytokines and other molecules such as IL-1 and INF-γ that are proinflammatory as well as leukotrienes, prostaglandins, complement factors, and clotting factors, all of which are also proinflammatory factors.[66,67] In addition, activated macrophages can release angiogenic factors necessary for neovascularization, which is required to promote chronic inflammation. Other factors that can result in local tissue damage can also be released from activated macrophages. These factors include fibrogenesis factor, elastase, collagenase, hyaluronidase, H_2O_2, acid hydrolases, and C3a.

In *in vitro* studies, macrophages have been shown to be activated by ingestion of small particles or by frustrated phagocytosis, in which the particle is too large to be phagocytosed.[11,68] *In vivo* animal studies have shown that macrophages and T-lymphocytes can be recruited to sites containing large numbers of particles and that proinflammatory cytokines (such as IL-1, tumor necrosis factor, and INF-γ) can be induced by cells containing large numbers of particles at these sites.[69–71] Several key *in vivo* studies in animals suggest that the threshold for stimulating an innate response depends on particle type as well as particle size.[72,73] Because the particles used in these studies were not generated in *in vivo* environments, the results cannot be interpreted as definitive responses. This is particularly true given that a variety of *in vitro* studies of particles have produced conflicting results. For example, Lee *et al.* saw no difference *in vitro.*[74] Haynes *et al.* found CoCr alloy to be better[75] than TiAlV at inducing an inflammatory response, but CoCr resulted in greater toxicity. Kaufman *et al.* and Wooley *et al.*[76] also found less inflammatory reaction to CoCr[77] compared to TiAlV. Collectively, these studies serve to illustrate the fact that differences in particle composition, size, and shape will impact the macrophage response to particulates and therefore can impact macrophage activation.

There are different mechanisms of macrophage activation that have been described.[66,78] Traditionally, activation was thought to be associated with the capacity of the macrophage to perform specific functions. Two categories of activation have been used to describe macrophage activation: acute and adaptive.[66] Acute relates to immediate activation of signaling pathways while adaptive requires transcription and translation of specific modulators. As we have increased our understanding of macrophage behavior, it is clear that macrophage activation is complex and involves distinctly different activities regarding responses to specific external stimuli as well as different modulators. For example, macrophages play a significant role in the down-modulation of inflammation and immunity by a process called alternative activation (in contrast to classical activation).[78] Recently, a specific mechanism of macrophage activation resulting in production of an inflammasome (defined as a multiprotein complex, the exact composition of which depends on the activator that initiates the inflammasome assembly). The inflammasome has been identified as being specifically associated with particles[51,58] and is characterized by the production and release of IL-1β, IL-18, and IL-33. The NALP3 inflammasome contains a NOD-like receptor that comprises three domains: a pyrin domain, a NACHT domain, and 11 LRR (leucine-rich repeat) domains.[79] Nalp3 (also called cryopyrin) activates caspase-1 which in turn cleaves prointerleukin-1β to generate active IL-1β.[79,80] The NALP3 inflammasome has been the most studied with respect to particles and is said to have a role in silicosis and asbestosis.[81] It may also play a role in apoptosis through overexpression of activated caspase-1.[82] Some investigators, including Hallab and Jacobs have advocated that the inflammasome is the primary mechanism driving the response to particles.[51,58] However, this definitive concept remains somewhat controversial, given the diversity of particle composition, shape, and size. Irrespective of the mechanism of activation, effector mechanisms of activated macrophages include the release of degradative enzymes (lysozymes) and the synthesis and release of biochemical factors that recruit other macrophages and monocytes, including lymphocytes and fibroblasts as well as foreign-body GCs, and osteoclasts.

Although phagocytosis is a fundamental activity of mononuclear cells, it requires a carefully orchestrated sequence of events that, because of particle-generating failure modes of nondegradable materials and diverse combinations of implant materials, will influence macrophage activation and the subsequent sequence of inflammatory events. Depending on the mechanism of activation, the inflammatory response to particles may lead to the maturation of cells to perform specific functions such as phagocytosis, antigen presentation, cell recruitment, and lymphocyte activation. Therefore, for activation, receptors on macrophages that interact with particles are important and will likely play a role in determining the ultimate response to particles. Several receptors including Toll-like receptors (TLR),[66,83,84] AR3 and Dectin-1 (scavenger receptors), and mannose receptor have been shown to be expressed by macrophages.[14] TLR4 could, when artificially ligated using antibodies, induce the activation of certain genes necessary for initiating an adaptive immune response.[85] As a group, these are called pattern recognition receptors. Different receptors bind to different ligands or patterns. Pattern recognition receptors have been shown to recognize and bind to biomaterials.[86–89] As such, they play a role in macrophage activation and induction of subsequent responses to particles.

4.403.3.2.2. Biodegradable materials

Historically, implant biomaterials were initially intended to last the lifetime of the patient. However, as metals and polymers were shown to degrade and abrade with time, new materials that were intended to degrade over a relatively short (usually within 1 year) period of time and be replaced by native tissue were explored. Implant materials that are intended to degrade over time include polymers (e.g., polylactic

acid (PLA), polylactic-*co*-glycolic acid (PLGA), and polyvinyl acetate (PVA)), silica-based bioglasses, and biologic materials (e.g., hyaluronic acid and type I collagen). These types of implants generally induce a greater acute inflammatory response than materials that are considered inert and nonresorbable and will always induce a persistent inflammatory response while breakdown products are removed from the implant site. Not only will degradation of the implant induce a greater mononuclear infiltrate, it will also often induce the formation of multinucleated GCs to aid removal of particles or pieces of materials that are of a nonphagocytosable size. Therefore, it is important that a resorbable biological or polymeric implant does not break down more quickly and overwhelm the breakdown product removal process, because doing so could lead to induction of an adverse inflammatory response that could impair healing or regeneration of the tissues adjacent to or at the implant site.

Although all degradable materials generate a persistent inflammatory response, there are a number of factors that can either accelerate or slow the material degradation process, which will, in turn, dictate the severity of the innate response to an implant. These factors include the (1) chemical composition of the implant, (2) physical composition of the implant, (3) mechanism of degradation, (4) load applied to the implant at the implant site, (5) pH of the local environment, and (6) the production of degradative enzymes at the implant site. Even small changes in chemical composition or implant design can lead to dramatic changes *in vivo* that may result in either success or failure of a device at a given site. Also, increases in applied load, and increase or decrease in pH or the concentration of degrading enzymes at a given implant site can dramatically alter the degradation rate of a resorbable implant. It is not surprising therefore that innate responses characteristic of any given material at a given site may be altered by the presence of one or more additional materials in a composite implant. For example, BMPs in additional to a carrier such as collagen can accelerate bone regeneration and healing, but can be characterized by the presence of acute inflammation (characterized by polymorphonuclear nuclear cells) as well as inflammatory infiltrates containing macrophages and GCs (present to remove the carrier) that may slow down the healing process.[90] These types of variable processes that result from the presence of different materials and breakdown products may be conflicting but will certainly be driven by similar processes discussed for particles of undegradable materials including macrophage activation, production of inflammasomes, and phagocytosis and for successful implants, will result in incorporation and or replacement of the implant with appropriate native tissues.

4.403.4. Evasion Innate Immune System Activation

Given the inherent foreign nature of biomaterials, the ability to evade activation of the innate immune response is limited and, as expected, dependant on material properties, size, and shape. Although small particles of biomaterials have been shown to activate the innate system, large, bulk implants that have been shown to facilitate healing and incorporation within the surrounding tissues can remain *in situ* for very long periods of time with little or no additional inflammatory response, effectively evading activation of the innate response. Stable, uninfected implants such as uncemented and cemented total hips and knees, spine fusion cages, dental implants, fixation devices, and maxillofacial devices have been shown to have minimal tissue responses once healed and stabilized.[14,91] Tissue apposed to stable bulk implants is usually native or composed predominantly of fibroblasts oriented into a thin fibrous layer that conforms to the geometry of the implant.

Increasing the potential for tissue integration with implant coatings used to stabilize implants has led to successful application for some biomaterials.[92–94] Coating of total hip implants with hydroxyapatite has been shown to enable better integration with direct apposition of implants to bone, thereby increasing the ability of the implant to remain well fixed and 'hidden' from the innate system.[95] Other types of coatings and surface modifications have been used for similar applications. For instance, surface modifying additives to SS will result in the formation of chromium oxide at the surface, which will increase resistance to corrosion[96] and therefore reduce possibility for the generation of corrosion products that will activate the innate system.

Materials used for applications that are inherently more dynamic pose unique challenges to evasion of the innate system. Under these circumstances, materials that are otherwise considered inert can activate the complement system and result in an adverse response. For example, implants used for vascular applications not only are exposed to blood components and proteins, but they are also exposed to shear stresses which may more readily induce conformational changes upon adsorbed proteins than in the case of those proteins that may adsorb to a more rigid surface such as a hydroxyapatite coating on a hip implant that will be present in a less dynamic environment. Therefore, plasma proteins that adsorb to a biomaterial surface such as a polymer, metal, or ceramic used in a dynamic environment (e.g., a vascular stent) may become activated because of the physical contact and shear action of blood flow. Examples of such molecules are IgG (which activates the classical pathway of complement),[97] C3 (which activates the alternative pathway of complement),[98] fibrinogen (which binds to GPIIb-IIIa on platelets), and FXII (which triggers contact activation). The effect of this initial protein adsorption is activation of the coagulation, contact, and complement systems. The subsequent complement activation deposits C3 fragments on top of the plasma protein layer.[99] C3 fragment deposition adds a substantial amount of protein to the initially adsorbed protein mass and can, under favorable conditions, totally cover the original protein layer.[98] After activation by thrombin and the anaphylatoxins C3a and C5a, cells such as platelets, PMNL, and monocytes bind to the protein film on the biomaterial surface. Adsorbed IgG has been shown to initiate the classical complement pathway on biomaterial surfaces[97] and, even though this activation mechanism deposits only minute amounts of C3b on the surface, the deposition is rapid and sufficient to instantaneously trigger the alternative pathway amplification loop. The relative importance of the different activation pathways is illustrated by *in vivo* studies, which have shown that in patients with C4 deficiency (who lack the classical pathway) undergoing hemodialysis, complement activation is much delayed, but eventually reaches the same amplitude as in patients with normal levels of C4.[100] This finding reflects the

fact that regardless of the recognition mechanism, the alternative pathway amplification loop generates the majority of the C3b molecules that bind to the material surface. *In vitro* studies have confirmed this mechanism and shown that the majority of surface-bound C3 fragments are iC3b covalently bound to the surface-adsorbed plasma proteins.[101]

However, it has been possible to evade this innate activation process through innovation. Protein and peptide coatings have been shown to decrease thrombogenicity[102,103] of cardiovascular devices. Specifically, heparin treatment of vascular biomaterials has been shown to promote hemocompatibility by either binding to regulators of the cascade system (the accepted hypothesis for the mechanism of action) or preventing activation of bound components of the cascade system that would otherwise lead to deleterious results, resulting in longer term success of vascular stents.[104] Further innovations, such as the coating of biomaterials and even multilayered coatings of cells with substances such as polyethylene glycol (a process known as PEGylation) have also been used to enable evasion of the innate immune system. Such encapsulated allogenic and xenogenic islet cells have been shown to survive and function for at least 6 months *in vivo*,[105] indicating that this approach could be used successfully to enable long-term evasion of the immune system.

4.403.5. Enhancement of Innate Immune System Activation

Interestingly, so-called adverse responses to biomaterials have more recently been harnessed and used as a means to augment the adaptive immune response, specifically as therapeutic and prophylactic vaccine adjuvants (defined as any substance that acts to accelerate, prolong, or enhance antigen-specific immune responses when used in combination with a specific vaccine antigen[106] http://en.wikipedia.org/wiki/Immunologic_adjuvant – cite_note-2) and as antigen-delivery systems.[107]

Adjuvants are believed to stimulate the immune system and increase the response to a vaccine without having any specific antigenic properties. There are many known adjuvants in widespread use, including oils, aluminium salts, and virosomes (virus particles that contain no active genetic material), although precisely how they work is still not fully understood. However, it is interesting to note that during the early days of commercial vaccine manufacture, an observation was made that large variations in the effectiveness of different batches of the same vaccine were associated with contamination of the reaction vessels used to produce the vaccines. This caveat suggests that irritants can enhance the effect of vaccines. It is not surprising then that, as requirements to ensure a lack of contaminants in commercially manufactured vaccines increased along with use of recombinant proteins as immunogens (which are poorly immunogenic but are increasingly selected to ensure greater purity of the manufactured antigens), additional types of adjuvants were explored. Nanoparticles and microparticles composed of a variety of biomaterials, including some of those typically used as biomaterials for implantable devices (e.g., PLGA, PLG, hyaluronic acid, and chitosan), were investigated in combination with various antigens and were found to boost the immune response to a variety of antigens compared to administration of the antigen alone. For instance, polystyrene (PS) nanoparticles coadministered with a mite allergen were shown to enhance immune responses to the pathogen[108] over the responses induced with the particles alone and the allergen alone in male NC/Nga mice injected intradermally with three different-sized PS nanoparticles (25, 50, or 100 nm). In that study, all particles boosted the immune response to the antigen, and a trend toward increased immunological responses was shown with smaller particles. Other *in vivo* studies have shown that iron oxide (Fe_3O) nanoparticles enhanced the response of an immunotherapeutic cancer vaccine,[109] whereas PLGA particles have been shown to effectively boost immune responses to a hepatitis B vaccine.[110–112] These, and similar studies, using a variety of different biomaterials and vaccine technologies, demonstrate the advantageous boosting potential of biomaterial particles.

The mechanism of action of these small-sized biomaterials as adjuvants has been investigated and appears to have a direct impact on the innate response to coadministered antigens. Small particles, when coadministered with antigen, initially act as delivery systems, providing a direct route of ingress to antigen-presenting cells as particles that are phagocytosed along with antigen (free, adsorbed, bound, or encapsulated) and carried to the lymph nodes. Within the lymph nodes, the macrophages containing the particles and antigen mature into dendritic cells (DCs).[113–115] The antigen is then positioned appropriately to induce a strong immunological response. In one study of poly(gamma-glutamic acid) (PGA) nanoparticles,[116] modulation of gene expression related to TLR signaling has been proposed as the mechanism by which this occurs. Encapsulation of antigen within resorbable nanoparticles has been shown to clearly alter antigen acquisition and processing by antigen-presenting cells and ensuing adaptive immunity.[117–119] The adjuvant activity of particles is thought to be related to the innate immune response to the materials and has recently been described at the molecular level as engaging the Nalp3 inflammasome and complementing the activity of TLR ligands.[119–121] The inclusion of antigen within erodible particles and subsequent delivery to DCs enable antigen-specific cell-mediated immunity and extended antigen presentation with protective outcomes. It is not surprising, then, that the size and dissolution rates of resorbable particles as well as surface chemistry and charge appear to be central in tuning and enhancing adaptive immune responses. According to Rice-Fecht *et al.* the tremendous power of particulate materials to enhance vaccine efficacy has only recently been recognized and used strategically in vaccine design.[119] It will be interesting to follow progress in this field to continue to better understand the body's innate response to biomaterials and also the favorable impact that biomaterials may have on the adaptive immune response to foreign antigens.

4.403.6. Concluding Remarks

Since the first recorded uses of implantable biomaterials, technology and our understanding of biomaterial/host interactions have continued to advance, making the use of novel medical devices increasingly important for therapeutic intervention aimed at increasing or restoring patient function. For all

applications, the drivers for success or failure of any given device are the immediate and subsequent innate responses to the biomaterials which will dictate how well healing and implant integration or removal will proceed with time. It is clear from the afore-mentioned studies and examples that selection of the biomaterial for a given application is critical. However, while it has become clear that the innate response to materials can have detrimental effects to the success of an implant, it is also clear that the innate system can be harnessed to advantage, enabling new applications for well-characterized biomaterials.

Glossary

Angiogenesis The physiological process involving the growth of new blood vessels from preexisting vessels.

Fibrosis The formation of excess fibrous connective tissue in an organ or tissue in a reparative or reactive process. This is as opposed to formation of fibrous tissue as a normal constituent of an organ or tissue.

Genotype The genetic makeup of an organism or a group of organisms with reference to a single trait, set of traits, or an entire complex of traits.

Immune system The system of biological structures and processes within an organism that protects against disease by identifying and killing pathogens and tumor cells. It detects a wide variety of agents, from viruses to parasitic worms, and needs to distinguish them from the organism's own healthy cells and tissues in order to function properly.

Inflammatory response A tissue reaction to injury or an antigen that may include pain, swelling, itching, redness, heat, and loss of function. The response may involve dilation of blood vessels and consequent leakage of fluid, causing edema, leukocytic exudation, and release of plasma proteases and vasoactive amines such as histamine.

Phenotype The observable physical or biochemical characteristics of an organism, as determined by both genetic makeup and environmental influences.

4.404.1. Introduction

When foreign materials are implanted in the human body, the immune system responds. The immune response protects us from being taken over by rapidly proliferating adventitious organisms. Mammalian immunity has evolved substantially from that of phylogenetically older animals such as invertebrates. A distinctive component of the immune system of

jawed vertebrates is adaptive immunity, which provides specificity to, and memory of, foreign pathogens. Adaptive immunity is an active component of the immune response to all materials that are implanted in the human body. Depending on the material, lymphocytes, the main cell type of the adaptive immune system, either actively contribute to material destruction and rejection or produce a cytokine milieu that leads to fibrosis or possibly material tolerance. Since biomaterials are increasingly used in combination products (drug delivery devices, gene delivery devices, tissue-engineering constructs, regenerative medicine constructs, etc.), the adaptive response to the material component can be critical to the viability and function of the entire construct. Indeed the other components of such combination products may also alter the adaptive immune response to the material; in fact, some methods of modifying the adaptive response to a biomaterial construct include adding another component to the construct, such as a drug (e.g., a corticosteroid). Knowledge of the baseline immune response to biomaterials provides researchers not only with an understanding of what happens to materials when they are implanted in the body, but also with a starting point by which the immune response can be manipulated to fit the needs of a biomaterial construct.

This chapter explains how the immune system recognizes biomaterials, and the consequences of the adaptive immune response to biomaterials and constructs that are known to contain biomaterials. The final section of the chapter provides an overview of approaches that may be used to alter the adaptive immune response to a material.

4.404.1.1. Cells and Structures of Adaptive Immunity

4.404.1.1.1. Organization of the immune system

The immune system is an integrated network of tissues, cells, and molecules that function together to resist disruption of homeostasis within the human body. Immunity generally refers to defense against infection, but immune cells respond to tissue damage, as well as to the presence of any foreign substances, infectious or noninfectious. The human immune system is loosely divided into two components: innate immunity and adaptive immunity. Innate immunity consists of barrier systems to prevent passage of foreign substances (e.g., epithelia and endothelia), phagocytic cells (neutrophils and macrophages), and blood proteins (such as complement). Adaptive immunity consists primarily of lymphocytes and the proteins that they produce, such as antibodies and cytokines. Though immune responses have been divided into these two categories, there is much overlap between the innate immune system and the adaptive immune system. For example, phagocytic cells of the innate system, such as macrophages, present the proteins contained in their phagosomes to lymphocytes, the cells of the adaptive system. As a result, most immune reactions in the human body involve both arms of the immune system; rarely is there an immune reaction to a pathogen whereby only innate or only adaptive immune cells respond.

The adaptive immune system has been further subdivided into two categories: humoral immunity and cell-mediated immunity. Humoral immunity is the principal defense mechanism against extracellular microbes and involves the production and secretion of antibodies by CD20+ B lymphocytes. Cell-mediated immunity is the principal defense mechanism against intracellular microbes such as viruses, and involves proliferation and response by CD8+ cytotoxic T lymphocytes. CD4+ T cells are involved in both humoral and cell-mediated responses and are responsible for producing cytokines that stimulate effector cell proliferation and maturation, and antigen-presenting cell (APC) maturation. Due to the incredible complexity of the immune system, it is imperative that the specific cells of the immune system are reviewed to permit comprehension of the various adaptive immune responses to biomaterials. Adaptive immune cells fall into two categories, mononuclear phagocytes and lymphocytes. These cell types and their subsets are discussed below.

4.404.1.1.2. Mononuclear phagocytes

Leukocytes that have one nucleus and the capability of phagocytizing large particles or small organisms (bacteria or dead cells) are referred to as mononuclear phagocytes. Among the mononuclear phagocytes, there are three notable, highly prevalent cell types: the monocyte, which is an immature/undifferentiated cell that exists primarily in the blood; the macrophage, which is derived from the monocyte and is particularly good at phagocytosing foreign organisms and damaged tissue, but less proficient at presenting engulfed proteins to lymphocytes; and the dendritic cell (DC), which is also derived from the monocyte, is less adept at phagocytosing foreign and damaged material, but is more capable of presenting foreign proteins to lymphocytes. Both DCs and macrophages express major histocompatibility complex (MHC)-II, on which phagocytosed foreign antigens are presented. These cells are referred to as APCs because of their ability to present foreign antigens, along with a costimulatory signal, to lymphocytes.

4.404.1.1.3. Lymphocytes

The only cells in the human body that have the capability of recognizing specific antigens are lymphocytes and, as a result, they are responsible for giving the human immune system specificity and memory. Lymphocytes are a functionally heterogeneous group of cells with several distinct populations. T lymphocytes (T cells) are the largest group and consist of CD4+ helper T cells and CD8+ effector T cells. Natural killer (NK) cells are often grouped with the T lymphocytes because they frequently express the T cell receptor (TCR) on their surface, a defining characteristic of all T cells, but NK cells also express receptors that are unique to the other lymphocyte populations. B lymphocytes are the cells responsible for producing antibodies and are therefore the principal effector cells of humoral immunity.

4.404.1.1.4. Cellular identification

Finally, regarding reference to the cells of the immune system, students and researchers should get into the habit of identifying immune cells not only by name, but also by the unique proteins that exist on the cell surface. This is because many of the cells of the immune system have a common origin and are differentiated on the basis of function, morphology, and protein expression. However, there is not always a clear distinction between cells, and cells with the same name can do very different things. For example, since macrophages and most DCs originate from monocytes, the distinction between the

Table 1 Details of the CD molecules that are important to the adaptive response to biomaterials

CD number	*Alternate name(s)*	*Expressing cells*	*Function*
CD3 (γ, δ, ε)	TCR complex	T cells, thymocytes	Required for cell surface expression of and signal transduction of the TCR
CD4	T4, L3T4	Class II MHC-restricted T cells, thymocyte subsets, monocytes, and macrophages	Signaling and adhesion coreceptor in class II MHC antigen-induced T cell activation
CD8 (α, β)	T8, Leu-2, Lyt2	Class I MHC-restricted T cells, thymocyte subsets	Signaling and adhesion coreceptor in class I MHC antigen-induced T cell activation
CD11 (a, b, c)	Noncovalently linked to CD18 to form LFA-1/ Mac-1/p150,95 integrins (a/b/c isoforms respectively)	a: all leukocytes b and c: granulocytes, monocytes/ macrophages, NK cells	Cell–cell adhesion
CD14	LPS receptor	Monocytes, macrophages, granulocytes (free in serum)	Binds lipopolysaccharides (LPS) and LPS-binding protein
CD63	Lysosome-associated membrane protein 3 (LAMP-3)	Activated platelets, endothelial cells, neutrophils, monocytes, macrophages	Unknown
CD68	Macrosialin family; LAMP family	Monocytes, macrophages, DCs, granulocytes, activated T cells, some B cells	Scavenger receptor
CD80	B7-1	DCs, macrophages, some B cells	Antigen costimulation
CD86	B7-2	DCs, macrophages, some B cells	Antigen costimulation

three cell types can be confused. Furthermore, a particular type of cell may do very different things, depending on its particular phenotype/genotype. A prime example of this is the division of macrophage cells into 'regulatory,' 'wound-healing,' and 'classical' phenotypes, which we will discuss in more detail in Section 4.404.3.1. Known immune cell surface proteins have each been assigned a 'cluster of differentiation' (CD) number (e.g., CD1, CD2, CD3, etc.). For example, all T lymphocytes have TCRs on their surface. The TCR has been assigned as CD3. Therefore, all T cells are CD3 positive (CD3+). This practice of referring to cells by CD number prevents the misidentification of cells, which may occur from characterizing cells by their cytokine profile or morphology. A summary of surface proteins that are important to immune cell differentiation is provided in Table 1.

4.404.2. Recognition of Biomaterials by the Adaptive Immune System

4.404.2.1. Indirect Effects on Lymphocytes

4.404.2.1.1. Attraction of leukocytes to the implant site

The implantation of a biomaterial results in damage to the superficial vasculature, epithelial tissue, and local muscle tissue. Therefore, the response to the biomaterial is related to the initial wound-healing process that occurs in response to the damage caused by the implantation. It is generally understood that there are three phases to wound healing: inflammation, proliferation, and remodeling/maturation. Lymphocytes peak in the damaged region on day 7, during the proliferation phase, whether a biomaterial is present or not; however, lymphocyte migration commences as soon as wounding occurs. Immediately upon damage to local vasculature, which is inevitable with almost any incision/puncture, damaged endothelial cells vasoconstrict, α-granules of platelets are opened, and a fibrin clot forms. The degranulation of platelets is the initiating event in leukocyte chemotaxis and activation and initiates migration of neutrophils, monocytes, and lymphocytes. The platelet α-granules contain hundreds of soluble proteins that are released at the time of degranulation. The notable factors are listed in Table 2. Of particular relevance to lymphocyte chemotaxis is the release of transforming growth factor-β (TGF-β); however, other factors, such as histamine, prostaglandins, prostacyclin, and thromboxanes, certainly contribute to the migration of all leukocytes as they cause vasodilation of the constricted vessels and extravasation of the leukocytes

Table 2 Contents of platelet α-granules released upon tissue wounding and their function[a]

Molecule	*Function*
Fibrin	Principle component of thrombus formation. Provisional matrix formation
Fibronectin	Cell adhesion
Factor XIII	Chemoattraction and adhesion
Circulatory growth factors	Mitogenesis, fibroplasia, regulation of chemoattraction
Complement	Antimicrobial, chemoattraction
Cytokines (TGF-β)	Chemoattraction, mitogenesis
Chemokines (CXCL1, CXCL4, CXCL5, CXCL7, CXCL8, CXCL12, CCL2, CCL3, CCL5)	Chemoattraction. CXCL4 (also known as platelet factor IV) and CXCL7 are most abundant. These factors are chemotactic for fibroblasts and monocytes, neutralize heparin, and inhibit collagenase
Platelet-activating factor	Platelet aggregation
Thromboxane A_2 (via platelet COX-1)	Vasoconstriction, platelet aggregation, chemotaxis
Serotonin	Induces vascular permeability, chemoattractant for neutrophils
Platelet-derived growth factor (PDGF)	Promotes angiogenesis

that adhere to the vascular endothelium. The fibrin clot that forms in the injured vascular tissue is very similar to the provisional matrix that forms on the exterior of an implanted biomaterial and is composed of collagen, platelets, thrombin, and fibronectin. Both the clot in the vascular tissue and the provisional matrix on the exterior of the biomaterial concentrate release factors that are involved in wound healing and the response to the biomaterial. In fact, the clot and the provisional matrix serve as scaffolds for the migrated cells, neutrophils, monocytes, lymphocytes, fibroblasts, and endothelial cells.[1]

Ultimately, upon damage during biomaterial implantation, acute inflammation ensues with its severity closely related to the following factors: (1) the extent of damage caused by implantation and therefore the magnitude of prostaglandin release; (2) the site into which the material is implanted; and (3) the extent of provisional matrix formation.[2,3] Neutrophils and mast cells make up the majority of the initial extravasating cells and are therefore characteristic of acute inflammation. Mast cells release histamine from their granules, which exacerbates the initial inflammatory response.[4,5] As inflammation progresses to the proliferation phase or foreign body response, monocytes/macrophages extravasate through vascular walls and migrate to the implant site. Such migration of monocytes/macrophages occurs in response to chemokine production. Once macrophages are recruited to the implantation site, they produce tumor necrosis factor (TNF-α), interleukin-6 (IL-6), platelet-derived growth factor (PDGF), granulocyte-colony stimulating factor (G-CSF), and granulocyte macrophage colony stimulating factor (GM-CSF) to recruit additional macrophages to the area.[1,6] Both Rhodes *et al.*[8] and Jones *et al.*[7] have shown that production of CC-chemokines, such as CCL2, CCL4, CCL13, and CCL22, are produced by macrophages (and possibly monocytes or DCs) responding/adhered to biomaterials and are important for lymphocyte recruitment. A different class of chemokines, the CXC chemokine family, specifically those lacking the glutamic acid-leucine-arginine (ELR) motif before the first cysteine of the CXC motif, are primarily responsible for lymphocyte migration in the body. CXCL9 and CXCL10 have been found to be spatially associated with lymphocyte accumulation in cutaneous wounds and are likely important mediators of lymphocyte migration to biomaterial implantation sites.[9] The major source of these chemokines is most likely the myeloid cells (primarily macrophages, but also DCs and monocytes) in the region of an implanted biomaterial. A list of the chemokines involved in the attraction of adaptive cells to a biomaterial implant site is provided in **Table 3**. **Figure 1** illustrates the events leading to material recognition by the adaptive immune system.

Table 3 Chemokines, their receptors, and migrating cells

Receptor	*Ligands*	*Alternative names*	*Target cell*
CXCR1	CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8	IL-8R_A, IL-8R-I	Neutrophils, lymphocytes (B and T cells), monocytes/macrophages
CXCR2	CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8	IL-8R_B, IL-8R-II	Neutrophils, lymphocytes (B and T cells), monocytes/macrophages, eosinophils
CXCR3	CXCL9, CXCL10, CXCL11	IP-10/MigR, GPR9	Lymphocytes (B and T cells)
CXCR4	CXCL12	HUMSTR, LESTER, fusin, HM89	Lymphocytes (B and T cells)
CXCR5	CXCL13	BNLR-1, MDR15, BLR11	Lymphocytes (B and T cells)
CXCR6	CXCL16	STRL33, BONZO, TYMSTR	Lymphocytes (B and T cells), NK cells, dendritic cells
CCR2	CCL2, CCL13	CD192 CCL2 = MCP-1	Monocytes, memory T cells, DCs
CCR3	CCL5, CCL7, CCL11, CCL13	CCL13 = MCP-4	Monocytes, T cells, eosinophils, basophils
CCR4	CCL2, CCL4, CCL5, CCL22	CCL4 = MIP-1	Monocytes, memory T cells, DCs
CCR5	CCL4, CCL13	–	NK cells, monocytes

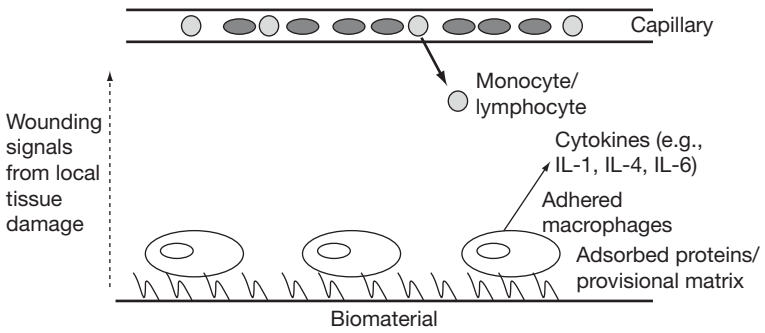

Figure 1 This figure illustrates the biomaterial implantation site following the acute inflammation stage. Macrophages adhering to the protein layer on the biomaterial produce cytokines that direct the lymphocyte response to the material (see **Figure 3** for more detail).

4.404.2.1.2. Activation of adaptive cells by innate cells activated through biomaterial contact

4.404.2.1.2.1. Paracrine/juxtacrine mechanisms

Upon interaction with a biomaterial, macrophages not only attract lymphocytes to the region but also activate the migrated T cells. The activation of lymphocytes by macrophages occurs through both contact and paracrine/juxtracrine mechanisms. The latter is the most common mechanism of lymphocyte activation by macrophages in the response to biomaterials that do not contain proteins. Specifically, material-adherent macrophages produce IL-1, IL-6, and TNF-α that activate local T lymphocytes. The role of the lymphocyte in these responses is yet to be completely determined; however, they are likely responsible for supplementing the production of signaling chemicals and growth factors, which guides the subsequent proliferative response. The form of activation of the responding lymphocytes is critical in the host response as the most prevalent responding lymphocyte, immature CD4+ T cells, can be differentiated into either inflammatory (Th1) or 'helper' (Th2) phenotypes. CD4+ Th1 cells produce IL-2, IFN-γ, and TNF-β, which causes prolongation of the inflammatory phase, and often increased release of nitric oxide and other reactive oxygen species. On the other hand, the 'helper' Th2 cells produce IL-4, IL-5, IL-6, IL-10, and IL-13, with the levels of each cytokine dependent on the specific activation of the T cell. These cells typically promote wound healing, with the exception that cells producing high quantities of IL-10 may inhibit cell proliferation and collagen levels. Since the responding lymphocytes depend on the adherent macrophages for cues, biomaterial surface chemistry, which impacts macrophage and FBGC adhesion and response, indirectly affects lymphocyte activation.[10–12] A reciprocal relationship also exists such that increased lymphocyte stimulation by paracrine/juxtracrine mechanisms can, in turn, result in increased/decreased macrophage stimulation.[10] It is interesting to note that though the Th2 response is typical to implanted biomaterials, B cells are rarely detected at the implantation site. This suggests that though Th2 responses prevail, antibody production at the biomaterial implant site rarely occurs.

4.404.2.1.2.2. Physical macrophage–lymphocyte interactions

Lymphocytes rarely adhere to materials that do not contain proteins, but rather adhere to the macrophage layer. Generally, the contact of lymphocytes with the macrophage layer does not stimulate activation of the cells; rather, juxtacrine cytokine production activates the lymphocytes. However, when the biomaterial contains foreign proteins, APCs (macrophages and DCs) phagocytose the proteins and present the processed peptides to the responding lymphocytes through MHC-II in a physical interaction between the cells. MHC-II presentation of foreign antigens by APCs to lymphocytes requires costimulation through CD80 and CD86. Without physical costimulation of the lymphocyte, activation does not occur, which is one mechanism of ensuring that the adaptive immune system does not respond to self-antigens. Biomaterials, such as poly (lactic-*co*-glycolic acid) and agarose, have been shown to upregulate costimulatory molecule (CD80 and CD86) expression on APCs, one reason biomaterials have been proposed as vaccine adjuvants.[13,14] **Figure 2** provides an illustration of MHC-II-mediated lymphocyte activation. Upon contact with an APC that is presenting a recognized (foreign) antigen on MHC-II with sufficient costimulation, the activated lymphocytes mount a specific response against the particular antigen. Such a response is considered a Th2 response and involves the activation of both CD4+ T lymphocytes and B lymphocytes with concomitant antibody (primarily IgG) production.[15] As a result, the adaptive immune response to the natural biomaterials that contain foreign proteins is often far greater than the response to synthetic biomaterials. Further details of the Th2 response are provided later in this chapter.

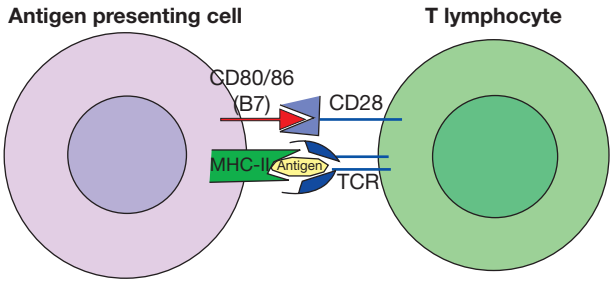

Figure 2 Antigen recognition by T lymphocytes requires proper binding of the host MHC-II protein displaying the recognized antigen with the T cell receptor (TCR). Coactivation involving CD80/86 with CD28 is necessary for activation of the T lymphocyte.

4.404.2.2. Direct Effects of Lymphocytes

It is generally assumed that there is no direct interaction between biomaterials and lymphocytes because, with respect to antigen presentation to T lymphocytes, the TCR, which recognizes the foreign antigen, requires costimulation by the MHC. Since biomaterials do not have or adsorb MHC proteins, T cells are not capable of recognizing the material directly. That is, material components must be internalized by APCs, which 'show' the antigens to the T cells (see **Section 4.404.2.1**). However, direct contact with soluble antigens can stimulate CD20+ B lymphocytes to differentiate into plasma cells and secrete antibodies specific for the antigen. Unlike T lymphocytes, B lymphocytes have the unique ability of recognizing and responding to nonprotein antigens (such as polysaccharides). In fact, activation of B lymphocytes by nonprotein antigens occurs independently of CD4+ T helper cells, whereas activation of B lymphocytes by protein antigens is dependent on costimulation by CD4+ helper T cells. As a result, B cells can recognize a wider range of antigens than T cells, leaving open the possibility that B cells will produce antibodies specific to a biomaterial. Although B cells are rarely detected at biomaterial implant sites, seldom are B lymphocytes suspected to contribute to the adaptive response to biomaterials.

There remains a possibility that T lymphocytes could be directly activated by biomaterials through nonantigen-specific mechanisms that are not currently understood. For example, proteins that adsorb to the material surface in small amounts, such as complement fragments, may cause nonspecific activation of lymphocytes.[16] However, such direct lymphocyte activation is unlikely to make a major difference in the response to a biomaterial as indirect activation of the lymphocyte populations is prevalent.

4.404.3. Consequences of the Adaptive Response

4.404.3.1. Spectrum of Adaptive Responses to Biomaterials

4.404.3.1.1. Inflammatory responses

The differentiation of the adaptive responses occurs during inflammation and is dependent upon the magnitude of damage, the site of implantation, and the material(s) implanted. With respect to adaptive immune responses, inflammation is divided into two segments, acute inflammation and chronic inflammation. Acute inflammation is synonymous with the inflammatory stage of wound healing; as mentioned, platelets degranulate (see Table 1); neutrophils migrate to the damaged tissue, followed by monocytes and lymphocytes. It is notable that acute inflammation can be minimized by limiting tissue damage (e.g., by using minimally invasive techniques) or through the use of certain anti-inflammatory compounds (e.g., glucocorticoids). Chronic inflammation generally coincides with the proliferation phase of wound healing, but the term also encompasses other immune responses that are distinct from wound healing. Unlike acute inflammation, chronic inflammation is quite variable depending on the stimuli encountered during acute inflammation. The presence of certain stimuli, such as pathogen-associated molecular patterns (PAMPs) that are found on bacteria cell walls (e.g., lipopolysaccharides), can be detected by monocytes, DCs, or macrophages, and alter the chronic inflammatory response. During chronic inflammation, APCs are critical mediators in differentiating the adaptive response by producing a cytokine milieu conducive to the formation of a particular lymphocyte response. The differentiation of the chronic inflammatory response is highly dependent on the materials that the infiltrating monocytes phagocytose and the cytokines that predominate in the local environment. An underlying matter to the form of inflammatory response that develops is the specific phenotype of the local matured macrophages and/or DCs. Macrophages have recently been divided into three subcategories, 'classically activated,' 'wound-healing,' and 'regulatory' based on their specific expression of several factors such as cytokines, and intracellular/transmembrane proteins.[17] Similarly, mature DCs have been subdivided into the following two categories: immunogenic DCs and tolerogenic DCs.[18–20] With respect to both macrophages and DCs, most of these cells are derived from the myeloid lineage with monocytes being the precursor of each cell type, plasmacytoid DCs being the exception to this. The specific phenotype of the myeloid cells that populate the biomaterial implant site has significant implications to the future adaptive immune response. Figure 3 illustrates the implications of macrophage phenotype polarization on the lymphocyte response.

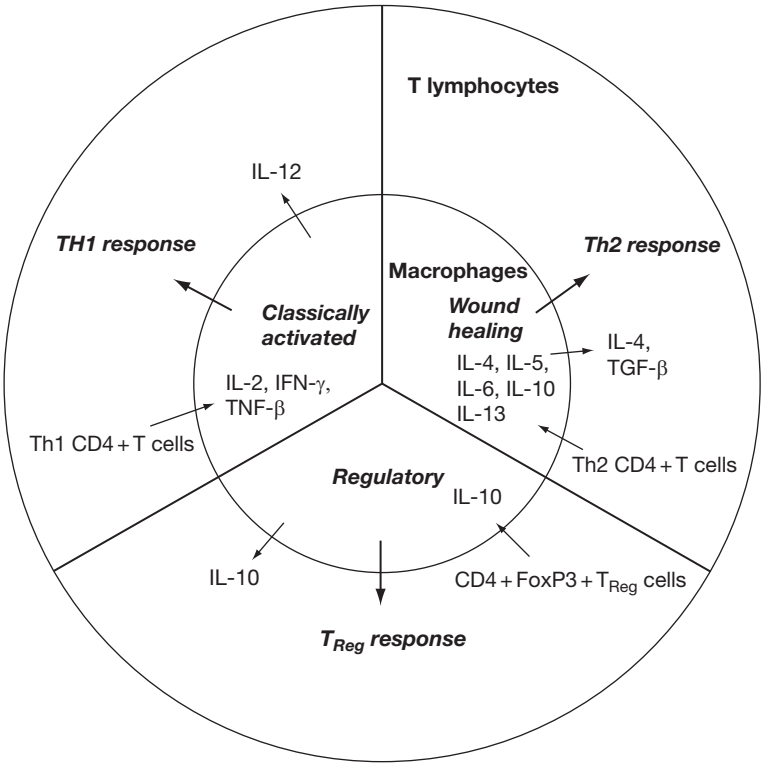

Figure 3 Most leukocytes, such as macrophages and T lymphocytes, have phenotypically diverse populations. Macrophage populations have been likened to colors on a color wheel, illustrating the fact that macrophages can take up a phenotype that is strongly 'wound healing,' 'classically activated,' or 'regulatory,' or one that is a blend of the aforementioned phenotypes. Similarly, T cells, particularly CD4+ T helper cells, display Th1, Th2, and T_{Reg} phenotypes. In this figure, the center of the diagram represents undifferentiated macrophages, known as monocytes. The outer edge of the inner circle represents fully differentiated macrophages separated by the different phenotype classifications. The different macrophage phenotypes produce factors that polarize the adaptive response to its different subsets. Predominant cytokines that cause this polarization are provided. Once the adaptive response has developed, the responding lymphocytes produce cytokines that affect macrophage activity. Therefore a feedback system is created, which permits progression of a specific immune response.

4.404.3.1.2. Range of T cell responses (Th1, 2, 17 rejection, tolerance, effect of duration, and magnitude)

Like innate immune cells, T lymphocytes have been characterized into several different varieties. The three major types of T cells (i.e., CD3+ cells) are CD4+ 'helper' T cells, CD8+ 'effector' T cells, and γδ-T cells. An immense amount of literature on CD4+ T cells has subdivided these cells into Th1, Th2, Th17, and regulatory (T_{Reg}) classifications: Th1 cells produce primarily IFN-γ and IL-12; Th2 cells produce IL-4, IL-5, and TGF-β; Th17 cells produce IL-17; and T_{Reg} cells produce Foxp3 and IL-10. Table 4 contains a breakdown of the different responses and their distinguishing characteristics. With respect to biomaterial–T cell interactions, Th1, Th2, and T_{Reg} cell populations are the most relevant. That is, Th17 cells and γδ-T cells have never been reported as being present at biomaterial implantation sites. However, it is conceivable that Th17 cells and γδ-T cells appear at some biomaterial implantation sites, but their presence has never been assessed.

The difference between Th1 and Th2 T cell responses is critical to defining the amount of matrix production that results on the surface of a biomaterial. If there are foreign proteins present, the Th2 response is expected to prevail. However, if foreign proteins are naturally internal to a cell included in the biomaterial matrix, such as with allogeneic cells, or viruses, the Th1 response is expected to prevail. Complete sterility of biomaterial surfaces, including freedom from endotoxins and any foreign proteins (denatured or not), is critical in biomaterial research to alleviate the possibility of negatively altering the host response to the biomaterial.[21] That is, biomaterial surfaces must be free of any possible contaminants. Otherwise when monocytes adhere to the surface during the initial recognition phase of the host response, they may take up the contaminating element, which would affect the eventual adaptive response. Furthermore, many researchers utilize fetal bovine serum (FBS) in their cell media, which may inadvertently alter the outcome of experiments involving a leukocyte response because of the presence of neoantigens of bovine origin.

Table 4 Characteristics of the various T cell responses

Response	*Cells involved*	*Characteristics*
Th1	CD4+ T cells, CD8+ T cells	Stimulus (foreign protein/antigen from within any cell), found on MHC-I and detected by T cells. IFN-γ, TNF-β, IL-2, and IL-12 are produced. Typically inflammation is prolonged (i.e., chronic inflammation) until the stimulus is no longer present. Macrophages and cytotoxic CD8+ T cells are the effector cells responsible for clearance of the stimulus. Little fibrosis occurs
Th2	CD4+ T cells, B cells	Stimulus found on MHC-II of APCs. IL-4, IL-5, IL-6, IL-10, and IL-13 are produced. Chronic inflammation is often associated with fibrous tissue formation, especially when IL-4 and TGF-β levels are high. B cells produce antibodies that mediate clearance of the stimulus
Th17	CD4+ T cells	IL-17 is strongly upregulated. Th17 cells promote inflammation in autoimmune diseases and in response to some viral infections
Regulation	CD4+, CD25+, Foxp3+ T cells	IL-10 is the predominant cytokine and is responsible for suppressing inflammation and the activity of effector cells (cytotoxic CD8+ T cells, macrophages, and B cells). If TGF-β levels are high, fibrosis occurs

4.404.3.2. Effects on Biomaterial-Only Devices (e.g., Probes, Implants, Biological Scaffold Materials)

4.404.3.2.1. Inflammation

The response to synthetic biomaterial-only devices is relatively straightforward compared to the response to multicomponent devices. As mentioned previously, inflammation occurs immediately upon implantation of a material in the body and defines the future adaptive immune responses. The proper inflammatory response can be critical to the application. For example, some biomaterials have been shown to cause an upregulation of matrix metalloproteinases (MMPs).[22] MMP upregulation is generally welcome in the local environment of artificial joints, catheters, probes, heart monitors, and any other material that is implanted and that does not need a supporting matrix on/around it. However, overproduction of MMPs would likely impair the performance/lifespan of materials that are intended to serve as scaffolds for proliferation of specific cells/tissue. Inflammation is essentially defined as the migration and localization of leukocytes in response to a stimulus that disrupts the homeostasis of the tissue. As a result of cell migration, the tissue becomes swollen and often painful. If the tissue is superficial, inflammation is associated with redness and heat. The inflammatory response can itself be detrimental to the performance of implanted medical devices such as artificial joints, as the migration of leukocytes and subsequently increased local cell density results in reduced mobility of the joint and increased pain. For most medical devices, some inflammation is acceptable, if it is short-lived, but prolonged or severe inflammation precludes proper functioning of the device. The adaptive immune system can prolong inflammation if there are foreign antigens present in the local environment of a medical device. Generally, it is desirable for the inflammatory response following implantation of a material to be very similar to the inflammatory response to a similar surgical procedure without the implantation of a biomaterial component, as the extent and duration of deviation from optimal wound-healing conditions affects the biocompatibility of the device. As a result, it is critical that medical devices should be sterile and also free of foreign antigens or endotoxins.

4.404.3.2.2. Foreign body response

The foreign body response to biomaterials is a well-documented response to materials that occurs due to monocyte/macrophage adherence on the surface of the material and local

production of mediators (such as IL-4), resulting in macrophage fusion. T lymphocytes have been shown to increase monocyte adhesion and macrophage fusion on biomaterial surfaces, enhancing the foreign body response, through indirect (paracrine) signaling.[23] Chang *et al.* have shown that lymphocytes indirectly enhance macrophage and FBGC activation at early time points by producing soluble mediators, and promote sustained activation at later time points through direct cell–cell mechanisms. A bilateral exchange between lymphocytes and macrophages/FBGCs occurs as macrophages/FBGCs actually support the activation of responding lymphocytes. That is, cytokine production by macrophages/FBGCs is correlated with activation of responding lymphocytes, which in turn may cause progression and prolongation of the foreign body response to the material.

4.404.3.2.3. Fibrosis

Fibrosis is a common phenomenon with respect to disease pathology, wound-healing, and material implantation. Soon after placement of a material in the body, myofibroblasts commence production of extracellular matrix (ECM) proteins, which replace the provisional matrix and provide long-term structure for cells to adhere. As mentioned earlier, the antithesis of ECM protein production is the production of MMPs. In fact, constant remodeling of the ECM occurs so that the initial matrix is more elastic and degradable, and becomes stronger through remodeling, such as with replacement of fibronectin and collagen III in the matrix with collagen I. The adaptive immune response certainly affects fibrosis on and around material surfaces by altering the microenvironment. Strong Th2 adaptive responses have been shown to result in strong collagen I-rich scar development, whereas T_{Reg} responses suppress fibrous tissue formation altogether. The fibrotic response to an implanted biomaterial can affect the function and/or lifespan of a medical device. For example, the formation of thick fibrous tissue impedes the function of medical devices in the joints. With respect to drug delivery devices, fibrous tissue development around the construct may act as a barrier and impede nutrient or product diffusion. Acellular tissue engineering scaffolds that are implanted with chemotactic agents for the attraction of desired cells into the scaffold could also be adversely affected by a strong fibrotic response. That is, fibrous tissue may impede the chemomigration of cells into the construct. On the other hand, angiogenesis (see below), a parallel phenomenon to fibrosis, would likely be welcome in acellular tissue-engineering scaffolds. Therefore, appropriate adaptive responses are essential to guiding an appropriate fibrotic response to the medical device.

4.404.3.2.4. Angiogenesis

Angiogenesis occurs simultaneously with fibrosis. Upon implantation of a foreign material, myofibroblasts and endothelial cells migrate to the implant and commence the formation of blood vessels and fibrovascular tissue. Angiogenesis is generally not detrimental in itself, but does permit the development of thicker fibrous tissue. In some situations, such as tissue-engineered constructs and drug delivery devices, angiogenesis on and around the construct may be beneficial, depending on the purpose of the device and the pharmaceutical that is being released.

4.404.3.2.5. Autoimmunity

Autoimmune responses are immune responses against a self-antigen and rarely occur with the implantation of biomaterial-only constructs. It has been suspected that one of the risks of silicone breast implants is an increased risk of rheumatologic disorders (e.g., connective tissue disease, scleroderma, or arthritis), and some studies have found increased autoimmune antibodies in the serum of individuals with implants; however, several epidemiological studies have found no correlation between silicone breast implants and rheumatic diseases. The concern of some researchers is that the silicone implant exposes previously hidden self-protein epitopes (see Section 4.404.2.2), which may occur in some patients without the stimulation of an autoimmune reaction.

4.404.3.2.6. Infection

A general risk of surgery, especially surgeries of invasive nature such as joint replacement, is the possibility of infection. Biomaterials actually increase the risk by providing pathogens (primarily bacterial) with a surface to proliferate and grow. As a result, biofilms form on and around implanted medical devices. It is very difficult for the innate immune system to fight these infections because of the rate at which they grow, the density of the bacteria on the surface of the material implant, and the difficulty faced with phagocytizing the bacteria. Therefore, infected medical devices typically require removal from the body. The only negative consequence of the adaptive immune response to biofilms is the sustainment of inflammation. However, this can hardly be viewed as a downfall of the adaptive response, with the alternative being eventual systemic bacterial infection and possible death of the host.

4.404.3.3. Effects on Combination Products (i.e., Vaccine or Tissue-Engineering Construct)

4.404.3.3.1. Magnitude of response

Combination products elicit an immune response to the biomaterial component as well as to the cellular component. Generally the response to the biomaterial component affects the response to the cellular component and vice versa. Due to the range of potential tissue-engineering constructs, an appropriate response is difficult to define. The maintenance of device function is critical throughout the inflammatory and wound-healing responses, as function is impossible to regain once lost. However, the purpose of an implanted biomaterial combination product is different in peptide-loaded vaccine microparticles and tissue-engineering constructs or cellularized scaffolds intended to supplement the function of an organ/tissue. Without doubt, limiting the magnitude of the response is essential for tissue-engineering constructs, but enhancing the magnitude of the response is desirable for vaccine microparticles.

Biomaterials have been shown to promote immune response to certain antigens, and have therefore been proposed as vaccine adjuvants. As wound healing and fibrovascular tissue formation require a Th2-like response, which normally occurs in response to biomaterial-only constructs, it is not surprising that biomaterials can promote/magnify the response to extracellular proteins. For the desired effect of magnification of a Th2 response to take place against biomaterial-based

vaccines, it is essential that the proteins originate from outside the responding APCs. That is, a biomaterial can be processed to act as a protein carrier as well as an adjuvant, and support a sustained immune response against a cell lysate or a specific protein that has been incorporated into the biomaterial construct.

4.404.3.3.2. Altered responses

The presence of a biomaterial has been shown to alter the immune response to foreign proteins and vice versa. As mentioned, the lymphocyte response to biomaterials is generally a Th2-type response. However, a Th1 response typically develops against allogeneic cells. Therefore, a tissue-engineering construct composed of allogeneic cells and a biomaterial supports competition between Th1 cells and Th2 cells, which have some opposing characteristics (e.g., TGF-β production by Th2 cells). The initial response to such constructs is likely to be against the presence of foreign proteins, so Th1 cells and CD8+ CTLs are likely to dominate at first. Depending on the specific construct, upon clearance of the cells with MHC1 mismatches, the Th2 response against the biomaterial may dominate, resulting in fibrovascular tissue formation.

4.404.3.3.3. Tolerance responses

With respect to a combination product, the term 'tolerance' has different meanings. 'Tolerance' may imply a strong wound-healing response in which the cellular component of the combination product is not harmed; however, others may view 'tolerance' as complete suppression of any immune response. For biomaterial-only components, tolerance may be achieved by simply altering the surface structure of the material, or implanting a drug delivery device that releases anti-inflammatory or antifibrotic compounds locally.[24] That is, upon resolution of the inflammatory response, it is possible to accumulate minimal fibrovascular tissue on and around a biomaterial-only construct. Similarly, cellularized syngeneic combination products are likely to be completely tolerated by the host immune system as no foreign proteins are present. However, achieving tolerance to combination products with foreign proteins is far more elusive, as allogeneic and xenogeneic cells are recognized and destroyed by the host immune system, even when 'hidden' from the APCs and lymphocytes by microencapsulation.[25] The implantation of allogeneic stem cells may be tolerated by the host immune system, but may become immunogenic upon differentiation and maturation. Some immune privileged sites in the human body have been identified including the eyes, the brain, the testicles, and the placenta and fetus.

A method of inducing tolerance to foreign proteins in combination products has yet to be discovered but will inevitably require the induction and proliferation of CD4+Foxp3+ regulatory T cells, and the antigen-specific CD8+ T cells to be rendered anergic. Anergy is a state of unresponsiveness following stimulation with an antigen that is recognized by the cell's TCR. In allotransplantation, immune suppression is generally achieved by lifelong delivery of glucocorticoids, which systemically suppress the entire immune system. Glucocorticoids are naturally produced by the adrenal cortex from cholesterol, with production regulated by the hypothalamic–pituitary–adrenal (HPA) axis. They have long been used in solid organ transplantation because of their nonspecific anti-inflammatory effect, direct effect on lymphocytes (B cells and T cells), and their ability to modulate cellular immune functions.[26] When systemically administered, corticosteroids cause a sequestering of T lymphocytes in the bone marrow, which reduces the number of T lymphocytes that circulate through the vasculature. As glucocorticoids are lipophilic molecules, they are able to freely cross plasma membranes and bind to specific intracellular receptors that belong to a family of transcription factors.[27] Central to their effects on the immune system is their ability to reduce activation of target genes by inhibiting NF-κ by changing confirmation of the protein into a chemically inert form.[28] They also strongly inhibit phosphodiesterase, causing cyclic adenosine monophosphate to accumulate intracellularly, which reduces lymphocyte activation.[26] Production of IL-1 in macrophages and IL-2 in T cells is also inhibited by glucocorticoids, which reduces the generation of CTLs. The anti-inflammatory effect of glucocorticoids results from the suppression of arachidonic acid release and suppression of macrophage phagocytosis. Ultimately, glucocorticoids suppress the immune system and prevent immune response to allotransplants, but as a result, this prevents immune tolerance to the organ/tissue. However, the full potential of glucocorticoid use in medicine may yet be seen as research indicates that glucocorticoids upregulate the formation and proliferation of T_{Reg} cells and tolerogenic DCs. Local sustained glucocorticoid delivery has been achieved through polymeric drug delivery constructs, but has never been used clinically. Therefore, systemic glucocorticoid use may inhibit the immune system and prevent immune responses, but at the same time prevent the induction of tolerance to foreign antigens, while local use suppresses inflammation but promotes tolerance to the foreign proteins. Figure 4 provides a summary of the role of lymphocytes in the various responses to material-only devices and combination products.

4.404.4. Approaches to Engineer Adaptive Responses with Biomaterials

Most work on manipulation of the immune response to biomaterials has been in the area of vaccine research and using biomaterials as adjuvants or delivery vessels, in which the desire has been to amplify the inflammatory response and adaptive immune response. At the same time, efforts have been made to create a biomaterial surface that is tolerated by the body, and not encapsulated with fibrous tissue. Others have incorporated steroidal or nonsteroidal anti-inflammatory drugs into the construct to suppress the initial inflammatory and subsequent foreign body response to the material.

4.404.4.1. Biomaterials as Vaccine Adjuvants and Antigen Carriers

For biomaterials to be effective for use in vaccinations, they must perform three functions: (1) promote the migration of APCs, specifically DCs; (2) activate the DCs to a proinflammatory, antigen-presenting phenotype; and (3) release the antigen such that the responding DCs take it up.[29] Generally, biomaterials acting as vaccine adjuvants are in the form of microparticles, but other designs are likely to be just as effective.

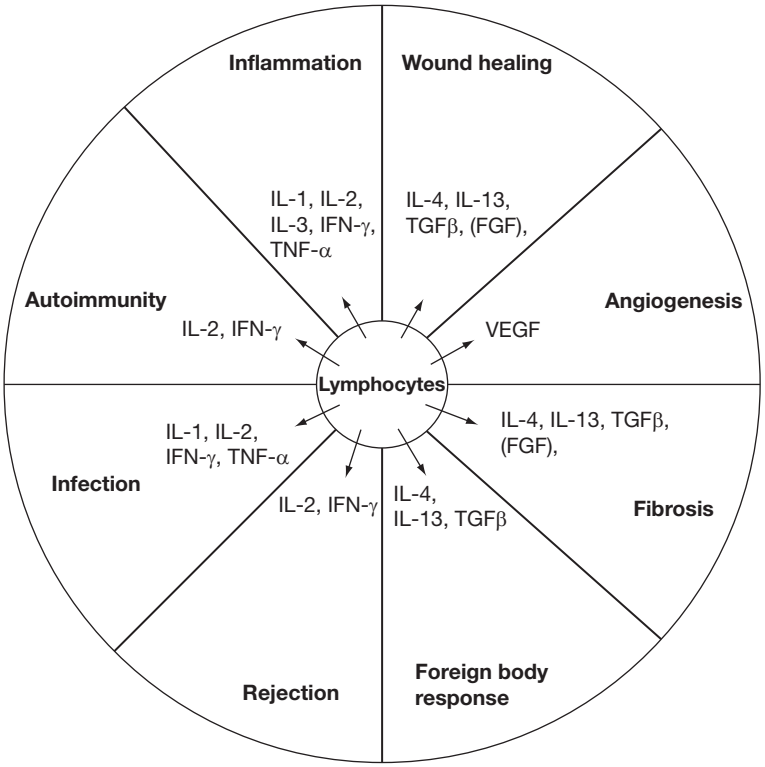

Figure 4 Once activated, lymphocytes affect the subsequent responses to biomaterials. This figure illustrates the specific responses that the adaptive immune system has influence over and lists the predominant protein factors that contribute to signaling of the various responses. With respect to autoimmunity, cell rejection, and the neutralization of infection, lymphocytes are essential contributors. With respect to fibrosis, angiogenesis, foreign body response, inflammation, and wound healing, lymphocytes are not essential, but contribute to the development and end result of each. As shown by the protein factors produced by lymphocytes, substantial overlap of the mediators supporting the different responses exists. In many respects the specificity of the response arises from the specific cell populations involved. For example, foreign body response occurs upon implantation of materials, which provide a surface for attachment of monocytes/macrophages. Since the foreign body response typically occurs concurrent with fibrosis, the cytokine milieu that signals for macrophage fusion is similar to that which signals for fibroblast proliferation and fibrosis. Similarly, autoimmunity, infection, and rejection are generally comparable responses to specific antigens from oneself, a pathogen, or an allogeneic/xenogeneic construct, respectively.

Regardless of the design, the biomaterial should promote inflammation, as inflammation from wounding due to material implantation is not likely a sufficient initiator of a primary response to an antigen. Current adjuvants are based on aluminum salts (hydroxides or phosphates), and act to promote/sustain the inflammatory response so that more antigen is taken up by the responding DCs, which results in an elevated adaptive response. All vaccines used clinically elicit a humoral (Th2) response, are usually composed of live attenuated, killed, or fragmented pathogens, and are typically delivered transdermally.

Biomaterials in the form of microparticles offer the potential of eliciting a Th1 response if they dump their protein contents into the cytoplasm of phagocytizing cells. Antigens within the cytoplasm of the cell are then presented on the surface of the cell by MHC-I, where reactive T lymphocytes recognize the foreign antigens. A delayed cell-mediated Th1 response is then likely to ensue. Such a response would be capable of destroying cells that express the antigen, and could be used to vaccinate against diseases that are currently not curable, such as cancer or AIDS, prior to or following disease induction. For example, most breast cancer tumors produce α-lactalbumin. A vaccination that promotes a strong cell-mediated immune response against cells expressing α-lactalbumin could be capable of destroying all malignant tissue.[30] Biomaterials therefore offer the potential to engineer unique vaccines against diseases that currently have no vaccine.

4.404.4.2. Surface Modification

The greatest body of work in modulation of the host response to biomaterials is in the area of surface modification. Most often, surface modification is intended to change cytocompatibility, as opposed to immunocompatibility. For example, RGD groups or other bioactive molecules are frequently added to the surface of materials to enhance cell adhesion or migration of a particular type of cell. However, modifications to the surface of a material inevitably alter the host immune response to the implant.[31] That is, changing the material surface alters the protein adsorption on the material, thereby affecting the subsequent response. Much of the research on biocompatibility before/after surface modification has involved *in vitro* culture tests, in which the outcome is the observation of cell morphology and differences between materials. Though some information regarding the biosafety of a material can be determined, these assays are poor indicators of

the host response to the material. Better *in vitro* indicators of the host response are derived from mixed leukocyte reactions and simulated foreign body reactions.

4.404.4.3. Anti-inflammatory Drug Release

The release of anti-inflammatory drugs from a biomaterial has been proposed as a potential solution for several medical conditions such as rheumatic diseases, asthma/allergy, fibrotic diseases, and transplant rejection, but has also been proposed as a solution to suppressing a detrimental host response to biomaterial medical devices (e.g., glucose monitors). Anti-inflammatory compounds, particularly glucocorticoids, are incredibly effective at suppressing the formation and release of inflammatory mediators, namely prostaglandins and leukotrienes. As a result, these compounds prevent the migration of inflammatory cells (neutrophils, monocytes, and lymphocytes) by reducing chemotaxis and cell extravasation. Glucocorticoids also suppress fibroblast proliferation, which leads to a significant reduction in fibrovascular tissue formation. Unfortunately, the benefit of anti-inflammatory compounds lasts only as long as the drug is present in the body. For example, once dexamethasone, a glucocorticoid, is completely released from a biomaterial disc, the body begins to recognize the material as a foreign body, and inflammatory and immunogenic reactions commence. This result occurs even if the drug is released over the course of several months. A permanent solution to the foreign body response is yet to be found.

4.404.5. Conclusions

The adaptive response is a component of the host reaction to both implanted biomaterial-only constructs and combination devices. With respect to biomaterial-only constructs, lymphocytes are generally hyporesponsive, but promote monocyte/macrophage adhesion to the material and FBGC formation. The adaptive response is most critical in relation to combination products. Among the list of potential lymphocyte responses, the most relevant to biomaterial devices include Th1 responses, Th2 responses, and regulatory responses. The desired adaptive immune response to a biomaterial device depends on the application. Typically the activation of lymphocytes requires the implantation of foreign (allogeneic or xenogeneic) proteins; however, it may be possible for a synthetic biomaterial-only construct to permit cellular recognition to nontolerated syngeneic protein epitopes, or for syngeneic cells to present nontolerated epitopes on their surface following *in vitro* processing. Biomaterials have recently been proposed as vaccine adjuvants as they permit modulation of adaptive immune responses and promote activation of lymphocytes and inflammation when associated with foreign proteins. In fact, through biomaterial surface modification or drug/protein association, adaptive immune responses can be altered to the benefit of medical devices that have a polymer component.

SOD	Superoxide dismutase
TCPS	Tissue culture polystyrene
TGF	Transforming growth factor
TNF	Tumor necrosis factor
VEGF	Vascular endothelial growth factor

4.405.1. Introduction

The key requirement of any implantable material or device is biocompatibility: quite simply, if a material is not biocompatible, it will not be accepted for use *in vivo*, and therefore that material is not suitable as a biomaterial, regardless of its mechanical and esthetic properties. Biocompatibility is defined as the ability of materials to function with an appropriate host response in a specific application.[1] This definition, used in its entirety, is robust and now widely accepted by the biomaterials community. With the expression 'appropriate host response' has evolved a dramatic increase in the number of applications for biomaterials in the field of modern medicine. For a given application, the appropriate host response will change depending on the prespecified functionality of the material that is implanted. An inevitable consequence of the implantation of a material *in vivo* is an inflammatory response, the mechanism by which the body reacts to the process of implantation, that is, surgical cutting of tissues and blood vessels, and the presence of the implanted material. Therefore, based on the fact that the host response will be triggered and some form of inflammatory response will occur when a material is implanted, the events occurring therein need to be modeled and measured; this would lead to a precise understanding of the ensuing inflammatory response, the processes and components involved, the driving forces that dictate the severity and longevity of the response, and their subsequent long-term consequences. With this knowledge, materials and systems can be produced that can control the inflammatory response and thus enhance the efficiency and biocompatibility of implanted devices, thereby further developing and realizing the potential of biomaterials used in tissue engineering processes for regenerative medicine. Can the inflammatory response be classified in terms of cell types and time? Furthermore, can the consequences of the many aspects of an inflammatory response be modeled for their effect on the implanted biomaterial itself? Can the body's innate defense be used to integrate the implanted device rather than let it remain a phase that must be endured towards long-term functional implantation?

The data obtained from *in vitro* models, which have been utilized to assess the ability of a material to induce or sustain certain elements of the inflammatory response have

successfully identified individual parts of this complex host response, making them more cost-effective and accessible compared to *in vivo* models. With the correct choices, these models can be effectively used as preliminary high throughput screens during the development of new materials. It is important to note that to achieve reliable data from *in vitro* systems the right type of models must be established, that is, the right cell type, culture conditions, and time periods. The introduction of a high degree of reproducibility to the models, which comes from careful experimental planning and high levels of control of variables within a system, is crucial, as are benchmark positive and negative reference points and controls.

This chapter discusses the evaluation of the process of an inflammatory response, the cells involved, and the drivers of these cellular responses: all elements that are required to be understood prior to the development of *in vitro* inflammatory models. Based on this, it is possible to develop *in vitro* models that can effectively act as screening tools for quantifying and characterizing the kinetics and the magnitude of the inflammatory response. A major cellular component of the inflammatory response is the leukocyte. This chapter defines leukocytes, their role in inflammation, and the way these cells can be utilized to derive scientifically relevant *in vitro* data that can predict *in vivo* events and device performance. The chapter also investigates their mode of communication and the ramifications of prolonged activity or stimulation of select cell types on the performance of the implanted material. In addition to the introduction of the inflammatory response, *in vitro* models, and the tools of analysis, specific examples highlighting the components of inflammation are also discussed to exemplify the consequences of different inflammatory events on the host and material and their role in determining the success of an implant. One such example would be the aseptic loosening of orthopaedic implants – how can this phenomenon be predicted and evaluated *in vitro* and these data used to develop materials with the correct properties so as to minimize the detrimental aspects of the inflammatory response and increase the longevity and performance of selected implants? As with the inflammatory response itself, the processes of research, data collection, and development of novel materials act as positive feedback and add to the knowledge base; the more the scientifically relevant data, obtained using controlled *in vivo* and *in vitro* models, is disseminated, the deeper becomes the understanding of what drives the cellular response at a fundamental level, thereby increasing the understanding of how certain types of material properties can be used to control and manipulate the cellular response. An important point to note is that the inflammatory response to a material is inevitable due to the process of implantation and should not be considered as a series of negative events that should be avoided or halted completely. Instead, it should be understood in order to harness and tailor it to manipulate the host environment for the efficient integration, or passivation, of the material within the body. The direct effect of a material on the host in terms of inflammation and the direct effect of the leukocytes on the material are critical. However, these events and this interaction have indirect effects on the cells and the surrounding tissue, and also possibly systemic effects. The impact and significance of these indirect effects are introduced, developed, and discussed in this chapter, and pertain to cells such as osteoblasts and stem cells within the host, and to the mediation of the function of these cells by inflammation.

4.405.2. Characterizing the Inflammatory Response

In order to develop relevant *in vitro* models for assessing inflammatory responses such as the breaking down of the leukocyte–biomaterial interaction, a comprehensive perspective of the inflammatory response and its components is required, and this should include the cell types involved, the methods of signaling and the end points in terms of the final tissue state, for example, a common end point is fibrous capsule formation. This section of the chapter discusses the different elements of the inflammatory response and how they can be utilized to develop standardized *in vitro* models. Each sequential element is discussed in chronological order as it occurs after injury *in vivo*, and the methods for *in vitro* experimentation are also discussed. The emphasis is on leukocyte–biomaterial interactions, but along with that, these responses require contextualization in a broader perspective to present some of the other elements that can dictate and affect the specific set of responses. **Table 1** provides a brief overview of the cytokines that are released by cells during the inflammatory process and their subsequent effects. The complexity of the relationships between each cell type is discussed further.

4.405.2.1. Protein Adsorption

Protein adsorption onto the surface of an implanted material is the first phase of the host response; the type, amount, and nature of the protein adsorbed onto the surface can dictate the subsequent cellular responses, a principle that is true for all cell types and not just for leukocytes involved in the inflammatory response.

Any implantation procedure that requires an incision will result in damage to the vascular tissue at the area of implantation, the element involved in hemostasis, which is the mechanism by which the body stops blood loss via the formation of a clot to plug the severed area. The protein systems within the circulating blood, which are involved in the coagulation cascade, play a role in determining the host response, the extent of the response, and the subsequent inflammatory responses as the initial protein adsorption acts as a direct interface and substrate for cell adhesion and signaling. There is a significant complexity in the details of serum protein–biomaterial interactions and the elements of this system, including complement and blood coagulation cascades, and their role in determining biocompatibility are a research area in their own right.[2–4]

When a material is implanted, the first response is the adsorption of the proteins circulating in the blood onto the material's surface, specifically albumin,[5] fibrinogen,[6] fibronectin,[7] vitronectin,[8] and γ-globulin and complement.[9] Detailed analysis of *in vivo* responses to implanted materials has highlighted the relationships between the presence of these proteins and their role in subsequent leukocyte reactions. Briefly, albumin acts as a passivator and has a minimal effect on increased monocyte/macrophage adhesion; it is therefore not generally a marker of a chronic inflammatory response. As it is more a marker of a passive material, it will not be

Table 1 Common cytokines that are used as markers of inflammation during material-induced protein, whole blood and leukocyte interactions *in vitro*

Cytokine	*Nomenclature*	*Description*
Interleukin-1β	IL-1α	Proinflammatory cytokines produced and secreted by monocytes/macrophages. Enable transmigration of inflammatory cells to site of implantation by increasing adhesion receptor expression on endothelial cells
Interleukin-1 receptor antagonist	IL-1β	
Interleukin-2	IL-2	IL-2 binding to T cell receptors stimulates maturation of T cells into antigen selected cytotoxic T cells
Interleukin-3	IL-3	Stimulates differentiation of hematopoietic stem cells to myeloid progenitor cells and stimulates proliferation of myeloid cells (granulocytes and monocytes)
Interleukin-4	IL-4	Stimulates proliferation of T and B cells and induces differentiation of CD4 T cells to Th2 cells and increases production of IL-4. Required for FBGC formation *in vitro*
Interleukin-5	IL-5	Produced by Th2 cells and mast cells and stimulates B cell growth
Interleukin-6	IL-6	Released by T cells and monocytes, stimulates the inflammatory response, also has a role in osteoclast activity
Interleukin-7	IL-7	Released by dendritic and stromal cells stimulates differentiation and proliferation of hematopoietic stem cells into lymphoid progenitor cells, that is, T and B lymphocytes
Interleukin-8	IL-8	CXC chemokine produced by macrophages, chemotactic to neutrophils and granulocytes
Interleukin-9	IL-9	Th2 cytokine, produced by CD4 + ve T cells, stimulates proliferation and prevents apoptosis of T and B cells
Interleukin-10	IL-10	Anti-inflammatory cytokine produced by monocytes and some lymphocytes can inhibit the synthesis of proinflammatory cytokines produced by monocytes and Th1 cells
Interleukin-12	IL-12	Produced by macrophages and stimulates T cells and production of IFN-γ, TNF-α
Interleukin-13	IL-13	Secreted by Th2 cells, required for the formation of FBGC *in vitro* and works with IL-4 in suppressing IFN-γ production by T cells
Interleukin-17	IL-17	Induces production of proinflammatory cytokines from macrophages
Basic fibroblast growth factor	FGF-basic	Growth factor that stimulates angiogenesis and fibroblasts important in wound healing
Granulocyte–macrophage colony stimulating factor	GM-CSF	Secreted by macrophages, T cells, and mast cells. Stimulates the production of monocytes from hematopoietic stem cells. Leads to an increase in monocyte number
Interferon-γ	IFN-γ	Produced by cytotoxic T cells, Th1 cells, increases lysosome activity in macrophages, promotes leukocyte migration to site of implantation
Interferon-γ-induced protein/ chemokine (C–X–C motif) ligand 10	IP-10	Secreted by monocytes, endothelial cells, and fibroblasts when stimulated by IFN-γ, chemotactic for monocytes and T cells and enhances T cell adhesion
Monocyte chemotactic protein-1/ chemokine (C–C motif) ligand 2	MCP-1/CCL2	Chemotactic for monocytes and T cells
Chemokine (C–C motif) ligand 4/ macrophage inflammatory protein	MIP-1/CCL4	Produced by monocytes and activates monocyte recruitment and activation of granulocytes (including neutrophils) to produce IL-1, IL-6, and TNF-α
Macrophage inflammatory protein-2β/ chemokine (C–X–C motif) ligand 3	MIP-2β/ CXCL3	Controls migration and adhesion of monocytes via binding to CXCR2
Platelet-derived growth factor	PDGF	Active in angiogenesis, significant in new tissue formation via fibroblast activation
Transforming growth factor-α	TGF-α	Produced in macrophages and plays a role in wound healing via epithelial cell activation and granulation tissue formation
Tumor necrosis factor-α	TNF-α	Proinflammatory cytokine produced mainly by macrophages but also some lymphocytes, stimulates the release of IL-1 and PGE2
Tumor necrosis factor-β/lymphotoxin	TNF-β	Produced by CD8 cytotoxic T lymphocytes, and similar effects to TNF-α, acts in a paracrine fashion with TNF-α and is inhibited by IL-10
Chemokine (C–C motif) ligand 5	CCL5/ RANTES	Chemotactic to T cells in combination with IL-2 and IFN-γ, induces the proliferation of natural-killer cells, a type of cytotoxic lymphocyte
Vascular endothelial growth factor	VEGF	Activates angiogenesis, the vascularization of new tissue

discussed further as the sole contributor or marker of the inflammatory response.

Studies by Anderson *et al.*[10] have specifically explored the relationship between protein adsorption onto a biomaterial surface and its role in determining the foreign body giant cell (FBGC) response to the material. The exact nature and role of the FBGC in determining the biocompatibility of a material, *in vitro*, are discussed in **Sections 4.405.2.2.4.2** and **4.405.2.2.6.** A direct relationship between fibrinogen adsorption and histamine release has also been reported and used as a marker of a prolonged inflammatory response.[11] Fibrinogen adsorption and histamine release also have a role in increasing vitronectin adsorption, which facilitates monocyte/macrophage adhesion *in vitro*, a phenomenon that will be discussed further in **Section 4.405.2.2.4.2**.

In combination with other components in the blood interacting with the surface, such as platelets, the associated protein systems, and the resultant clot formation, specific plasma protein adsorption onto the surface results in the formation of a provisional matrix[10] which drives the next stages of wound healing and inflammation. The implant biomaterial dictates the levels of protein formation and the conformation of the

proteins adsorbed on the surface, and thus directs the subsequent cellular response by defining the composition of the protein layer. The 'provisional matrix' contains vasodilators, chemoattractants, cell signaling cytokines, and biological agents that can dictate the cellular response via recruitment of the correct inflammatory cell to the interface. In addition to acting as a beacon for specific cell types via the release of cytokines, the conformation of the proteins on the surface can determine how the cells adhere and thus, the subsequent cell signaling events within the specific cell; this results in the control of the activation and duration of a response via the signals presented to the cell through and by the protein layer. The specifics of these events are discussed in the subsequent sections when introducing the different cell types involved in the inflammatory response and the methods of their analysis.

The phenomenon of plasma protein adsorption and its proven role in enhancing (in the case of fibronectin and fibrinogen) or inhibiting (in the case of albumin) the inflammatory response provides a platform for analysis that can act as a very cost-effective and rapid screening technique for the assessment of biomaterials, prior to characterizing the cellular response. Protein adsorption studies can be used as early indicators of the suitability of a material for implantation.

4.405.2.1.1. *Characterizing protein adsorption* in vitro

An array of different *in vitro* studies have been carried out that have characterized protein adsorption onto many different types of biomaterials *in vitro*, in both competitive complex mixtures, usually whole serum, which contains all the proteins,[12–14] or noncompetitive solutions of single or 'spiked' controlled mixtures of specific individual proteins, to form a known solution of specific proteins.[15,16] The *in vitro* analysis of protein deposition onto a surface under a given set of parameters can be achieved qualitatively or quantitatively, and an array of techniques is available to provide information on protein adsorption onto a surface, the stability of that protein on the surface, the probability of protein displacement by other proteins (Vroman effect), the conformation of the protein, and the availability of receptor sites for cell interactions on the surface.

The quantification of the amount of protein adsorbed and the depth of an adsorbed protein layer can be achieved by such methods as scanning angle reflectometry,[17–19] attenuated total reflectance Fourier transform infrared spectroscopy,[14] and quartz crystal microbalance.[20] Other common methods of characterizing the type of protein adsorbed onto a surface can include desorption of proteins from a surface using sodium dodecyl sulphate and characterization of the eluted protein via western blotting. Western blotting and any immunohistochemistry techniques employed to characterize a protein layer allow investigations into the different types of protein adsorbed onto a surface, distribution of a specific protein on a test substrate, and conformational integrity of the protein on the surface and, therefore, its ability to induce specific cellular responses. Such studies have provided information regarding the relationship between vitronectin, fibronectin, and fibrinogen and their role in FBGC formation, an indicator of the inflammatory response and a phenomenon that has been used to develop some of the most widely used *in vitro* models (see **Section 4.405.2.2.4.2**). Therefore, based upon these known relationships, it is possible to use protein adsorption studies as early indicators of the inflammatory potential of a given material.

4.405.2.2. Cellular Indicators in the Inflammatory Response

The initial host response to any implantation could possibly be controlled by protein systems circulating within the blood and in the platelets.[21] The interaction of these systems with the site of injury/implantation results in the formation of a temporary, stabilizing matrix, which is rich in cell signaling factors and proteins that dictate subsequent cellular responses. Due to the process of implantation, the subsequent cellular response is to defend, in the form of the inflammatory response, as the body tries to restore and then maintain homeostasis by reacting to the presence of the foreign body, that is, the biomaterial or implanted device. This is achieved either by integration into a functional tissue or by encapsulation of the device, thus effectively sealing it off from the rest of the body by the formation of a fibrous tissue capsule. The next section of the chapter describes the cellular elements that play a role in determining if a material is integrated, passivated, isolated, or subjected to continuous inflammation defense, the latter ultimately requiring explantation, and thus determining the suitability and efficiency of any implanted device.

Inflammatory responses are often divided into two major phases or types – acute and chronic.[22,23] Acute inflammation is characterized by the presence of polymorphonuclear leukocytes (PMN or PML), predominantly neutrophils and monocytes/macrophages, but can possibly also involve eosinophils and basophils; the term PMN refers to the multilobed morphology of the cell nucleus. Neutrophils, eosinophils, and basophils are collectively also called granulocytes and are characterized by the presence of large numbers of specific and azurophilic granules as well as vesicles in their cytoplasm. If the granule contents are released extracellularly through the processes of 'frustrated' phagocytosis and/or exocytosis, the potent antimicrobial and tissue remodeling molecules such as lysozyme, proteolytic enzymes, and neutral proteases are deposited nonspecifically into the host tissue and stimulate an increase in the magnitude and duration of the acute inflammation. Phagocytosis and frustrated phagocytosis are phenomena associated with the immune cell response to invading material, which is normally microbiological. With respect to biomaterials, this response is conducted by neutrophils and macrophages that are trying to deal with the presence of an implant by killing it and digesting it and thus eliminating the foreign body. Thus, the severity of this process is a good key indicator of the biocompatibility of the implanted substrate. The acute inflammatory response is then followed by the chronic inflammatory response, characterized by the continued and persistent presence of macrophages. The degree of chronic inflammation, ultimately driven by the provisional matrix, will either result in integration of the material and the formation of a fibrous capsule around the material or its rejection by the host. Many models depicting the different stages of inflammation *in vitro* have been developed for screening materials prior to implantation and rely heavily on the thorough characterization of selected cell responses to a material in a controlled environment.

4.405.2.2.1. *Neutrophil material interactions* in vitro

Neutrophils are the most abundant leukocytes in humans and make up ~60% of all white blood cells. At the site of implantation, neutrophils move from the blood, through the blood vessel wall, to the site of injury by the process known as diapedesis or leukocyte extravasation; this phenomenon is driven by the release of chemotactic cues at the site of implantation due to tissue damage and bleeding, and the formation of the provisional matrix. The blood clots and the provisional matrix contain a milieu rich in activated platelets, which release TGF-β (transforming growth factor-β), PDGF (platelet-derived growth factor), CXCL4 (platelet factor 4), LTB4 (leukotriene 4), and IL-1 (interleukin-1),[10] all of which are chemotactic to both neutrophils and monocytes. Neutrophils are the quickest to respond chemotactically to the presence of these molecules and arrive at the site first; the presence of inflammatory cytokines in the local environment also promotes vasodilation, thus facilitating the migration of the inflammatory cells from the blood to the site of implantation. The levels of signaling molecules released into the supernatant by the blood–biomaterial interaction can be quantified *in vitro*, using ELISA (enzyme linked immunosorbent assays) or western blotting techniques. Due to the significance of these chemokines and the intense research activity in the area of inflammation in general, commercial kits for the accurate quantification of these substances are readily available, and the measurements obtained can be used as an early characterization of the level of acute inflammation due to the presence of these chemokines over a sustained period. Higher levels of signaling will result in a greater number of neutrophils being recruited to the site. Due to their predominance and small size, ~10 μm in diameter, neutrophils are the first PMN to reach a site of injury, and for this reason are often studied as markers of acute inflammation. Neutrophils are phagocytes and upon activation can release a series of factors that not only further stimulate neutrophil migration to the site but also act as chemoattractants for monocytes and other cell types. The *in vitro* models aimed at quantifying neutrophil responses to biomaterials often involve quantifying the amount of reactive species produced by the neutrophils when cultured in direct contact with specified test materials, and the quantification of cytokine and chemokine release, which can activate other cell types. As part of the process of phagocytosis, neutrophils undergo a respiratory burst, which is an oxygen-dependent reaction, resulting in the formation of a number of high energy unstable reactive oxygen species (ROS). These play a direct role in defense and the innate nonspecific host response. Neutrophils take up molecular oxygen, which reacts with membrane-bound NADPH oxidase, and this results in the formation of superoxide radicals. These radicals are instantaneously converted to hydrogen peroxide (H_2O_2) by the enzyme SOD (superoxide dismutase). H_2O_2 is a highly reactive compound and reacts with oxygen radicals or trace elements in the local environment to form hydroxyl radicals. In turn myeloperoxidase (MPO) reacts with H_2O_2 to form hypochlorous acid, an agent involved in the destruction of bacteria. As this process is well documented, elements associated with the respiratory burst and formation of ROS are extensively used in *in vitro* studies to assess the levels of activation induced in neutrophils by a test substrate or a microorganism.

To accurately assess neutrophil responses to biomaterials, methods of isolation of neutrophils should minimize induced activation of these cells prior to contact with the test substrate. Therefore, two main models exist for assessing neutrophil activation in response to a stimulus *in vitro*; one uses direct contact with whole blood[24–27] and the other involves culturing the test substrate with purified neutrophils.[28] The preferred source of cells for both models is human adult whole blood donated by healthy volunteers; this is a common source of supply for all human-derived leukocyte cells used in *in vitro* models due to the ease of access and minimal invasion required to derive specific cell types. The process generally involves collection of a volume of blood by venous puncture and heparinization or similar anticoagulation treatment, optional layering on to dextrose to clump and sediment red blood cells, followed by layering of blood onto a density centrifugation medium, and finally, centrifugation. From this point, the protocol becomes more specific for neutrophil activation and requires removal of the sedimented pellet containing red blood cells and neutrophils, lysis of the red blood cells, and further washing and centrifugation steps to separate out an intact and viable neutrophil population.

Culturing with whole blood allows neutrophil activation to be studied with many of the plasma proteins still present, and many of the inflammatory pathways still intact, such as platelet interactions, especially if samples are citrated rather than heparinized in anticoagulation. This is a situation that can be argued to be closer to the *in vivo* environment than a purified single cell type of isolated neutrophils. Data collected from this model usually demonstrate enhanced neutrophil activation due to the presence of the provisional matrix and factors that add to the indirect activation of cells. While, at least in theory, this approach seems extremely relevant and therefore the optimum situation, minimal control over cell number and individual cell type is afforded in these models; as a result, specific relationships between selected material variables and a specific cell response are not easily determined; moreover, reproducibility can also be an issue due to the lack of control over the starting cellular components. Models that use purified neutrophils allow control and consistent reproduction with respect to initial cell number and starting cell populations, thus eliminating not only the indirect interactions between other leukocytes and test substrate, but also the activation of blood proteins that can themselves have an activating effect on leukocytes. This method allows the direct investigation of the role of neutrophil activation, the release of factors associated with the activation, and the development of models and hypothesis relating to material-induced neutrophil activation, and subsequent inflammatory cell responses. In addition, desired levels of neutrophil activation can be induced in the cells prior to and during culture to mimic increased neutrophil activation due to signaling from the provisional matrix. Substances such as PMA[29] or fMLP[30] are often used *in vitro* to induce neutrophil activation, either to act as a positive control in an assay or to validate the *in vitro* models. An important point to note is that, prior to scientific data collection, time must be taken to validate the use of any *in vitro* model; therefore, investigations into the correct type of model and data required must be carried out before data collection. Regardless of the model used, that is, whole blood compared

to purified cells, methods of characterizing the neutrophil response *in vitro* are the same.

4.405.2.2.2. ROS production and measurements in vitro

While it is possible to identify neutrophil adhesion to a substrate via their distinct (PMN) morphological characteristics, the information obtained from these types of basic adhesion studies is subjective and limited in terms of defining the inflammatory potential of a material. These techniques have concentrated on profiling the activation level of neutrophils induced by test substrates and are based on identification and quantification of the products associated with the metabolic respiratory bursts, which is reflective of neutrophil activation, and chemokine and cytokine release. Chemiluminescence (CL) has emerged as a technique for defining the activation state of neutrophils,[31,32] as CL is a natural product of oxygenation activity, that is, neutrophil respiratory burst is directly related to activity. In inflammation, the respiratory bursts refer to the release of ROS such as superoxide and hydrogen peroxide, which are associated with phagocytosis, a characteristic of neutrophils and monocytes as they try to digest foreign body particles. Therefore, the greater the driving force of a material to induce phagocytosis by neutrophils, the greater the stimulation and level of neutrophil activation, as quantified by the release of ROS and the increase in CL. Kits for such assays are commercially available, and these often rely on the addition of luminol[33,34] to increase the sensitivity of the CL and can, therefore, detect even small changes in neutrophil activation.

NADPH oxidase is a membrane-bound enzyme found on phagosomes in neutrophils. NADPH is only activated during the respiratory burst and therefore its production is also used as a direct measure of neutrophil activity.[35–37] NADPH oxidase generates superoxide (ROS), and its activity can also be measured by luminescence in addition to sensitive, commercially available ELISA assays. Another factor that is often measured, due to its role in the neutrophil respiratory burst, is MPO,[38,39] which is found in the granules contained within the neutrophil cytoplasm. Upon activation, MPO produces hydrogen peroxide, H_2O_2, another ROS involved in phagocytosis. MPO production can also be measured via ELISA; therefore quantifying the amount of MPO or NADPH associated with a specific biomaterial and comparing their relative production to subsequent inflammatory responses is a valuable approach. Western blotting techniques can also be used to determine the presence of the enzymes involved in the production of ROS in a semiquantitative or quantitative manner, if electrophoresis is combined with image analysis. Due to the availability of antibodies against MPO and NADPH, immunohistochemistry can also be used as a tool to determine the homogenity of MPO and NADPH, and their production and release in selected areas of the biomaterials and associated cell clusters.

In addition to measurements of ROS production associated with phagocytosis, it is also possible to quantify the release of lysozyme held within the neutrophil granules. Lysozyme production is an oxygen-independent mechanism; its release is known to enhance polymer degradation *in vivo*[32] and is a phenomenon associated with frustrated phagocytosis.[40] Frustrated phagocytosis occurs when the size and dimensions of the materials and associated products, that is, wear debris, are too big for the cells to engulf, internalize, and therefore phagocytose completely, resulting in the cell releasing its hydrolytic enzymes contained within the primary and secondary granules, that is, lysozyme, extracellularly.

4.405.2.2.3. Cytokine production by neutrophils

Another common technique used as an indicator of neutrophil activation, both *in vivo* and *in vitro*, is the measurement of the production and release of cytokines that are chemotactic to PMNs, monocytes, and lymphocytes. The latter cell types are also associated with the second phase of inflammation, that is, chronic inflammation. Neutrophils play a role in the maintenance and severity of an inflammatory response by the release of factors such as IL-10 and IL-12, both of which are chemotactic to both neutrophils and other inflammatory cells, and play a role in determining the longevity of the inflammatory response. This is discussed further in **Section 4.405.2.2.4.3**.

4.405.2.2.4. In vitro monocyte material interactions

Previous sections of this chapter have concentrated on the elements of inflammation associated with acute inflammation, that is, plasma protein adsorption, clot formation, platelet activation, and neutrophil adhesion and activation. The process of acute inflammation normally resolves within 1 week. The level of signaling associated with these events and then further induction over and above the levels associated with the process of implantation and normal wound healing, that is, solely material-induced inflammatory responses, will determine the intensity of the second phase of inflammation, that is, the chronic inflammatory response.[41] The activation of the chronic inflammatory response is characterized by the presence of monocytes and lymphocytes, or mononuclear cells, at the site of implantation.[42–45] For biocompatible materials, the chronic inflammatory response, traditionally, lasts no longer than 2 weeks and is followed by the production of fibrous tissue into which macrophages are embedded, and fibroblasts and other cell types invade, thus resulting in neovascularization of the healing tissue. The specific type of tissue depends on the local environment, that is, osteoblasts or endothelial cells, to name but a few, dependent on the specific application of the implant, that is, bone forming or vascular replacement, and stimuli from the implanted material. It is widely accepted that monocytes and macrophages are the major cellular components that determine the severity and duration of the chronic inflammatory response; therefore, much attention has been paid to developing the correct *in vitro* models for assessing macrophage–material responses, both *in vivo* and *in vitro*. The next sections of the chapter focus on the methods of isolation, purification, and characterization prior to cell seeding onto an implant, and subsequent methods of analysis and markers of interest. The role of lymphocytes in propagating the chronic inflammatory response and the use of coculture models in *in vitro* leukocyte–material interaction models is also discussed.

4.405.2.2.4.1. Monocyte isolation from human whole blood

As stated previously, monocyte/macrophage material interactions have been the focus of much research already, which has been well disseminated and widely published. The available literature indicates that the sources of monocytes can be varied and range from commercially available cell suspensions to

genetically altered, and primary-derived cells. The focus of this chapter is to define cellular responses to biomaterials and the development of *in vitro* models, and in this context, a preferred source or the cell of choice for further discussion is the primary isolated monocyte/macrophage from human whole blood.

As with neutrophil isolation, a major consideration for any isolation technique is to minimize cellular activation in the process of isolation. It is also important to know the starting level of activation for a population of cells at time = 0 as they come into contact with the material for investigation. Therefore, when the cells come in contact with the material, their level of activation is known, and the material-induced cellular responses can be accurately measured and reproduced. Methods of isolation involve venous blood collection, followed by treatment with heparin or another anticoagulation agent, layering onto a density centrifugation medium, centrifugation, and collection of the cloudy PBMC layer.[46] Flow cytometry (FACS) analysis studies have proved that this layer is rich in both lymphocytes (T and B) and monocytes, and the cells collected from this layer are analyzed for their expression of CD3 (T lymphocyte), CD19 (B lymphocyte), CD14 (monocyte marker), and CD45 (generic leukocyte antigen used to label the whole population), and the relative percentage of lymphocytes to monocytes in these cell populations is routinely characterized before experimentation (**Figure 1**). Further isolation steps can be employed to purify either a population of lymphocytes or monocytes from this cell population. Traditionally, simple adherence steps have been used, and these are still routinely being used, to separate the monocytes from lymphocytes, based on the fact that cultured monocytes will adhere to a substrate. Standard tissue culture polystyrene works efficiently, while lymphocytes do not adhere and thus remain in the supernatant. However, subsequent studies have proven that this is not the case and that the monocyte population is contaminated with lymphocytes (**Figure 2**); so the use of adhesion as the sole purification step should be limited and preferably supported with subsequent, more efficient techniques to further purify these cells. Additionally, this technique has limited relevance in studies that are designed to evaluate specific cell–material interactions, as, to do this, one must have control of the starting components and not rely on the efficiency of adherence as a method of determining and purifying the

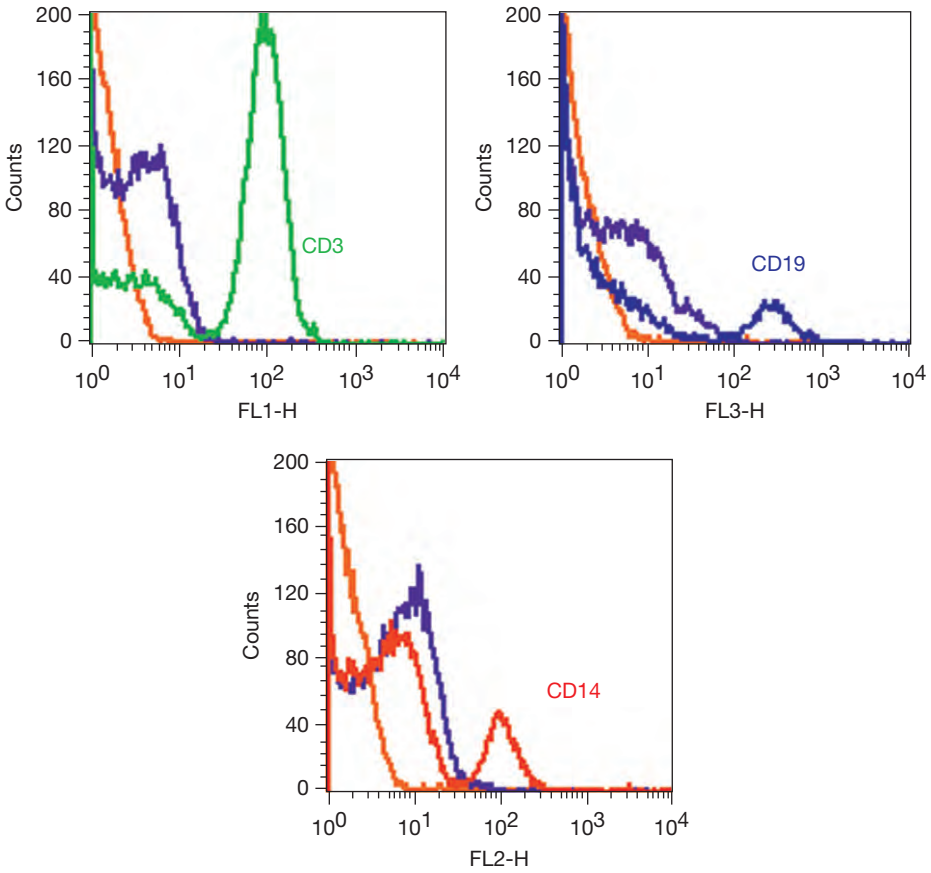

Figure 1 An example of flow cytometry analysis (FACS) of cloudy peripheral blood mononuclear cell (PBMNC) layer obtained from monocyte isolation protocol described in **Section 4.405.2.2.4.1**. Cells were labeled with fluorescein isothiocyanate (FITC)-conjugated CD3 (T cell marker), Cy-5-conjugated CD19 (B cell marker), and PE-conjugated CD14 (monocyte marker). FITC, PE, and Cy-5 are all fluorescent tags that allow detection and quantification of expression by the flow cytometer. Results show that the cloudy layer prior to magnetic purification is a mix of T and B lymphocytes and monocytes; therefore this cell population is not suitable for models focusing on, specific interactions between monocytes and materials, but can be used for coculture models, **Section 4.405.2.2.5**. Purple lines on the histograms are isotype controls (levels of inherent nonspecific staining due to the staining procedure, therefore levels of positive expression are taken above these levels only). The orange lines on all three graphs are measures of the associated autofluorescence associated with the cell population and are used as a negative control and to set the threshold limits of detection by the FACS machine.

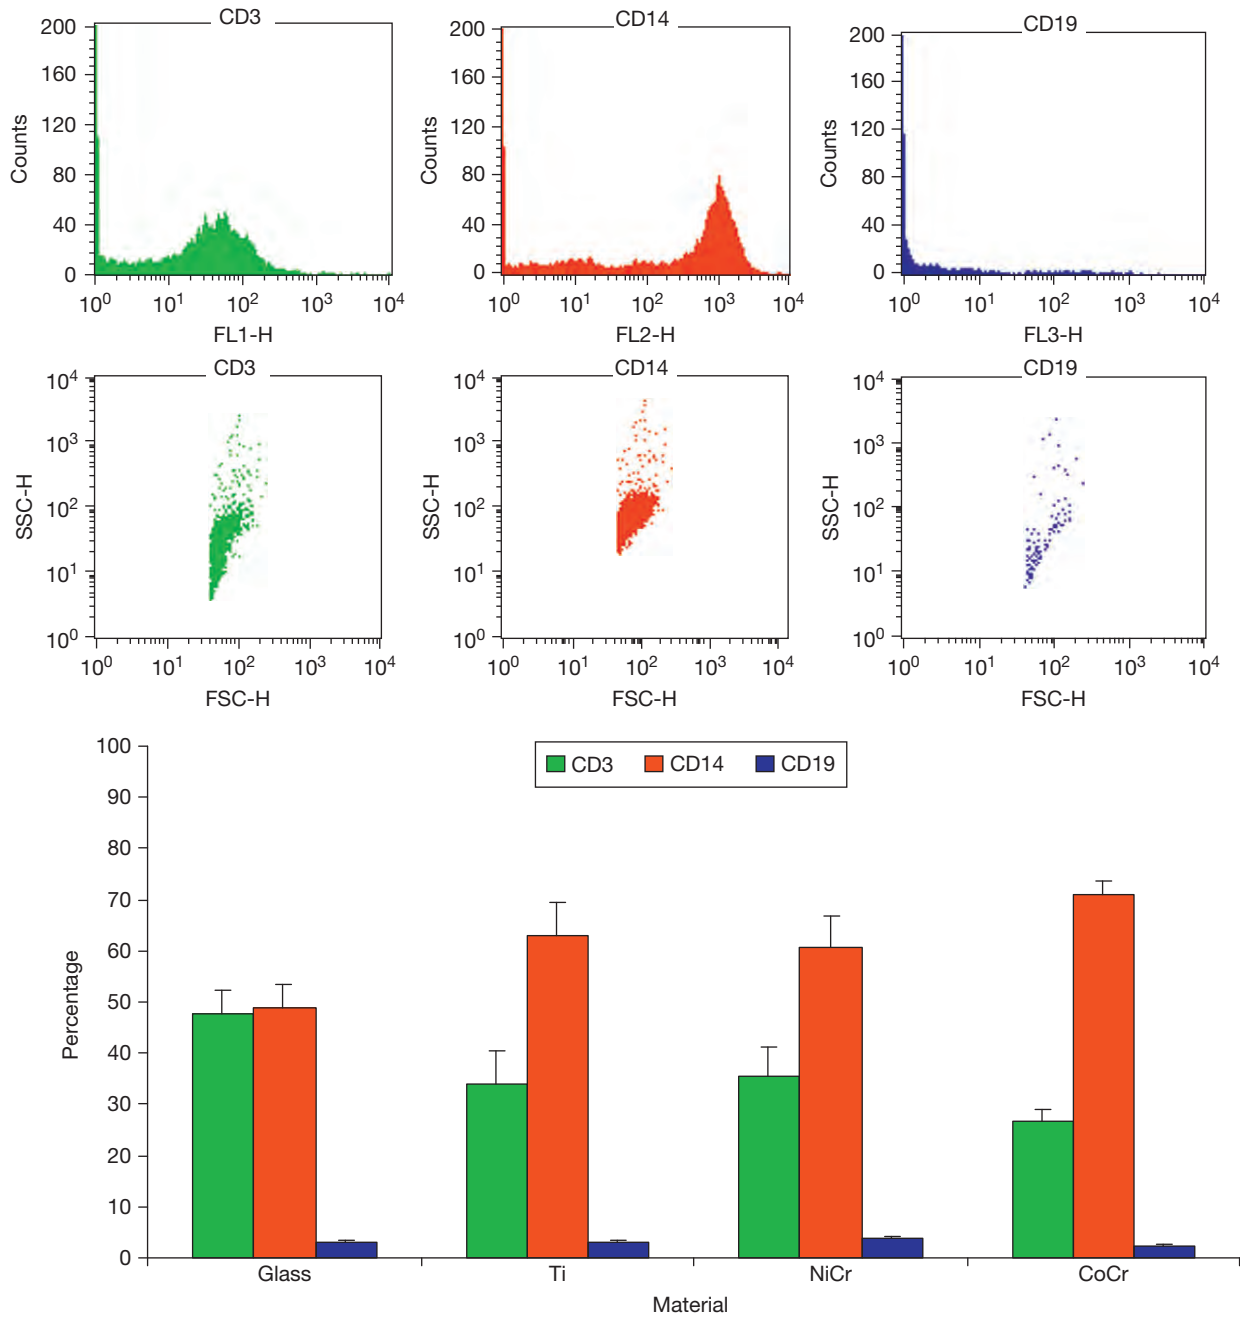

Figure 2 An example of analysis of adherent cell populations to test substrates. Both T lymphocytes and monocytes adhere to all test substrates, but B cells remain in the supernatant. This method can be used as a comparison between materials in terms of levels of supported T lymphocyte and monocyte adhesion as an indicator of a sustained inflammatory response. These results also prove that T lymphocytes adhere to substrates; therefore isolation of monocytes from lymphocytes cannot be ascertained via traditional adherence techniques, **Section 4.405.2.2.4.1**. Reproduced from Muna Khassaf, M. Ph.D. Thesis, Liverpool University, Liverpool, 2004.

starting cell population. This, however, does not suggest that methods of quantifying cell adherence to a material are of no relevance; in fact, it is quite the opposite, and these types of investigations are discussed in more detail in **Section 4.405.2.2.5**, which focuses on the use of monocyte/lymphocyte coculture models *in vitro*.

Further purification and enrichment of either a monocyte or a lymphocyte population from the PBMNC layer can be achieved by using commercially available magnetic bead systems. These systems contain nonphagocytosable magnetic beads, the nonphagocytosable element being important to minimize activation associated with cell/bead interactions. The beads are coated with specific antibodies that target a specific cell type or receptor, that is, CD3, CD19, or CD14, to name but a few. The beads bind to the target cell and can be isolated by positive or negative selection. Positive selection

involves the binding of the beads to the cells of interest, that is, CD14 beads bind to monocytes to positively select the monocyte population for further culture. After binding, the cells are placed in a magnetic field and separated from the nontagged cells by the magnetic field that draws the labeled cells to the side of the tube, immobilizing them in the magnetic field. The untagged cells can then be removed by simply decanting the supernatant by pouring, as the technique relies on the fact that the tagged cells will be pulled to the side of the vessel and held there while within the magnetic field. To culture positively tagged cells requires the inclusion of a detachment protocol, which is also usually a component of the kit, and is designed to detach the beads from the tagged cells with minimal induced activation. An alternative method of isolation that can reduce cell activation and is particularly useful and relevant for monocytes is negative selection. This technique involves using a combination of beads coated with CD3 and CD19 to remove the T and B lymphocyte populations from the PBMNC layer, thus leaving the CD14-rich monocyte layer untagged so that the two fractions can be easily separated when in contact with a magnetic field. Successful implementation of this protocol can result in a >98% pure monocyte cell population.

Highly purified single cell-type solutions are required to carry out specific research projects aimed at understanding how specific material characteristics induce specific changes and levels of activity in certain cell types and their resultant effects, in terms of inflammatory cytokine production and cell viability, and formation of other, more mature, cell types. This single cell-type information can be used as a set of indicators for the biocompatible nature of a material, that is, FBGC. Furthermore, to evaluate the interaction of lymphocytes and monocytes and to study the propagation of material-induced inflammation, simple steps can be taken to eliminate one of the cell types, that is, either T or B lymphocytes from the cell solution, subsequently characterizing the change in cellular response in terms of cytokine production, activation, and adherence of the cell populations. Such studies have highlighted the specific relationship between T lymphocytes and monocytes, the effects of juxtacrine and paracrine signaling on cellular responses, and have demonstrated how these interactions can be used to further investigate biomaterial-induced reactions *in vitro*. This is discussed further in **Section 4.405.2.2.5**.

4.405.2.2.4.2. Characterizing monocyte adhesion in vitro, *indicators of FBGC formation*

As stated earlier, cells respond to the adsorbed protein layer and the provisional matrix. The abundance of ligands, in this case, specific peptide sequences associated with the adsorption of conformationally correct proteins and activated platelets, dictates how the cell interacts with the surface and thus, with subsequent cell signaling. Therefore, levels of cell activation, and, more specifically, monocyte activation can be determined after a short time period by characterizing how monocytes bind and which specific integrins are expressed. Many different studies have been conducted using purified human monocytes from blood with material substrates in direct contact and evaluated the feasibility of the use of expression of integrins to indicate the ability of a material to induce FBGC formation,[47–49] a distinct marker of chronic inflammation.

Initial monocyte/macrophage adhesion occurs through binding of the β_2 integrins, specifically, MAC-1, CD11b/CD18 complexes, to fibronectin, fibrinogen, and the complement proteins. Therefore, the nature of the previously described provisional matrix dictates the levels and type of integrin binding and the subsequent monocyte responses. This relationship between monocyte adhesion and complement proteins provides further evidence for protein adsorption and inflammatory cells being a part of the continuous cascade of events that can be used to develop *in vitro* models and provide standardized tests.

These studies have demonstrated that β_1 integrin is the major indicator of FBGC formation. It is not present to the same extent on immature adherent macrophages, but its expression is increased with activation and fusion of macrophages into FBGC. The roles of β_2, $\alpha_x\beta_2$, $\alpha_5\beta_1$, $\alpha_2\beta_1$, and $\alpha_3\beta_1$ integrins in determining the severity of inflammatory reactions has also been highlighted. *In vitro* integrin expression can be determined and characterized using a number of methods. Polymerase chain reaction, PCR, and real time PCR can be used to measure mRNA expression and changes in mRNA regulation, and they can be determined as a function of increasing time in culture. Differential expression of the integrins of interest can be used to classify specific integrin expression profiles and relate these to cytokine production and levels of activation. Immunohistochemistry, immunogold labeling, and SEM can be used to visualize the formation and distribution of specific integrins on cell membranes, and their presence and distribution mapped to direct spatial cues on the material surface. These types of studies incorporate specific antibodies to a targeted integrin and facilitate data collection on the distribution of specific integrins and its relation to cell function. In addition, these studies provide valuable information on the specific relationships between integrins that can either enhance or inhibit specific aspects of the monocyte response. Using a slightly different antibody-specific surface receptor binding approach, it is also possible to inhibit the action of integrins by blocking the target binding sites on a material. This enables a more in-depth study of either the role of that integrin, or the effects of inhibition of the signaling induced by integrin binding to a surface. This kind of research provides an approach to producing surfaces that minimize inflammatory responses by dictating how the cell binds to the material.[50,51]

Integrin signaling profiles can also be used to elucidate the role of monocytes in prolonging the complement response to an implanted material and in further propagating the inflammatory response. These models can be used as early indicators of the likely severity of the inflammatory response by correlating integrin expression levels with the propensity of the cells to fuse and form FBGCs, as discussed in **Section 4.405.2.2.6**.

4.405.2.2.4.3. Inflammatory cell recruitment: Chemokines and cytokine production

The circulating inflammatory cells respond to stimuli and cues released by the formation of the provisional matrix and the activation of protein systems within the blood. During direct contact in the first phase of localization at a site of injury, invading neutrophils and monocytes adhere to specific ligands and peptides on the surrounding surfaces and this, in turn,

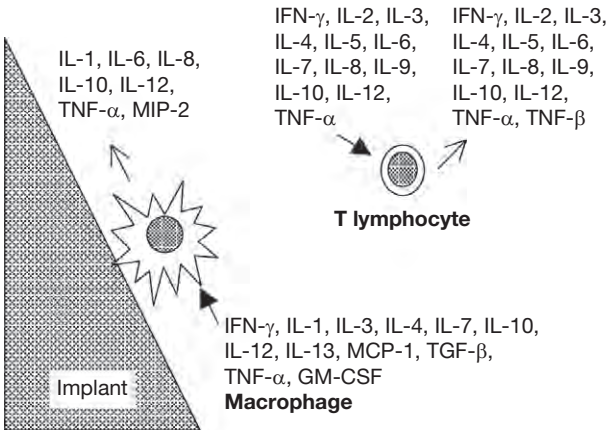

Figure 3 A simplified representation of some of the cytokines and growth factors potentially involved in the inflammatory responses to an implant. IL-1 to IL-13, interleukin-1 to -13; IFN-γ, interferon-γ; G, M, and GM-CSF, granulocyte, macrophage, granulocyte and macrophage colony stimulating factors; TNF-α, tumor necrosis factor-α; TGF-β, transforming growth factor-β; MCP-1, monocyte chemotactic protein-1. Adapted from Rhodes, N. P.; Hunt, J. A.; Williams, D. F. *J. Biomed. Mater. Res.* **1997**, *37*, 481–488.

initiates a level of cellular activity within the inflammatory cells, which results in the production of either pro- or anti-inflammatory cytokines (Figure 3). Chemokines are a family of small cytokines, and as their name suggests, are so called due to their chemotactic effects. Chemokines are often released by a cell upon stimulation by another cytokine: in the case of inflammatory chemokines, from inflammatory cells such as monocytes and neutrophils. Thus, for example, these cells can be stimulated by IL-1 or another cytokine to release chemokines that will recruit other inflammatory cells to the area. There are four main classes of chemokines: CC, CXC, C, and CX_3C, and their classification is dependent on the position of the first two cysteine residues. CC chemokines like MCP-1 (monocyte chemoattractant protein-1) or CCL2 are chemoattractants for monocytes and T cells. CXC chemokines like IL-8 are chemoattractants for neutrophils and some lymphocytes through interactions with CXCR1 and CXCR2 receptors. This subtopic rapidly becomes complex and is filled with detail. For the chemokines to be effective, their binding to a specific receptor on a cell surface is required, that is, CC chemokines bind to CC receptors, CCR and CXC chemokines bind to CXC receptors, CXCR and CX3C chemokines bind to CX3C receptors, CX3CR. Levels of binding dictate intracellular cell signaling, and methods such as traditional ELISA and western blotting methods have been developed that measure not only the levels of chemokine in the supernatant, but also the availability of chemokine receptors on a cell surface when cultured in contact with certain stimuli such as biomaterials.[28,52] This can be achieved using any technique that relies on specific binding of an antibody to its receptor and so can include immunohistochemistry, preferably followed up by quantitative histomorphometry using image analysis, western blotting, FACS, or other quantitative colorimetric assays. Once again, as with integrin binding studies, the knowledge of specific chemokine/receptor interactions has also been used as a tool for developing *in vitro* models that inhibit the binding of selected chemokines by blocking the receptor with an antibody, thus facilitating research into the mechanism of how specific chemokines are responsible for cellular behavior, in both a single and synergistic fashion.[53–56] *In vitro* models have also been used to develop early screening tests that relate the expression of receptors to inflammatory host response outcomes. These studies are extremely relevant when dealing with particulate material and wear debris, and these types of particles are often associated with aseptic loosening of orthopaedic implants as they are localized in the surrounding host tissues. When leukocytes are cultured in direct contact with particulate material, the cells can be analyzed dynamically while in contact with the stimulus to investigate the kinetics of the reaction with increasing time. In addition to providing extremely valuable information on interactions, this research approach is advantageous as it involves minimal loss of activity and cleaving of receptor sites due to processing. These models are discussed further in Section 4.405.2.2.3.

Monocytes/macrophages are the dominant cellular element in the propagation of the inflammatory response, and there is significant scope and potential in research that focuses on utilizing and understanding the roles of this cell type. Thus, for example, determining which chemokines are responsible for inducing monocyte recruitment to a site of implantation and also understanding the effects of these chemokines on subsequent cytokine release and their role in the inflammatory response raises a set of questions, the answers to which could be used to directly control the later phases of inflammation. *In vitro* models that use both primary-derived monocytes from human whole blood and immortalized cell lines with controlled levels of activity have identified an array of proinflammatory and anti-inflammatory cytokines that have specific effects on monocyte and leukocyte recruitment and levels of their activation and induced phagocytosis, that is, proinflammatory, IL-1β, VEGF, IL-8, MCP-1, MIP-1α, tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), granulocyte and macrophage colony stimulating factors (GM-CSF), RANTES,[57–59] and anti-inflammatory, IL-4, IL-6, IL-10, IL-11, IL-13, and IL-1 receptor antagonist.[60] Profiling cytokine release, by measuring the amount of cytokines released into the supernatant, has become a common method for assessing the inflammatory and biocompatible properties of an array of test materials, and commercially available kits are now readily accessible that can quantify single or multiple cytokines in one assay, thus allowing direct comparisons of cytokine amounts within a given culture system. The collective data from these studies are still variable and therefore hard to use directly as the sole defining indicators of the biocompatibility of a test material. The variability in data is mostly the result of differences in protocol and differences in experimental parameters. Important variables include differences in starting cell populations, that is, immortalized monocyte cell lines compared to primary-derived monocytes from blood, levels of inherently induced activation either by the process of isolation or by chemical reagents used to stimulate the cells prior to contact with the test materials, and fundamental variables such as different types of medium and serum used in the *in vitro* cell models. Raising experimental variables as an issue in this area of research highlights and exemplifies the

importance of defining and standardizing (where possible) the experimental approach more broadly. The experimental parameters listed earlier highlight just a few of the experimental variables that should be standardized if efficient, reproducible, and translatable *in vitro* models that can be used to predict and define *in vivo* inflammatory responses are to be developed,. It is a complex issue, as levels of inflammation are also controlled by cell–cell signaling, a factor that is influenced not only by the test material, but also by the number and type of cells in the model. Therefore, prior to the introduction of a test material, the effect of the *in vitro* environment on a cellular response should be characterized, and appropriate controls included in any *in vitro* model, that is, profile the cytokine release of an optimized cell number of monocytes cultured in contact with the same area of TCPS as test substrates, with the inclusion of positive controls such as activated monocytes as reference points to normalize or contextualize material-induced data.

Derivation of standardized *in vitro* models will help dissect out important material properties. Thus, key current research questions such as how surface chemistry can control monocyte behavior and ultimately dictate the biocompatibility of a material could be systematically determined. Schutte *et al.*[59] highlighted that there are two opposing schools of thought regarding material chemistry-induced monocyte activation. First, the theory investigated and proposed by Anderson and coworkers[61] stipulates that material chemistry can control cytokine production and subsequent foreign body reactions, while Ratner *et al.* believe that data obtained from other studies[62,63] provide evidence that the inflammatory response to materials with the same surface topography and mass dimensions is the same, regardless of changes in the surface chemistry.

In vitro models that combine purified cell populations in a controlled system can be used to determine if changes in surface chemistry alone can affect monocyte adhesion and subsequent levels of activity, based upon successful data collection from this type of approach. Biomaterials with specific surface chemistries and associated properties, that is, hydrophilicity, could be produced that may be able to induce a controlled level of inflammation and use the associated cytokine profiles to control the induction of other cell subsets. This point is discussed further in **Section 4.405.2.2.5**. The ultimate validation of these hypotheses would come from implantation of materials that can induce specific responses predicted *in vitro*; these should be correlated with the *in vivo* outcome, for example, comparison of one material predicted to be passive and inducing minimal FBGC formation with another one that indicated a strong FBGC reaction, and including characterization of the host response responsible for producing these differences *in vivo*. Full dissemination of the inflammatory and biocompatible nature of a material needs to extend beyond just short-term wound healing and address the effects of the induced inflammatory response on the surrounding environment, and then progress to systemic responses in terms of specific tissue formation and cellular functionality, which is discussed in **Section 4.405.2.2.4**.

4.405.2.2.5. Monocyte/lymphocyte coculture models

As previously discussed, data obtained from *in vitro* models have been extremely useful in terms of identifying specific cellular interactions with biomaterials and subsequent cytokine release and have been used as generic indicators of the propagation and severity of an inflammatory response.[43,64,65] Thus far, many of the *in vitro* models discussed have focused on single monocyte cultures, but realistically, *in vivo*, monocytes interact with and are affected by a range of other cell subsets and systems. Examples include plasma proteins and mast cells that react with fibronectin and release histamine, which in turn recruits more monocytes to the site in addition to releasing IL-4 and IL-13, all of these being known to be essential for monocyte fusion into FBGC. One of the major cell types that plays a role in modulating and/or enhancing a monocyte-driven inflammatory response is the lymphocyte, more specifically, the T lymphocyte. Different subpopulations of T lymphocytes are activated and have been characterized depending on biological cues derived from the provisional matrix and the adherent monocytes and neutrophils.[66,67] CD8 + ve T lymphocytes are cytotoxic T lymphocytes and secrete products that are designed to destroy specifically targeted (by antigen) cells or molecules to which they have bound. CD4 + ve T lymphocytes bind to MHC class II-presenting cells, commonly, activated macrophages and dendritic cells, and produce lymphokines, which are chemotactic to other inflammatory cells. CD4 cells also bind to MHC class II-presenting B cells and further activate them to produce antibodies as part of the humoral response. CD4 +ve T lymphocytes can be further classified into Th1 or Th2, depending on the production of lymphokines. Th1 lymphocytes are characterized by the production of IL-2, IFN-γ, and TNF-β, resulting in further macrophage activation, while Th2 lymphocytes are involved in the production of anti-inflammatory cytokines IL-4 and IL-10, and the propagation of tissue remodeling and acceptance of a material/transplant. When assessing the response induced by a material *in vitro*, it has become apparent that, when cultured in contact with monocytes and lymphocytes as described in **Section 4.405.2.2.4.1**, the lymphocytes adhere in association with the monocytes and not to the material itself.[68,69] The lymphocytes and monocytes use positive feedback mechanisms upon activation, and the presence of lymphocytes increases monocyte adherence to a material and its subsequent fusion to form FBGC; the presence of the monocytes stimulates lymphocyte proliferation and the production of IL-2 and IFN-γ at the material interface. Based upon the sequence of events discussed in this chapter, it is reasonable to suggest that the initial levels of activity are induced by the material itself, or at the very least, the formation of the provisional matrix; the matrix, however, can be controlled by an array of material factors including chemistry, roughness, shape, surface energy, micro- and nanotopography, to name but a few.

Direct material-induced T cell activation has been studied *in vitro* and it has been found that certain polymers can be presented to T cells as mitogens (polymer particles that have been opsonized by specific plasma proteins), which, in turn, could go on to stimulate T cell responses and, therefore, be used as *in vitro* models for assessing the cytotoxic nature of a material.[70] Stimulation by mitogens *in vitro* can be assessed by the expression of CD69 (an early T cell activation marker) and CD25 (IL-2 receptor), and the production of previously

mentioned cytokines. This can be achieved using traditional techniques such as immunohistochemistry or FACS, ELISA, or by developing commercially available quantitative proteomic arrays. The general consensus from these studies, which have isolated T cells and assessed material-induced levels of activation, is that, to accurately assess material-induced inflammatory responses, cocultures of monocytes and lymphocytes are required. Nevertheless, these studies have been invaluable in identifying specific markers expressed by T cells whose levels can be used to measure levels of activation and subsequent cytokine production, and assess their effect on the inflammatory response.

Studies by MacEwam *et al.*[69] have also investigated the role of juxtacrine (cell–cell contact) and paracrine (cells separated by a membrane or matrix) signaling in the relationship between monocytes and lymphocytes that are in contact with biomaterials, and have found that while both types of cell signaling enhanced cellular responses in terms of cytokine production, paracrine signaling, *in vitro*, gave the greatest response in terms of cytokine production and associated monocyte activation. Therefore, one could summarize that the development of these models *in vitro* could lead to more relevant *in vitro* screening processes than either single or direct coculture models. Nevertheless, more work needs to be done to establish the most effective *in vitro* model for accurate modeling of the *in vivo* inflammatory responses.

The data obtained from models to date have established that biomaterials can induce the activation of monocytes and lymphocytes *in vitro*, resulting in differing profiles of cytokine expression, via pathways other than the classical or the alternative pathways of induction.[10] Classical induction refers to the *in vitro* stimulation of monocytes with LPS and the production of proinflammatory cytokines and nitric oxide. Alternative induced-monocyte activation involves stimulation by IL-4 and IL-13 (required for FBGC formation), inhibition of proinflammatory cytokines and the production of anti-inflammatory cytokines, and the upregulation of mannose receptors (a characteristic of FBGC formation). Material-induced stimulation of monocytes can be profiled using the same guidelines, that is, the production of pro-/anti-inflammatory cytokines and the expression of characteristics that indicate FBGC formation and subsequent fibrosis or tissue remodeling and acceptance. A number of the key elements in these processes have been highlighted throughout this chapter, as also the need for standardization of *in vitro* processes, if the data are to be correlated from different studies and an understanding of how material parameters can induce specific elements of cell activity is to be gained. This knowledge of the direct relationships can then be used to develop materials that can induce controlled levels of inflammation and thus bridge the gap between the current characterizations of passive or proinflammatory outcomes based upon *in vitro* models. Currently, *in vitro* models from various research centers are used solely to indicate the possible inflammatory potential of materials. With the development of standardized *in vitro* models, data could be combined, related, and correlated to improve materials, thereby increasing the efficiency of the models and evolving the next generation of 'smart materials' for regenerative medicine.

4.405.2.2.6. *Foreign body giant cell formation* in vitro

FBGC can become a significant component of the chronic inflammatory phase, *in vivo*.[71,72] FBGC are made up of adherent monocytes that have fused together in what is considered to be an attempt to increase their surface area to phagocytose particles that are larger than any single cell can span and engulf. Their analysis, in relation to monocyte culture models, has been discussed in **Section 4.405.2.2.4.2**. FBGC are not efficient phagocytes, but they do play a role in the production and release of ROS, in an attempt to degrade and digest the underlying material. Therefore, they do have a role in material degradation. Their formation, or the potential of adherent monocytes to form FBGC *in vitro*, can be assessed via the analyses of the expression of mannose receptors, the upregulation of β1 integrins and downregulation of β_2 integrins, the up regulation of CD44 and CD47, and the presence of dendritic cell-specific transmembrane protein (DC-STAMP).[10] To form FBGS *in vitro*, cells must be stimulated with IL-4 and IL-13. If FBGC formation was present on a material without the additional stimulation of IL-4 and IL-13, it would be a strong indication of the material's chronic inflammatory potential, without even considering the induction from frustrated phagocytosis. This phenomenon, occurring solely by stimulation from direct contact with a material *in vitro*, has not yet been reported, but continued developments in the knowledge base of *in vitro* leukocyte–biomaterial interactions and the optimization of factors such as cell number could soon lead to the development of such models, and they could be used as a benchmark for the standardization and improvement of current *in vitro* models.

4.405.2.3. Leukocyte Interactions with Wear Particles

One of the most widely used applications of the *in vitro* leukocyte–material models is the assessment of the level of induced inflammation associated with wear particles. The approach is used to simulate, *in vitro*, the *in vivo* situations in which articulating surfaces produce wear debris either by design, deliberate material degradation or by physical abrasion, which are correctly termed wear particles. One of the most widely studied applications comes from the generation of wear particles in total joint replacements, particularly hip joints and total hip arthroplasty. The generation of wear particles associated with these implants can be a constant source of stimuli for inflammatory cells, resulting in fibrous capsule formation around the joint implant caused by the chronic inflammatory response and the associated aseptic loosening, the latter due to poor bone formation around the site of the implant, increased osteoclast activity induced by chronic inflammation, and failure of the implanted device.[64,73–75] To reduce the risk of failure due to aseptic loosening, a significant amount of research effort has focused on generating materials that produce fewer wear particles or generating ones that do not induce significant chronic inflammatory responses. The *in vitro* analyses of induced inflammatory responses have been invaluable in classifying the optimum size range and shape.[76,77] The optimization of the *in vitro* models for the dissemination of clinically relevant data in these circumstances involves optimizing the cell:particulate number ratio to elicit

an optimum response, which must also reflect the *in vivo* environment that is constantly replenishing its source of monocytes from the cardiovascular system. Results from these studies have identified optimal particle sizes, shapes and types of particles (i.e., ion) that are proinflammatory. The *in vitro* models have demonstrated that particles in the size range of 0.24–7.2 μm are the most proinflammatory, and that elongated particles generate a greater proinflammatory response compared with rounder particles. This research is clear proof that data from optimized *in vitro* models can be used to increase the efficiency of biomaterial implants. On the other hand, without these data, *in vivo* studies would need to rely on thorough analysis of failed implants retrieved from patients or *in vivo* models, all of which are costly, time consuming approaches and may be influenced by other host factors such as infection, and underlying disease factors, and are therefore limiting in a short time frame, in terms of optimization of material design.

4.405.2.3.1. The role of in vitro leukocyte models: Controlling the inflammatory response

This chapter has discussed the use of *in vitro* leukocyte models in determining the inflammatory potential of a material and how this has traditionally been used as a marker of biocompatibility. In Section 4.405.1, biocompatibility was defined as "a material's ability to perform with an appropriate host response in a specific application."[1] The term appropriate host response extends far beyond inflammation and refers to the integration of the material/implant and its ability to induce functionality either as cellular responses or as tissue formation at the appropriate site. The inflammatory response is an inevitable event and, as such, should not be viewed as either good or bad. On the contrary, it should be fully understood so that materials can be designed to use the host defense system to induce an inflammatory response that drives the host response toward desired end points. For example, the amount of PGE-2 (prostaglandin E2) released by macrophages should be directed and controlled as, below a certain concentration, PGE2 is stimulatory to osteoblasts (bone-forming cells), but upon saturation and above certain levels, it becomes inhibitory to osteoblasts and induces osteoclasts (bone resorbing cells).

To date, many studies have simply stopped at evaluating the cytokine profiles associated with an inflammatory response to a material *in vitro*, and have based their conclusions on the fact that acute inflammatory responses result in fibrous encapsulation. A passive material and chronic inflammatory responses can also result in a larger fibrous encapsulation due to the activation of fibroblasts. Recent studies have proved that chronic inflammation also plays a role in tissue remodeling and integration of implants *in vivo*, and so, to reflect this, there is the need for *in vitro* models suitable for the investigation of the effect of inflammatory cytokines on functional tissue-forming cell types, that is, osteoblasts for bone contacting application, and epithelial cells for intraocular devices, and stem cells.[78–81] These models are now emerging, and they combine either direct coculture or stimulation of a functional cell type with inflammatory medium (either collected directly from inflammatory cells cultured in contact with a material or artificially supplemented with known concentrations of cytokines). As with the development of *in vitro* inflammatory models, these novel studies still require optimization and standardization if they are to realize their potential. Nevertheless, these kinds of studies are changing the concept of the inflammatory response and are directing our thinking toward the fact that the inflammatory response is a tool that should be used and controlled to enhance the efficiency of an implanted device, mainly by improved integration due to material-induced cellular function from the time of cell/material contact. The derivation and development of these *in vitro* models would not be possible if specific material-induced cell interactions were not already characterized and understood, highlighting the need for constant improvement of our knowledge of these interactions, which can be gained from both purified cell culture models and more comprehensive coculture models ranging from controlled cell phenotypes to whole blood and bone marrow models.

Glossary

Activation energy The energy that must be overcome in order for a process, such as a chemical reaction or adsorption, to occur.

Anaphylatoxin Molecule able to trigger degranulation of endothelial cells, mast cells, and phagocytes, which produce a local inflammatory response.

Complement system Part of the immune system called the innate immune system that is not adaptable and does not change over the course of an individual's lifetime. However, it can be recruited and brought into action by the adaptive immune system (Wikipedia).

Coulombic interaction Electrostatic interaction between molecules, particles, or bodies. Like charge repels each other and opposite charges attract each other.

Enthalpy change ΔH is equal to the heat absorbed by a chemical reaction.

Entropy change ΔS denotes change in a systems 'disorder.'

Free energy Energy released during a process, such as adsorption or chemical reaction.

Heat capacity Heat capacity is the capacity of a body to store heat.

Nucleophile An electron-rich chemical reactant that is attracted by electron deficient compounds. For instance, water and alcohol are oxygen nucleophiles, amines, and ammonia nitrogen nucleophiles.

Point of zero charge (pzc) The condition when the electrical charge density on a surface is zero. It is usually the pH value at which a solid submerged in an electrolyte exhibits zero net electrical charge on the surface (Wikipedia).

4.406.1. Introduction

4.406.1.1. Proteins of the Human Body and Relevance for Biomaterials

Studies on protein adsorption from blood plasma or whole blood are an accepted method to assess biomaterials, especially in blood-contacting applications. The 20 amino acids in the human body are combined in different ways to build up a huge number, ~100 000, of different proteins. Many of these are found in blood and other body fluids, and some are bound to tissues as frameworks for soft tissues, bone, and hair. It is suggested that proteins make up about 75% of dry body weight.[1] The total protein concentration in native blood is ~70 mg ml^{-1}. High-resolution, two-dimensional electrophoresis shows the

presence of over 150 bands from blood plasma, and it is estimated that more than 5000 different proteins can be observed by this method.[2] However, in the majority of studies related to protein adsorption to biomaterials, only plasma proteins of sufficiently high concentrations are considered, as these are supposed to compete effectively at the interface. Andrade and Hlady limited them to concentrations above $\sim 1\,\mathrm{mg\,ml^{-1}}$, and ended up with a group of plasma proteins named 'The big twelve': albumin, IgG, LDL, HDL, α-macroglobulin, fibrinogen, transferrin, α-antitrypsin, haptoglobulins, C3, IgA, and IgM.[2] However, other proteins outside this narrow group are also of obvious significance, for example, proteins of the coagulation pathways and the complement system. A common denominator for the latter is their surface deposition on top of preadsorbed proteins upon activation of humoral cascade systems that may be at or in the close vicinity of biomaterials. Electrophoresis and Western blots of proteins that were eluted from polyethylene glycol (PEG)-modified liposomes, in one study, revealed adsorption by considerably more than 12 different proteins.[3] However, for practical reasons and based on experience, the analysis of protein adsorption is limited to a relatively few proteins that function as markers of specific binding and activation pathways. For example, deposited fibrinogen predicts the surface binding and activation of platelets and white cells the generation of emboli; surface-bound high molecular weight kininogen (HMWK) is a good marker of activation of the intrinsic pathway of coagulation; and IgG and C3b predict surface activation of the complement system. The identification of specific proteins at surfaces is most commonly performed using immunologic/antibody or protein-labeling techniques and is usually complemented by the analysis of the soluble protein degradation fragments. A selection of analytical techniques to study protein adsorption are listed in **Table 4**.

4.406.1.2. Nonspecific and Specific Surface–Protein Interactions

Proteins in solution accumulate spontaneously at biomaterial and other interfaces, and in the present context, we consider chemically inert surfaces with low solubility in aqueous solutions and blood plasma as examples of such interfaces.

The adsorption process is exothermic (i.e., with spontaneous release of heat)

$$\Delta G = \Delta H - T\Delta S \qquad [1]$$

where, ΔG is the change in Gibbs free energy, ΔH change in enthalpy (generation/loss of bondings), T temperature, and ΔS is the change in entropy.[4] In most cases, a change in system entropy (here, the system includes solution, surface/interface, and the protein that adsorbs from solution) drives the process with an increase in free water that is liberated from between the adsorbent and adsorbing proteins, and an increase in adsorbed protein internal mobility. A part of the liberated energy is needed to partially denature the adsorbing protein, with $\Delta H = \int \Delta c_p \mathrm{d}T$, where $\Delta c_p = c_{p,\,\text{denatured protein}} - c_{p,\,\text{native protein}} > 0$. For some proteins, the adsorption process is driven by enthalpy,[4,5] although such proteins are only exceptions. Adsorbed, that is, partially denatured proteins normally acquire an increase in heat capacity, c_p.[5] As mentioned earlier, proteins change their conformation during the adsorption process, increasing the exposure of hydrophobic protein residues/domains and internal molecular entropy. The degree of denaturation increases upon prolonged contact or residence time. The increase in entropy because of an increase in free water and internal molecular entropy, is suggested to be the main contributor of the driving energy that enables protein adsorption (**Figure 1**). Attractive coulombic protein–surface interactions (interaction force $\sim 1/r^2$, r is distance from surface) are other important contributors to the adsorption process; and once a physical protein–surface interface is established, close range attractive van der Waals interactions (interaction force $\sim 1/r^6$) also help anchor proteins to the surfaces.

Relatively well-understood exceptions to adsorbing artificial surfaces are charge neutral interfaces/surfaces with high water retention and/or high surface mobility, such as surface-immobilized PEGs or sugars, and water–lipid and solid–lipid interfaces. Surfaces inside the human body, for example, the exterior of cell membranes, albumin-associating cell surfaces, extracellular materials such as glucosaminoglycans (GAGs), and mucosae with high oligosaccharide content behave, with respect to spontaneous adsorption, similarly to PEGs. Most internal body surfaces carry a negative net charge at physiological conditions and thus exert repulsive forces between surfaces and macromolecules, that is, proteins, GAGs, and other organic molecules, and macromolecules contribute together with ions of body fluids to retain body water and to keep the biological structures and molecules apart. This also significantly contributes to homeostasis. It should also be pointed out, in this context, that cells and proteins do indeed interact a lot with one another, although such interactions are more specific and largely regulated via receptor–ligand interactions. The description of this is, however, out of the scope of this chapter. Other, more or less specific interactions occur when biomaterials adsorb proteins belonging to the humoral cascade systems and eventually activate them. The intrinsic pathway of coagulation is activated on negatively charged surfaces upon contact with blood or blood plasma.[6,7] The key proteins in these events are HMWK, coagulation factor XII, coagulation factor XI, and prekallikrein.[7,8] The fibrinolytic system may be activated downstream as a consequence of coagulation, but not primarily by the biomaterial itself. The complement system deposits complement factor 3b (C3b or iC3b) and its degradation products onto virtually all types of adsorbing surfaces, especially the nucleophilic ones.[9,10] For a description of the blood cascade systems and biomaterials (see **Sections 4.406.3** and **4.406.4**).

The aforementioned surface properties are often grouped into a simpler classification to separate protein-adsorbing surfaces from protein-resistant surfaces (**Tables 1** and **2**).

Generally, protein adsorption leads to both immediate and delayed effects in the vicinity of the implanted biomaterials.

The rate of single protein adsorption ($R_{\text{adsorption}}$) is Langmuir-like, and proceeds according to equation

$$R_{\text{adsorption}} = \frac{f(\Theta)P}{\sqrt{2\pi MkT}} e^{-E_a/RT} \qquad [2]$$

where k is the rate constant, P molecular pressure ($\mathrm{N\,m^{-2}}$), M mass of one molecule (kg), T temperature (K), Θ fraction of

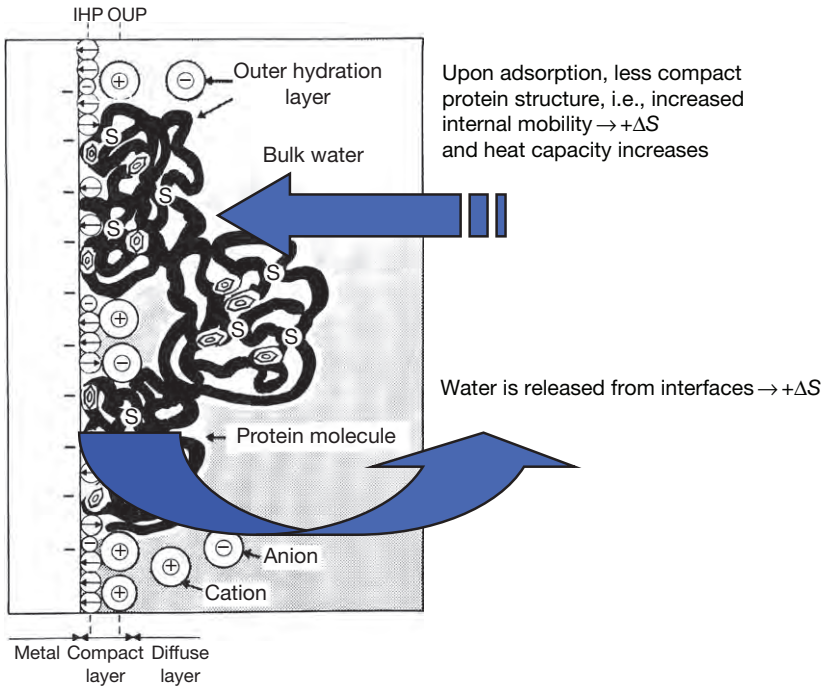

Figure 1 Schematic illustration of the electrochemical double layer at the biomaterial–electrolyte interface. Water molecules shown as individuals, (→), where the arrow symbolizes the dipole moment and as a structured hydration layer. IHP and OHP are inner and outer Helmholtz planes, respectively. A primary strongly adsorbed protein layer with more or less compact molecules and a second loosely held layer consisting of more 'native' molecules are also indicated by (ring molecule) aromatic amino acid, (S) disulphide bridge. Reproduced from Ivarsson, B.; Lundström, I. *CRC Crit. Rev. Biocompat.* **1986**, *2*(1), 1–96.

Table 1 General surface and protein properties that determine adsorption

Surface properties	*Protein properties*
Free energy (hydrophobicity/hydrophilicity)	Overall hydrophobicity
Charge and electric field divergency	Charge and dipole size and localization
Ion binding	Prosthetic groups
Redox/corrosion potential	Ion binding
Hydrogen bonding capacity	Hydrogen bonding residues
Surface water structure/binding strength	Water binding and localization
Acid/base properties (pcz)	pI
Surface impurities	Specific interacting residues
Surface topography at micro- and nanoscale	Quarternary, tertiary, and secondary structure, dipole size and localization
Oxide (thickness, growth, dielectric constant, water, and ion sorption)	Number of internal disulphide bridges
Interactions with small (organic) molecules	Size (molecular weight)

Table 2 Pro- and antiadsorption factors

Proadsorption factors	*Antiadsorption factors*
Dehydration of interfaces	Strong water binding to interfaces
Increase of protein interior mobility	Low protein flexibility
Coulombic interactions	High protein lateral mobility
Dipoles in a divergent electric field	Low net coulombic interactions
Van der Waal interactions at close contact	High surface smoothness

sites occupied (max. 1), $f(\Theta) = 1 - \Theta$, and E_a is activation energy of adsorption.

The balancing rate of single protein desorption ($R_{\text{desorption}}$) is described as

$$R_{\text{desorption}} = -\frac{dN}{dt} = \nu N^{\chi} e^{-E_a^{\text{des}}/RT} \quad [3]$$

where N is the surface concentration of adsorbed proteins, χ kinetic order of desorption, E_a^{des} the activation energy of desorption, and ν is 'attempt frequency' at overcoming the barrier to desorption.

4.406.1.3. Phenomena Related to Protein Adsorption

- Lowered system energy – release of heat
- Coverage Θ – 1 monolayer of adsorbed single proteins equals 50–90% of the total arithmetic area
  - from single protein solutions, 1–5 nm (70–350 ng cm^{-2}), thick film
  - from serum/plasma, 3–20 nm (210–1400 ng cm^{-2}), thick film
  - hydrophobic surfaces tend to adsorb slightly more than hydrophilic surfaces
  - higher protein concentration in solution → thicker protein film
- Firm but not completely irreversible binding – protein exchange processes occur more often on hydrophilic than hydrophobic surfaces.
- Residence time – leads to an increase in conformational changes, with more denaturation on hydrophobic than on hydrophilic surfaces.
- Specific uptake of proteins may take place (e.g., factor XII/IgG).
- Adsorbed fibrinogen may be displaced by other proteins (Vroman effect).
- Cascade reactions may be initiated
  - coagulation, fibrinolytic, and kinin systems
  - complement
- Surfaces become opsonized, that is, they are recognized as foreign bodies by cells.
- Spontaneously generated reactive body C3b* binds to denatured proteins.
- Thickening of the protein layer with time. Both intact and proteolytically fragmented proteins reside at surfaces and in their close vicinity.

The adsorption of proteins to biomaterials would not be interesting or even relevant to study if the adsorbed layer was only a passive bystander or a biologically passive entity. This is, however, not the case. Adsorbed proteins participitate in surface-initiated coagulation with concomitant fibrinolytic activity; generate kallikrein, thrombin, and bradykinin; mediate immune complement activation; and generate biologically active protein degradation products. Also, both cells and bacteria may bind to the adsorbed proteins. Surface–protein interactions lead to the generation of cell-regulating signal molecules such as C3a, C4b, C5a, C5a-des arg, C3d, C3dg, bradykinin, fibrinogen degradation products (FDPs), monomeric fibrin, etc. Last but not least, both surface-bound proteins or protein fragments and soluble fragments interact intensively with the surrounding cells and tissues. This signaling in turn affects local homeostasis via recruitment of specific cells to the site of biomaterial implantation, cell differentiation, wound healing, blood flow and interactions, etc. **Table 3** lists selected protein–cell interactions and indicates, thereby, a strong rationale for research in this area.

4.406.1.4. Nonspecific and Specific Biomaterial Surface–Protein Interactions

Blood proteins and proteins from body fluids adsorb with low specificity and relative unpredictability to biomaterials.

Table 3 Selected protein–cell interactions

Protein	*Major function*	*Cell receptor*	*Cell type*
Serum albumin	Body transport and clearance protein, binds to certain cell surfaces ('passivates'), maintains the osmotic balance	gp30 and gp18	Endothelial, hepatocytes?
Fibrinogen (Fib)	Forms fibrin during blood coagulation	CD11b,c, CD41a, CD51, CD61	Platelet, endothelial, myeloid, NK, osteoclast, tumor
Fibronectin (FNT)	Extracellular matrix protein that binds cells via RGD-sequence	CD49c, d, e, CD41a, CD61	Platelet, B lymphocyte, monocyte, fibroblast, epithelial, keratinocyte, tumor
Immunoglobulin G (IgG)	Opsonizes a nonself cell surface, activates complement	Fc	PMN, macrophage
High molecular weight kininogen (HMWK)	Component of the intrinsic pathway of coagulation, binds to negatively charged surfaces	β1 and β2 receptors	Endothelium, platelets and neutrophils, monocytes, macrophages
Complement factor 1q (C1q)	Binds to IgG and IgM and initiates classical complement activation, related to collagen activation of platelets	cC1q-RI, C1q-Rq, gC1q-R	B lymphocyte, T lymphocyte, monocyte/macrophage, PMN, eosinophil, platelet, fibroblast, endothelial, epithelial, smooth muscle, mesengial
Complement factor 3b (C3b) and C4b	Key adsorbed complement proteins, formed by cleavage of C3 to C3a and C3b, C4 to C4a and C4b	CR1(CD35)	Erythrocyte, phagocyte, B lymphocyte, T lymphocyte, eosinophil
Complement factor 3dg/3d (C3dg,C3d)	Surface-bound complement peptide after proteolytic cleavage of C3b, opsonin	CR2(CD21)	B lymphocyte, T lymphocyte
Complement factor 3bi (C3bi)	Inactivated C3b	CR3 (CD11b and CD18) and CR4 (CD11c)	Monocytes, macrophages, PMNL dendritic cells, myeloid cells, NK, B cells, T cell subset

Protein adsorption to biomaterials can be analyzed by a number of techniques. No single method reveals answers to all questions and many studies seem therefore inconclusive or contradictory, the experiments seem too simplified, and the relevance is questionable in a broader biological context. As body fluids are complex and contain protein-borne humoral systems, only adsorption data from human blood and serum will be discussed in this chapter.

For example, adsorbed albumin has been identified on virtually all types of surfaces in contact with blood serum or plasma. Therefore, the adsorbed protein layer has been called a 'biolayer.' The main reason for this unpredictability is that artificial surfaces lack specific protein receptors, such as those expressed on the exterior or interior of cells, and hence artificial surfaces are simple in a biological context. Nevertheless, different surfaces show some kind of selection that can be related to their different physical/chemical surface properties. For instance, hydrophilic, negatively charged surfaces bind and activate factor XII and HMWK; positively charged surfaces seem not to do that, they may instead bind lipoproteins. Fibrinogen is displaced from hydrophilic negatively charged surfaces but not from hydrophobic. Surfaces with specific IgG uptake are strong complement system activators. When we look more closely into the chemical identity of the surface, there appear some surface selection rules; amine and hydroxyl groups interact strongly with the immune complement system, and negatively charged carboxyl, sulphate, phosphate, and hydroxyls activate the intrinsic pathway of coagulation. No specific chemical groups are, on the other hand, known to activate the tissue pathway of coagulation. What really may be of significance in nonspecific surface binding is the partial denaturation of proteins during long residence times. This makes biomaterials appear as gigantic immune complexes or worn out macromolecules. Now the surrounding proteins, cells, and tissues have to deal somehow with this entity. In a few cases, the impact is positive, while in the majority of cases it is negative. A more complete understanding of the implications of these processes has yet to be achieved.

4.406.2. Surface Wettability, Topography, and Protein Adsorption

4.406.2.1. General

One important physical property of nonsoluble surfaces is their water wettability. This term is coupled to and interchangeable with terms such as surface energy, surface free energy, contact angle, and critical surface tension, although the latter refers to liquids. They all focus, in our context, on the same surface property, its hydrophilicity/hydrophobicity.[11–13] Surface free energy

$$\gamma_{\text{total}} = \gamma_{\text{dispersive}} + \gamma_{\text{polar}} \quad [4]$$

that is, the total surface energy that we normally measure or observe is composed of two components, one describing polar interactions between atoms and materials and the other describing nonpolar interactions. Biomedical metal oxides and bioceramics are designed to be chemically stable and

Table 4 Analytical techniques to study protein adsorption on biomaterials

Technique	*Characteristics*
ELISA	Immunologic technique, single or complex protein solutions, samples with different geometries can be studied, does not require optically reflecting surfaces, quantitation of adsorbed proteins can be difficult, time consuming, cheap
SDS-PAGE	Electrophoretic analysis of desorbed proteins, identification can be made by antibodies, not quantitative, time consuming
Electrophoresis	Analysis of desorbed proteins, identification by antibodies, 2D analysis separates proteins according to molecular weight or charge, very many different proteins can be observed, time consuming
Radiolabeling techniques	Single labeled proteins adsorb from single or complex protein solutions. Can be quantitated accurately in the desorbed or adsorbed state, no restrictions regarding material or surface geometry, not proper for studies on complex cascade reactions at surfaces, Vroman effect can be studied, protein nativity can be impaired by the labeling procedure, nonspecific absorption of ^{125}I may occur
QCM-D	Detects dynamic surface–protein interactions and changes in surface viscoelastic properties, relatively good adsorbed mass quatitation possible in single and complex protein solutions Energy dissipation reveals protein film properties
OWLS	Optical technique, good quatitation, can be combined with immunologic protein identification, commercial availability?
SPR	Quantitative, excellent for studies on dynamics of adsorption and protein–ligand biointeractions, not particularly appropriate for analysis in complex protein solutions
Ellipsometry	Good surface quantitation, no protein labeling required, single and complex protein solutions can be used, adsorbed protein identification by antibody techniques, quick, requires optically reflecting smooth surfaces, complex theory, measurements can be performed in solution or in air
Infrared spectroscopy	Quantitation by protein amide bands, low accuracy, time consuming, single or complex solutions, expensive, protein identification difficult
Spectrophotometry	Quantitation of desorbed proteins or by determination of depleted amounts, mainly single protein solutions, cheap, good accuracy, requires large adsorbing surface areas, not dependent of surface topography or its physical properties
Fluorescence spectroscopy	Detects fluorescing molecules or markers in proteins, high sensitivity, quick measurements but tedious labeling work, single or complex solutions possible, quenching may occur, protein nativity may be disturbed by labeling procedure
AFM	Oscillating mode preferred, measurements in solution or in air possible, appropriate to visualize single adsorbed protein, can be quantitative, labor intense, requires good training for accurate interpretation, protein identification in complex solutions difficult
XPS	Measures signal intensity, for example, N^{1s} (relative to controls), dependent on substrate surface chemistry and the organization of the adsorbed protein film

Table 5 Water contact angles of common biomaterials

Material	*Static water contact angles (°)*	*Surface energy, surface-free energy (mN m^{-1})*	*Critical surface tension (mN m^{-1} or dyn cm^{-1})*	*References*
Metals and ceramics	5–60	High: >40	High: >40	[11–13]
Solid polymeric biomaterials	30–110	Low–medium: 20–45	Nonpolar: 18–33 polar: 22–45	[11–13]

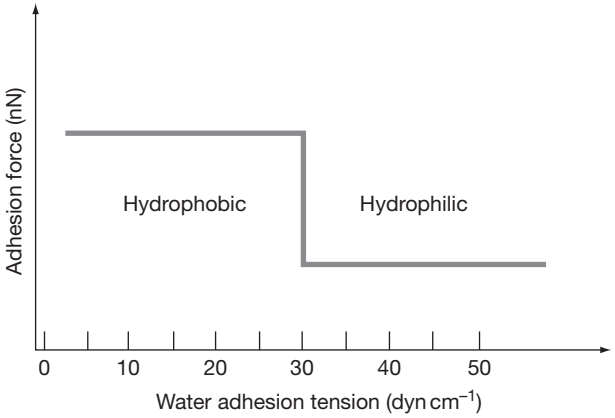

Figure 2 Schematic picture of protein adhesion forces on protein coated tips to surfaces with different water adhesion tension values. In the transition region, the static water contact angle is 55–65°. Reproduced from Lestelius, M.; Liedberg, B.; Tengvall, P. *Langmuir* **1997**, *13*(22), 5900–5908.

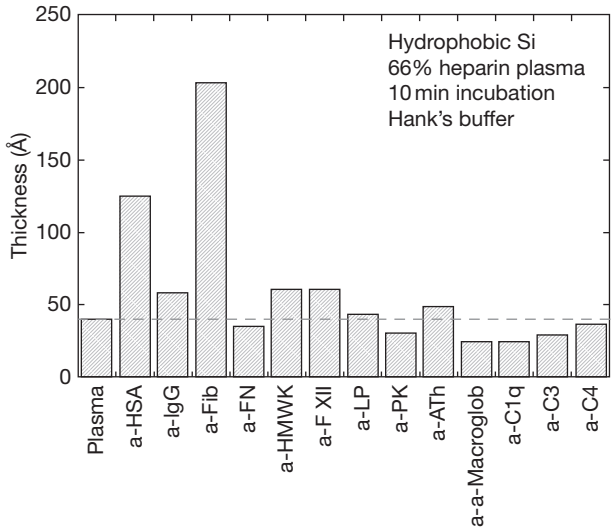

Figure 3 Plasma proteins on hydrophobic silicon silanized with diclorodimethyl (DDS). The dotted line indicates the average heparin plasma layer thickness after 10 min of adsorption in heparin plasma (equals ~450 ng cm^{-2}). Polyclonal antibodies against fibrinogen, human serum albumin, IgG, high molecular weight kininogen, and factor XII bound into the plasma layer. Staple heights below the plasma level indicate a detergency effect by respective antibody solution.

exert, predominantly, polar force interactions on proteins. Polymers possess mixed properties and exert both polar and dispersive (nonpolar) force interactions, that is, they are, commonly, more hydrophobic than metal oxides (Table 5). The structure of the polymer surface is physically less dense than metal or ceramic interfaces, and the outermost molecules may undergo flip-flop rotations, thereby changing character from hydrophilic to hydrophilic and vice versa, which is an adaptation to the environment. The flip-flop process may be instantaneous or take hours, depending on the material and the polarity of the environment or lack of it.

Hydrophobic and hydrophilic surfaces exert different force interactions on proteins when expressed as adhesion forces[13] (see the principle in Figure 2). Hydrophobic surfaces, with structurally more ordered water, attract proteins to a greater extent than hydrophilic surfaces which have less ordered, but more tightly bound, water.

4.406.2.2. Hydrophobic Surfaces

Typical hydrophobic surfaces expose their methyl ($-CH_3$), methylene ($-CH_2-$), methoxy ($-OCH_3$), or trifluoromethyl ester ($-OCF_3$) groups toward the surroundings.[14] Many polymeric biomaterials are hydrophobic, for example, PTFE, PDMS, PET, polyethylene, and polypropylene. The static contact angle is often larger than 80°. In a classical work, Robert Baier suggested that blood compatible materials display a critical surface tension of 20–30 dyn cm^{-1}, that is, they are hydrophobic and have low surface free energy[15] (Table 5).

Hydrophobic surfaces bind to proteins more firmly than hydrophilic surfaces (Figure 2). The main reason for this is the increase in interactions between the hydrophobic surface and hydrophobic protein domains that become exposed during the adsorption process. Interfacial water is then displaced more easily from the contacting hydrophobic surfaces compared to the same process on hydrophilic surfaces with a stronger water binding. The amount of adsorbed protein is then similar to that of electrically conducting materials, such as gold, and antibody mapping of the contents of a blood plasma protein film reveals characteristics that are common to virtually all hydrophobic surfaces. The main proteins exposed on the surface are fibrinogen and albumin (see Figure 3).

4.406.2.3. Negatively/Positively Charged Surfaces

Negatively charged surfaces are surfaces with a negative charge in physiological environments (pH 7). Such surfaces possess an isoelectric point (pI or point of zero charge, pzc) below pH 7.[16–18] Some oxides are strongly acidic, for example, SiO_2 (pzc ~ 1.7–3.5), WO_3 (pzc ~ 0.2–0.5), Ta_2O_5 (pzc ~ 2.7–3), Sb_2O_5 (pzc ~ 0.4–1.9), and Nb_2O_3 (pzc ~ 4.1). Others are amphoteric and include metal and semiconducting oxides such

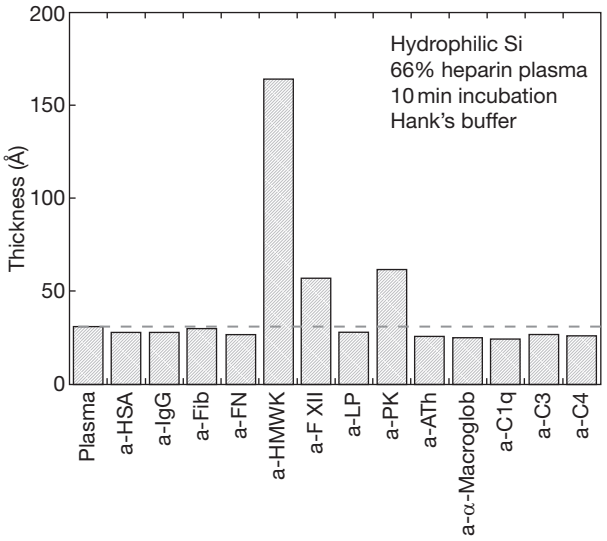

Figure 4 Plasma proteins on negatively charged hydrophilic silicon with pzc ~ 4–5. The dotted line indicates the average heparin plasma layer thickness after 10 min of adsorption from heparin plasma (equals ~400 ng cm^{-2}). Polyclonal antibodies against high molecular weight kininogen, factor XII, and prekallikrein bound into the plasma layer. Staple heights below the plasma level indicate a detergency effect by respective antibody solution.

as TiO_2 (pzc ~ 3.9–8.2), ZrO_2 (pzc ~ 4–11), and Cr_2O_3 (pzc ~ 6.2–8.1). Basic oxides, possessing a positive surface charge at pH 7, include Y_2O_3 (pzc ~ 8.9), α-Fe_2O_3 (pzc ~ 9.4–9), ZnO (pzc ~ 8.7–9.7), and MgO (pzc ~ 12.1–12.7). Al_2O_3 is most often considered basic (pzc ~ 7–9).

Surfaces with a negative charge deposit approximately 400 ng cm^{-2} plasma proteins during short-time incubations and activate the intrinsic pathway of coagulation, but do not retain much fibrinogen after an observed initial adsorption/desorption phenomenon that takes place within seconds. Negative surfaces adsorb and activate plasma proteins such as HMWK, factor XII, and prekallikrein (see Figure 4).[19] During prolonged plasma contact times, at the order of tens of minutes to hours, complement factor 3b is commonly deposited onto previously adsorbed and partially denatured proteins.

4.406.2.4. Surface Nano-Roughness and Protein Adsorption

Increased surface roughness results in increased protein adsorption. The reason is related to both macro- and micro-scale; for ~ $R_a \geq 0.1\,\mu m$, there is an increase in the general surface area, whereas, at the submicron level, $R_a < 0.1\,\mu m$, increased adsorption may result from effects on macromolecules in a divergent electrical field, resulting in an attractive force toward regions with higher field strength (corners, kinks, ..., see Figure 5). This force is the result of a charge-dipole that is induced along the axis of the protein molecule. Thus, the dipole (macromolecule) interacts with an E-field gradient and also polarizes the outermost layers of the surface. As the direction of the induced dipole always opposes the E-field direction, the attractive force is independent of field polarity. One could, therefore, expect protein accumulation at asperities with sizes

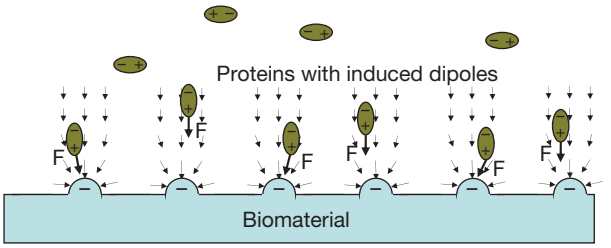

Figure 5 Proteins in divergent electric field. An attractive force toward a denser field section is generated by static or induced macromolecule dipoles. Other attractive or repulsive forces such as columbic, hydrophobic, and van der Waals forces omitted for clarity.

of the order of 1–100 nm, at crystallites; and surface charge may then be used for selecting the direction of molecule adsorption. Exactly how this works out in real life is not well understood and is hard to control, but these phenomena should also induce certain effects at the macro level and be observable during cell spreading, cell motility, and gene expression.

4.406.2.5. Protein Displacement Phenomena

When blood plasma is adsorbed onto negatively charged surfaces such as Ta, Si, and Ti or biopolymers such as polyurethane, proteins adsorb during the early adsorption phase, and become eventually replaced by other plasma proteins. Hydrophobic and positively charged surfaces show no or little protein exchange. The early adsorption of plasma fibrinogen onto negatively charged surfaces and its later displacement by HMWK and other plasma proteins is called the Vroman effect.[20,21] Frequently, the displacement of other plasma proteins in other circumstances are also collectively called 'Vroman effects'[22]; but the distinction between these two is important. The original observation, made way back in the 1960s by Vroman and Adams, was that adsorbed plasma proteins were detectable using antibodies on Ta-oxide in a time-dependent order, viz, albumin, IgG, fibrinogen and fibronectin, and HMWK (Figure 6).[23] The phenomenon has been well described, by the same investigators, for blood plasma adsorption into narrow spaces.[24]

The reasons for plasma protein exchange have not yet been understood in detail but may be as follows. In the early phase, the adsorption of a specific protein increases if its concentration is high, it is structurally flexible, of low molecular weight (quick diffusion), and exerts no columbic repulsions on the surface (pI ~ 7). Albumin fulfils these criteria the best and readily adsorbs from plasma. The adsorbed proteins modify surface electrodynamic conditions, whereby, similar proteins or other proteins with higher surface affinity but lower bulk concentration enter the surface, and the former may be displaced by the entering protein, and so forth.

4.406.2.6. Protein-Resistant Surfaces

Surfaces with low or zero net charge, high water retention capability, and high surface mobility are protein- and hence cell-resistant. Comixtures of surface-immobilized polyethylene glycols or -oxides (PEG or PEO) with the basic structural backbone element $-(-C-C-O-)_m$ are widely used for this purpose

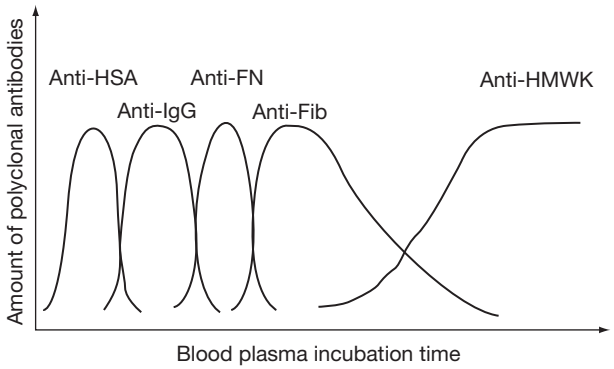

Figure 6 The Vroman plasma protein displacement phenomenon.[22,23] The *x*-axis shows time elapse of incubation of a negatively charged surface, such as glass, Ta-oxide, or Ti-oxide in blood plasma, and the *y*-axis the amount of surface-bound polyclonal antibodies after different plasma incubation times. Observe that this phenomenon reflects antibody access to its surface located antigen, and does not necessarily reflect a true surface displacement of plasma proteins, and may show the antigen accessibility only.

in biotechnology. One consequence of the low surface protein retention is a low cell binding, which may be for good or for bad. The literature indicates that the preferred molecular weight of immobilized PEGs is of the order of 1–5 kD.[25,26] Other protein-resistant molecule classes are, for instance, immobilized natural or artificial hydrogels, proteins (e.g., albumin), polypeptides, sugars, and GAGs, although many of them also have known biological (side) effects, something we avoid whenever possible. One common problem in body fluid-contacting systems is the stability of such surface constructs. It is a relatively easy task to prepare an *in vitro* protein-resistant surface with a molecular pressure equivalent to 1 mg ml^{-1} protein in solution and no chemical reactivity, but a much more complicated task *in vivo* and at 70 mg ml^{-1} protein concentration. Also, the reactive chemistry of human humoral cascade systems, including inflammatory conditions, normal metabolism, and the spontaneous generation of reactive protein cleavage products add to the problem.

4.406.3. Surface-Activated Coagulation

4.406.3.1. Intrinsic Pathway

The intrinsic pathway of coagulation is activated on negatively, but not at positively, charged biomaterial surfaces. An excellent introduction to the initiation of blood coagulation at artificial surfaces was written by Colman *et al.*[27] Hydrophobic surfaces activate coagulation differently, namely, via platelets that interact with the adsorbed fibrinogen.[28] It is in this context that the importance of fibrinogen binding to hydrophobic and electrically conducting surfaces, such as gold,[29] becomes critical and thus explains why it should be avoided.

The physiological role of the intrinsic pathway of coagulation in diseases is, however, obscure as the pathway is not required for the initiation of hemostasis *in vivo*.[30] The significance of factor XII in thrombosis remains controversial, but in mice, a deficiency of factor XII or factor XI attenuates the development of thrombi.[31,32] Furthermore, inhibition or deficiency of factor XII protects mice from ischemic brain injury without causing hemorrhage.[33] In humans, factor XI deficiency may be associated with a hemorrhagic phenotype. Factor XI may also participate in thrombosis in humans, because a deficiency of this protein is associated with a reduced risk of ischemic stroke but not of myocardial infarction.[34] One important physiological role of the intrinsic pathway in tissues may be the amplification of a developing thrombus.[30] One speculation related to negatively charged biomaterial surfaces is, therefore, enhanced fibrin formation when compared to wounds without implants (shams).

4.406.3.2. Tissue Pathway

There is no tissue factor (TF) activity in normal blood, but TF is captured in wounds by platelet P-selectin and PSGL-1, leading to TF accumulation and thrombus formation at the site of injury.[30] Interestingly, the tissue pathway of coagulation was recently connected to complement activation.[35,36] The observations were that both C3 and C5 are necessary for monocyte- and/or granulocyte-mediated release of TF with a concomitant increase in risk of antiphospholipid antibody-mediated thrombophilia,[35] and a risk of C5a for thrombus formation at endothelial surfaces.[34] Hence, the anaphylatoxin C5a appears to be a key molecule for both the complement and the tissue pathway coagulation systems. The implication of this result for implanted biomaterials is that coagulation, and thus wound healing, is probably modulated via both the complement system and the tissue pathway of coagulation. The significance and details of this, however, remain obscure, and it will be of fundamental interest in the forthcoming *in vivo* studies of complement-activating surfaces.

4.406.4. Immune Complement at Biomaterials

4.406.4.1. Prevailing Model of Activator/Inhibitor Surfaces

The contact of blood with a great majority of biomaterials results in complement deposition on the surface and/or activation of the complement system.[10] Findings from the 1980s showed that the use of extracorporeal devices such as cardiopulmonary bypass oxygenators, hemodialysers,[37,38] and heart–lung machines caused significant systemic inflammation. Blood analyses from cardiopulmonary bypass patients revealed that these patients suffered from ~30 min transient leucopenia which generated soluble inflammatory molecules such as thromboxane B_2 and MPAP. The blood reaction was coupled to a large surface area-mediated complement activation that also generated C5a, a potent anaphylatoxin and inflammatory mediator.[9] It was understood at that time that a common denominator for these activating membrane surfaces was a specific surface chemistry and a large contact area. A high level of activation was observed on cuprammonium cellulose; moderate with cellulose acetate and low with polycarbonate or polyacrylonitrile.[9] Based on these observations, Chenoweth proposed a model for complement-activating surfaces.[10] In this model, surface-triggered activation proceeds via the alternative pathway and is mediated by nucleophilic surfaces exposing hydroxyl (−OH) or amine ($-NH_2$) groups. Negatively charged surfaces were suggested to be nonactivators.

A good, state-of-the-art overview of biomaterials-related complement activation and its clinical implications is found in Nilsson.[39]

4.406.4.2. Spontaneous, Classical, and Alternative Complement Activation

The spontaneous tick-over cleavage in plasma of C3 to reactive C3b* and C3a may be the origin of initial surface deposition of C3b at complement-susceptible surface sites, such as adsorbed and partially denatured plasma proteins and nucleophilic sites, that is, complement activation via the alternative pathway. Surface-bound C3b may in turn bind to the complement factor Bb and Properdin, forming the stabilized alternative convertase C3bBbP, which in turn cleaves more C3, and so on (Figures 7 and 8).

Furthermore, experiments with model surfaces suggest modifications in the Chenoweth model, even though it is basically a good complement activation model. It appears that the alternative pathway is not the only pathway involved in surface-mediated complement activation. Immobilized mercaptoglycerol, mercaptoethanol, and IgG, activate the complement via the classical pathway[40–42] in contrast to activation by immobilized IgA via the alternative pathway.[41] One interesting feature of the different pathway model studies was the rapid surface deposition of complement factor 3b (C3b) upon activation via the classical pathway and slow C3b deposition via the alternative pathway. A few, well-known biomaterials demonstrate complement C3b deposition. Thus, hydrated aluminum (pzc∼8–9) in blood plasma activates and rapidly deposits proteins via the classical pathway,[43] spontaneously oxidized titanium (pzc∼5–6) does this in a mixed manner (Figure 9) and silicon (pzc∼2–3) uses the spontaneous or alternative pathway for activation.[44] These model experiments reveal that the complement mainly binds to already adsorbed proteins, but a minor fraction possibly also binds directly to surface groups.[45] The result is not surprising, as the complement is an integral part of the humoral clearance system whose functions include the removal of denatured proteins and debris. The preclinical and clinical significance of complement activation on biomaterials is not well understood, although, in one *in vivo* study, recognized complement activator surfaces recruited more inflammatory cells than nonactivators to the site of subcutaneous implantation in the rat.[46] This reaction is no surprise either, as the complement system also assists the cellular part of the immune system during organ rejection and in autoimmune diseases.

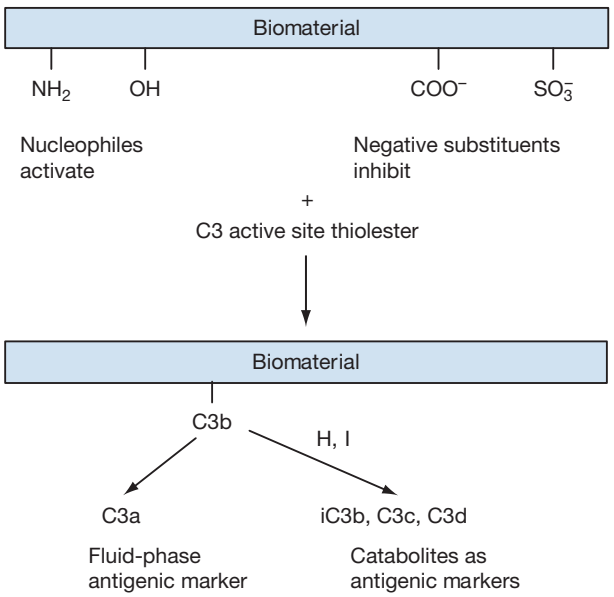

Figure 7 Modified Chenoweth model of complement activation at biomaterial surfaces. Nucleophilic surfaces activate via the alternative pathway and negatively charged surface groups inhibit activation. C3b binds to adsorbed proteins and partly to (material) surface nucleophilic groups.

4.406.5. Consequences of Protein Adsorption

4.406.5.1. Blood Compatibility

Clinical experience indicates that it is very difficult to design a truly blood compatible artificial surface, which, almost without exception, deposits blood proteins. For example, tiny amounts of plasma fibrinogen, $<10\,\mathrm{ng\,cm^{-2}}$ is needed to bind and activate platelets at polystyrene,[47] and all surfaces with hydrophobic character (contact angle in water $>60°$) tend to attract fibrinogen. On the other hand, negatively charged hydrophilic surfaces, comprising the majority of oxide surfaces, activate the intrinsic pathway of coagulation and bind factor XII, HMWK, prekallikrein, C3, and many other proteins; all of these interact more or less with the surrounding cells (Table 3). PEG-like surfaces seem to offer the best compromise with respect to blood compatibility of passive surfaces, the main reason being, of course, the low protein-binding capability, with a concomitant low number of denatured surface-bound proteins and low number of cell-binding sites. Such surfaces are widely used in blood tubings and for biosensor nonfouling prevention. However, platelet and other blood cell activation need not be related to direct platelet binding to surfaces. In one study, circulating and

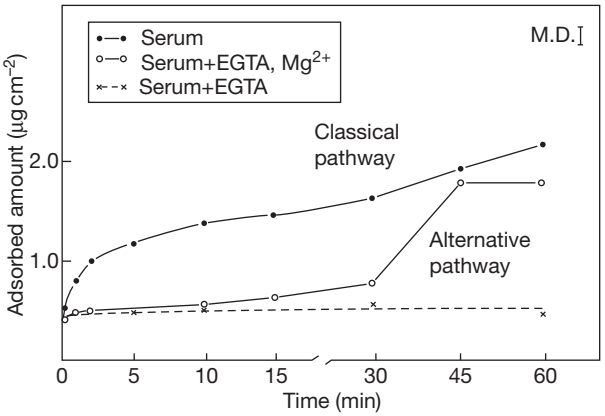

Figure 8 Time course of classical and alternative pathways of complement deposition on model IgG-coated surfaces in whole blood serum, without or with added EGTA or EDTA. Observe the time delay during alternative pathway activation.[40]

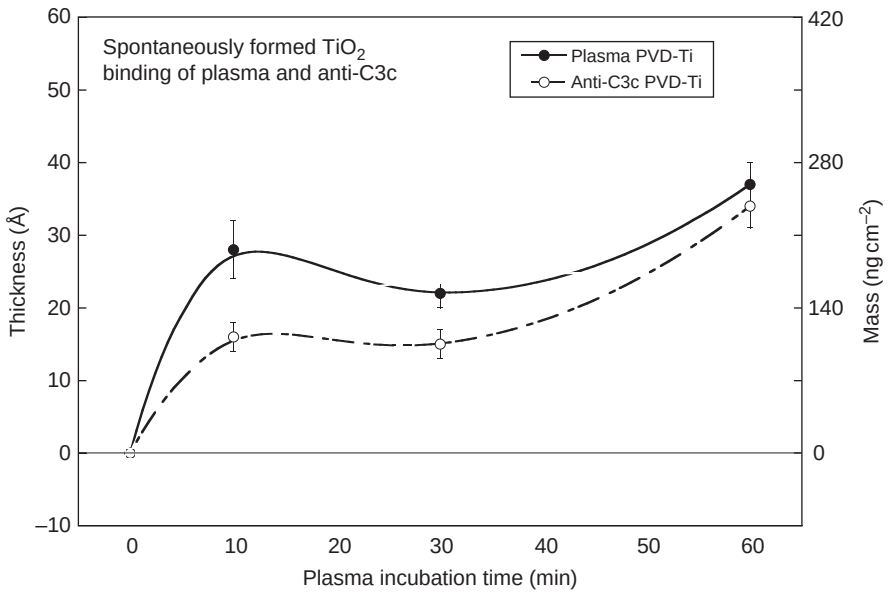

Figure 9 Blood plasma and anti-C3c deposition to spontaneously oxidized titanium that was physically vapor deposited (PVD) to silicon. The plasma value is subtracted from antibody.

surface noncontacted platelets were shown to release their granula contents into the circulation without binding to the test surface.[48] In clinical applications, heparin coatings are often used in blood tubings and large blood-contacting surfaces of heart–lung machines and dialysis apparatus.[49] Immobilized heparin catalyses the degradation of thrombin by the formation of thrombin–antithrombin (TAT) complexes which are subsequently cleared from the circulation. This is, in contrast to PEG, a biologically active surface. Other attempts to mimic low activation or coagulation downregulator surfaces have been made by immobilization of phoshorylcholine[50] and plasminogen to obtain fibrinolytic surface activity via the generation of plasmin.[51]

4.406.5.2. Inflammation and Wound Healing

Adsorbed and partially denatured proteins attract inflammatory cells and redirect, prolong, or enhance the wound healing process around implants. The details of these complex events are not well understood, although it is known that the healing process is different from that at sham sites. Implants in soft tissue become surrounded by a fibrous capsule, more inflammatory cells are recruited to complement-depositing and fibrin-generating interfaces than to sham sites, macrophages and giant cells reside for a long time in tissues outside implants, and the generation of signal molecules is altered during the early healing phase upon the insertion of an implant.[46,52] These changes in the healing process are likely due to changes in communication between implant interfaces and the tissues via adsorbed proteins and activated humoral cascade systems, such as the complement, coagulation, fibrinolytic, and kinin systems, all of which may participitate. The sole presence of a foreign surface is sufficient to change the dynamics of the entire healing process, and can also be observed on the gene level as different materials show quite different gene expressions.[53]

4.406.5.3. Adsorbed Proteins and Biomaterials-Related Infection

Biomaterials-related infection is, according to the traditional Gristina A, 'race for the surface' model, a competition between colonizing bacteria and colonizing tissue cells.[54] Irrespective of the accuracy of this model, adsorbed proteins are sometimes suspected to participitate in bacterial adhesion via host protein-binding adhesins; *S. epidermidis* and *S. aureus* can bind to adsorbed fibrinogen and most likely, also to fibronectin. However, in a recent study on the effect of adsorbed serum proteins and surface colonization via biofilm formation of *S. epidermidis*, it was observed that bacterial biofilm formation was heavily suppressed by adsorbed serum proteins, hydrophobic surfaces were more easily colonized than hydrophilic surfaces, and PEG-coated surfaces resisted biofilm formation very well.[55] The study convincingly shows that adsorbed blood plasma proteins and surface binding strength may assist or resist biomaterials-related infection at the surface, and the response of the surrounding tissue to bacteria is, most likely, much more important in this context.

A recent interesting approach to tissue defense against infection is the identification of antimicrobial peptides (AMPs). The peptides in mammals, defensins, and cathelicidins are expressed by immune and epithelial cells.[56,57] A recent finding shows that many bacteria are killed by the complement anaphylatoxins C3a and C3a-desArg peptide,[58] and C4a.[59] This now opens interesting perspectives, and hypothetically, a sustained short-term tissue infection defense can be an important aspect of complement activation by biomaterials.

4.406.6. Summary and Future Directions

Blood plasma proteins bind to biomaterials. The thickness and composition of the protein film formed vary with surface

chemistry, charge, hydrophilicity/hydrophobicity, water retention capacity, and exposure time. PEG and other hydrogel-like surfaces bind least plasma proteins, and cells often go into apoptosis in such environments. As cells need surface anchorage for proliferation and proper differentiation, this represents an unwanted effect after implantion, but is most often desired in, for example, biosensor applications.

The intrinsic pathway of coagulation is initiated by negatively charged surfaces, and hydrophobic surfaces bind plasma fibrinogen and fibronectin. Complement factor 3b binds to virtually all types of surfaces, although the process may be slow (hours). Cell-surface receptors in turn bind to the adsorbed proteins and change cell expression and activity thereafter.

Future research in this area is needed to increase our understanding of interfacial protein–cell communication, both in the short and the long term. Few studies have until now been devoted to the protein content and biochemistry of the implant-protein film–cell interface, and it is anticipitated that more attention will be given to this aspect in future studies.

Glossary

Bacteria Unicellular, prokaryotic (lacking a membrane-bound nucleus) microorganisms that rarely harbor membrane-bound organelles.

Colloid A colloid is defined as nonliving particles dispersed homogeneously within another substance (e.g., milk).

Colonization The presence of bacteria on or in a biomaterial without tissue invasion.

DLVO theory The DLVO theory is a physicochemical equation used to model simplified bacterial adhesion. The theory includes the effects of charge and van der Waals forces.

Electrostatic forces Electrostatic forces arise when two charged surfaces interact. Atoms with opposite charge signs attract while those with similar charge signs repel. The magnitude of this force is dependent on the overall charge of the surfaces and the ion content of the solution surrounding them.

Infection Invasion and multiplication of microorganisms in body tissues.

Lewis acid–base: polar forces Lewis acid–base interactions or polar forces are based on electron-acceptor–electron-donor interactions between polar moieties, in polar media (such as water).

Lifshitz–van der Waals forces Lifshitz–van der Waals (LW) are electrodynamic interactions arising from the attraction or repulsion of molecules due to the unequal distribution of electrons between bound atoms.
Nonspecific bacterial adhesion Bacterial adhesion resulting from a combination of physicochemical forces, excluding specific adhesin bonding.
Opportunistic infection Infection by an organism that does not ordinarily cause disease but becomes pathogenic under certain circumstances, for example host immunosuppression.
Polar forces See Lewis acid–base interactions.
Specific bacterial adhesion Adhesion mediated by highly specific, stereochemical interactions between complementary components on the interacting surfaces such as adhesins.
Surface energy Quantifies the disruption of chemical bonds that occurs when a surface is created.
Thermodynamic theory The thermodynamic theory is a physicochemical equation used to model simplified bacterial adhesion. The theory includes the effects of van der Waals forces and polar interactions.
XDLVO theory The XDLVO theory is a physicochemical equation used to model simplified bacterial adhesion. Like the DLVO theory, the XDLVO theory includes the effects of charge and van der Waals forces. Additionally polar forces are included in the model.

4.407.1. Introduction

One of the most common and serious complications associated with the implantation of any biomaterial into a biological system such as the human body is bacterial infection. Bacterial colonization of a biomaterial through contamination can lead to the development of an infection, which is notoriously difficult to treat. These infections are associated with significant patient morbidity, prolonged treatment times, delays in healing, and in many cases, costly surgical procedures for removal and implantation of a new implant.[1] All biomaterials, ranging from the most simple and commonplace such as sticking plasters, to life-supporting and more complex devices such as cardiac pacemakers, are at risk of bacterial colonization and the subsequent development of an infection. These infections may occur at virtually any stage in the life-cycle of the biomaterial, from pre- or perioperative stages, to months or even years postoperatively. In all instances, however, the presence and growth of bacteria in the vicinity of the biomaterial represents failure of the device, despite the fact that the device may otherwise be free of any material or functional defects.

Many implanted biomaterials are intended for long-term implantation and are designed to be integrated into the tissue of the host. The fate of these biomaterials upon implantation, that is, whether the biomaterial successfully integrates or an infection develops, has been described as the result of the race for the surface.[2] According to this description, the implant becomes primed for cellular adhesion by the formation of a layer of host extracellular matrix proteins immediately upon implantation into the body. Following this conditioning of the surface, both host cells and potentially also bacteria, compete to colonize the available surface. Should the host cells win the race for the surface, any subsequently approaching contaminating bacteria would meet an intact cellular layer that is accessible to the host immune system. In this scenario, successful colonization of the biomaterial surface by bacteria is considered to be much less likely. Conversely, should bacteria win the race for the surface, then the bacteria are afforded an opportunity to adhere to the biomaterial, grow, spread, and fully colonize the implant surface. Once colonized by bacteria, the biomaterial is much more likely to inhibit cellular adhesion, limit tissue integration, and the development of an infection is favored.

Obviously, not all implants develop an infection, and furthermore not all implanted devices are colonized by bacteria (**Chapter 4.410, Sterilization of Biomaterials of Synthetic and Biological Origin**). The factors and processes that can influence the outcome of the race for the surface and determine whether or not a particular biomaterial may become infected or not, arise out of a complex interplay between the competing factors of (1) the contaminating bacteria, (2) the host, and (3) the device/biomaterial itself. These three factors plus their interdependent relationships comprise what is known as the biomaterial-associated infection triangle, shown in **Figure 1**.

The first apex in the biomaterial-associated infection triangle represents the implanted device or the biomaterial of which it is composed. On a fundamental level the surface topography and chemistry of the biomaterial(s) are known to influence the way and the numbers in which contaminating bacteria adhere to the biomaterial. The topic of biomaterial surface chemistry and topography and their influence on bacterial adhesion will be discussed at length in **Section 4.407.6**.

On a practical level, the wide variation in the function, anatomical location, and mechanical impact of the device on the surrounding tissues contribute significantly to the variability in the incidence of infection between different devices (**Chapter 6.609, Orthopedic Implant Use and Infection**). For example, percutaneous devices such as polymeric catheters or metal external fixation pins create a path through the normally protective barrier provided by the skin and are thus particularly prone to infection. Devices which are completely implanted, on the other hand, such as cardiac pacemakers, or intramedullary nails are less susceptible by comparison with percutaneous devices, yet are also susceptible to infection arising out of perioperative contamination or hematogenous seeding. The development of the modern fracture fixation plate serves as an example of the effect of mechanical impact on infection. The original fracture fixation plates bridge the fracture and compress the two bone fragments together and create local periosteal necrosis at the point of contact. In an effort to minimize necrosis, which is an obvious negative aspect of these devices, design modifications were incorporated to protect the periosteum and minimize necrosis. The new devices offered greater protection of the local tissues and this was found to significantly improve resistance to infection.[3] Infections associated with short-term, external implants such as contact lenses[4] or dentures,[5] are also commonplace; however, these are obviously more easily treated, as the colonized biomaterials are easily removed.

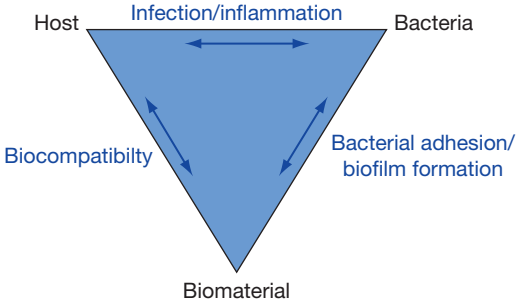

Figure 1 The biomaterial-associated infection triangle.

The second apex in the biomaterial-associated infection triangle represents the host, which plays a very critical role in the development of infection. The factors involved include the medical status of the patient, any comorbidities, wounds, skin lesions, bone fractures, or prior infections.[6] Similarly, the operative conditions in which the device was implanted, the antibiotic prophylaxis administered and postoperative care afforded to the patient will influence the development of infection.[7,8] All these factors can affect susceptibility to infection independent of any interaction with the biomaterial or contaminating bacteria. Aside from these, the host is also involved in crucial interrelationships with the biomaterial. The interaction between the host and the biomaterial is expected to vary somewhat from biomaterial to biomaterial, that is, the host will interact differently with different biomaterials dependent upon the nature of the implanted biomaterial. In general, however, it has been established that the host's ability to clear and eliminate contaminating bacteria is compromised in the vicinity of implanted biomaterials.[9] Frustrated phagocytosis and opsonin deficiency have been observed adjacent to biomaterials.[9,10] The details of the host response to implanted biomaterials and how this impacts upon the development of infection is outside the scope of this chapter and so for further information on this topic, the reader is directed toward some relevant literature.[9–13]

The third and final apex in the biomaterial-associated infection triangle represents the contaminating bacteria and their potential to colonize the biomaterial and/or surrounding tissue. As a brief introduction to the nonbiologist, bacteria are unicellular, prokaryotic (lacking a membrane-bound nucleus) microorganisms that rarely harbor membrane-bound organelles. Bacteria typically range in size from 0.5 to 5 μm in length and the most common physical characteristic used to differentiate bacteria is cell shape or morphology. The most common and simple morphologies include spherical cells (cocci) and elongated rod-shaped cells (bacilli) (**Figure 2**). Bacteria may also be differentiated on the basis of the structure of the cell wall into Gram-positive and Gram-negative (further described in **Section 4.407.3.1**).

Bacteria and eukaryotic cells differ significantly from each other in their growth rate. In a laboratory environment, with optimal nutrient and temperature requirements, the specific growth rate of many commonly encountered bacteria in the

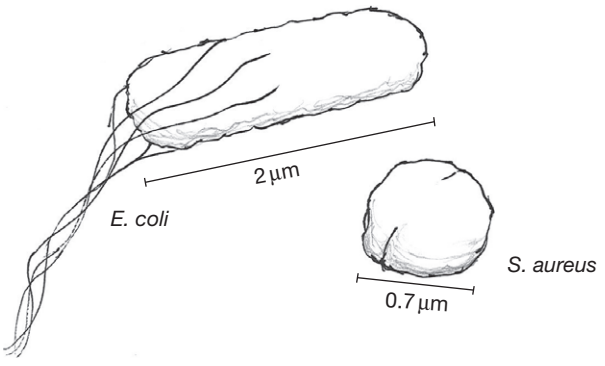

Figure 2 A simplified schematic of two bacterial species *Escherichia coli* (bacillus) and *Staphylococcus aureus* (coccus).

logarithmic phase of growth may be extremely high in comparison with eukaryotic and particularly many mammalian cells. A bacterial species such as *Escherichia coli* may have a cell doubling time as short as 20 min under ideal conditions in the laboratory, while eukaryotic cells may have a doubling time of anywhere between 6 and ~24 h. The growth rate *in vivo* may be significantly reduced, particularly should a sessile community known as a biofilm develop. Another important point to note with respect to bacterial adhesion to biomaterials is the fact that each species of bacteria includes innumerable strains. A bacterial strain is defined as a subset of a bacterial species differing from other bacteria of the same species by some minor, but identifiable difference. Strains within a species may differ slightly from one another in many ways such as their ability to utilize nutrient sources or some minor morphological differences, or as described here, they may also differ with respect to their ability to adhere to host proteins and biomaterials.

The most common bacterial species encountered in biomaterial-associated infections are opportunistic pathogens, that is, bacteria that do not normally cause infections in a healthy host. The bacteria involved are often normal or transient residents of the human skin such as the Gram-positive *Staphylococcus aureus* or *S. epidermidis* and sometimes Gram-negative species such as *E. coli* or *Pseudomonas aeruginosa* (**Figure 3**).

Many of these species are commonly present on the skin of a large percentage of the human population at any given time and it is a combination of decreased host ability to resist infection coupled to the insertion of a biomaterial that can, in a certain percentage of cases, afford these bacteria the opportunity to cause an infection. The contaminating bacteria thus progress from innocent, relatively harmless bystanders, to the agents responsible for the failure of the device, courtesy of implantation of a biomaterial into a host with a localized deficiency, in its ability to fight an infection.

The bacterial species and strains that successfully adhere to a biomaterial and cause an infection do so via the use of numerous virulence factors. Virulence factors may enable bacteria to adhere to biomaterials, surrounding tissue or extracellular matrix proteins, to grow and develop on the cell/biomaterial surface, and resist host defense mechanisms. The single biggest factor in the pathogenesis of bacterial infection associated with biomaterials is the ability of a microorganism or microorganisms to develop a biofilm on the surface of an implanted biomaterial. According to its definition, a biofilm is a sessile bacterial community characterized by cells that are irreversibly attached to a substratum or interface or to each other. These bacteria are embedded in a matrix of extracellular polymeric substances that they have produced, and exhibit an altered phenotype with respect to growth rate and gene transcription.[14] The first step in the development of the biofilm is the initial contact between the contaminating bacterium and implanted biomaterial, and from this first step, infection can develop via the numerous stages of biofilm development (for details see **Figure 4**). Once a biofilm has formed on the device, surrounding tissues may be damaged as a result of the host response to the infection and adjacent tissues may also get infected. In addition, the biofilm is often much more resistant to antibiotic treatment than the free living, individual contaminating bacteria, which had initially adhered to the implant,[15] despite the fact that antibiotic penetration into the biofilm is not necessarily restricted.[16] Faced with an antibiotic-resistant biofilm, the only solution likely to result in successful elimination of the infection is to surgically remove the device, if implanted, followed by antibiotic therapy. The delays in healing, increased patient morbidity and significant costs mean that biomaterial-associated

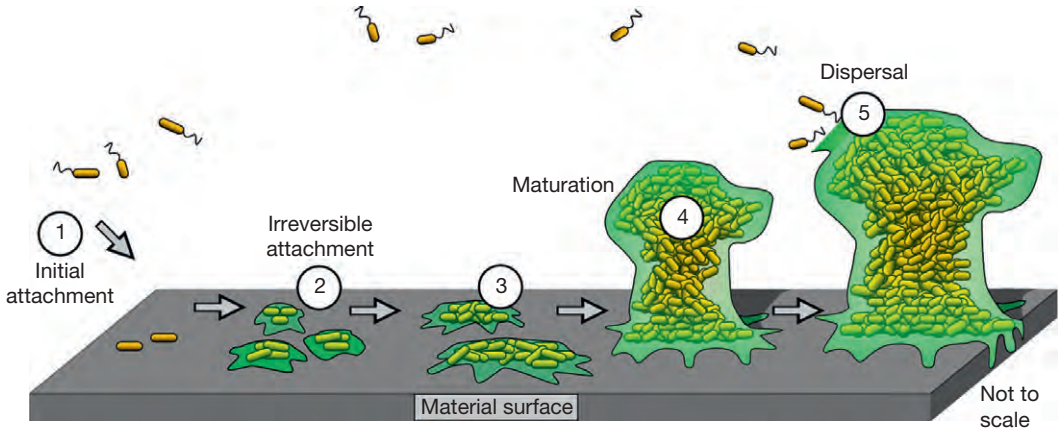

Figure 4 Diagram illustrating the main stages of bacterial biofilm formation.

infections are considered a significant clinical problem. For further details on biofilm formation and associated problems please refer to the published literature where many relevant reviews can be found.[14,17–19]

The significance of bacterial adhesion on biomaterial-associated infection should not be underestimated, considering that the number of adherent bacteria, their ability to grow and spread on the biomaterial surface, and their potential to spread to surrounding tissues and organs, all depend upon this initial interaction between bacterium and biomaterial. The implanted biomaterial will significantly influence these events, and basic research questions involving why contaminating bacteria may adhere more or less abundantly to any particular biomaterial are important fundamental questions that have been extensively investigated by the scientific community. The parameters which influence bacterial adhesion to a biomaterial, the methods used to measure this adhesion, and the theories developed to explain it will all be discussed in this chapter.

A biomaterial is defined as a nonviable material used in a medical device intended to interact with biological systems.[20] This definition has, however, more recently been expanded to include tissue engineered materials,[21] which may also include cells preimplantation. Due to the wide range of biomaterial applications, this chapter will aim to describe bacterial adhesion to a multitude of material types as well as composite materials. Also applicable is a multitude of device types from wound healing plasters, bandages, dentures, and contact lenses, to sutures, catheters, external fixation devices, artificial hips and knees, stents, and cardiac pacemakers. Finally, surface modification has become a major field of work in biomaterial science to improve various aspects of currently available biomaterials, and we will describe the effects of numerous modifications of biomaterial surfaces on bacterial adhesion as well as modifications designed to create so-called bacteria-repellent biomaterials.

4.407.2. Laboratory Methods for the Study of Bacterial Adhesion

The initial adhesion of bacteria to a biomaterial is an important step in the pathogenesis of biomaterial-associated infection. Studies on these initial adhesion events play an important role in the evaluation of a biomaterial, particularly those expected to be exposed to bacterial contamination, such as contact lenses, or those with antiinfective or bacteria-repellent properties, such as polymer brushes or antimicrobial coated surfaces on catheters. Despite the fact that a vast amount of published literature is available characterizing bacterial adhesion to a wide range of biomaterial types, a relatively limited number of techniques are in regular use for the estimation of bacterial adhesion to such surfaces. The laboratory techniques routinely used to measure bacterial adhesion to biomaterial surfaces range from the simple static adhesion assay in which test surfaces are immersed in a bacterial suspension, to the more advanced bioreactors and flow chambers, which can allow measurement of bacterial adhesion under controlled hydrodynamic conditions. The most sophisticated technology currently employed to evaluate bacterial adhesion to biomaterials allows measurement of the strength of adhesion of an individual bacterium to a particular biomaterial surface. This is achieved using modern biophysical approaches such as AFM, optical tweezers, and micromanipulation.

Depending on the actual application of the biomaterial, the choice of technique and experimental approach used to evaluate the interaction between bacterium and biomaterial can, and should, vary. Particularly, the technique used should replicate as much as possible the interaction between bacteria and the surface under the conditions expected to be encountered *in vivo*, particularly with respect to hydrodynamics. Regardless of the biomaterial used, the interpretation of the results of a bacterial adhesion study will be greatly assisted by parallel investigations into bacterial and biomaterial properties and an awareness of the influence each property can have on the interpretation of results (**Box 1**).

4.407.2.1. Static Adhesion Assay

The most commonly reported test method to assess bacterial adhesion to biomaterials is the static adhesion assay. This is because the assay is simple to perform and does not require specialized equipment or advanced personnel training. In a standard static adhesion assay, a sample of the biomaterial to be tested is immersed in a suspension of bacteria for a

Box 1 Important considerations for laboratory procedures investigating bacterial adhesion to biomaterials

Preparation of the biomaterial sample	The preparation protocol should be identical to, or as close as possible to, commercial protocols (if relevant). This includes any cleaning and sterilization protocols and should be replicated exactly for each sample
The physical and chemical properties of the biomaterial	For a full characterization of the biomaterial, the data to be collected should include; surface roughness, surface wettability (hydrophilicity/hydrophobity and surface charge), surface chemical composition and finally whether the surface swells or even dissolves when immersed in fluid. Any changes in these factors can lead to a significant change in the bacterial adhesion profile
Conditioning film	Under *in vivo* conditions the biomaterial is immediately covered by a conditioning film of proteins and solutes. The presence or absence of a conditioning film can have a profound effect on the adhesion of bacteria to the biomaterial and can be an important factor in the evaluation of bacterial adhesion to any biomaterial
Solution choice and molarity	The ionic content of the medium used to suspend the bacteria will have an influence on the results, both in theory (see **Section 4.407.4**) and also in practice. A standard molarity buffer solution such as PBS is most commonly utilized; however, use of physiological fluids, nutritive culture media or changing solution molarity or pH can influence the results of the study
Bacterial species	The choice of the most appropriate bacterial species to be selected is dependent on the biomaterial under investigation and the potential uses of the biomaterial. The most common bacteria used in biomaterials testing include *Staphylococcus epidermidis*, *S. aureus*, *Pseudomonas aeruginosa*, and *Escherichia coli*. Dependent upon application, however, other more relevant organisms should be chosen. For example biomaterials with an intended use in the oral cavity should consider using an oral species of bacteria such as *Streptococcus mutans*
Source and number of bacterial strains	Recently cultured, clinical isolates may provide the most clinically relevant bacterial adhesion data, however, use of a freely available laboratory strain will increase cross reference with other studies performed on the same strain. There is also a recommendation that at least three strains from any given species should be tested to account for the variation observed within strains of the same species
Physical and chemical properties of the bacteria	The bacteria-related characteristics that can influence adhesion should be characterized such as; exopolymer production, presence of a capsule, surface hydrophobicity, surface charge, and bacterial motility should be described when appropriate (see **Section 4.407.3**)
Bacterial inoculum preparation method	The choice of nutritive medium, the density of bacteria added to the sample, the final suspension medium/fluid, number of washes in saline solution and the phase of growth of the bacteria can all have an influence on bacterial adhesion and should be standardized
Bacterial enumeration method	This may be achieved by plating, microscopy, turbidometry, flow cytometry, radiolabeling, fluorescent staining, antibody detection or biomass evaluations. The relative benefits and drawbacks of each of these methods are shown in **Table 1**
Bacterial removal method (if required)	Prior to enumeration of adherent bacteria, it is common for protocols to include steps to allow loosely adherent cells to be removed from the sample. An important consideration for such steps is that it involves the passage of the material through an air liquid interface which can disturb some weakly attached bacteria. If possible, a standardized rinsing procedure should be reported and followed to aid reproduction in other laboratories. In many adhesion protocols, the adherent bacteria are forcibly removed from the surface for subsequent enumeration. The use of sonication has become a common method for such bacterial removal, with methods utilizing chemical removal agents such as Tween or Trypsin sometimes used

Table 1 Bacterial enumeration and visualization methods

Method	*Benefit*	*Drawback*
Sonication followed by agar plating	Reproducible, allows multiple samples to be measured in one experiment	Laborious, requires removal of bacteria from surface and is time consuming
Microscopy	Accurate	Often requires transparent substrate or fixation. Many fields of view must be visualized to obtain a reliable estimation: laborious
Turbidometry/ spectrophotometry	Simple, quick	Measurements of optical density display much reduced sensitivity and accuracy
Fluorescent labeling	May allow microscopy on nontransparent materials	May alter bacterial cell surface and adhesion properties and many fields of view must be visualized to obtain a reliable estimation. Not suitable for autofluorescent biomaterials
Radiolabels	Accurate, sensitive	Safety and cost issues. Requires removal of bacteria from surface, time consuming
Biomass estimation	Simple and quick	Reduced accuracy
Antibody labeling	May be fluorescently labeled to allow visualization on non transparent biomaterials	Laborious and many fields of view must be visualized to obtain a reliable estimation
Flow cytometry	Quick measurement of even mixed populations of bacteria	Laborious, requires removal of bacteria from surface

predetermined period of time, after which the adherent bacteria are enumerated and compared against adhesion to control surfaces. The assay is simple and inexpensive, reliant merely on the availability of the biomaterial in suitable, relatively flat, samples. For example, Harris *et al.*[22] uses the static adhesion assay to assess the effect of surface topography on bacterial adhesion between different orthopedic materials and found that under the conditions of the assay, a smooth surface can result in a reduction in bacterial adhesion for some materials in comparison with microrough equivalents. The static adhesion assay, however, is not standardized and numerous variations in the methodology are common, making comparison between published findings difficult. Static adhesion-type studies also suffer in respect of sampling time, hydrodynamics, and methods for enumeration. Results from a static adhesion assay are measured at a single point in time after a predefined incubation period. Bacterial adhesion at other time points is not measured, which can result in biomaterial-related influences on bacterial adhesion being missed due to reduced sampling times. A second limitation of the static adhesion assay is the fact that the very limited hydrodynamic forces exerted upon the sample are not representative of the clinical situation. A proportion of bacteria adherent on the biomaterial sample will have adhered as a consequence of sedimentation due to gravity; however, sedimentation is expected to contribute minimally to the total amount of bacterial adhesion in many biomaterial applications. For example, in a dynamic fluid such as is present around catheters, any bacteria that approaches the biomaterial, does so in fluid flow rather than sediment through a still solution. The approach of a bacterium to a catheter surface is thus not realistically replicated in static adhesion assays. Finally, to allow enumeration and quantification of the adherent bacteria, the sample coupons are routinely passed through air liquid interfaces and the number of adherent bacteria is determined after serial dilution and plating onto nutrient agars. However, the passage of the coupon through an air liquid interface can potentially cause reproducibility and standardization issues, due to the fact that an unknown amount of bacteria will be removed during each passage through this interface (**Box 1**).

To overcome these issues and provide a better model to investigate bacterial adhesion in more natural environments where hydrodynamics are an important factor, it is increasingly common to see such investigations performed using bioreactors or flow chambers (**Table 1**).

4.407.2.2. Bioreactors

The equipment utilized to perform bacterial adhesion assays under conditions of controlled hydrodynamics broadly fall under two main apparatus types: bioreactors and flow chambers. Bioreactors provide an environment that allows for the controlled interaction between bacteria and biomaterial with the facility for easy sample removal and evaluation of the number of adherent bacteria or the interaction via culture, microscopy, etc. Examples of bioreactors include annular reactors, rotating disc reactors, and the CDC Biofilm reactor. Typically, these reactors are batch apparatus, whereby, bacterial suspension is added to the experiment chamber containing the material samples to be tested, the suspension is then mixed with the samples for a set period of time, and the number of adherent bacteria calculated after this period of time. Typically, bioreactors are used to measure both bacterial adhesion, and subsequent biofilm growth and the results published are generally a combination of these two features (e.g., see Murga *et al.*)[23]

4.407.2.3. Flow Chambers

Flow chambers differ from the bioreactors in ct that, the liquid to which the samples are exposed is continuously refreshed from an external source. Solutions are streamed past the samples at a controlled rate and bacterial adhesion under these conditions can be measured. Flow chambers are particularly useful in modeling *in vivo* flow situation, for example, blood flow. The two most commonly reported flow chambers are the modified Robbins device (MRD) and the parallel plate flow chamber (PPFC).

4.407.2.3.1. Modified Robbins device

The MRD is a multiple sample flow chamber used for quantifying bacterial adhesion after set time periods.[24] In the MRD, samples of biomaterials are placed in series in a fixed position within a chamber and essentially form part of the channel through which the bacteria in suspension is passed (**Figure 5**).

In a standard experiment using an MRD, a bacterial suspension flows through the device for a set period of time usually followed by the passage of a bacteria free solution to remove loosely and nonadhered bacteria. The sample materials are then removed and the adherent bacteria are visualized or enumerated to give the number of adhering bacteria under

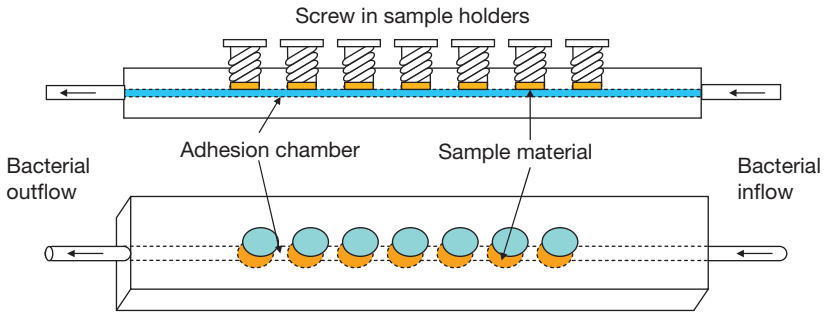

Figure 5 A schematic of a modified Robbins device.

the experimental conditions. The MRD and other similar flow chambers allow fine control of fluid hydrodynamics, are capable of holding multiple samples of biomaterials, and allow quick generation of data. One example of the use of a MRD is the study of bacterial adhesion to cyanoacrylate tissue adhesives, in which adhesion was determined to progress quickly to biofilm formation and there was no or weak bactericidal activity of the material.[25] The use of MRDs has come under scientific scrutiny due to the gradient of conditions along the length of the apparatus, such as a change in temperature and fluid flow rate. Linton *et al.*[26] demonstrate this gradient by illustrating the changing level of adhesion from the proximal to distal samples within the chamber. Despite this, the MRD is still routinely used in laboratories, for example, in the measurement of disinfection efficacy testing of contaminated surfaces.[27]

4.407.2.3.2. Parallel plate flow chamber

Static adhesion assays, bioreactors, and the MRDs are popular due to their ease of use and ability to generate data from multiple samples simultaneously; however, the results are recorded at a single point in time. To generate a continuous dataset of bacterial adhesion, in a non destructive manner, PPFCs are commonly used.[28,29] Numerous flow chambers are commercially available and many custom made versions have also been described in the literature. The construction of PPFCs involves placement of a transparent piece of the sample biomaterial in a chamber, while another piece of transparent material above it seals the chamber to create a channel (**Figure 6**). This setup generates a window through which bacterial adhesion within the channel may be visualized. A pump and tubing system allows a bacterial suspension, or other fluid such as PBS, to flow through the chamber at a controlled rate. Through the use of a microscope and camera, images are regularly captured and the adhesion of bacteria to the material may be monitored. The benefit of the PPFC is that

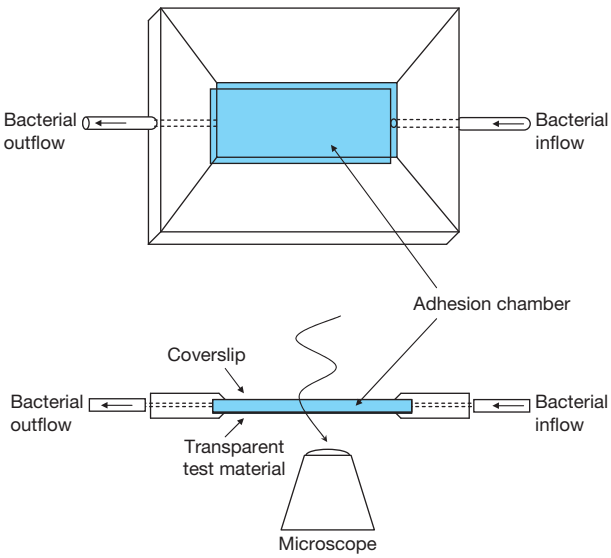

Figure 6 Schematic of a parallel plate flow chamber, top: plan image, bottom: cross-section.

the interaction between bacteria in solution and the biomaterial can be observed in real time and there is no requirement to rinse samples or estimate numbers through plating. Adherent bacteria may then be counted manually or automatically by utilizing computer analysis software on the captured images.

A standard PPFC setup uses light microscopy, therefore, transparent substrates must be used which precludes use of many materials, such as metals, ceramics, or polymers. Various strategies have been employed to overcome this limitation. One such strategy has been to deposit extremely thin films of the material in question onto glass slides. This allows bacterial adhesion to be visualized by light microscopy through the thin coating. This has been achieved, for example, by deposition of titanium onto glass slides.[30] However, coating a glass slide with such a thin film creates a surface that is not chemically or physically identical to the biomaterial one wishes to study, and this may result in a bacterial adhesion pattern that differs from that to the biomaterial under investigation. Another method used to visualize adherent bacteria on nontransparent materials involves the fluorescent labeling of bacteria. However, the fluorescent labeling may influence the surface properties of the bacteria and such an effect could have an impact on the adhesion pattern of the bacteria and should be checked prior to use.[31] Green fluorescent protein (GFP)-labeled bacteria, which have been genetically modified to intrinsically produce a GFP, can also be used to measure bacterial adhesion to nontransparent biomaterials using a fluorescence microscopy and are considered to have a reduced impact on cell surface properties in comparison with fluorescence labeling using a dye. GFP-labeled bacteria are a viable option for testing bacterial adhesion on nontransparent biomaterial surfaces[32]; however, in the case of highly autofluorescent biomaterials, such as most polymers, alternative solutions are required due to the high level of background fluorescence from the material preventing the detection of the fluorescently labeled bacteria.

The PPFC has recently been used to mimic the competition for adhesion between contaminating bacteria and host cells that occurs in a host implanted with a biomaterial in the presence of contaminating bacteria.[33] The adhesion of bacteria to a surface is followed by mammalian cell adhesion, with an ensuing competition for the available surface, that is, the race for the surface as described by Gristina.[2] The outcome of such an experiment can provide an indication of the biomaterial-related factors that influence the race for the surface and may develop into an important tool for biomaterial–bacterial interaction studies, helping to bridge the gap between *in vitro* studies and the clinical situation.

4.407.2.4. Measuring Bacterial Adhesion Forces

In addition to quantifying the number of bacteria adherent to a biomaterial surface, a number of other measurements of interest may also be made. Measurement of dynamic changes during the adhesion of a bacterium to a biomaterial surface may be achieved by the use of a quartz crystal microbalance[34] or surface plasmon resonance.[35] However, these studies have not been extensively used for biomaterial-related investigations into bacterial adhesion as yet. The strength or quality of adhesion of a bacterium to a biomaterial surface may be measured

by methods such as fluid dynamic gauging[36] or jet impingement,[37] although these techniques are rarely cited in the literature. In jet impingement, an incompressible, Newtonian fluid jet impinges on a smooth rigid surface. The resultant pressure forces diminish rapidly away from the jet axis. By directing the jet at a layer of bacterial or mammalian cells, the area from which the cells have been removed provide information as to the detachment strength between the cell and the material.[37] The jet impingement technique allows much variation in jet velocity, exposure time, and the cells and materials that may be used; however, it requires some technical expertise and is not commonly used in experimental studies involving bacterial adhesion.[37] The quality or strength of adhesion is more commonly measured in a PPFC, whereby the number of adherent bacteria can be quantified on a biomaterial surface before and after the passage of an air bubble through the flow chamber. The passage of the bubble through the flow chamber results in detachment force, which will remove a proportion of the adherent bacteria from the biomaterial. The proportion removed is dependent upon the strength of the adhesion.[30]

To directly measure the adhesion strength of a bacterium to a biomaterial surface, critical force techniques such as optical tweezers, atomic force microscopy (AFM), and micromanipulation may be employed. Optical tweezers have been used in a limited capacity to date to measure bacterial adhesion to materials and have centered on measurement of the specific adhesion of bacteria to proteins rather than specifically to biomaterials. Using AFM and related techniques, it is now increasingly common to physically probe biomaterial samples to measure the forces involved in bacteria–material interactions on a nanometer and subnanometer scale.[38–43] Force measurements in the pN to nN range may be detected by AFM and this has been used to measure the interaction between bacterial cell surfaces and biomaterials.[40] AFM probes composed of the biomaterial under investigation are capable of probing bacterial lawns and measuring the forces between the biomaterial and the bacteria. Due to the limited availability of many newer biomaterials in a form suitable to be appended to an AFM tip, an alternative strategy has been developed, whereby the bacteria are actually attached to the AFM tip and used to probe the biomaterial.[41] One example of the use of AFM in bacterial adhesion studies was to show the effect of topography on the resistance of *S. aureus* to removal by physical force.[44] Bacteria on abraded stainless steel surfaces were found to require twice the force to remove than those on polished stainless steel. The use of AFM has allowed for a greater understanding of the interaction forces between bacteria and biomaterials and has immense potential to contribute further understanding and potentiate developments to limit or prevent bacterial adhesion to biomaterials (**Chapter 3.302, Atomic Force Microscopy**).

4.407.3. Bacterial Characterization Methods

As described in **Section 4.407.2**, there are many ways to quantify bacterial adhesion to a surface. However, to gain a better understanding of why bacteria adhere in greater or fewer numbers to any biomaterial one must have an understanding of not only the biomaterial but also the characteristics of the bacteria. Despite the relative simplicity of a bacterial cell, there is a great variety of features expressed by these organisms. The most commonly studied characteristics of bacteria can be divided into two key areas: structural characteristics and physicochemical characteristics. Some of the commonly used methods for determining these features will be summarized in this section.

4.407.3.1. Structural Characteristics

The first and perhaps the most fundamental aspect to characterize bacteria is the cell wall. Bacteria can be divided into two distinct groups depending on the retention of Gram stain due to the cell wall structure. This staining method was originally developed in 1882 by H.C. Gram to distinguish certain bacteria. Bacteria with a thick peptidoglycan layer surrounding the plasma membrane retain the Gram stain and are therefore called Gram-positive. Bacteria with a thin peptidoglycan layer between an outer membrane and the inner plasma membrane lose the Gram stain after washing and are called Gram-negative. For further discussions on the bacterial cell structure the reader is directed to some relevant literature.[45–47] This distinction can be applied to most common bacteria, some examples of which are illustrated in **Table 2** with a summary of the differences between the organisms.

The basic cell wall structure of a bacterium may not influence adhesion directly, however, differences between the adhesion of Gram-positive and Gram-negative species of bacteria to surfaces have been reported.[48] The more complex features,

Table 2 Overview of Gram-positive and Gram-negative bacteria

	Gram-positive	*Gram-negative*
Color after Gram and Safranin counter staining	Dark blue/violet	Red/pink
Characteristics of cell wall	Thick peptidoglycan layer	Thin peptidoglycan layer surrounded by periplasm
	No outer membrane	Outer membrane with lipopolysaccharides and proteins
	Negatively charged teichoic acids are often present	No teichoic acids
Examples	*Staphylococcus aureus*	*Pseudomonas aeruginosa*
	Streptococcus mutans	*Escherichia coli*
	Staphylococcus epidermidis	*Salmonella typhimurium*

Source: Madigan, M. E.; Martinko, J. M.; Parker, J. *Brock Biology of Microorganisms*; Prentice Hall: London, 1997; 8th edn., chap. 3, pp 53–108.

which build upon the cell wall probably affect this difference. Bacterial proteins and cell wall structures fulfill a diverse range of functions, for example, motility, gene transfer, and most importantly in the context of this chapter; adhesion. With the advancement of molecular biology techniques it is now possible to detect the presence of the genes known to code for adhesion enabling proteins and the level of their expression.[49,50] Cell surface appendages such as flagella, cilia, and fibrils are also present on some bacteria species and are also capable of influencing bacterial adhesion to surfaces (further discussed in Section 4.407.5). Electron microscopy is a particularly powerful tool for visualizing adhesion structures and the way they function.[51]

4.407.3.2. Physicochemical Characteristics

Though the surface proteins and surface appendages that may be present on a bacterium have a significant role in bacterial adhesion, physicochemical features must also be considered. A major area of characterization concentrates on the more fundamental aspects of defining the physicochemical features of a bacterium. Commonly, the following aspects of a bacterium are considered: wettability (hydrophilicity/hydrophobicity), electrostatic charge, and intermolecular forces. These characteristics assume particular importance in the application of colloidal theories to the study of bacterial adhesion (discussed in Section 4.407.4). Although appendages and proteins may form strong, specific bonds between the bacterium and a surface, it is believed that it is the physicochemical nature of the bacteria and surface, which exert the initial influences upon whether such bonds form or not. Therefore, measurement of these parameters should form part of the investigative strategy into bacterial adhesion to any biomaterial. There are a wide range of methods to measure physicochemical forces associated with bacteria; the most commonly implemented techniques are described below.

4.407.3.2.1. Bacterial adhesion to hydrocarbons: The BATH test

The BATH test, also known as the MATH test (microbial adhesion to hydrocarbons), was developed to be a rapid and relatively simple test of bacterial hydrophobicity.[52] The test determines the distribution of a bacterial suspension between water and a hydrocarbon, for example hexadecane, octane, or xylene. To perform this test, water, the selected hydrocarbon, and the bacteria are mixed together for a short period of time, typically 120 s. The mixture is then allowed to settle for 15 min, at which point, an emulsion of the hydrocarbon in water will have separated from the bulk of the water due to the hydrophobicity of the hydrocarbon. The location of the bacteria in this partition will depend on the overall hydrophobicity of the organism; hydrophilic bacteria will be located in the water component and hydrophobic organisms will be found associated with the hydrocarbon emulsion. Therefore, by taking a measurement of the optical density of the water component one can determine the relative abundance of bacteria in the water fraction, and thus calculate relative hydrophobicity.[52] A variation on the BATH technique: the microbial adhesion to solvents (MATS) test was developed later with the aim of specifically calculating the Lewis acid–base energy of bacteria by using multiple solvents with different properties.[53]

Despite the simplicity of these tests, these techniques have rarely been used in recent published work due to the problems associated with the method. These problems have been identified as (1) the charge of the hydrocarbons present,[54] (2) the inability to quantify the hydrophilicity of bacteria,[55] and (3) the results are only semiquantitative. More recently, the BATH technique has been largely superseded by the use of contact angles on bacterial lawns.

4.407.3.2.2. Contact angles on bacterial lawns

Contact angles are commonly used as a relatively simple method of estimating the free energy at the surface of a biomaterial. A contact angle refers to the angle made between a solid/liquid/gas interface on a surface. One method of creating a three phase interface is by simply adding a droplet of fluid to a solid surface in air. This produces a measurable, surface-dependant angle as illustrated in Figure 7. By controlling the variables around the three phase interface it is hypothetically possible to calculate both the polar and apolar free energy at a surface. A contact angle is normally measured using a digital goniometer, which photographs the liquid interface and automatically calculates the angle.

To measure a bacterial contact angle, a homogeneous surface of bacteria must be created. Typically, bacteria are grown in suspension to a suitable density and deposited onto filter paper using negative pressure.[56] The contact angle changes as the bacterial lawn dehydrates, so to gain consistent results the lawn must be dried in ambient conditions until the contact angle plateaus and becomes stable, normally after 1–3 h.[57] Despite the broad use of contact angle goniometry, the technique is not ideal for measuring the features of a bacterial lawn as a number of fundamental assumptions about the method must be questioned: for example, is the surface actually smooth and heterogeneous? does the liquid used alter the surface?[21] In measuring bacteria contact angle, the question also arises as to how does the drying affect the bacteria and their interactions with the liquid? Additionally, factors such as the choice of growth medium have also been reported to affect the results generated by this method.[58] Despite doubts about the accuracy of bacterial contact angles, the technique permits relative comparisons between bacteria and is commonly published.[59–70] Contact angles from a large number

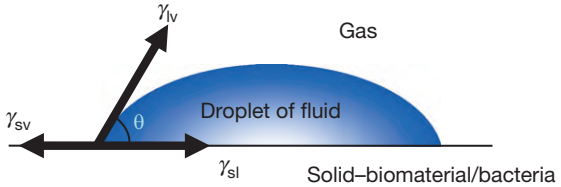

Figure 7 Contact angle (θ) measured between the three phases of the bacterial lawn, the liquid droplet and the surrounding gas. (Liquid–vapor surface tension (γ_{lv}), solid–liquid interfacial tension (γ_{sl}), and solid–vapor interfacial tension (γ_{sv}). Reproduced from Ratner, B. D. In *Biomaterials Science: An Introduction to Materials in Medicine*; Ratner, B. D., Hoffman, A. S., Schoen, F. J., Lemons, J. E., Eds.; Elsevier: Amsterdam, 2004; p 40.

of strains of bacteria have been characterized and whole papers are devoted to documenting the results.[58] In addition to hydrophobicity, bacterial contact angles can also be used to estimate both the polar and apolar energies of a bacterial lawn. To do so three liquids must be used, two polar (e.g., water and formamide) and one apolar (e.g., methylene iodide, cyclohexane, or α-bromonaphthalene). The different types of liquid provide information about how the surface interacts when faced with a polar or apolar liquid. The surface energy of a given material surface or bacterial lawn may then be calculated using the surface energy equations. More detail on the specifics for deriving estimations of free energy from contact angles on bacterial lawns can be found in this review by Sharma.[66]

4.407.3.2.3. Zeta potentials

Zeta potentials are a measure of bacterial surface charge.[57,63,70–75] To understand how the technique works one must first understand the affect of surface charge in a fluid, specifically the formation of an electrical double layer (EDL). When a charged surface, such as the surface of a bacterium, is immersed in an ion-containing fluid, ions of the opposite charge will be electrostatically attracted to the surface. The strength of this attractive force is greatest proximal to the surface and ions with the opposite charge become bound to the particle, or bacterium, forming a feature known as the Stern layer (Figure 8). The electrostatic force then decreases exponentially with increasing distance away from the surface and the concentration of counterions also decreases. The difference in charge between the surface and the bulk fluid creates an electrical potential and the decrease in electrical potential to zero creates a diffuse layer of ions. Together, this diffuse layer of counterions and the charged surface are described as the EDL. In an experimental setup to measure zeta potential, the bacteria moves through the fluid, and as it does so, the proximal adsorbed ions in the Stern layer will move with the surface, while the diffuse layer is more dynamic with ions entering and leaving. This leads to a hypothetical point where on one side ions are immobile and adsorbed, and on the other side ions can slide with the bulk fluid. This is known as the slipping plane and fundamental to the zeta potential theory (Figure 8).

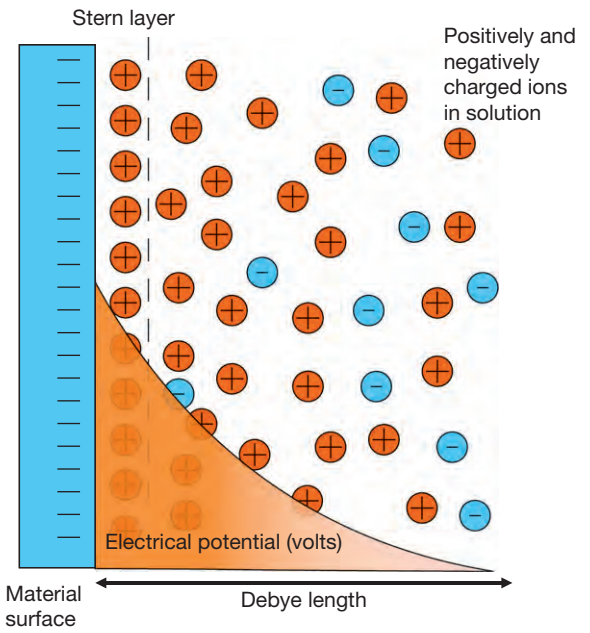

Figure 8 An illustration of an electrical double layer surrounding a negatively charged surface.

The zeta potential technique involves the migration of a charged particle or bacterium in a liquid toward an electrode with the opposite charge, a form of electrophoresis. The speed at which this occurs depends on pH, fluid viscosity, the dielectric constant, the strength of the electrical field around the electrodes, and most importantly the charge of the bacteria. A more highly charged bacterium will move rapidly to the oppositely charged electrode while an uncharged bacterium will remain stationary. The velocity of the particle toward the oppositely charged electrode is measured using a laser and it is this speed which can be substituted into an equation, Smoluchowski's formula,[76] to calculate the zeta potential. The zeta potential is normally expressed in millivolts (mV) and describes the electrical potential between the Stern layer and the bulk fluid, or more concisely the electrical potential at the slipping plane, that is, a measure of charge.

The most commonly used techniques to characterize bacterial physicochemical properties have been summarized (Table 3). However, many of these methods are based on theories, which require critical assumptions that bacteria may not fulfill. This is due to the numerous deviations of bacterial cells from ideal particles with perfect model surfaces. Therefore, the results of these characterizations can only be accurately compared with other bacterial characterization studies when the method utilized is consistent.[77] Additionally, one must always consider that when applying the outcomes of a bacterial characterization analysis the adhesive ability of a bacterium cannot be characterized by physicochemical results alone. For example, contact angles and zeta potentials describe the net characteristics of the bacterial cell surface, omitting individual features such as specific adhesion molecules and cell surface structures. Similarly, only detecting the presence of surface structures, or genes encoding adhesion-related proteins may provide an insight into the adhesive potential of a bacterium; however the actual expression of these features cannot be guaranteed *in vivo* and no information on the physicochemical

Table 3 List of the different characterization techniques discussed and what may be determined from each

Technique	*Use*
Gram staining	Determines the basic structure of the cell wall
Gene/protein analysis	Determines the presence of genes encoding adhesive molecules, surface appendages and the expression of these genes
Microscopy	Visualizes surface structures
BATH/MATH test	Describes hydrophobicity/polar intermolecular forces
Contact angles	Describes wettability, polar, and apolar intermolecular forces
Zeta potentials	Describes surface charge

interaction with the biomaterial is attained. Another important point is that the commonly measured bacterial characteristics are strain and not species dependant.[57] This illustrates the importance of not simply relying on estimating the affects of the aforementioned characteristics on bacterial adhesion, but the need for actual empirical testing for each relevant biomaterial or microorganism. Regardless of the limitations, the proper use of these techniques and a careful interpretation of their significance allow scientists to better interpret bacterial adhesion results and allow hypotheses to be formulated regarding bacterial adhesion to biomaterial surfaces. In the next section, these physicochemical aspects of bacteria will be discussed in relation to bacterial adhesion theories.

4.407.4. Theory and Mechanisms of Bacterial Adhesion

4.407.4.1. Physicochemical Models of Bacterial Adhesion

In order to model and estimate the outcome of bacteria–surface interactions, bacteria may be treated as colloidal particles in a suspension. A colloid is defined as nonliving particles dispersed homogeneously within another substance. By viewing bacteria in a suspension as a colloid it is possible to model bacterial adhesion to a surface as the product of a number of physical or chemical properties of both the bacteria themselves and the biomaterial to which they adhere. These physical and chemical properties may be measured in the laboratory as described in Section 4.407.3. In the study of bacterial adhesion to surfaces, three colloidal models are commonly applied; the thermodynamic theory,[78] the Deryaguin–Landau–Verwey–Overbeek (DLVO) theory,[79,80] and the extended-DLVO (XDLVO) theory.[78]

4.407.4.1.1. The thermodynamic theory

The first theory we will consider is the Thermodynamic Theory, which describes the potential Gibbs free energy change of colloidal adhesion, that is, when the bacteria adheres to a surface. In simple terms, the theory describes the total change in free energy, which is the energy available in a closed system to produce work or a reaction. This is calculated from Lifshitz–van der Waals forces (described in Section 4.407.4.2.1) and Lewis acid–base interactions (described in Section 4.407.4.2.3) when a particle is in contact with a surface, thereby assuming a distance of zero between the particle and the surface. A more detailed review of the thermodynamic theory is described by Morra *et al.*[81]; however, for the purpose of this chapter we shall simplify the theory to eqn [1]

$$\Delta G_{ADH} = \Delta G_{LW} + \Delta G_{AB} \quad [1]$$

ΔG_{ADH} is the Gibbs free energy change of adhesion, ΔG_{LW} is the Gibbs free energy change of the Lifshitz–van der Waals forces, and ΔG_{AB} is the Gibbs free energy change of the Lewis acid–base forces.

The laws of thermodynamics stipulate that a decrease in free energy favors stability. Therefore, when the outcome of eqn [1] is negative, adhesion is favored. The thermodynamic theory of bacterial adhesion is most accurate with uncharged surfaces or in the presence of large quantities of ions.[63,70]

Summary of the thermodynamic theory

Considers Lewis acid–base and Lifshitz–van der Waals forces
Assumes adhesion is always reversible
Distance independent: always calculated for a distance of zero
Does not include the affects of surface charge or the electrolyte concentration of the surrounding fluid

4.407.4.1.2. The DLVO theory

The second commonly used theory is the DLVO theory. The DLVO theory, much like the thermodynamic theory, assumes that adhesion is the product of interfacial energies. The DLVO theory also includes Lifshitz–van der Waals interactions, however, omits the effects of acid–base interactions. Instead, electrostatic forces are included. The interaction between a particle and a surface as predicted by the DLVO theory can be simplified as in eqn [2]:

$$U^{DLVO} = U^{LW} + U^{EL} \quad [2]$$

U^{DLVO} is the total interaction energy, U^{LW} is the Lifshitz–van der Waals interaction energy, and U^{EL} is the electrostatic interaction energy.

The DLVO theory is commonly used to model bacterial adhesion in the literature.[82–86] The DLVO theory is most accurate when electrostatic forces are the predominant interactions and also considers Lifshitz–van der Waals interactions.[63,70] However, the DLVO theory does not incorporate the Lewis acid–base component, which is the ability of a surface to accept or donate electron density to its surroundings. The theory is, therefore, limited in its accuracy because it omits an important aspect of surface chemistry.[63,70,85,86]

Summary of the DLVO theory

Considers Lifshitz–van der Waals and electrostatic interactions
Adhesion can be reversible
Distance dependent: calculated over a range of distances to produce a curve
Does not include the affects of polar interactions

4.407.4.1.3. The XDLVO theory

The most advanced of the theories commonly used for bacterial adhesion is the XDLVO theory. The XDLVO theory combines the features of the thermodynamic and DLVO theories in an attempt to more comprehensively assess colloidal adhesion. The XDLVO was originally devised to model biopolymer adhesion to surfaces,[78] but has since been used in microbial research to more accurately model bacterial adhesion than the existing theories.[63,70,85,86] A simplified version of the XDLVO theory is described in eqn [3]:

$$U^{DLVO} = U^{LW} + U^{EL} + U^{AB} \quad [3]$$

U^{DLVO} is the total interaction energy, U^{LW} is the Lifshitz–van der Waals interaction energy, U^{EL} is the electrostatic interaction energy, and U^{AB} is the Lewis acid–base interaction energy.

Summary of the XDLVO theory

Considers Lifshitz–van der Waals, electrostatic, and Lewis acid–base interactions
Adhesion can be reversible
Distance dependent: calculated over a range of distances to produce a curve

The use of any of the above theories requires some fundamental assumptions about the system to which they are applied to be made:

1. The interacting surfaces are molecularly smooth without a measurable topography.
2. The interacting surfaces are inert and nonreactive under normal conditions.
3. The substance in which the suspension is held is isotropic and maintains bulk properties throughout.

These assumptions must always be considered when applying these theories to bacterial adhesion, as these criteria are often not met by the biomaterial or the bacteria. All of the theories described deal with the free energy of (colloid) bacteria–surface interactions. Bacterial adhesion is hypothetically favorable when the product of the equations associated with the theories is negative. It is important to note that the outcome of these models is always semiquantitative, predicting either an increase or decrease in bacterial adhesion for one set of parameters in comparison with a different set of parameters. For example, for two closed systems otherwise identical, bacterial adhesion will be affected by varying specific parameters such as surface charge or hydrophobicity of the bacteria or the biomaterial.

4.407.4.2. Forces of Colloidal Adhesion

To understand the physicochemical theories applied to microbiological studies, it is important to also understand the forces just mentioned. The three components commonly identified as important in colloidal and bacterial adhesion are Lifshitz–van der Waals, Lewis acid–base, and electrostatic forces. The source of these components will be described in more detail in Section 4.407.4.2.

4.407.4.2.1. Lifshitz–van der Waals: Apolar molecular forces

Lifshitz–van der Waals forces arise from the attraction or repulsion of molecules due to the unequal distribution of electrons between bound atoms.[87] When electrons are unequally distributed between atoms, one atom will gain a net negative charge by having extra electrons, while the other atom will be positively charged due to the excess charge of the nucleus resulting from the loss of electrons. When this arrangement of electrons occurs the atoms are called a dipole. An example of two dipoles interacting is illustrated in Figure 9.

Figure 9 An example of Lifshitz–van der Waals forces between two molecules of hydrogen chloride. The net positive charge of the hydrogen atom attracts the net negative charge of the chlorine atom.

Dipoles can exist due to a number of different reasons[87]:

1. In a molecule such as hydrogen chloride, a dipole is formed due to the higher positive charge of the chlorine nucleus than that of the hydrogen nucleus, this leads to the migration of electrons toward the chlorine nucleus leaving the hydrogen positively charged
2. Alternatively, molecules without this predisposition to form dipoles may temporarily gain a charge differential due to the varying probability of the arrangement of orbiting electrons. This can happen in any atom and creates a very weak- and short-lived intermolecular force
3. A dipole may also be induced by the proximity of another charged molecule. Induced dipoles occur due to the displacement of electrons of one molecule brought about by the attractive or repulsive affect of another. The dipole in this case is formed when a permanent dipole, for example, HCl, interacts with any other atom

Altogether the sum effect of these interactions is called the Lifshitz–van der Waals force. The Lifshitz–van der Waals forces are collectively defined as the apolar energy component. Lifshitz–van der Waals forces are relatively long range and inversely proportional to the distance between the two components. Due to the range of these forces they are often believed to initiate bacterium–biomaterial interactions by either attracting or repelling the bacterial cell at a relatively large distance.

4.407.4.2.2. Electrostatic forces

Electrostatic forces arise from the charge of two interacting surfaces, which can be two solid surfaces, but can also relate to a solid surface and a bacterium. In a liquid, the electrostatic charge of a surface may be caused by the dissociation of surface groups or by the adsorption of charged molecules from the surrounding medium. In nature, most surfaces and bacteria carry a negative charge[88] and therefore, the electrostatic component normally describes a repulsive force.

We have previously encountered electrostatic forces in Section 4.407.3.2. When a surface bearing a charge is submerged in an ion-containing medium, a feature known as the EDL is created, the first part of which is the charged surface itself. The second part of the double layer is the ions carrying the opposite charge which migrate to surround the surface. This layer of complimentary ions is known as the diffuse layer, as the concentration of ions is greatest at the surface and then exponentially decreases with distance away from the surface.[89] The distance to which an electrical potential still exists is known as the Debye length. The presence of ions around a charged surface leads to the dampening of the electrostatic force and therefore a decrease in the Debye length. The distance over which these electrostatic forces can influence bacterial adhesion or repulsion is at zero or equilibrium at the Debye length.

The strength of the force exerted by charged surfaces is dependent on the relative charge of the surfaces, the distance between the surfaces and the number of ions present in the medium around the surfaces. The XDLVO theory predicts that when bacteria and surfaces carry the same charge, adhesion between the two will increase with increasing ionic strength.[63,70] This prediction has been validated experimentally by controlling the ionic strength of the fluid media used in bacterial adhesion experiments.[63,64,70,83,90] The trend of

increased adhesion with increased fluid ionic strength plateaus at ionic strengths greater than ~0.1 M, thus including physiological fluids, which have a concentration of around 0.15 M. At this molarity, the Debye length is too short to cause an observable repulsion.[91] Because the electrostatic force decreases exponentially as a function of ionic strength, liquids with high ion contents, such as physiological fluids (0.15 M), are dominated by the other forces present. As a consequence of the limited influence of electrostatic forces in physiological conditions, bacterial adhesion *in vivo* is influenced more by the effects of the other forces such as Lifshitz–van der Waals forces and Lewis acid–base: polar forces.

4.407.4.2.3. Lewis acid–base: Polar forces

The final parameter, the acid–base interaction, describes the affect of attractive hydrophobicity and repulsive hydration around surfaces. The majority of the acid–base component is brought about by the presence of molecules capable of forming hydrogen bonds. Hydrogen bonds are ~1–2 orders of magnitude stronger than Lifshitz–van der Waals forces and can dominate bacterial adhesion.[92] Hydrogen bond formation requires both a hydrogen bond donor and a hydrogen bond acceptor. The donor is always a hydrogen atom bound to an atom such as oxygen, nitrogen, or fluorine, which strongly attracts the hydrogen electrons; the hydrogen bond acceptor is another oxygen, nitrogen, or fluorine atom bound elsewhere. The hydrogen in the acceptor molecule gains a positive charge due to the relocation of electrons around the bound atom with the more positively charged nucleus. The hydrogen then interacts with the electronegative receptor atom and a strong attractive force is created. Hydrogen bonding is of high importance in water due to the fact that the water molecule is both a hydrogen bond donor and an acceptor. These forces normally make up 90% of all noncovalent interactions in water, and it is the number of hydrogen bonds formed by a surface which influences a characteristic of surfaces known as wettability, the surfaces ability to bond water. When a surface is highly hydrophilic, that is, forms a high density of hydrogen bonds with water, it becomes very difficult for other molecules to approach the surface due to the surface bound water molecules. If however the surface is hydrophobic there is less resistance to adhesion between the surface and colloid or bacteria.

In summary, the three forces discussed in this section and commonly referred to when modeling bacteria as colloids are; Lifshitz–van der Waals, Lewis acid–base, and electrostatic forces (Table 4). The Lifshitz–van der Waals forces act over the longest range; however, the polar Lewis acid–base interactions (hydrogen bonds) are the strongest. The electrostatic forces are highly dependant on the media in which the material is placed and values are therefore not provided.[93] Additionally, the affects of four common functional groups on these forces is illustrated in Table 5. Apolar functional groups can also be described as hydrophobic and polar groups are hydrophilic. The comparisons made in this table are relative and dependant on the environment in which the functional group is found.[94]

Table 4 The range and strength of the intermolecular forces used when modeling bacteria as colloids

Force	*Range (nm)*	*Strength (kJ)*
Lifshitz–van der Waals	0.3–0.4	<2
Hydrogen bond (Lewis acid–base)	0.2–0.3	12–16
Electrostatic forces	Dependant on media	

Stryer, L. Biochemistry. W. H. Freeman: San Francisco, CA, 1975

4.407.4.3. Interpreting the Theories

The application of the DLVO equation can lead to many predicted outcomes for any given particle or bacterial cell, three of which are shown in Figure 10. The patterns illustrated represent three cases within a continuous dataset.

To understand the application of the DLVO theory, graphs of the total free energy as a function of distance between the particle and surface are often generated. Adhesion becomes favorable when the total free energy of adhesion is negative. Figure 11, curve A, shows a situation in which a large energy barrier, possibly caused by strong electrostatic repulsion, prevents bacteria from adhering to the surface. Curve B has a much smaller energy barrier and it is possible for bacteria to adhere in two minima. An expanded version of curve B is illustrated in Figure 11. The proximal minimum or primary minimum is labeled D, and when a bacterium is in this position it is described as irreversibly adhered. The secondary minimum, labeled E in Figure 11, is the distance at which a bacterium maybe reversibly adhered. If a bacterium enters the secondary minimum it may dissociate, translocate, or overcome the energy barrier, and enter the primary minimum.[82] Curve C has no energy barriers and the hypothetical bacteria

Table 5 Four common functional groups with corresponding forces

Functional group	*Polar/apolar*	*Charge*
Methyl ($-CH_3$)	Apolar	Neutral
Hydroxyl ($-OH$)	Polar	Neutral
Amine ($-NH_2$)	Polar	Positive
Carboxyl ($-COOH$)	Polar	Negative

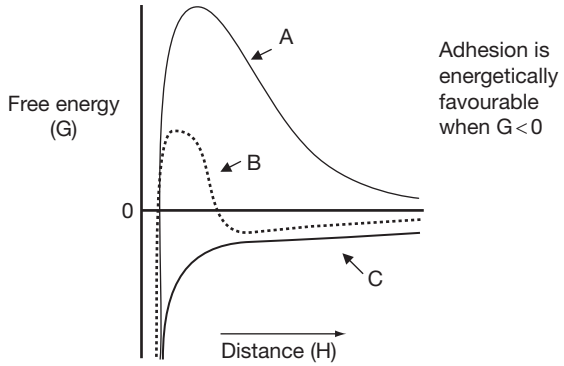

Figure 10 Three possible outcomes of the application of the DLVO theory to a particle approaching a surface with the same charge. The curves are discussed in the main text. Adapted from van Loosdrecht, M. C.; Lyklema, J.; Norde, W.; Zehnder, A. J. *Microbiol. Ecol.* **1989**, *17*, 1–15.

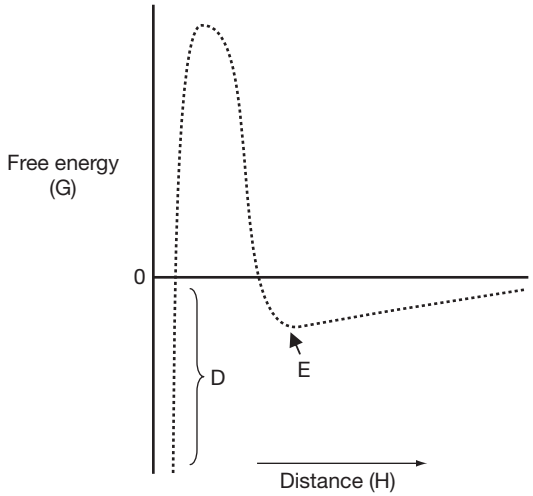

Figure 11 Prediction of the relationship between the free energy of a particle approaching a hydrophobic surface. D is the primary minimum and E is the secondary minimum. Adapted from van Loosdrecht, M. C., Lyklema, J., Norde, W., and Zehnder, A. J. *Microbiol. Ecol.* **1989**, *17*, 1–15.

will be attracted to the surface with increasing force as it approaches the surface. Curve C can be formed when the bacteria and surface are of opposite charges and electrostatic attraction occurs in addition to the attractive Lifshitz–van der Waals forces. The curves shown in Figures 10 and 11 are examples of the possible outcomes of the theory; however, there are an infinite number of curves that may be generated depending on the exact conditions.

Physicochemical theories are often used in bacterial adhesion studies; however, these equations were designed for colloids, not living bacteria. Though accurate when experimental conditions can be controlled, physicochemical modeling will never replace other empirical methods of testing bacterial adhesion. Instead, these theories allow scientists to predict how fundamental forces will affect bacterial adhesion and help explore experimental data. The physicochemical theories provide a good foundation for understanding bacterial adhesion, and in the following section, we shall discuss some of the additional biological aspects of bacterial adhesion.

4.407.5. Mechanisms of Bacterial Adhesion

Broadly speaking, bacteria may adhere to a biomaterial in one of two ways, either directly to the bare biomaterial or indirectly via a conditioning film deposited on the biomaterial. In general, bacteria may be considered to adhere in a nonspecific manner with bare biomaterials and this is largely how the biomaterial–bacterial interaction is investigated *in vitro* and bears closest resemblance to adhesion patterns predicted by the theoretical models. This scenario may be considered analogous to direct bacterial contamination of the biomaterial prior to implantation. However, once the biomaterial is placed in a physiological fluid, after implantation for example, it immediately becomes coated in a conditioning layer of extracellular matrix (ECM) proteins. The presence of a protein layer on the surface of the biomaterial affords contaminating

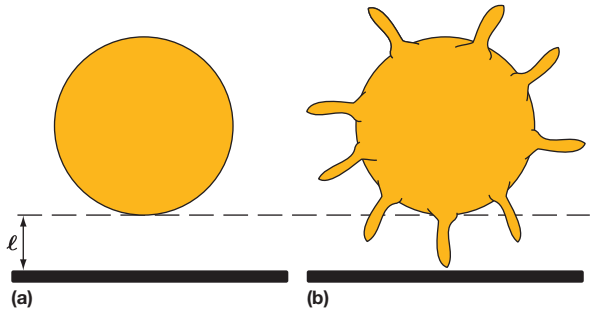

Figure 12 Illustration of the way in which surface structures on bacterium interact with a surface. (a) A spherical particle at the closest approach to a surface (l) and (b) the same spherical particle coated with smaller surface structures. Reproduced from van Oss, C. J. *J. Mol. Recognit.* **2003**, *16*, 177–190.

bacteria the opportunity to adhere in a specific way with the proteins now present on the implant surface. Specific adhesion may be investigated *in vitro* by preconditioning biomaterial samples in defined or complex proteinaceous solutions. However, it is difficult to replicate the exact constitution of the conditioning layer present *in vivo*. Furthermore, it is difficult to separate the relative contribution of nonspecific and specific mechanisms of bacterial adhesion upon infection propagation either *in vitro* or *in vivo*.

4.407.5.1. Nonspecific Adhesion

Many bacteria have surface structures, which function to aid adhesion. These structures can breach the energy barrier, which separates bacteria from a surface. The repulsive force existing between a particle and a surface is a function of distance proportional to the radius of the particle.[89] Therefore, surface structures with a small cross-sectional area allow bacteria to interact with a surface over a decreased distance, which reduces the repulsive energy barrier (Figure 12).

Cell appendages may also aid adhesion through motility, as has been shown for the flagella of *P. aeruginosa*.[95] Increased adhesion to surfaces mediated by the presence of cell structures that do not confer motility has also been described. Ishii *et al.* have shown that a wild-type *Acinetobacter* isolate adhered in greater numbers to surfaces than a surface appendage-deficient mutant. The wild type also became irreversibly attached, something that many of the mutant cells were not able to achieve.[96] The bacteria in the Ishii study were shown to be nonmotile, suggesting that it was not motility, but rather another feature of the cell appendages driving adhesion.[96] A similar trend was also observed using *Listeria monocytogenes*, when the adhesion of flagellum-deficient mutants to stainless steel was reduced 10-fold compared with the wild-type bacteria under conditions preventing motility.[97]

Similar to cell surface structures, the production of exopolymers can also help bridge the energy maximum, allowing irreversible adhesion. Exopolymers are organic substances secreted from the bacterial cell and include bacterial slime, biosurfactants, and proteins, all of which may influence bacterial adhesion. In particular, the slime produced by bacteria is known to increase bacterial adhesion.[98,99] Furthermore, exopolymers can condition material surfaces and affect wettability.

This conditioning has been shown to facilitate an increase in bacterial adhesion, even allowing bacteria to adhere to surfaces that are not predicted to allow adhesion according to the DLVO theory.[85] Some exopolymers have further effects aiding bacterial adhesion, for example, by locally increasing the ion concentrations around a surface to reduce electrostatic repulsion and directly bridge the bacteria to the surface.[100]

In contrast to the production of molecules that increase bacterial adhesion, some bacterial species exude biosurfactants to inhibit adhesion of other bacteria to a surface. Some bacterial species do this as a survival strategy in a competitive environment. A decrease in bacterial adhesion is believed to be achieved via a reduction in water surface tension mediated by the extracellular molecule. A reduction in surface tension increases wettability – which in effect makes the surface relatively more hydrophilic. For example, one biosurfactant, isolated from *Lactobacillus acidophilus*, inhibits over 70% of *Enterococcus faecalis* adhesion to glass.[101] The principle of making an implant surface more hydrophilic to achieve a reduction in bacterial adhesion is a technique, which has been adopted by the biomaterial community to reduce bacterial adhesion (**Section 4.407.6.1**).

4.407.5.2. Specific Adhesion

Analogous to the accepted premise that bacterial adhesion to a biomaterial is the first step in the development of biomaterial-associated infection, bacterial adhesion to tissues, cells, and molecules of their host is the first step in classical infections in which biomaterials are not involved. In these infections, such as osteomyelitis, urinary tract infections or endocarditis, bacterial adhesion proceeds through a specific recognition mechanism that occurs between bacterial surface structures, called adhesins, and molecules present in the host, in a ligand-receptor type interaction. Numerous pathogenic bacteria such as *S. aureus*, *E. coli*, and the Streptococci are known to possess a range of such adhesins, which enable the bacteria to specifically adhere to the host environment, enabling the pathogen to efficiently colonize or infect a certain niche in the host organism.

A large number of adhesins have been identified in many bacterial species. These adhesins may recognize simple or complex carbohydrate structures, membrane proteins or extracellular matrix components of the host and the particular set of adhesins possessed by an individual bacterium depends largely upon the species, but can also vary within strains of the same species. Some of the most extensively studied adhesins include those of the most prominent pathogens such as *S. aureus*, which has been found to express multiple adhesins for target molecules such as collagen, fibrinogen, bone sialoprotein and vitronectin, for example. These are also very important adhesion/binding proteins for eukaryotic cells. These adhesins have been named microbial surface components recognizing adhesive matrix molecules (MSCRAMMs)[102] and evolved as virulence factors in human infections prior to the advent of implanted biomaterials (**Figure 13**).

Despite the fact that there are no adhesins specific for biomaterials, such as metals or polymers, it has been shown that adhesins are capable of mediating specific interactions between bacteria and biomaterials by binding to the extracellular matrix proteins deposited on the device immediately upon implantation (**Figure 14**) (**Chapter 4.406, Protein Interactions with Biomaterials**).

The specific interaction between adhesins and extracellular matrix components deposited on the biomaterial is not accounted for in the physicochemical theory of bacterial adhesion, as the adhesins have not been found to influence any of the bacterial factors present in the physicochemical equations, such as surface free energy or zeta potential. Notwithstanding this fact, it has been shown that when a relevant or suitable protein layer is deposited on the surface of the biomaterial, bacterial adhesion is affected. For example, bacterial adhesion may be significantly enhanced to a protein-conditioned surface when the cognate adhesin is expressed by the tested bacterial strain, and also a reduction in adhesion has been shown when the isogenic mutant lacking in the specific adhesin was tested.[42,103] The actual conformation and composition of the complex protein layer deposited on the biomaterial *in vivo* is influenced by the physicochemical properties of the biomaterial. Therefore, there will be a variable influence on bacterial adhesion, dependent upon biomaterial interaction with the ECM matrix, and the subsequent conformation and composition of the protein layer, as well as the presence or absence of the range of adhesins expressed by the contaminating bacteria.[104]

To quantitatively measure the specific interaction forces between a bacterial cell and a substratum, AFM can be employed. As described already (**Section 4.407.2.4**), the

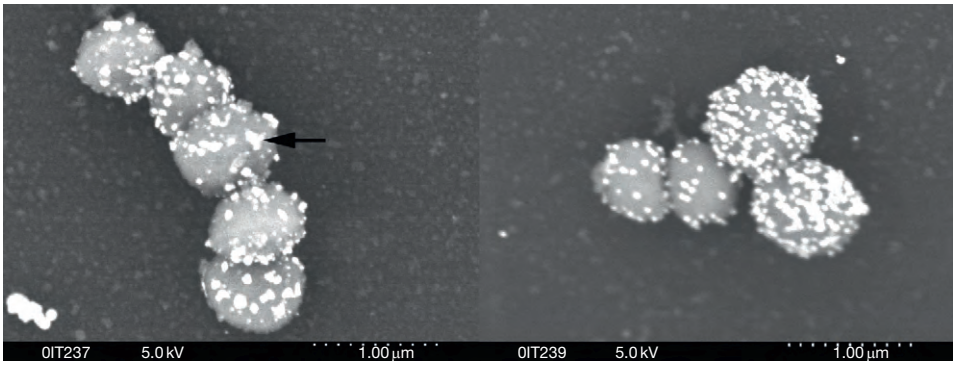

Figure 13 Immunogold labeled *S. aureus* identifying protein A, an MSCRAMM common amongst *S. aureus* isolates. Reproduced from Harris, L. G.; Foster, S. J.; Richards, R. G. *Eur. Cell Mater.* **2002**, *4*, 39–60.

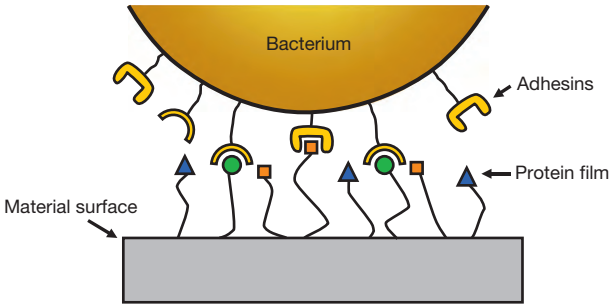

Figure 14 Specific adhesion between a bacterium and biomaterial surface proceeds via adhesins interacting with eukaryotic ECM proteins deposited zupon the biomaterial surface.

interaction forces between a viable bacterial cell (on an AFM tip) and a biomaterial surface measures a so-called real-life interaction.[42] Using this technique AFM has shown that interaction forces of −3 to −5 nN are present when bacteria adhere specifically to protein covered materials. The strength of this interaction is 2–3 times greater than the interaction observed in the absence of a specific interaction, that is, without the adsorbed protein layer on the biomaterial.[105] The strength of this interaction arises from multiple similar interactions between adhesins and host molecules, with each individual binding[106] measured at a few tenths of a nN. The total interaction forces between a bacterium and the protein covered biomaterial are obviously the result of the sum of specific interactions and nonspecific interactions, that is, those interactions described in physicochemical theories. The nonspecific interaction forces contribute relatively minor forces of up to −2 nN.[105] Considering the facts that every implanted biomaterial develops a complex conditioning film of ECM proteins immediately upon implantation, and the majority of bacteria possess numerous ECM recognizing adhesins, the specific interaction between bacteria and biomaterial, via conditioning film proteins, is an extremely important mechanism of bacterial adhesion to implanted biomaterials.

The importance of the adhesins for the progression of infection has inspired attempts at developing vaccines targeted at preventing MSCRAMM-mediated adhesion of Staphylococci to implanted biomaterials.[107] Biomaterial-based strategies to reduce bacterial adhesion *in vivo* may also be developed to take advantage of the specific nature of this type of bacterial adhesion.

4.407.6. The Influence of Biomaterial Surface Properties on Bacterial Adhesion

The success of an implant is to a great extent governed by the bulk properties of the implant material, but upon implantation it is the surface structure and surface chemistry, for example, charge, topography, hydrophobicity, and zeta potential, which determine the biological response. This is true not only for eukaryotic cells, but also prokaryotes. As described in Section 4.407.4, bacterial adhesion occurs as a result of physicochemical interactions. These interactions are influenced by the bacterial strain itself and the surrounding environment, such as pH, ionic concentration or protein concentration, and the biomaterial itself will also influence this process. Biomaterials can generally be defined into metals, ceramics, polymers, natural materials, and composites. It is beyond the scope of this chapter to describe the proposed reasons, influences, mechanisms, or theories put forward as to why certain bacteria adhere in fewer or greater numbers to every available biomaterial; however, this section will describe the bacteria–surface interface from a more fundamental perspective of chemistry and topography.

The surface of a material represents the boundary/exterior of a three-dimensional structure and therefore in general, this surface layer has increased surface energy.[108] This energy is a result of unsaturated or unterminated bonds, that is, the atoms at the surface are not bonded to the maximum number of neighboring atoms and are therefore in a higher energy state than atoms in the interior.[109] The laws of thermodynamics dictate that a material surface in any environment will try to reduce this energy to the state of the lowest free energy. This is hypothetically achieved by, for example, minimizing the total surface area, such as a liquid forming a droplet; however, this is not possible for a solid. A solid will therefore try to react with the surrounding environment, such as the formation of an oxide layer on titanium. Such reactions occur within nanoseconds of the surface being exposed to, for example, air.[108]

The surface of a biomaterial is formed by the individual manufacturing processes for that material and the surface is conferred a specific chemical composition and surface structure or topography. The combination of surface chemistry and topography influences the wettability (hydrophilicity/hydrophobicity) of the biomaterial surface and these three factors are the main influence on bacterial adhesion from the perspective of the biomaterial. The following section will focus on the affect of biomaterial surface chemistry and topography on bacterial adhesion. Bacteria will seldom adhere directly to a biomaterial; a conditioning film always form immediately upon implantation into the body. Therefore, this section shall also briefly describe the fundamental influences on protein adsorption to the surface as this will dictate the cell and bacteria interactions which follow.

4.407.6.1. The Influence of Surface Chemistry on Bacterial Adhesion

When a biomaterial is placed in a biological environment, water is amongst the first molecules to reach the surface. This process occurs within nanoseconds.[110] The orientation of the water molecules on the surface is influenced by its polarity and the wettability of the surface. The subsequent protein interaction is consequently influenced by the orientation of the water molecules.[110,111] The importance of the cascade of molecules absorbing to a surface becomes more apparent when the number and diversity of these molecules is considered. There is an array of more than 200 proteins in plasma, which can interact with the surface and these interactions are influenced by surface chemistry and structure. In turn, this adsorbed protein layer/conditioning film influences pro- and eukaryotic cellular interactions. The surface of a material is therefore integral in controlling the biological reactions.[108,112,113] Protein adsorption occurs within the micro- and millisecond time frame, but can also continue for

longer periods of time.[110,111] The way in which proteins adsorb to a surface is strongly influenced by surface chemistry. Protein adsorption is not fully understood, and proteins are strongly affected by interactions with solid materials.[110] Many proteins contain nonpolar, polar, and charged residues, and the orientation of a protein can therefore change depending on the surroundings.[114] Surfaces which are at neither extreme of hydrophobicity/hydrophilicity are thought to bind protein moderately, allowing reorientation depending on surrounding biomolecules, thus increasing possible interactions with the surroundings.[115] Fibronectin is one of the more influential proteins for eukaryotic cell adhesion and has been shown to adhere strongly to hydrophobic surfaces. However, owing to the conformation caused by this adsorption, the fibronectin is unable to reorientate to aid eukaryotic cell adhesion when the surface is very hydrophobic. When adsorbed onto less hydrophobic surfaces, however, fibronectin can reorientate to aid eukaryotic cell adhesion[115,116] As described in detail in Section 4.407.5 bacteria adhere in a nonspecific and specific manner and surface chemistry will therefore, have an important influence on specific adhesion.

Many studies have focused on the relationship of surface wettability and bacterial adhesion.[74,75,82,117–121] The wettability of both the bacteria and the biomaterial will influence the ability of the bacteria to adhere. Firstly, the wettability of the bacteria; by using contact angles, a simple measure of wettability, it has been shown that more hydrophobic species of bacteria adhere more efficiently to hydrophobic materials, in this case polystyrene.[74,75] More recently, this has been investigated using different strains of the same species. More hydrophobic strains of *S. epidermidis* adhere more readily to polyethylene, also a relatively hydrophobic polymer, at low shear stress in protein-free media, than the more hydrophilic strains.[122] Findings from Li and LoganLi and Logan[64] also identified that bacteria such as *E. coli D21f2*, which are more hydrophobic adhere less readily to more hydrophilic biomaterials than less hydrophobic strains. From the perspective of the wettability of the biomaterial, more hydrophilic surfaces, with wettability between 9° and 22°, had the lowest bacterial adhesion for all the strains tested, and the more hydrophobic surfaces, with wettability between 52° and 68°, had increasing bacterial adhesion. These studies, to a certain extent, confirm the theories described in Section 4.407.4, where colloidal interaction theories are described as a means of predicting bacterial adhesion.

Efforts to alter the surface chemistry of biomaterials to influence the adhesion of bacteria have been shown to successfully do so. For example, poly (ethylene glycol) modification of polyurethane has been shown to decrease hydrophobicity and this dramatically decreased the adhesion of *E. coli* and *S. epidermidis*.[123] Furthermore, it has been reported that surface thiocyanation decreases the hydrophobicity of polyvinylchloride, increasing the wettability from 72° to 50°.[124] The subsequent reduction of *S. epidermidis* and *S. aureus* adhesion by ~90% was identified to be as a result of the increase in surface hydrophilicity and not cytotoxicity.[124] However, surface modification to improve the wettability does not always lead to reduced bacterial adhesion. Cunliffe *et al.* grafted various surface functional groups onto glass substrates to assess the effect of these on protein adsorption and the adhesion of different species of bacteria.[125] The bacteria used were *L. monocytogenes*, *Salmonella typhimurium*, *S. aureus*, and *E. coli* and the grafted surfaces included a wide range of functional groups with varying the wettability, thereby altering surface free energies. In general, the bacteria, the cytochrome C, and bovine serum albumin adhered more readily to hydrophobic surfaces. Both *L. monocytogenes* and *E. coli* followed the same trend as the proteins. However, *S. aureus* and *S. typhimurium* differed, specifically, the hydrophilic surface produced by acetamide functional groups was more susceptible to bacterial adhesion from these two species, than the relatively hydrophobic Krytox perfluoropolymer.[125] Cunliffe *et al.*[125] identified that the surface of the various bacteria, their ability to adhere to bare and protein-conditioned surfaces and their ability to produce exopolymers play an important role in the adhesion to these surfaces, thereby highlighting the importance of characterizing both the biomaterial surface and the bacterial surface before any conclusions can be drawn. More recent work has shown that similar levels of adhesion were achieved by *S. epidermidis* on very hydrophilic surfaces with a water contact angle of 28°, and very hydrophobic surfaces with a water contact angle of 101°.[82] This particular study measured not only adhesion at one time point but also reversible and irreversible bacterial adhesion and the ability of the bacteria to slide along the surface in a form of mobile adhesion. Though the total number of bacteria adhered to each surface was similar, the bacteria were ten times more mobile on the hydrophilic surfaces, where the bacteria were also able to detach from the surface, showing reversible adhesion.[82] For further information on reversible/irreversible and mobile/immobile bacterial adhesion please see relevant literature.[82,126–128]

4.407.6.2. The Influence of Surface Topography on Bacterial Adhesion

To evaluate bacterial interactions with surfaces it is important to have an understanding of not only the surface chemistry and wettability but also surface structure or topography. Titanium implants, for example, can have a titanium oxide (TiO_2) surface layer which can be between 5 and 200 nm thick[129] which results in ~45 at.% surface oxygen, making the surface relatively hydrophilic. However, depending on the manufacturing process this surface can be relatively smooth (R_a of 0.2–0.4 μm) or have micron size surface features, as shown in Figure 15 (see Chapter 6.622, The Effect of Substrate Microtopography on Osseointegration of Titanium Implants).

The interaction of bacteria with these two surfaces of the same chemistry but differing in topography, leads to distinctly different bacterial interactions.[22] Increasing surface roughness has also been identified as a factor leading to increased bacterial adhesion elsewhere.[22,129–131] As previously mentioned, bacterial strains of the same species may differ in their interaction with the same surface due to, for example, different surface charge. However, surface roughness has consistently been reported as one of the major influencing factors, which can lead to increased bacterial adhesion independent of bacterial strains or species investigated.[22,130,132–137]

The affect of surface topography is not included in any of the bacterial adhesion theories described in Section 4.407.4. This is because one of the assumptions the theories are built upon is that the surfaces are perfectly flat that is, no discernable

surface features. Despite being omitted from the theories, the affect of topography has commonly been discussed in work studying the physicochemical aspects of bacterial adhesion. Attempts to understand the affect of topography on the XDLVO theory suggest that increased adhesion to rough surfaces is due to the localized conditions created by surface features, such as peaks. These localized conditions effectively decrease the range of the repulsive components described in the theory,[138] in the same way as bacterial surface appendages do (**Figure 12**), as described in **Section 4.407.5.1**.

Topography has also been identified as a major factor in eukaryotic cell adhesion.[139,140] Topography on the micron scale is purposely incorporated into titanium implants to improve tissue integration,[129] and nanotopography has been shown *in vitro* to influence stem cell differentiation without external stimulus.[141] Ploux *et al.*[142] investigated the adhesion of both a eukaryotic cell type and a bacterial strain in parallel to identify the affect of chemistry and topography. The shape and size of topographical features have been shown to play an influential role in eukaryotic cell adhesion in numerous studies.[139,140,143–153] Fibroblasts were one of the first cell types to be shown to exhibit contact guidance, where the cells react to and align with surface features during adhesion.[139,140,148,150] There is, therefore, a trade-off in designing implantable materials between the need for roughness, for eukaryotic cell adhesion, and limiting the dimensions of these features in order to discourage bacterial adhesion. The influence of surface roughness in relation to bacterial cell adhesion has not only been identified for biomaterials, but also for surfaces used in food preparation areas, where the roughness of stainless steel is monitored for scratches and surface irregularities.[130] Scratches to the surface of dentures have been linked to increased bacterial adhesion, where the crevices created provide the ideal environment for bacteria to adhere and create biofilms[5,134,135] More recently, a few papers have highlighted ordered topographical shapes, including the influence of nanotopographies on bacterial adhesion.[136,142,154,155]

The interpretation of the shape of the surface features and how they would influence bacterial adhesion is often overlooked, and **Figure 16** illustrates why the topography should also be evaluated.

The measures for surface roughness illustrated in **Figure 16** shows R_a, the average roughness, and R_z, the average maximum height profile. Surface topography has been investigated thoroughly in relation to bacterial adhesion,[44,130,136,137,154,156] but without proper evaluation of the surface features, such as those shown in **Figure 16** a full interpretation of the bacterial interaction cannot be made. **Figure 16(a)** shows a surface where the peaks and troughs of the surface permit the bacteria to attach in secluded areas, while **16(b)** shows a surface where this is not possible, and the bacteria will be more exposed. As surface area available for bacterial adhesion has been shown to be important in influencing bacterial retention, the size and shape of surface features are extremely important in influencing bacterial interactions, as shown in **Figure 16**.[136,142,155] Experiments using artificial topographies in flow chambers have shown that adhesion to edges both downstream and upstream were favorable compared to flat control areas. Increased bacterial adhesion was particularly pronounced at the edges when the topographical features were in a similar size range to the adherent organisms, that is, the features accommodated the size of the bacteria.[67,92,156]

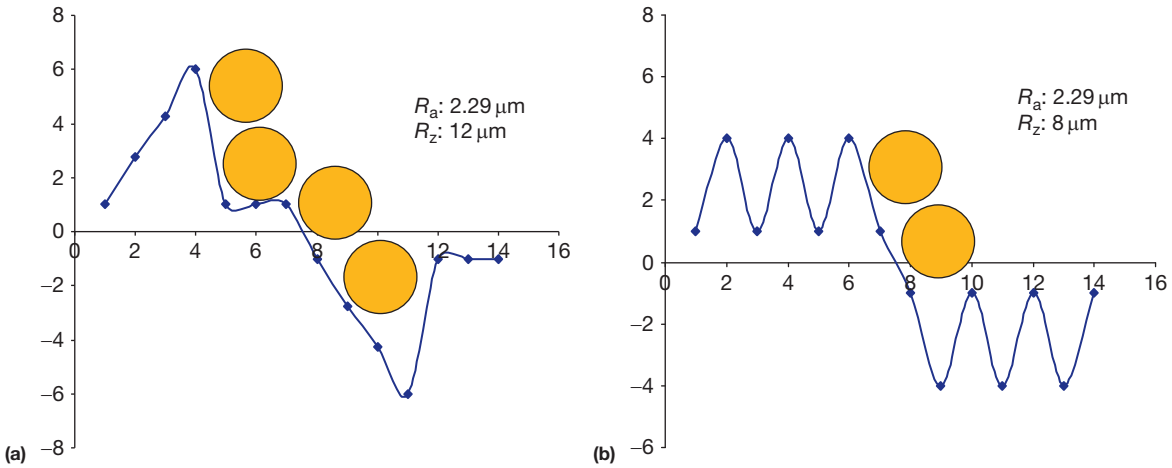

Figure 16 Illustration of the interpretation of surface topography, where two surface with the same roughness (R_a) have very different surface features, (a) one which would allow bacteria to adhere and proliferate, and the other (b) which would not allow adhesion to the same extent.

Topography is one of the major influences on bacterial adhesion and, dependent on the application, the topography of the implant can be manipulated to reduce bacterial adhesion and/or improve tissue biocompatibility. The surface topography can be increased, even made porous or pitted to improve tissue interactions, such as osseointegration, and thereby effectively seal the implant from the surrounding environment, and this is especially important in percutaneous implants.[157] This porous/pitted topography does not necessarily reduce bacterial adhesion, however, the improved soft tissue integration can prevent contaminating bacteria from accessing the subcutaneous tissue-implant interface. On the opposite side of the spectrum the surface can be polished to remove any distinct features, which could propagate bacterial adhesion, as increased roughness has been linked to increased bacterial adhesion.[22,44,130,136,137] Polishing such surfaces may, however, also prevent soft tissue adhesion, leaving liquid filled voids as has been observed surrounding some polished steel orthopaedic implants.[158] Such liquid filled voids could allow bacterial propagation as vascular system and host defence mechanisms may not be able to penetrate the fibrous tissue capsule. The topography of the biomaterial may, therefore, have significant impact on *in vivo* infection rate aside from the impact on bacterial adhesion.

There are many studies which evaluate both the surface chemistry and the topography. Nevertheless, there are few general conclusions which can be drawn, which may stem from the use and understanding of surface characterization techniques, methods used to evaluate the bacterial interactions and finally the wide range of strains investigated. However, two general adhesion patterns have been found; bacterial adhesion to relatively hydrophilic surfaces is normally reduced or the adhesion is weaker than to relatively hydrophobic surfaces, and increased bacterial adhesion is associated with increased surface roughness, although the size of the surface features may also play an influential role in bacterial adhesion.

4.407.7. Strategies to Reduce Bacterial Adhesion

The biomaterial-based strategies developed to reduce or prevent the incidence of infection associated with implanted devices broadly fit into three general categories; those that incorporate an antimicrobial agent to actively kill contaminating bacteria, those that have a modified chemistry to reduce bacterial adhesion, and finally, those with modified surface topographies and surface features to reduce bacterial adhesion (see **Chapter 4.417, Tethered Antibiotics** and **Chapter 4.418, Engineering Interfaces for Infection Immunity**).

Active killing of bacteria is achieved by antimicrobial agents either immobilized on the surface of, or gradually released from, the biomaterial or coating. Those that immobilize antibacterial agents directly on the surface may display a progressive reduction in activity as a consequence of the surface becoming coated with extracellular matrix proteins and host cells, which limit contact between adherent bacteria and the antimicrobial agent. The alternative active antimicrobial strategy: release of the antimicrobial agents from a biomaterial or coating, has largely been limited to the release of antibiotic agents. Suboptimal release profiles of the antibiotic from the biomaterial can lead to the development of resistance, which is an emerging threat to the treatment of infections in general, extending beyond the treatment of biomaterial-associated infections. Devices that are particularly prone to bacterial infection, such as catheters or external fixation pins, are available with numerous antibiotic coatings, such as the rifampin minocycline-impregnated catheters.[159] Nonantibiotic agents have also been incorporated into biomaterials with the same aim of killing adherent bacteria, such as silver,[160] quaternary ammonium compounds,[65] peptides,[60] furanones,[161] nitric oxide,[162] and numerous other molecules making their way through research and into commercial production.[163]

The second strategy to reduce the incidence of infection involves the prevention or reduction of bacterial adhesion to biomaterials. Careful consideration of the physicochemical factors that can increase or decrease bacterial adhesion to a biomaterial may be applied in the manufacturing process of the biomaterial. This is normally achieved by surface modification of biomaterials, which effects a change in protein adsorption, subsequently affecting both bacterial and cellular interactions.

Another biomaterial modification strategy, which will influence the development of infection is the modification of surface topography to reduce bacterial adhesion and/or promote tissue adhesion. Areas where this is of significant interest are percutaneous implants,[157] for which improved tissue integration can reduce the implant susceptibility to infection at the percutaneous region, where any cracks or crevices in the surface would make the implant more susceptible to bacterial colonization. For further information on the effect of topography as a strategy to reduce bacterial adhesion please refer to **Section 4.407.6.2**. In the following section, biomaterial surface modification strategies that aim to reduce or eliminate bacterial adhesion will be briefly described.

4.407.7.1. Highly Charged Surfaces

Bacteria generally possess a net negative surface charge[164] and so, in general, a negatively charged biomaterial surface is expected to display reduced adhesion of bacteria, due to repulsion forces. A biomaterial with positive charge, on the other hand, is expected to encourage bacterial adhesion, and this has been demonstrated in the available literature.[61,62] It has been shown in PPFC experiments that Gram-negative bacteria adhere to a positively charged surface, as expected, in high numbers. However, these adherent Gram-negative bacteria are unable to divide and grow.[48,165] In the same experiments, Gram-positive bacteria did not display an impairment of surface growth on positively charged surfaces. The reason for the observed difference in adhesion and growth patterns of Gram-positive and Gram-negative remains unclear. Overall, the indication is that negatively charged surfaces reduce the chance of bacterial adhesion while positively charged surfaces increase the chance of bacterial adhesion. When one considers the later steps in the development of an infection, such as growth of the bacterium and biofilm formation, then positively charged surfaces, displaying strong electrostatic attraction will limit the growth of the bacteria[48] and thus, perhaps limit biofilm formation, despite the fact that these surfaces display increased initial adhesion. To make a choice between a

biomaterial displaying reduced initial bacterial adhesion or one displaying disrupted biofilm formation is difficult and warrants further investigation to weigh the relative importance of minimizing initial adhesion versus the potential of adherent bacteria to form a biofilm on the surface of the biomaterial. In addition, any initial bacterial adhesion may, over time, develop into a biofilm and as many studies have failed to correlate *in vitro* findings to their *in vivo* findings[166] further elucidation of these processes are necessary. Despite the promise shown by highly charged surfaces, as previously mentioned in **Section 4.407.4.2.2**, the effect of surface charge is highly reduced in ion-containing solutions such as bodily fluids.[91] Thus, some care must be taken when interpreting the results from *in vitro* findings, particularly when an experiment is performed in a solution with a low molarity.

4.407.7.2. Low Surface Energy Materials

Low surface energy polymeric coatings have also been found to inhibit bacterial adhesion to biomaterials by providing a surface to which contaminating bacteria adhere in fewer numbers.[167,168] Tsibouklis *et al.*[168] found reduced bacterial adhesion poly(methylpropenoxyfluoroalkylsiloxane)s and poly(perfluoroacrylates)s, which are low energy surfaces. These polymers contain a flexible linear backbone and the presence of side chains that displayed low molecular interactions. AFM analysis showed that the bacteria were unable to colonize test surfaces films, which was considered to be due to the inability of the bacterial exopolymers to wet or become attached to the low energy surface.

4.407.7.3. Polymeric Coatings Including Polymer Brushes

Many polymeric coatings have been developed over the past decades and many have shown promise in reducing bacterial adhesion.[169–174] Of all the nonfouling surfaces developed, polymer brush coatings have shown the greatest efficacy in reducing bacterial adhesion, with reductions observed in the orders of magnitude.[175] In brief, polymer brushes consist of densely packed polymer chains grafted to a surface, where the average distance between any two attached chains is smaller than the radius of two coiled polymer chains when solvent.[176] Hydrophilic polymer brushes are highly hydrated in aqueous solution and it is hypothesized that the bacteria are hindered in their approach due to the hydrated layer formed with the brushes, which compresses as a result of the bacterial approach and reduces the motility of the polymer brush. Under these conditions the approaching bacterium is repelled and bacterial adhesion either does not occur or is reduced. Numerous examples of polymer brush-like surfaces have been developed and shown in the literature to reduce bacterial adhesion.[175,177,178]

Though polymer brushes are effective at reducing bacterial adhesion, they do not completely eliminate bacteria from material surfaces *in vitro*. The question thus arises as to the utility of such a coating *in vivo*. One commercially available polymer brush has been tested *in vivo* in a mouse model and biofilm formation was reduced in comparison with uncoated controls.[177] It did appear that infections still developed in the surrounding tissues, although biofilm formation on the biomaterial itself was reduced due to the polymer brush coating.[177] As more and more brushes are developed and the stability of these materials is improved, it is anticipated that many such coatings will be developed for future clinical use.

4.407.7.4. Bifunctional Polymer Brush-Like Coatings

The polymer brushes mentioned in the previous section display reduced bacterial adhesion. Moreover, they also display reduced eukaryotic cell adhesion due to a mechanism believed to operate in a similar way to the prevention of bacterial adhesion.[179,180] In order to prepare bifunctional coatings, which prevent microbial adhesion while supporting tissue cell growth, attempts have been made to create a polymer brush-type construct using poly(L-lysine)-graft-poly(ethylene glycol) (PLL-*g*-PEG) copolymers with attached RGD molecules. Additionally, polyelectrolyte multilayers of hyaluronic acid and chitosan have been developed, which also have been modified to display an arginine-glycine-aspartic acid (RGD) peptide sequence toward the exposed surface of the polymer brush.[178,180–182] The RGD peptide sequence is a recognition sequence for integrin receptors through which mammalian cells connect to their ECM molecules. Thus, a polymer brush displaying the RGD sequence may significantly reduce bacterial adhesion, yet not display a reduction in eukaryotic cell adhesion. In an experimental setting, the bifunctional coating did indeed display reduced bacterial adhesion and supported eukaryotic cell adhesion in separate experiments.[178,181,182] More recently, a flow chamber system confirmed this with bacteria and osteoblast cells being cultured in the presence of each other.[183] These bifunctional polymer brushes have significant potential in reducing bacterial adhesion, and the expectation is also that this will translate into a reduced infection rate *in vivo*. The abrasion resistance of these coatings, however, must be suitably tough for the desired use of the material and survive insertion during surgery. In addition, the coatings must also be able to withstand routine sterilization processes such as dry heat-, steam-, gamma-, or ethylene oxide sterilization. These issues represent the challenges faced by polymer brushes to become more readily available in the clinics.

4.407.7.5. Plasma Activation and Coatings

Plasma is the fourth state of matter, and high energy plasma can be used to alter surfaces by changing the chemistry at the surface of a material. There are many different ways in which plasma can be used to modify a surface: it can be direct activation of a surface, coating of the surface with thin polymer films, ion implantation or vapor deposition of, for example, metal or ceramics. Plasma surface modification of polymers to increase the surface energy has been shown to have an effect in reducing bacterial adhesion for several polymers, but the methods of plasma treatment vary and there can be a problem with the stability of the surface modification. In addition, the use of O_2 plasma on devices such as PVC endotracheal tubes could potentially increase eukaryotic cell adhesion, which may consequently cause problems. Finally, where plasma treatments are utilized there may be an etch affect, which could potentially lead to increased bacterial adhesion by increasing the topographical features, and this must therefore also be investigated. Specific examples of plasma activation will briefly be described in this section.

Oxygen plasma glow discharge has been successfully used to reduce bacterial adhesion on polymers such as PVC. Adhesion of *P. aeruginosa* to plasma-treated PVC with ~20–26 at.% surface oxygen was compared to untreated PVC which contains ~10 at.% surface oxygen *in vitro*.[59] These treated surfaces were more hydrophilic than the untreated PVC, and the etching effect of the plasma increasing surface roughness was not found to be significant. *P. aeruginosa* is known to be hydrophobic (negatively charged), and the incorporation of oxygen to the PVC surface leads to an increase in surface energy and therefore, the surface will bond water more easily and repel the hydrophobic bacteria to a greater extent. When *P. aeruginosa* adhesion was quantified, a 70% reduction in the number of bacteria adherent to the plasma-treated PVC was observed.[59] In addition Balazs *et al.* have used radio Frequency (RF) oxygen gas plasma followed by NaOH and $AgNO_3$ treatments to further investigate bacterial adhesion to silver-containing PVC.[184] They found, contradictory to the glow discharge method, that the oxygen plasma alone did not reduce bacterial adhesion. This may be a result of the etching effect of the plasma as the oxygen incorporation was greater with the RF treatment. The surface with silver incorporation was shown to be superhydrophobic. However, no topographical measurements were performed. A 100% reduction in adhesion of viable bacteria was observed with $NaOH/AgNO_3$ with and without oxygen plasma pretreatment.

Constant discharge plasma treatment with 20% O_2 in a He environment was carried out on the polymer PET, and the effect on *S. epidermidis* ATCC 35984 adhesion was investigated.[185] This particular technique aimed to increase the etch affect, but the observed increase in roughness was not correlated to decreased bacterial adhesion: all the plasma-treated surfaces significantly reduced bacterial adhesion. The altered chemistry was hypothesized to be the reason for reduced bacterial adhesion, although no chemical surface analysis was performed. It is believed that the plasma treatment leads to oxygen incorporation and thereby increases surface energy, which would make the surface hydrophilic. This in turn could lead to less bacterial adhesion, especially if the bacteria have a negative surface charge.

CF_4 plasma has also been used to reduce protein adhesion and subsequently inflammatory cells to PMMA intraocular lenses.[186] The use of CF_4–Ar plasma in a postdischarge reactor was investigated on dressings to obtain an antibacterial layer.[187] Various treatment times were investigated with adhesion of *E. coli*, *S. aureus*, *Bacillus subtilis*, and *Candida albicans* (yeast). The exposure to the Ar/CF_4 led to an increase in fluorine with increasing treatment time. After the longest exposure time (80 min), fluorine content was found to be 41 at.% on the wool, 29 at.% on the cotton, and 45 at.% on the polyamide. The antibacterial effect was shown to be greatest with wool, where all the microbes tested were inhibited from adhering, although the effect was reduced with polyamide, irrespective of the atom % fluorine. Additionally, very little effect was shown with cotton. The method in which the fluorine binds to the surface of the dressing is probably the reason why bacterial adhesion was affected differently on the different dressings.

Fluorine has also been the focus when utilizing ion implantation techniques to titanium where, amongst other ions, Ca^+, N^+, and F^+, oxidation, ion plating TiN, ion beam mixing with Ag, Sn, Zn, and Pt with Ar^+ have been examined for their effect on *Porphyromonas gingivalis* and *Actinobacillus actinomycetemcomitans* adhesion.[188] The titanium with F^+ ion implanted surfaces had a significant reduction in bacterial adhesion for both types of bacteria, while none of the other surface treatments had a significant effect. The titanium with F^+ ion implantation surfaces did not affect cell proliferation of L929 cells when incubated for 10 days.

The effect of Ti/Ag plasma vapor deposition onto titanium, on the adhesion of Gram-positive *S. epidermidis* and Gram-negative *Klebsiella pneumoniae*, was investigated by Ewald *et al.*[189] Silver in concentrations from 0.7 to 9% was incorporated utilizing PVD of titanium and a 50% reduction in bacterial adhesion was observed for all the concentrations of silver. The presence of silver was determined, but actual concentration available on the surfaces was not. Cytotoxicity evaluation showed no significant effect of silver on endothelial and osteoblast cells. These results indicate that the presence of a low percentage of silver on a surface could effectively influence bacterial adhesion without having an effect on eukaryotic cells.

The incorporation of silver using these plasma activation processes results in bacterial killing, but silver is also known to have a detrimental effect on eukaryotes.[190] Therefore, the incorporation of silver into any biomaterial must consider potential cytotoxic effects. There are currently many studies evaluating the use silver nanoparticles, however, the cytotoxicity of many such silver nanoparticles are still under investigation.[191–194]

PVD coatings incorporating antimicrobials could also be an effective approach, though for most polymers the temperatures needed would be detrimental to the bulk material and to most antimicrobial agents. In addition, the interface between the bulk material and coating is known to be weak and susceptible to shearing off under pressure/force.

This section has described a range of ways in which to reduce bacterial adhesion, and overall there are a few factors, which should always be taken into consideration; the biomaterial and its bulk properties, the surface chemistry and topography and the environment of the potential application. However, where increased eukaryotic cells adhesion and reduced prokaryotic cells are desirable, some of the techniques described above could be a useful tool, not necessarily hindering bacterial adhesion, but reducing its occurrence.

4.407.8. Summary and Perspectives

Bacterial adhesion to biomaterials is often considered the first in a sequence of events that may culminate in the most feared complication associated with the implantation of a biomaterial into the human body: biomaterial-associated infection. For the cases in which an infection occurs, the first approach of a bacterium to a biomaterial may constitute the biggest single step in the development of an infection. The ability of the contaminating bacterium to adhere to the biomaterial or the surrounding tissue is dependent upon a complex interaction between the contaminating bacterium, the host and the biomaterial itself. Should the bacterium successfully

evade host defenses and adhere to the biomaterial, then a sequence of events unfolds whereby the relatively weak and reversible initial adhesive interactions proceed to stronger, irreversible interactions and ultimately to microcolony formation, and the development of a biofilm. The resultant infection may cause a delay in healing, implant loosening, an increase in morbidity or prolong the duration the patients stay in hospital (see **Chapter 6.609, Orthopedic Implant Use and Infection**).

Given the fact that the number of biomaterial-associated infections is expected to rise in tandem with the expected increase in the use of biomaterials, understanding the basic interactions behind the processes that lead to infection assumes high clinical importance. All stages of the development of a biomaterial-associated infection obviously cannot be studied entirely in one *in vitro* experiment; although the initial adhesion of bacteria to biomaterials is extremely amenable to *in vitro* investigation. *In vitro* experiments have provided the majority of the scientific data available that have furthered our understanding of how biomaterial surface properties influence the bacterial adhesion process. Not only is bacterial adhesion to biomaterials the first step in the infection process, but it is also the only step in the infection process that can be significantly manipulated by a biomaterial scientist to reduce the adhesion of bacteria and thus, reduce susceptibility to infection (antimicrobial activation notwithstanding). Once bacterial adhesion occurs the development of the biofilm is much more dependent upon the virulence factors possessed by the bacteria and the host response, rather than on the biomaterial surface that has been colonized.

This chapter has attempted to give an overview of the available techniques used to study the interaction between bacteria and biomaterials, and in addition, how these techniques have been used to identify how biomaterials of various types influence the process of bacterial adhesion. However, a single, clear, and simple rule of thumb governing the reasons for and influences on the variable adhesion of bacteria to the various biomaterials has not been identified. This difficulty stems from the complexity of a situation involving the adhesion of a wide range of diverse bacterial species and strains to another wide range of diverse biomaterials and manufacturing methods investigated. The variations in methodologies used to experimentally investigate the initial adhesion of a bacterium to biomaterials such as the use of different apparatus or bacterial strains and species or an incomplete physicochemical and topographical analysis of biomaterial and bacteria have all hindered the development of a single overriding theory. Nevertheless, some of the general trends that have come from the literature and may be described include biomaterial surfaces with higher surface energy, that is, more hydrophilic surfaces, generally have less bacterial adhesion and these surfaces are generally those that would promote tissue integration. Polymeric surfaces due to their innate low surface energy are therefore in theory more susceptible to bacterial adhesion, but as these surfaces also limit tissue adhesion, many surface treatments focused on increasing the surface energy are currently being evaluated and some have reached the clinic. Metal surfaces such as titanium are more susceptible from the topographical perspective as the surface energy as a result of the TiO layer is relatively high. This is also true for ceramic materials, and consequently one of the most important factors to consider, when mindful of bacterial adhesion, is a proper evaluation of the topography. Topography has been found to have an overriding effect over chemistry for bacterial adhesion to many biomaterials. It has been postulated that increased bacterial adhesion may be due to increased surface area with increasing roughness, although, topographical features such as cracks, pits, crevices, allow the bacteria to adhere in areas where they are less exposed to factors from the host environment, such as fluid flow and frictional forces, and this is independent of the surface chemistry. Currently, with the increased use of so-called tissue engineered materials, which often encompass composite material, scaffolds with porosity and surface texture to improve not only cellular integration but also promote vascularization, the importance of evaluating these materials for potential bacterial colonization becomes apparent.

These general trends have been largely elucidated from *in vitro* experiments. However, on a very fundamental level, the significance of changing the pattern of bacterial adhesion to biomaterials, as observed *in vitro*, must be carefully weighed when extrapolating to an *in vivo* situation. The limitations of *in vitro* studies, such as the lack of host defenses, conditioning film and specific bacterial adhesion mechanisms serve as the primary justifications for performing *in vivo* experiments. Each of these factors plays a vital role in the outcome of infection, but cannot be replicated to the extent required in an *in vitro* experiment. Adhesion of a bacterium to a biomaterial covered in conditioning layer of proteins may proceed in a specific manner *in vivo* and should adhesin molecules, extracellular polymers, surface structures, and complex conditioning films be incorporated into an *in vitro* bacterial adhesion study, it can allow for a more realistic interpretation of bacterial adhesion to a particular biomaterial. However, these factors can make it virtually impossible to isolate the separate effects of potentially numerous influencing factors on the progression of bacterial adhesion, such as biomaterial physicochemistry versus conditioning film or nonspecific versus specific adhesion effects on bacterial adhesion. A second limitation centers on the actual clinical impact of a reduction in bacterial adhesion that has been achieved *in vitro*. A bacteria-repellent surface may, for example, reduce bacterial adhesion under controlled hydrodynamic conditions by 90% *in vitro*; however, in an *in vivo* situation, with the combined effect of host conditioning layer and perhaps the lack of a hydrodynamic force to remove bacteria from a surface, retention of the same activity cannot be assumed. Furthermore, despite reducing bacterial adhesion, any remaining bacteria may be more than capable of causing an infection, especially considering the rapid growth rate of bacteria means numbers may be replenished within a matter of hours. Potentially, a step forward in attempts to bridge the gap between *in vitro* bacterial adhesion assays and *in vivo* studies is achieved by the progression of the PPFC from exclusively a bacterial adhesion test to incorporate an experimental race for the surface or competitive assay between mammalian cells and bacteria, with serum-containing medium providing a conditioning film. By including cellular interactions in the bacterial adhesion

assay, these coculture competitive-type assays allow for a greater investigation into the potential for standard, modified, antifouling, antimicrobial, or bifunctional surfaces to not only reduce bacterial adhesion, but also provide relevant data for the outcome of the race for the surface.

Ultimately, for biomaterials that are to be implanted into highly infection-susceptible sites, such as intravascular catheters, or devices for the fixation of open fractures of the long bones, antimicrobial activated surfaces are the most successful strategy. Nevertheless, the basic science behind bacterial adhesion to biomaterials still has a role to play in the development of biomaterials. A wealth of information is available with sophisticated methodologies to alter the physicochemical and topographical properties of biomaterials to achieve any one of a number of functions, and altering the surface properties of the biomaterial to reduce bacterial adhesion is a target that is well within the grasp of the biomaterials community. The information gleaned from *in vitro* studies has also provided direction for the development of novel biomaterials such as the bifunctional surfaces that are capable of attracting mammalian cells to the biomaterial surface, while reducing the opportunity for bacterial adhesion and growth on biomaterials. Strategies to reduce bacterial adhesion and encourage host integration are extremely important for all biomaterials. Thus, a combined approach optimizing both aspects is likely to be the focus for future biomaterial-based research into bacteria repellent surfaces.

Abbreviations

ADAM	A disintegrin and metalloproteinase
BMP2	Bone morphogenetic protein 2
ECM	Extracellular matrix
EGF	Epidermal growth factor
FAK	Focal adhesion kinase
GTPase	Enzyme that can bind and hydrolyze guanosine triphosphate (GTP)
HA	Hydroxylapatite
HY	Hyaluronic acid
iC3b	Inactivated complement C3b
ICAM	Intracellular adhesion molecule
IGF-1	Insulin-like growth factor-1
PDGF	Platelet-derived growth factor
PGE_2	Prostaglandin E_2
RGD	Arginine-glycine-aspartic acid
TCP	Tissue culture plastic
TGF-β	Transforming growth factor-β
Ti	Titanium
VCAM	Vascular adhesion molecule
VEGF	Vascular endothelial growth factor

4.408.1. Introduction

Many biomaterials used in tissue engineering have sufficient mechanical properties with no toxicity and low or no pathological responses. However, one-third to one-half of these implants require replacement within 10–25 years.[1,2] With the current increase in demand for implants in younger patients and in rapidly aging populations, there is a need to improve the functional integration and life span of these implants at the cellular level in order to be able to substitute or augment complex tissues and organs. In many cases, stimulation of the ingrowth of specific, native, or seeded cells to form a continuum with the biomaterial is required. In addition, there are patients in whom aging, disease, or unique tissue responses, due to genetics or environmental issues, compromise the success of the implant. Therefore, novel approaches to tissue engineering are needed to address such specific physiological conditions. For bone implants, the formation of a direct and intimate implant–bone interface called osseointegration is crucial for the biomechanical stability of the implant, the ability to provide load transfer at an optimal level, and biocompatibility.[3] Osseointegration requires an interaction between the cells in the bone and the biomaterial. One of the major pathways by which cells adhere and interact with their extracellular environment is through integrins, which activate intracellular-signaling pathways essential for cell survival, growth, and differentiation. Therefore, understanding the role of integrins in the response to implant materials is essential for the

success of these materials in osseointegration and other tissue interactions. Discussed in this chapter are brief overview of integrins, their cellular functions, their signaling pathways, and biomaterials having integrin-activating surfaces, with particular attention to bone. Our goal is to consider the value of integrin-mediated tissue engineering in addressing some of the issues for long-term implant stability and function.

4.408.2. Integrins

4.408.2.1. Integrins Subunits and Adhesion

The integrins are a superfamily of cell adhesion receptors that bind to the extracellular matrix (ECM) proteins; they also mediate certain cell–cell interactions. Integrins are found only in the metazoans with no known homologs in plants, fungi, or prokaryotes.[4] They are transmembrane receptors composed of a α- and β-heterodimer, and the combination of the α- and β-subunits determines the ligand specificity of the integrin, even though many integrins can bind to the same ligand. In mammals, at least 19 α- and 8 β-integrin subunit genes have been identified and they encode polypeptides forming at least 25 different receptors (**Table 1**).[5,7,8] Alternative splicing of mRNA of some α- and β-subunits and posttranslational modifications in integrin subunits further increase the diversity of the integrin family to 24 α- and 9 β-subunits.[6,9–11] Although more than 20 integrin heterodimers have been identified, the majority of which recognize ECM components, there are also counter receptors on the surface of neighboring cells.[6]

Table 1 Combinations of integrin subunits and their protein ligands

Subunits		*Ligands*
β_1	α_1	Collagens, laminins
	α_2	Collagens, laminins, fibronectin
	α_3	Laminins, fibronectin, collagens, thrombospondin
	α_4	Fibronectin, VCAM, osteopontin
	α_5	Fibronectin, fibrinogen, ADAMs
	α_6	Laminin, ADAMs
	α_7	Laminins
	α_8	Fibronectin, tenascin
	α_9	Tenascin, collagen, osteopontin, laminin, VCAM, ADAMs
	α_{10}	Collagens
	α_{11}	Collagens
	α_v	Fibronectin, vitronectin, thrombospondin
β_2	α_L	ICAMs
	α_M	ICAM, fibrinogen, iC3b
	α_X	Fibrinogen, ICAM, iC3b
	α_D	VCAM, ICAMs
β_3	α_{IIb}	Collagens, fibronectin, vitronectin, von Willebrand factor fibrinogen, thrombospondin, matrix metalloproteinase-2, disintegrins
	α_v	Fibronectin, vitronectin, fibrinogen, thrombospondin, von Willebrand factor, osteopontin, laminin, disintegrins, tenascin, bone sialoprotein, ADAMs
β_4	α_6	Laminins
β_5	α_v	Vitronectin, bone sialoprotein, fibronectin
β_6	α_v	Fibronectin, tenascin
β_7	α_4	Fibronectin, VCAM
	α_E	E-cadherin
β_8	α_v	Collagens, laminins, fibronectin

Subunit–ligand-binding structures were reported by Plow *et al*.[5] and Van der Flier and Sonnenberg.[6]

ICAM, intracellular adhesion molecule; VCAM, vascular adhesion molecule; iC3b, inactivated complement component C3b; ADAM, a disintegrin and metalloproteinase.

The ECM is a complex network of high molecular weight proteins such as laminin, fibronectin and collagens, and polysaccharides. The ECM provides structural support to the cells, acts as a physical barrier or selective filter for soluble molecules, provides a substrate for cell migration, and sequesters growth factors and other molecules that are important for cell activities, growth, and differentiation. According to the specificity of integrin–ligand binding, all mammalian integrins can be grouped in several categories: (1) laminin-binding integrins ($\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_6\beta_1$, $\alpha_7\beta_1$, $\alpha_9\beta_1$, $\alpha_v\beta_3$, $\alpha_6\beta_4$, and $\alpha_v\beta_8$); (2) collagen-binding integrins ($\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_9\beta_1$, $\alpha_{10}\beta_1$, $\alpha_{11}\beta_1$, and $\alpha_{IIb}\beta_3$); (3) leukocyte integrins ($\alpha_L\beta_2$, $\alpha_M\beta_2$, $\alpha_X\beta_2$, and $\alpha_D\beta_2$), and (4) arginine-glycine-aspartic acid (RGD)-recognizing integrins ($\alpha_5\beta_1$, $\alpha_V\beta_1$, $\alpha_V\beta_3$, $\alpha_V\beta_5$, $\alpha_V\beta_6$, $\alpha_V\beta_8$, and $\alpha_{IIb}\beta_3$) (for review, see Takada *et al*.[12]). RGD was identified as the amino acid sequence in fibronectin and other cell adhesion proteins that could modulate cell attachment.[13] RGD sequences have been found in diverse species such as sea urchins, amoebae, and mammals.[12] Integrins containing the α_4, α_5, α_8, α_{IIb}, and α_v-subunits bind to ECM proteins, mostly fibronectin and vitronectin that contain the RGD sequence. Laminins and collagens also contain RGD sequences but these are often cryptic and inaccessible.[6] In general, integrins on hematopoietic cells bind to counter receptors on other cells (e.g., intercellular adhesion molecules, ICAMs, vascular cell adhesion molecule-1, VCAM-1, and disintegrins/metalloproteinases such as the different ADAMs) or plasma proteins (e.g., fibrinogen) and complement factors (iC3b).[6] Although most integrins are widely expressed in various tissues, some integrins are expressed only in a certain type of cell or tissue. For example, $\alpha_{IIb}\beta_3$ integrin is found in platelets, $\alpha_6\beta_4$ in keratinocytes, $\alpha_E\beta_7$ in T cells, and $\alpha_4\beta_7$ is limited to a subset of memory T cells.[12] The integrin receptors that have been most studied in bone are the vitronectin receptor ($\alpha_v\beta_3$),[14] the type I collagen receptor ($\alpha_2\beta_1$),[15] and the fibronectin receptor ($\alpha_5\beta_1$),[16,17] and they have been found in human osteoblasts.[18,19] Osteoblasts primarily express β_1, while osteoclasts express both β_1 and β_3.[18] Various hormones and growth factors have been shown to modulate integrin levels in osteoblasts and osteocytes.[20,21] The $\alpha_v\beta_3$ integrin is the major integrin involved in osteoclast-mediated bone resorption, although osteoclasts also express $\alpha_2\beta_1$ and $\alpha_v\beta_1$.[22]

4.408.2.2. Integrin Structure

Integrins are composed of noncovalently associated α- and β-subunits; these subunits are type I glycoproteins, consisting of large extracellular and short cytoplasmic domains,[8] and will be briefly described. The length of the α-chain is 1008–1152 amino acids, and it contains a cytoplasmic domain of 22–32 amino acids and a transmembrane domain of 20–29 amino acids. The length of the β-chain is around 770 amino acids, and contains a cytoplasmic domain of 20–50 amino acids (except for cytoplasmic domain of β_4 integrin),[23] and an intramembranous domain of 26–29 amino acids.[24]

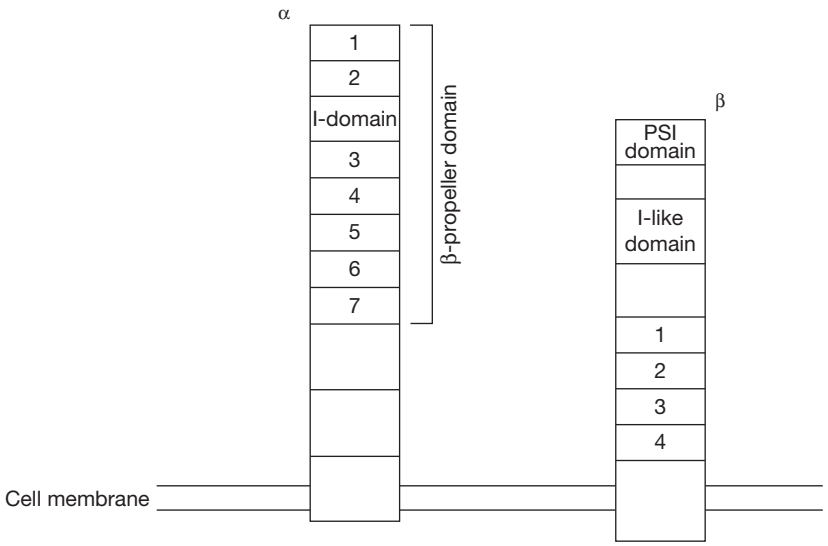

Figure 1 General integrin structure. Organization of the various domains in the of α- and β-subunits. The presence of the I-domain depends on the type of α-subunit. The I-domain is present in seven human α-subunits between β-propeller repeats 2 and 3. The RGD site is located at the interface between the β-propeller domain on the α-subunit and the I-like domain on the β-subunit. All β-integrin subunits contain an I-like domain and EGF-like repeats (1, 2, 3, and 4 on the β-subunit in the diagram). PSI: plexin–semaphorin–integrin domain. The general integrin structure was reported by Takada *et al*.[12] and Takagi and Springer.[25]

The overall shape of the associated integrin subunits can be described by the presence of two, long stalk regions containing C-terminal segments from both α- and β-subunits that connect the extracellular ligand-binding globular headpiece to the transmembrane and cytoplasmic domains (**Figure 1**).[5,6,8,26] The crystal structure of the integrin subunits has been elucidated in great detail in the last decade using various techniques, including electron microscopy, X-ray scattering, site-directed mutagenesis, and computer modeling.[26–31] It has been demonstrated that the extracellular part of the human $\alpha_V\beta_3$[30,31] and $\alpha_{IIb}\beta_3$[29] integrins consists of several domains. The ligand-binding site of integrins is composed of the β-propeller domain of the α-subunit and the I-like domain of the β-subunit. The I-like domain appears to directly bind to ligand in integrins that lack I-domains, and indirectly regulate ligand binding by integrins that contain I-domains. The RGD site is located at the interface between the β-propeller domain on the α-subunit and the I-like domain on the β-subunit.[30] The β-propeller domain contains seven repeats of ~60 amino acids and is folded into a seven-bladed β-propeller structure (corresponding to these repeats) that is similar to the β-subunit of a heterotrimeric G-protein. X-ray scattering and mutagenesis studies have demonstrated that a number of amino acid residues that are critical for ligand binding to the human $\alpha_{IIb}\beta_3$[32] and $\alpha_5\beta_1$ integrins are located within the β-propeller domain.[28]

I-like domains (~200 amino acids) are homologues to the A domain of the von Willebrand factor[33] and contain a metal-ion-dependent adhesive site (MIDAS) and a structurally similar metal-binding motif.[8,30,34] Integrins require divalent cations such as Ca^{2+} or Mg^{2+} for binding to their ligands. Upon ligand binding, the I-like domain undergoes a conformational change from the closed (inactive) to the open (active) state.[25,30,31] Based on the presence of the I-like domain in the α-subunits, mammalian integrins can be grouped into integrins that have the I-like domain (α_1, α_2, α_{10}, α_D, α_E, α_L, α_M, and α_X) and those without it (α_3, α_4, α_5, α_6, α_7, α_8, α_9, α_V, and α_{IIb}).[12] A critical role for the I-like domain of the β_1-subunit[35] and β_2-subunit[36] in ligand binding has been demonstrated.

4.408.3. Integrin Function

4.408.3.1. Cells Adhesion, Survival, Growth, and Differentiation

The binding of ECM proteins to the integrins triggers a series of intracellular signaling events that lead to changes in conformation and cell behavior such as adhesion, proliferation, survival or apoptosis, cell shape, motility, gene expression, and differentiation. Integrins have the ability to transduce signals from the ECM to the cytoplasm and to the nucleus of the cell.[37] Evidence of integrins also being mechanotransducers of force has come from studies in which mechanical stress was applied to cell surface receptors using a magnetic twisting device.[37] The integrin β_1, associated with the cytoskeleton, showed increased stiffening (ratio of stress to strain) which was directly proportional to the stress applied. Integrins and their ligands have a critical role in embryonic development, immune responses, leukocyte homing and activation, bone formation and resorption, clot retraction, cellular responses to mechanical stress, apoptosis, angiogenesis, and hemostasis, and are also involved in cancer and other human diseases, and can be receptors for many viruses and bacteria.[4,7,38–41] The involvement of integrins in these various normal and pathological processes has been demonstrated in several studies using integrin knockout animals. Integrins have been shown to be crucial for development (β_1); immune responses (β_2); cancer, inflammatory responses, and atherosclerosis (β_3 integrins); vasculogenesis (α_V); lymphangiogenesis ($\alpha_9\beta_1$); thrombus formation ($\alpha_{IIb}\beta_3$); and the integrity of the

skin ($\alpha_6\beta_4$) (for review, see De Arcangelis and Georges-Labouesse[42] and Takada *et al.*[12]).

Integrins, particularly $\alpha_5\beta_1$, regulate cell proliferation and apoptosis.[43,44] Overexpression of the α_5-subunit in transformed cell lines suppresses tumorigenicity and anchorage-independent proliferation but promotes anchorage-dependent proliferation. It also upregulates early gene expression of c-fos, c-jun, and jun-B, and this correlates with cell proliferation.[43] In myoblasts, the α_5-subunit promotes anchorage-dependent proliferation,[45] and cell attachment to fibronectin via the α_5-subunit promotes cell survival in Chinese hamster ovary cells.[46] However, in myoblasts, cell attachment alone is not sufficient to protect myoblasts from cell death, unless particular growth factors are present,[45] and thus regulation of cell survival by the α_5-subunit's is cell-type dependent.

The interactions of integrins with the ECM and their other ligands are critical for normal cell function and survival, and integrins have specific, nonredundant, and important functions that are apparent in the phenotypes of the integrin knockout mice. Preimplantation development is blocked by the absence of β_1 while perinatal lethality is found in knockouts of α_3, α_6, α_8, α_v, β_4, or β_8 integrins. Major developmental defects are apparent when α_4, α_5, α_v, or β_8 are absent. Knockouts of α_L, α_M, α_E, β_2, and β_7 have defects in leukocyte function, β_6 in inflammation, α_{IIb}, β_3, and α_2 in hemostasis, β_3 in bone remodeling, and α_1 and β_3 in angiogenesis.[4,47]

4.408.3.2. Bone Cells

Early studies with soluble RGD-containing peptides demonstrated that integrins have an important role in bone formation as these peptides inhibited bone formation and resorption, and decreased the expression of bone matrix proteins.[17,48,49] Conversely, when RGD peptides were bound to a substrate, they stimulated osteoblast proliferation.[50] Since osteoblasts sequentially express specific bone matrix proteins during development (fibronectin, alkaline phosphatase, and type I collagen being early markers of osteoblast differentiation *in vivo*, and osteocalcin being expressed in the later stages[51]) and many of them have RGD sequences, experiments with integrin-perturbing antibodies have shown major effects on bone structure. The $\alpha_5\beta_1$ integrin was shown to be important in mineralization of osteoblast cultures,[52–54] as inhibition of $\alpha_5\beta_1$ in early the osteoblast cultures resulted in the inhibition of mineralization and osteocalcin expression, compared to untreated control cultures.[53] Integrin subunits α_v, α_2, and β_1 have also been shown to mediate human osteoblast adhesion through the generation of focal adhesion sites.[14] Neutralization of α_1- and α_2-integrin subunits and type I collagen has also been shown to inhibit BMP2-induced mineralization and alkaline phosphatase activity in cultured immortalized 2T3 mouse osteoblast cells.[55] In addition, blocking the α_2 integrin with specific inhibitory antibodies in mOG2-luciferase-transfected MC3T3-E1 preosteoblast cells greatly inhibited osteocalcin promoter expression as well as osteocalcin mRNA expression in a dose-dependent manner, while blocking the α_5-subunit did not have any effect.[56] In agreement with this, blocking the α_2-subunit significantly inhibited alkaline phosphatase activity and osteocalcin secretion of rat bone marrow stromal cells.[57] Takeuchi *et al.*[58] demonstrated that blocking of the α_2-subunit with α_2-inhibitory antibodies significantly inhibited alkaline phosphatase activity and disrupted ECM organization in cultured MC3T3-E1 cells, while blocking of the α_5-subunit did not have any effect. Blocking $\alpha_2\beta_1$ integrin with inhibitory antibodies significantly inhibited mineralization in the UMR-106-01-BSP osteosarcoma cell line cultures in a dose-dependent manner.[59] The binding of osteoblast RGDs has been shown to prevent apoptosis.[60] In addition, specific integrins also mediate the response of osteoblasts to fluid-shear stress[61] and the differentiation of human bone marrow stromal cells into the osteoblast lineage.[62,63] In studies with MG-63 human osteoblast-like cells grown on titanium, antibodies to $\alpha_5\beta_1$ reduced osteoblast proliferation but not differentiation. Using siRNA strategy, the α_2-silenced MG-63 human osteoblast-like cells were used to show that $\alpha_2\beta_1$ affected the expression of alkaline phosphatase and osteocalcin, and that the responses of these cells to various hormones and growth factors varied.[64] The RGD sequence is found in numerous bone matrix proteins such as bone sialoprotein, collagens, fibronectin, thrombospondin, vitronectin, decorin, and tenascin.[5]

Other cells in bone are also dependent on integrins for their function. Osteocytes have been shown to bind to the canalicular wall through the β_1-containing integrins and the $\alpha_v\beta_3$ integrin.[20,65] It was also shown that the β_1 integrins on osteocytes mediate specific aspects of mechanotransduction and affect bone geometry in mice undergoing hind limb unloading.[66] Integrins may play a particularly important role in cells of the osteoblast lineage, which are constantly involved in a remodeling process; this process requires the translation of mechanical forces and changes in the extracellular environment into internal biochemical signals which in turn lead to the formation and remodeling of the bony skeleton.[63] Bone resorption by osteoclasts is also dependent on integrin activity, the $\alpha_v\beta_3$ integrin being critical for osteoclast function (see reviews Nakamura *et al.*[22] and Teitelbaum[67]).

4.408.3.3. Integrins and Growth Factor Receptors

In many cases, integrins are necessary for the optimal activity of particular growth factors as cells need to be adherent to the substrate via integrins. The receptors for insulin/insulin-like growth factor-1 (IGF-1), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), and thrombin require cell attachment. Integrin clustering and association with cytoskeletal elements and focal adhesion kinase (FAK) promote integrin-growth factor receptor complexes that can partially activate the signaling of these growth factors.[4,68–74] The integrin $\alpha_v\beta_3$ has been immunoprecipitated as a complex with IGF-1, PDGF, and VEGF receptors, and the $\alpha_5\beta_1$ integrin has been shown to be associated with EGF receptors.[68] Signaling through β_1 and β_3 has been implicated in transforming growth factor β (TGF-β) signaling,[75,76] and the RGD peptide has also been shown to stimulate the transcription and secretion of TGF-β upon integrin activation.[77] In addition, TGF-β has been shown to upregulate integrins in epithelial cells and myofibroblasts.[78,79]

Integrins have a critical role in regulating adhesion, proliferation, and differentiation of cells in the osteoblast lineage and in other cells in the bone. Therefore, testing integrin-modulating peptides to stimulate bone formation was a logical

step in tissue engineering of bones. The ultimate design of implant materials with integrin-activating capacity also requires a knowledge of integrin-signaling pathways, and this further complicates our ability to design specific biomaterials that are anabolic to the bone.

4.408.4. Integrin-Signaling Pathways

4.408.4.1. Intracellular-Signaling Pathways

Many integrins are not constitutively active even though they are expressed on the cell surface and require activation to transmit intracellular signals and thus change cell behavior.[4] A major mechanism by which integrins transmit signals intracellularly is through integrin binding and clustering, which results in the formation of focal adhesion sites at which the integrins connect the ECM with the intracellular cytoskeleton (see Danen and Yamada[80] and Van der Flier and Sonnenberg[6] for excellent reviews and diagrams of integrin signaling). Intracellular signals are then propagated by the association of proteins, such as talin, FAK, src, and RAS, with the other components in the focal adhesion site. Talin links integrins to the actin cytoskeleton either directly or indirectly by interacting with vinculin and α-actinin. FAK($pp125^{FAK}$), a tyrosine kinase, binds to the β_1 integrin cytoplasmic tail,[81] and initiates a signaling cascade of autophosphorylation.[82] Intermediate steps involving phosphorylation lead to the transient phosphorylation of mitogen-activated protein kinases (MAP kinase; ERK1 and ERK2) on their threonine and tyrosine residues. Furthermore, ligand binding and tension induce phosphorylation by members of the Src protein kinase family, including c-Src, Csk, and Fyn, at the focal adhesion sites which leads to the recruitment and activation of downstream signaling molecules, for example, Rho-like GTPases, phospholipase-C (PLC), and the ERK- and JNK-signaling cascades[83,84] (**Figure 2**).

The Rho family of GTPases plays an important role in cytoskeletal rearrangement, and its members are active when they are bound to GTP but inactive when bound to GDP.[86] GTP-activation of Rho-like GTPases is regulated by guanidine exchange factors (GEFs), GTPase-activating proteins (GAPs), and guanidine dissociating factors (GDIs). Rho is believed to act upstream of integrin activation[85] and plays a major role in actomyosin-based contractility during the formation of stress fibers and focal adhesions in spread cells.[86] Two other small GTPases that have been located upstream of integrin activation are R-ras[87] and Rap1.[88,89] Ultimately, this signaling cascade leads to cytoskeletal rearrangement, anchorage-dependent entry into the S-phase and gene transcription.[90] Integrin-mediated signaling is characterized by the formation of a signaling complex that is modified and strengthened by multiple interactions between its components which are also linked to numerous other pathways. Such multiple interactions make it difficult to define the primary and crucial regulatory interactions in integrin-mediated signaling.[91]

The nuclear target proteins of MAP kinases include Fos and Jun (members of the AP-1 transcription complex) which control gene expression.[92] Myc is another nuclear regulatory factor involved in transcriptional control of preosteoblastic proliferation,[93] which is also activated. The immediate early genes, c-fos and c-jun, are required for the G0/G1 transition while c-myc is present in measurable quantities throughout the cell cycle and is believed to be involved in the G1 to S transition.[43] AP-1 promoters are found in several bone ECM proteins, such as type I collagen,[94] alkaline phosphatase,[95] osteocalcin,[96,97] and osteopontin.[98] Overexpression of c-fos in transgenic mice results in the development of osteosarcomas[99,100] while mice lacking c-fos develop osteoporosis due to the lack of osteoclast formation even though osteoblast function appears to be normal (probably due to redundant cell-signaling pathways).[100,101] In addition, actively dividing cells express more c-jun than quiescent cells.[102] Mitogens, such as growth factors (EGF and TGF-β) and serum, also induce c-fos and c-jun expression.[93] Osteoblasts that bind to metal implants also induce c-fos and c-jun expression leading to increased cell proliferation.[103]

4.408.5. Integrin Binding to Biomaterials

4.408.5.1. Initial Binding of Serum Proteins to Implant Materials

Previous studies have shown that the surface of the implant material is covered with serum proteins during the first minutes after its implantation into a living tissue.[104,105] This process of protein adsorption is a multistep process that is characterized by distinct events during each stage. Initially, small rapidly diffusing proteins are absorbed onto the implant surface. This stage is then followed by adsorption of larger proteins that mediate cell adhesion (mostly fibronectin and vitronectin).[106] Therefore, it is believed that cells in the adjacent host tissues are never in direct contact with the naked surface of the material and are rather in contact with the absorbed proteins that direct the processes of cell adhesion, proliferation, and further differentiation. However, one study suggests that cells may bind directly to the material using the $\alpha_5\beta_1$ integrin.[107] Adsorption of mineral ions, particularly calcium and inorganic phosphate,[108] also affects cell binding to metals, and due to the presence of an oxide layer on all metals there is spontaneous formation of an apatite layer on some metals,[109] which may partially explain why many metals are very biocompatible with bone (**Figure 3**).

Various substrate properties of the implant, such as surface roughness, surface energy, physicochemical properties of the substrate as well as its local environment (pH, concentration, composition, and functional groups of proteins, strength of solution, temperature) (*Vroman effect*)[110] affect the composition of the absorbed protein layer.[111] Metals and hydroxyapatite have been reported to actively adsorb serum proteins *in vitro*.[112–115] These proteins include fibronectin, vitronectin, and osteopontin, although other proteins and some serum components may contribute to the formation of an organic film on the implant surface immediately upon its exposure to tissue culture medium or to biological fluids. For commercially pure titanium, properties such as surface roughness, chemical composition of the oxide layer and surface wettability may also play an important role in determining the amount of the adsorbed proteins *in vitro*.[114] Both hydrophobic and hydrophilic surfaces are able to adsorb proteins *in vitro*. Even though cells tend to attach better to rough hydrophilic surfaces, these surfaces usually have lower affinity for protein

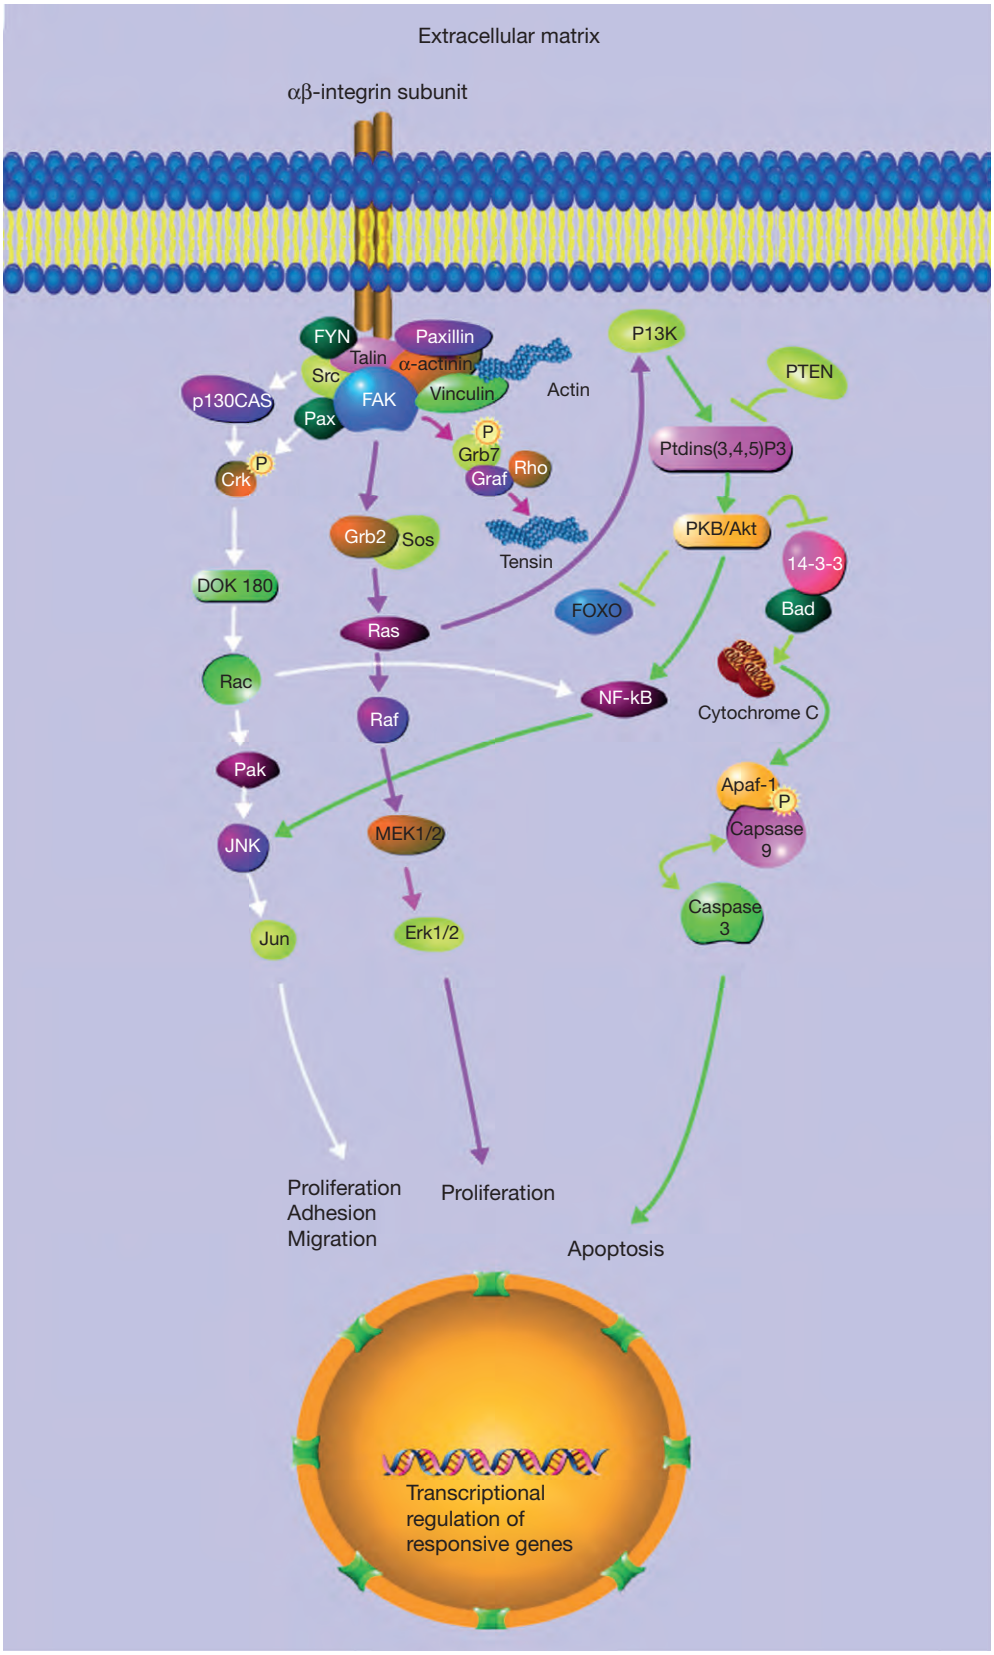

Figure 2 Simplified diagram of integrin-signaling pathways. A major mechanism by which integrins transmit signals intracellularly is through integrin binding and clustering which results in the formation of focal adhesion sites where integrins connect specific extracellular matrix proteins with the actin-based intracellular cytoskeleton and also initiate numerous signaling pathways. These events lead to changes in cell adhesion, migration, cell–cell interations, cell proliferation, apoptosis, and regulation of responsive genes.

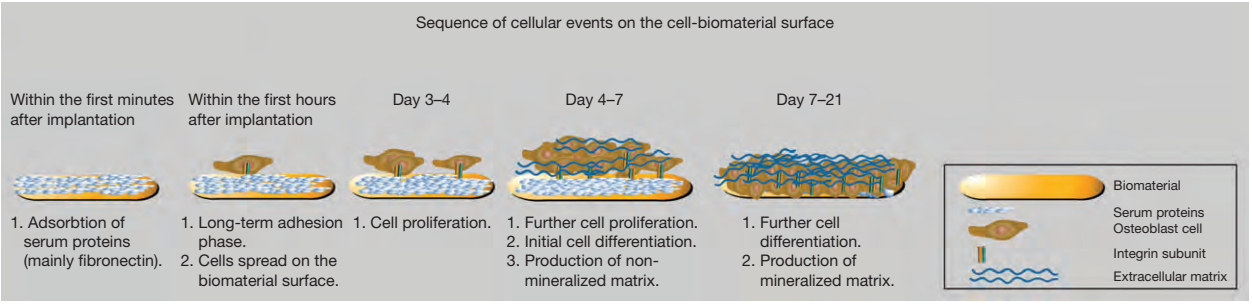

Figure 3 Sequence of events at the cell-biomaterial surface for bone. Within the first few minutes of implanting a biomaterial into a living organism, serum proteins adsorb to the surface of the biomaterial, followed by cell adhesion and spreading that are mediated mostly by integrins. In the next few days, cells begin to proliferate at the surface, and then differentiate by producing an extracellular matrix which subsequently mineralizes.

adsorption.[114,115] However, more fibronectin is adsorbed by a rough Ti–6Al–4V surface compared to the smooth tissue culture polystyrene surface.[115] Interestingly, it has been shown that metal substrates, such as titanium and stainless steel, do not absorb as much serum fibronectin, vitronectin, and albumin as does hydroxyapatite.[112,116,117]

Fibronectin has long been thought to be the principal adhesion-promoting protein both *in vitro* and *in vivo*. However, even though concentrations of fibronectin and vitronectin in the blood are similar, fibronectin has a much lower competitive ability compared to vitronectin.[118,119] Previous studies have demonstrated that cell adhesion is dependent on fibronectin only when its serum concentration is below 3%. At higher concentrations, adsorption of fibronectin declines and vitronectin becomes the predominant adhesive protein.[120,121] It has been suggested that, at higher concentrations, adsorption of fibronectin can be inhibited by other serum proteins, whereas the adsorption of vitronectin may not be affected.[120] *In vitro* studies have also shown that the adhesion of many cell types in culture also depends mostly on vitronectin rather than on fibronectin.[112,118,122,123] Both fibronectin and vitronectin appear to be required for the adhesion of human osteoblast to various substrates (stainless steel, cpTi, and Al_2O_3). However, vitronectin seems to promote cell adhesion better compared to fibronectin; this was demonstrated by depleting these proteins in the culture medium.[122] In addition, tissue culture grade polystyrene adsorbs vitronectin more actively than fibronectin and may therefore promote cell adhesion on its surface.[118] As suggested, the active conformation of fibronectin may be substrate-dependent, whereas it is substrate-independent for vitronectin. Therefore, when adsorbed onto a substrate, vitronectin may have a higher biological activity in enabling increased adhesion of cells *in vitro*.[123,124]

Several lines of evidence demonstrate that, on a nanoscale level, the adsorbance of proteins onto the surface of metal (cpTi) and nonmetal (polyethersulfone) substrates does not depend on the roughness of these materials.[125,126] However, fibrinogen adsorption increased proportionally with an increase in the nanoscale roughness of quartz-deposited tantalum, but the degree of adsorbance was dependent on the nature of the adsorbed proteins with more globular proteins, such as bovine serum albumin, showing little response to nanoscale increases in roughness.[127] Surface roughness has a large effect on cell responses. However, there is little or no substantial evidence of a difference in protein adsorption due to surface roughness. Surface properties do affect osteoblast proliferation and differentiation as differential expression of integrins and osteoblast activities was observed when these cells were cultured on smooth, sandblasted, or plasma-sprayed titanium.[128,129] Cells of the osteoblast lineage respond to surface roughness of the materials in ways that are cell-maturation specific. The MG-63 cells, a human osteoblast-like osteosarcoma cell line, responded to an increasing surface roughness by decreasing proliferation and increasing differentiation with an increase in alkaline phosphatase activity and osteocalcin production.[130] Production of local factors was also modulated by surface roughness with an increase in the production of both TGF-β and PGE_2. On rougher surfaces, MG-63 cells exhibit enhanced responsiveness to 1,25-dihydroxyvitamin D_3. These effects also appeared to be prostaglandin-mediated since indomethacin prevented an increase in the expression of differentiation markers. Osteoblasts appear to be able to detect minute differences in the surface properties of metals, as shown by their differential responses to cpTi Grades 1 and 4.[131]

4.408.5.2. Integrin-Mediated Cellular Responses to Implant Materials

The next development in the sequence of events on the surface of implant materials consists of the consecutive stages of cell adhesion, proliferation, the production of ECM proteins, and differentiation, which in bone is followed by mineralization of the organic scaffold. Adhesion is one of the initial biological responses of cells to implant materials and is one of the indicators of biocompatibility (for review, see Anselme[111]). Two phases of cell adhesion are distinguished, a short-term attachment phase due to simple gravity of the cells (occurs within the first seconds or minutes of contact) and a longer adhesion phase due to specific physicochemical properties of a material (occurs from minutes to several hours).[132] Following adhesion, cells spread out on the surface and adopt a morphology that is characteristic of the cell type and this is influenced by the surface topography and physicochemical properties of the material.[111] Adhesion, therefore, is a prerequisite for the subsequent proliferation and differentiation of cells.

The expression of specific types of integrins varies depending on the stage of cell differentiation, type of the material, and surface properties of the material. Therefore, each cell type and

stage of differentiation displays different arrays of integrin expression. To illustrate some of these differences, bone cells will be used as an example of the complexity of integrin expression. It has been shown that the intracellular signaling pathways of osteoblast adhesion to the metal implant material such as Ti–6Al–4V are similar to integrin-mediated adhesion to ECM proteins which in turn leads to integrin-mediated responses such as increased proliferation.[103] The integrins $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_5$ but not $\alpha_4\beta_1$ and $\alpha_6\beta_1$, were found to be expressed on normal human osteoblasts by flow cytometry.[129] Primary human osteoblasts express predominantly α_2, α_4, α_v, β_1, and β_3 integrin subunits when grown on Ti–6Al–4V, Co–Cr–Mo, and tissue culture plastic (TCP).[133] Initial adherence of osteoblasts to the surface of metal (including cpTi) substrates and their adherence during stages of osteoblast proliferation and differentiation were shown to be mediated through the $\alpha_5\beta_1$ integrins.[107,128,134] Other studies have shown that osteoblasts growing on TCP predominantly express the $\alpha_5\beta_1$ receptor and shift to the $\alpha_2\beta_1$ when cultured on cpTi or Ti–6Al–4V.[24,64,133] Integrin expression in human osteoblasts also varies depending on degradable polymeric implant materials *in vitro*.[135] Fibronectin, vitronectin, and human osteoblast bone marrow precursor cells bind better to hydroxylapatite (HA) than to metals, suggesting that improved integrin-mediated cell binding may be one of the mechanisms that lead to better clinical bone integration in HA-coated implants.[116]

The expression of the α_2, α_5, β_1, and $\alpha_v\beta_3$ integrins is also substrate-dependent and is enhanced in cells cultured on implant materials with rough surfaces compared to tissue culture plastic.[128,136] However, studies on how topography affects integrin expression and cell behavior are difficult to interpret due to the use of different cell types, integrin antibody sources, and surface topographies prepared by using different methods for *in vitro* studies.[24] TGF-β_1 is upregulated in human osteoblasts growing on rough surfaces and has been shown to stimulate the expression of α_5.[137] On the other hand, α_5 was reduced while α_2 was increased when osteoblast-like cells were treated with 1,25-dihydroxyvitamin D_3. However, it is difficult to directly correlate integrin expression with surface roughness since integrin expression is also dependent on the physicochemical properties of the substrate.[129,133] For example, using MG-63 cells, signaling via the α_5-subunit was shown to be required for DNA synthesis and expression of alkaline phosphatase, but these effects did not appear to be dependent on the surface roughness of chemically polished, grit blasted, and acid-etched titanium, each with different surface microstructures.[134,138] In another study by Mendonca *et al.*,[139] bone-specific mRNAs expression showed a higher increase on surfaces that were nanostructured compared to machined or acid-etched surfaces. *In vivo*, turned and dual acid-etched surfaces, placed in rat femurs, showed that ECM protein synthesis was greatest near the rougher surface which led to an increase in bone–implant contact during the early stages of bone healing.[140]

4.408.5.3. Inflammatory Responses

Following the formation of an adsorbed protein layer, a cascade of inflammatory processes occurs on the biomaterial surface, and their extent depends on the implantation procedure, target tissue/organ, and the properties of the adsorbed protein layer. The presence of specific proteins in the adsorbed layer influences the interaction of inflammatory cells with biomaterials and the subsequent inflammatory responses.[141,142] Inflammatory cells, such as monocytes and macrophages, are among the first cells to arrive at the bone–implant interface. Of the β_1 integrins, in monocytes/macrophages, there are $\alpha_5\beta_1$, $\alpha_4\beta_1$ (bind to fibronectin) and $\alpha_6\beta_1$ (binds to laminin). Of β_2 integrins, they express $\alpha_L\beta_2$ and $\alpha_D\beta_2$ (bind to ICAM), $\alpha_X\beta_2$ and $\alpha_M\beta_2$ (bind to fibronectin). Of the β_3 integrins, monocytes/macrophages express only the $\alpha_V\beta_2$ (bind to vitronectin).[143] It has been demonstrated that initial monocyte adhesion to the implant surface is mediated mainly by the β_1 integrin, and that both β_1 and β_2 are involved in macrophage adhesion, which is followed by its fusion into multinucleated foreign giant cells and further activities.[142,144] These integrin subunits have previously been shown to be involved in the adhesion of monocytes and macrophages to endothelium and their movement to the sites of inflammation.[145] Therefore, expression of the β_1 and β_2 integrins is important for the inflammatory reaction of live tissue to implant insertion and biocompatibility of the biomaterial itself. Indeed, the binding of $\alpha_M\beta_2$ integrin (Mac-1) to P1 and P2 domains of fibronectin adsorbed onto the surface of biomaterials is important for the initial recruitment and accumulation of monocytes/macrophages at the tissue– material interface.[146,147] Interestingly, RGD sequences in fibrinogen were shown not to be involved in fibrinogen-mediated acute inflammatory responses to implanted biomaterials.[146] The recent discovery of numerous resident tissue macrophages (OsteoMacs) on the endosteum and periosteum of bone may impact the bone formation process and is likely to play an important factor in the future design of implant materials for bone.[148]

4.408.6. Functionalizing Implant Surfaces Using Adhesion Molecules

4.408.6.1. General Description of Functionalizing Implant Surfaces

In order to improve physicochemical and mechanical properties of materials and stimulate the biological responses of osteoblast cells on their surfaces, various types of modifications have been proposed. These include, but are not limited to, the generation of new metal alloys, development of their osteoconductive three-dimensional structures (porous tantalum, titanium fiber mesh),[149,150] modification of metal substrates by roughening their surface by acid-etching, grit-blasting, plasma-spraying, anodization, etc.,[151] coating of metal surfaces with HA,[152] and incorporation of growth factors and other biologically active molecules into implants.[153,154]

On the basis of the fact that integrins mediate cell adhesion to substrates, biological modification of implant materials has recently become one of the most interesting approaches in the development of new biomaterials (for review, see Lutolf and Hubbell,[155] Hersel *et al.*,[156] and Kim *et al.*[157]). This strategy mostly focuses on the immobilization of short peptides on the surface of synthetic or natural metallic or nonmetallic materials in order to improve their adhesive

abilities, stimulate osteogenic differentiation of cells, and increase bone healing.[158–165]

4.408.6.2. *In Vitro* Studies Using Adhesion Molecules on Implant Surfaces

In vitro, RGD coating, compared to uncoated substrates, has been shown to increase cell attachment, spreading, proliferation, and differentiation of osteoblasts[158,160,166] and other cell types such as tenocytes[167] and oral epithelial cells.[168] Massia and Hubbell[169] have shown that cellular responses of adhered cells depend on the density of the immobilized RGD peptides. A minimal RGD density of 1 fmol cm^{-2} was enough for complete spreading of the cells; however, the formation of focal contacts and well-organized stress fibers was seen only at a concentration of 10 fmol cm^{-2}. After 3 weeks in culture, surfaces modified with a 15 amino acid peptide containing RGD at a density of 0.62 pmol cm^{-2}, significantly enhanced mineralization in rat calvarial osteoblast cultures compared with a RGD surface density of 0.01 pmol cm^{-2}.[170] Various studies have reported an increase in adhesion, proliferation, and osteogenic differentiation of osteoblast-like cells growing on RGD-coated substrates. Using the KUSA/A1 bone marrow cell line, *in vitro*, Itoh *et al.*[171] have demonstrated a significant increase in adhesion, proliferation, and osteogenic differentiation of cells growing on E_7PRGDT peptide-coated hydroxyapatite discs compared to uncoated discs. Covalently linked RGD peptides on silk increased human osteoblast adhesion, ECM matrix production, and mineralization compared to silk alone or the control peptide, RAD, conjugated to silk.[172] The coating of cpTi grade 2 substrates with fibronectin, but not with vitronectin, significantly increased the initial adhesion of MC3T3-E1 osteoblast-like cells, their subsequent proliferation at day 3 and alkaline phosphatase activity at day 7. Interestingly, significantly more fibronectin adsorbed onto the titanium surface compared to vitronectin, measured colorimetrically by protein adhesion assay, and stimulated MC3T3-E1 proliferation and differentiation.[173] This may indicate that fibronectin adsorbs at higher amounts onto implant surfaces than vitronectin and thus mediates further biological events at the bone–implant interface.

Modifying metal surfaces with a surface-grafted chitosan in conjunction with an RGD peptide reduced bacterial adhesion and promoted osteoblast function of MC3T3-E1 cells.[174] Similar findings were found with MC3T3-E1 on Ti using polyelectrolyte multilayers (PEMs) of hyaluronic acid (HY) and chitosan (CH), coupled with surface-immobilized RGD. The HY/CH PEM-functionalized Ti decreases bacterial adhesion, but the adhesion of osteoblasts is poorer than on Ti. Osteoblast adhesion was significantly improved, along with alkaline phosphatase expression, when the RGD peptide was added to the HY/CH PEM-functionalized Ti.[175] RGD-containing peptides covalently bonded to Ti were shown not only to promote osteoblast attachment but also to promote cell survival when exposed to agents that induce apoptosis.[176] The development of new methods to modify the surface of titanium with oligonucleotide-RGD peptide conjugates[177] or coating titanium implants with a tailor-made cyclic-RGD peptide that binds to specific integrin receptors on the cell surface through multimeric phosphonates[178] may be a promising technology for tissue engineering of metal implants. *In vitro* studies have demonstrated that RGD-coated metal implants have improved early bone formation and biocompatibility compared to non-coated substrates.

4.408.6.3. *In Vivo* Studies Using Adhesion Molecules on Implant Surfaces

In vivo studies using several animal models have reported that implant materials coated with RGD peptides improve early bone formation around implants. Using a rat model, Ferris *et al.*[163] showed that bone formation was significantly higher around RGD-coated smooth titanium implants at 2 and 4 weeks compared to control gold-coated titanium implants. Using a miniature pig model, Germanier *et al.*[179] demonstrated that new bone formation around RGD-coated, sandblasted and acid-etched (SLA) cpTi implants was significantly higher at 2 weeks but not at 4 weeks compared to uncoated control implants. Similarly, a study in canines by Elmengaard *et al.* demonstrated that the coating of plasma-sprayed, porous-coated Ti–6Al–4V implants with cyclic-RGD significantly increased bone formation in the inner gap zone (0–375 μm), surrounding the unloaded RGD-coated implants at 4 weeks. In addition, a push-out test on the mechanical properties of the bone–implant interface showed a significant increase in apparent shear stiffness and much less fibrous tissue surrounding cyclic-RGD-coated implants in both loaded and unloaded models compared to uncoated controls.[180] RGD-Ti fiber mesh implants, inserted into the cranium of a rabbit, showed an increase in bone formation/bone ingrowth compared to porous titanium fiber mesh disks without RGD.[181] Bone–implant contact of screw implants in dog mandibles was increased at earlier time points in an RGD-peptide- and dose-dependent manner in RGD-titanium implants compared to titanium alone. However, volume density of the periimplant bone was similar in collagen-coated or RGD-peptide-coated titanium implants compared to titanium alone.[182] Early bone apposition to a modified, SLA surface coated with an RGD-peptide-modified polymer (PLL-*g*-PEG/PEG-RGD) compared to standard SLA implants was examined in the maxillae of miniature pigs. At 2 weeks, RGD-coated dental implants demonstrated significantly higher percentages of bone-to-implant contact compared to controls (61.68% vs. 43.62%; $p < 0.001$).[179] In another study, titanium screws were coated with type I collagen (Ti/Coll), RGD peptide (Ti/RGD) or type I collagen and chondroitin sulfate (Ti/Coll/CS) and implanted in rat tibiae. Direct contact of the bone with the implant surface was statistically higher with Ti/RGD and Ti/Coll/CS compared to the uncoated Ti implants but was not different between the Ti/RGD and Ti/Coll/CS implants.[183] Similar results were found with a porous titanium (Ti) fiber mesh implant coated with cyclic-RGD peptides and inserted into the cranium of a rabbit. RGD-Ti implants were also compared to porous titanium fiber mesh disks without RGD sequence (Ti) and with an open control defect. Histologic and histomorphometric examinations were performed at 2, 4, and 8 weeks after the operation. A significant increase in bone formation, or bone ingrowth, was seen in the RGD-Ti group compared to the Ti group after 4 and 8 weeks. All control defects stayed open at all the three time points.[181] A comparison of the

results of *in vitro* and *in vivo* studies suggests that the reason for RGD's early anabolic effects on bone formation, *in vivo*, may be due to increased cell adhesion, proliferation, and cell survival combined with the stimulation of early osteoblast differentiation.

In a few studies, early bone formation was not increased with RGD-functionalized implants. The coating of a porous implant with RGD, compared to uncoated screws, demonstrated an increase in the percentage of bone-to-implant contact in the threads of a screw in rabbit femurs at 8 and 12 weeks but not at 4 weeks.[184] Using a canine model, Schliephake *et al*.[185] found no significant difference between alveolar bone formation around RGD-coated and -uncoated Ti–6Al–4V implants at 1 and 3 months, though they observed a significant increase with time in bone formation around RGD-coated implants. Coating metal titanium implants with polymer networks containing rat bone sialoprotein (bsp-RGD(15)), did not enhance bone formation in the periimplant region at 2 or 4 weeks in a rat femoral ablation model.[186] Whether the differences in the responses of bone to RGD peptide implants are due to particular bone applications or the nature of the coating is not known. The technique used to immobilize the peptide coating may also influence the outcome.

4.408.6.4. Functionalizing Biomaterials with Short Versus Long Peptides

There are several reasons for using full-length proteins coated onto material surfaces instead of short peptides.[24,187] In most cases, the biological activity of short peptides is lower compared to that of the full-length protein.[2] Studies by Pierschbacher and Ruoslahti[188] have demonstrated that the adhesion of normal rat kidney cells to a polystyrene surface was considerably higher on fibronectin-coated surfaces compared to those coated with fibronectin-derived short peptides. The presence of a PHSRN (Pro-His-Ser-Arg-Asn) synergy domain enhanced the adhesive activity of the $\alpha_5\beta_1$ integrin compared to that of the RGD alone.[189] Self-assembled monolayers (SAMs) of alkanethiols on gold, functionalized with the FNIII7-10 recombinant fragment presenting RGD and PHSRN adhesive motifs in the correct structural context, exhibited significantly higher osteoblast-like cell adhesion, FAK activation, and proliferation rate than biomaterials presenting an RGD ligand or the RGD–PHSRN. FNIII7-10 functionalized surfaces also displayed specificity for the $\alpha_5\beta_1$integrin while cell adhesion on RGD or RGD–PHSRN was primarily mediated by the $\alpha_v\beta_3$ integrin.[190] As the RGD sequence is recognized by various integrins, it may lead to the nonspecific binding of cells of various types and may therefore attenuate a specific response. The RGD peptide may not be appropriate for all stages of cell differentiation. As full-length proteins usually bind to more than one integrin, different types of cells can adhere to the material. In bone, there is sequential synthesis of matrix proteins *in vivo*[51] and not all the proteins contain the RGD sequence. The RGD-binding integrins may also require the presence of other peptides for adherence to a substrate.[24]

Most of the studies on RGD and other short biomimetic peptides were done *in vitro* where the conditions are different than the conditions *in vivo*, especially in the bone healing models. Therefore, our current knowledge may not be biologically completely accurate and we may not get the desirable effect *in vivo*. However, most of the *in vivo* studies have given results that are comparable to the *in vitro* findings on short and long peptides. Using a goat model, Bernhardt *et al*.[191] showed that the coating of titanium implants with full-length type I collagen resulted in a significant increase in periimplant bone formation at 5 and 12 weeks compared to RGD-coated titanium implants. Other binding peptides have also been shown to influence cell behavior. The GFOGER peptide, compared to collagen-coated or -uncoated titanium, improves binding of the $\alpha_2\beta_1$ integrin, increases periimplant bone formation and osseointegration, as characterized by an increase in bone– implant contact and mechanical fixation, in an *in vivo* rat tibia cortical bone implantation model.[192] In the same publication, *in vitro* studies with the same peptide demonstrated that bone marrow stromal cells displayed enhanced cell adhesion, osteoblast-specific gene expression, and calcification compared to titanium alone. In a different study, collagen-coating alone was not sufficient to accelerate differentiation of rat calvarial osteoblasts on Ti–6Al–4V but it did increase cell adhesion.[193] Interestingly, *in vitro* studies with siRNA directed against the $\alpha_2\beta_1$ integrin have been shown to inhibit osteoblast differentiation and bone formation, suggesting that stimulating this collagen integrin may be anabolic with respect to bone formation.[64] The coating of soluble laminin-5 on titanium implant disks from cell-conditioned medium has been shown to improve cell attachment and production of hemidesmosome proteins in human gingival epithelial cells.[194]

4.408.6.5. Functionalizing Biomaterials with Multiple Peptides

The design of smarter biomaterials that target particular cellular responses and physiological conditions may provide more successful tissue engineering outcomes. Covalently attached RGD and heparin-conjugated fibroblast growth factor 2 (FGF-2) bound to hydrogels increased the survival and growth of primary nerve cells and neural stem cells compared to either agent alone in hydrogel.[195] The application of RGD peptides with other factors in compromised bone situations may also have therapeutic potential. Tetra-cell adhesion molecule (T-CAM) coating, composed of four cell adhesion molecules, an RGD sequence, a PHSRN sequence, a tyrosine-histidine sequence (YH), and a glutamic acid-proline-aspartic acid-isoleucine-methionine (EPDIM) on the rough-surfaced titanium implant, increased periimplant bone formation in rabbit femurs with poor local bone conditions and minimal primary stability.[196]

The development of dental implants that utilize different biomimetic coatings for use at the gingival region and other coatings such as the RGD peptide for bone may also be promising.[197]

The effects of cyclic-RGD-coated implants on tissue integration and implant fixation in two cancellous bone-gap models were examined in canines. Loaded RGD-coated implants with 0.75-mm gap and unloaded RGD-coated implants with 1.5-mm gap were placed into the distal femur and proximal tibia of canines, respectively. Control gap implants, without RGD, were inserted contralaterally. Mechanical implant

fixation was improved in the RGD-coated implants. Unloaded RGD-coated implants showed a significant increase in bone at 4 weeks, and both loaded and unloaded implants showed a significant reduction in fibrous tissue anchorage.[180]

In vitro/*in vivo* experiments that test a particular composite are also helpful in showing the efficacy of a particular implant design. Proliferation, alkaline phosphatase and osteocalcin activity in MC3T3-E1 cells, osteoblast-like cells, was increased when they were cultured on TGF-β_1-loaded collagen/chitosan composite microgranules.[198] The TGF-β_1-loaded microgranules demonstrated a higher capacity for bone regeneration in rabbit calvarial defects after 4 weeks compared to TGF-β_1-unloaded microgranules. Thus, collagen coating did not enhance bone formation in this model, unless coupled with a growth factor.

4.408.7. Conclusions

The crucial role that integrins play in mediating cell–matrix interactions allows them to be key regulators of cell behavior. Therefore, modulation of integrin function has the potential to influence tissue engineering outcomes if integrin activities could be harnessed appropriately for specific biological applications. Due to the fact that integrins are a diverse family of receptors, are large molecules with multiple activities associated with particular peptide regions, and have a complex signaling pathway, our ability to control their function with specifically designed biomaterials is a difficult task. In addition, each cell type and stage of cell differentiation in a tissue expresses different arrays of integrins, so control of their function at one stage of development with a biomaterial may not be appropriate for the next stage in tissue development. However, functionalization of implants with the RGD amino acid sequence has resulted in some success with significant increases in early bone formation both *in vitro* and *in vivo*. In general, *in vitro* studies have been helpful in the design of *in vivo* studies aimed at augmenting bone with integrin-activating peptides or the ligands for integrins, such as specific ECM proteins.

However, our ultimate goal to provide an implant that will last longer in younger patients or for our rapidly aging population still needs to be realized with integrin-activating implants. The outcomes of the majority of the studies have only been tested for several weeks or, at most, a few months. We do not know if integrin modulation will improve the long-term functional integration and life span of these implants. In the future, we may want to consider deactivating particular integrins in certain circumstances, for example, to prevent fibrous tissue growth, but there is little information on this approach in scientific literature. Another possibility is to design implants with sequentially available peptides so that we may provide a better outcome, for example, with an early peptide, stimulating proliferation, and a latter peptide, anabolic for cell differentiation. It is also important to test the particular applications of these functionalized implants. Would these types of implants be more helpful in patients with osteonecrosis or other bone debilitating diseases? These studies are needed to ultimately determine the utility of integrin-modulating peptides in tissue engineering.

Glossary

Acetabulum It is a concave surface of the pelvis, where the head of the femur meets with the pelvis forming the hip joint.

Adipocytes These, also known as lipocytes and fat cells, are the cells that primarily compose adipose tissue, specialized in storing energy as fat.

Demixing It refers to the separation of the components of a mixture.

Dexamethasone Dexamethasone is a potent synthetic member of the glucocorticoid class of steroid hormones, is anti-inflammatory, and acts as an immunosuppressant.

Electron-beam lithography It uses electrons to define a pattern and is the most high-fidelity top-down fabrication method.

Electrospining It refers to the use of an electrical charge to draw very fine (typically on the micro or nanoscale) fibers from a liquid.

Etching Wet etching is the process of using strong acid or mordant to cut into the unprotected parts of a metal surface to create a design in intaglio in the metal (in modern manufacturing, other chemicals may be used on other types of material). Dry etching is the use of ion bombardment to etch into a surface.

Focal adhesions FAs (cell–matrix adhesions) are specific types of large macromolecular assemblies through which both mechanical force and regulatory signals are transmitted.

Integrins They are receptors that mediate attachment between a cell and the tissues surrounding it, including other cells or the extracellular matrix (ECM). They are also involved in cell signaling and thereby define cellular shape, mobility, and regulate the cell cycle.

Interference lithography (or holographic lithography) A technique for patterning regular arrays of fine features without the use of complex optical systems or photomasks.

Mesenchymal stem cells (MSCs) MSCs are multipotent stem cells that can differentiate into a variety of cell types, including osteoblasts, chondrocytes, myocytes, adipocytes, endothelia, and β-pancreatic islets cells.

Nanocolloids They are nanoscale colloidal spheres that can be dispersed across a surface and used as an etch mask.

Osteoblast Osteoblast is a mononucleate cell that is responsible for bone formation.

Photo(optical) lithography It is a process used in microfabrication to selectively remove parts of a thin film or the bulk of a substrate. It uses light to transfer a geometric pattern from a photo mask to a light-sensitive chemical photoresist.

Photoresist It refers to a light-sensitive material used in many industrial processes, including photolithography and photoengraving, to form a patterned coating on a surface.

Tribology Tribology is the science and technology of interacting surfaces in relative motion. It includes the study and application of the principles of friction, lubrication, and wear.

Abbreviations

BHK	Baby hamster kidney
Ch	Chromosome
CNT	Carbon nanotube
DiGE	Two dimensional (2D)-fluorescence difference gel electrophoresis
DNA	Deoxyribonucleic acid
EBL	Electron beam lithography

ES Cells	Embryonic stem cells
FA	Focal adhesion
FAK	Focal adhesion kinase
GRASP55	Golgi reassembly stacking protein 55
LH	Laser holography
MAPK	Mitogen-activated protein kinase
MARs	Matrix attachment regions
MDCK	Madin-Darby canine kidney
MEF	Mouse embryonic fibroblast
mRNA	Messenger ribonucleic acid
MSC	Mesenchymal stem cell
PAA	Poly(acrylic acid)
PDGF	Platelet-derived growth factor
PL	Photolithography
PLO	Poly-L-ornithine
PMMA	Polymethylmethacrylate
PnBMA	Poly(*n*-butylmethacrylate)
PS-PnBMA	Poly(styrene)-poly(*n*-butylmethacrylate)
Q-PCR	Quantitative-polymerization chain reaction
RNA	Ribonucleic acid
ROCK	Rho kinase
SSCs	Skeletal stem cells
SUN	Sad1 and UNC-84 homology domain

4.409.1. Introduction

Multicellular organisms provide a highly complex environment with many different chemical, physical/mechanical, and geometrical stimuli that affect cell phenotype, differentiation, and development. Researchers have looked at surface chemistry[1–4] growth factors, and mechanical forces[5,6] as factors in cell, and more specifically, stem cell differentiation, but nanotopography and its effects on cell behavior have been studied intensively only in the last decade. Topography varies with different tissues and also within the tissue microenvironment ranging from macro (i.e., bone or ligament) to micro (i.e., shapes of neighboring cells) to nano (i.e., protein folding and collagen binding) (64-nm repeat pattern).[7,8]

The initial study of Carrel in 1911[9] indicating that cells respond to shape opened new directions in the emerging field of cell biology and later, tissue engineering. In 1952, Weiss and Garber[10] first used the term 'contact guidance' to define cell alignment to topography. Since then, many studies of different substrates/biomaterials with different topographies and cell types have emerged.

Photolithography (PL) was the first and most widely used method that allowed the fabrication of micron-scale ($>1\,\mu m$) features (width, diameter) such as grooves or pits with submicron depths (1–0.1 μm).[11] Over the last decade, with the advancement of microfabrication, the effects of microtopography have been documented for several cell types, including changes in cell morphology, adhesion, contact guidance, motility, cytoskeletal organization, apoptosis, macrophage activation, and gene expression in different cell types, including fibroblasts, osteoblasts, osteoclasts, macrophages, endothelial, smooth muscle, epithelial, retinal, neural, and mesenchymal stem cells (MSCs).[12–19]

Current advances in the fabrication techniques, from PL to electron-beam lithography (EBL), have enabled scientists to study cell responses at the nanoscale level ($<0.1\,\mu m$). Interestingly, it was recently demonstrated that many different cell types, including fibroblasts, osteoblasts, osteoclasts, endothelial, smooth muscle, epithelial, epitenon, neural, and MSCs, respond strongly to nanoscale topography and are influenced in a similar way to the microtopography, ranging from morphology and adhesion to genomic regulation.[20–35]

Given that different cell types show different responses to different surface topographies, there is a continuous need for the development of 'next generation' biomaterials and medical implants. The surface properties of biomaterials, that is, porosity[36] or wettability (hydrophilicity/hydrophobicity),[37,38] are important for their application and critical for the adhesion process of adjacent cells in the case of implants. The measurement of the wettability of a material (contact angle in the presence of different liquids) provides us with very useful information about the cytocompatibility of the material. Previous work by Keisler[39] showed that surface roughness may have an effect on contact angle, the increase or decrease of which depended on its initial value. Roughness, measured in Ra, has been increasingly used as a parameter in implant topography. However, roughness is hard to reproduce and the results can be conflicting even for surfaces with similar roughness levels.[40,41]

Consequently, new avenues of scientific inquisition may enable the development of biomaterials that are safe, reliable, and 'smart,' perform ideally in their respective biological environments, and interact appropriately with the tissue type which they interface.

Furthermore, on a basic science level, the use of the recently developed field of nanotopography, in combination with new

biomaterials, will help us to overcome the need for defined media, with patterned surfaces/materials used as noninvasive tools to study cellular function.

4.409.2. Manufacturing Surface Topography

Here, we discuss various methods of nanoscale fabrication.

4.409.2.1. Photolithography

The microchip industry has traditionally used PL to fabricate micron-scale designs. In order to do this, a light-sensitive substrate (photoresist) is spread as a thin film onto silicon wafers. Light can then be directed onto the resist through a patterned mask, exposing the photosensitive layer in a precise pattern. The resist is then developed (analogous with photography), and the nonexposed or exposed area (depending on the resist used) can be removed, thus leaving a topography of resist around areas of exposed silicon. The resist is then baked to make it hard and the substrate is ready for etching.

Etching can be wet (chemical) or dry (reactive ion bombardment), both having the effect of simultaneously removing the hard resist and etching into the substrate. This leaves the samples resist-free and with a topographical pattern. In electronics, doping can take place to give electrical properties to the substrate. For biological purposes, it is desirable to stop after etching and grow cells on the patterned material. It is also possible at this stage to emboss, or cast, the pattern into a polymer suitable for cell growth, such as polycaprolactone or polymethylmethacrylate (PMMA).

While PL was used by many of the pioneers of cell response to microtopography,[16,42,43] its usefulness for producing nanotopography is limited. Thus, alternative fabrication techniques have been sought.

4.409.2.2. Laser Holography (LH)

Clark *et al.*[44] developed an interference technique used to produce ultrafine masks for X-ray printing. Samples coated in photoresist can be exposed to patterns produced in a two-mirror interferometer, producing a linear light pattern whose period is given by: period $= Ll/2\sin\Theta$ ($L = (l =$ light wavelength of light, and $\Theta =$ half angle of the recombination of the beams).

Development of the photoresist (as with PL) results in the formation of an etch mask. Dry etching can then be used to give depth to the pattern. Clark *et al.* successfully produced patterns with a 260-nm groove width and 100–400-nm depth and showed baby hamster kidney (BHK) fibroblast, Madin-Darby canine kidney (MDCK) epithelial, and primary neurite contact guidance.

This technique, however, is still limited in the variety of patterns that can be produced, the smallest size of the dimensions that can be made, and cost.

4.409.2.3. Electron-Beam Lithography

In order to achieve even better resolution, electron beams are now being used as a radiation source for photoresist development to expose the radiation-sensitive polymer resist. In electronics, the smaller the devices can be made, the more engineers can fit on a chip and the faster they can sell; this has led to Moore's law where the density of transistors on a chip has been seen to double every 1.9 years since the 1960s.[45] Thus, there is a massive push at present to develop nanochips. This calls for the use of precision nanofabrication. At present, EBL (e-beam) offers the best precision and resolution (down to 510 nm in *X*- and *Y*-axes, and <1nm in the *Z*-axis). For this technique, computer-aided design software is used to control electron deflection and exposure time onto a radiation-sensitive resist (thus rather than shining a 'block' of light through a mask exposing all areas to be patterned in parallel, the electrons are guided with great precision onto the resist directly, and the pattern written serially). The resist is then developed and etched to produce a topography, as with PL.

This use of EBL in biological applications has been limited due to distortion of the beam when deflected by more than 1 mm, limiting the size of the patterns produced. Recently, techniques using interferometric control have been developed to allow movement of the sample in the e-beam writer and thus stitching of the patterns into large areas (with a stitch accuracy of ~ 20 nm).[11]

E-beam is, however, expensive and time-consuming due to serial exposure to define the pattern, and the more complex the pattern, the more complex the programming, and the more time taken. It is interesting to note that researchers are now also able to produce biomimetic designs using e-beam, such as reproducing collagen banding.[46] However, fabricators are now becoming successful in producing much cheaper nanotopography over larger areas. Such techniques (including colloidal lithography) are potentially very useful to biologists due to their low costs.

4.409.2.4. Colloidal Lithography

This technique uses nanocolloids as an etch mask, and can be used to produce large areas of nanotopography with short-range order. The colloids are dispersed as a monolayer and electrostatically self-assembled on a surface (i.e., the intercolloidal spacing is altered by changing the charge on the particles). The colloids are then etched away, as is the surrounding substrate material, by directed reactive ion bombardment.[47,48] If the etch is directly from above, this technique produces nanocolumns; by altering the angle of etch, nanospheres and nanocones may also be produced.

4.409.2.5. Polymer Demixing

As well as top-down fabrication techniques, some bottom-up methodologies have also been trialled with cells. Polymer demixing relies on the spontaneous phase separation of polymer blends, and the demixing of island topographies allows the production of single chemistry substrates ideal for cell testing as the complexities of mixed surface chemistries can be ignored. The method also allows the production of islands with controlled heights from 10 to 100 nm depending on the polymer blend used.

The surface of a solid amorphous polymer, or polymer mixture, is expected to be smooth and featureless. However, under certain circumstances, marked topography can be

obtained from a spontaneous demixing of the components of a binary blend, that is, in thin films of certain polymer mixtures on selected substrates.

The factors that determine demixing have been extensively studied. Principally, the mutual compatibility of the polymers controls the behavior. The relationship between polymer compatibility and generation of topography in thin films of the blend is illustrated by examining a blend of poly(styrene) with a series of brominated polymers, poly(*p*-bromo$_x$-styrene), where x is the fraction of aromatic rings that are brominated, $1 \geq x \geq 0$. The compatibility of the brominated polymer with poly(styrene) depends on the extent of bromination.[49] When $x = 1$, the polymers are incompatible and the compatibility increases as $x \rightarrow 0$. A measure of the compatibility is the thickness of the interfacial boundary layer between a poly(styrene) film and a poly(*p*-bromo$_x$-styrene) overlayer. Neutron reflectivity data showed a monotonic correlation between the interfacial layer thickness and the extent of bromination of the bromopolymer.[50] Thin films of blends of the bromopolymer and poly(styrene) have smooth surfaces at low values of x. As x increases, topography appears, becoming more marked with increase in x, corresponding to the decreasing compatibility. We have used the fully brominated polymer, $x = 1$, in our studies of cell interactions.

The type of topography depends on the relative amounts of the polymer components of the blend.[49] In the poly(styrene)-poly(*p*-bromostyrene) system, islands of the brominated polymer protrude from a sea of the poly(styrene) when the weight fraction of the bromopolymer is less than $\sim 60\%$. At higher weight fractions, the bromopolymer islands link up to form a sheet with holes that expose the underlying poly(styrene). Similar changes in topography have been observed with other binary polymer mixtures.

The topography can be controlled further by changing the overall thickness of the polymer film. With spin-cast samples, this is readily accomplished by varying the concentration of the polymer blend solution and/or the spin speed. In general, increase in thickness of the cast films results in islands that are higher and wider. A concomitant change in the number density of the features is observed. More subtle control of the topography may be obtained by varying the molecular weights of the polymer components.[51]

From the point of view of producing materials to study cell interactions, it is desirable to reduce the experimental parameters by having the cells exposed to only one chemistry; the poly(styrene)–poly(*p*-bromostyrene) system produces a surface with patches of poly(styrene) and patches of poly(*p*-bromostyrene). In this case, the surface chemistry can be changed by annealing the films.[50] Heating the film to the glass transition temperature of the poly(styrene) causes the poly(styrene) to migrate over the surface, forming an overlayer, thus achieving topography with one chemistry at the surface. The topography is altered by this process, which typically causes the islands to grow in height and width. However, a minimum annealing gives a thin overlayer of poly(styrene) with little change in the topography.

Another polymer mixture, which gives an island topography similar to the above, is poly(styrene)–poly(*n*-butylmethacrylate) (PnBMA).[51] In this system, an overlayer is formed at room temperature. The cast film develops topography that is covered spontaneously by a thin overlayer of the acrylate.

The process of formation of the demixed polymer film is complex, involving the compatibility of the polymer components, their air–polymer and polymer–substrate surface tensions, polymer component molecular weight, solvent used, rate of solvent evaporation, etc. The film is generally also metastable and can change if the temperature is sufficient to allow movement of one, or both, polymer components. These factors have been considered in the papers of Affrossman[50,52] and references therein and the relevant paper for the PS–PnBMA system.[51]

More recently, developments in phase separation with block copolymer systems have allowed the fabrication of nanosurfaces with an order approaching the one achieved by EBL.[53]

4.409.3. History of Differentiated Cell Guidance by Nanostructures

In 1964, Curtis and Varde[54] showed that fibroblast cells orientated themselves in the direction of silica fibers with diameters between 10 and 30 μm. Since this period and over the last 40 years, research has continued to focus on the topographical effects of micron size features; however, more recently, work has begun to focus on the effect of nanotopographical features. This work is driven by the abundance of nanoscale features known to be present within the extracellular matrix (ECM), and to which a cell readily comes into contact within its native environment. Not only have a wide variety of cell types been studied, such as neurons, fibroblasts, smooth muscle cells, and osteoblasts but also a variety of topographic patterns. Nanotopography has also been shown to have an effect on several cellular aspects, including proliferation,[55] morphology, adhesion,[56] and gene expression,[30] which will be discussed further.

4.409.3.1. Grooves

Nanogrooves have been studied extensively in relation to feature size and cell type. Studies have shown that fibroblast, epithelial, endothelial, osteoblast, smooth muscle, and neural cells undergo topographic guidance and have an elongated morphology when cultured on nanogrooved substrates.[13,31,57–60] In relation to feature size, evidence shows that an increase in cell alignment along the groove is inversely proportional to groove width.[31,61] In a recent publication, grooved substrates were also used to identify RACK1, a stabilizer of focal adhesions (FAs), as a modulator of contact guidance.[62] Breast cancer cells that overexpress RACK1 were shown to have a decreased sensitivity to topographical guidance when cultured on nanogrooves. By knocking down RACK1 expression, the authors were able to observe recovery in topographical guidance response with regard to the nanogrooved substrates.

4.409.3.2. Pits

Nanopits of varying degrees of disorder were also shown to influence the morphology and adhesion of osteoblast cells. In a paper by Biggs *et al.*,[29] the authors found that not only did nanopit topographies show a contrast in cell morphology and

adhesion when compared to a flat control, but changes were also observed according to the geometry of the nanopits. It was shown that nanopits with an ordered geometry caused FA length and formation in contrast to nanopit substrates with a slight degree of disorder, which saw an increase in FA length and formation together with increased cell spreading. Similar results regarding adhesion were also obtained when using fibroblast cells.[56]

Lim *et al.*[63] also looked at the effect of varying the depth of nanopits on integrin-mediated FA formation and found that nanopits of < 29 nm increased cell adhesion, various integrin subunits, and phosphorylated focal adhesion kinase (FAK), a protein involved in signal transduction, when compared to a flat control.

4.409.3.3. Pillars

In contrast to low adhesion topographies, nanopillars have been shown to have the opposite effect on cell adhesion. In a study by Milner *et al.*, the effect of different pillar diameters was explored, and results showed that an increase in cell adhesion was observed with a decrease in feature size; however, a decrease in feature size also correlated with a decrease in proliferation. Conversely, nanopillars with larger feature sizes showed a decrease in the initial cell adhesion but with increased proliferation when compared to flat control.[55]

Again, in a second study that looked at nanopillar feature height on the proliferation and adhesion of fibroblasts,[64,65] the authors found that by varying the height of nanopillars over a range of 95 to 13 nm, the level of adhesion could be controlled, with nanopillars of the smallest height inducing the largest increase in cell adhesion and nanopillars of 95 nm having a negative effect on cell adhesion.

4.409.4. The History of Stem Cells and Nanotopography

Until recently, adult and embryonic stem (ES) cells were considered the two main types of stem cells; the former being derived from adult tissues are more accessible, but exhibit less pluripotency than embryonic stem cells. The main drawback of the latter, however, is that they are derived from embryos and therefore involve many ethical issues. The discovery of induced pluripotent stem cells in 2007, whereby a pluripotent stem cell can be produced following viral transfection of a terminally differentiated cell using four key genes, has the potential to address all these issues and provide both pluripotency and accessibility; however, even these stem cells are not void of ethical issues.[66]

In terms of the differentiation of stem cells in normal culture, this is usually induced by the addition of differentiation factors into the medium; for example, in the case of osteogenic differentiation, addition of dexamethasone, for adipogenic differentiation, insulin, and in the case of neural differentiation, retinoic acid. However, several studies over the last decade have shown that nanotopography alone can provide the means to induce differentiation without the need for defined media – an important factor when culturing cells which may ultimately be transplanted into patients.

4.409.4.1. Embryonic Stem Cells

The main drawback of studying ES cells and one possible reason behind the lack of research using ES cells in this field, besides ethical issues, is their requirement for a feeder layer of mouse embryonic fibroblasts (MEFs). In terms of studying the response of ES cells to nanotopography, this is especially significant as any nanotopographical pattern is likely to be masked by the presence of the feeder cell layer. This, however, may change with the recent development of cell culture techniques that no longer require a layer of feeder cells.[67]

Several studies, however, have looked at both differentiation[68,69] and retention of the self-renewal/proliferation capacities of ES cells.[70,71] A study by Gerecht *et al.*[72] investigated the effect of grooved substrates on the morphology and proliferation of ES cells. In line with other similar studies using terminally differentiated cells, changes in morphology and cytoskeletal organization, such as alignment and elongation, were observed in ES cells cultured on nanogrooves. In addition, ES cells cultured on nanogrooves were shown to have reduced proliferation rates when compared to ES cells cultured on flat controls.

In another study by MacFarlin *et al.*,[70] the authors studied the effect of culturing ES cells, which are prone to spontaneous differentiation in culture, on flat culture dishes with a feeder layer, and on grooved substrates in both the presence and absence of a feeder layer. Results of the study showed that when cultured on the grooved substrates with a feeder layer in contrast to a flat control with feeder layer, the rate of spontaneous ES differentiation was significantly reduced. In contrast to this, ES cells cultured on nanogrooves alone showed much higher levels of spontaneous differentiation when compared to a flat substrate with a feeder layer. These results indicate that in the context of a feeder layer, nanotopography can play a synergistic role in the promotion of ES cell self-renewal; however, the mechanism by which it is governed is still not fully understood.

Several studies have looked at the directed differentiation of ES cells into various cell types, including adipocytes[73] and neurons.[74] In the study by Chao *et al.*, the authors examined the neuronal differentiation of human embryonic stem (hES) cells in response to culture upon polymer-grafted carbon nanotubes (CNT). The authors showed that by grafting CNT with poly(acrylic acid) (PAA), a polymer more commonly known for its negative effect on neuronal differentiation, this effect can actually be reversed. The authors observed enhanced neuronal differentiation of the hES cells on PAA-grafted CNT, in comparison to both PAA alone, and poly-L-ornithine (PLO), a common polymer substrate for the neuronal differentiation of hES cells. In addition to enhanced differentiation, similar results were obtained regarding cell viability, with the PAA-grafted CNT results being comparable to those of PLO, in contrast to that of PAA alone.

This study highlights the importance of the context in which a polymer is used. In this case, by grafting a polymer onto a nanotopography such as CNT, its properties have been altered from being unfavorable for neuronal differentiation into a material that can provide an environment more suitable for both cell growth and differentiation of ES cells.

4.409.4.2. Skeletal Stem Cells

Skeletal stem cells (SSCs) have been an exciting target for tissue engineering since their discovery by Freidenstein in 1976,[75] not only because of their accessibility within the bone marrow, but also because they have been shown to differentiate into a variety of cells, including osteoblasts and adipocytes,[76] chondrocytes,[77] smooth muscle cells,[5,78] and neurons.[79]

The differentiation of SSCs into osteoblasts has been observed in two key studies. In the first study, the authors looked at SSC differentiation on a variety of nanopit topographies with varying degrees of order, ranging from a square geometry, near square or semi-disordered geometry and random.[80] Each nanotopography is embossed in PMMA to ensure similar surface chemistry. When cultured on these topographies, SSCs showed increased levels of bone cell markers as identified by immunofluorescence analysis only when grown on topographies with semi-ordered nanopits, in contrast to all other topographies studied. The authors further supported this data by carrying out quantitative PCR and microarray analysis, which identified high levels of genes associated with osteoblast development and comparable to the levels of a positive control.

In a similar study looking at the differentiation of SSCs into osteoblast cells, Oh *et al.*[81] developed a range of CNT topographies with diameters in the range of 30–100 nm. In this study, osteogenic differentiation was observed to occur in SSCs cultured on CNT with a 100-nm diameter. Interestingly, however, this topography was also observed to have the lowest level of cell adhesion. This is in contrast to observations of cell adhesion on the smallest, 30-nm diameter CNT to which a high level of adherent cells could be observed but with no osteogenic differentiation. In this study and other similar studies, these differences in cell adhesion and differentiation have been attributed to the ability of the cell to develop mature FAs, ultimately leading to changes in gene expression.[30]

Neuronal differentiation of SSCs, a process known as transdifferentiation, has been identified in several studies using differentiation factors.[82] Controversially, this has led to SSCs being considered by some as more pluripotent than once thought.

The following study by Yim *et al.*[79] provides an example of SSC differentiation into neurons using nanogrooved surfaces. Neuronal differentiation was observed in SSCs cultured on 350-nm grooves, as identified by the expression of MAP2 and β-tubulin III, in the absence of differentiation factors. This nanotopography alone was also shown to express higher levels of MAP2, as indicated by quantitative PCR, when compared to levels observed in cells cultured on flat controls in the presence of either 1 or 30 μM retinoic acid.

4.409.4.3. Neural Stem Cells

Neural stem cells have the ability to differentiate into three cell types. These include neurons and two nonneural cell types, astrocytes and oligodendrocytes, which act to protect and support neurons.

In two separate papers, neural stem cell differentiation into neurons using nanotopography has been investigated, using electrospinning to produce nanofibers. Yang *et al.*[83] investigated the effect of varying fiber dimensions from microscale to nanoscale and their orientation, that is, aligned or random on neural stem cell differentiation. The authors found that when comparing aligned microfibers and aligned nanofibers, the rates of differentiation were higher on the nanofibers. Consistent with this when comparing the random nanofibers and the random microfibers, differentiation rates were also found to be higher on the random nanofibers.

In a more recent but similar study by Christopherson *et al.*,[84] the authors also studied the effect that fiber diameter has on the differentiation of neural stem cells. In this case, they studied fiber diameters ranging between 283 ± 45, 749 ± 153, and 1452 ± 312 nm. In correlation with the study by Yang *et al.*, the authors of this paper also found that differentiation of the neural stem cells was supported on fiber diameters within the nanoscale range rather than microscale.

As suggested by the authors in Yang *et al.*, both papers indicate that it is the fiber diameter that plays a key role in directing the differentiation of neural stem cells rather than fiber orientation.

4.409.5. Low Adhesion Materials

It is fair to say that in biomaterials research, there has been a major drive to consider how to increase cellular adhesion and proliferation on materials surfaces; however, this is not always the effect desired. There are many applications where low adhesion is required, such as in stents, catheters, heart valves, and acetabulum, where cell migration and tissue formation are problematic. While it is at present difficult to see if topography can have roles where tribological issues are involved, it is possible to foresee that in areas such as catheters and valves topography could play a key role.

Topographies that produce low adhesion in fibroblasts and SSCs have already been patterned inside tubes using polymer demixing to form nanoislands.[85–87] The next step should be the production of the islands on the internal surface in the bulk of the tube polymer. This could perhaps be achieved by embossing the low adhesion shapes and then precision rolling – in a manner similar to that outlined by Seunarine and others.[88] Curved surfaces could be achieved using this method.

Nanoislands produced by polymer demixing are, in fact, tunable to low or high adhesion.[64] Very small islands (< 20 nm) promote adhesion in most cell types tested (endothelial,[21] fibroblastic,[24] and mesenchymal stem[89]). As the islands increase in size, they become less adhesive. Islands produced from a blend of poly(styrene)–poly(butylmethacrylate) were adhesive to fibroblasts at 10-nm in height, but almost completely nonadhesive at 50-nm in height.[90]

Topographies produced by colloidal lithography have shown a similar trend, with very small nanocolumns (11-nm high) producing increased osteoprogenitor response,[89] while larger nanocolumns (160-nm high) produced a significant (but far from complete) reduction in fibroblast adhesion.[91,92] Interesting work has also been done on topographies fabricated through the colloidal route. They first showed 100-nm high columns to reduce epithelial cell adhesion[93] and then went further to show, again in line with the polymer-demixed nanotopographies, that increasing column size decreased epithelial cell adhesion.[94] They then further showed that the 160-nm high nanocolumns imparted properties of low adhesion on osteoblasts.[95]

Using another fabrication method, that of interference lithography, a recent paper further supported these observations of size and adhesion. Choi and others fabricated sharp nanoposts (pointed columns) and nanogratings (very sharp grooves) of different heights. They used three size ranges (50–100, 200–300, and 500–600 nm high) and found decreased adhesion and spreading as size increased.[96]

Nanopits (depth) can also be important, for example, nanopits fabricated in a square array by EBL with diameters of ~100–150 nm and center–center spacing (pitch) in the range of 300 nm. Again, these adhesion effects have been shown to be size-dependent. A study that used three pit sizes (diameter (nm):pitch (nm) – 35:100, 75:200, and 120:300) and fibroblasts as a cell model, showed that as pit diameter increased, filopodial interaction increased, but cell spreading decreased, that is, the interaction of the filopodia with the pits prevented adhesion.[97] A previous study with pit diameters of 150 nm showed almost no epitenon attachment.[22] However, we know that large pits (in the range produced by PL) promote increased cellular response in, for example, SSCs.[98] Thus, there is a large gap in our knowledge of the transition between nonadhesive and adhesive pits.

This is further complicated by pit symmetry being implicated as important. This was originally mooted by Curtis and others in 2004.[99] Subsequent studies have used 120-nm diameter, 300-nm pitch pits in both square and hexagonal arrangement. Both with SSCs[100] and with fibroblasts,[97,101,102] the hexagonal arrangement has been shown to be the least adhesive.

4.409.6. Nanotopography as a Noninvasive Tool for Cell Biology

4.409.6.1. Responding to the Cellular Environment

Cells are responsive to intercellular cues, such as cadherin linkages, and to the constraints of their environmental niche, including its mechanical and chemical properties. The ECM, composed of proteins such as fibronectin and vitronectin, provides protein and mechanical signals for cell attachment,[15,103,104] survival,[15] and differentiation.[5] Nanofeatures can physically direct cells, by processes such as contact guidance[31,57] and direction of filopodia[97,105] (**Figure 1**). Cells interact directly with the protein layer on biomaterial surfaces, and the conformational state,[106] density, and arrangement of these adhesive proteins[15,103,104] and stiffness of the underlying substrate[5] have the potential to influence cell responses. As a result, the ECM is an important factor in cell–material interactions.

FAs are mechanosensitive, multipartite protein assemblies that are the sites of cellular anchorage to the ECM. Chemical signaling cascades can be initiated at these sites in response to a mechanical stimulus by resident and recruited kinases such as FAK and ROCK (Rho kinase), a process known as indirect mechanotransduction. A crucial component of FAs are the integrins, a family of heterodimeric proteins capable of bidirectional signaling. These proteins interact directly with specific amino acid sequences (such as the RGD motif) on their ligands in the ECM. Blocking a β_3 integrin was shown to decrease cytoskeletal nanoimprinting (**Figure 2**) (where the cytoskeleton adapts to the form of the nanofeatures), while the addition of anti-β_1 antibody was shown to enhance nanoimprinting to nanocolloidal substrates.[107] It has been proposed that distension of the plasma membrane may be involved in cellular detection of the topology of nanostructured substrates.[108] In this model, negative features (such as nanogrooves or nanopits) could promote opening of mechanosensitive ion channels, while release of the G-protein Rac may be stimulated by interaction with positive features (such as nanopillars).

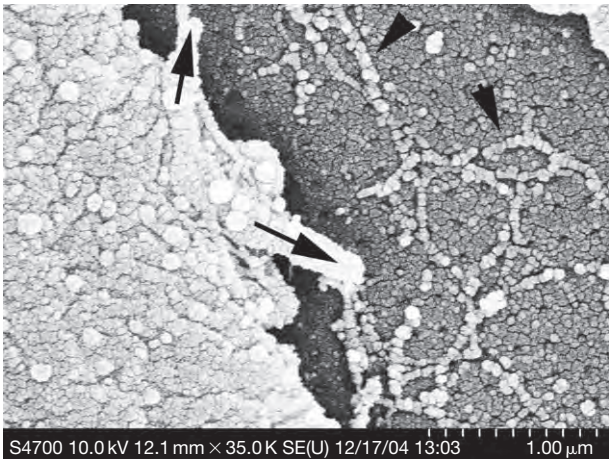

Figure 1 Filopodia and topography. Cells are far larger than nanoscale features – here, a mesenchymal stem cell can be seen cultured on 40-nm diameter pits (originally defined by electron-beam lithography and then imprinted into polymethylmethacrylate). The filopodia (arrows) are used in 'cell sensing' of the surface and are a much closer length scale to the nanofeatures. Note that the scanning electron microscopy image is overexposed to help see the topography and that the cell has produced fibrils of extracellular matrix (arrowheads) on the surface.

Physical tugging on FAs can induce growth of these structures[109] and expose cryptic binding sites. A recent study noted that conformational 'melting' of the FA protein talin allowed it to bind additional vinculin.[110] The cytoskeleton is physically attached to FAs via filamentous (F-)actin, which is partly responsible for the rapid relay of mechanical signals to the nucleus. Direct mechanotransduction involves pulling of the cytoskeleton on the nucleus to effect changes in downstream gene- and protein expression. Biggs *et al.* (2008)[31] noted that the pitch of nanogrooves (the authors examined 10-, 25-, or 100-µm groove spacings, all with a depth of 330 nm) was important for determining the degree of cytoskeletal alignment. The study found that only the 10-µm spacing pitch grooves could induce contact guidance of the cells and align FAs and microtubules along the nanogrooves. On the 25-µm pitch grooves, FAs were primarily localized to regions where the cells were bridging between adjacent grooves and ridges, and on the 100-µm-spaced grooves, the adhesions appeared similar in size, number, and orientation to the planar control, with an analogous cytoskeletal arrangement. Cytoskeletal disorganization can also occur in response to nanosubstrates such as hexagonally arrayed nanopits.[56,102] The tensegrity model[111,112] describes the components of the cytoskeleton in terms of their opposing forces. Actin provides the tensile

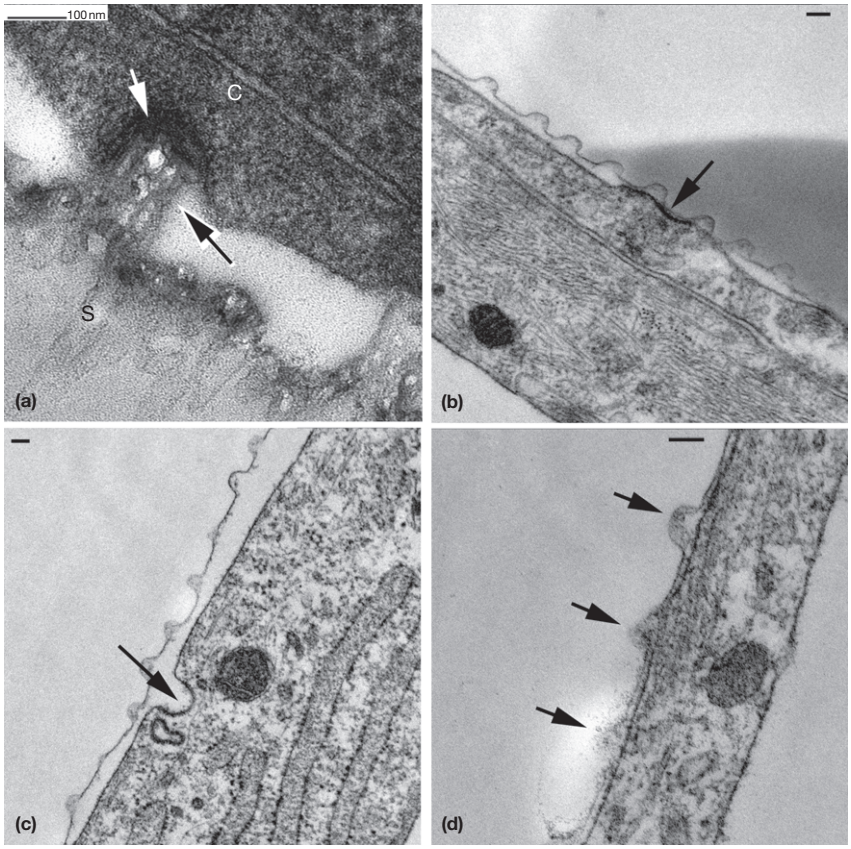

Figure 2 Nanoimprinting. (a) A fibroblast cell (C) is imprinted (white arrow) by a column (black arrow) defined by colloidal lithography in a polymethylmethacrylate (PMMA) substrate (S). Substrates fabricated by Dr Duncan Sutherland (iNano, Denmark). (b) A mesencymal stem cell on a NSQ50 substrate originally defined by electron-beam lithography (120-nm diameter pits with square arrangement (300-nm center–center spacing but with $\pm$50-nm error (highly osteogenic)) embossed into PMMA – arrow shows the start of the formation of a clathrin-coated pit in response to the surface. (c) Shows a more mature endocytosis pit forming (arrow). (d) Shows that nanoimprinting also occurs with the cells trying to fill the pits (arrows, quite rare). All scale bars are 100 nm.

element, with microtubules resisting compression and intermediate filaments generating prestress in the structure. Altered cytoskeletal tension in cells cultured on nanotopographies, most likely generated within the cell as a result of the altered arrangement of FAs, has the potential to alter cellular gene and protein expression through direct mechanotransduction.

4.409.6.2. Mechanotransduction in the Nucleus

Surrounding the nucleus is a meshwork of Type V intermediate filaments, the lamins, which are the major components of the nucleoskeleton, the mechanical bridge between the cytoskeleton and the nucleus. The nuclear lamina is physically associated with actin and vimentin via nesprins and SUN (Sad1 and *UNC*-84 homology domain) proteins[113] (discussed in Wang *et al.*[114]). Micromanipulation experiments have neatly illustrated that transmission of force can occur from the peripheral cytoplasm into the nucleus,[115] demonstrated the mechanical interconnection of chromosomes and nucleoli,[116] and shown the importance of the nuclear lamina in force transmission.[117,118] The structure of the nuclear lamina is shown in Figure 3(a). Compared to micromanipulation, nanotopography has additional advantages of being noninvasive and nondestructive, and can be used as a tool for the investigation of mechanotransduction and cell biology, with surfaces that can be modified to suit the requirements of the study.

Nuclear reshaping has been shown to induce alterations in gene expression.[119] Topography-induced redistribution of chromosomal territories (the space occupied by a given chromosome within the nucleus, reviewed in Cremer and Cremer[120]), or intraterritory loci (the location of particular genes) could affect the cellular transcriptional profile. There are foci of transcriptional activity within the nucleoplasm, where active, transcription-competent RNA polymerase II and transcription factors are clustered. Genes can loop out from chromosome territories to move into these areas, and such repositioning can increase the likelihood of their being transcribed[121,122] (discussed in West and Fraser[123]). Alternatively, movement of genes or territories toward the periphery of the nucleus could promote downregulated transcription. Wang *et al.*[114] suggested a number of models by which tensile forces from FAs could modulate gene expression.[114] It was proposed that the assembly or activity of transcription factor complexes could be affected directly or indirectly by tension-mediated alterations in the nucleoskeleton. In addition, local DNA melting at matrix attachment regions (MARs), where the DNA

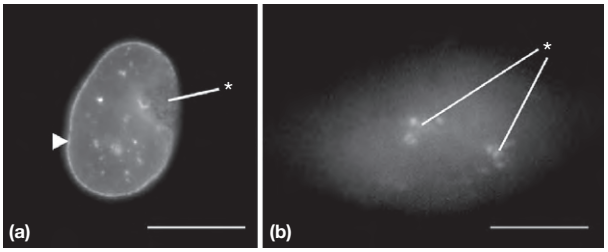

Figure 3 Nuclear lamina and chromosomes. (a) The nucleus has a protective 'skeleton' in the form of a peripheral lamina (arrowhead), which encloses the DNA and other subnuclear components, and can transmit mechanical forces from the cytoskeleton into the nucleus. This nucleus has been immunostained for lamin B, and part of the peripheral lamina is visible covering the nucleus at the focal plane examined (*). (b) Chromosomes can be repositioned in response to mechanical force, such as the cytoskeletal rearrangement induced by culture on topography. This is an example of a fluorescence *in situ* hybridization stained nucleus of a cell on a topographical substrate, stained for chromosome 1 (*). Bars = 10 μm.

is anchored to the lamina, could affect its accessibility for transcription. Furthermore, the authors suggested that gene expression or mRNA transport could also be affected by tension-mediated changes in nuclear pores. Reddy *et al.*[124] elegantly demonstrated that repositioning of a gene to the nuclear lamina could downregulate its transcription and lead to association with lamin B and nuclear envelope proteins.[124] The authors concluded that transcription was being reduced by physically blocking access to transcription factors and by facilitating the assembly of a repressive chromatin architecture.

Nanotopography provides a useful means to investigate mechanotransductive effects on the nucleus. Nanocolumn substrates were shown to induce repositioning of chromosome 3 (Ch 3)[125,126] relative to planar controls. The Ch 3 centromeres were more closely apposed in cells cultured on the nanocolumns, probably as a consequence of the decreased cell spreading and nuclear area. On hexagonally arrayed nanopits, the intercentromeric distance was reduced for both Ch 3 and Ch 11, and the cells were markedly less spread than controls.[126] As the authors noted, the changes were consistent with the tensegrity model. Tension on the cytoskeleton and nucleus should be reduced, which is likely to have lessened the force exerted on chromosomes. **Figure 3(b)** shows an example of Ch 1 territories on a topographical substrate, visualized by fluorescence *in situ* hybridization (FISH).

4.409.6.3. Transcriptomic and Proteomic Effects

To investigate the molecular basis for cell–topography interactions, transcriptomics and proteomics are valuable. These techniques are useful for the large-scale characterization of changes in mRNA and protein abundance between control and test substrata, and the identification of responsive molecules. The study of the transcriptome and the mRNA profile of the cell, using microarray analysis, has the major advantage that the transcript abundance of many thousands of genes can be studied simultaneously. There are additional levels of regulation following transcription, however, and proteomics has the benefit that it permits analysis of the functional effectors.

Culture of mesenchymal stem cells on nanogrooves appeared to stimulate differential expression of genes involved in MAPK (mitogen-activated protein kinase) signaling, which is implicated in key cell processes such as cell growth and differentiation. Interestingly, on 330-nm deep nanogrooved substrates, various transcripts involved in integrin and PDGF (platelet-derived growth factor) signaling were upregulated in cells cultured on 100-μm pitch nanogrooves, whereas transcripts corresponding to these pathways were downregulated in cells cultured on nanogrooved surfaces with a 10-μm pitch.[31] This suggests that there is a transcriptional effect downstream of the changes in size and orientation of FAs on these substrates, which is probably induced by both direct and indirect mechanotransductive pathways. Fibroblasts cultured on a low adhesion hexagonal array of 120-nm wide pits with a depth of 100 nm (spaced 300 nm from center to center) showed downregulation of integrin and fibroblast growth factor signaling. On this surface, including another low adhesion substrate with 10 nm nanocolumns, fibroblasts also showed downregulation of mRNAs encoding ECM proteins and proteins involved in the innate immune response.[102] In contrast, transcripts for signaling proteins were upregulated in fibroblasts cultured on polymer-demixed nanoislands.[27] These observations illustrate that different nanotopographies can induce distinct transcriptional responses as a result of the specific character of the mechanostimulus, which makes such substrates attractive as versatile tools for the study of cell biology.

Some pioneering studies have applied the proteomic technique DiGE (two-dimensional (2D)-fluorescence difference gel electrophoresis) to the study of cellular interactions with nanotopography. This 2D-gel based technique allows the detection of differential protein abundance between control and test states using fluorescent dyes and is discussed in further detail in the context of biomaterials research in Mcnamara *et al.*[127] The basic schema for this technique is shown in **Figure 4**.

On a surface with a partially disordered arrangement of nanopits, DiGE revealed that the cytoskeletal proteins, actin and vimentin, were upregulated in abundance relative to a planar control after 5 weeks of culture.[34] This may have enabled the cells to cope with the demands of cytoskeletal reorganization or altered their capabilities for direct mechanotransduction, which was supported by downregulation of the FA-associated protein zyxin. In addition, Golgi reassembly stacking protein 55 (GRASP55), which is involved in MAPK signaling, was downregulated in cells cultured on the nanopits. In combination with histological results and other differential protein changes, the authors concluded that this was consistent with the tendency toward differentiation rather than proliferation in cells cultured on the nanosurface.

DiGE was also used to examine the temporal response of osteoprogenitors to disordered nanotopography over 6 weeks of culture.[20] The authors noted osteoid nodule formation on the nanotopographical substrate 2 weeks before nodules appeared on the control surface and concluded that the topography had hastened the maturation of these cells. Unlike in the DiGE studies discussed earlier which only examined cellular proteins, in this investigation, an extraction regime that permitted harvest of both intracellular and ECM proteins was used. Compared with controls, vimentin and osteonectin

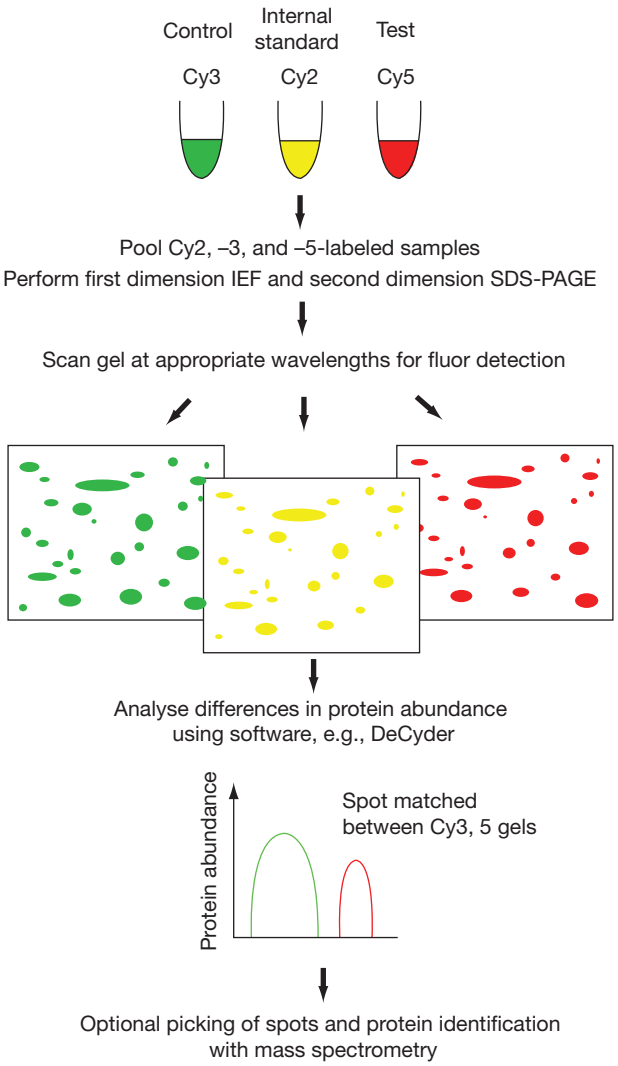

Figure 4 Basic workflow for two-dimensional-fluorescence difference gel electrophoresis, using a three-dye labeling approach (known as minimal labeling). Cy2, -3, and -5-labeled samples are co-resolved on a single gel. The Cy2-labeled samples are used in spot normalization and matching between gels, and differences in protein abundance are quantitated using software. If desired, a picklist can be generated for manual or robotic spot picking and analysis by mass spectrometry, to identify proteins of interest. A modification of this technique, called saturation labeling, is a higher sensitivity approach that is technically challenging but useful for the study of scarce samples such as those typically obtained from cells cultured on small surface areas of nanotopographical substrata. Adapted from Mcnamara, L. E.; Dalby, M. J.; Riehle, M. O.; Burchmore, R. *J. R. Soc. Interface* **2010**, *7*, S107–S118.

(an ECM protein specific to bone lineage cells) were upregulated in cells on the topography following 3 weeks of culture. These proteins are markers of differentiation in this cell type, and interestingly, the abundance of both proteins was not distinguishable from levels in the control cells at later time-points. The authors noted differential regulation of a number of proteins involved in MAPK–ERK (extracellular signal-regulated kinase) signaling, further implicating this pathway as an important regulator of the cellular response to nanotopography. Most of the differential protein regulation occurred before the sixth week (prior to osteoid mineralization), which the authors corroborated with a liquid chromatography-based technique, dimethyl labeling, at the week six time point. This showed minimal changes between the control and nanosurfaces.

4.409.7. Conclusions and Future Perspectives

Nanoscale surfaces will almost certainly find use in several areas of science.

4.409.7.1. Orthopedics

Nanotopography has the potential to improve osteointegration of orthopedic implants. Nanostructuring can be used to promote or discourage cell adhesion and provides the opportunity to generate surfaces that more closely approximate the natural cellular environment. This could be achieved by the introduction of controlled disorder, combinations of feature types and sizes, and tissue-specific architecture. Hardwearing nanostructures that resist denudation from the surface are desirable, such as nanoscale depressions (e.g., nanopits) that can be sunk into the substrate to direct cell behavior. Nanocoatings that can be applied to implant surfaces, such as by vapor deposition,[128] are also advantageous, particularly if these can be utilized to functionalize specific areas of the device with features tailored to induce certain desirable cell responses in that region.

4.409.7.2. Stem Cells and Regenerative Medicine

Topographically patterned substrates currently used in cell culture are more advantageous than the use of defined media in that they allow cell growth and development to be tailored to a specific application without the need to use potentially harmful chemicals within the body. Currently available successful applications of terminally differentiated cells include the generation of skin using keratinocytes and fibroblasts,[129] tissue-engineered airway,[130] and a whole bladder.[131]

Stem cells are a very important tool in tissue engineering. In combination with topography, these cells not only open up the potential to produce patient-specific tissues, reducing the risk for tissue/organ rejection, but through the understanding of material properties that elicit specific responses, they could also allow the formation of complex tissues in the future.

4.409.7.3. Nanotopography for Cell Biology

Nanotopography can provide a tunable stimulus for manipulating cell responses. The ability to produce a variety of feature types with definable size ranges for the noninvasive modulation of cellular architecture, gene expression, and behavior makes nanotopography a valuable tool for fundamental biological research and translational studies. Increasing our understanding of the cell and molecular biology underlying cell–substrate interactions has the potential to revolutionize future materials design for the rational direction of cell responses.

Glossary

Animal model A living animal used to evaluate biomaterials, medical devices, and drugs to be used to treat human diseases, for the purpose of better understanding of the materials and devices' safety, efficacy, and functionality without the added risk of causing harm to human beings during the process.

Bioburden Population of viable microorganisms on a raw material, components, a finished product, and/or a package.

Chemical sterilants Chemicals that are used to destroy all forms of microbiological life, including fungal and bacterial spores.

Disinfectant Substance that is applied to nonliving objects to destroy microorganisms that are living on the objects.

Disinfection A process that eliminates many or all pathogenic microorganisms on inanimate objects with the exception of the bacterial endospore.

Electron beam (e-beam) Continuous or pulsed stream of high-energy electrons.

Ethylene oxide An organic compound with the formula C_2H_4O. It is a colorless flammable gas with a faintly sweet odor. It is used as sterilant.

Extracellular matrix A complex network composed of fibrillar proteins (collagens) and gels of polysaccharide that provides structural support and anchorage for cells and regulates intercellular communication.

Gas plasma Ionized gas contains ions and electrons in about equal number.

In vitro A procedure performed *in vitro* (Latin: within the glass) is performed not in a living organism but in a controlled environment, such as in a test tube or cell culture dish.

In vivo *In vivo* (Latin for 'within the living') is experimentation using a whole, living organism such as animal testing and clinical trials.

Medical device An implant or instrument intended for use in the treatment or to affect the structure or function of the body.

Sterility assurance level A term used in microbiology to describe the probability of a single unit being nonsterile after it has been subjected to the sterilization process.

Sterilization An extreme physical and/or chemical process that effectively inactivates or kills all forms of life, especially microorganisms (e.g., fungi, bacteria, viruses, spore forms, etc.) from a surface, equipment, food or medication, biological culture medium, or medical devices.

4.410.1. Introduction

Biomaterials are commonly used to make medical devices or processed to make implants for clinical applications. The biomaterials covered in this chapter include synthetic materials and materials of biological origin that are used to replace or restore function to a body tissue or in contact with body fluid. As they enter sterile body tissues or the vascular system or have contact with blood or other sterile body fluids, they are considered to be critical items. They include orthopedic devices such as total knee and hip replacements, spinal implants, and bone fixation devices; cardiac implants such as artificial heart valves and pacemakers; soft-tissue implants such as acellular dermal matrix for abdominal wall repair and breast reconstruction, and injectable collagen for soft-tissue augmentation; and dental implants to repair teeth and bony tissue in the oral cavity. In general, they are required to be sterilized before use. If sterilization is not feasible, they should be properly disinfected.[1]

Sterilization is the complete elimination of all forms of microbial life, including highly resistant bacterial endospores. Sterilization of medical devices is accomplished by the use of physical or chemical processes that inactivate all forms of microbial life. The effectiveness of a sterilization process is measured by the probability of sterility for each product sterilized (the sterility assurance level or SAL). SAL describes the probability of a single product unit being nonsterile. The sterilization processes used by medical device manufacturers are typically designed to achieve an extremely low probability for any product unit being nonsterile – a chance of one in a million (i.e., a SAL of 10^{-6}), and at the same time to maintain the essential safety and function of the medical devices for intended applications.[2] For certain biological medical devices, FDA considers a SAL of 10^{-3} as an adequate sterility level because harsh sterilization processes may adversely affect the functionality of such biomedical devices (e.g., tissue-based biological meshes and engineered tissue products). Unfortunately, most of the sterilization methods are not suitable for use on biological materials. For example, heat and high doses of γ-irradiation (>30 kGy) used to reach a SAL of 10^{-6} are effective but they denature and weaken the collagen structure.[3]

Disinfection, on the other hand, is to eliminate the recognized pathogenic microorganisms with a chemical or physical procedure, but not necessarily to eliminate all microbial forms on medical devices. High-level disinfection with an FDA-cleared sterilant kills virtually all microorganisms, except bacterial spores. The use of some EPA-registered germicides may only achieve a low-level (some viruses and bacteria) or intermediate-level (mycobacteria, most viruses, and bacteria) disinfection.

In addition to SAL, there are other critical requirements on sterilization method used for a biomaterial or medical device. First, the sterilization should not cause any significant change in the material that would elicit an adverse response from the body. Next, the sterilization should not significantly alter physical and mechanical properties of the material that would compromise the implant's function.

This chapter reviews current sterilization methods used for biomaterials, selection of sterilization methods, and the effects of sterilization treatments on the properties of biomaterials of synthetic and biological origin. The emphasis is given to sterilization of implantable biomedical devices; however, information presented here is also applicable to surgical and diagnostic instruments (e.g., cardiac and urinary catheters). During the past two decades, there has been an increase in medical devices that are made of new biomaterials and require new sterilization methods. The chapter also reviews several novel, low-temperature sterilization systems. For standards and guidance documents for sterilization equipment, process control, and process validation, readers are referred to the ANSI/AAMI/ISO 11737[4,5] documents, which have been developed through a joint effort between academia, medical devices industry, and government regulatory agencies.

4.410.2. Sterilization Methods

Both physical and chemical mechanisms can be used to inactivate microbial life-forms. Physical methods include the use of heat, pressure, filtration, and ionizing radiation, while

chemical methods include the use of various gas and liquid sterilants (e.g., ethylene oxide (EO), gas plasma, phenol, glutaraldehyde, etc.). A brief description on the mode of action for different disinfection and sterilization methods is provided in this section, followed by more comprehensive discussions, in later sections, on their specific application for sterilization of different synthetic and biological materials.

4.410.2.1. Heat and Pressure

The dry-heat sterilization destroys microorganisms by destructive oxidation of cell components. To kill resistant spores by dry heat, it usually requires a temperature of about 160 °C for 2 h. Dry-heat sterilization is suitable for materials that are heat stable, such as metal implants that might be damaged by moist heat, or for those that are impenetrable to moist heat.

Moist heat in the form of saturated steam under pressure is the most wildly used method to sterilize solutions and surgical tools. It inactivates microorganisms by the irreversible coagulation and denaturation of enzymes and structural proteins. To kill resistant bacteria spores by moist heat, it generally requires 121 °C for 15–30 min. Moist heat is commonly used for sterilization of heat and moisture stable materials through which steam can penetrate, such as stainless steel implants and surgical tools. It is not suitable for biomaterials that are heat and moisture sensitive, such as degradable polymers and biological collagen matrix.

An autoclave is a device that uses high-pressure steam to sterilize. The parameters that affect efficacy of sterilization include steam, pressure, temperature, and time. The two common steam sterilizing temperatures are 121 and 132 °C. At constant temperatures, sterilization times vary depending on the type of items as well as the sterilizer type.

4.410.2.2. Ionization Irradiation

Ionizing radiation includes electromagnetic waves (e.g., short wavelength ultraviolet (UV) ray, X-ray, γ-ray), and subatomic particles (e.g., α particle, β particle, neutron) that carry enough energy to ionize atoms or molecules. UV ray, X-ray, γ-ray, and high-energy electron radiation are used for disinfection and sterilization of biomaterials and medical devices.

UV irradiation is used to control airborne microorganisms and surface decontamination for the environment of biomaterial production and processing. An example is the partial contamination control in biological safety cabinets by UV sources with a forced air flow/filtration system. The short wavelength UV light (~254 nm) disrupts the structure of nucleic acids through the formation of thymine dimers and therefore destroys the reproductive capabilities of microorganisms. However, UV radiation alone is not considered to be an effective disinfection or sterilization method because of its poor penetrating power, long treatment time, and the susceptibility to air movement.[1,6] In addition, UV radiation damages many types of plastics. UV radiation may be incorporated as a part of the overall strategy for bioburden control and sterilization during a manufacturing process.

γ-Radiation has been used as a low-temperature sterilization method for over a half-century. γ-Rays are high-energy photons emitted by a ^{60}Co source and have no mass or charge. The wavelengths of γ-rays are less than 10^{-10} m, with frequencies greater than 10^{18} Hz and energies at the 100-keV level. γ-Radiation has far greater penetration power than electron beam (e-beam) (Figure 1). It is a safe, cost-effective sterilization for a wide range of medical products (e.g., tissues for transplantation, pharmaceuticals, medical devices, disposable medical equipments). γ-Radiation kills microorganisms by attacking the DNA molecule through both direct and indirect mechanisms. γ-Sterilization does not leave any chemical residues, and does not impart radioactivity.

X-ray technology for sterilizing medical devices has already been in commercial use for 15 years. X-rays, emitted by electrons, are high-frequency, short-wavelength electromagnetic photons with a very broad energy spectrum. X-rays and γ-radiation differ because of their origins and their energy spectra overlap. X-rays produced by linear accelerators can reach the megavoltage energy level and have higher energy than γ-rays produced by radioactive γ-decay. The maximum photon energy is the same as the kinetic energy of the incident electrons that are used to generate X-rays. Unlike γ-radiation, X-rays are concentrated in the direction of the incident e-beam, and their angular dispersion decreases as the electron energy increases. The high intensity in the forward direction enhances the efficiency of X-ray utilization. The penetration of high-energy X-rays allows one to process large packages and pallet loads of medical devices with very good dose uniformity. The fast process, excellent dose uniformity, and better penetration than γ-rays or e-beam make the X-ray technology an alternative sterilization method for medical devices.

E-beam sterilization uses high-energy e-beam from accelerators to irradiate biomaterials or biomedical devices in their final packages. Unlike photons, fast electrons have both mass and charge. Thus, the range of penetration of high-energy electrons is limited and depends on their energy, the atomic number of the absorbing product, and its density. E-beam inactivates microorganisms by the same mechanisms as γ-radiation does. One of the advantages for e-beam radiation is that its high-energy power can sterilize in seconds instead

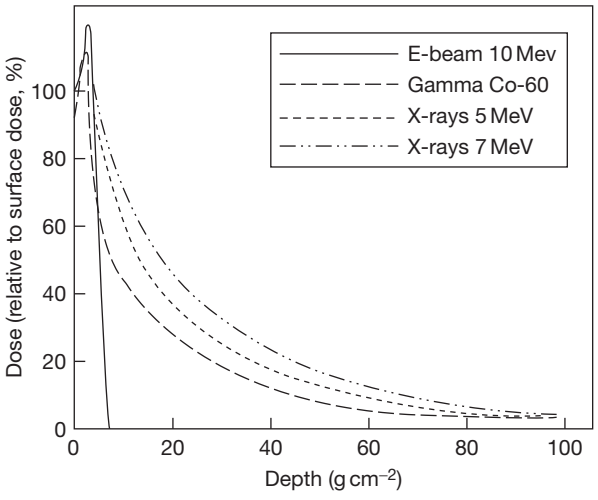

Figure 1 Dose and penetration depth profiles of e-beam, γ-, and X-rays. Note that the penetration depth is a function of both distance and material density. Adapted from Dethier, P.; Bol, J. L.; Mullier, B. *European Medical Device Technology* **2010**, *1*(2) (http://www.emdt.co.uk/article/x-ray-sterilisation-technology-future).

of hours or days compared with other methods. It was shown that bacterial spores show greater sensitivity to e-beam than γ-irradiation.[7] For many polymeric biomaterials, the short exposure time to radiation treatment results in significantly less material degradation than with γ-irradiation. The limitation of e-beam, when compared to γ- or X-rays, is its poor penetration in depth (Figure 1), especially for high-density biomaterials because of the electron's rest mass ($9\,e^{-28}$ g). Depth penetration by e-beam is primarily dependent on kinetic energy. The majority of disposable light density medical products are compatible with e-beam sterilization treatments. E-beam technology has now become a strong competitor to the more traditional γ-irradiation process.[8]

While the primary event of interaction with matter differs among X-rays, γ-irradiation, and electron irradiation, the main interactions with matter are similar, with minor differences. Ionization events under irradiation are initiated by secondary electrons, which then activate chemical reactions and free-radicals-mediated oxidative degradation. The effects of irradiation types on biomaterials are affected by dose rate, exposure time, and penetration depth. γ-Irradiators typically deliver dose rates from between 2 and 10 kGy per hour, whereas electron accelerators can deliver dose rates thousand times higher. The huge dose rate disparity leads to great differences in irradiation exposure times and thermal effects that could alter reaction pathways. A substantial difference in degradation effects between γ-irradiation and e-beam also reflects much higher penetration of γ-irradiation through the polymeric materials.[9]

4.410.2.3. Chemical Sterilant

4.410.2.3.1. Ethylene oxide

EO is bactericidal, sporicidal, and virucidal, and has been widely used as a low-temperature sterilant since the 1950s. EO is a colorless gas that is flammable and explosive.

EO's microbiocidal activity is a result of alkylation of proteins, DNA, and RNA in microorganisms, which prevents normal cellular metabolism and replication and thus renders affected microbes nonviable.[10–12] EO's high reactivity in combination with high diffusivity plays a major role in the inactivation of microorganisms.

In EO sterilization process, the major factors that affect the lethality of sterilization include EO concentration, temperature, humidity, and exposure time.[12,13] The bioburden reduction increases with the increase of EO concentration, exposure time, and temperature. Humidity is another critical variable in EO sterilization. In the range of 30–90% humidity, the humidity does not have significant impact on lethality, and sterilization efficacy decreases markedly below 30% and above 90%. The commonly used operational ranges for EO concentration, temperature, humidity, and exposure time are 450–1200 mg l^{-1}, 29–65 °C, 45–85%, and 2–5 h, respectively.[12]

Besides the major parameters mentioned above, other variables, such as product bioburden, device/package properties, load density, and configuration, should also be considered. In addition, the raw material composition, material diffusion properties, sensitivity to both negative and positive pressure changes, and maximum allowed heat and moisture as well as chemical tolerance to EO should be analyzed to determine if the EO is a suitable sterilization method for the material.

The potential hazards of EO to people and the environment, such as mutagenicity potential and risks associated with handling a flammable gas, have limited its use.[14–16] However, if the recommended practices are followed and current Occupational Safety and Health Administration EO regulations are met, EO can be used safely.

In addition to EO toxicity concerns at work place, it should be noted that EO and EO derived residues in sterilized products also encounter toxicity issues. EO and its derivatives, such as ethylene chlorohydrin, formed in the presence of chloride ions, and ethylene glycol, formed by reaction of EO with water, are toxic residues. The allowable EO residual and its derivatives by categorization of products are specified by International Organization for Standardization.[17] Removal of EO and its derivatives from the EO-sterilized biomaterials to the acceptable level is essential to ensure the safety of the medical device, and the removal process sometimes becomes a challenge.

Despite EO's toxicity and safety concerns, for some sensitive materials, EO is the only acceptable sterilization method.[18] In contrast to irradiations and heat sterilizations that have deleterious effects on biological materials and polymers,[19] EO is compatible with a wide range of materials, and its penetration properties make EO sterilization the most suitable process for the majority of heat- and/or moisture-sensitive medical products.[20]

4.410.2.3.2. Sterilant solutions

In addition to EO, a few other sterilants have also been used for sterilization. They include formaldehyde, hydrogen peroxide (HP), and peracetic acid (PAA)-based systems, as well as other oxidizing agents used in liquid and gaseous processes.

PAA is a strong oxidizing agent, and its oxidation potential is greater than that of chlorine or chlorine dioxide. PAA has bactericidal, fungicidal, virucidal, and sporicidal properties, and has been widely used in medical disinfection processes.[21–24] System 1E (Steris Corp, Mentor, OH) is a liquid chemical sterilant processing system that uses PAA to sterilize heat-sensitive devices such as endoscopes and their accessories.

PAA is a clear and colorless liquid and has a strong pungent acetic acid odor. It is commonly produced by the reaction of acetic acid with HP [I] and therefore PAA solution contains HP (up to 25%) and acetic acid (up to 35%).

$$CH_3-\overset{\overset{O}{\|}}{C}-OH + H_2O_2 \rightarrow CH_3\overset{\overset{O}{\|}}{C}-O-OH + H_2O \qquad [I]$$

PAA oxidizes the outer cell membrane of vegetative bacterial cells, endospores, yeast, and mold spores. A rapid penetration of PAA into microorganisms and the release of oxygen and free radicals critical for the oxidation and destruction of microbial enzymes are likely linked to PAA sterilization efficacy.[24] PAA–methanol mixture could effectively inactivate viruses in bone and porcine intestine.[22,23] It also works synergistically with HP in microorganism inactivation.[25] The efficacy of the PAA sterilization is affected by its ability to access the locations that need to be sterilized, for example, diffusion throughout the matrix or access into the center of the narrow lumen.

PAA's strong oxidation property is critical to its sterilization efficacy. However, this property may also reduce the biological, chemical, and structural integrity of biological materials,

for example, collagen matrix, as oxidation of proteins often renders them inactive, eliminating their bioactive properties.[26] PAA is unstable and readily degrades into acetic acid, oxygen, and water, which helps to alleviate concerns about its residual toxicity.

Similar to PAA, HP also inactivates microorganisms (bacteria, yeasts, fungi, viruses, and spores) through oxidization. It can be converted into highly reactive hydroxyl radicals (OH), which attack membrane lipids, DNA, and other essential cell components to inactivate bacteria. HP is more effective as a sporicide than as a bactericide.[21]

HP appears colorless in dilute solution, and is one of the most powerful oxidizers known. HP is naturally present in milk and honey to preserve them from spoilage. It is also the chemical that the phagocytes use to kill the bacteria that enter the bloodstream. It can be readily decomposed to water and oxygen spontaneously or by enzymes known as peroxidases possessed by living beings.

Formaldehyde is used as a biocide in liquid or gaseous form for sterilization. Because it is toxic, mutagenic, and carcinogenic, its use is limited.

4.410.2.4. New Methods

4.410.2.4.1. Supercritical carbon dioxide

Dense carbon dioxide was firstly found to have the bactericidal effect in the 1950s.[27] The supercritical state is a unique physical state that is reached at a specific temperature and pressure combination defined as the 'critical point' (**Figure 2**). Supercritical carbon dioxide (SC-CO_2) exhibits properties of both the gaseous and liquid physical states. It has the viscosity of a liquid and the transport efficiency of a gas which allow for efficient delivery with high penetration properties. The unique properties of SC-CO_2 make it an appealing medium for sterilization. Its high diffusion characteristics allow for deep penetration into materials. In addition, it is nontoxic and can easily be removed by depressurization and outgassing.

The effectiveness of SC-CO_2 on microorganisms is related to various treatment parameters, which include temperature, pressure, treatment time, and the use of additives.[28–30]

SC-CO_2 can inactivate a variety of microorganisms,[31] but SC-CO_2 alone is not enough to achieve an industrial level of sterilization (SAL 10^{-6}) of some microbes, including bacterial endospores and viruses.[30,31] To enhance the inactivation of microbes, sterilants that contain PAA are commonly used. As described in the previous section, PAA has bactericidal, fungicidal, virucidal, and sporicidal properties and has therefore been used in medical disinfection processes.[23,24,32] When SC-CO_2 is used with additives such as PAA, it can inactivate 6 $\log_{10}$ of bacterial endospores on spore strips.[30,33]

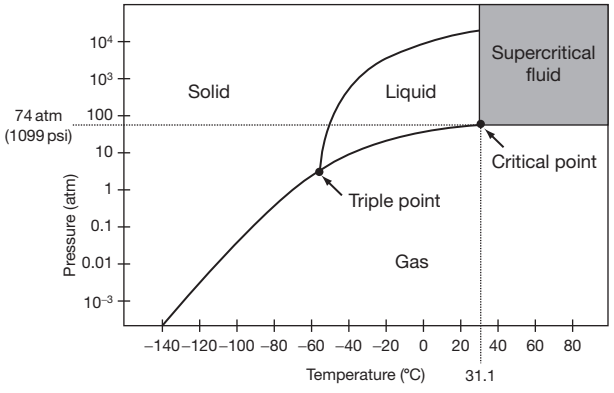

Figure 2 Phase diagram of CO_2.

SC-CO_2 treatment is compatible with many biological materials, including bone and acellular dermal matrix, and it leaves no toxic residues in the treated materials.[34,35] It has been shown that the SC-CO_2–PAA sterilization caused little change in the biochemical and biomechanical properties of acellular dermal matrix.[35]

Nova2200 is an equipment that uses SC-CO_2 with or without sterilant to sterilize heat-, moisture-, and irradiation-sensitive biomaterials. During the Nova2200 process, the CO_2 is pumped into the chamber and the pressure and temperature are modulated until the critical point is surpassed yielding the supercritical state within the chamber. This is the presterilization step. The pressure and temperature are then held constant ($P = 1346$ psi, $T = 35\,^{\circ}C$) within the supercritical phase requirements. The sterilization time is then initiated and the required exposure time is executed (t_{sc}). Following the completion of sterilization exposure phase, the chamber pressure is reversed to allow retrieval of the sterile samples. The complete process of achieving the supercritical phase and its reversal is represented by the total process time (t_{total}).

The sterilant component of the NovaSterilis system consists of a solution containing PAA and H_2O_2. At the onset of the sterilization process, the sterilant is placed into the SC-CO_2 chamber.

The linearity of bioburden reduction as a function of time and the D_{10}-value for the Nova2200 process are determined using the most resistant microorganism, *Bacillus atrophaeus* spores, for this sterilization process.

Tissue samples inoculated with 8 logs of *B. atrophaeus* spores are packaged in the final package configuration. The Nova2200 is run under constant pressure and temperature for increasing supercritical exposure times. The tissue samples are extracted and enumerated to determine the remaining logs of the reporter organism. **Figure 3** displays the results of a validation study using Nova2200.

These validation data demonstrate that the Nova2200 produces a linear sterilization profile over time. The outcome of this data set yields D_{10} values for the Nova2200 sterilization process. On the basis of the ISO 14160 guidance document the following formula is applied to determine the required dose (i.e., supercritical exposure time) to achieve an SAL $= 10^{-6}$ for the Nova2200 process.

$$\text{Exposure time for the sterilization} = D_{10} \times [6 + \log(100 + \text{bioburden})]$$

4.410.2.4.2. Gas plasma (ionized gas)

The low-temperature plasma method is considered to be a promising method for some biomedical materials that are not compatible with heat and chemicals.[36–38] The advantages of the gas plasma method are shorter process cycle and suitability for more complex medical instruments (especially those containing hollow parts for minimal intrusive procedures).

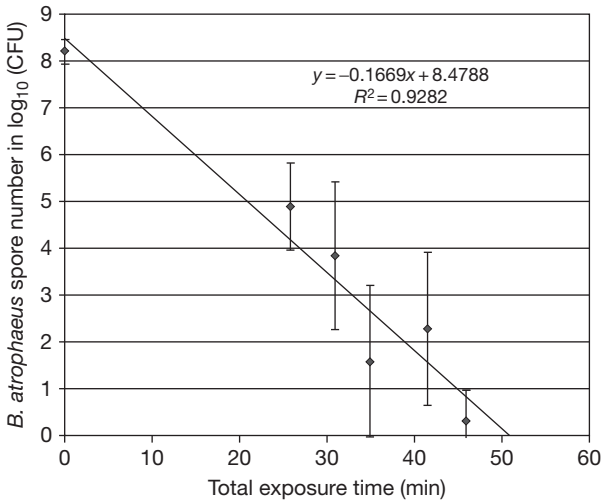

Figure 3 *Bacillus atrophaeus* spore colony forming unit (CFU) reduction by SC-CO_2–PAA as a function of total treatment time. Adapted from Qiu, Q. Q.; Leamy, P.; Brittingham, J.; Pomerleau, J.; Kabaria, N.; Connor, J. *J. Biomed. Mater. Res. B Appl. Biomater.* **2009**, *91*(2), 572–578.

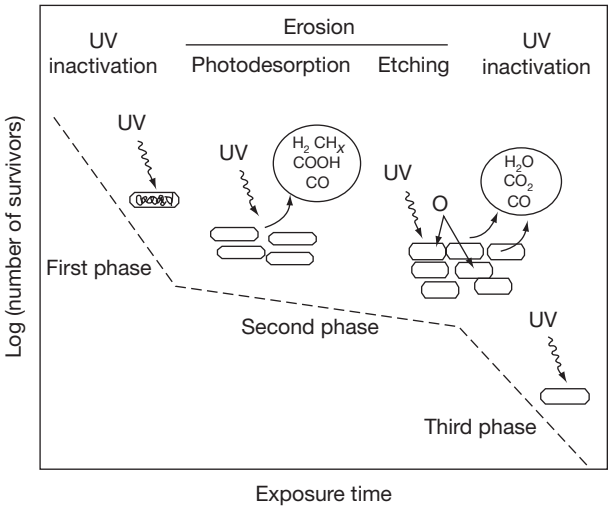

Figure 4 Schematic illustration of killing mechanisms during three phases of gas plasma sterilization. Adapted from Moisan, M.; Barbeau, J.; Crevier, M. C.; Pelletier, J.; Philip, N.; Saoudi, B. *Pure Appl. Chem.* **2002**, *74*(3), 349–358, with permission from IUPAC.

It addresses the issues of prions (the Creutzfeldt–Jakob diseases) and biofilms.

Gas plasmas are generated by exciting gas molecules with radio frequency or microwave to produce charged particles (free radicals). Gas plasma process uses mechanisms combining the action of UV irradiation generated from excited molecules and that of oxygen free radicals (**Figure 4**). UV irradiation causes lesions of DNA strands of microorganisms. Intrinsic photodesorption resulting from UV photons breaks chemical bonds of the other microorganism materials to produce volatile by-products (e.g., CO and CH_x). Reactive species within a plasma field (atomic and molecular radicals or excited molecules in a metastable state) undergo chemical reactions with cell components to initiate spontaneous etching and thereby disrupt the structure and metabolism of microorganisms, yielding the final oxidation products such as CO_2 and H_2O.[37,38]

The type of seed gas is an important variable affecting the effectiveness of the plasma sterilization process. FDA cleared the use of HP plasma sterilizers in the United States. Another gas plasma system uses PAA–acetic acid–HP vapor. The HP gas plasma system typically operates at 37–44 °C and has a cycle time of 50–75 min. The instruments, devices, and materials are placed in a sterilization chamber. Upon evacuation (<10 torr), HP solution is injected into the sterilization chamber where HP is vaporized to diffuse through the entire chamber, exposing all surfaces of the materials to the sterilant. The electrical field that is applied to the chamber creates gas plasma, initiating the inactivation of microorganisms by the combined use of HP gas and the generation of hydroxyl and hydroperoxyl free radicals. The end by-products of the cycle are oxygen and water vapor, and sterilized materials do not contain any toxic residue. The process is able to inactivate a broad range of microorganisms, including resistant bacterial spores. Materials and devices that cannot tolerate high temperatures and humidity, such as some plastics, electrical devices, and corrosion-susceptible metal alloys, can be sterilized by HP gas plasma. This method has been compatible with most medical devices and materials tested (>95%).[39,40] Certain materials (e.g., cellulose products, cotton, certain packaging materials), however, are not compatible with HP plasma units. Cellulosic materials absorb the sterilant, often leading to incomplete sterilization of the device.

The effects of low-temperature gas plasma on some biomaterials of biological origin such as collagens are not well understood. Critical process variables, for example, killing efficacy and mechanisms of action, remain to be investigated further for various plasma species. The weak penetrating power of plasma species severely limits plasma effectiveness in the presence of organic residues and packaging materials. Complex geometries of some biomedical devices may present another challenge to plasma sterilization.[36] Low-temperature HP gas plasma sterilization was found to be unsuitable for sensitive biological materials.[41] The osteoinductive capability of human demineralized bone matrix (DBM) with gas plasma sterilization was evaluated in a rat model. DBM pellets were implanted in soft-tissue pockets at the epaxial musculature. Histological evaluation of explanted materials after 9 weeks of implantation showed that all sites implanted with aseptically harvested DBM contained new bone elements (new bone, cartilage, or bone marrow elements). Gas plasma sterilized DBM sites contained no new bone elements (similar to the steam-sterilized negative controls), suggesting that the osteoinductive ability of DBM was destroyed by low-temperature gas plasma. In another study, exposure of potentially wet ophthalmologic surgical instruments with small bores and brass components to plasma gas led to degradation of the brass to copper and zinc.[42,43]

The STERRAD plasma sterilization system (Advanced Sterilization Products, Irvine, CA) uses a discovered synergism between HP and low-temperature gas plasma for rapid inactivation of microorganisms and the removal of harmful residues.

4.410.2.4.3. Other

A number of other methods have been studied in recent years. They include the use of ozone, chlorine dioxide, high-intensity

visible light, and ultrasonic waves. The effectiveness of these methods and their compatibility with biomaterials of diverse chemistry remain to be evaluated.

4.410.2.5. Selection Criteria of Sterilization Method for Biomaterials

Each sterilization method has its own advantages and limitations, and may have adverse effects on certain types of medical devices and biomaterials being sterilized (Table 1). Before discussing the selection of a suitable sterilization method for a particular medical device or biomaterial, we need to consider several general factors that affect the efficacy of sterilization. The first factor is the natural bioburden of biomaterials and devices. The higher the natural bioburden level is, the stricter the sterilization requirement is. Although contaminating microflora consist primarily of vegetative bacteria, spores are more resistant to sterilization and therefore are the FDA-required test organisms. The second factor is the access by the sterilant. The sterilant (gas or liquid) must come into direct contact with microorganisms during the sterilization process. The presence of biofilms on the biomaterial and device designs that limit the contact will reduce the efficacy of sterilization by impairing exposure of the sterilant to the microbial cells. The third factor is the type of biomaterials used for construction of medical devices. Biomaterials must be compatible with sterilization processes. Certain components, such as salt and organic residues, may compromise the efficacy of sterilization. The last, but not the least important, is the intended use of the biomedical devices or biomaterials. The sterilization process should not alter material properties and stability that are critical to material function.

Despite the extensive research, the selection of an appropriate sterilization method is still an art to some extent. Sterilization of collagen-based medical devices is an excellent example. Collagen gels, foams, tubes, sponges, and extracellular tissue matrices (e.g., demineralized bone, decellularized dermis, and other acellular soft-tissue matrices) are marketed for a wide range of medical applications, such as soft-tissue fillers, wound dressings, conduits of damaged nerves and blood vessels, replacement of heart valves, dura repairs, abdominal wall reconstruction, and breast augmentation. Sterilization methods used for the manufacturing of these collagen-based biomedical devices include glutaraldehyde vapor cross-linking, EO, PAA, e-beam, and γ-irradiation. The selection of one method over others typically represents the optimization for the overall manufacturing process, cost, and performance of the intended clinical applications.

4.410.2.6. Sterilization Validation

The purpose of microbiologic sterilization validation is to assess the microbiologic lethality of a sterilization, while ensuring residue levels in compliance with the requirements.[17] The validation of EO sterilization processes, which will be used as an example in this section, is outlined in ISO 11135.[44]

There are three microbiologic approaches in decreasing order of utilization: (1) overkill method; (2) combined biologic indicator–bioburden method; and (3) bioburden method (Table 2).

The first step is to identify the natural bioburden of the product undergoing sterilization. The second step is to identify which of the native bioburdens has the most resistance to the sterilization process. For EO sterilization, *B. atrophaeus* spores were identified as the most resistant organism and therefore, it is used as the model organism for the sterilization validation. For different sterilization methods, the model organism may be different. For example, for HP plasma process and PAA immersion process the model organism is *B. stearothermophilus*.[45]

The 'overkill method' determines cycle lethality from the half-cycle method, which demonstrates a 6-log reduction in population of biological indicator microorganisms in the half cycle. Using the same process parameters, except exposure time, full sterilization cycle achieves at least a 12-log reduction by doubling the half-cycle time. Because of its simplicity and the robust SAL, it is the most popular approach.

The 'combined biologic indicator/bioburden method' requires a low population of the product bioburden and the microorganism's resistance to be known, as well as a high level of confidence that the bioburden data are representative of

Table 1 Comparison of sterilization technologies

Technology	*Advantage*	*Disadvantage*
Heat/steam (autoclave)	Nontoxic, inexpensive, rapidly microbiocidal, rapid cycle time, good penetration	Deleterious for heat- and/or moisture-sensitive materials
Ethylene oxide (EO)	Compatible with most biomaterials, low-temperature setting for heat- and moisture-sensitive materials, good penetration	Potential hazards to staff and patients; lengthy cycle/aeration time; EO is toxic, a probable carcinogen and flammable
γ-Irradiation	Nontoxic, good penetration	Deleterious to polymers and biological materials
E-beam	Nontoxic, rapid cycle time	Deleterious to polymers and biological materials; penetration distance is limited
Supercritical CO_2	Good for moisture- and heat-sensitive materials, little or no damage on materials	Limited chamber size; sterilant residue in materials
Peracetic acid/ hydrogen peroxide (Steris System I)	No activation required; odor or irritation not significant	Materials compatibility concerns, both cosmetic and functional; limited clinical use, used for immersible instruments/materials only; point-of-use system, no long-term sterile storage
HP or PAA gas plasma (Sterrad 100)	No toxic residues; low temperature setting suitable for heat- and moisture-sensitive materials	Not suitable for cellulose (paper), linens, and liquids; not suitable for devices with lumens

Table 2 The differences among ISO methods of establishing sterilization radiation dose for medical products

Terms	*ISO 11137-Method 1*	*ISO 11137-Method 2*	*ISO 13409*
Rationale	Based on bioburden level of the product	Based on the γ-resistance of microorganism population present in the product	An adaptation of ISO11137-Method 1 to substantiate 25 kGy dose
Scope	Normal manufacturing processes	Normal manufacturing processes / Consistent and very low bioburden	Product with bioburden less than 1000 cfu, manufactured less than 1000 units per batch
Sample requirements	Bioburden estimation: 10 Verification dose experiment: 100	Incremental dose experiment: 180 (2A), 160 (2B) Verification dose experiment: 100	Bioburden estimation: 10 Verification dose experiment: 10–90
Verification dose establishment	Estimated bioburden and Table B1 (p. 20 – ISO 11137) used to determine verification dose	Incremental dose series irradiated to samples (20 samples per dose). Then the initial verification dose (D*) chosen among the incremental doses satisfying required conditions	Verification dose $= I + [S \times \log$(average SIP bioburden) where I, S can be found in **Table 3** (p. 6 – ISO 13409)
Verification dose experiment	The verification is accepted if the numbers of positive cultures are $\leq$2/100 performed cultures	The verification dose can be calculated, if the numbers of positive cultures are $\leq$15/100 cultures, by applying formula: D** = DD*kGy + [log(CD*)](DS)kGy, where DD* is actual dose in the experiment; CD* is number of positive sterility tests; DS is the estimated dose required to inactivate 90% of organisms surviving at D** dose	If sample size 10–20: the verification exempted if no more than one positive culture observed If sample size $\geq$ 30: the verification exempted if no more than two positive cultures observed
Dose establishment	Found in Table B1 by matching between the average bioburden and desired SAL	Using formula: sterilization dose = D** + [− log(SAL) − log (SIP) − 2](DS)	If the experiment passed then the dose of 25 kGy is substantiated
Advantages	Following the perception that dose-setting work would be based on the natural presence of microorganism in and on products[116,117,172]		Can be applied for products manufactured in small numbers (less than 1000 product units) and low bioburden levels (less than 1000 cfu)
Disadvantages	Required number of samples was too large compared with bone (tissue) bank production, where the number of product units per batch may be only one, and number of batches is several tens		The radiation sterilization dose could not be reduced less than 25 kGy, if the average bioburden of the grafts is significantly decreased

'worst case' conditions. It requires a validated bioburden recovery method and identification of the microorganisms that are typically found in or on the routine products.[46,47]

The 'bioburden method' is based on inactivation of the microbial population in its natural state.

Besides the half-cycle method, there are two other commonly used methods for calculating cycle lethality: the survivor curve and the fraction-negative method. The survivor curve is the bioburden counts as a function of exposure time with other parameters remaining constant. It should include at least five points. From the curve, the D_{10}-value can be obtained and the EO exposure time required to achieve a specific level of sterility can be determined from the D_{10}-value.[44,48,49] The fraction-negative method is based on the analysis of growth/no growth data from the sterility tests.[44,46,48] The exposure time required to achieve a specified sterility level is calculated from the D-value.

4.410.3. Sterilization of Biomaterials of Synthetic and Biological Origin

Biomaterials can be divided into four categories: metals, polymers, ceramics, and materials of biological origin. A composite is formed when two or more different types of materials are combined. The biomaterials in these four categories are briefly reviewed and the sterilization methods used for these materials are discussed in the following sections.

4.410.3.1. Synthetic Biomaterials

4.410.3.1.1. Metals

Because of their excellent mechanical properties, metals are widely used for load-bearing implants in orthopedic surgery (e.g., joint prostheses for hips and knees), as well as in maxillofacial, cardiovascular, and dental surgeries. Among the

metals used for medical devices, the most commonly employed are stainless steels, titanium and titanium alloys, and cobalt alloys.

For metallic implants, their surface characteristics such as the chemical composition, roughness, and surface energy are important parameters associated with their biocompatibility during the implant–body interactions. Sterilization treatments modify the surfaces of metallic medical devices and therefore, it is critical to select appropriate sterilization method for medical devices that contains metallic component(s).

Metallic devices are commonly sterilized using dry heat, steam autoclaving, γ-irradiation, and EO. E-beam can be used for metallic devices of small sizes only because of its limited penetration distance.

The metals are covered by an oxide layer which can be altered by the sterilization process. The changes in a metal's surface characteristics will modify its corrosion behavior and biocompatibility. Among various sterilization methods, including dry heat, steam autoclaving, EO, PAA, and plasma-based sterilizations, plasma-based sterilization appeared to have less effect on the oxide layer thickness, roughness, and morphology than other methods.[50] A study revealed that steam sterilization affects the oxide film properties of stainless steel, and the oxide film deteriorates as the number of cycles increases.[51] Dry heat, steam autoclave, and EO treatment lead to discoloration on NiTi alloy and titanium surfaces, which have been shown to represent areas of increased thickness of oxide layers or a deposited contaminant.[50,52] The steam autoclave and PAA treatments also cause premature corrosion which leads to cracks and pits on NiTi alloy surfaces. The deterioration of the oxide film and damage of the implant integrity may lead to heavy metal release to the surrounding tissues.

Cell attachment assays showed some correlations between surface change of NiTi alloy from sterilization and cellular responses.[52,53] On EO-sterilized surfaces that showed occasional bluish discoloration and a microscopic particulate contaminant, murine fibroblasts showed modest decreases in cell attachment levels. The autoclaved surfaces that had greatest discoloration and heaviest particulate contamination exhibited a lower level of cell attachment, and the cell spreading was diminished compared with the EO-treated group.

4.410.3.1.2. Polymers

The polymers used as biomaterials include polyvinylchloride (PVC), polyethylene (PE), polypropylene (PP), polymethyl methacrylate (PMMA), polystyrene (PS) and its copolymers, polyesters, polyamides (Nylons), fluorocarbon polymers, rubbers, polyurethanes, polyacetal, polysulfone, polycarbonate, and biodegradable polymers.[54] With a wide range of mechanical, thermal, chemical, and physical properties and ease of manufacturability, synthetic polymers have been used in a wide range of applications including cardiovascular, soft tissue, dental, and orthopedic surgeries.[55] In addition, degradable polymers are used in drug-delivery systems.

As polymers have a wide range of thermal and chemical stabilities and different levels of sensitivity to moisture, heat, and irradiation, the sterilization method selected for a specific polymer should be based on its compatibility with the treatment method.

Steam and dry-heat sterilization use high temperature and high steam pressure. They are not suitable for polymers that have low melting temperature (e.g., PE and PMMA) and are sensitive to moisture (e.g., PVC, polyacetals, PE, polyamides, and PLA). The polymers that can be sterilized by these methods are PTFE and silicone rubber.

EO and chemical sterilization use low temperature and thus are suitable for temperature-sensitive polymers. Because they either use moisture (EO) or the sterilization takes place in solution (chemical sterilization), they are not suitable for moisture-sensitive polymers.

Radiation sterilization can deteriorate polymers as the irradiation causes scission and cross-linking in polymer chains, which lead to brittleness, discoloration, cracking, and degradation of polymer. Their physical properties may continue to deteriorate over time after sterilization.

For example, γ-irradiation, one of the most common sterilization methods used for polymers, has been found to cause degradation of ultra-high-molecular-weight PE (UHMWPE), which led to loosening of the implant, pitting and delamination of the polymer, and the formation of debris particles.[55,56] The sterilization of UHMWPE with γ-irradiation results in a loss in fracture roughness of 50% and a decrease in tearing modulus of 30%.[57] This dramatic reduction could result in a 50% decrease in the residual strength of the components, and maximum permissible crack size under service loading and service life. The time required for a crack to grow from its original size to the maximum permissible size could be decreased by 30%, resulting in earlier failure. However, it was also reported that the sterilization of hydroxyapatite-reinforced PE composites by γ-irradiation at a dose of 25 kGy produced a cross-link structure in the PE matrix in the composite, and this network resulted in the increase in modulus, thereby increasing the creep resistance.[58]

It is well known that γ-radiation generates free radicals which can in turn lead to cross-linking and chain scission of a polymer. The dominance of one of these mechanisms over the other is highly dependent upon the sterilization environment. For example, chain scission is the dominant mechanism when the sterilization of UHMWPE is performed in air, while cross-linking appears to be the principal mechanism when the material is irradiated in nitrogen.[59] The chain scission mechanism is a time-dependent process and is especially important to the structural integrity of the polymer, and could be detrimental to the integrity and performance of the polymer as the material continually evolves with time.[60] Scission is further complicated by the uptake of oxygen. Oxygen is extremely reactive with the free radicals produced by irradiation. Peroxy radicals form, which in turn can break down and lead to further radical production so that the total number of free radicals generated and total extent of chain scission are greatly increased. The dominant response to γ-irradiation appears to be chain scission.

Another commonly used sterilization method for polymers is EO. EO is suitable for polymers that are resistant to moisture and temperature, and not appropriate for moisture- and heat-sensitive polymers. Studies have revealed that EO residue levels and effects are highly dependent on the type of polymer material used.[61] Thus, the effect of EO residues must be evaluated for each type of material or device.

For heat- and moisture-sensitive polymers, HP gas plasma is a sterilization method that may be suitable. Unlike EO sterilization, the materials sterilized by low-temperature HP gas plasma do not need to be outgassed prior to use. The plasma process has been found to induce near-surface cross-linking which improves the polymer's resistance to abrasion and mechanical damage.[62] The low-temperature HP gas plasma process does not alter the bulk properties and in this respect the sample is equivalent to the nonsterile (control) in terms of its structure and fatigue resistance. However, the plasma treatment results in a modified surface which renders it more resistant to abrasive wear than the nonsterile case.

4.410.3.1.3. Ceramics/bioactive glasses

Because of their relative inertness to body fluid, high compressive strength, and esthetically pleasing appearance, bioceramics have been used as restorative materials in dentistry (e.g., crowns, cements, and dentures), as bioactive coatings, and as the ball in the articulating region of a hip joint. On the basis of their ability to maintain chemical, physical, and mechanical properties while in the host, they can be classified as nonabsorbable (inert), bioactive, and biodegradable or resorbable.[63] Inert bioceramics are very stable and can resist corrosion, and are therefore used as structural-support implants. They include alumina, zirconia, silicone nitrides, and carbons and are used in bone plates, bone screws, and femoral heads. They can also be used as drug-delivery devices. Bioactive ceramics include bioactive glasses and hydroxyapatites (HA), and resorbable ceramics include calcium phosphates and calcium aluminates. Biodegradable bioceramics are used as drug-delivery devices, and for bone repair, and regeneration. They also find applications in spinal fusion, and maxillofacial and dental surgeries. Upon implantation in the host, bioactive ceramics and glasses have a series of reactions at the material and host body fluid interface which lead to strong bonding with adjacent tissue.[64–66] They are used in the repair of dental and periodontal defects, small bone defects, and replacement of middle ear ossicles, and as bone plates and screws.[67–71]

In general, ceramics/bioactive glasses are compatible with γ-irradiation and e-beam irradiation. Steam and EO sterilization are compatible with ceramics that are not sensitive to moisture.

The essential requirement for an artificial material to bond to living bone is believed to be the formation of a biologically active apatite-like layer on its surfaces in the body.[72] Bioactive ceramic and glass materials such as bioglass, HA, glass–ceramic A-W, diopside, and pseudowollastonite (psW) are generally known to have the ability to form bone like apatite in the body environment. It was reported that steam autoclaving, HP plasma, EO, and γ-irradiation have no significant effect on psW-coating structure and surface morphology.[73] However, the HA-like layer formed after soaking in the simulated body fluid (SBF) was much thinner on the surface of the samples sterilized with EO, indicating that EO sterilization might affect the bioactivity of the ceramic. It was believed that the residual ethylene gas might have affected the nucleation and crystal growth of HA-like layer.

4.410.3.2. Materials of Biological Origin

Biomaterials that are from biological origin include allografts and biological material derivatives. Allografts are used widely in the surgical practices of sports medicine and orthopedic surgeries including anterior cruciate ligament (ACL) reconstruction,[74,75] meniscal transplantation,[76] and osteoarticular reconstruction.[77,78] The major factors that play a critical role for allograft to be successful in clinical application include sterility, reduction of antigenicity, and preservation of the natural biological and biomechanical properties.

Allografts eliminate the disadvantage associated with autografts, including the perioperative pain and morbidity associated with harvesting the graft, uncertain quality of the graft material, and limited graft shapes and sizes. However, one major drawback to using allograft is the potential risk of disease transmission and infection. To eliminate these potential risks, donor screening, aseptic processing, and storage are important steps.[79] Although allografts are recovered and processed aseptically with use of in-process bactericidal and virucidal steps via physical cleaning and chemical treatments, they do not entirely remove all risk of bacterial and viral contamination. Therefore, following tissue processing, terminal sterilization is used to reach assurance of sterility required for medical devices.

γ- and e-beam irradiations are the most commonly used methods for allograft sterilization. There are important differences of these two sterilization methods. With two-sided irradiation, the acceptable depth-dose distribution is 30 and 8 cm of water for γ- and e-beam irradiation, respectively.[80] For soft-tissue grafts such as skin, pericardium, or tendons that have low thickness and density close to that of water, both sterilization methods provide sufficient penetration depth and thus are appropriate to be used for these tissue grafts. However, for grafts with high density ($>2\,g\,cm^{-3}$), for example, bone, the acceptable thickness of a graft exposed to γ-irradiation is about 10–15 cm and only 3 cm for e-beam.[80] The limited penetration of fast electrons in comparison with γ-rays makes it less favorable, and sometimes an inappropriate method, for bone graft sterilization.

In general, it is believed that there is a dose-dependent effect of irradiation on biological matrix in either hard or soft tissues, and high doses of irradiation adversely affect graft integrity and efficacy. The effect of sterilization on the graft's mechanical and biological properties and their clinical performances are associated with graft type, sterilization parameters (e.g., dose, temperature), preservation condition, bioburden level, etc.

EO was one of the first methods used to sterilize allografts such as soft tissues and bone.[19] As the chemical residues left in allografts by EO sterilization could lead to graft failure and the agent is carcinogenic,[81–83] currently only a few tissue banks use EO for sterilization of allografts.

A major difficulty in developing an effective sterilization method for the materials of biological origin comes from its complex chemistry–structure–function relationship. Multiple functional elements are integrated into molecular complexes that in turn are assembled into higher level structures. It is conceivable that modifications, either chemical or physical, will alter the biological properties. In the following sections, allografts and biological materials in different categories are briefly described, and the sterilization methods used for these materials are reviewed.

4.410.3.2.1. Soft tissues

Soft tissues such as acellular dermal matrix grafts have been increasingly used in tissue repair and regeneration in recent

years, including replacement and solidus or repair of diseased or damaged skin, heart valve, blood vessel, tendon, ligament, abdominal wall reconstruction, and breast augmentation and reconstruction.[84–91] These tissue materials contain structural proteins with proper extracellular architecture and biomechanical properties, and may include signaling proteins that can direct phenotypic expression of in-migrating host cells to repopulate. Upon sterilization, extensive biochemical and structural modifications could decrease the tissue's regenerative capability to be integrated into the patient's own tissues via remodeling.

The commonly used sterilization method for soft tissues is ionizing irradiation. To achieve an SAL of 10^{-6}, a dosage between 10 and 35 kGy is needed for γ, e-beam, or X-ray irradiation for solid matrices, processed tissue extracellular matrices (ECMs) (insoluble collagen of dermis and small intestine submucosa) for cellular tissue grafts (heart valve, skin, meniscus, and tendon). It is well known that ionizing irradiation produced major structural damage at a dosage above 10 kGy.[92,93] Damage to collagen by γ-irradiation included cross-linking and molecular fragmentation or degradation via peptide chain scission,[94–97] which could not only result in the significant modification of mechanical properties[3,98–107] and collagen matrix microstructures,[108–111] but also affect biocompatibility,[110,112–115] and the stability against enzyme degradation and thermal denaturation profiles.[92,100,104,109,110,115]

Nevertheless, successful use of γ-irradiated human soft tissues in patients has been well documented,[116–118] even though there is little basic information available on whether and/or how γ-irradiation alters cell repopulation and tissue matrix remodeling. This is a significant knowledge gap in our understanding about the effect of ionizing radiation on soft-tissue materials (also generally true for all collagen-based medical devices). It is noted that substantial knowledge related to preprocessing before irradiation and the use of radioprotectants against radiation damage does exist, but is kept as the corporate trade secrets from public disclosure. In recent years, a number of tissue matrix products have been approved by FDA, and they are sterilized successfully using γ or e-beam irradiation. These products include Permacol biological implant (Covidien, CT), Strattice reconstructive tissue matrix (LifeCell Corporation, NJ), Veritas collagen matrix (Synovis Surgical, MN), and Xenmatrix surgical graft (Davol Inc., RI).

EO sterilization could cause some damage to the dermal structure, but when combined with mild glycerol treatment beforehand there was very little damage.[93,119] GLY-ETO sterilization gave a dermal matrix with good morphology, pliability, and tensile strength. However, because of its safety concerns related to its reaction products, particularly ethylene chlorohydrins, its use on soft tissues in hydrous state is limited. However, it may be used for freeze-dried or lyophilized soft tissues. For example, the processed skin or small intestinal submucosa (SIS) that are frozen and lyophilized or freeze-dried to produce a dry sheet can be packaged into gas permeable pouches and sterilized with EO gas or irradiation.

It was reported that acellular dermal matrix can be sterilized by SC-CO_2. Biochemical and biomechanical evaluations showed that the SC-CO_2 treatment with PAA sterilant did not cause significant changes in porcine acellular matrix's susceptibility to collagenase digestion, tensile or tear strength, indicating limited alteration of the tissue structure following SC-CO_2 sterilization.[35]

When acellular dermal matrix was sterilized with PAA, it retained the integrity of dermal structure and major components of the basement membrane, and it supported the reconstitution with keratinocytes and fibroblasts.[120]

Glycerol treatment is not a recognized method of sterilization and has issues of clinical acceptability although it has been shown to inactivate viruses, bacteria, and fungi.[93,121–123]

4.410.3.2.2. Hard/dense tissues

When hard/dense tissue allografts are implanted, they need to mimic the mechanical properties of the replaced tissues for a certain time period until the graft incorporates with and be remodeled into host tissue. Therefore, it is critical that they meet the mechanical and biological requirements of the replaced tissues. γ-Irradiation is an effective method for terminal sterilization of biological tissues because of its efficacy against viral and bacterial disease transmission. However, γ-irradiation has deleterious effects on mechanical and biological properties of hard and soft tissues in a dose-dependent manner, especially at high does range (>25 kGy).[105,124–128]

As bone allografts have a large variety in sizes and some are rather large pieces, γ-irradiation is commonly used because it does not have a size limitation on bone graft like e-beam irradiation. γ-Irradiation affects bone mechanical properties, remodeling, osteoinduction, and osteoconduction, and dose-dependent, deleterious effects of conventional γ-irradiation on the biomechanical properties of tissues are well documented.[3,80,124,126,128,129] In general, γ-irradiation adversely affects bone allografts biomechanical properties including maximum load, maximum stress, bending strength, strain energy, and modulus, which are major clinical concerns as bone grafts are used in load-bearing applications. However, it was also found that in a low dose range (<25 kGy), there is no clear correlation between γ dose and mechanical properties, especially when bone allografts are irradiated at low temperature (e.g., on dry ice).[130]

Other dense tissues, such as human bone-patellar tendon-bone (BPTB) allografts, also exhibited a similar dose-dependent manner on biomechanical properties.[3,99,131] It was found that even at a dose of 25 kGy or below, there was a significant reduction in biomechanical properties of human BPTB, and an increase of failure rate of the ACL construction in comparison to nonirradiated allograft. The effect becomes more significant with the increase of the dose.

In addition to dose, the effects of irradiation are also related to other factors, such as bone types, hydration, and preservation solution used. It is believed that cancellous bone is more resistant to γ-irradiation than cortical bone.[124,132] The dose-dependent reduction in mechanical properties positively correlates with the grafts biological performance. The nonunion rate increased with the increase of irradiation dose of the bone allografts with rate increasing from 0 to 12.5 and 33% as the γ-dose increased from 0 to 25 and 75 kGy.[133] Bone induction was eliminated when allografts were irradiated at the doses from 20 to 40 kGy.[134] Moreover, irradiated collagen was much more soluble and the implants were almost resorbed without new bone formation.[134] It was also discovered that degradation of collagen by irradiation of 25 kGy led to a

significant reduction in bone formation when it was implanted with BMP.[135]

The mechanisms of γ-irradiation damage of bone tissues are not clear, but there is evidence showing that the damage is induced by free radical attack on the collagen. It is believed that the collagen phase is more vulnerable to γ-irradiation than the mineral phase of cortical bone tissue,[136] and the integrity of bone's collagen significantly affects the mechanical strength and fracture resistance of bone tissue.[137]

The effects of γ-irradiation on peptide backbone of collagens of bone and tendons have been investigated. It was shown that γ-irradiation led to scission of the peptide backbone,[92] and reduced the concentration of intermolecular cross-links in tendon collagen.[138] Similar destruction of the peptide backbone[92] and reduction in intermolecular cross-link density[139] have also been reported for human femoral cortical bone secondary to γ-irradiation.

The mechanisms of tissue damage by γ-irradiation are different for tissues in dry and wet state.[80,140] In dry state, the irradiation and the free radicals generated in the matrix during the irradiation cause scissions in polypeptide of collagen matrix. The free radicals irradiation may also establish cross-linking of matrix but the extent is limited because of the movement constraint of polypeptide and free radicals in dry state. In wet state, γ-rays and free radicals generated in irradiation also cause scissions in collagen matrix as in dry state. But the cross-linking reaction of collagen matrix could be more significant than in dry state. The free radicals generated in protein matrix and water could cross-link the polypeptides which have less motion constraint. Thus, the scissions and cross-linking occur concurrently during the irradiation and the reaction may cascade even after the irradiation. The structural changes, for example, scissions and cross-linking, alter the mechanical and biochemical properties of collagen matrix, resulting in changes in strength and toughness, and bone defect healing.

In contrast to bone graft, DBM appeared not to be significantly affected by γ-irradiation in terms of its osteoinductivity and higher dose even increased this property.[141–143] As DBM has characteristics that are unique and different from those of bone grafts, the effect on DBM will be reviewed and discussed in a separate section.

The scissions caused by direct irradiations cannot be avoided. However, if the secondary chemistry, for example, generation of free radicals and reactive oxygen species, that occurs during irradiation is minimized, the damaging effects to the tissue could be substantially reduced.[140,144] When treated with a radioprotectant solution, cancellous bone dowels show an ultimate compressive strength and modulus of elasticity equal to irradiated (18 kGy) and nonirradiated control bone grafts.[144] The free radical scavenging solution also alleviates the biomechanical impairment of γ-irradiated femurs.[140]

Similar to bone treated with radioprotectant solution, other dense tissues, for example, tendon, that were treated with a radioprotectant solution (containing propylene glycol, dimethyl sulfoxide, mannitol, and trehalose) and then treated with 50 kGy γ-irradiation at low temperature showed comparable biomechanical properties to the nonirradiated and 18 kGy groups.[145]

4.410.3.2.3. Demineralized bone matrix

DBM is composed of structural proteins, mainly type I collagen, and signaling proteins that regulate cell migration, proliferation, and differentiation. Upon implantation, it can be integrated into host tissue through resorption and remodeling.

Since the discovery of the bone inductive property of DBM,[146] DBM has been used to induce bone formation in various clinical applications, including long bone defects, craniofacial defects, joint surgery, tumor surgery, and spinal fusion.[147–154]

Unlike bone grafts that have to maintain a certain level of mechanical strength for clinical applications, DBM products generally do not have requirements on their mechanical strength. Instead, the osteoinductive potential of DBM is critical for its application. DBM is made through a number of processing steps such as demineralization with acid solution, lip and lipoprotein removal, lyophilization, and sterilization. A variety of combinations of acid, HP, and alcohol have been used by tissue banks for bioburden and viral inactivation.[141] Some of the processing steps have potential effects on osteoinduction.

One of the greatest challenges for DBM products sterilization is to keep their osteoinductivity while ensuring their sterility. Osteoinductivity could be affected by various factors including sterilization method, temperature, moisture level, and storage.

EO has been used for DBM sterilization. The osteoinductive properties of demineralized bone have been shown to be retained following sterilization with EO.[155] As EO requires elevated levels of temperature and humidity to maintain its effectiveness as a sterilization agent, it might affect osteoinductivity depending on the temperature and moisture level used as heat and moisture significantly affect the osteoinductivity of DBM.[156–158] When DBM was in hydrous state, it lost its osteoinductivity more easily than in anhydrous state.[159,160]

Despite the fact that irradiation causes polymer oxidation, chain scission, and the release of free radicals, the effect of irradiation on DBM osteoinductivity has mixed results. Some studies showed γ-irradiation of higher dose increased DBM osteoinductivity.[141–143] Urist reported that processed demineralized bone retained 80% of its activity when irradiated to 40 kGy.[161] Hydration and temperature also play a role in radiation effect on osteoinductivity. For example, 35 or 50 kGy at ambient temperature was shown to inactivate lyophilized decalcified rat bone but had no effect on hydrated material maintained at $-72\,^{\circ}C$.[162] It was reported that the osteoinductivity of hydrated DBM subjected to e-beam irradiation is diminished after 12-month ambient storage, whereas the anhydrous DBM retains its osteoinductivity potential.[159]

Autoclaved demineralized bone produced a foreign body reaction in test animals without any sign of osteoinduction.[163] It was found that 70% alcohol does not destroy osteoinductivity.[141] However, 70% alcohol is not considered as a sterilant for terminal sterilization. Osteoinductivity could also be lost by prolonged exposure to acid, base, acidic alcohol, fixatives, as well as UV radiation and ultrasonic energy. It was reported that exposure to 3%HP abolishes DBM osteoinductive capacity.[164]

Research on methods for terminal sterilization continues to identify effective methods of sterilization that do not inactivate DBM.

Currently, there is no best way to sterilize allograft tissues, and combinations of different sterilization methods are commonly employed to achieve a desired sterility level. For example, Allowash formula (LifeNet, Virginia Beach, VA) uses irradiation (10–13 kGy) in combination with reagents such as detergents, antibiotics, alcohols, and HP to inactivate microorganisms.[165] The BioCleanse tissue sterilization process (Regeneration Technologies, Alachua, FL) uses a low-temperature chemical sterilization process with liquid sterilant and then irradiates the tissue (25 kGy).

The biomaterials reviewed in this chapter, their applications, and the sterilization methods used are summarized in Table 3.

4.410.4. Evaluation of Effect of Sterilization on Biomaterials

Sterilization will alter a biomaterial's properties and thus may affect its clinical performance. *In vitro* and *in vivo* tests are often used to evaluate the impact of sterilization on the safety, efficacy, and functionalities of biomaterials and medical devices. For example, the Instron is used to measure the change of biomechanical strength; X-ray photoelectron spectroscopy (XPS) for chemical analysis of surfaces; atomic force microscopy (AFM) for surface topography analysis; the small animal models (e.g., mouse and rat) are used for biocompatibility, cell repopulation, and revascularization; etc.

4.410.4.1. Selection of Analytical Methods

A quick survey of research literature reveals a large number of analytical methods that have been used to assess the effect of sterilization on biomedical devices or biomaterials. Considering the number of biomaterial types, the number of intended applications, and different sterilization methods, one would not be surprised by the large number of analytical methods used. Instead of reviewing what analytical methods can be used to investigate the sterilization impact for a given biomaterial type, we prefer to discuss here a general framework that may help to establish the correlation between *in vitro* test results and *in vivo* performance expectations.

Among the challenges for evaluation of sterilization impact is that the data from *in vitro* tests on a biomaterial or a biomedical device often could not predict the possible outcomes of *in vivo* performance well. Two biomaterials with similar structures and *in vitro* test results after sterilization could behave differently *in vivo*. The *in vivo* biological performance is affected by so many factors that may interact with any chemical or structural modification caused by sterilization. The *in vitro* tests could not possibly provide all information for one to predict the potential *in vivo* biological outcomes, and each type of *in vitro* test method provides only a snapshot for a certain type of sterilization damage. Various analytical methods may be loosely sorted into four different tiers according to the type of information that the tests provide (Figure 5). The human clinical evaluation is the only first tier method that can fully evaluate the impact of sterilization on biomaterials for implantation. The *in vivo* functional animal models, immunological assay, and *in vivo* degradation kinetics are the second tier methods that can provide data to predict possible outcomes in similar clinical conditions. Biocompatibility tests, toxicity test, and histochemistry belong to the third tier methods. The third tier method may only obtain information of specific biological interactions. The majority of chemical analysis, mechanical test, structural characterization, shelf life stability test, and other biological tests are considered to be the fourth tier methods. While the fourth tier analytical methods may not directly predict clinical outcomes, they provide valuable data for process optimization and critical information for understanding the mechanisms of actions or failures after sterilization.

4.410.4.2. Effect of γ-Irradiation on a Regenerative ECM Matrix: A Case Study

Decellularized soft-tissue matrices of human and animal origin have excellent initial biomechanical properties and extracellular architecture that support the repair and regeneration of diseased human tissues. The native ECM components (e.g., collagen and other signaling proteins) are capable of supporting phenotypic expression of in-migrating host cells to repopulate, to revascularize, and to remodel the implanted ECM into the patient's own tissues without tissue reactivity and rejection after implantation and thus eliminate problems associated with the use of many alloplastic materials. γ-Irradiation was first tested for terminal sterilization of freeze-dried ECM matrix to ensure product safety.

Four methods were initially used to evaluate the effect of γ-irradiation. They are (a) the histological analysis to assess the changes of tissue's ECM structure (the fourth tier method), (b) the tensile test of rehydrated ECM strips to measure the change of strength (the fourth tier method), (c) nude mouse subcutaneous implantation to evaluate the host cell repopulation and revascularization (the third tier method), and (d) a functional abdominal wall reconstruction model (African green monkey) to evaluate tissue regeneration (the second tier method). Histological analysis and tensile test were selected because biomechanical strength and extracellular architecture were important properties for the intended applications. Histological analysis and tensile test of ECM strips rehydrated in 0.9% saline at ambient temperature did not observe significant difference between control ECM material and sterilized ECM material that were γ-irradiated at −80 °C (15 kGy).[166] The nude mouse subcutaneous implantation study showed that both control ECM and γ-sterilized ECM were capable of supporting host cell repopulation and revascularization. However, the primate functional model revealed that γ-irradiated ECM had a very rapid turnover, which prevented the regeneration of functional abdominal wall.[167] In this case, the selected third tier and fourth tier methods did not provide any useful insight for the possible modes of failure in a fully functional model.

In a separate study[168] using the paramagnetic resonance (a forth tier method), it was observed that ionizing irradiation resulted in the accumulation of two long-lived organic free radicals in the sterilized ECM matrix. The transformation (reaction) kinetics of free radicals produced was extremely slow in the nitrogen environment. The presence of oxygen and moisture greatly accelerated free radical reactions in the tissue matrix. The presence of long-lived free radicals in sterilized

Table 3 Biomaterials and corresponding sterilization methods

Material	*Applications*	*Sterilization method*
Metals and alloys		
316L stainless steel	Fracture fixation, stents, surgical instruments	γ, e-beam
CP-Ti, Ti–Al–V, Ti–Al–Nb, Ti–13Nb–13Zr, Ti–Mo–Zr–Fe	Bone and joint replacement, fracture fixation, dental implants, pacemaker encapsulation	γ, e-beam
Co–Cr–Mo, Cr–Ni–Cr–Mo	Bone and joint replacement, dental implants, dental restorations, heart valves	γ, e-beam
Ni–Ti	Bone plates, stents, orthodontic wires	γ, e-beam, gas plasma
Gold alloys	Dental restorations	γ, e-beam
Silver products	Antibacterial agents	γ, e-beam
Ceramics and glasses		
Alumina	Joint replacement, dental implants	γ, e-beam, autoclave
Zirconia	Joint replacement	γ, e-beam, autoclave
Calcium phosphates	Bone repair and augmentation, surface coating on metals	γ, e-beam
Bioactive glasses	Bone replacements	γ, e-beam
Porcelain	Dental restorations	γ, e-beam, autoclave
Carbons	Heart valves, percutaneous devices, dental implants	γ, e-beam
Polymers		
Polyvinychloride	IV sets, dialysis devices, catheter, connectors, and cannulae	Autoclave, γ, e-beam, EO
Polyethylene	Orthopedic implants, catheter	EO
Polypropylene	Sutures, artificial vascular grafts, hernia repair	γ, e-beam, EO
Polyethylenterephthalate	Sutures, artificial vascular grafts, heart valves, meshes	γ, e-beam, EO
Polyamides (Nylon)	Sutures, catheters	γ, e-beam, EO
Polytetrafluoroethylene (Tyflon)	Soft-tissue augmentation, artificial vascular grafts	γ, e-beam, EO, autoclave
Polyurethanes	Blood-contacting devices	γ, e-beam, EO
PVC	Tubing	γ, e-beam, EO
Polymethyl methacrylate	Dental restorations, intraocular lenses, joint replacement (bone cements)	γ, e-beam, EO
Poly(dimethyl siloxane)	Finger joints; heart valves; breast implants; in ear, chin, and nose reconstruction	γ, e-beam, EO
Silicones	Soft-tissue replacement, ophthalmology	γ, e-beam, autoclave
Biodegradable polymers: polylactide, polyglycolide, poly (glycolide-*co*-lactide), poly(dioxanone), poly(trimethylene carbonate), poly(carbonate)	Drug-delivery systems, resorbable sutures	γ, e-beam
Hydrogels	Ophthalmology, drug-delivery systems	γ, e-beam
Composites		
BIS-GMA-quartz/silica filler	Dental restorations	γ, e-beam
PMMA-glass fillers	Dental restorations (dental cements)	γ, e-beam
Materials with biological origin		
Allografts	Orthopedic implants, soft-tissue repair	γ, e-beam, SC-CO_2
Bovine pericardial tissue	Heart valve prosthesis, soft-tissue repair	γ, e-beam
Equine pericardium	soft-tissue repair	Cross-linking and alcohol
DBM	Bone defect repair, spinal fusion	γ, e-beam
Fetal bovine dermis	Bone defect repair	EO
Human dermis	Soft-tissue repair	γ
Porcine dermis	Soft-tissue repair	γ, EO, e-beam
Porcine subintestinal submucosa	Soft-tissue repair	EO

Source: Williams, D. In *Concise Encyclopedia of Medical & Dental Materials*; Williams, D., ed.; Pergamon Press and MIT Press, 1990; pp xvii–xx; Wong, J. Y.; Bronzino, J. D., Eds. *Biomaterials*. CRC Press: Boca Raton, FL, 2006.

ECM matrix suggested the possibility of a time-dependent, oxygen- or moisture-mediated degradation process after sterilization. This type of damage might not be observed if ECM matrix was evaluated immediately after sterilization.

The rapid turnover of ECM matrix observed in the primate model demonstrated that chemical degradation analysis (susceptibility to proteases) and biological stability test (calorimetric analysis) might be more valuable methods. Calorimetric analysis[169] showed that the stability of ECM matrix changed significantly after γ-irradiation. The onset denaturation temperature of type I collagen decreased from 60 to ~35 °C with a dose of 12 kGy (**Figure 6**). Multiple peaks were observed in

γ-irradiated ECM matrix, clearly demonstrating an increase in collagen conformational heterogeneity and collagen destabilization and possible degradation. Further study found that e-beam irradiation caused substantially less damage than γ-irradiation on ECM matrix. ETO sterilization method caused the least amount of change among five sterilization methods (γ-irradiation, e-beam irradiation, ETO, gluteraldehyde cross-linking, and EDC cross-linking) (Figure 7).

There is evidence that the decrease in thermal stability of tissue matrix is correlated to the increased vulnerability to enzyme degradation.[170,171] To understand mechanisms that triggered the rapid *in vivo* degradation of γ-irradiated ECM matrix, four proteolytic enzymes (collagenase, pepsin, trypsin, and proteinase k) were selected for the determination of the susceptibility of ECM matrix to enzyme degradation.[167] The selection of those four enzymes was on the basis of the ECM components and their perceived functions (Figure 8). In all cases, γ-irradiated ECM was digested faster than control ECM. Trypsin assay indicated that γ-irradiation exposed lysine and arginine residues in collagen fibrils, probably via collagen

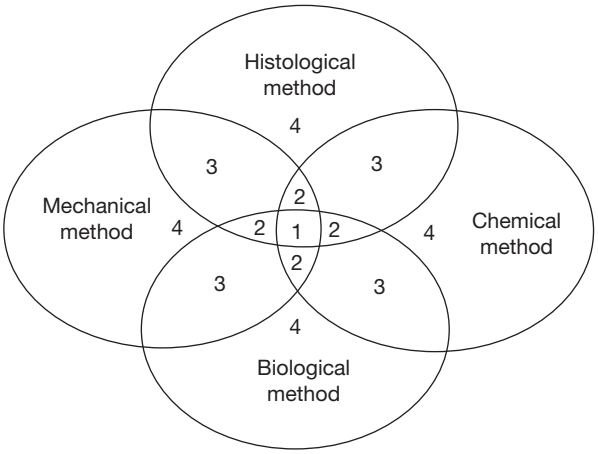

Figure 5 Four tiers of analytical methods for the evaluation of biomaterials.

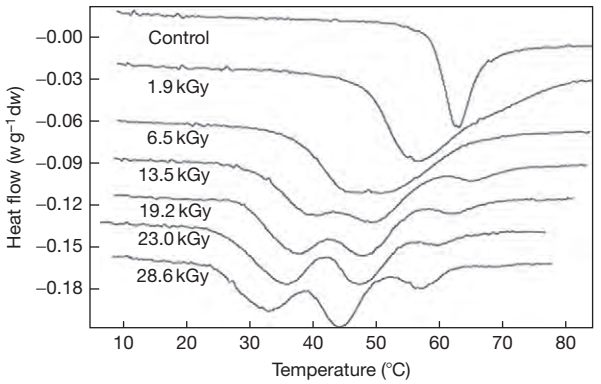

Figure 6 Effect of γ-irradiation on collagen stability in rehydrated ECM matrix tissue matrix. Collagen thermostability was determined using DSC at heating rate of 3°C min^{-1} under constant nitrogen purge. ECM matrix was rehydrated in 0.9% saline before testing. Reproduced from Sun, W. Q.; Leung, P. *Acta Biomater*. **2008**, *4*, 817–826.

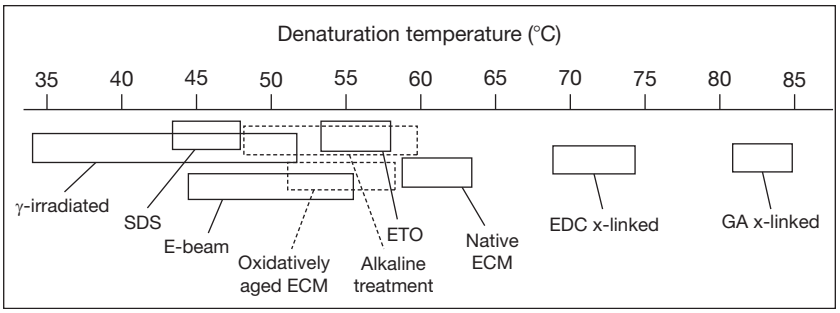

Figure 7 Effects of processes on ECM matrix stability as measured by calorimetric analysis.

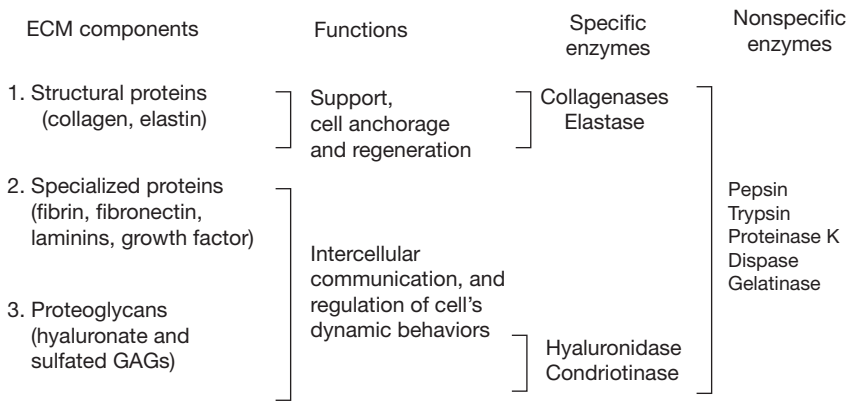

Figure 8 ECM components, their perceived functions, and enzymes selected for the evaluation of sterilization effect by γ-irradiation.

chain scission. Proteinase K assay showed destabilizing collagen conformational changes after γ-irradiation. *In vitro* fibroblast cell culture confirmed the results of ECM matrix degradation upon cell attachment.

The ECM matrix case study demonstrated the importance of selecting the appropriate analytical methods to evaluate the effect of sterilization on biomaterials.

Glossary

Cell recognition motifs Short amino acid sequences that are specific recognition sites for cell-surface receptors.

Chemical (surface) conjugation Formation of covalent bonds between functional groups on a surface and reactive groups on a biomolecule.

Differentiation The process in which a less specialized cell becomes more specialized (e.g., bone-marrow-derived stem cell gives rise to red blood cell).

Endothelium A thin layer of flat epithelial cells that lines the heart, serous cavities, lymph vessels, and blood vessels and actively prevents spontaneous blood clotting.

Extracellular matrix (ECM) A gel of polysaccharides and fibrillar proteins, with growth factors, that provides mechanical support as well as chemical signaling for epithelial tissues.

Integrin Member of a family of dimeric transmembrane cell-surface receptors that bind specific amino acid sequences in extracellular proteins and participate in cellular signaling programs.

Moiety A specific segment of a molecule.

Oligo- (prefix) Few; a small number of (e.g., oligopeptide, a molecule composed of ~3–20 amino acids).

Osseointegration The growth action of bone tissue as it assimilates surgically implanted devices or prostheses, as measured by bone–implant surface contact and mechanical fixation.

Amino Acid Abbreviations

A	Alanine
C	Cysteine
D	Aspartic acid
E	Glutamic acid
F	Phenylalanine
G	Glycine
H	Histidine
I	Isoleucine
K	Lysine
L	Leucine
M	Methionine
N	Asparagine
O	Hydroxyproline
P	Proline
Q	Glutamine
R	Arginine
S	Serine
T	Threonine
V	Valine
W	Tryptophan
Y	Tyrosine

Abbreviations

3D	Three-dimensional
AFM	Atomic force microscopy
ATRP	Atom transfer radical polymerization
ePTFE	Expanded PTFE
EC	Endothelial cell
ECGF	Endothelial cell growth factor
ECM	Extracellular matrix
ELISA	Enzyme-linked immunosorbent assay
EPC	Endothelial progenitor cell
FEP	Fluorinated ethylene propylene
FN	Fibronectin
$FNIII_{10}$	Fibronectin tenth type III repeat
$FNIII_{7\text{-}10}$	Fibronectin 7th – 10th type III repeats
FNIIICS	Fibronectin type III connecting segment
IPNs	Interpenetrating polymer networks
LCST	Lower critical solution temperature
LM	Laminin
NGC	Nerve guidance channel
NGF	Nerve growth factor
OEG	Oligo(ethylene glycol)
pNIPAM	Poly(*N*-isopropylacrylamide)
poly(OEGMA)	Poly(oligo[ethylene glycol] methacrylate)
PDMS	Polydimethylsiloxane
PEG	Poly(ethylene glycol)
PET	Poly(ethylene terephthalate)
PLA	Poly(lactic acid)
PNS	Peripheral nervous system
PTFE	Poly(tetrafluoroethylene)
QCM	Quartz crystal microbalance
RGD	Arginine-glycine-aspartic acid
S/V	Surface area-to-volume ratio
SAMs	Self-assembled monolayers
SPR	Surface plasmon resonance
ToF-SIMS	Time-of-flight secondary ion mass spectroscopy
UV	Ultraviolet
VEGF	Vascular endothelial growth factor

4.411.1. Introduction

Proteins and peptides have a myriad of natural functions useful in biotechnology. These functions include cell adhesion ligands, signaling molecules, anticoagulants, high-affinity effectors (e.g., antibodies), and catalysts. Immobilization of proteins and peptides onto surfaces enables powerful devices and analysis platforms including cell culture substrates, bioactive coatings for tissue engineering scaffolds, antithrombogenic surfaces, enzymatic bioreactors, biosensors, diagnostic assays (e.g., enzyme-linked immunosorbent assay, ELISA), and drug delivery devices (Table 1).

Surface-bound biopolymers of diverse biochemistries usually mediate interactions between cells and biomaterials, whether or not the surface modification is intended (Figure 1) (Chapter 4.416, Growth Factors and Protein-Modified Surfaces and Interfaces). Many surface-adsorbed proteins and peptides can interact with cells in many ways, but only a few of the 20 000 known proteins of the human proteome have specific motifs for cell adhesion receptors. These surface-associated proteins may provide anchoring points for specific recognition by cell-surface receptors. Subsequent cell adhesive events trigger signaling programs that regulate cell fate processes including spreading, migration, proliferation, and differentiation.[1,2] In addition, surface-bound enzymes may catalyze local and systemic immune responses *in vivo* (i.e., complement activation, coagulation cascade activation).[3] Consequently, control of cell–material interactions via manipulation of proteins and peptides at interfaces is a critical aim of much work in the field of biomaterials.[4–6]

This chapter discusses various cell-binding proteins and active peptides that might be immobilized on biomaterials and surveys immobilization methodologies available for doing so. We detail several functional parameters (e.g., ligand surface density, spatial arrangement) that directly influence application outcomes. Given the expanse of literature involving engineered cell culture substrates and implantable biomaterials, the examples in this chapter focus on cell adhesion and subsequent cell and tissue behaviors modulated by peptide- and protein-modified surfaces.

Table 1 Functions and applications of immobilized peptides and proteins

Protein/peptide functions	*Immobilized protein/peptide applications*
Cell adhesion ligands	Cell culture substrates Bioactive implant surfaces
Signaling molecules/anticoagulants	Thromboresistant surfaces
High-affinity interactions	Affinity separations Targeted drug delivery Diagnostic assays Biosensors
Enzymatic catalysis	Bioseparations Biosensors Bioreactors Diagnostic assays

4.411.2. Peptides Versus Proteins

Since Pierschbacher and Ruoslahti showed that the cell attachment activity of fibronectin (FN) could be duplicated with small fragments containing the arginine-glycine-aspartate (RGD) tripeptide, there has been tremendous interest in immobilizing oligopeptides in place of full-length proteins as biomaterial surface modifiers.[7–9] The discovery of integrin family cell-surface receptors and their amino acid binding motifs raised the appeal of peptides for targeting specific receptors to control specific cell responses.[10] Other advantages of

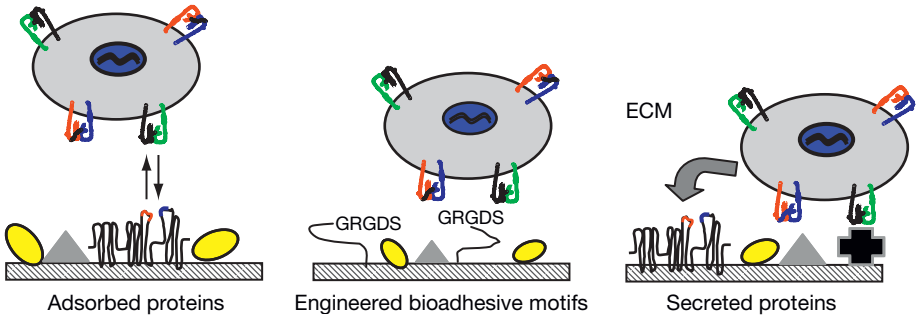

Figure 1 Mechanisms controlling cell adhesion to biomaterials.

Table 2 Design considerations: proteins versus peptides

	Protein	*Peptide*
Ease of immobilization	X	X
Cost		X
Degradability	X	
Nonimmunogenicity		X
Receptor specificity	X	X
Receptor affinity (activity)	X	
Achievable ligand density		X
Stability		X

oligopeptides over full-length proteins include low cost, easy synthesis, high levels (and control) of ligand availability, high achievable signal density, and cell-surface receptor selectivity (Table 2).

Nevertheless, there are some advantages of immobilizing full-length proteins onto biomaterial supports versus oligopeptides. First, the full protein might possibly be presented in its native conformation so as to facilitate native, high-affinity interactions with cell-surface receptors. Second, whereas oligopeptide-modified surfaces typically include only receptor-binding motifs, presentation of the protein exposes cells to the receptor-binding motif as well as other distinct complementary protein domains that modulate responses. Also, the fact that proteins can be simply, and to some extent stably, adsorbed from solution onto surfaces, in addition to covalent and affinity immobilization routes, allows great versatility in their use in surface modification strategies.

The use of full-length proteins on surfaces is, however, limited by difficulties in controlling the activity of the immobilized species with respect to orientation and conformational changes. Also, a protein might include several receptor-binding domains that allow interactions with various cell types or elicit a variety of responses from a given cell type. Similarly, immobilized proteins may provide a relatively low density of any particular binding domain, and thus do not allow enrichment of specific biological responses. Finally, proteins present particular processing challenges for *in vivo* applications. There are difficulties in securing and sterilizing purified natural sources of proteins. In addition, certain proteins have elevated immunogenicity versus a protein-derived oligopeptide.

Limitations associated with use of peptide-modified surfaces include decreased peptide bioactivity relative to native protein, the general requirement of covalent attachment chemistry to produce the bioactive surface, and the absence of domains for cellular modification of the adhesive environment. In spite of generally impressive *in vitro* results with RGD-modified surfaces, careful investigations of bioactivity involving soluble ligand have found peptide bioactivity significantly lower than that involving the native ligand.[8,9,11] These effects are due not only to the absence of protein secondary structures in most peptides but also to the absence of modulatory and complementary domains. As will be discussed in following sections, in the case of matrix protein, FN, robust cell integrin recognition and binding relies on synergistic contributions from disparate peptide domains.[12–14] Nevertheless, recombinant biosynthetic techniques have recently enabled use of protein fragments that present adhesive domains in a correct structural context.[15,16]

Ultimately, the choice of protein versus peptide will be driven by application considerations. For instance, to promote nerve regeneration across critical-sized gaps, full-length laminin (LM) protein has been immobilized within nerve guidance channels (NGCs).[17,18] However, as LM is a large protein with several cell receptor recognition sites, LM-coated scaffolds may facilitate attachment by several cell types *in vivo*, including those involved in scar formation (i.e., glial cells). Therefore, Massia and colleagues have immobilized the LM-derived IKVAV peptide to prepare surfaces that selectively promote neuronal cell attachment with minimal glial cell or fibroblast attachment *in vitro*.[19] Table 3 lists various proteins and peptides used to promote cell adhesion to biomaterial supports.

4.411.3. Immobilization Strategies

Strategies for immobilizing proteins and peptides at surfaces can be classified into three approaches: passive/physical adsorption, affinity/capture, and covalent tethering (Figure 2). These approaches can be further segregated in terms of the physical nature of association, longevity of association, and ease of use. Adsorption and capture are relatively easy but mostly rely on multiple weak and often nonspecific binding interactions (hydrophobic, van der Waals, and electrostatic), although some affinity pairings are quite strong. Covalent tethering involves potentially difficult chemical modifications to the substrate but achieves long-term immobilization. Available covalent tethering techniques offer superior control of molecular orientation.

Table 3 Proteins and peptides for facilitating cell adhesion and signaling on surfaces

Adhesion motif	*Origin*	*Receptor interactions (α/β designations refer to heterodimer receptor subtypes)*	*Functions and applications*	*References*
Fibronectin	Extracellular matrix, blood serum	αVβ3, α5β1, αIIbβ3	Extracellular matrix organization, wound healing	20–23
RGD	Fibronectin 10th type III repeat ($FNIII_{10}$), laminin α1 chain, collagen	αVβ3, α5β1, αIIbβ3, α3β1, αvβ1, α4β1	Cell adhesion, orthopedic implant integration	7–9,24–28
PHSRN	$FNIII_9$	α5β1, αIIbβ3	Cell adhesion to FN, synergy with RGD	13,15,29
REDV	Fibronectin type III connecting segment (FNIIICS)	α4β1	Vascular endothelial cell attachment	30
Type I collagen	Extracellular matrix	α1β1, α2β1	Wound healing, connective tissue, bone matrix	31
GFOGER	Type I collagen α1 chain	α2β1, α1β1	Osteoblast differentiation and orthopedic implant integration	32–35
Laminin-111	Extracellular matrix	α3β1, α6β1, α6β4	Neural cell attachment, neurite extension, epithelial cell polarization	31,36,37
YIGSR	Laminin β1 chain	α1β1, 67 kDa laminin receptor	Vascular endothelial cell attachment and migration, corneal epithelial cell attachment, nerve tissue regeneration	28,38–43
IKVAV	Laminin α1 chain	110 kDa laminin receptor	Selective neuron attachment, neurite outgrowth	19,28,44–46

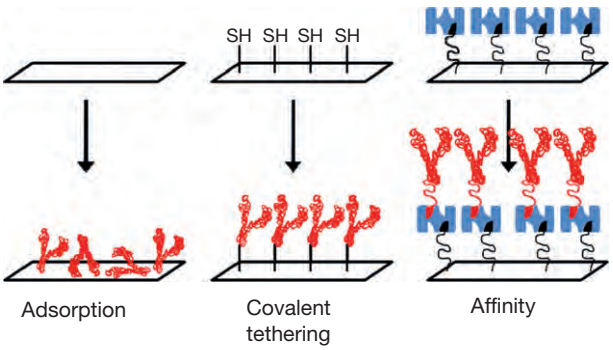

Figure 2 Mechanisms for immobilization of proteins and peptides at surfaces.

The longevity and conformational stability of adsorbed and captured polypeptides depend heavily upon the size and flexibility of the molecule (Table 4).

4.411.3.1. Adsorption

When biomaterials are placed in contact with biological fluids, proteins and other biomacromolecules dynamically adsorb onto the biomaterial surface. This observation has stimulated simultaneous efforts to understand protein adsorption and to exploit the phenomenon for bioactive surfaces. Efforts to intentionally adsorb protein on surfaces to elicit or prevent a biological response date back to the 1950s when purified collagen was adsorbed onto Petri dishes for maintenance and directed differentiation of cultured cells.[47,48] Protein adsorption involves many (i.e., electrostatic and hydrophobic) surface force interactions, and, in some cases, produces protein denaturation.[49–51] Multiple weak interactions between protein and surface produce a metastable or highly stable state of adsorption that is often irreversible under most conditions, even on surfactant rinsing. Although detailed physical relationships are not fully understood, critical surface characteristics modulating adsorption include chemistry, topography, and charge. In addition, the unique size and macromolecular structure of the adsorbent protein will influence the nature of the protein layer.[50,52]

From mixed protein solutions, like blood, plasma, and serum, the composition of an adsorbed protein layer varies over time in a sequence of adsorption, rearrangement, and desorption processes driven by the proteins' ionization states and molecular weights as well as the surface energy.[50,52] Relatively low-molecular-weight proteins that are high in concentration may be the first to adsorb to the surface but can be subsequently displaced by relatively high-molecular-weight proteins that are relatively low in concentration and slower diffusing.[53] Dynamic serum protein adsorption onto implanted biomaterials has been viewed through this paradigm known as the 'Vroman effect.'[4,50,52,54,55] The resulting serum protein layer may impart bioactivity by providing a scaffold for cell attachment. Alternatively, an adsorbed protein film may passivate the surface, rendering it minimally bioactive, as observed with albumin and other proteins that resist subsequent protein adsorption while having minimal cell adhesive properties, if any.[56,57]

In the context of cell adhesion, the earliest studies involved surfaces with proteins adsorbed from pure protein solutions.[58] Substrates coated with collagen, FN, or LM have been employed for fundamental studies of cell adhesion, proliferation, migration, and differentiation for decades.[36,48,58–64] Out of this work has come the discovery of focal adhesions and integrin receptors.[21,22,65] Furthermore, adsorption remains the most straightforward and widely used technique for placing full-length proteins onto surfaces as substrates for studying

Table 4 Protein and peptide immobilization methods

	Adsorption	*Affinity/capture*	*Covalent binding*
Ease	High	Moderate to low	Low
Loading level possible	Low (depends on S/V)	High	Depends on S/V and site density
Leakage/loss	Relatively high	Low to none	Low to none
Cost	Low	Moderate	High

protein interactions, bacterial and mammalian cell adhesion, blood clotting, and tissue engineering methods.

4.411.3.2. Covalent Tethering

Whereas adsorbed proteins are bound to surfaces by multiple but relatively weak and nonspecific interactions, covalent immobilization techniques chemically bond biomolecules to surfaces through specific functional groups. Thus, even small oligopeptides that do not stably adsorb on surfaces can be immobilized permanently to surfaces, sometimes at high density, and, infrequently, in specific orientations. As peptides and proteins share identical amino acid chemistry with the same functional groups, a broad suite of reaction routes are available for covalent tethering of proteins and peptides to diverse biomaterial surfaces (particularly polymers).[7,66,67] Covalent attachment techniques generally require appropriately matched reactive functional groups on both the protein or peptide, and the surface of the biomaterial. These include hydroxyl (–OH), amino ($-NH_2$), carboxyl (–COOH), thiol (–SH), and vinyl ($-CH{=}CH_2$) groups. The polypeptide itself typically has amine, carboxyl, and perhaps thiol or hydroxyl functionalities as part of the canonical amino acid composition. To place reactive groups on inert polymer and metal surfaces that lack them, several chemical modification methods are available.[7,68–71]

Enhanced control of surface density, spacing, and orientation of the immobilized protein or peptides can be achieved using indirect surface functionalization approaches (**Table 5**). For instance, chemisorbed end-functional self-assembled monolayers (SAMs) (e.g., alkanethiols on gold, triethylsiloxanes on metals or ceramics) or physisorbed end-functional polymer-brush thin films may control immobilized surface density through the design of the component molecule or polymer structure.[72–74,79–87] Alternatively, surface-initiated polymer graft preparations and covalently immobilized interpenetrating polymer networks (IPNs) may be used.[76–78]

Further optimization can be achieved using recombinant proteins that limit the number of reactive groups available for linkage to a surface. For instance, limitation of the number of peptide or protein cysteine groups may limit available orientations when immobilized via gold thiolate[88–90] or disulfide bond formation.[91]

4.411.3.3. Affinity or Capture Immobilization

Highly specific molecular recognition between naturally occurring binding pairs is exploited in an alternative strategy for oriented attachment of proteins and peptides on surfaces using affinity recognition adapted from chromatography separations.[92,93] Several distinct affinity methods have been used in many different iterations for decades: the protein A- or protein G-IgG,[94] glutathione-*S*-transferase,[95] and biotin–streptavidin are notable examples.[96–98] A very recent affinity immobilization method involves use of the enzymatic action of HaloTag™ against chloroalkane substrates and use in fusion protein immobilization.[99–101]

The biotin–avidin interaction, the strongest known noncovalent bond (unbinding forces up to 250 pN), has been used extensively to pair various biomolecules and surfaces for applications from chromatography to biosensing.[79,97,98,102–105] Recombinant forms of the protein avidin, including nonglycosylated types with limited nonspecific adsorption, and the bacterial form, streptavidin, are exploited for this use.

There are many variations on the following approach: (1) a (strept)avidin molecule is immobilized on the biomaterial surface by adsorption, (2) the protein or peptide of interest is covalently tagged with a biotin molecule, and (3) the surface is incubated in the solution of biotinylated molecules. Each avidin molecule binds up to four biotin molecules independently with high affinity ($K_d \sim 10^{-15}\,M^{-1}$).[106] This multifunctionality makes avidin–biotin an attractive linking cassette. For instance, molecular adlayers of biotin-derivatized poly(ethylene glycol) (PEG) have provided a useful platform for specific binding of avidin or streptavidin, and subsequent immobilization of biotinylated proteins and peptides. Hydrophilic PEG serves as a flexible linker to present biotin on the surface. Patel *et al.* used adsorbed poly(lactic acid) (PLA)–PEG–biotin on a polystyrene substrate as a base for patterning avidin molecules. Subsequent

incubation of the patterned substrates in a solution of biotinylated RGD- or IKVAV-containing peptides resulted in surfaces that achieved spatially controlled growth of endothelial cells (ECs) or neurons.[44]

Another capture technique is illustrated by degradable hydrogels that covalently incorporate peptide motifs with intrinsic affinity to bind growth factors or other active proteins. A portion of the active protein molecules will be sequestered to the hydrogel surface whereas the internally localized protein may be released as the scaffold is degraded by cell-secreted enzymes. This approach has been illustrated in covalent cross-linking of a factor XIIIa-containing peptide into a fibrin matrix using factor XIIIa transglutaminase cross-linking. The heparin-binding peptide subsequently immobilized heparin in the matrix. The immobilized heparin then interacted with a growth factor to slow its release from the matrix (**Chapter 4.420, Drug Delivery via Heparin Conjugates** and **Chapter 4.427, Cell-Demanded Release of Growth Factors**).[107,108]

4.411.4. Functional Parameters

There are several design considerations involved in rationally designing protein- and peptide-modified surfaces for the purpose of modulating cell–material interactions. Thus, a set of functional parameters by which ligand-presenting surfaces can be evaluated, and cell or tissue interactions, interpreted, is described. These include surface density, spatial arrangement, temporal presentation, and biological activity (i.e., biomolecular orientation and conformation) (**Figure 3**). **Table 6** summarizes the primary effects of these functional parameters on biological responses and major approaches to characterization of these parameters. The biological effects of these parameters are discussed in the context of cell–material adhesion events because of the critical significance of these interactions in biotechnology. However, similar considerations apply to other applications (e.g., biosensing, separations, etc.).

4.411.4.1. Surface Density

The density of tethered peptides or proteins on a surface is a major determinant of biological responses, including cell adhesion and differentiation as well as *in vivo* responses.[16,78,109–111]

In immobilizing proteins or peptides by adsorption or by tethering to functional surfaces, control of surface density is primarily achieved by varying the concentration of protein or peptide in the source solution.[110] In covalent tethering strategies that involve functional interlayers like SAMs, brush polymers, or graft polymers, the variable ratio of functional to nonfunctional end groups allows an extra level of control over the final surface density of immobilized species.

The peculiar relationship between adhesive ligand density and cell migration speed is well documented with RGD-modified surfaces. At low ligand density, cell migration is slow.

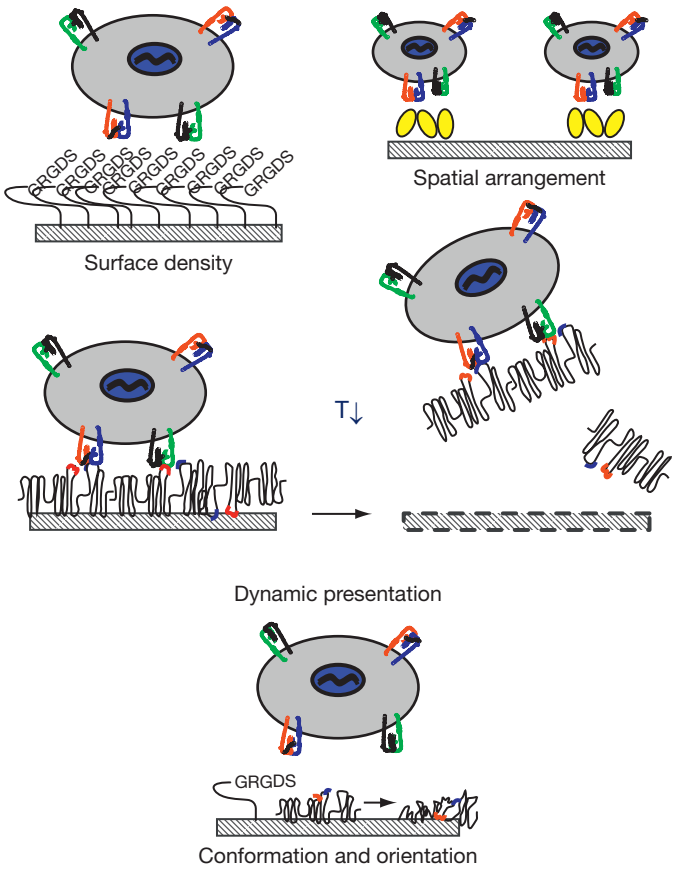

Figure 3 Functional parameters for protein- and peptide-modified surfaces.

Table 6 Design, characterization, and control strategies for protein- and peptide-modified surfaces

Functional parameter	*Primary cell/tissue effects*	*Characterization*	*Control strategy*
Surface density	Adhesion strength Migration efficiency	Radiometry Fluorometry SPR QCM	Solution concentration Surface functionalization Multivalency

Dynamic presentation	Differentiation Cell-type selectivity	Radiometry Fluorometry SPR QCM	Engineered ligands Tailored degradability
Biological activity (biomolecular orientation and conformation)	Receptor affinity	ELISA ToF-SIMs	Surface chemistry Engineered ligands

With increasing ligand density, cell migration speed increases until a saturation level after which cell migration speed decreases with increasing ligand density.[112] The biphasic behavior illustrates the delicate balance between receptor–ligand attachment and detachment processes in cell migration. Furthermore, this example illustrates the importance of tuning the surface density of immobilized ligands to elicit specific cellular responses.

Techniques for quantifying the surface density of immobilized ligands can be classified in two groups: direct labeling and surface spectroscopy. Radiometry is a direct approach that involves tagging a native protein with a radioactive isotope (e.g., ^{3}H, ^{32}P, ^{35}S, ^{14}C, ^{125}I, or ^{131}I) that does not alter the structure or bioactivity of the protein. After immobilization, the surface radioactivity is compared to a standard solution to yield surface density values with at least 0.01 ng cm^{-2} sensitivity.[110,113,114] An analogous approach using fluorescent tags has increased in popularity.[115–118] In spite of unprecedented analytical sensitivity and adaptability across different biomaterial configurations, the primary drawbacks of radiometry are the safety hazards and regulatory burdens of radioactive materials. Also, it is not clear whether the radioactive labels alter interaction between the protein and the surface. Fluorescence-associated techniques are safe and accessible but limited by fluorophore-surface quenching phenomena and instability that complicate relationships between fluorescence intensity and absolute surface density. Furthermore, fluorescent techniques have lower sensitivity than radiolabeling. Surface plasmon resonance (SPR) spectroscopy and quartz crystal microbalance (QCM) exploit optoelectronic surface phenomena to detect biomolecule deposition and interaction in real time.[119–123] In spite of precise surface density measurements (0.1 ng cm^{-2} sensitivity),[124] the SPR technique is limited to planar metal substrates. QCM offers 1 ng cm^{-2} sensitivity[122] but requires coatings onto the QCM crystal surface and some consideration of solid–fluid phase viscoelastic coupling in analyzing the QCM signal.[125,126]

4.411.4.2. Spatial Arrangement

In living systems, the nano- and microscale organization of adhesive molecules serves to dictate the function of single cells and the cooperation of multicellular assemblies. Specifically, the nanoscale spacing of adhesive motifs is a critical determinant of receptor specificity and signaling amplification[26,75,127–134] while microscale patterns of extracellular matrix (ECM) components serve to maintain tissue architecture.[135] Thus, the spatial arrangements of proteins and peptides on biomaterial surfaces are expected to influence their functions *in vitro* and *in vivo*.

Homo- and heterotypic cell–cell contact is a hallmark of mammalian tissues at all stages of development and has major implications for barrier integrity, signaling, and maintenance. Broadly, the composition of ECM dictates the localization of cell types (e.g., epithelium vs. stroma) over micron length scales. One approach for investigating cell–cell contact-associated signaling *in vitro* involves immobilizing cells on discrete regions of adhesive ECM molecules. Thus, soft lithographic techniques have been used extensively to demonstrate micrometer- and nanometer-scale spatial control of protein adsorption on biomaterial surfaces for detailed studies of constrained single- and multicell behaviors, including visualization of individual focal adhesions.[109,136–142]

The general strategy, termed 'soft lithography,' involves a lithographically patterned relief on which an elastomeric (typically polydimethylsiloxane (PDMS)) precursor is cured, transferring the pattern to the elastomer. This 'stamp' may then be 'inked' in a solution of the protein to be patterned and pressed onto the surface of interest. The proteins are transferred, arraying the adsorbed protein with high fidelity (down to 100 nm features). Coyer *et al.*[138] recently demonstrated a subtractive approach that uses stable features on a silicon template to remove protein from a featureless PDMS stamp, leaving sub-100 nm patterns of protein for transfer onto surfaces. These strategies have been extended to patterning of SAMs, allowing an additional level of control over surface characteristics (e.g., tethering functionality). Furthermore, backfilling with protein-adsorption-resistant molecules (e.g., PEG or oligo(ethylene glycol) (OEG)-terminated alkanethiols) results in robust interfaces for *in vitro* studies. Another application to control the spatial arrangement of peptides or proteins at surfaces is to generate gradients of cell adhesive ligands.[143–146]

Nanoscale clustering of cell-surface receptors is a step in cell adhesion that is critical for adhesion-related intracellular signaling and subsequent cell behaviors.[129,133,134] In some cases, a single growth factor molecule may bind multiple tyrosine

kinase receptors. The induced dimerization of the receptors results in cross-phosphorylation at the cytoplasmic regions of the receptors and initiation of intracellular signaling cascades.[147] Thus, nanoscale ordering of adhesive ligand presentation on biomaterial surfaces may enhance a variety of biological responses. To this end, there has been extensive investigation of the nanoscale geometric arrangements that enrich specific cellular functions. Massia and Hubbell[132] controlled the surface density of RGD peptides on functionalized glass to determine that 440 nm lateral spacing is sufficient to promote fibroblast spreading, whereas 140 nm spacing is required for development of focal contacts and stress fibers. Griffith and colleagues used a polymer linker to independently control surface density and local clustering (50 nm resolution) of five- or nine-headed RGD ligands. Their results indicated that clustering reduced the surface density of ligand required for NR6 fibroblast cell migration. Petrie *et al.*[75] have recently employed multivalent ligands to enhance implant osseointegration, as discussed later.

4.411.4.3. Dynamic or Temporal Presentation

The native ECM dynamically organizes multiple cell types to coordinate tissue development and repair processes through temporally controlled presentation of cell adhesion molecules. The complex of adhesion ligands available at the interface is regulated in time by cell-mediated remodeling (e.g., enzymatic cross-linking and degradation, further matrix deposition) and environmental cues (e.g., temperature, pH).[148] Thus, for biotechnological applications to mimic ECM, it is useful to design protein- and peptide-modified surfaces responsive to cellular and environmental stimuli over time.

'Smart surfaces' for biomedical applications have been designed to modulate the availability or bioactivity of immobilized ligands in response to stimuli including temperature, pH, electric fields, and light[149–151] (**Table 7**). For instance, surfaces grafted with poly (*N*-isopropylacrylamide) (pNIPAM) have been used extensively as thermosensitive cell culture surfaces for control of cell and cell sheet adhesion.[152–154] pNIPAM is a member of a class of polymers that exhibit a lower critical solution temperature (LCST). Above the LCST, these polymers become less solvated and assume a collapsed conformation that promotes adsorption of cell adhesion proteins. Below the LCST, the polymer is hydrated and, like PEG, becomes resistant to protein adsorption. The LCST for pNIPAM is 32 °C and the transition between collapsed and solvated states is fully reversible.[155,156] Thus, cell culture substrates coated with pNIPAM can support serum protein adsorption, cell adhesion, and spreading at 37 °C. Decreasing the temperature below 32 °C causes the pNIPAM transition to the solvated state, triggers desorption of adhesion proteins, and initiates release of adherent cells or sheets of cells.[153,154] Interestingly, the conformational change in pNIPAM is sufficient to alter the affinity of integrins for immobilized RGDS.[157] By adding chemical substituents to modulate LCST and by patterning copolymers, Okano and colleagues have optimized the system for 'cell sheet engineering' with applications including corneal transplants and myocardial patches.[158–162]

Alternatively, photosensitive molecules can be used to modulate the bioactivity of covalently immobilized proteins and peptides. For instance, adding a bulky, photolabile chemical moiety to an oligopeptide cell adhesion motif can prevent its recognition by integrin receptors. In response to ultraviolet (UV) light, the obstructive chemical group can be removed to restore integrin recognition. This approach is facilitated by 'caged' reagents.[163] Various caged RGD molecules have been designed and immobilized to enable photo-triggered cell adhesion.[164–166]

4.411.4.4. Biological Activity: Conformation and Orientation

The three-dimensional (3D) structure of a protein, and even an oligopeptide, is directly linked to its biological activity. In the native ECM, component proteins like FN bind to several other ECM proteins and might adopt several conformational states. Conformational changes in a protein may alter cell and tissue responses by exposing or burying different cell adhesion motifs, exposing cryptic receptor recognition sites, or, in the case of enzymes, disrupting active sites. Meanwhile, the rotational state or orientation of a protein, particularly at an interface, might determine its bioactivity by modulating the accessibility of recognition motifs or active sites. Thus, control of conformation and orientation of surface-immobilized proteins and peptides is a major biomaterials design consideration.

Upon contact with a biomaterial surface, the fate of an interfacing globular protein is highly variable. After initial adsorption, the protein might (1) change orientation, (2) change conformation while retaining biological activity, or (3) conformationally denature and lose activity.[167–169] The dynamics of the protein–surface interaction depend heavily upon surface energy, surface charge, and surface chemistry, as well as the structural characteristics of the protein. Like the affinity of a cell-surface receptor binding an adhesion motif, the affinity of antibody binding to a specific biomolecule antigen is sensitive to changes in the accessibility of the epitope. Thus, antibody-based techniques like ELISA can be used alongside cell culture assays to detect differences in bioactivity of immobilized species with high sensitivity.[170,171] For instance, Grinnell and Feld[172] initially observed substrate-dependent cell spreading and antibody binding on FN-coated substrates. Subsequent studies of adsorbed FN indicated that the extent of molecular unfolding varied across substrates.[173–178] Garcia *et al.* later showed that these substrate-driven conformational differences manifested in altered integrin receptor specificity and correlated to differences in proliferation and differentiation of cells cultured on FN-coated surfaces.[179,180]

Polypeptides immobilized via covalent coupling or high-affinity interactions may avoid conformational changes, especially when linkers or inert interlayers are employed. Control

of protein orientation requires reliable tethering via specifically located functional groups on the protein, and low surface interactions once tethered. As amino or carboxyl moieties may be located at various locations in a protein, coupling through these groups will likely result in a random set of molecular orientations. Even worse, the reactive functional group might be part of a receptor-binding motif or enzymatic active site that would be disrupted by tethering. Alternatively, 'orthogonal coupling chemistry' involves introduction of a less common functional handle at a specific site (e.g., a free cysteine via site-directed mutagenesis) or use of 'click' chemistry reactions to achieve uniform molecular orientation.[143,181,182] Site-specific functionalization, including biotinylation, has been employed to prepare protein microarrays and enzymatic biosensors.[105,183–187]

Many cell adhesion studies involving RGD-containing peptides serve to illustrate the importance of biomolecular design for controlling bioactivity at the interface. Just as RGD's cell adhesive activity was discovered, it was observed that the identities of the amino acids flanking the RGD tripeptide (i.e., primary structure) strongly affect its activity.[8,9] As a result, numerous combinations of amino acids have been substituted (e.g., CGRGDSY) in the flanking sequence to modulate activity or to facilitate immobilization (e.g., cysteine for thiol-mediated immobilization or tyrosine for radiolabeling).[7,188,189] In the context of the full-length FN protein that binds integrin α5β1, the secondary structure of the RGD motif is a (presumably stiff) loop joining two β sheets within the 10th type III domain ($FNIII_{10}$).[190,191] The isolated $FNIII_{10}$ domain, however, is highly flexible and, in this context, RGD targets integrin αVβ3.[192–194] On the hypothesis that the flexibility of the RGD motif controls its binding specificity and affinity, cyclic RGD peptides have been prepared to constrain RGD to a loop and thereby enhance cell attachment.[24,25,195–197] Cell adhesion to FN is a synergistic effect of binding to RGD (on $FNIII_{10}$) and a PHSRN motif located on the neighboring $FNIII_9$ domain. Surfaces presenting mixtures of RGD and PHSRN enhance cell adhesion versus RGD or PHSRN alone. However, surfaces that present a recombinant $FNIII_{7-10}$ fragment include RGD and PHSRN in a 3D orientation and spacing and allow binding of the pair by a single integrin receptor.[29,198] Such surfaces promote superior α5β1 integrin engagement and cell attachment versus an RGD–PHSRN oligopeptide in which the two motifs are linked by a polyglycine tether.[15]

As mentioned earlier, cell culture assays and antibody-based techniques (e.g., ELISA) provide measures of the bioactivity of immobilized peptides and proteins without specifically interrogating conformation or orientation. These details may be directly examined using surface analysis techniques including time-of-flight secondary ion mass spectroscopy (ToF-SIMS), atomic force microscopy (AFM), ellipsometry, and circular dichroism. These techniques are reviewed elsewhere.[199–201]

4.411.5. Sample Applications

4.411.5.1. Orthopedic Applications

The generally desired course of action in implant osseointegration and regeneration of bone tissue includes (1) recruitment of osteoprogenitors to injury/implant sites, (2) adhesion of osteoprogenitors to implant/scaffold surface, and (3) induction of osteoblast-specific cell behaviors including matrix formation and matrix mineralization.

In therapeutic interventions involving implanted materials, much of the above process is mediated by cell–material interactions modulated by immobilized biomolecules on surfaces. Initially, to promote cell adhesion onto orthopedic implants, work focused on the RGD adhesive peptide derived from many of the ECM proteins present during bone development (e.g., bone sialoprotein, osteopontin, thrombospondin, and FN). RGD-modified surfaces enhanced osteogenic cell adhesion, proliferation, and differentiation measured by increased alkaline phosphatase activity, osteocalcin expression, and matrix mineralization *in vitro*.[76,77,202–210] In addition, RGD immobilization on implant surfaces supports bone formation *in vivo*[202,211,212] although the functional significance of this effect to implant performance is debatable.

RGD immobilization on biomaterials remains a popular strategy for driving osteoprogenitor differentiation *in vitro* and implant osseointegration *in vivo*. However, for all of the positive results associated with RGD peptide-presenting surfaces, the approach is limited by three critical factors:[213]

1. Low bioactivity in short adhesive peptide versus complete protein.
2. Limited receptor specificity.
3. Absence of complementary ligands for robust differentiation.

Indeed, independent studies have demonstrated that presentation of RGD on implant surfaces does not enhance implant osseointegration.[16,214–217] Thus, a second generation of peptide- and protein-modified surfaces has emerged to promote integrin-specific cellular recognition to drive robust osteoprogenitor adhesion and differentiation to achieve rapid osseointegration (**Figure 4**). One featured approach is covalent tethering of mixtures of RGD and another peptide that either enhances binding of RGD-binding integrins or targets a non-RGD-binding integrin.[34,35,218,219] Examples include mixtures of RGD and the FN-derived PHSRN synergy site peptide tethered on nonfouling supports.[220,221] In native FN, RGD is located in the 9th type III structural repeat while PHSRN is located in the 10th type III repeat. Independently, each motif scarcely contributes to binding, but together, they synergistically bind to α5β1 for stable adhesion.[29,222] While the mixed surfaces promote integrin binding and cell attachment, their comparability to complete FN is unknown. Furthermore, the synergistic effects require precise spatial orientation that cannot be maintained with short, tethered peptides.[213] However, a recombinant FN fragment (7th to 10th type III repeats, $FNIII_{7-10}$) that presents RGD and PHSRN in the correct spatial orientation retained the synergistic binding effects when tethered to model surfaces via carbodiimide chemistry. Petrie and García conducted detailed characterization of ligand density and bioadhesivity of model surfaces featuring $FNIII_{7-10}$ tethered on a nonfouling SAM background. SPR analysis of ligand tethering and a centrifugation assay for cell adhesion indicated precise control of cell-surface adhesivity. The surfaces also promoted α5β1 integrin ligation while enhancing proliferation and focal adhesion formation versus RGD-presenting surfaces and those presenting an RGD–PHSRN peptide that spaced the

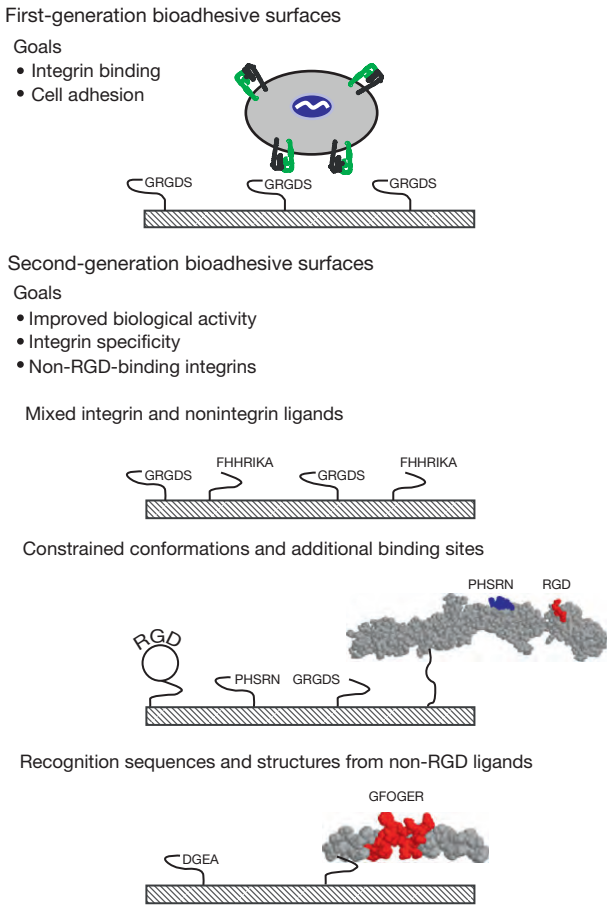

Figure 4 Biomolecular engineering strategies for bioadhesive surfaces. First-generation substrates concentrate on tethering RGD to direct integrin binding and cell adhesion. Second-generation strategies focus on enhancing biological activity, integrin specificity, and binding non-RGD integrins. Reproduced from Garcia, A. J.; Reyes, C. D. *J. Dent. Res.* **2005**, *84*(5), 407–413.

two motifs with a polyglycine linker.[15] Petrie and García demonstrated the benefits of α5β1 integrin-targeting surface treatments *in vivo* by covalently immobilizing $FNIII_{7-10}$ on poly(OEGMA) brushes grown from clinical grade titanium substrates via atom transfer radical polymerization (ATRP). In a rat tibial implant model, the poly(OEGMA)-$FNIII_{7-10}$ surface treatment improved osseointegration, as evidenced by a 70% increase in bone contact area versus clinical standard titanium (Figure 5). The integrin-targeting interface also enhanced mechanical fixation versus implants functionalized with RGD peptide.[16,75]

Protein adsorption remains the simplest approach to conveying bioactivity to a material surface. As simplicity is of great value to the clinical approach, Petrie and García have developed a clinically translatable, single-step passive adsorption strategy for immobilization of $FNIII_{7-10}$ on titanium implants that has enhanced osseointegration in a rat cortical bone defect. Notably, the adsorbed integrin-targeting $FNIII_{7-10}$ fragment enhanced osseointegration versus adsorbed full-length FN.[223]

Whereas little work has focused on biomolecular surface treatments to target non-RGD-binding receptors, García and colleagues have engineered biointerfaces to target α2β1 to promote signals essential for osteoblast differentiation.[34] Characterization of titanium substrates functionalized with a passively adsorbed triple-helical oligopeptide featuring the GFOGER adhesive motif indicated cell adhesion activity and osteoblast-specific gene expression resembling complete type I collagen.[35] Applied *in vivo* for a rat cortical bone–implant model, a facile, single-step application of GFOGER enhanced titanium implant osseointegration versus adsorbed full-length type I collagen.[35] Furthermore, GFOGER coatings passively adsorbed onto polymeric scaffolds, in the absence of exogenous cells or growth factors, significantly accelerated and increased bone formation in nonhealing rat femoral defects compared to uncoated scaffolds and empty defects.[224]

4.411.5.2. Cardiovascular Applications

In cardiovascular conditions where bypass procedures are required, autologous vascular grafts are often unavailable and synthetic substitutes have been developed. These biologically inert materials have proven suitable only as large-diameter blood vessels in specific physiological conditions (i.e., high flow, high shear). However, as small-diameter vascular grafts (diameter < 6 mm), synthetic materials suffer from low patency rates because of thrombotic occlusion. The primary strategy for avoiding thrombus formation is to mimic the anticoagulant characteristics of the lumen of native vasculature.[225] In a healthy blood vessel, a confluent EC layer covers the lumen, interfaces with flowing blood, and actively prevents thrombosis. Therefore, formation of a stable endothelium in small-diameter synthetic vascular grafts has emerged as a major goal in cardiovascular research.[225] Early *in vitro* endothelialization efforts pioneered by Herring revealed that common synthetic graft materials (expanded PTFE (ePTFE), poly(ethylene terephthalate) (PET), polyurethanes) do not promote EC adhesion sufficiently to retain a seeded cell layer under pulsatile flow conditions.[226,227] While certain animal vascular implant models do endothelialize, human implants generally fail.[228] As a result, attention turned to bioactive coatings to enhance EC adhesion to vascular implant materials. Early work involved passive adsorption of FN onto ePTFE grafts and indicated some improvement in EC retention versus untreated grafts.[229] Adsorbed bioactive coatings were found suboptimal compared to covalent immobilization of adhesive proteins and peptides. For instance, covalently immobilized RGD peptides enhanced EC retention versus adsorbed FN.[230] The RGD theme was used in various studies including strategies that incorporated the peptide into the structure of the graft polymer. RGD was paired with the antithrombogenic protein, heparin, toward an EC adhesive surface that will resist thrombosis even in partial endothelialization.[230] Unfortunately, the RGD motif is bound by cell-surface receptors found on various cell types in blood, including platelets. The effects of platelet activation on graft success are thought to be detrimental although they are not completely understood.[225] To target the α4 integrin that is absent from the

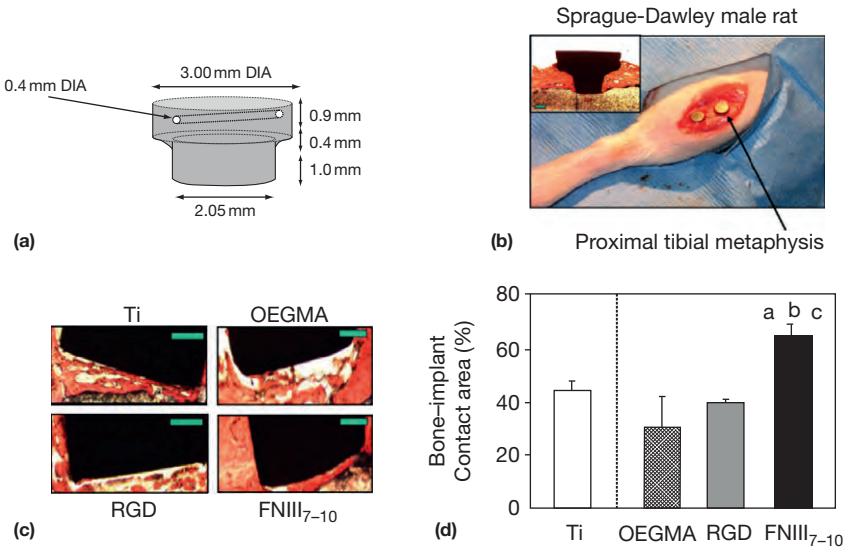

Figure 5 Integrin specificity modulates *in vivo* implant osseointegration. (a) Schematic of tapered titanium implant used in rat tibia implant model. (b) Photograph showing placement of implants in rat tibia. Two implants were placed in each tibia. Inset micrograph is of longitudinal section of entrenched implant after 4-week implantation, stained with Sanderson's rapid bone stain and van Gieson counterstain. (c) Histological sections at 4 weeks postimplantation showing bone (orange)–implant (black) contact (scale bar 0.5 mm). $FNIII_{7-10}$-tethered implant surfaces displayed greater bone tissue formation and connectivity compared to other surface treatments. (d) Bone–implant contact area: a versus RGD ($p < 0.02$); b versus Ti-serum ($p < 0.02$); c versus poly(OEGMA) ($p < 0.02$). Reproduced from Petrie, T. A.; Raynor, J. E.; *et al*. *Biomaterials* **2008**, *29*(19), 2849–2857.

surface of platelets, Massia and Hubbell[231] integrated an FN-derived REDV peptide. Similarly, recombinant FNIIICS-1 has been designed for integrin specificity. In moving to clinical application of *in vitro* endothelialized synthetic grafts, Zilla and colleagues coated ePTFE grafts with fibrin glue prior to seeding with autologously isolated ECs.[232] After culturing to confluence (6–11 days), grafts were anastomosed to vasculature above or below the knee and patients monitored for 7 years. The majority of fibrin-treated grafts remained patent after 7 years.[233] A wider study indicated similar results after 10 years.[234]

In situ endothelialization is an attractive alternative strategy for achieving antithrombogenic, small-diameter synthetic vascular grafts. In this ideal approach, circulating and bone-marrow resident endothelial progenitor cells (EPCs) are recruited to a cell-free synthetic implant where an endothelium forms *in vivo*.[225] Biomolecular surface treatments may be helpful in this approach. Growth factors including vascular endothelial growth factor (VEGF) and EC growth factor (ECGF) are involved in vascular development, induce EPC maturation into EC, and are potent EC mitogens.[235,236] Accordingly, immobilization of VEGF or ECGF in adhesive coating is a promising strategy for localized expansion of ECs at the luminal surface of a synthetic vascular graft. *In vitro* studies with ECGF showed enhanced EC proliferation.[237] *In vitro* experiments involving VEGF immobilization using enzyme-degradable linkers for cell-demanded release showed enhanced EC proliferation and EPC maturation into EC.[238] However, further characterization of growth-factor-associated strategies is required to prevent intimal hyperplasia that has been found in response to VEGF-releasing synthetic grafts *in vivo*.[239,240]

4.411.5.3. Neural Applications

In clinical interventions for peripheral nervous system (PNS) damage, the goal is axon regeneration such that proximal sprouting axons can bridge a defect gap to contact the distal stump.[241,242] The intervention must also prevent scar tissue invasion or other microenvironmental interference. Physical guidance of axons has been accepted as a requirement for nerve repair since the nineteenth century.[241,243] Today, NGCs are made from nondegradable synthetic materials (PTFE and silicone), biodegradable synthetic polymers (PLA, poly(caprolactone), polyurethane), and natural materials (e.g., ECM extracts, fibrin/fibrinogen, and agarose). The ideal NGC is a porous, biodegradable scaffold that can support cell adhesion and delivery of bioactive factors *in vivo*.[241] While the design of characterization of such biomaterials lies outside the scope of this chapter, we discuss the use of peptide- and protein-modified surfaces in development of NGCs.

Like cells in the bone and cardiovascular compartments, neural cell behavior is modulated by specific interactions with ECM proteins and growth factors. Early strategies to probe neural cell-ECM dynamics keyed on immobilization of ECM proteins, particularly LM, to enhance cell adhesion and neurite outgrowth. In the 1980s, LM was identified as an active promoter of neural cell attachment, differentiation, and neurite outgrowth *in vitro*.[244,245] Thus, it was immediately proposed as a bioactive coating to improve performance of NGCs. Later, Kleinman and colleagues identified two cellular recognition domains in LM that specifically bind cell-surface receptors expressed by neural cells. These peptides were YIGSR (from LM β1 chain, bound by a 67-kDa receptor) and IKVAV (from LM α1 chain, bound

by 110 kDa receptor).[246,247] Aebischer and colleagues covalently functionalized fluorinated ethylene propylene (FEP) films with YIGSR, IKVAV, and RGD (also found in LM) and characterized the surfaces with competitive cell attachment assays.[248,249] Using cell lines known to express the 67 or 110 kDa receptors, Raineri *et al.* demonstrated peptide-modified surfaces for receptor-specific neural cell attachment. Other groups employed bioactive surfaces to recreate neural architecture *in vitro* with chemically patterned substrates to control cell attachment and neurite outgrowth.[248,250,251] Toward development of neuron-selective adhesive coatings for NGCs, Hubbell and colleagues immobilized IKVAV peptides on cell adhesion resistant dextran coatings. Culture of PC12 (neuronal), fibroblast, and glial cells indicated that these substrates promoted substantial neuronal attachment with minimal fibroblast and glial cell adhesion.[19] Recently, Gomez and colleagues demonstrated the axon-lengthening effects of locally immobilized nerve growth factor (NGF).[252,253] Together, these *in vitro* studies have identified biomolecular targets for potential clinical applications for neural tissue engineering.[254,255]

4.411.6. Conclusions and Outlook

Interactions between cells and biomaterial surfaces are mediated by surface-immobilized proteins and peptides. Today, the initial state of the interface can be controlled with remarkable precision, owing to contributions from biochemistry, cell biology, synthetic chemistry, and materials science over the last five decades. Purification of the ECM proteins that direct myriad cell behaviors *in vivo* and identification of the peptide motifs involved in specific cell-surface receptor binding have spawned a variety of chemical techniques for immobilizing active, cell adhesion ligands on various biomaterials with precision. Furthermore, fundamental cell biology studies on model substrates have elucidated key functional parameters that may predict performance of host tissues, via cells, to implanted biomaterials. Recently, surfaces featuring rationally designed, integrin-targeting ligands presented with nanoscale spatial order have proven effective in the context of orthopedic implant integration.

Expanded use of orthogonal coupling chemistry for oriented immobilization of integrin-targeting ligands (e.g., 'click' chemistry) along with stimulus-responsive ligand presentation schemes should enable new applications for protein- and peptide-modified surfaces. Implanted dynamic surfaces may be able to withstand the initial assault of the host immune system and synchronize presentation of multiple ligands to the course of wound healing or differentiation programs.

Glossary

Cell surface display A directed evolution technique in which libraries of protein or peptide mutants are displayed on the surface of a cell (typically, a bacteria or yeast cell) and screened to identify variants with desired properties.

Combinatorial protein engineering (directed evolution) An approach to protein engineering where libraries of mutants are created and screened to identify protein variants with desired properties.

Consensus residue The most common residue at a given position when related sequences are aligned.

DNA shuffling A method to create genetic diversity by randomly recombining DNA *in vitro*.

Error-prone PCR A method to create genetic diversity by employing PCR with increased mutation frequencies.

Fluorescence-activated cell sorting (FACS) A technique to sort single cells based on their light scattering or fluorescent characteristics; used to isolate clones from cell surface display and *in vitro* compartmentalization libraries.

Genotype–phenotype linkage The connection between a protein variant and its corresponding DNA sequence, which allows amino acid mutations to be identified following library screening.

Homology The similarity between DNA or protein sequences.

***In vitro* compartmentalization (IVC)** A directed evolution technique in which protein or peptide libraries are encapsulated within cell-like compartments or emulsions, each containing one or more gene(s) and the encoded protein(s).

***In vitro* display** A directed evolution technique which physically links a protein or peptide mutant to the DNA or mRNA encoding for that protein or peptide using *in vitro* transcription and translation.

Phage display A directed evolution technique in which libraries of protein or peptide mutants are displayed on the surface of a bacteriophage and screened to identify variants with desired properties.

Posttranslational modification The modification of a protein after it is translated; describes processes that are

natural (i.e., glycosylation) and artificial (i.e., conjugation to polymers).

Rational protein engineering An approach to engineer proteins by introducing mutations based on knowledge of the protein structure and function.

Site-directed mutagenesis The mutation of a defined site in a gene and its corresponding amino acid mutation in the translated protein.

Structure–function relationship The link between a protein's amino acid sequence and structure and its biological activity.

Abbreviations

^{10}Fn3	10th fibronectin type III domain
APEx	Anchored periplasmic expression
ATP	Adenosine triphosphate
BMP-2	Bone morphogenetic protein 2
BSA	Bovine serum albumin
bZIP	Basic-region leucine zipper
CTA1	Cholera toxin A1
DARPins	Designed ankyrin repeat proteins
dNTPs	Deoxyribonucleotides
ECM	Extracellular matrix
EDTA	Ethylenediaminetetraacetic acid
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
ELISA	Enzyme-linked immunosorbent assay
Fabs	Antibody antigen-binding fragments
FACS	Fluorescence-activated cell sorting
FDA	Food and Drug Administration
FGF-1	Fibroblast growth factor-1
GCSF	Granulocyte-colony stimulating factor
Gβ1	Streptococcal protein G β1 domain
Her2	Human epidermal growth factor receptor 2
HGF	Hepatocyte growth factor
hGH	Human growth hormone
hGHR	Human growth hormone receptor
IFN-β	Interferon beta
IL-12	Interleukin-12
IL-2	Interleukin-2
ITCHY	Incremental truncation for the creation of hybrid enzymes
IVC	*in vitro* compartmentalization
Lpp	Lipoprotein
NESP	Novel erythropoiesis stimulating protein
NMR	Nuclear magnetic resonance
OmpA	Outer membrane protein A
PCR	Polymerase chain reaction
PDB	Protein Data Bank
PDGF	Platelet-derived growth factor
PEG	Polyethylene glycol
PPyCl	Chlorine-doped polypyrrole
PVP	Polyvinylpyrrolidone
RATCHITT	Random chimeragenesis on transient templates
RGD	Arginine-glycine-aspartic acid
scFvs	Antibody single-chain variable fragments
scTCRs	Single-chain T-cell receptors
SOSM	Shotgun ortholog scanning mutagenesis
StEP	Staggered extension process
TCR	T-cell receptor
TGF-α	Transforming growth factor alpha
TNF-α	Tumor necrosis factor alpha
TNFR	Tumor necrosis factor receptor
tPA	Tissue plasminogen activator
uPA	Urokinase plasminogen activator
VEGF	Vascular endothelial growth factor

4.412.1. Introduction

Biomaterials are playing an increasing role in regenerative medicine, serving as medical devices, drug delivery systems, and tissue implants and replacements.[1–3] Early material designs focused on providing mechanical support and proper diffusion of nutrients and waste for cell growth. However, as the field has expanded, it has become clear that these factors alone are not sufficient to promote cell proliferation and differentiation.[4] To help tissue growth and regeneration, biomaterials need to mimic the interactions between cells and their natural environment.

Signals that direct cell fate are mainly received from three sources: the extracellular matrix (ECM), neighboring cells, and soluble factors.[3,5] Protein–protein interactions play a significant role in all these components. For example, the ECM is composed of a meshwork of proteins, such as fibronectin and collagen, which interact with a myriad of cell surface receptors. In addition, neighboring cells communicate through membrane proteins like cadherin and cell adhesion molecules, and families of growth factors and cytokines control cell proliferation and migration by activating signaling pathways through their respective receptors. Thus, biomaterial design must consider and incorporate these protein–protein interactions to provide a customized material interface with the cell surface receptors that mediate these biological functions. This can be accomplished by presenting proteins on the surface of materials or encapsulating proteins inside materials.

Natural proteins, however, are often not ideal for use in biomaterials applications. Many are simply difficult to obtain. Purification from natural sources can be challenging, and the quality or composition can vary significantly from among batches or sources. There is also the risk of disease transfer and immunogenicity from proteins derived from animal sources. Recombinant production can circumvent those problems, but certain proteins, such as silk, collagen, and growth factors, still prove difficult to express in their native forms. Even when a protein can be produced and purified, Nature might not have optimized it for use in biomedical applications.

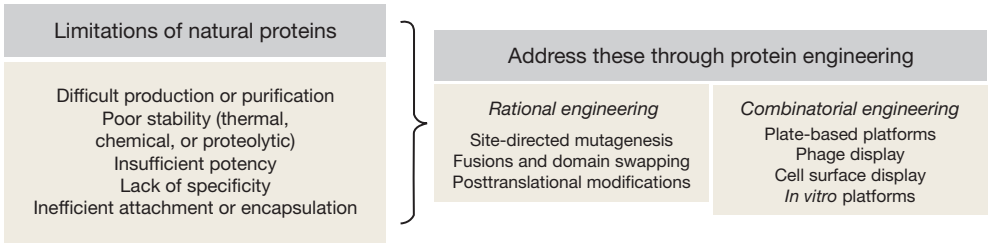

Figure 1 Chapter overview. To promote proliferation and differentiation, biomaterials need to mimic interactions that cells experience in their natural environment. One approach is to create customized materials that interact with and modulate cell surface receptors through protein ligands. Natural proteins, however, are often not optimal for use in biomaterials. In this chapter, we provide an overview of the two main protein engineering approaches that can be used to address these limitations: rational and combinatorial engineering.

For example, the protein of interest may lack the specificity or potency required to obtain a desired biological activity. In addition, many proteins, such as growth factors and cytokines, are not stable in the body due to thermal or proteolytic susceptibility, or possess fast *in vivo* clearance due to their small size. Furthermore, a protein's three-dimensional structure can be denatured upon exposure to chemical or UV-based methods often used for biomaterial incorporation, and attachment to materials can inactivate or reduce a protein's activity due to denaturation or steric constraints.

The principles of protein engineering can be applied to address all of these limitations (Figure 1). Rational protein engineering approaches require some knowledge of the protein's structure and function, but, when this information is available, can enable facile introduction of effective mutations for improved properties. Alternatively, combinatorial engineering approaches, also known as directed evolution, do not require existing knowledge of the protein's structure and function. However, directed evolution requires creation of a diverse library of protein variants and a high-throughput screening method to identify mutants with a desired phenotype. In this chapter, we provide a general overview of protein engineering, including both rational and combinatorial methods. In addition, we discuss specific considerations and challenges in creating proteins for biomaterial applications. Given the large body of work in this field, the chapter is not meant to be comprehensive, but provides key examples within each topic for illustrative purposes.

4.412.2. Rational Engineering

Rational protein engineering is the targeted redesign of a protein based on knowledge of the protein's structure and function. Rational modifications to proteins are most often done through site-directed mutagenesis. The challenge in this approach is to identify appropriate residues for mutation and predict their effects on protein properties. Rational protein engineering methodology varies greatly in complexity. The most basic level of analysis is to simply examine the protein's amino acid sequence, searching for homology with other proteins or unique residues, such as cysteine. If available, three-dimensional structures of proteins can be extremely helpful in guiding mutagenesis. More recently, computational algorithms are being used to employ physics-based modeling to fine-tune predictions.

Despite the plethora of techniques available for predicting the effects of mutagenesis, knowledge of protein structure–function relationships is still limited, making site-directed mutagenesis challenging. An alternative route is to identify protein domains with a known desired function. These domains, which can be peptides or entire proteins, can be fused together to gain enhanced or altered functionality with less uncertainty. However, problems still arise because fusions often alter the protein's spatial orientation and presentation and can be detrimental to activity.

Rational protein engineering also extends beyond amino acid sequence through posttranslational modifications. Natural processes, such as glycosylation, can be controlled to modify protein properties. Synthetic conjugations, notably attachment to polyethylene glycol (PEG), are also common because of established experimental protocols and the biological inertness of certain polymers. However, applications for posttranslation modifications are generally limited to increasing the molecular weight or stability of proteins.

Below, we describe specific techniques and provide examples for each of the three main approaches to rational engineering: site-directed mutagenesis, protein fusions and domain swapping, and posttranslational modifications.

4.412.2.1. Site-Directed Mutagenesis

Site-directed mutagenesis is the mutation of a defined site in a DNA sequence and, consequentially, the corresponding amino acid sequence. It is a common tool in molecular biology to study a protein's structure–function relationship, and many *in vitro* techniques, most of which are based on polymerase chain reaction (PCR), have been developed to efficiently introduce mutations, deletions, or insertions into existing genes by overlap extension (Figure 2(a)).[6] One of the most widely used methods is the QuikChange Site Directed Mutagenesis protocol developed by Stratagene, Inc. (La Jolla, CA)[7,8] (Figure 2(b)). In this protocol, virtually any plasmid can be mutated in just a few simple steps. First, a pair of oligonucleotide primers that are complementary to the plasmid, except for the desired mutation, are extended by PCR. The resulting reaction is treated with the enzyme *Dpn* I, which digests methylated and hemimethylated DNA. Almost all DNA isolated from *Escherichia coli* is methylated, thus the *Dpn* I selects for synthesized DNA containing the mutations. The mixture is then transformed into competent *E. coli* cells for isolation and amplification. This basic technique has been extended to introduce multiple amino acid mutations in addition to single point mutations.[6]

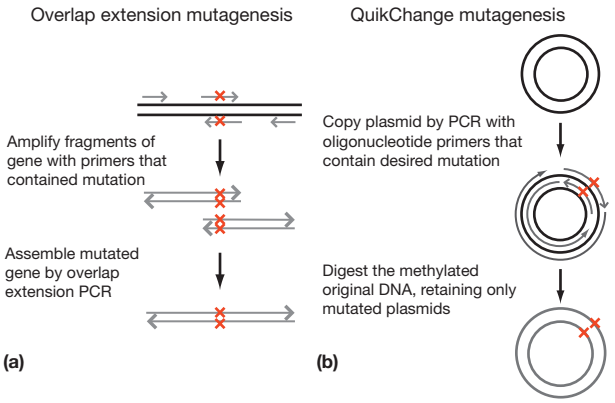

Figure 2 Site-directed mutagenesis methods are well established. Two commonly used techniques are overlap extension and QuikChange mutagenesis. Both employ oligonucleotide primers and PCR and can be used to introduce mutations, deletions, or insertions into target genes.

Because of the plethora of well-practiced mutagenesis techniques, the true challenge for using site-directed mutagenesis to rationally engineer a protein is how to select which residues to mutate and to decide which amino acids they should be mutated to. We describe three main approaches: (1) analyzing a protein's amino acid sequence, (2) extracting information from three-dimensional structures, and (3) employing computational algorithms to model proteins and predict mutations *in silico*.

4.412.2.1.1. Analyzing amino acid sequences

4.412.2.1.1.1. Sequence homology

In some cases, simply knowing the primary structure of a protein can provide sufficient information for rational protein engineering. If structure–function relationships have not been elucidated, comparing a protein's sequence to the sequences of related proteins, such as other species (orthologs) or family members (paralogs), can identify potential sites to mutate. The basic assumption of this approach is that natural evolution has already sampled and selected the optimal amino acids at a given position. When homologous proteins are aligned, the consensus residues (amino acids that appear in the majority of the proteins) have been shown to contribute most favorably to the protein's function.[9,10]

This homology-driven strategy was first applied toward engineering proteins for improved thermostability. One initial report described the improved stability of immunoglobulin variable domains.[10] By aligning sequences from a database of immunoglobulins, Steipe and colleagues assigned free-energy contributions to protein stability based on the frequencies of amino acids in every position. Six out of 10 predicted individual mutations were found to be stabilizing. In a simpler analysis, residues to mutate were identified only by their low occurrence rate among homologs.[11] Sequences of 130 chaperone proteins were aligned, and residues that occurred at a low frequency (<20%) were replaced with the most frequently occurring residue at that position. Out of the 18 mutations identified, 13 were stabilizing: a 72% success rate. Stability of enzymes can also be improved with this method. In one example, a consensus mutant phytase based on 13 fungal enzymes achieved a 15–22 °C increase in unfolding temperature compared to its parental variants.[12]

This consensus mutation concept is now being applied to improve protein properties other than stability. For example, a luciferase protein was aligned with similar proteins from 14 different species.[13] Point mutations were chosen at positions where wild-type differed significantly from the consensus residue and their effects were evaluated individually. Favorable mutations were then combined to create a mutant luciferase that exhibited a fourfold increase in total light output compared to wild-type. Taking this approach even further, a novel fluorescent protein was successfully created by combining consensus mutations from 31 different fluorescent proteins.[14]

4.412.2.1.1.2. Cysteines and disulfide bonds

In two special cases, general knowledge of protein structure and function allows proteins to be engineered without homology information. For this purpose, two handles can be used: cysteine residues (which are able to form disulfide bonds) and glycosylation sites. Glycosylation is a posttranslation modification involving carbohydrate groups and is discussed further in Section 4.412.2.3.1. Cysteine is a unique amino acid as its side chain contains a free thiol group, which often reacts with another thiol (usually another cysteine residue) to form a disulfide bond. If properly formed, disulfide bonds can stabilize proteins and promote stability. However, if incorrectly formed within the protein or between proteins, they can create misfolded protein variants or inactive dimers and oligomers. Thus, cysteine pairs can be introduced into proteins to form disulfide bonds in an attempt to stabilize proteins. Determining the site of disulfide bond insertion usually requires higher order structural information, which is discussed in Section 4.412.2.1.2. In the reverse approach, cysteines can also be removed when they interfere with a protein's stability; this usually occurs when there is an odd number of cysteine residues. Such was the case with both human interferon (IFN-β) and granulocyte-colony stimulating factor (GCSF).[15,16] Free cysteine residues in these proteins were replaced with serine (the amino acid most similar to cysteine), resulting in improvements in thermal and pH stability.

It should be noted that disulfide bonds do not always stabilize proteins. One example of this was found in the case of human fibroblast growth factor-1 (FGF-1),[17,18] which contains three cysteine residues. Two of these cysteine residues are highly conserved, occurring in 11 and 18 out of the 18 FGF family members, and were thought to form a disulfide bond. However, when these two cysteines were both substituted with serine, the protein's half-life at 37 °C increased from 0.26 to 13 h. It was hypothesized that the presence of a disulfide bond in FGF-1 actually destabilizes the protein and is evolutionarily favored to provide more responsive control over FGF-1 levels in the body. For regenerative medicine applications, however, a more stable variant of FGF-1 would be desirable.

4.412.2.1.2. Applying three-dimensional structures

Knowledge of a protein's three-dimensional structure provides significantly more information than the sequence alone, allowing hypothesis-driven mutations to be introduced. There are currently more than 50 000 protein structures in the Protein Data Bank (PDB) (PDB annual report 2009). Structures are

most often determined through X-ray crystallography (~90%) but can also be obtained through nuclear magnetic resonance (NMR) and electron microscopy.

Structural information allows protein visualization and determination of the three-dimensional location of residues; this information can be used for a variety of purposes. One application is to determine which residues are surface-exposed. Residues on the protein surface interact with water, thus it is often more favorable for those residues to be hydrophilic, as hydrophobic residues can decrease protein stability and promote aggregation. This is often a problem when a protein is truncated or a single protein domain is expressed alone for a particular biological application. For example, production of a subunit of cholera toxin A1 (CTA1) maintained the desired adjuvant activity of the full protein, but exhibited poor solubility.[19] However, by mutating two hydrophobic residues located on the newly exposed surface to hydrophilic amino acids, the solubility of the CTA1 subunit was improved threefold over the wild-type subunit.

Another approach where structural information is useful in protein engineering is the introduction of disulfide bonds to increase protein stability (see **Section 4.412.2.1.1.2**). Disulfide bonds are covalent cross-links between cysteine side chains in a protein and can potentially stabilize the protein against unfolding. By analyzing the crystal structure of dihydrofolate reductase, researchers were able to locate a free cysteine in the protein and inserted a cysteine residue in an adjacent protein chain.[20] The formation of this disulfide bond stabilized the reductase, but also resulted in a loss in activity, presumably from restriction of the enzyme's motion. Other disulfide bond introductions have been more successful. For example, a disulfide bond was introduced into the bacteriophage T4 lysozyme, which improved its half-life 2.5-fold over wild-type enzyme.[21,22] However, it is often difficult to predict from structural information alone what locations in proteins will be amenable to modification. As a result, there have been many studies that used model proteins in an attempt to develop more rational guiding frameworks. For example, the stabilities of two proteins, a trypsin inhibitor and a glucoamylase, were characterized after introduction or removal of disulfide bonds and mutation of residues that are known to participate in stabilizing interactions.[23,24] These studies revealed that disulfide bonds can stabilize both folded and unfolded states, and the overall effect on protein stability is a result of many balancing factors.

Structures can also provide information on covalent and noncovalent interfaces between protein domains and between proteins and their ligands. This information can then be used to promote or disrupt these interactions. In one example, insulin normally assembles into dimers or hexamers of protein subunits; an oligomeric state is beneficial for transport and storage, but can slow absorption by the body. In pursuit of a fast-acting insulin, researchers hoped to create a monomeric form of the protein and therefore studied the dimerization interface.[25,26] They pursued two strategies to achieve this goal: (1) introducing charge repulsions by inserting charged amino acids and (2) creating steric clashes by substituting amino acids with larger side chains. With this combined approach, insulin mutants were created that remained monomeric at pharmaceutically relevant concentrations (approximately millimolar) and resulted in two- to threefold improvements in absorption post injection.

Disrupting protein–protein interactions can also be an effective method to engineer receptor antagonists. An early example was the redesign of the human growth hormone (hGH).[27] A single hGH molecule has two interfaces that can bind two separate hGH receptors (hGHRs), inducing receptor dimerization and activation. From the crystal structure of hGH bound to hGHR, a glycine in one of the binding interfaces was identified for substitution with the bulkier amino acid arginine. This mutation disrupted the binding interaction through steric hindrance while leaving the second hGHR-binding interface intact. Thus, the hGH mutant could only bind a single receptor, preventing dimerization and activation of hGHR, thereby acting as an antagonist. In a related approach, a fragment of the hepatocyte growth factor (HGF) was also converted to an antagonist.[28] In this system, one HGF ligand binds to one Met receptor and activation of Met is achieved through ligand-induced dimerization. Through structural analysis, residues in the ligand interface were mutated to prevent dimerization. The resulting HGF fragments retained binding affinity, but no longer dimerized and activated the Met receptor.

Structural knowledge can also be applied to manipulate the specificity of protein interactions. This strategy was employed when researchers introduced a new T-cell receptor (TCR) into cells that already contained endogenous TCRs.[29] TCRs are formed by two subunits (α and β), and undesired hybrids could form between the introduced and endogenous TCR subunits. To prevent this, researchers studied the TCR-α- and TCR-β-chain interface and noticed a complementary steric interaction, where an amino acid in the β-domain fits into a pocket in the α-domain. To obtain specificity with their exogenous TCR, the authors cleverly reversed this interaction, mutating the TCRs such that the amino acid in the α-domain now fit into a pocket in the β-domain. This strategy conferred selective assembly of the introduced TCR chains to each other while maintaining the TCR's antigen-binding capability.

4.412.2.1.3. Predicting through computational modeling

In recent years, many computational algorithms have been developed to model protein folding and behavior, further increasing the ability to rationally choose sites for mutation.[30–33] These methods can estimate the energetic interactions between atoms in the proteins, taking into account steric, solvation, and electrostatic effects. Performing experiments *in silico* enables many more mutations to be considered compared to site-directed mutagenesis, and the power of these methods to engineer proteins for desired properties is rapidly growing. Computational approaches have now been successfully used to improve protein stability,[34] tailor-binding affinity, and cell trafficking,[35] and even create novel protein folds.[36]

Much of the early work in this area was focused on improving protein stability. Using three-dimensional structures as guides, parameters such as side-chain packing and hydrophobic surface area could be optimized. In one example, researchers were able to demonstrate their computational power by analyzing the stability of 10^9 mutants of the streptococcal protein G β1 domain (Gβ1).[37] Variants of Gβ1 were created that remained completely unfolded, formed a

disordered molten globule, or exhibited improved stability over wild-type. The model was also able to specifically target only interior protein residues, leaving surface epitopes alone. This is an important component, as a protein could be engineered for improved stability while leaving its binding interactions and biological function unaffected. Using this approach, 10^{28} mutants of the cytokine GCSF were computationally screened for stability, resulting in a mutant with an extended shelf-life up to 10-fold over wild-type and no deleterious effects on *in vivo* activity[38] (Figure 3).

Another strategy is the design of a protein interaction with its binding partner. This can be performed on a basic level by considering electrostatic interactions between proteins, such as a ligand-receptor interaction. One study by Sarkar and colleagues hoped to improve the biological potency of GCSF by maintaining wild-type affinity of GCSF for its receptor at the cell surface, but reducing the affinity of GCSF for its receptor once it was internalized into acidic components within the cell.[35] It was hypothesized that this differential binding would lower the chance of GCSF being trafficked for degradation. The researchers were able to model the electrostatic interactions between GCSF and its receptor at the cell surface (physiological pH) and inside intracellular compartments (low pH) and found two locations where a histidine residue could be substituted. Histidine's unique pK_a allows it to be neutral at physiological pH and charged at low pH, thereby disrupting any electrostatic interactions and altering binding affinity. As predicted, the two GCSF histidine mutants exhibited reduced intracellular degradation and enhanced cell proliferation by 50–100%, depending on dosage.

Electrostatic interactions are only a part of this complex story. To more fully model protein interactions, properties such as packing, desolvation energy, and the burial of hydrophobic surface area should also be taken into account. All these factors were incorporated into a Poisson–Boltzmann continuum model to improve the binding affinity of two antibodies for their targets by 10- to 140-fold, achieving final dissociation constants of 52 and 30 pM, respectively.[39] In another example, the affinity between integrin lymphocyte function-associated antigen-1 and its ligand intracellular adhesion molecule-1 was improved ~20-fold by also including proper folding as a modeling parameter.[40]

Novel binding specificities have also been achieved by promoting interactions to a desired target while purposefully impairing binding to unwanted proteins.[41] This strategy combining positive and negative design was employed to identify peptides that bound human basic-region leucine zipper (bZIP) transcription factors.[42] Engineered peptides selectively bound their targets over representative bZIPs from all 20 bZIP families, despite the substantial overlap in sequence and structure between the bZIP proteins.

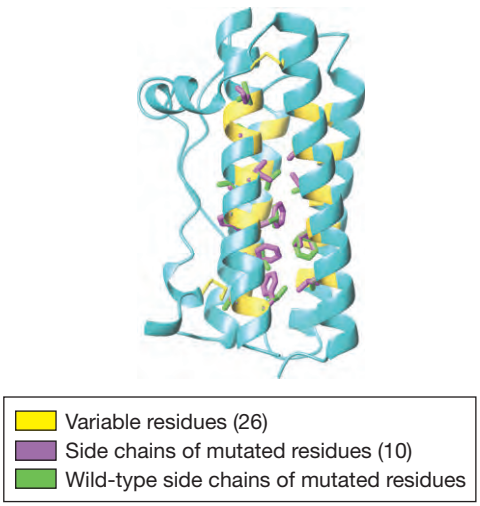

Figure 3 Computational modeling of hydrophobic core packing. Using the structure of bovine granulocyte-colony stimulation factor (GCSF) as a model, the core residues of human GCSF were identified (yellow) and optimized for enhanced packing while minimizing changes in overall protein structure. The resulting GCSF variant had 10 mutations (wild-type side chains in green and substituted side chains in purple) and possessed enhanced thermal stability while retaining full biological activity. 4.412.2.2. Fusions and Domain Swapping

Despite progress made with site-directed mutagenesis approaches, predicting the effects of mutations remains a great challenge. Alternatively, if a desired property already exists in a different protein, rational engineering can often be accomplished by simply fusing or swapping peptide and protein domains (Figure 4). In certain cases, the introduction of short peptides into a protein framework or 'scaffold' can be sufficient to gain binding capabilities. However, to achieve high binding affinity and specificity, combinations of recognition sequences must often be used and their surrounding residues optimized. Problems with binding specificity and structural context can also be solved by fusing entire proteins or protein domains instead of peptides. Furthermore, protein domain fusions can bring the added benefit of properties besides improved binding affinity, such as increased biological potency and circulation half-life.

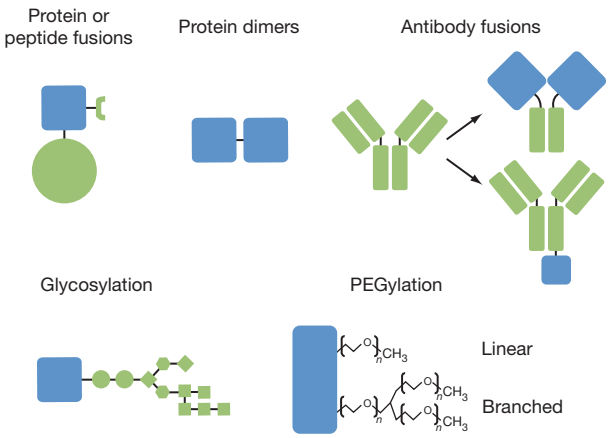

Figure 4 Rational protein engineering through fusions and posttranslational modifications. Besides site-directed mutagenesis, a variety of methods can be used to rationally engineer proteins. Functionality can be added by genetically fusing the target protein to itself to form a dimer or to other proteins and peptides. Natural and synthetic molecules, such as carbohydrates or polyethylene glycol, can also be conjugated posttranslationally to proteins. Blue = protein of interest, Green = fusion partner.

4.412.2.2.1. Peptide fusions

One of the simplest protein recognition sequences is the three amino acid sequence arginine-glycine-aspartic acid (RGD).[43–45] This motif was originally identified as the minimum sequence in fibronectin that maintained recognition for the integrin family of receptors, which are responsible for cell adhesion. RGD was subsequently identified in many different proteins that exist in the ECM, such as vitronectin, collagen, and fibrinogen, and its use was heavily pursued in applications to improve material biocompatibility or to block cell adhesion in cancer. The first approaches focused on the RGD motif, and many RGD-containing peptides were synthesized in a variety of structural contexts – linear and cyclic – with different neighboring amino acids.[46] These peptides were found to be effective in promoting cell adhesion and proliferation[47] and in blocking integrin receptor interactions.[48,49]

Unfortunately, one binding epitope alone is often not sufficient to achieve high affinity or specificity. This was a common limitation to the RGD peptides mentioned above,[50] as many had suboptimal binding affinity for a range of integrin receptor family members. To improve these properties, multiple-binding epitopes can be combined together. Fortunately, several recognition sequences in addition to RGD were discovered in fibronectin and other proteins.[43,51,52] Fusing two or more of these motifs together can result in improved recognition, but the order of the fused epitopes and the linker between them can play a major role on their presentation and often requires optimization. To investigate this, RGD was fused with two other peptides from fibronectin (PHSRN and PRRARV) in different arrangements to find an optimal combination *in vitro*.[53] The selected constructs were then tested in rat models, and the attachment of RGD with the PHSRN motif was found to more effectively elicit macrophage adhesion and activation.[54]

4.412.2.2.2. Protein fusions

The use of short peptide fusions ultimately limits the binding affinity and specificity that can be achieved. This can be overcome by expanding fusion partners to entire proteins or protein domains. Continuing the example of the RGD peptide described above, improved binding specificity to defined integrin receptors has been achieved by replacing the RGD and PHSRN peptides with entire fibronectin domains to better mimic the natural protein structure.[55–57] In addition, protein fusions can enhance biological activity through a variety of other mechanisms. For example, enhanced agonistic chimeras were constructed from epidermal growth factor (EGF) and transforming growth factor α (TGF-α).[58] EGF and TGF-α both bind to and activate EGF receptor (EGFR) but elicit distinct responses due to differences in intracellular trafficking. By fusing truncated versions of EGF and TGF-α, several EGF/TGF-α chimeras were created with optimal binding and cell trafficking properties, resulting in 10-fold improvements in mitogenic activity compared to EGF or TGF-α alone.

Larger proteins can also increase biological potency by extending circulation lifetime in the body. This increased half-life results from an increase in size, as the kidneys rapidly filter out lower molecular weight proteins below a threshold of 60 kDa. A straightforward approach is to create a dimer by genetically fusing two copies of the protein together, as was done with erythropoietin.[59] The erythropoietin dimer had the benefit of improved pharmacokinetics, as well as increased specific activity due to avidity effects. Alternatively, molecular weight can be increased by fusing completely unrelated proteins. Recently, an unstructured polypeptide, XTEN, was developed as a generic fusion partner to increase molecular weight.[60] XTEN was designed to mimic the effect of conjugating proteins to synthetic polymers, such as PEG (see **Section 4.412.2.3.2**), and increased the half-life of a 39-residue peptide, exenatide, by 100-fold.

Besides increasing a protein's molecular weight, certain protein fusions can act as carrier molecules. For example, human serum albumin is the most abundant protein in serum and has an *in vivo* half-life of several weeks.[61] Fusing albumin to a soluble form of CD4, a T-cell membrane protein, was shown to improve the half-life 140-fold over soluble CD4 alone in a rabbit model without any change in activity *in vitro*.[62] Similarly, over a 100-fold increase in circulation half-life was seen after fusing albumin to hirudin, a thrombin inhibitor.[63] Again, the type of fusion can require optimization: fusing albumin to the *C*-terminus of hirudin inhibited its biological activity, whereas fusing it to the *N*-terminus did not. The complications with complete albumin fusions led some researchers to instead fuse albumin-binding peptides. These shorter peptides have been shown to possess the desired effects with examples of half-life improvements of 3-fold with a natural albumin-binding domain taken from streptococcal protein G[64] and 37-fold with an engineered peptide.[65]

Antibody domains are another common protein fusion partner.[66–68] Antibody constant regions can increase a protein's circulation half-life by increasing the molecular weight as well as by promoting interactions with various receptors. Such fusions might also increase the binding avidity of proteins due to the divalent nature of antibodies. Both of these benefits were seen with etanercept, a fusion between the extracellular domain of tumor necrosis factor receptor (TNFR) and the constant region of IgG.[69] The affinity of the fusion increased 50-fold compared to the monomer and resulted in a 5-fold increase in circulation half-life.[70] The divalent antibody structure can also be exploited to join variable domains with different binding specificities, thereby creating bispecific proteins.[71,72] For example, variable domains targeting a tumor-associated antigen and a surface receptor on immune cells, such as EGFR and the T-cell receptor CD3, respectively, can be fused to retarget effector immune cells to cancer cells. High antibody affinity and specificity can be exploited to target cytokines as well, allowing localized delivery of cytokines and reduced systemic toxicity.[73,74] Several fusions between antibodies specific for various tumor markers and immune stimulatory cytokines, such as interleukin-2 (IL-2) and interleukin-12 (IL-12), are currently in clinical trials.

4.412.2.3. Posttranslational Modifications

4.412.2.3.1. Glycosylation

Many modifications, such as phosphorylation, acylation, methylation, and glycosylation, occur naturally after translation to control protein behavior and function. Although of interest from a purely biological standpoint, these processes are also attractive for protein engineering, as they are potential

opportunities to optimize proteins for different applications. Unfortunately, the rules governing most of these modifications are unknown or insufficiently characterized. For example, despite considerable efforts, phosphorylation and *O*-linked glycosylation sites are just beginning to be accurately predicted with accuracies from 70 to 90%.[75–78] Much increase in knowledge is required before these modifications can be inserted rationally into proteins. The exception is *N*-linked glycosylation, which occurs cotranslationally in most cases and is therefore heavily determined by primary structure.[79–81] The consensus sequence required for this modification is the tripeptide sequence asparagine-X-serine/threonine, where X is any amino acid except proline.

Armed with this motif, researchers have pursued *N*-linked glycosylation as a strategy for protein engineering. One major application is to use glycosylation to increase a protein's molecular weight, much like the fusions proteins mentioned above. Erythropoietin was one of the earliest proteins to be altered in this manner. This was an appropriate model system because erythropoietin is already heavily glycosylated – 40% of the native protein's molecular weight is carbohydrate – and its activity is known to be dependent on its three native glycosylation sites.[82] Several dozen glycosylation sites were introduced at locations known not to be involved in the binding of erythropoietin to its receptor.[83] However, only a few of the resulting mutants were successfully glycosylated and retained biological activity. By combining two of these mutants, a novel erythropoiesis stimulating protein (NESP) was created. NESP had five *N*-linked glycosylation chains, retained biological activity *in vivo*, and exhibited a threefold increase in half-life.[84] This strategy has been extended with varying degrees of success. For example, glycosylation sites were identified in tissue plasminogen activator (tPA) that contributed to or detracted from tPA's specificity and clearance.[85] In other work, several glycosylation sites were successfully introduced into more challenging targets: the hormone leptin, which naturally is not glycosylated, and the cytokine megakaryocyte growth and development factor, which normally undergoes *O*-linked glycosylation.[86]

4.412.2.3.2. PEGylation

Despite the existence of a consensus sequence, successful and effective *N*-linked glycosylation remains challenging to predict. An alternative approach is to mimic nature by conjugating proteins with synthetic molecules instead. The most popular polymer for protein conjugation is PEG. PEG is a stable, water-soluble polymer that has been shown to be nontoxic and nonimmunogenic.[87] Conjugation to PEG, also known as PEGylation, has been shown to effectively reduce protein clearance, improve temperature and pH stability, prevent enzymatic degradation, and protect against immunogenicity.[87–89] Most importantly, PEG has been approved by the Food and Drug Administration (FDA), and many PEGylated drugs, such as the asparaginase (Oncaspar) and adenosine deaminase (Adagen), are currently in use in the clinic.

However, PEGylation is not a formulaic procedure. There are several parameters that can affect the outcome, such as the size and type of the PEG polymer, the number of PEGs conjugated, and the type of conjugation. Initial work with asparaginase and adenosine deaminase used low-molecular-weight, single-chain PEG polymers (~5 kDa) and conjugated proteins through their free amino groups on lysines residues and the *N*-terminus.[87,89] Notably, in addition to increasing biological potency by extending half-life, PEGylation also reduced the immunogenicity and incidence of hyperallergic reactions from asparaginase, which is produced in bacteria.[90,91]

Since these early examples, different avenues for PEGylation have been explored to develop protein conjugates that are more homogeneous and efficacious, such as the use of larger or branched PEG molecules. In one case, when IFN-2α was PEGylated with a 5 kDa polymer, no advantage was seen over unconjugated interferon in clinical trials.[87,92] In contrast, conjugation with a 40 kDa branched PEG polymer (Pegasys) reduced renal clearance 100-fold and extended the half-life from 9 to 77 h.

Alternative conjugation methods are also being developed to improve control over the PEGylation reaction.[93] Lysine is one of the most prevalent amino acids; thus when its ε-amino group is used as the PEG attachment site, heterogeneous products result which can block binding and biological activity. By exploiting the slightly lower pK_a of the *N*-terminal amino group over the lysine side chain, specific conjugation at the *N*-terminus can be achieved, as first demonstrated with human GCSF.[94] PEGylation can also be performed through thiol groups on cysteine residues. Thiol chemistry is well established, but free cysteines are generally rare in proteins. Cysteines have been inserted into hGH, GCSF, and interferon for successful site-specific PEGylation.[95] Enzymes have also begun to be used for specific conjugation. For example, transglutaminase was exploited for attaching an amino-PEG molecule to single glutamine residues in IL-2.[96] Enzymes with other amino acid substrates, such as tyrosine, are known and could also potentially be used for specific conjugation in the future.[97]

Site-specific incorporation of nonnatural amino acids offers ultimate control over the point of attachment. Pairs of orthogonal tRNA and tRNA synthetases can insert amino acids with a unique chemical handle at defined locations in proteins, enabling specific conjugation to PEG or other molecules without the risk of nonspecific attachment.[98] This method has been used to effectively reduce the heterogeneity of PEGylated hGH and enabled the creation of variants with single, uniform PEG conjugations.[99] Site-specific conjugation of PEG to hGH using nonnatural amino acids resulted in several promising candidates that exhibited improved half-life over the current commercial formulation.[100]

4.412.2.3.3. Other emerging modifications

The success of glycosylation and PEGylation has sparked research into other potential protein modifications. A survey of different nonionic water-soluble polymers identified polyvinylpyrrolidone (PVP) as a potential PEG alternative.[101] Several polymers had greater circulation lifetime than PEG, but PVP exhibited minimal tissue accumulation. Unlike PEG, PVP can also be polymerized with additional functional groups, potentially allowing more opportunities for targeting and control than PEG. PVP was conjugated to tumor necrosis factor-α (TNF-α) and exhibited a twofold improvement in antitumor activity *in vivo* compared to TNF-α conjugated to a PEG molecule of similar molecular weight.[102]

Outside of synthetic polymers, fatty acids have also been conjugated to proteins. Fatty acids have a weak binding

interaction with albumin and can be used to increase circulation half-life in a similar strategy to the albumin and albumin-binding peptide fusions described above. In one study, chains of 10 to 16 carbon atoms were conjugated to insulin through a lysine amino group and the resulting proteins were screened for binding affinity to insulin receptor and biological activity.[103] Although attachment of a 14-carbon fatty acid chain decreased the affinity to 46% of unconjugated insulin, this acylated analog (Insulin Detemir) resulted in a more stable insulin profile over time with lower variability.[104,105]

4.412.3. Combinatorial Engineering

Although there are many examples of where rational protein engineering has been successful, our understanding of the relationships between protein sequence, structure, and function is far from complete. Thus, many attempts to rationally engineer proteins fail, and introducing complex properties, such as altered enzyme substrate specificity or novel molecular recognition interfaces, is often unachievable. Combinatorial-based methods provide a powerful alternative for protein engineering. Also known as directed or *in vitro* evolution, combinatorial engineering does not require any prior knowledge of protein structure or function. Instead, it mimics the process of natural selection in the laboratory in three steps. First, diversity is introduced into a gene of interest to create a library of DNA sequences. This mutant DNA is then translated into a protein library. Finally, the protein library is screened for a desired property and improved mutants are isolated. This process can be repeated multiple times with additional diversity introduced in each round of evolution. Critical to this process is the maintenance of a genotype–phenotype linkage, meaning that, once a desired protein is identified from the library, its DNA sequence, and hence amino acid sequence, can be determined.

Major advances in molecular biology have allowed directed evolution to become the dominant approach for protein engineering. The technology can be divided in two main parts that are mostly independent: (1) methods to generate library diversity and (2) platforms to express and screen protein libraries. These last two steps in the evolution process are combined because of the requirement to maintain a link between genotype and phenotype.

4.412.3.1. Library Creation

As the first step in the directed evolution process, constructing an appropriate gene library is crucial for overall success. Key decisions are the level of diversity to be introduced and where in the protein to introduce such diversity. High diversity will likely increase the probability of generating an improved mutant; however, this will also increase the number of protein variants that lose their activity. The location of protein mutations is important because the level of diversity that can actually be sampled by current screening platforms is limited. Even the best platforms are limited to screening approximately 10^{14} proteins, which is equivalent to randomizing only 11 amino acids. Therefore, targeting diversity to specific amino acids allows a more thorough library evaluation.

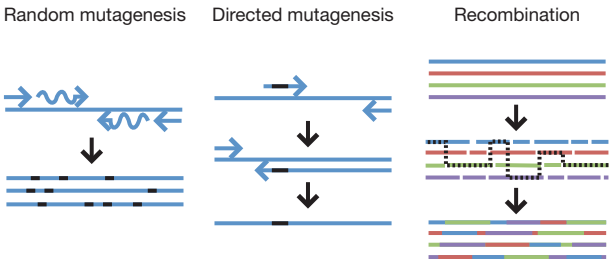

Figure 5 Library creation methods. There are three main approaches to library construction: random mutagenesis, directed mutagenesis, and recombination. Each technique enables different types of mutations to be introduced into a gene such that the optimal method is often a combination of all the three approaches.

On account these factors, trade-offs must be made for different protein engineering applications. To help overcome this dilemma, many different strategies for library creation have been developed. They can be divided into three categories: random mutagenesis, directed mutagenesis, and recombination[106,107] (Figure 5). In random mutagenesis, mutations are created throughout the protein, most commonly by error-prone PCR. This approach is often taken when no previous knowledge of structure–function exists and in attempts to find a protein's 'hot spots.' Directed mutagenesis is the mutation of specific residues in a protein. As mentioned above, limiting the diversity to specific amino acids or regions enables improved sampling of the resulting library. Lastly, recombination introduces diversity by fragmenting a pool of homologous genes and randomly assembling the pieces back into full-length mutants. This increases the likelihood of active proteins in the library and is also a powerful way to combine vastly different sequences. Each of these three methods has its advantages, and a combination of the three is typically used in current combinatorial engineering projects.

4.412.3.1.1. Random mutagenesis

As the name implies, random mutagenesis is the introduction of mutations, insertions, or deletions randomly throughout the entire gene. The predominant methods rely on increasing the error rate in natural DNA copying processes. The earliest techniques were cell-based, using chemical or physical mutagens to introduce errors.[106,108] Specialized bacterial strains were also developed that lack DNA proofreading or editing mechanisms.[109] However, both these approaches have several drawbacks. For example, they lack discrimination: mutations can occur in the gene of interest, the plasmid carrying the gene, or the chromosome of the host. This can result in unwanted alteration of the host or loss of mutator phenotypes. Treated hosts and mutator strains also grow slowly and generally have a low error frequency, requiring several cell divisions for only one or two mutations.

Because of these disadvantages, methods based on PCR have almost completely replaced cell-based methods. PCR is a fast, widespread technique and by nature is specific to the gene of interest. Besides the template sequence and amplifying primers, a PCR reaction is composed of DNA polymerase, deoxyribonucleotides (dNTPs), and buffer. All the three of these components can be exploited to adjust the mutation

frequency of a PCR reaction.[107,110] The simplest component to modify is the buffer. Magnesium chloride ($MgCl_2$) is an important compound in PCR reactions that stabilizes DNA and its interactions with DNA polymerases. Errors can be introduced by stabilizing noncomplementary pairs with higher $MgCl_2$ concentrations.[111] In addition, $MgCl_2$ can be substituted with manganese chloride ($MnCl_2$) to generate even higher error rates.[112]

Unfortunately, manipulating mutation rates with $MgCl_2$ and $MnCl_2$ can severely reduce the efficiency of the PCR reactions. To achieve increased error rates without reducing product, the dNTP composition of the reaction can be changed. Misincorporation can be promoted by lowering the concentrations of certain dNTPs relative to others.[111] For example, by lowering the concentration of dATP, 'wobble' pairs can be formed between G and T, leading to A→G mutations. In the next round of duplication, these can also lead to T→C mutations. Although effective in increasing error rates, simply lowering the level of dATP clearly limits the types of mutations possible. An ideal mutation strategy would allow all point mutations with equal probability. This goal is more approachable using nucleotide analogs, which can be incorporated across different natural bases. In this case, a universal base analog which can pair with all the natural bases equally is desired, and many different analogs have been produced and tested.[107] The best results are often achieved by combining the strengths of different analogs. For example, one analog can be optimized for transition mutations (purine to purine or pyrimidine to pyrimidine) and one can be used to introduce transversion mutations (purine to pyrimidine or vice versa).[113]

Finally, the DNA polymerases themselves can be engineered for increased mutation frequencies. The *Taq* polymerase from *Thermus aquaticus* has a natural high error rate of 8×10^{-6} per bp because it lacks a 3′→5′ proofreading mechanism.[114] This error rate is still not sufficient for most protein engineering applications, but mutation of *Taq* polymerase at its dNTP-binding site allowed a 20-fold higher error rate to be achieved.[115] However, mutational biases still exist as *Taq* polymerase is fourfold more likely to mutate A and T than G and C. As an alternative, a modified *Pfu* polymerase from *Pyroccocus furiosus* can be used, which has been mutated to remove its proofreading ability and hinder its dNTP binding.[116] Proprietary polymerases are also available to achieve balance in mutations. Mutazyme (Stratagene) claims to mutate G and C threefold more than A and T, and a mix of Mutazyme and Taq, called Mutazyme II, is purported to balance their respective biases to produce an even spectrum of mutations.

While much progress has been made in developing technologies for random mutagenesis, PCR-based methods still have an inherent limitation because they generally create only point mutations and rarely perform insertions or deletions. Methods have been developed to insert specific sequences in a random manner, but only more recently has a technique been developed to randomly insert or delete nucleotides.[106,117,118] The random insertion or deletion method is technically challenging, combining several digestion, ligation, and amplification steps with a random Ce(IV) nuclease treatment. But, with this method, up to 16 bases have been successfully inserted and deleted.

4.412.3.1.2. Directed mutagenesis

If some information about the protein's structure (and perhaps function) is known, libraries can also be created by directed mutagenesis, where diversity is generated at specific amino acids within a protein. With the advent of inexpensive and widely available methods for DNA synthesis, the number of amino acids that can be mutated ranges from one to many, and substitutions at particular locations can be controlled. Entire genes, or alternatively, sets of oligonucleotides, can be synthesized by commercial suppliers with nucleotides randomized at defined positions. With careful design to allow sufficient overlap between them, the oligonucleotides can be incorporated into full-length genes using the PCR assembly and overlap extension techniques discussed in **Section 4.412.2.1**.[119]

The most straightforward method to randomize a codon is to replace it with NNN, where N can be any of the four bases (A, T, G, or C) with equal probability. This will result in $4 \times 4 \times 4 = 64$ different codons which encode for all 20 amino acids. One disadvantage of using NNN codons is that redundancy in the genetic code causes biases. For example, certain amino acids, such as serine and arginine, are encoded by six codons, whereas others, such as methionine and tryptophan, are encoded by only a single codon. Thus, an NNN codon is six times more likely to encode a serine than a methionine. A second complication is that the set of all 64 codons includes the three stop codons, resulting in undesired truncations in the protein library.

To limit the effects of this bias, the possible number of codons can be restricted by limiting the variation in the third codon position (**Table 1**). For instance, instead of A, G, C, and T, only two or three nucleotides can be allowed at this position.[106,120] Depending on which combinations are selected, it is possible to completely avoid stop codons. For example, if the third position is limited to only a C or T, no stop codons are included, but the penalty is that only 15 of the 20 amino acids are encoded. Thus, a balance must be made between bias, truncations, and diversity. A common compromise is restricting the third codon to a C or G. The resulting 32 possible codons encode for all 20 amino acids and only 1 stop codon.

Besides amino acid bias and the introduction of stop codons, randomizing individual nucleotides also make it difficult to encode specific subsets of amino acids. For example, one might want to randomize a surface residue with only polar amino acids instead of all 20 possible amino acids. Or one might want to exclude the amino acid cysteine from the library to avoid undesired disulfide scrambling with other residues in the protein. All these challenges can be solved by constructing DNA libraries from defined codon mixtures.[121,122] However, the cost and technical hurdles faced in building these types of

Table 1 Codon bias in library design

	Number of total sequences	*Number of amino acids*	*Number of stop codons*
NNN	64	20	3
NNC/G/T/(NNB)	48	20	1
NNG/T/(NNK)	32	20	1
NNC/G/(NNS)	32	20	1
NNC/T(NNY)	32	15	0

libraries are significant, and thus these methods are not as widely used. Alternative approaches, such as using hybridization to isolate desired codons, are being actively pursued.[123]

4.412.3.1.3. Recombination

DNA recombination is the process of rearranging pieces of DNA, often between homologous regions. This process occurs in natural evolution and has been exploited for combinatorial protein engineering in the past decade with the development of DNA shuffling technology. In this short time period, recombination for DNA library construction has emerged as a strong complement to the random and directed mutagenesis methods described above.[124]

DNA shuffling was the first method to allow simple DNA recombination *in vitro*.[125,126] The starting material is a pool of homologous genes, such as a random library generated through error-prone PCR or genes from related species or family members. This pool is first digested with the enzyme DNAseI, which nonspecifically cleaves the DNA to create small fragments around 50 base pairs long. PCR assembly is then used to randomly reassemble or 'shuffle' the fragments into full-length genes, each composed of pieces from multiple original templates. The PCR assembly process can also be used to introduce additional randomized mutagenesis through error-prone PCR.

Many alternative techniques to perform recombination have followed, each with its own advantages and disadvantages.[124] For example, a slightly simpler method called staggered extension process (StEP) was developed to eliminate the fragmentation stage. In this method, recombination occurs by extending template sequences through extremely short annealing and extension steps, and the entire process occurs in a single tube.[127] Unfortunately, both shuffling and StEP require significant homology between templates for successful recombination. Therefore, alternative methods were developed to perform recombination with lower homology templates. In one method, random chimeragenesis on transient templates (RATCHITT) allowed recombination with only five base pairs of homology.[128] Pushing even further, incremental truncation for the creation of hybrid enzymes (ITCHY) required no homology.[129,130] However, these alternative methods have their concurrent drawbacks, many of them being more technically challenging than the original DNA shuffling protocol.

Despite their differences in recombination, all these techniques begin with the same material: a pool of homologous genes. As mentioned above, a random library created by error-prone PCR is a straightforward option.[131] A more focused approach is to recombine mutations identified from a previous protein engineering screen or selection, thereby increasing the probability of retaining proper protein structure and function. Alternatively, a family of natural genes from one or multiple species can be recombined in a method known as 'family shuffling'; the rationale for this strategy is that Nature has already selected mutations that are ideal for proper protein fold and function through millions of years of evolution.[132]

Bypassing the digestion step, the starting material for recombination can be performed or supplemented with custom-made DNA fragments. For example, primers can be used to introduce diversity into specific regions of genes with error-prone PCR.[133] These sections can then be recombined using the constant primer regions for homology, thereby combining elements of random mutagenesis, directed mutagenesis, and recombination. Completely synthetic oligonucleotides can be used as the source template as well.[134,135] Finally, as a complementary strategy to both family and synthetic oligonucleotide shuffling, orthologous mutations can be doped into a shuffled library to bias mutations toward those that Nature has already selected for folding and function, in a process known as shotgun ortholog scanning mutagenesis (SOSM).[136]

4.412.3.2. Screening Platforms

Once a gene library is constructed, the next step in the combinatorial engineering process is to express and screen the protein library for desired properties. To increase the chances of finding improved protein mutants, the three main objectives of screening platforms are to (1) express the library members in a folded, functional form, (2) reliably screen the library to identify mutants with a relevant phenotype, and (3) screen the highest number of possible proteins. The challenge is to do all of these things while maintaining the genotype–phenotype linkage, as once a protein is isolated from a library, the only way it can be identified is through sequencing the DNA that encoded it.

Screening platforms can be categorized on the basis of their approach to maintaining the genotype–phenotype linkage (**Figure 6**). Plate-based platforms rely on the physical separation of mutants into different wells of microtiter plates. This provides flexibility on the choice of protein expression system and enables a variety of screening readouts such as enzymatic or biological activity. But, depending on the plate density, throughput is limited to $\sim 10^4$–10^6 members. Higher throughput screening can be achieved using phage display and cell surface display (up to 10^{10} members). In these platforms, proteins are displayed on the surface of bacteriophage or cells, which package the encoding DNA inside. These libraries can then be screened by biopanning or flow cytometry to identify proteins with high binding specificity and affinity against a target of interest. Surface display on eukaryotic cells can also take advantage of their protein expression machinery for higher quality library expression. Most recently, *in vitro* techniques have been developed to physically link proteins to the DNA directly or to create artificial cells by emulsification. These platforms achieve the highest throughput, with the potential to screen up to 10^{14} protein variants.

4.412.3.2.1. Plate-based platforms

Perhaps the simplest in concept, plate-based platforms for directed evolution offer great flexibility in protein expression and screening. Unlike the display platforms discussed below, both *in vivo* and *in vitro* protein expression systems can be employed. The key requirement, however, is the ability to isolate sequences in separate wells to maintain the genotype–phenotype linkage described above. For *in vivo* expression, such as in *E. coli*, this can be done by picking colonies individually and inoculating cultures in the wells themselves.[137,138] For *in vitro* expression, a library of DNA templates can be diluted such that there is only one sequence per well.[139,140] These single templates can then be amplified by single-molecule PCR and used for subsequent *in vitro* transcription and translation reactions.

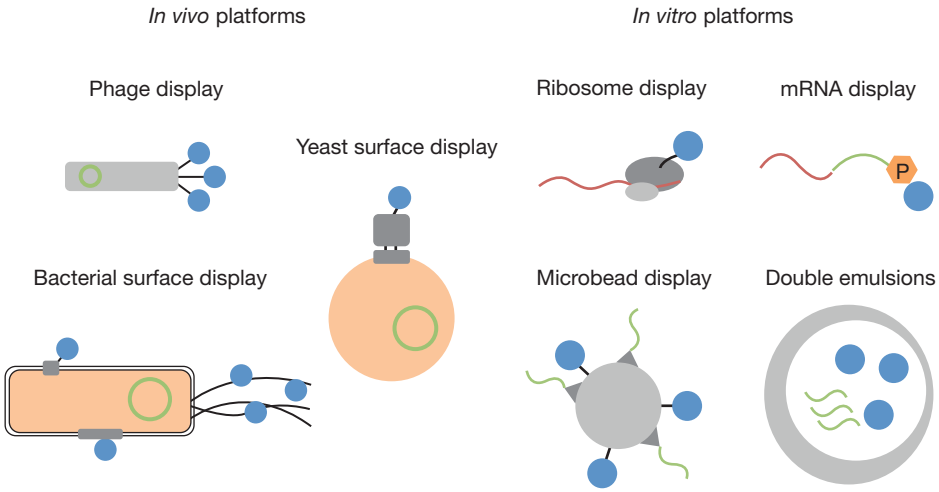

Figure 6 Screening platforms for combinatorial protein engineering. Directed evolution requires the maintenance of a genotype–phenotype linkage while screening for desired protein properties. A variety of *in vivo* and *in vitro* platforms have been developed to fulfill this requirement. Blue = protein to be engineered, Red = RNA, Green = DNA.

The options for screening are also quite diverse, as any assay compatible with a plate-based format can theoretically be used to analyze the protein mutants. One major application is enzyme engineering, where enzymatic activity can be reported through colorimetric or fluorescent readouts.[141,142] For example, the stereoselectivity of an aldolase was altered 100-fold and detected using a dye, which turns purple upon reduction.[138] Protein libraries can also be challenged with increases in temperature to screen for thermal stability, resulting in up to 500-fold increase in half-life at high temperatures.[137] Furthermore, the plate-based format is amenable to more complex assays such as measuring biological responses. For example, a screen was developed to measure the ability of EGF mutants to bind to the EGF receptor and transduce the signal inside the cell, as measured by luciferase expression.[143] In addition, a screen to measure antiviral activity was used to engineer a variant of human IFN-α with 10^2- and 10^5-fold specific activity relative to human IFN-α1 and IFN-α2a, respectively.[144] Recently, we developed a more general platform that enables efficient screening based directly on a cellular readout.[145] We applied this technology to identify EGF mutants that stimulate increased fibroblast cell proliferation over wild-type EGF, but the platform can potentially be combined with any cell-based functional assay.

The limitation of plate-based platforms is their throughput. In most instances, including the examples provided above, 96-well plates are used for expression and screening. This limits the library size that can be reasonably screened to $\sim 10^4$. This number can be improved by using robotic systems or increasing the plate density with 384-, 1536-, or even 6144-well plates.[146] But, the technical requirements and challenges of these methods limit their widespread use.

4.412.3.2.2. Phage display

To increase throughput and the library size that can be screened, display platforms were developed to establish physical genotype–phenotype linkages, removing the need to separate clones into individual microtiter wells. Phage display was the first method developed to accomplish this goal and is still the most widely used evolution platform.[147–150] The original phage-display system fuses peptides to surface-exposed p3 proteins of filamentous bacteriophage M13. *E. coli* are transfected with the phage genome containing this modified fusion protein. The *E. coli* produce phage with peptides displayed on their surface and the genome packaged inside, providing the genotype–phenotype linkage. Screening is accomplished by panning mixtures of phage against an immobilized target and washing to remove nonbinding clones. Phage displaying a peptide that binds a target of interest remains bound during these washes and can be eluted and amplified by reinfecting *E. coli* cultures.

The original phage-display system has been dramatically streamlined since its inception. Phage display is especially convenient for discovering small peptides that bind to desired targets. Peptide cloning systems and linear and cyclic peptide library kits are now commercially available (New England Biolabs, Inc.). Using phage-display technology, peptides have been isolated that bind to a variety of targets, including different integrin receptors, an HIV envelope protein, and even semiconductor surfaces.[151–153] In addition, peptides identified from phage-displayed libraries can be used as custom tags or fusion partners. For example, a phage-displayed peptide library was screened to isolate sequences that bound a model biopolymer, chlorine-doped polypyrrole (PPyCl).[154] PPyCl does not normally support cell growth. However, when it was treated with the identified peptides fused to the adhesive sequence RGD (see **Section 4.412.2.2.1** and **Chapter 4.414, Molecular Biomimetic Designs for Controlling Surface Interactions**), cells were able to attach and proliferate similar to standard tissue-culture-treated surfaces. In another application, a phage-displayed library was screened to identify a peptide that bound to albumin, thereby improving circulation half-life when fused to a protein (see **Section 4.412.2.2.2**).[65]

Variations have also been developed to expand phage display's applicability beyond simple peptides. For example, the spacing and valency (the number of copies of the displayed

protein per phage) can be optimized by controlling the expression levels of the fusion protein or by changing the fusion partner from p3 to one of the other four phage surface proteins, p6, p7, p8, or p9.[149,155] The types of proteins that can be displayed have also been expanded by controlling where the protein folds (cytoplasm vs. periplasm) and the transport mechanism of the fusion protein out of the cell.[156,157]

With these improvements, antibody antigen-binding fragments (Fabs) and single-chain variable fragments (scFvs) have been successfully displayed on phage.[158,159] Nonantibody scaffolds, ranging from the 95-residue 10th fibronectin type III domain (^{10}Fn3) to the 174-residue bilin-binding protein, have also been engineered to bind various targets.[160,161] The affinity maturation of growth factors and cytokines has also been demonstrated. For example, binding affinities of hGH and IFN-α2 to their receptors were increased 400- and 60-fold, respectively.[155,162]

Thus, many different types of proteins can be engineered with phage display, and panning allows very large libraries to be assayed. Library sizes of up to 10^{10} are possible, limited only by the transformation efficiency of *E. coli*.[149] Although phage display has been applied successfully in many cases, the use of *E. coli* as the expression host and the requirement for transport across the cell membranes can make its application to more complex proteins difficult. However, the major drawback of phage display is that the general enzyme-linked immunosorbent assay (ELISA)-based panning protocol does not allow precise control over the binding affinity and cannot differentiate between proteins with minor differences in affinity or kinetics, as is the case with flow cytometry-based screening methods, discussed below.[147] On the other hand, panning affords some flexibility in how the target ligand is presented. Ligands can be presented on myriad solid surfaces, including plates, beads, and even surface-plasmon-resonance chips. Furthermore, phage can be panned against whole mammalian cells to engineer specific cell-targeting sequences[163] or injected into live animals for *in vivo* screening.[164]

4.412.3.2.3. Cell surface display

Alternative combinatorial engineering platforms have been developed to display peptides and proteins as fusions on the surface of cells instead of on phage. This permits the use of fluorescence-activated cell sorting (FACS) to screen libraries. Proteins displayed on the cell surface can be labeled with fluorescent ligands and screened with single-cell resolution based on light scattering and fluorescence intensity.[165,166] Advanced flow cytometers can screen cells at speeds up to 10^9 cells per hour and isolate desired populations in real time. In addition, multiple wavelengths can be measured at the same time, allowing separation based on more than one parameter (i.e., levels of protein expression and target binding). This precise control over the library screening process enables discrimination between proteins with only a twofold difference in binding affinity, which is far superior to what can be achieved with panning-based methods.[167]

Bacterial and yeast surface display platforms have been developed to present proteins on the surfaces of *E. coli* and *Saccharomyces cerevisiae*.[166,168] Display on other bacteria and yeast (such as gram-positive *Streptococcus* or *Pichia pastoris*), insect cells, and mammalian cells is also possible but these are more recent technologies and as a result are not yet as widely used.[169–173]

4.412.3.2.3.1. E. coli *surface display*

E. coli is the most well-characterized microbe, and transformation and protein expression techniques are fully developed. Thus, *E. coli* was the first system to be developed for the engineering of peptides and proteins by cell surface display. Although it is a simple organism, *E. coli* display initially proved to be difficult, with problems of cell toxicity and transport across the inner and outer membranes and the cell wall. Thus, various fusions were used as anchors to present proteins on membrane proteins, lipoproteins, flagella, and pilin,[174,175] and many of these systems were successful in displaying peptides or small proteins. For example, a peptide library was inserted into a loop of the *E. coli* outer membrane protein A (OmpA). Using this system, peptides with 1–10 nM binding affinity were identified to bind various targets such as human serum albumin and the HIV surface protein gp120. In addition, a flagella display system is commercially available (FliTrx, Invitrogen). The FliTrx peptide library was screened against serum from patients with the inflammatory celiac disease to identify common antigenic domains.[176]

The first successful method to display larger proteins on bacteria was the Lpp–OmpA system, a three-part fusion composed of the signal sequence from the major *E. coli* lipoprotein (Lpp), the outer membrane protein OmpA, and the target protein.[177] scFv libraries were successfully displayed on *E. coli* using this system and screened against a model target, the small molecule digoxigenin.[177,178] However, intact antibodies and larger, more complex proteins (such as ones containing disulfide bonds) could not be presented. To overcome these difficulties, more complex techniques were developed to fold and display proteins in the periplasm of *E. coli* and to subsequently remove the outer membrane and cell wall to generate spheroplasts that could be labeled and screened by flow cytometry. Such anchored periplasmic expression (APEx) and E-clonal technologies allow the display of full-length antibodies, but are technically challenging as the spheroplasts are extremely delicate.[179,180] Despite this, full-length antibodies were engineered to bind small model targets with affinities of up to 20 nM.

4.412.3.2.3.2. Yeast surface display

In response to technical difficulties encountered with *E. coli*, yeast surface display was developed as an alternative method for protein engineering.[167,168,181] *S. cerevisiae* is a model eukaryotic microbe. Like *E. coli*, it offers the convenience of well-known experimental methods for transformation and culture. In addition, yeast contains the foldases, chaperones, and translation machinery necessary to properly express eukaryotic proteins. This is a significant advantage over *E. coli* protein expression, which is relied on for both phage and bacterial display. The downside to *S. cerevisiae* as a host is that its transformation efficiency is lower than *E. coli*, reducing the library sizes to 10^7–10^9 members. Larger library sizes could be produced for both bacterial display and yeast display by combining multiple transformations, but screening is limited by the throughput of commercial flow cytometers (10^7–10^9 cells per hour). However, library quality is just as important as library size. For example, when an identical

immune scFv library was presented on the surface of yeast or phage, yeast display identified all of the HIV-gp120 specific scFvs selected by phage display and twice as many novel antibodies.[182]

In contrast to the variety of bacterial display systems, there is one dominant system for yeast surface display. In this system, the protein of interest is fused to the adhesion protein agglutinin Aga2p, which is attached by two disulfide bonds to the cell wall protein Aga1p.[167,181] Approximately 10^5 proteins are displayed on each yeast cell, and short epitope tags are included in the display construct at the *N*- and *C*-terminus of the protein of interest to measure the expression levels. Thus, two-color fluorescent labeling of yeast cells can be performed simultaneously – one label can be directed against the epitope tag and one against the protein to be engineered. This enables library screening against a binding target of interest to be normalized for expression levels. In other words, a protein that exhibits poor yeast expression but binds a high amount of ligand can be distinguished from a protein that is expressed at high levels but binds weakly to a target.

Yeast surface display has been used to successfully screen synthetic and natural scFv libraries.[183,184] As proof of principle, an scFv was isolated with a binding affinity of 53 fM and a dissociation half-life of greater than 5 days.[183] Since then, scFvs have been engineered to bind a wide variety of targets, from neurotoxins to TNF-α.[185,186] Furthermore, a single variable light-chain domain devoid of disulfide bonds was engineered to bind the huntingtin protein htt using yeast surface display, opening the door for potential intracellular targeting.[187] Extremely large, complex proteins have also been amenable to yeast surface display. A few prominent examples are the EGFR extracellular domain, which contains 621 residues and 25 disulfide bonds,[188] single-chain T-cell receptors (scTCRs),[189] and human class II major histocompatibility complexes, displayed as noncovalent heterodimers.[190]

Besides binding affinity, yeast surface display has also been used to engineer proteins with increased thermal stability.[191] In the first example of this approach, scTCRs with increased yeast surface display levels also exhibited increased soluble expression levels and thermal stability. This engineering strategy has been extended to other proteins, particularly receptors that are difficult to express.[192] In addition, we have recently engineered HGF fragments with increased stability. In this example, mutants with increased thermal stability were also displayed at higher levels on the yeast cell surface and exhibited significantly higher soluble expression yields.[193]

The yeast surface display system has also proven to be robust for engineering proteins with therapeutic potential.[194] The human proteins EGF and IL-2 have been engineered for 30- and 150-fold increased binding affinity for their receptors, respectively.[136,195] The engineered EGF mutants, which had faster kinetic on-rates of binding, significantly enhanced EGFR activation, compared to wild-type EGF.[196] The high-affinity IL-2 mutants were able to stimulate persistent T-cell growth while wild-type IL-2 did not, revealing properties of IL-2 receptor subunit binding and consequential cell signaling. In addition, folded cystine-knot (knottin) peptides, named because they contain a constrained disulfide-bonded core, have been recently engineered with high affinities and differing specificities against a variety of integrin receptors, including αvβ3, αvβ5, α5β1, and αiibβ3.[197–199] Given their unique integrin-binding specificities, these engineered peptides have interesting potential applications as ECM mimics for promoting cell adhesion and differentiation.

4.412.3.2.4. In vitro *platforms*

Although phage and cell surface display platforms significantly increase the throughput over plate-based systems, they rely on *in vivo* protein expression and thus their library size is limited by cellular transformation efficiency. To reach even higher library sizes, *in vitro* protein expression methods have been employed, allowing library sizes of up to 10^{14} to be created.[200] In addition, *in vitro* expression allows the production of proteins that otherwise would be toxic to cells and can potentially remove cellular expression biases. *In vitro* systems also do not require cloning, thereby simplifying the library generation process and enabling recursive mutagenesis between each cycle, more closely mimicking true evolution.

To express proteins *in vitro*, transcription and translation machinery is extracted from various ribosome-rich sources, including *E. coli*, wheat germs, and rabbit reticulocytes.[201] Reaction mixtures are typically supplemented with substrates such as amino acids and an energy source. These cell extracts vary in their expression yield and protein quality, as might be expected from prokaryotic versus eukaryotic systems.

There are three major platforms for *in vitro* evolution: ribosome display,[202–205] mRNA display,[206,207] and *in vitro* compartmentalization (IVC).[208,209] Because of their more recent development compared to phage display, the use of these *in vitro* platforms in protein engineering is not as widespread; however, there have been significant contributions as described below.

4.412.3.2.4.1. *Ribosome display*

Ribosome display was the first of the three methods to be introduced.[202,204] In ribosome display, the stop codon is purposely left out of the genetic template, causing the ribosome to pause at the end of the mRNA after protein translation. This forms a noncovalent complex composed of the mRNA, ribosome, and translated protein, which is stabilized by cooling the reaction to 4 °C and adding a magnesium buffer. Attempts to improve the stability of this complex by incorporating additional molecular interactions have been developed, but its noncovalent nature still makes subsequent steps technically challenging. Screening of a library of complexes is performed by panning against immobilized targets, as the complexes are much too small to be sorted by flow cytometry. Bound proteins are eluted by addition of ethylenediaminetetraacetic acid (EDTA), which chelates the magnesium, and individual sequences are recovered by reverse transcription of the mRNA.

The large library sizes afforded by ribosome display allowed the evolution of very high-affinity proteins. For example, a scFv library was screened against insulin, and a clone was recovered with a binding affinity of 82 pM.[202,210] Designed ankyrin repeat proteins (DARPins), a type of nonantibody scaffold, have also been engineered to bind many different targets with ribosome display.[211] A notable achievement was the evolution of a DARPin to bind human epidermal growth factor receptor 2 (Her2) with a binding affinity of 90 pM.[212,213] More recently, ribosome display has been extended to more diverse proteins

and targets. For example, 14-residue peptides that bind copper (II) and zinc finger proteins that bind specific DNA sequences have been isolated.[214,215]

4.412.3.2.4.2. *mRNA display*

mRNA display was developed to provide a covalent genotype–phenotype linkage, eliminating the issue of mRNA and protein dissociation inherent in ribosome display.[200,206,207] Similar to ribosome display, a stop codon is not included in the genetic template; the difference is that, after *in vitro* transcription, the library of mRNA templates is linked to the small molecule puromycin by ligation or hybridization to a short DNA linker.[216] During translation, the ribosome pauses at the RNA–DNA junction and puromycin is actually incorporated by the ribosome into the protein, as if it were an amino acid, to form a covalent mRNA–puromycin–protein fusion. Properly formed complexes are purified and panned against targets, as in ribosome display. Sequences can be recovered by reverse transcription and release of the DNA by RNA hydrolysis.

Like ribosome display, mRNA display has been used to screen extremely large peptide libraries. In one example, completely random peptide libraries of $\sim 10^{13}$ were screened to identify an 88-residue peptide with 5 nM affinity to streptavidin and an 80-residue peptide with 100 nM affinity to adenosine triphosphate (ATP).[217,218] More complex proteins have also been successfully displayed. The 10th domain of fibronectin (^{10}Fn3), which has an immunoglobulin-like fold, was evolved to bind TNF-α with a binding affinity of 20 pM from a starting library of 10^{12}.[219] The ability to express a wide range of proteins and the ease of library construction was further demonstrated by displaying the human proteome from a cDNA library and screening for calmodulin-binding proteins.[220]

4.412.3.2.4.3. In vitro *compartmentalization*

The third *in vitro* evolution platform, IVC, attempts to combine the advantages of *in vitro* display, cell surface display, and plate-based platforms into one system by creating artificial cells.[209,221] The artificial cells are water-in-oil emulsions formed by stirring an *in vitro* transcription and translation mixture with surfactants and oil. Emulsions can also be formed by vortexing, extrusion, or microfluidics; each method produces droplets of varying size (from picoliter to femtoliter volume) and heterogeneity.[208] Analogous to single-molecule PCR used in plate-based platforms (see **Section 4.412.3.2.1**), clones are separated by carefully diluting the template such that each emulsion contains a single mutant sequence. Translation and transcription are then performed inside of the emulsions, and thus the genotype–phenotype linkage is maintained by compartmentalization.

Several systems have been developed to enable library screening by panning or flow cytometry. For panning, a DNA display system was developed in which the template is biotinylated and the proteins are expressed as a fusion to streptavidin.[222] Thus, a DNA–biotin–streptavidin–protein complex is formed in the emulsions and can be panned against immobilized targets. For flow cytometric sorting, microbead display and double emulsion systems have been introduced. In the first system, the DNA and proteins are linked to microbeads, forming DNA–bead–protein complexes large enough to be detected by flow cytometry instrumentation.[223,224] In the second system, water-in-oil emulsions can be re-emulsified into a second aqueous phase.[225,226] The water-in-oil-in-water double emulsions can be sorted as if the droplets were cells. The flexibility of IVC also allows the creation of custom screens. For example, a unique DNA-binding screen was conceived where zinc finger proteins could be screened to bind a target sequence in emulsions.[227]

Most of the IVC screening systems have currently only been demonstrated with model systems. However, the use of IVC for protein engineering has great potential, as it combines the flexibility of plate-based assays with larger library sizes and high-throughput, quantitative screening techniques like flow cytometry. IVC is also starting to be combined with other platforms, such as yeast surface display, to leverage the advantages of each system.[228]

4.412.4. Protein Engineering Considerations for Biomaterials: The Interface Between Proteins and Materials

4.412.4.1. Protein Encapsulation or Attachment

Once a protein has been engineered by the methods described above, the final step is to incorporate the protein inside of or onto the surface of the biomaterial. This can be done by noncovalent or covalent interactions through specific or nonspecific linkages[4,229,230] (**Figure 7**). The challenge in both approaches is to ensure that the process does not inactivate the protein and that the material allows proper access or release of the protein.

Noncovalent protein incorporation can be done through encapsulation or absorption. This is accomplished by combining the protein of interest with the material's precursors before polymerization. After polymerization, the protein can escape

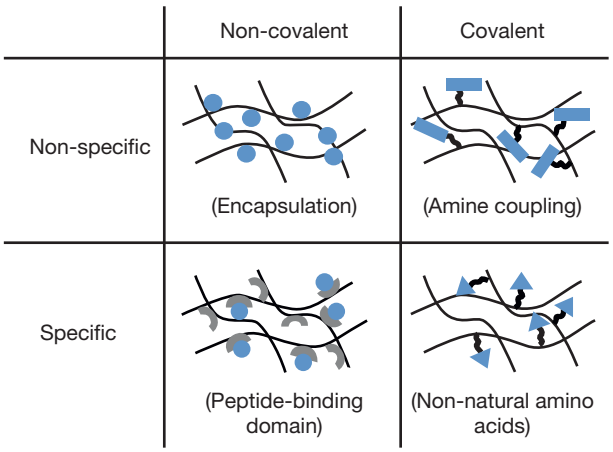

Figure 7 Approaches to protein encapsulation and attachment. Once a protein has been engineered by the methods described in this chapter, it must be incorporated into the biomaterial. This can be done by noncovalent or covalent interactions through specific or nonspecific linkages. An example is shown for each possibility. The challenge in all of these approaches is to ensure that the process does not inactivate the protein and the material allows proper access or release of the protein.

by diffusion out of the material or by degradation of the material over time. Thus, as can be expected, the speed of release is highly dependent on the material's properties. Spheres of dense biodegradable polymers can be used for slower release. Tuning the sphere's size was shown to have a large effect on the diffusion of bovine serum albumin (BSA).[231] In contrast, hydrogels can be used for faster kinetics because of their more porous composition,[232] and enzymatic cleavage sites can be used to increase material degradation or protein release.[4,233] Combinations of these materials can be used to design highly controlled delivery systems.[234] In one example, vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) were released with distinct kinetics from a hydrogel and were able to stimulate development of mature vasculature, which was an improvement over a material where both were released individually.

Methods to covalently attach proteins to materials overlap with many conjugation techniques discussed in the posttranslational modifications section (**Section 4.412.2.3**). The most basic approach is to attach proteins through their primary amines (the *N*-terminus and the ε-amino group of lysine residues). For example, EGF was coupled to a surface in this manner through a flexible linker.[235] The tethered EGF retained activity similar to that of soluble EGF, while EGF that had been nonspecifically absorbed onto the surface did not. Interestingly, tethered EGF was also shown to enhance differentiation of progenitor cells versus soluble EGF, presumably due to increased local concentrations and protection against internalization and degradation.[236] Other proteins, such as insulin and fibronectin, have also been coupled to surfaces by amine linkages and have improved the attachment and proliferation of fibroblast cells.[237,238] As an alternative, if a protein has a basal level of affinity for a material, general, nonspecific cross-linking by reactive linkers can be used.[239]

Unfortunately, the lack of specificity in these types of conjugation methods results in a risk of the protein becoming inactivated during attachment. Therefore, methods to attach proteins to materials through specific residues or locations are now being pursued. For example, VEGF naturally contains a known collagen-binding domain. VEGF was shown to be retained in a collagen-based material through this domain and activate the VEGF receptor *in vitro*.[240] Extending this to proteins without natural affinities, HGF was genetically fused to a collagen-binding domain from fibronectin. This allowed the growth factor to bind a collagen-based biomaterial and improve endothelial cell proliferation.[241] Another common binding partner, heparin, has been employed successfully for specific protein attachment as well.[239,242,243] Besides protein-binding domains, the use of nonnatural amino acids to site-specifically conjugate proteins to materials through a chemical functional group is emerging as a feasible option.[244]

Regardless of the attachment method, the protein density and presentation has a significant effect on its success as a biomaterial. For example, endothelial cell survival or death has been linked to parameters such as the curvature of the material surface and size of protein patterning.[245] Using RGD peptides as a model system, the clustering of ligands was shown to improve the adhesion of fibroblasts to a surface.[246] Furthermore, changing the level of clustering was shown to affect the behavior of preosteoblast cells.[247] Closely spaced islands of RGD peptides promoted cell spreading, whereas widely spaced islands induced differentiation. The effect of distribution can have opposite effects on different cell types, however, and the true cause of this dependence remains unknown.[248]

4.412.4.2. Protein-Based Biomaterials

In addition to acting as interfaces between materials and tissue, proteins can be used as the materials themselves.[249] Proteins have significantly less polydispersity compared to polymers and their amino acid sequence can be precisely defined. Natural proteins, such as silk, collagen, and ECM proteins, were first investigated for use as biomaterials. However, these proteins are difficult to produce and purify, and do not offer the same material flexibility or tunability compared to synthetic polymers. Therefore, more recently, the protein engineering methods described above have been used to tailor properties such as mechanical strength, degradation rates, and biocompatibility.

For simpler recombinant production, natural proteins have been reduced to shorter, more manageable domains. For example, short collagen fragments were designed with 'sticky ends' that formed disulfide-bonded triple-helices.[250] These fragments can be easily synthesized and were able to assemble into strands of nearly 1 μm in length, much longer than natural collagen which forms fibers ~300 nm in length.

Control over the mechanical properties of natural proteins has also been achieved. For example, altering the β-sheet structure of silk can change the strength of spun fibers.[251] In addition, novel peptides can be designed to self-assemble into a wide range of materials, from hydrogels to nanotubes.[252] The control over amino acid compositions also enables unique features such as reversible polymerization based on environmental pH and divalent ion concentration.[253]

Finally, proteins can be engineered for biocompatibility. For example, known cell interaction domains, such as the RGD peptide, can be easily inserted into protein-based scaffolds. Furthermore, protease sites have been introduced to allow for controlled and localized degradation. In one study, a protein and PEG hydrogel was constructed containing RGD motifs and recognition sites for plasmin and matrix metalloproteinases (proteases involved in the natural bone remodeling process). When bone morphogenetic protein 2 (BMP-2) was encapsulated in this hydrogel system, bone healing in an *in vivo* rat model was observed.[254] In addition, removal of the protease sites prevented healing, highlighting the importance of proper biomaterial degradation for biological activity.

All the parameters described above are now being combined into single biomaterial systems. Recently, an elastin-like protein was constructed with an RGD site for improved cellular adhesion and a urokinase plasminogen activator (uPA) site for localized degradation.[255] Cross-linking could be controlled to form hydrogels with defined mechanical elasticities. In addition, the amino acid sequence of the uPA site could be mutated to produce 200-fold differences in degradation rates. The ability to tailor both the mechanical and biological properties promises to propel engineered proteins to the forefront in the development of biomaterials.

4.412.5. Conclusions and Future Directions

The important role of proteins in biomaterial design is widely recognized; however, to date, the majority of these players are naturally occurring proteins or peptide fragments that have been encapsulated in or attached nonspecifically to natural and synthetic polymers. This has gradually changed as improved methods for covalent attachment have been developed and protein-based biomaterials gain prominence. We expect the marriage between proteins and biomaterials to continue to blossom as the protein engineering methods described in this chapter are further applied to molecules of interest to the regenerative medicine field. An exciting outlook for the future is the role that rational and combinatorial engineering will play in creating customized protein interfaces composed of designer ligands and cell surface receptors. These efforts will generate a toolkit of proteins and peptides beyond those that Nature has provided, resulting in novel molecules for a myriad of biomaterials applications. More specifically, with the help of engineered proteins, biomaterials will be optimized for cellular attachment, proliferation, or differentiation. Computational design and more intricate combinatorial screening methods will also be further developed to streamline protein discovery and characterization. In addition, as more protein candidates are introduced, ligand attachment and presentation will come under even more scrutiny. The focus will turn to techniques that lend more control over the protein density, release, and activity, such as site-specific attachment through specific binding domains or nonnatural amino acids. On the horizon, there are great opportunities for merging the fields of protein engineering and materials science to create biomaterials that will interact and integrate with cells and tissues in a petri dish or in a living organism.

Glossary

Alkylsilanes A class of reactive chemical compounds, often used for their alkyl-derivatized terminal functional groups, which spontaneously form covalent bonds to hydroxylated surfaces.

Alkylthiol A class of chemical compounds containing one or several –SH groups, often used as anchoring groups that spontaneously form a covalent-like bond to several coinage metal surfaces.

Fibronectin A glycoprotein found in the extracellular matrix.

Integrin A class of proteins (receptors) that mediate cell interactions with neighboring cells, tissues, and extracellular matrix proteins.

Lithography A method by which a pattern or design is printed onto a substrate.

Mask A plate consisting of transparent and opaque areas, usually made of glass, quartz, or plastic, which together constitute the design of a given pattern.

Microscale Feature sizes ranging from 0.1 μm to 1 mm.

Nanoscale Feature sizes ranging from 1 to 100 nm.

Polydimethylsiloxane (PDMS) A widely used, transparent silicone elastomeric polymer.

Poly(ethylene glycol) (PEG) (also known as poly (ethylene oxide), PEO) A biocompatible polyether. Surface-grafted PEG is known to resist protein and cell adsorption.

Resist A polymeric film which homogenously coats an underlying substrate. If the polymer is radiation-sensitive, it becomes known as photoresist.

Resolution The smallest possible feature size accurately reproduced from the desired pattern.

RGD A cell-adhesive peptide sequence, Arg-Gly-Asp, known to interact with integrin receptors in cell membranes.

Self-assembled monolayer (SAM) A molecular coating that spontaneously chemi- or physisorbs onto a surface to form a single molecule-thick film.

Streptavidin A tetrameric protein synthesized by *Streptomyces avidinii* bacteria, very tolerant of harsh environments. It has four specific high-affinity binding sites for its ligand, biotin, and is often used as a linker molecule to biotinylated biomolecules.

Throughput A measure of the number of samples that may be processed at a given time.

Abbreviations

AFM	Atomic force microscopy
BSA	Bovine serum albumin
DNA	Deoxyribonucleic acid
DPN	Dip-pen nanolithography
EYFP	Enhanced yellow fluorescent protein
MAPL	Molecular assembly patterning by lift-off
nCP	Nanocontact printing
PEG	Poly(ethylene glycol)
PLL	Poly(L-lysine)
POPC	1-Palmitoyl,2-oleoyl-*sn*-glycero-3-phosphocholine
POPS	1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phospho-L-serine (sodium salt)
SA	Streptavidin
SAM	Self-assembled monolayer
UV	Ultraviolet light
μCP	Microcontact printing

4.413.1. Introduction

The term biointerface refers to the interconnection between a synthetic or natural material and a tissue, microorganism, cell, virus, or biomolecule. The topology, morphology, physical structure, and chemical or biological composition of these interfaces, and their lateral distribution at dimensions ranging from the macro- through the micro- to the nanoscale, strongly influence the behavior of the system. Biointerface science is a highly multidisciplinary field. Scientists and engineers from multiple disciplines work together with the aim of interrogating the mechanistic aspects of interfacial processes, and to develop techniques for the creation of precisely engineered interfaces with the goal of directing biological response to (bio)materials. Biointerface science and engineering is thought to advance our knowledge and capabilities in fields such as biology, biotechnology, bioanalytics, drug delivery, medicine, tissue engineering, and regenerative medicine. One key challenge facing any new biomaterials application is the choice of materials with appropriate bulk properties (e.g., mechanical strength, stability, controlled degradability) and surface functionalities able to direct a favorable biological response in the context of the specific application. The outcome of this focus on the controlled design and tailoring of specific surface properties is a new material that outperforms the conventional bulk material – an advanced material.

The drive to miniaturize devices, thereby rendering the research and development process more efficient and less expensive, has spread from the electronics industry to other fields of science. Now that micro- and nanofabrication have become widely used to tailor surface properties, widespread evidence of the influence of nanoscale physicochemical properties such as surface chemistry, surface energy, and topography of materials on proteins, cells, viruses, and bacteria has emerged. Although it is still unknown how cells ranging from 10 to 100 μm in size identify their spatial position in a multicellular system that ultimately assembles into an organism, the important role played by their substrate and neighboring cells in a laboratory environment has been recognized by the scientific community. Cell–cell and cell–matrix contacts are dynamic, responding and adjusting to protein clusters formed at connection sites. The size and shape of the protein clusters, influenced by the ligands to which they bind on the surface, deeply influence the ability of cells to maintain their function.

Micro- and nanopatterning are used today to achieve not only accurate micro- and nanostructured surfaces, but also biomolecular positioning on the substrate, as reviewed by Blättler *et al.*,[1] which can ultimately influence cellular morphology,[2,3] adhesion,[3,4] proliferation,[5] differentiation,[3,5,6] migration,[3,4] and apoptosis,[4] as well as conformation and functionality of individual proteins attached to the surface.[6]

Micro- and nanopatterning techniques allow researchers to access a new dimension of detail and to thereby recognize and understand surface characteristics that favor the preservation of function of proteins, peptides, and cells, which in turn reflect on the success of the applied patterning strategy. Further studies may also improve our knowledge on how cellular systems integrate physicochemical cues on the surface and how they ultimately translate them into biochemical responses. Additionally, the precise spatial positioning of cells on surfaces greatly promotes the development of cellular and molecular sensors, which are relevant in several fields, from medical diagnosis to lab-on-a-chip applications and biosensing. In this context, we can take advantage of the fact that each cell, as a sensing element, can both express and recognize specific receptors, signaling proteins, and enzymes, which guide the investigation of cell behavior, drug discovery, antibody selection, and RNA interference. Arrays of micropatterned cells can be generated for use as miniature biosensors, allowing the parallel detection of a large number of bioentities and the reduction of the number of samples required, while contributing to the development of more sophisticated detection methods.

As the field of micro- and nanotechnology rapidly evolves, summarizing the drawbacks and advantages of each technique in the context of biointerfaces is a challenging task. Their limitations are constantly being overcome, better scale resolution and less time consumption being two of the most sought-after changes. As technology develops, it commonly seems to be part of the solution to realize the positive characteristics of a key enabling technology by associating it with a second technology that overcomes the technological disadvantages of the first. The final selection of patterning technique will be closely related both to its cost-effectiveness and to the unique aspects of its output, which should match the requirements set by the research project.

The purpose of the first section of this chapter (Section 4.413.2) is to summarize distinct patterning techniques, as depicted in Figure 1, used for the creation of advanced biointerfaces at the micro- and nanoscale in two dimensions, highlighting their main characteristics, advantages, and shortcomings. The techniques are presented separately for top-down and bottom-up processes. In Section 4.413.2, we disclose several examples of the application of those

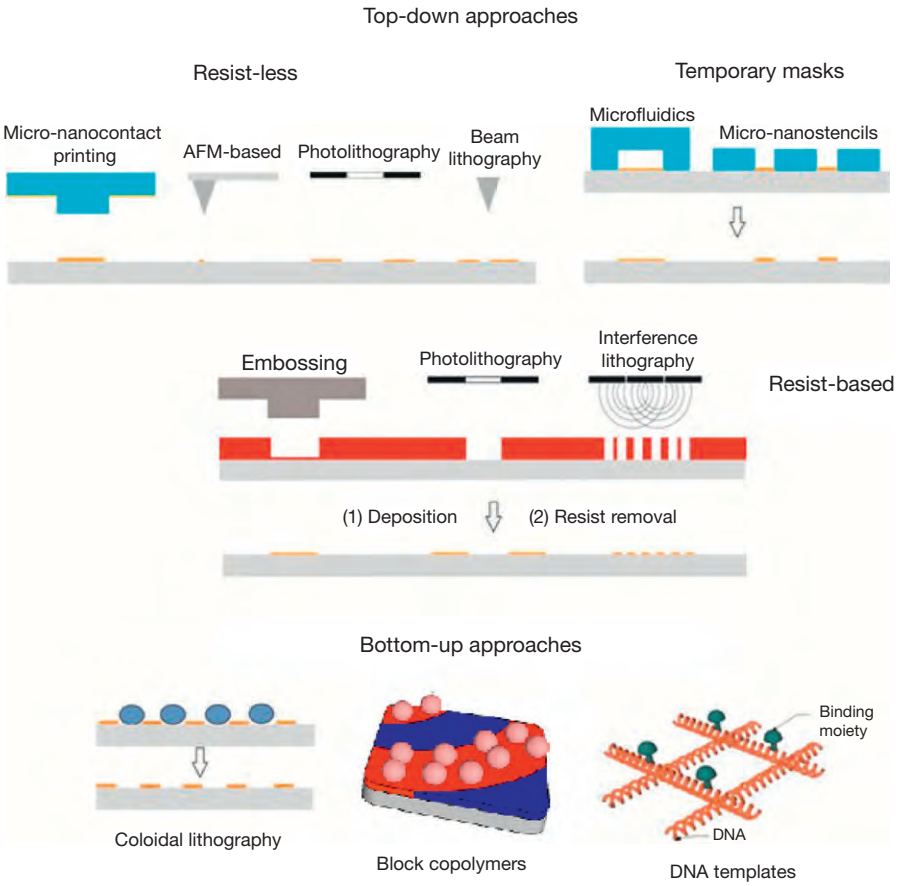

Figure 1 The distinct surface patterning techniques can be classified as bottom-up and top-down approaches. Top-down approaches can be further classified into resist-less, resist-based, and temporary mask-based. The figure summarizes schematically most of the technological strategies that will be presented in the following sections.

technologies toward the production of biopatterns composed of deoxyribonucleic acid (DNA), peptides, proteins, cells, bacteria, and viruses and their (potential) applications in specific fields. Related information on these topics may also be found in **Chapter 4.406, Protein Interactions with Biomaterials**; **Chapter 3.320, Nanostructured Polymeric Films for Cell Biology**; **Chapter 3.321, Microarrays in Biomaterials Research**; **Chapter 4.411, Peptide- and Protein-Modified Surfaces**; **Chapter 4.412, Rational and Combinatorial Methods to Create Designer Protein Interfaces**; **Chapter 4.414, Molecular Biomimetic Designs for Controlling Surface Interactions**; and **Chapter 4.416, Growth Factors and Protein-Modified Surfaces and Interfaces**.

4.413.2. Patterning Techniques

4.413.2.1. Top-Down Approaches

Top-down patterning approaches use large instruments to create smaller features, namely at the micro- and nanoscale, on a given substrate. These approaches can require expensive instrumentation, the quality of which may define the resolution achieved.

4.413.2.1.1. Photolithography

Once the geometrical pattern of interest is decided upon, a CAD software is required to lay it out, after which a physical template – called a (photo-)mask – can be manufactured. The mask and a high-energy beam are the two essential elements of photolithography, a type of projection lithography that transfers the pattern of the mask to the substrate, typically by using ultraviolet light (UV).

The substrate is first coated with a radiation-sensitive organic polymer – known as photoresist – and then selectively exposed to radiation, which shines through the transparent areas of the photomask. Depending on the properties of the photoresist, the polymer chains may either break or become cross-linked in the irradiated areas, making them soluble or insoluble, respectively, to particular solvents – the so-called development solutions. The first kind of resist is known as positive resist, and the second, negative resist. After the substrate is immersed in the resist development solution, the pattern on the surface is either an identical replica of the mask template (if a positive resist was used) or its complimentary geometrical image (if a negative resist was used). If required the photoresist can be removed from the substrate by using suitable chemicals or plasma.

The newly patterned substrate can then be used as a mold to produce polydimethylsiloxane (PDMS) replicas of the original template; these replicas can either serve as a substrate directly or be used as stamps for soft-lithographic processes. The PDMS replicas are produced via a parallel, single-step fabrication mode, which represents one of the main advantages of the technique. For this reason, as well as its high accuracy, photolithography became a major technique for production of patterns from micron to submicron scales on solid-state surfaces. However, photolithographic techniques can require clean rooms, expensive equipment, and high maintenance costs, which may make them inconvenient.

4.413.2.1.1.1. Resist-based patterning (MAPL)

The molecular assembly patterning by lift-off (MAPL)[7] is a technique, which approaches the simplicity of microcontact printing (μCP), to form biofunctionalized patterns on an adsorption-resistant background. This technology (represented in **Figure 2(a)**) relies on an initial step based on photolithography (see **Section 4.413.2.1.1**) to create the desired pattern of resist-protected and -unprotected areas on top of a substrate, typically, glass, silica, or metal oxides. The partially protected wafer is dipped into a solution containing a polycationic bottlebrush copolymer, (poly(L-lysine)-*graft*-poly(ethylene glycol) (PLL-*g*-PEG)), end-functionalized with bioactive molecules such as biotin or RGD. Subsequently, the wafer is exposed to an organic solvent (typically *N*-methylpyrrolidone, NMP) that removes the remaining photoresist while keeping the biofunctional copolymer intact. In a final dip-and-rinse step, nonfunctionalized PLL-g-PEG is adsorbed on the now-bare parts of the wafer, resulting in a pattern of areas that either strongly resist or actively promote biointeraction. The surface density of the bioligands in the bioactive sections can be controlled either by adjusting the fraction of functionalized PLL-g-PEG chains on the copolymer backbone in the synthesis process or by assembling mixed adlayers from solutions containing a defined molar ratio of functionalized to nonfunctionalized PLL-*g*-PEG during the first dip-and-rinse step. The MAPL technique has also been used to create microarrays of vesicles[8] and to pattern polymers on gold surfaces.[9] Recently, Kim *et al.*[10] used a protein-friendly photoresist, called PDMP (poly(2,2-dimethoxy nitrobenzyl methacrylate-*r*-methyl methacrylate-*r*-poly(ethylene glycol) methacrylate)), to pattern multiple proteins on surfaces. The process consists of spin-coating a resist onto a biotin-functionalized surface and, once the photolithographic process is completed, to develop the PDMP resist in near-neutral physiological buffer solution. In a subsequent step, streptavidin (SA) is grafted to the exposed biotinylated surface. The process can be repeated several times, as the development process does not affect the already-patterned proteins.

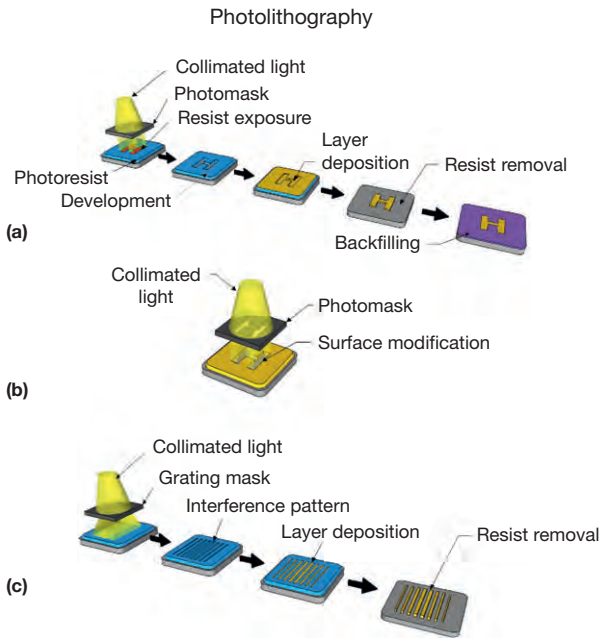

Figure 2 Photolithographic techniques. (a) Resist-based patterning. A beam of light (yellow) is shined through a photomask (gray) onto the photoresist (blue), selectively softening it. Subsequent development removes the softened region, and then deposition and backfilling are used to create the desired surface chemical contrast. (b) Direct patterning. The surface is directly modified by the light beam. (c) Extreme ultraviolet interference lithography (EUVIL). Collimated extreme UV light forms a complex interference pattern upon passing through the grating mask, selectively softening the photoresist.

The control allowed by MAPL over not only the pattern geometry, but also over the type and density of bioligands on the surface, has made it a technique of great relevance. Other advantages of this technology include its simplicity, its noninteractive areas characterized by low nonspecific adsorption of (bio)molecules, the biospecificity of the created interactions, the ease of functionalization of PEG to produce patches composed of multiple types of cell binding sites, and the reproducibility and consistency of the quality of the resulting pattern across the whole wafer (with dimensions around 10 cm), on top of the advantages of photolithographic wafer fabrication, such as variety of form, size, and geometry of the templates. It is also possible to replace the biofunctionalized polymer adsorption step by the assembly of a protein such as fibronectin (which is not adversely affected by the use of the NMP solvent), thus creating a cell-interactive/PEG pattern contrast.

4.413.2.1.1.2. Direct patterning

A chemical pattern can be created on a radiation-sensitive coated surface by selectively exposing regions of it to light via a photomask (as shown in **Figure 2(b)**). Christman and coworkers[11] used this strategy to pattern a surface coated with a pH-reactive polymer, poly(3,3′-diethoxypropyl methacrylate) containing 5% diphenyliodonium-9,10-dimethoxyanthracene-2-sulfonate (DIAS), a molecule that generates protons upon being activated by light. Specifically, upon exposure to a UV light through a photomask, the acetal groups present on the polymer are site-specifically hydrolyzed to aldehydes. These aldehydes can be easily derivatized with molecules of interest as they are highly reactive. By means of a much simpler approach, Xue and coworkers[12] recently created patterns of aldehydes by direct oxidation of an octadecyltrichlorosilane (OTS) monolayer using a UV light source. Anzioned *et al.*[13] employed deep UV light source exposed through a photomask to micropattern a PLL-*g*-PEG-coated glass surface. This caused the protein-repellent PEG chains in the exposed areas to be

selectively cleaved, and thus allowed for the selective adsorption and patterning of fibronectin at the microscale.

4.413.2.1.1.3. Extreme ultraviolet interference lithography

Interference lithography, although closely related to photolithography, is not based on a photomask to selectively expose a surface to be patterned to light. Rather, the principle of interference lithography relies on the use of a light interference pattern projected onto a photoresist, as shown in **Figure 2(c)**. The pattern is created between two or more coherent light beams and consists of a nanometer-spaced periodic series of fringes with minimal and maximal light intensity. For producing the interference pattern, the coherent light source is split by a prism or diffraction grating into two or more waves which, once recombined, generate the desired interference fringes. The typical methods of beam splitting are based on prisms and diffraction gratings.

The main advantage of this methodology, in comparison to e-beam lithography (EBL), is that large areas of photoresist can be nanopatterned. However, the designs that can be generated are limited to the configuration fringes that can be created. Investigators[14,15] have exploited this technique to pattern distinct kinds of resist, including poly(methyl methacrylate) (PMMA) and calixarenes, attaining a pattern resolution of 11 nm. Using several diffraction grating configurations, the resists were patterned in dots, arrays, circles, and rings. Following the same procedure used in the MAPL technique, Städler *et al.*[16] used extreme ultraviolet interference lithography (EUVIL) to selectively nanopattern PMMA coated on Nb_2O_5 surfaces and graft the exposed areas to a PLL-*g*-PEG-biotin polymer. After the PMMA lift-off process, the surface was backfilled with the protein-repellent polymer (PLL-*g*-PEG) and the biotins patterned on the surface used to create SA nanopatterns. Recently, Turachanin and coworkers[17] presented the use of a variant of EUVIL to directly chemically pattern a surface functionalized with a self-assembled monolayer (SAM) of 4′-nitro-1,1′-biphenyl-4-thiol by converting the nitro groups into amino groups upon exposure of the surface to the interference light pattern. Using this approach, chemical patterns with a resolution of 60 nm were achieved.

4.413.2.1.2. Beam-based lithography

There are two main technologies based on the use of a beam to write patterns at the micro- and nanoscale on surfaces, as shown in **Figure 3**.

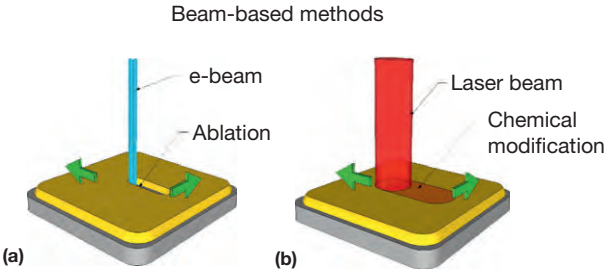

Figure 3 Schematic diagram depicting beam-based lithographic techniques: (a) e-beam-based and (b) laser-based.

4.413.2.1.2.1. Electron beam lithography

Electron beam lithography (E-beam lithography or EBL) (**Figure 3(a)**) is a technique based on the use of a beam of electrons to locally polymerize or remove a resist-coated surface. If starting with an already-polymerized resist, a development step is required in order to remove the unpolymerized polymer film. In a following step, the exposed areas of the surface are usually etched in order to transfer the pattern to the desired surface.

EBL allows the creation of complex nanopatterns on surfaces, although it is time consuming, as large areas must be produced via a stacking methodology. The different techniques that use EBL to create chemical or protein patterns can be classified into resist-based, direct ablation (resist-less), and e-beam-initiated chemical reaction. Further description of EBL may also be found in **Chapter 3.301, Surface Analysis and Biointerfaces: Vacuum and Ambient *In Situ* Techniques**.

- *Resist-based:* High-resolution patterns can be created using EBL on PMMA deposited on surfaces[18] by selective removal of the polymer. Investigators[19] removed areas of PMMA and adsorbed an aminopropyl silane onto the exposed substrate areas. After the lift-off of the remaining PMMA, DNA nanopatterns were created by selective adsorption onto the positively charged aminated surfaces. The grafting of proteins of interest could be easily achieved via functional derivatization of the amino groups.
- *Direct ablation:* Zhang *et al.*[20] used an e-beam to locally remove a perfluorosilane SAM adsorbed on a silicon surface and functionalize the exposed areas with aminosilanes. Derivatization of the amino patterned areas with a biotin linker allowed the investigators to create 100-nm-wide protein patterns of SA and biotinylated GFP. In the same year, Senaratne *et al.*[21] used a similar strategy to pattern dinitrophenyl (DNP) groups on a PEG-modified silicon oxide surface. The DNP patterns were then used to pattern anti-DNP antibodies with a 10-nm lateral resolution. More recently, Pesen *et al.*[22] used EBL to selectively remove bovine serum albumin (BSA) protein adsorbed on a glass surface, and subsequently backfill the newly exposed areas with fibronectin, in order to create patterns with protein contrast. As an alternative strategy to create chemical contrast patterns, the e-beam can be used to selectively remove a thin layer of SiO_2 deposited on TiO_2. In a second step, molecules such as dodecyl phosphate (DDP) can be selectively adsorbed on the exposed TiO_2 surfaces, and finally, the SiO_2 can be coated with PLL-*g*-PEG protein-repellent polymer.[23] Recently, Rundqvist *et al.*[24] presented the use of an e-beam to selectively deactivate a fibronectin-coated surface in order to create a nanoscale pattern of active proteins.
- *E-beam-initiated chemical reaction:* Chemical reactions can be induced directly on surfaces via e-beam exposure. Mendes *et al.*[25] used an electron beam to locally reduce nitro functionalities in SAMs of 3-(4-nitrophenoxy)-propyltrimethoxysilane to amino functionalities, forming chemically well-defined surface patterns on the 100-nm scale. Hong and coworkers[26] utilized an e-beam to locally cross-link thin films of PEG on SiO_2 surfaces and thus create 200-nm diameter spots of hydrogels. More recently, the same

approach was applied to nanopattern eight-armed PEG chains modified with biotin, maleimide, aminooxy, and nitrilotriacetic acid (NTA), in order to create multicomponent protein patterns after sequential e-beam patterning of the distinct polymers.[27] A more sophisticated approach was employed by Winkler *et al.*[28] to create gradients on surfaces of PEG protein-resistant groups. The strategy is based on varying the e-beam exposure time of a dodecanethiol (DDT)-coated gold surface. Whereas the pristine DDT SAM hardly permits any substitution process, the e-beam irradiation induces defects (such as the formation of alkene bonds, which destabilize the SAM) that promote the exchange reaction with a PEG-thiol. Depending on the exposure time, the amount of alkene bonds created on the SAM varies and, thus, the substitution process can be controlled.

4.413.2.1.2.2. Laser beam lithography

A focused laser beam can be utilized to micropattern functionalized surfaces by inducing local photochemical reactions, as represented in **Figure 3(b)**. Jonkheijm and coworkers[29] employed a laser beam to induce a thiol–ene reaction between a thiol-containing surface and a biotinylated olefin, in order to create a micropattern of biotinylated areas. A similar strategy[30] was employed to selectively deprotect a surface coated with carboxylic acid groups, thus creating reactive sites for proteins. More recently, investigators[31] created chemical contrast nanopatterns (up to 110 nm) by utilizing an argon laser beam to selectively desorb 1-hexadecyne SAMs formed on Si surfaces and backfill the fresh Si surfaces with an amine-terminated SAM. Nanoscale resolution was achieved in that case by reducing the lateral distance between the lines written by the laser.

4.413.2.1.3. Embossing

Hoff *et al.*[32] were the first to describe the use of nanoimprint lithography (NIL) for creating chemical contrast on surfaces. As **Figure 4** shows, a nanostructured mold is imprinted into a heated PMMA film spin-coated onto a silicon wafer. Next, a dry etching step converts the topography formed by the variation in PMMA film thickness into a PMMA/silicon oxide contrast by removing the thinner PMMA regions completely. The exposed SiO_2 surface is then passivated with a perfluorosilane layer.

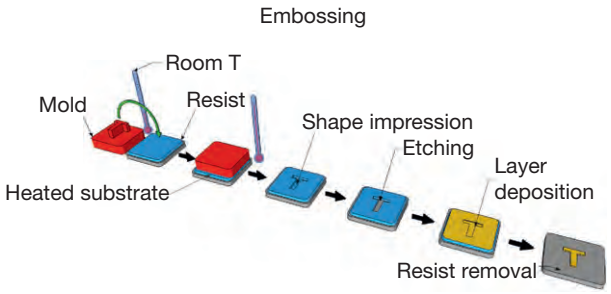

Figure 4 Schematic diagram depicting the embossing technique as used in nanoimprint lithography (NIL) and microimprint lithography (MIL). The substrate coated with resist (blue) is heated up and the target pattern (red) is embossed into the resist film. A subsequent etching step removes the thinner regions of resist entirely, locally exposing the bare substrate.

Finally, the remaining PMMA is stripped away with acetone and the freshly exposed SiO_2 regions are functionalized with an aminosilane. Biotin-succinimidyl ester is then covalently linked to the primary amine of the aminosilane layer in order to create SA patterns on the surfaces, which can be further derivatized with biotinylated biomolecules. Falconnet *et al.*[33] used a similar approach on Nb_2O_5 surfaces to create SA patterns. After the reactive etching process, the fresh oxide areas are derivatized with a biotin-functionalized bottlebrush copolymer, poly(L-lysine)-*graft*-poly(ethylene glycol)-biotin (PLL-*g*-PEG/PEG-biotin). Finally, after the PMMA stripping process, the background is backfilled with protein-resistant PLL-*g*-PEG.

4.413.2.1.4. Soft lithography

Soft lithographic[34] methods are characterized by the use of a chemically modifiable and inexpensive elastomeric material as a stamp to transfer micro- or nanostructured complex patterns from a master, or mold, onto a target material of choice. The elastomeric stamp, typically PDMS, represents an inverted replica of the structure to be produced. Elastomers can generate a conformal contact at the molecular level over large areas of a wide range of substrates of interest, one of the primary advantages of soft lithography. Tight contact is even possible with curved surfaces.[34] The sealing between the target material and the stamp is mediated by van der Waals forces and therefore reversible, so this procedure can be repeated several times using the same mold and stamp.

The Young's modulus of fully cross-linked PDMS, typically in the low MPa range, is suitable to achieve conformability but may reduce the pattern resolution. To obtain high-resolution patterns in the submicrometer range, without any distortions, new types of elastomers were successfully developed, including hard-PDMS,[35] polyolefin plastomers (POPs),[36,37] poly(ethylene)/poly(methyl methacrylate) composite stamps,[38] perfluoropolyethers,[39] domed stamps,[40] and poly(methyl methacrylate) (PMMA) stamps.[41] More information about some of these polymers may also be found in **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**.

Soft lithography is a low-cost and high-throughput technique that does not require clean rooms to produce high-quality patterned micro- and nanostructures. It avoids the resolution limits imposed upon photolithography by optical diffraction. Furthermore, PDMS samples are suitable for biological applications, as PDMS is stable at temperatures ranging from 37 to 95 °C, chemically inert,[42] optically transparent,[43] minimally autofluorescent, gas-permeable,[44] and biocompatible.[42]

4.413.2.1.4.1. Direct microcontact and nanocontact printing

Microcontact printing (μCP) and nanocontact printing technologies are suitable for directly immobilizing small, surface-active molecules, polymers, or biomolecules onto spatially and geometrically well-defined areas of a material by mechanical contact, as shown in **Figure 5(a)**. This technique entails an inking step of the molecules of interest on a PDMS stamp. The excess solution is dried and the remaining layer at the surface of the stamp is placed in contact with the surface of the required material, for a period of time ranging from a few seconds to minutes, after which the stamp is peeled off, leaving a pattern of the molecules of interest on the surface of the material. The bonds that connect the transferred molecules

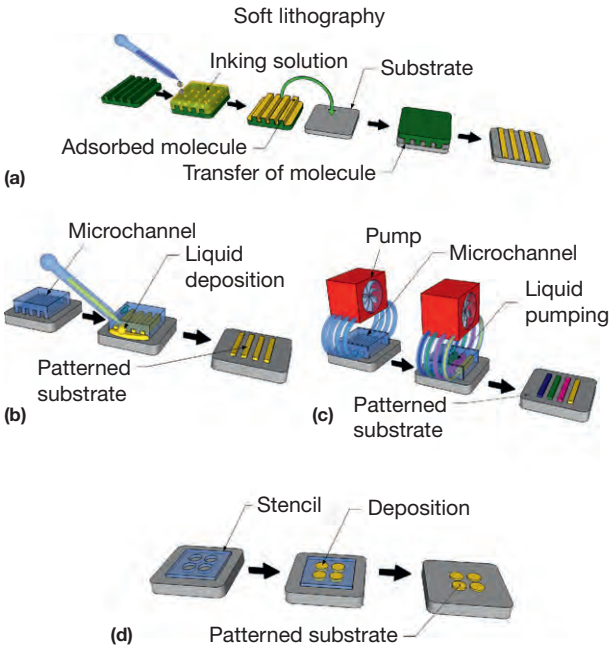

Figure 5 Soft lithographic techniques used to pattern surfaces with chemicals and biomolecules. (a) Direct micro- and nanocontact printing. A flexible stamp (green) is coated with the *ink* (yellow) and pressed onto the surface (gray) to produce the desired transfer pattern. (b) Microfluidic patterning technique based on the use of capillary forces to fill the channels with the solution of interest. (c) Advanced microfluidic patterning technique based on the use of pumps and tubing to address distinct solutions in each channel and thus create multicomponent patterns. (d) Stenciling technique. Micro- or nanostencils (blue) act as temporary masks to create surface patterns (yellow) by site-specific deposition of material through the mask.

and the surface of the material being stamped can be mainly electrostatic or covalent, depending on the species involved. The surrounding unmodified areas may subsequently be backfilled.

Being an additive process, the material wastes incurred in contact printing are minimal, in comparison with techniques such as subtractive printing, described in the following section. Contact printing methods additionally take advantage of the reusability of the photomask and the low cost and flexibility of the stamp to serve as a versatile, cost-effective, high-throughput patterning technique that allows the scientist to work in parallel with cells,[45] proteins,[46–49] oligonucleotide arrays,[50] or gold,[51] on several different materials varying from glass slides[52,53] to polymers,[51] hydrogels,[47,54] and SiO_2.[55]

Most of the methods of patterning proteins discussed in this chapter are restricted to the patterning of planar surfaces. However, Foley and coworkers[56] took advantage of the elastomeric properties of PDMS stamps to integrate biomolecules into nonplanar substrates – namely onto the bottom of microchannels – by deforming them under pressure until they conformed to the microchannel structure. This μCP strategy was shown to work for both flat and three-dimensional (3D) stamps bearing continuous or discontinuous patterns.

The potential drawbacks of microfluidics include mechanical instabilities imposed by the soft stamp – such as lateral collapse or pairing of narrowly spaced features, or sagging of the region between two features widely apart[57] – which limit the pattern geometries that can be produced[37]; blurring of the pattern caused by diffusion of the solution of molecules stamped[58,59]; the risk of contamination of the surface to be patterned by transference of molecules or fragments from the stamp material (e.g., low molecular weight residues when employing PDMS) with consequences for the wetting and adhesion properties of the patterned substrate[60]; and, for applications with multiple printing steps, the difficulty of achieving precise alignment of the stamp with previous printing steps and the resulting pattern inhomogeneity along large surfaces.

To surpass the mechanical stability problems, robust stamp materials and stamp designs have been proposed, such as the ones described in **Section 4.413.2.1.4**.

4.413.2.1.4.2. Subtractive printing

An elegant approach to avoid the loss of patterning resolution due to PDMS nanostructured stamp collapse or instability is the use of subtractive printing. This technique, presented recently by Coyer *et al.*,[61] is based on the use of a nanotemplate (a silicon mold engraved with the pattern of interest) to selectively subtract a protein adsorbed on a flat elastomeric stamp (see the discussion of stamping in **Section 4.413.2.1.4**). The remaining proteins on the stamp form the desired pattern, which can be transferred to the desired surface by direct contact. Combining multiple flat stamp inking processes with subtraction steps allows the fabrication of complex patterned structures of distinct proteins. Until now, this strategy has not, to the best of our knowledge, been used to create chemical nanopatterns.

4.413.2.1.4.3. Microfluidics

Microfluidic patterning is based on the creation of microchannels on the target surface by fabricating the desired geometries on a PDMS stamp, which is then pressed onto the material surface. The stamp can be produced via replication of a master originally produced by photolithography. While the stamp is in contact with the surface, capillary forces (**Figure 5(b)**), pumps (**Figure 5(c)**), or electroosmosis are used to fill the microchannels formed at the interface with a solution of the desired (bio)molecules to be patterned. The compliance and the hydrophobic properties of the PDMS confine the solution to the channels, and the molecules are therefore delivered to the desired areas of the substrate. The bonds between the stamp and the material may be reversible or irreversible. Microfluidic patterning can be particularly useful as an alternative to μCP if a drying step would damage sensitive biomolecules, or when close control over the molecular density of the immobilized component in the material surface is a key requirement.

Microfluidic patterning combines the advantages of being a parallel, additive technique with the unique characteristic of spatially separate microchannels, allowing different solutions to flow over different regions of the same sample to form multimolecule patterns for multiplexed applications. Another interesting attribute is the laminar flow behavior inside the microchannels, meaning that adjacent streams of fluids do not intermix appreciably over macroscopic length scales once they are mutually parallel. This fact allows the concurrent patterning, in a single channel, of different components ('wall-less' microfluidics), which investigators have shown by

organizing multiple ligands and cells within selective patterns, as reviewed by Kane *et al.*[62]

The intrinsic drawback of this technique, when relying on spontaneous capillarity, is its poor speed, which limited its application to large areas in the past. However, the use of external pumping devices with controlled flow rates, down to nanoliters per minute, has successfully addressed this shortcoming. More information about microfluidic techniques may be found in **Chapter 3.309, Fluid Mechanics: Transport and Diffusion Analyses as Applied in Biomaterials Studies**.

4.413.2.1.4.4. Stenciling

Microstencils made of soft silicones, such as PDMS, can be used as temporary masks for surfaces. The softness and elasticity of PDMS microstencils cause them to spontaneously seal to any smooth surface by forming a so-called conformal contact. (**Figure 5(d)**). Once the microstencils are in place, chemicals[63] and proteins[64] can be adsorbed on the unprotected areas or, alternatively, plasma can be used to selectively modify the exposed surfaces.[65] Once the surface modification is accomplished, the microstencil is manually lifted off, yielding a patterned surface. One of the main drawbacks of the PDMS stencils is that they cannot be reused, as they are stretched and deformed during the peel-off process. New materials have been proposed as free-standing alternatives, such as parylene-C stencils[66] or hybrid elastomer metal stencils,[67] allowing them to be reused. Parylene-C stencils, unlike PDMS stencils, are free-standing and rigid, creating regular, well-arranged patterns. However, parylene-C does not form a conformal contact; therefore, the liquid confinement is dependent on the hydrophobicity of both the substrate surface and the stencil. This limits its application to hydrophobic surfaces, preventing, for instance, the use of clean glass as a substrate. To overcome this issue, hybrid stencils,[67] made of steel stencils with micropatterned elastomeric O-gaskets around the stencil apertures, have been proposed as a much more versatile alternative, allowing the creation of protein patterns on both hydrophobic and hydrophilic surfaces.

A nanostencil is a stencil with nanometer-size apertures. Rigid nanostencils made of silicon have been widely used to create patterned nanostructures of distinct materials (i.e., metals, semiconductors) on surfaces.[68–71] The strategy is based on the controlled deposition of such materials through the nanostencil apertures, which act as a 'shadow mask.' There are multiple examples of nanopatterned materials, and the first studies involving chemical or protein patterning have just been presented.[72,73]

4.413.2.1.5. Scanning-probe lithography

Scanning-probe microscopes, such as the tunneling microscope (STM) and atomic force microscope (AFM), are used both to observe surfaces and to fabricate nanoscale structures. Scanning-probe lithography is a powerful mechanical tool to produce nanometer patterns and devices, and to investigate material properties using the scanning tip. A general overview of scanning probe microscopy may be found in **Chapter 3.302, Atomic Force Microscopy**. This technology is mainly serial but multiple probes can be used, thus increasing speed by writing in parallel. Examples of such parallelization include the Millipede, an ultra-high-density, high-date-rate data storage system[74]; the Snomipede, a fusion between the former Millipede concept and scanning near-field photolithography, capable of performing parallel transformations at high resolution over macroscopic areas;[75] and dip-pen nanolithography (DPN) arrays.[76–78] The combination of high spatial resolution, alignment accuracy, throughput, and reproducibility makes scanning-probe lithography a promising technique to produce a wide variety of patterns at the nanoscale.[79]

AFM-based nanolithography is a very flexible and high-resolution technology which easily adapts to different study conditions, including ambient air, liquids, gases, humidity, and temperature differences, making it ideal to match required conditions such as for biomolecules.[80] Its degree of resolution depends on the tip shape, cantilever strength, scan domain, and the number of measurements per scan and, under the appropriate circumstances, enables the manipulation of surfaces at the single-atom level.[81] AFM instrumentation and tips are widely commercially available.

Among the several AFM-based methods used to nanopattern surfaces, nanografting, nanoshaving, anodic oxidation, the Millipede, and the Snomipede are part of a range of techniques that act by chemically or physically modifying the surface to produce a pattern, with subsequent site-specific adsorption of the patterning molecules from the solution. These harsh approaches have an associated handicap regarding the material types that can be micro- and nanopatterned. In contrast, DPN and nanopen are part of the new generation of AFM-based technologies that directly deliver the material to be patterned on the surface of the target substrate without the help of a resist, a stamp, substrate irradiation, or solvents, thereby avoiding surface damage or cross-contamination.

4.413.2.1.5.1. Dip-pen nanolithography

DPN arose from the idea of transforming a common AFM problem into a virtue of a new technology. When an experiment is conducted in air, capillary forces condense the water of the air in between the small distance that separates the tip and the surface sample, influencing imaging approaches. Mirkin and coworkers[82] showed that when the water flows from the tip to the sample surface, multiple nanometer patterns may be formed, as shown in **Figure 6(a)**. This phenomenon allows direct writing on the surface of the samples, opening a new door to the nanopatterning field. DPN, therefore, relies on the spontaneous formation of a meniscus, which acts not only as a conduit for ink transport but also, in some cases, as a reaction vessel. The latter case allows materials precursors on the tip to be synthesized directly on the target material when in contact with the meniscus during the transfer process.[83] The transferred molecules – such as DNA,[84] proteins,[85] or enzymes[86] – act as *ink*, *drawing* (i.e., patterning) the molecules on the substrate via either chemisorption or physisorption. When the velocity of the tip across the surface is increased, the transport of molecules is interrupted and the probe acts as an imaging tool which provides feedback on the pattern characteristics. Progress in this field of molecular printing involving DPN has recently been thoroughly reviewed by Braunschweig and coworkers.[87]

In summary, DPN is an additive technique that allows both hard and soft material to be patterned with minimal material

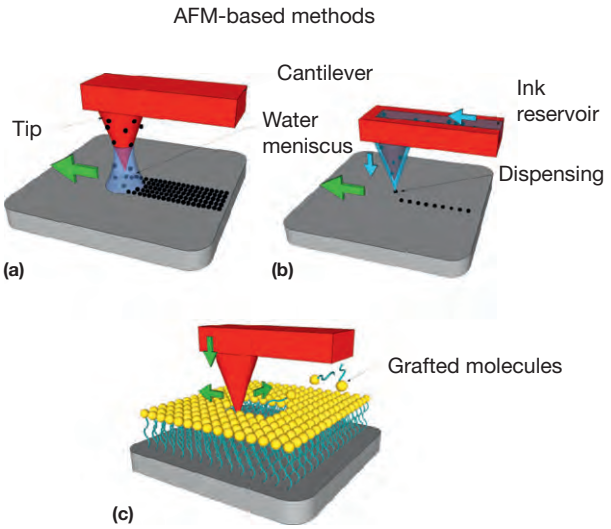

Figure 6 AFM-based patterning methods. (a) Dip-pen nanolithography (DPN). Nanopattern created by an AFM tip (red) previously dipped in the solution of interest (molecules of the solution represented in black). The meniscus formed by condensation of environmental water between the material surface and the AFM tip allows the transport of the molecules from the tip to the surface, which self-assemble, thus creating the pattern. (b) Nanodispensing technique represented by nanofountain probe (in red), characterized by an annular aperture connected to a reservoir containing the solution (or *ink*) of interest following the same principle as DPN. (c) Nanografting. This technique is based on spatially controlled shaving of molecules from the substrate (yellow) with the AFM tip (red), thus creating the pattern.

losses, and there is no need for exposing the substrate to harsh conditions such as radiation or solvents. As the movement of the tip is computer-controlled, the pattern may be easily changed at any point. Molecules are then precisely placed, at will, where needed. An excellent review on the DPN applications was written by Salaita *et al.*[88] As is true for all scanning-probe techniques, DPN has the drawback of being a serial process, which implies low throughput and, therefore, increased cost. This shortcoming has been partially overcome by parallel DPN, making DPN a highly interesting nanoscale patterning technique.

4.413.2.1.5.2. Nanodispensing techniques

Nanopen technology can be interpreted as an improved dip-pen technique. In nanopen lithography, the solution of interest flows through a nanometer pipette-like device – the pen – onto the surface to create the desired pattern, under the control of a nanoscale control tool which spatially manipulates the writing pen.

Among the advantages that nanopen technology retains from its precursor is the ability to achieve nanoscale resolution[89] while still enabling the fabrication of complex pattern geometries. Furthermore, the pipette design is capable of transferring two solutions of interest – also known as inks – onto the substrate,[87] thus allowing a combinatorial approach of molecule-based patterning at the nanoscale.

One shortcoming of nanopen technology is that feature dimensions are limited by the size of the pipette used. This limitation is overcome by nanoscale dispensing,[90] which replaces the pipette with a sharp tip cantilever with a 200-nm hollowed aperture at the apex, allowing for dispensing of volumes down to 5 attoliters with a lateral spacing below 500 nm. A further improvement, represented in **Figure 6(b)**, is the nanofountain probe,[91] which uses an annular aperture at the tip to achieve sub-100-nm resolution. Both of these systems rely on specialized probes, and one can foresee even higher-resolution patterning systems based on further probe refinements.

4.413.2.1.5.3. Nanografting lithography

Nanografting is an AFM nanolithographic technique characterized primarily by spatially controlled nanoshaving of the substrate surface, as shown in **Figure 6(c)**. This operation carefully applies a selected force to a thin film on the substrate, displacing the desired molecules from it. The desorbed molecules are discarded and the free areas are then available for the chemisorption or physisorption of the molecules of interest such as DNA,[92,93] proteins,[94,95] and antibodies.[92]

The highlight of this technique is the selective scratching by controlled manipulation of the AFM tip on the surface, allowing for high-resolution sub-100-nm patterns.[96] However, the energy delivery in this process may be aggressive to the surface, so the materials involved must be selected carefully.

4.413.2.2. Bottom-up Approaches

Bottom-up approaches use molecular entities or particles to build up systems of higher degrees of complexity. Usually, the technologies that are part of this group take advantage of the tendency of the molecules involved to self-assemble into organized structures at the micro- or nanoscale, which would be difficult to achieve by other means.

4.413.2.2.1. Colloidal lithography

Colloidal lithography is based on the use of colloidal particles with sizes ranging typically from 10 to 1000 nm, self-assembled in hexagonally close-packed patterns on a surface, and serving as a temporary mask (**Figure 7(a)**). The self-assembly process can be tuned by varying either the wettability properties of the surfaces and/or the particle chemistry.[97–99] Valsesia *et al.*[100] used colloids to selectively protect a SAM of MHDA (1-mercaptohexadecanoic acid). Upon plasma treatment of the surface and subsequent colloid striping, the ablated areas were backfilled with HDT (*n*-hexadecanethiol) and the MHDA nanopatterns were used to graft proteins at the nanoscale. In contrast, Cai and Ocko[101] used the particles as a mask during a silanization process with a PEG-silane. This procedure allowed them to generate nanopatterned protein-attractive areas surrounded by protein adsorption-resistant PEG-silane. Michel and coworkers,[35] in turn, used colloidal lithography to create pillars of TiO_2 on a SiO_2 background. In this case, the polystyrene colloids, assembled on a silicon wafer coated with a thin film of TiO_2, locally protected the TiO_2 surface during reactive etching that resulted in the exposure of SiO_2 in the unprotected background area. After removal of the colloids, the TiO_2 pillars were selectively functionalized with alkanephosphates, while the SiO_2 background was functionalized with a protein-repellent polymer, PLL-*g*-PEG. Blätter *et al.*[102] added an extra step to the fabrication process

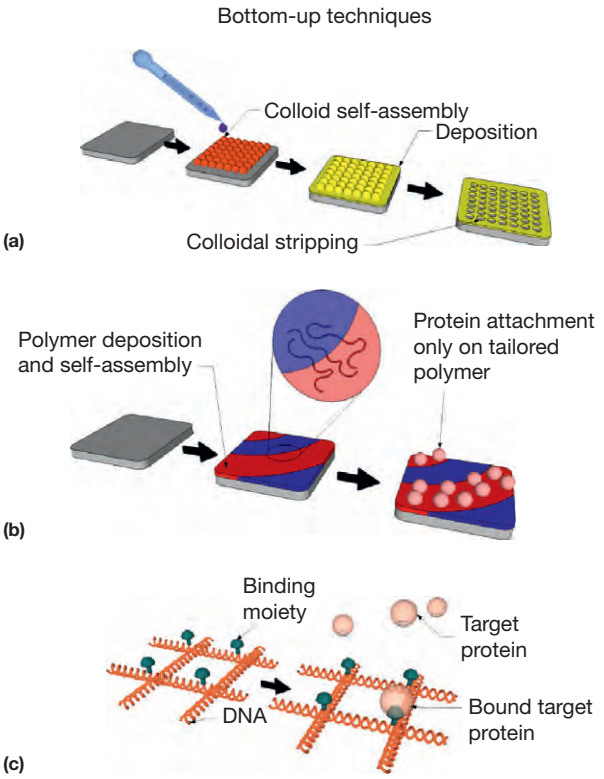

Figure 7 Bottom-up patterning approaches. (a) Colloidal lithography. This method is based on the use of colloidal particles (orange) dispersed in a solution, which self-assemble in hexagonally close-packed patterns on a surface, acting as a temporary mask. The subsequent deposition of a substance of interest (yellow), followed by the removal of the colloids, forms the nanopattern. (b) Block copolymers. Two chemically different polymers (represented in red and blue) covalently bonded at one end self-assemble into ordered structures (represented in Step 2). Their function can include biological activity, represented by the interaction with a biomolecule (pink) in the scheme. (c) DNA templating. DNA-functionalized surfaces (orange) are designed to exhibit binding moieties (green) at intervals of choice, which then bind target proteins from solution to form a protein pattern (pink).

previously described: following the polystyrene colloid assembly, the size of the particles was tailored by shrinking via exposure to an O_2/N_2 plasma for selected etching times. The reduction of the particle diameter by an order of magnitude, from approximately 2000 to 200 nm, allowed the investigators to reduce the size and increase the separation of the patterned features. More recently, Malmström *et al.*[103] used the colloids as a mask during a SiO_2 deposition procedure on a gold-coated surface. After removal of the colloids, the exposed gold areas were selectively functionalized with thiols.

4.413.2.2.2. Block copolymer micelle nanolithography

The ability to create nanoscale arrays of ordered nanoparticles on surfaces is useful in diverse fields, including electronics, optics, and materials development.[104,105] Block copolymer micelle nanolithography is a straightforward strategy to create such ordered nanoparticle structures. This strategy uses micelles of self-assembled block copolymers with a large solubility difference between their hydrophilic and hydrophobic segments.[106,107] In aqueous conditions, the block copolymers assemble into nanoscale double-layered micelles, with a hydrophilic core segregated from the bulk solution by a hydrophobic region. These hydrophilic cores can be loaded with salt precursors (e.g., metal salts or oxides), after which the vesicles are allowed to self-assemble in hexagonally close-packed patterns on surfaces. Once assembled, the salt precursors reduce and yield the desired nanoparticles embedded in the micelle block copolymer matrix. The last step of the process consists of the removal of the block copolymers by means of a hydrogen, oxygen, or argon plasma treatment in order to obtain gold dot patterns on the desired surface. The main advantage of this technology is that the distance between the resulting nanoparticles on the surface can be finely tuned just by varying the molecular weight of the block copolymers. This strategy has been used to create gold[108] and silver[109] nanodot arrays, as well as binary mixtures of gold and iron oxide nanoparticles.[110,111] Applications of self-assembling biomolecules are also discussed in **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**.

4.413.2.2.3. Block copolymers

Block copolymers consist of at least two chemically different polymers covalently bonded at one end.[112] The engaging characteristic of block copolymers is their intrinsic tendency to self-assemble into ordered domains at the nanoscale (**Figure 7(b)**), which would otherwise require both extreme effort and cost to be recreated by alternative (top-down) techniques.[113] These complex structures are the result of both the interaction energy between the blocks and chain stretching. Chemically different blocks favor phase separation, while the connectivity of the copolymer chains prevents this from happening, leading to spontaneous formation of well-defined structures, limited by the dimensions of the copolymer chain to around 5–50 nm,[113,114] without phase separation at the macroscopic level.[115] The morphology of the resulting nanopatterns depends on the relative volume fraction of each component polymer[114] and their molecular weights. Typically, spherical, cylindrical, or lamellar shapes are observed[113] and known to be thermodynamically stable.[116]

Both the individual blocks and the resulting domains of the copolymers can be modified at will. The size, shape, and arrangement of the nanopattern domains are chemically tunable,[117] while the physical, chemical, electric, and magnetic properties of each block can be additionally tailored via the incorporation of metals, ceramics, and semiconductors, thus equipping the assembled material with additional functionalities. The latter includes biological activity, conductivity, reactivity, or degradability.[112] For all these reasons, block copolymer technology has been extensively used for fabrication of nanomaterials.

4.413.2.2.4. DNA templating

Immobilizing proteins with controlled spacing and precision at the nanometer scale, using a DNA template, offers the opportunity to mimic nature's own biomolecular recognition processes and assembly machinery. Thus, this technique presents a unique way to further study, understand, and exploit fundamental biomolecular interactions, providing vital insights into the field of proteomics, medicine diagnosis, and tissue engineering.

Directed DNA templating uses the intrinsic function of DNA as molecular organizer of the bases adenine, thymine, guanine, and cytosine to create nanostructures with multiple geometries. If one wants to use this methodology, one must define the number, length, and mutual connections between the designed sequences of oligonucleotides, while keeping in mind the intended DNA topology structure. Those parameters play an important role, as the success or failure of the self-assembly strategy is intrinsically determined by their affinity and specificity.

Three specific topologies of DNA seem to be especially relevant in the context of biointerfaces, namely linear, branched, and networked, as reviewed by Campolongo and coworkers.[118] Briefly, the specificity of hybridization (the process of joining two complementary strands of DNA) makes DNA particularly useful for molecular recognition at the nanoscale, such as in pathogen detection as well as in drug delivery and medical diagnostics.

Branched DNA architectures, in turn, present multiple ends available for further functionalization. These systems present higher complexity, can perform 2D or 3D assembly, and are useful in the biosensing field for multiple biomolecule detection.

Finally, the networked topology is characterized by the DNA cross-linking through self-assembly of subunits based on end recognition. In this case, the formed topology can be applied for production of protein arrays and antigen detection.

From a chemical perspective, DNA can not only be conveniently engineered in the laboratory with Angstrom-level accuracy, but also tailored by covalently binding a collection of different functional groups, as represented in **Figure 7(c)**. Additionally, there is a range of enzymes available both to confirm the formation of the desired DNA structure and to modify its structure at will.[119] Excellent reviews about this technique have recently been published by Chhabra *et al.*[119] and Li.[120]

4.413.3. Biointerfacing with Patterned Surfaces

The nature of interfacial phenomena is intrinsically interdisciplinary, encompassing the fields of engineering, physics, chemistry, and biology. To understand the complex relationship between surface chemistry and biological systems, the scientific community has combined the topographical and chemical modification of surfaces to create multifunctional systems that may incorporate biological cues such as vitamins, oligonucleotides, saccharides, peptides, and proteins on solid substrates. The introduction of tissue cells, bacteria, and viruses to these model biointerfaces allows the study and interpretation of their behavior in relation to a biologically significant environment in two and three dimensions. The ability to fabricate biomimetic surfaces intrinsically relates to the development of technology to operate at the micro- and nanoscale in a controlled, precise, and reproducible way. The considerable progress made in the micro- and nanoengineering fields to date has encouraged scientists and engineers to pursue the study of increasingly realistic biological systems, which holds great promise for the fields of tissue engineering and regenerative medicine, immunology, neuroelectronics, biosensors, (targeted) drug delivery, medical imaging, and diagnostic devices for drug discovery and screening.

The concept that cell behavior *in vivo* is governed to a large degree by interactions with neighboring cells and the extracellular matrix (ECM) has become widely accepted by the scientific community. Typical experimental models studying the cell–cell adhesion proteins involved in intercellular connections are based on patterning techniques that provide tight control over the distribution of such ligands on the material surface, and, until 2002, these patterns were restricted to non-membrane proteins. Fang *et al.*[121] reported patterned membrane protein arrays and their use for ligand screening, thereby pointing the way to a new method of compound screening, as membrane-bound proteins are the main targets of modern drugs, and enabling highly parallel studies of the fundamental processes involved in cell−cell communication. Intercellular engagement, however, results from the recruitment and rearrangement of adhesion protein complexes that involve both immobile and laterally mobile proteins.[122] *In vitro* recreation of the lateral mobility of proteins of the cellular membrane is made possible by artificial model membranes, which include Langmuir monolayers, planar bilayers, lipid vesicles (liposomes), and substrate-supported planar bilayers. One important feature of the latter is the potential to generate micropatterned membranes on a solid substrate via microfabrication techniques. Among the technologies described in **Section 4.413.2**, μCP, microfluidics, and scanning-probe microscope techniques follow the principle of spatial control of the deposition or removal of lipid membranes, while photolithographic approaches imply either UV polymerization or deep UV decomposition of lipid bilayers, as reviewed by Morigaki.[123]

In this section, we introduce significant experimental methodologies used to study biologically relevant interfaces via surface patterning down to the nanoscale in the cellular, bacterial, and viral fields. Further discussion of relevant topics may also be found in **Chapter 4.407, Bacterial Adhesion and Biomaterial Surfaces**; **Chapter 4.409, Surfaces and Cell Behavior**; **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**; and **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**.

4.413.3.1. Vesicle and Membrane Patterns

As the cell membrane is a critical component to understanding the functionality of the cell and investigating its structural and dynamic aspects, artificial bilayer membranes are preferred biomimetic platforms to study, for example, heterogeneities and molecular organization in the bilayer at the submicron scale, for the insertion of transmembrane proteins, and to gain access to both sides of the bilayer if deposited on porous substrates.

4.413.3.1.1. Vesicle arrays

Membrane protein microarrays have the potential to serve as a sensitive and efficient analytical tool for applications in drug discovery and screening.[8,121] While DNA/RNA, and to some extent also protein microarrays, are used routinely, the organization of membrane proteins at surfaces in general, and in an array format in particular, poses a number of specific challenges related to the need to accommodate them

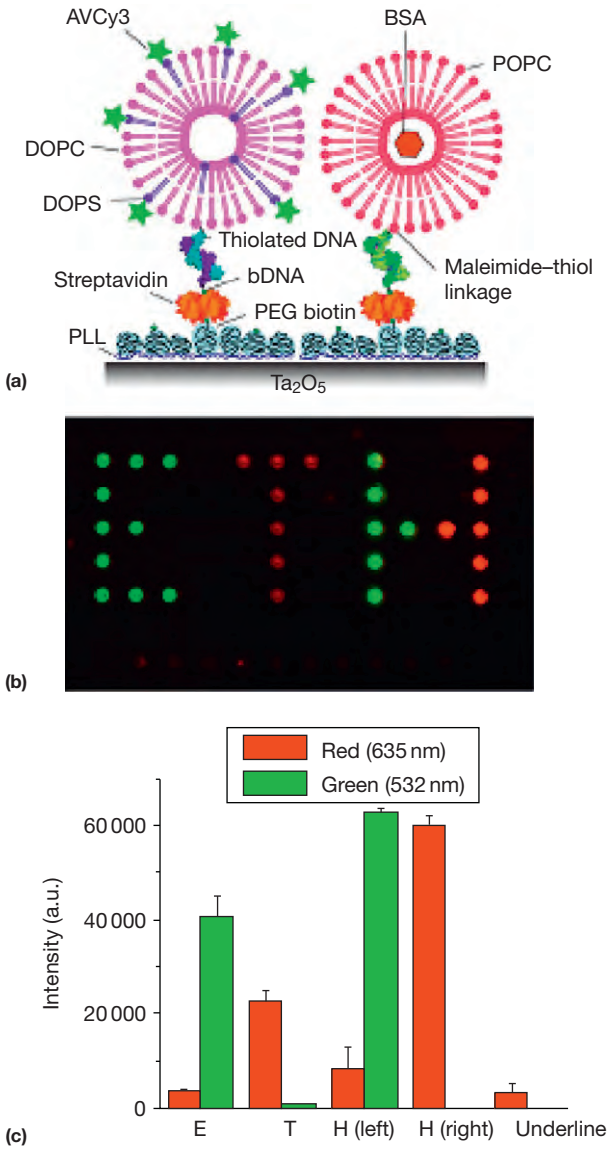

Figure 8 (a) Schematic, (b) microarray fluorescent reader image, and (c) fluorescent intensity signal of the green and red channel of two different surface-immobilized vesicles. A Ta_2O_5 waveguiding chip is coated with PLL-*g*-PEG/PEG-biotin. In a second step, complexes of streptavidin (SA) and biotinylated DNA are spotted onto the chip. Finally, the surface is exposed to a solution of two kinds of functionalized vesicles (Figure b left ('E'): A5Cy3-modified DOPC/DOPS vesicles; right ('T'): BSA647-loaded 1-palmitoyl,2-oleoyl-*sn*-glycero-3-phosphocholine vesicles tagged with DNA via the maleimide-thiol linkage. In addition, controls are included: 'H' (left): SA534; 'H' (right): SA633. The DNA-tagged vesicles selectively decorate the corresponding spots on the surface. Reproduced from Städler, B.; Bally, M.; Grieshaber, D.; *et al. Biointerphases* **2006**, *1*, 142–145, with permission from the American Vacuum Society.

in their natural, lipid-based microenvironment in order to preserve their functionality. In particular, such fragile proteins cannot be spotted and dried for the production of arrays, in contrast with DNA and more stable proteins. To this end, different approaches have been exploited, generally based on solid-supported phospholipid bilayers, liposomes, or polymersomes. In this context, there is an interest in developing patterns of vesicles as a potential carrier of membrane proteins in a heterogeneous array format for multiplexed readouts.

Städler *et al.*[8,124] have proposed an approach that combines conventional microspotting and site-specific immobilization of DNA-tagged nano-objects (lipid vesicles in this specific case) through specific DNA–DNA hybridization. They prepared nonfouling, homogeneous PEGylated surfaces presenting biotin, onto which SA complexed with primary DNA strands was deposited from solution using the pin and ring spotting technique, as shown in Figure 8. For proof of concept, two types of vesicles, each tagged with a different DNA sequence (DNA1 and DNA2), were mixed in solution and exposed to the microarray containing the predefined spots of complementary DNA strands. The vesicles tagged with the complementary DNA1 were functionalized with green-labeled annexin A5 as a representative membrane-binding protein, while the vesicles tagged with complementary DNA2 were loaded with red-labeled BSA. To monitor the sorting of the vesicles to their complementary DNA spots of the microarray chip and judge the selectivity of this process, a fluorescent microarray reader was used.

Control experiments, shown in Figure 9, showed that the presence of the SA was essential in order to provide spots of single-stranded bDNA on the surface for the immobilization of the DNA-tagged vesicles. In Figure 9(aI), Column A represents spotted complexes of SA633 and bDNA1, while B contained only spotted bDNA1. The subsequent immobilization of the DNA-tagged A5Cy3-functionalized vesicles occurred only where the single-stranded DNA was immobilized via SA (Figure 9(aII)). In Column B, less than 1% of the green channel compared to Column A was detectable, demonstrating that no vesicles were surface-immobilized. The results demonstrate the feasibility of solution-based arraying of not only membrane-bound proteins, but also of arraying proteins confined to small compartments that have potential applications in high-throughput studies of enzymatic reactions performed in vesicular nanocontainers.

4.413.3.1.2. Supported membrane arrays

Cell–cell interactions are a key aspect of the development of tissue. Transmembrane cell–cell adhesion proteins, such as the members of the cadherin family, play an important role in the formation and maturation of cell–cell contacts that control paracellular diffusion (tight junctions) and maintain the structural continuum of the epithelium (desmosomes).[125] As the underlying molecular processes in cell membranes are highly dynamic, only platforms that allow for mobility of ligands *in vitro* have a chance to mimic their lateral mobility, recruitment, clustering, and binding, while the commonly used *in vitro* models with proteins immobilized on culture dishes fail to capture this lateral mobility. Supported lipid bilayers, prepared by a fusion of liposomes or proteoliposomes on glass surfaces, have been shown to retain the inherent mobility of incorporated membrane proteins.[126]

Perez *et al.*[122] have described a system for investigating how this lateral mobility influences cadherin-based cell signaling: the GPI-modified E-cadherin protein (hEFG) was tethered to a supported lipid bilayer produced by a fusion of

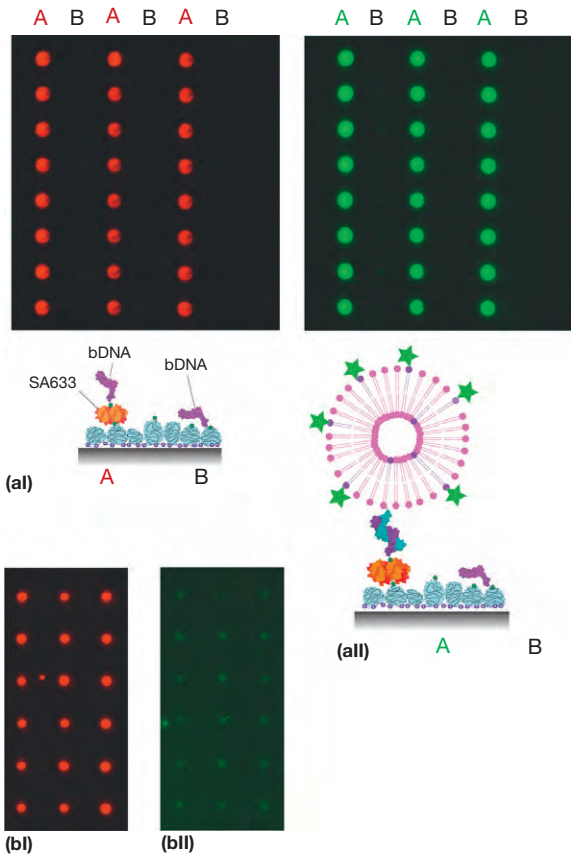

Figure 9 Spotted array of SA633 and bDNA1 complexes (A columns) and bDNA1 alone (B columns) (aI). Subsequent immobilization of the A5Cy3-functionalized DNA-tagged vesicles occurred in Column A, while in Column B, a green signal which is less than 1% compared to Column A is detected (aII). Spotting onto PLL-*g*-PEG without the biotin function leads to smaller spots of SA633 and bDNA1 (bI), and only 2% of vesicles compared to (aII) Column A can be surface-immobilized (bII). Reproduced from Städler, B.; Bally, M.; Grieshaber, D.; *et al*. *Biointerphases* **2006**, *1*, 142–145, with permission from the American Vacuum Society.

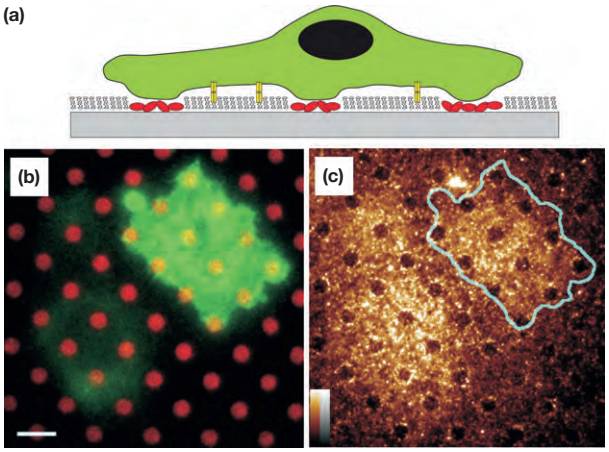

Figure 10 (a) Schematic of cell adhesion to the micropatterned surface, color-coded to correspond to the other panels in this figure. (b) Adhesion of MCF-7 cells (green) onto a hEFG/egg PC bilayer surface, micropatterned with an array of 5 μm diameter fibronectin dots (red). MCF-7 cells were transfected with enhanced yellow fluorescent protein (EYFP)-Mem, yielding a mixed population of cells expressing different levels of this protein. This panel contains three cells which are all detectable at long exposure; the cell visible in the upper right of this lower exposure image expressed the highest level of EYFP. (c) Cy5-hEFG distribution in the same field of view as panel B. Color map is shown in the lower left corner of this panel. The outline of the bright cell shown in panel B is overlaid in light blue. Scale bar = 10 μm. Reproduced from Perez, T. D.; Nelson, W. J.; Boxer, S. G.; Kam, L. *Langmuir* **2005**, *21*, 11963–11968, with permission from American Chemical Society.

proteoliposomes. However, when endothelial (MCF-7) cells were seeded on such functionalized supported membranes, they were found to be unable to spread as a consequence of the mobile nature of membrane-tethered ligands, which prevents cells from being able to exert tensile forces needed for the spread and survival of anchorage-dependent cells. The solution to this problem was found with the approach of using small immobile anchors to allow for cell spreading while facilitating cell interaction with mobile ligands in the bilayer patterns between the adhesion sites (cartoon in Figure 10(a)). The authors used μCP of fibronectin dots of 5 μm diameter that served as integrin-mediated adhesions, allowing the cell to spread across multiple fibronectin adhesion dots (Figure 10 (b)). Apart from being able to spread, cells interacted with ligands presented on the supported lipid bilayer, evidenced by the clustering of hEFG protein, as illustrated in Figure 10(c). There was also evidence that these spread and hEFG protein interacting cells were viable, so the platform used constitutes an appropriate model for studying cell–protein interaction. This study highlights the frequent need for more complex patterns with not just one, but two or more complementary functionalities presented in a spatially controlled manner, in this specific case, the promotion of interaction of cells not with the features themselves but with targets associated with the intervening regions that present membrane-tethered proteins.

4.413.3.2. Cell Adhesion and Function on Patterned Surfaces

The cellular microenvironment is known to be a key aspect of cell adhesion, development, and function, and steers cellular activities such as spreading, apoptosis (programmed cell death), proliferation, differentiation, and motility.[127,128] Cell shape, interactions with neighboring cells and with the extracellular matrix, and substrate rigidity and dimensionality – all affect cell adhesion and function in a complex regulatory process.[129] The emergence of patterning techniques in 2D and 3D has fostered new approaches to study cell adhesion and development in a reductionist format, enabling the quantitative interrogation of the impact of single microenvironmental parameters on cellular function. A plethora of published studies convincingly demonstrate that the presentation of ECM cues in a micropatterned (where the pattern size is comparable to cell dimensions) and nanopatterned (where the pattern size is comparable to the dimension of single adhesion complexes) format steers cell adhesion and development.

In the following section, examples of the use of micro- and nanopatterned substrates are provided, which highlight the importance of pattern geometry on cell adhesion, shape, survival, differentiation, and division. In terms of patterning aspects, a typical approach would be to produce cell-adhesive ECM protein or peptide patterns (consisting of fibronectin, collagen, vitronectin, laminin, or RGD peptide) by a top-down or bottom-up technique on a background that is nonadhesive to proteins and cells, thus confining whole cells or subcellular components to the specific pattern geometry. Varying the size, composition, shape, and spacing between the printed features allows the influence of the individual geometrical/spatial parameters on function and metabolism to be deciphered in a time-resolved manner.

4.413.3.2.1. Cell shape and its impact on cell survival/apoptosis

Chen and coworkers[130] used μCP to create patterns of ECM-coated adhesive islands, and investigated the adhesion, spreading, growth, and survival/apoptosis of human and bovine capillary endothelial cells as a function of ECM pattern shape and size as well as distance (pitch) between the patterns. Figure 11 shows the relationships between the adhesive island area, apoptosis, and DNA synthesis (which correlates with growth). Cells were found to spread on the larger, fibronectin-coated patterns, where they adopted a flat morphology and largely survived. In stark contrast, cells adhering to increasingly smaller patterns retained a more spherical, less spread shape, and increasingly underwent apoptosis. When cells were allowed to spread across small, but closely spaced, adhesive patterns (maintaining the total cell–matrix contact area constant), they again showed high survival rates. Cell shape was thus found to govern whether individual cells grow or die, regardless of the type of matrix protein or antibody to integrin used to mediate adhesion, indicating the fundamental importance of local geometric control of cell growth and viability in the context of developmental regulation within the tissue microenvironment.

4.413.3.2.2. Cell adhesion to nanopatterned surfaces

The presentation of bioligands with tailored surface densities and precisely controlled spatial distribution at the submicrometer to molecular scale is of high interest to the biointerface community, as such designed surfaces have the potential to shed light on many important biological processes. Examples include the formation of multivalent binding (e.g., between carbohydrates and proteins or bacteria), which determine the affinity/avidity and specificity of many biological processes, as well as cell–matrix interactions and cell signaling. Precise control and presentation of biochemical cues at the low nanometer or molecular level remains challenging, however, particularly if large surfaces areas are required for statistically meaningful studies, which cannot cost-effectively be produced by EBL. Bottom-up self-assembly techniques have a clear advantage in this respect.

A successful example of large-scale nanopatterning is the self-assembly of diblock copolymers of polystyrene-*block*-poly(2-vinylpyridine) (PS-*b*-P2VP) incorporating a gold precursor ($HAuCl_4$) into reverse micelles in toluene.[108] Controlled retraction of a substrate from the micellar solution resulted in a uniform and well-ordered monolayer of micelles at the substrate

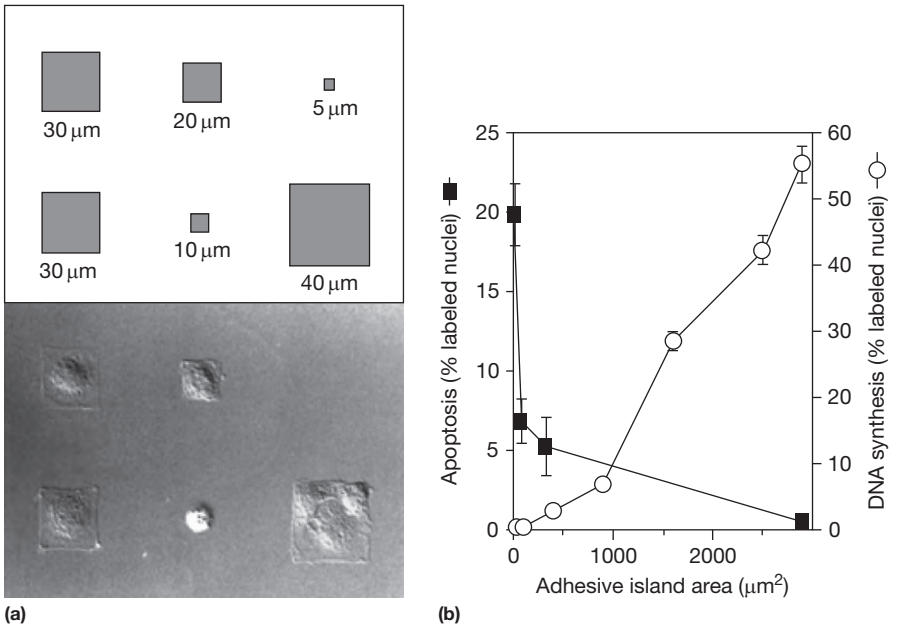

Figure 11 Effect of spreading on cell growth and apoptosis. (a) Schematic diagram showing the initial pattern design containing different-sized square adhesive islands and Nomarski views of the final shapes of bovine adrenal capillary endothelial cells adhered to the microfabricated substrate. Distances indicate lengths of the square's sides. (b) Apoptotic index (percentage of cells exhibiting positive TUNEL staining) and DNA synthesis index (percentage of nuclei labeled with 5-bromode-oxyuridine) after 24 h, plotted as a function of the projected cell area. Figure 12 Micellar block copolymer lithography and biofunctionalization. (a) Scheme of diblock copolymer micelle lithography. (b–e) Extended gold (Au) nanodot (3–8 nm in diameter) patterns are displayed by SEM. Variation in the size and separation of the Au nanodots has been achieved by the use of $HAuCl_4$-loaded PS-*b*-PVP with different molecular weights of the polymer components, assembly (a) and reactive plasma treatment. (f) Biofunctionalization of the Au nanodot pattern with integrin-receptor-interactive cyclic RGD-thiols and passivation of the background with PEG. As the gold dot is sufficiently small, it is most likely that only one integrin transmembrane receptor directly interacts with one dot. The Au dots are presented as side view micrographs taken with a high-resolution transmission electron microscope. Reproduced from Spatz, J. P.; Geiger, B. In *Methods in CellBiology*; Wang, Y-L., Discher, D. E., Eds.; Elsevier, 2007; Vol. 83, pp 89–111.

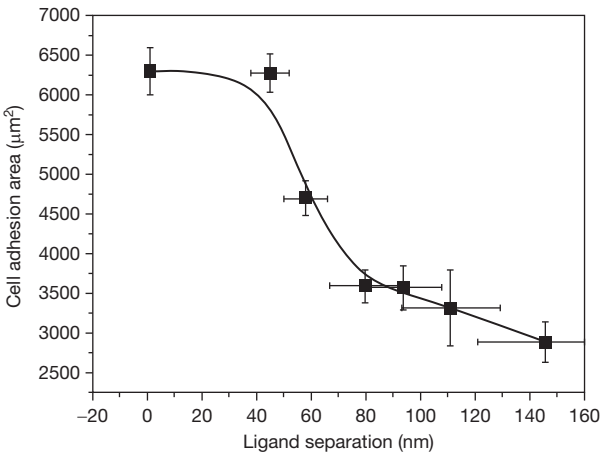

Figure 13 Projected cell adhesion area per cell adhering to different ligand (dot) separation for MC3T3 osteoblasts cultured on integrin-interactive RGD-presenting gold nanodot patterns with a range of different interparticle spacings. Reprinted from Arnold, M.; Cavalacanti-Adam, E.; Glass, R.; *et al*. *ChemPhysChem* **2004**, *5*, 383–388, with permission from Wiley.

surface, as shown schematically in Figure 12(a). Subsequent treatment of these films with reactive gas plasma converted the gold-loaded micellar film into an array of highly regular Au nanoparticles. The size and spacing of the gold nanodots could be controlled by appropriate choice of the molecular weights of the copolymer components (Figure 12(b)–12(e)). Spatz and coworkers[131,132] also demonstrated fabrication of Au nanodot pattern geometries of two different length scales (micro and nano) by the use of inorganic block copolymer micellar monolayers in combination with EBL.

The Au nanodots were subsequently functionalized with cyclic RGD-thiols, a peptide that shows high affinity to $\alpha_v\beta_3$-integrin receptors in the cell membrane (Figure 12(f)). When placed on functionalized Au nanodot patterns separated by varying widths, MC3T3 osteoblasts spread very well and formed focal adhesions (FAs) on patterns if the Au nanodot (and therefore RGD) interparticle spacing was $<\sim$60 nm, comparable to their spreading on uniform RGD- or fibronectin-coated surfaces. In stark contrast, cell spreading on substrates with Au nanodots spaced $>\sim$70 nm was very limited, and FA formation strongly reduced (Figure 13). These findings provide strong evidence that close proximity/clustering of ECM-engaged integrin receptors at the molecular scale is a prerequisite for strong adhesion through FAs and that there is a universal length scale for integrin clustering and activation, as these properties are shared by a variety of cultured cell lines.[133]

4.413.3.2.3. Cell differentiation on micropatterned surfaces

The differentiation of cells into different lineages can be regulated by the local microenvironment. McBeath and coworkers[134] have demonstrated that human mesenchymal stem

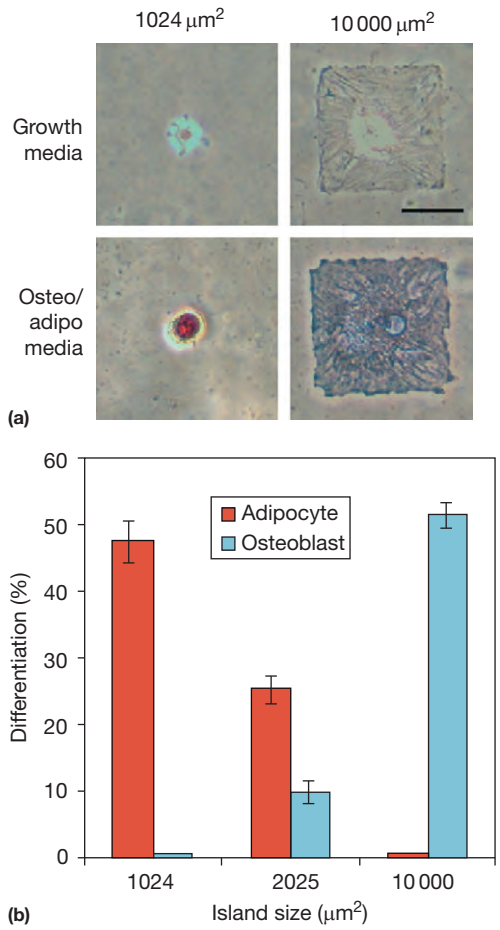

Figure 14 (a) Single hMSCs cells cultured on either small (1024 μm^2) or large (10 000 μm^2) fibronectin patterns after 1 week of growth in mixed media, fixed and stained for both alkaline phosphatase (AP) and lipids. (b) Percentage of differentiation plotted against the island size. hMSC adipogenesis occurred only on the small patterns, osteogenesis occurred on the large ones, and a mixture of both lineages was observed on intermediate-sized patterns. The percentage was determined only for islands containing single cells. Reprinted from McBeath, R.; Pirone, D. M.; Nelson, C.M.; Bhadriraju, K.; Chen, C. S. *Dev. Cell* **2004**, *6*, 483–495, with permission from Science.

cells (hMSCs) can be made to differentiate into adipocytes or osteoblasts by varying the area of the cell adhesive island on which they spread. The micropatterns were created by direct μCP of fibronectin on flat PDMS surfaces. To prevent cell attachment outside the patterns, the surface was backfilled with Pluronics® (PEG–PPO block copolymers).

When cells were confined to a small area, they differentiated into adipocytes, while if they were allowed to spread on an area ten times larger, they differentiated into osteoblasts (Figure 14). The authors showed that cell shape, dictated by the pattern size, regulated the switch in lineage commitment by modulating endogenous RhoA activity. These results also shed light on the close relationship between mechanosensation and commitment of stem cell fate.

4.413.3.2.4. Effect of micropatterned surfaces on cytoskeletal architecture

The shape of the island on which the cell grows affects the internal organization of the cytoskeleton and induces rearrangement of microtubules and actin filaments. This adapted organization affects cell metabolism, especially during the process of cell division. During cell division, cells adopt a more round cell shape while still remaining attached to the surface by means of retraction fibers formed by actin-associated proteins. Thery *et al.*[135] tuned the orientation of the force that these retraction fibers exert over the mitotic cells by changing the design of the ECM micropatterns to which the cells were confined. This study elucidated the effect of the retracting forces on the spindle orientation during the cell division process. Figure 15 shows five distinct patterns produced by μCP of fibronectin and the distinct spindle orientations induced by the corresponding patterns.

4.413.3.2.5. Cell motility on micropatterned gradients

During development of the nervous system, axon growth and neuronal connections are directed by guidance molecules *in vivo*. The guidance molecules create gradient patterns to establish the cell growth cone in the required direction. Further discussion of these and related topics may be found in **Chapter 5.532, Nerve Tissue Engineering**. The signaling environment of the cell can be studied *in vitro* if micropatterned gradients of the guidance molecules are recreated on the surface. von Philipsborn *et al.*[49] used the μCP technique to recreate on a surface a gradient of ephrin A5, a protein known to guide retinal ganglion cells's (RCA) axons. The gradient consisted of an array of patterned features with increasing areas over one direction, in order to generate a unidirectional stepwise increase of ephrin A5 on the surface. Once the retinal ganglion cells were cultured, the axons grew in the direction in which the patterned features were larger, as the surface concentration of ephrin A5 was correspondingly higher. Figure 16(a) shows an axon growth cone of a cell navigating the gradient pattern. The same laboratory later demonstrated the use of a microfluidic patterning strategy to create gradients of the same protein, and demonstrated that the slope of the concentration gradient modulates the growth cones' guidance.[136] Microfluidic patterning allowed for the easy creation of such gradients by loading each subsequent channel with solutions of increasing ephrin A5 concentrations. Upon adsorption of the proteins onto the surface, this process yielded an ephrin A5 concentration that increased unidirectionally along the pattern. Figure 16(b) depicts how growth cone advancement can be tuned depending on the characteristics of the gradient.

4.413.3.2.6. Tissue engineering

The field of tissue engineering uses living cells in a variety of ways to restore, maintain, or enhance tissues and organs.[137] Inside the body, cells lie either in direct contact or in close proximity to other cell types in a tightly controlled architecture that ultimately regulates the resulting tissue function. Tissue engineering strategies to recreate the geometry of tissues will benefit from both the intercellular interactions and the methods to control the local environment. Therefore, patterned coculture models hold the potential to mimic both the local environment

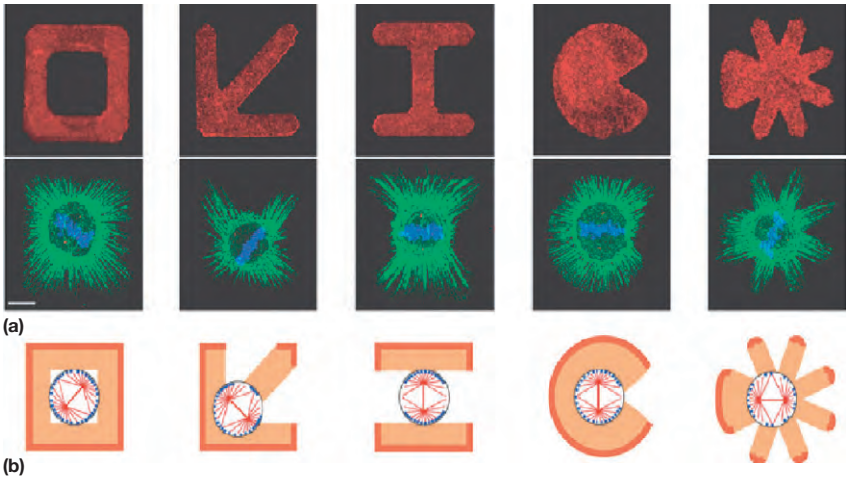

Figure 15 (a) Mitotic single cells growing on five distinct fibronectin micropatterns (red fluorescent staining). Retraction fibers (actin green fluorescent staining) and chromosomes (blue Hoechst staining) indicate the spindle orientation. (b) Schematic micropatterns (orange), anchoring sites for retraction fibers (dark orange), and corresponding distributors of force generators (blue). Figure 16 (a) Ephrin A5 protein gradient (green) and retinal ganglion cell (RGC) navigating cones (red) seen with a fluorescence microscope. (b) Temporal RGC axons in gradients produced by μFN. Fluorescence images of a stepwise gradient of ephrinA5 spanning a distance of 320 μm. The stop zone shifts further into a shallow gradient than a steep one. Phalloidin-stained axons are shown in black, antibody-stained ephrin in red. Adapted from von Philipsborn, A.; Lang, S.; Bernard, A.; *et al. Nat. Protoc.* **2006**, *1*, 1322–1328 with permission from Macmillan Publishers Ltd.; Lang, S.; von Philips, A. C.; Bernard, A.; Bonhoeffer, F.; Bastmeyer, M. *Anal. Bioanal. Chem.* **2008**, *390*, 809–816, with permission from Springer.

of tissues, through the location and shape of biological and physical gradients,[138] and the reciprocal regulation and functional relationship between at least two cellular types in the context of tissue formation. For example, Bhatia's laboratory[64] used the microstenciling technique to pattern human liver cell clusters (Figure 17(a)) and study how an environment of fibroblasts affects hepatocyte function (Figure 17(b)). An exhaustive comparison of the gene expression profiles, metabolism, canalicular transport, and susceptibility to hepatoxins was performed between hepatocyte microclusters with and without a fibroblast cell environment. This study may serve as an inspiration to use patterned cocultures instead of cellular purified elements as a tissue model, which could also be useful for the fast screening of drugs. The subject of tissue engineering is further treated in Chapter 5.507, Tissue Engineering and Selection of Cells.

4.413.3.3. Bacteria at Patterned Interfaces

Bacterial adhesion is the first step in the cascade of processes from surface colonization to biofilm formation. The latter is of great medical relevance, as biofilm formation is a key aspect of infection, given the ability of bacteria to protect themselves from the action of drugs, such as antibiotics, by forming a polysaccharide-rich matrix. The underlying molecular

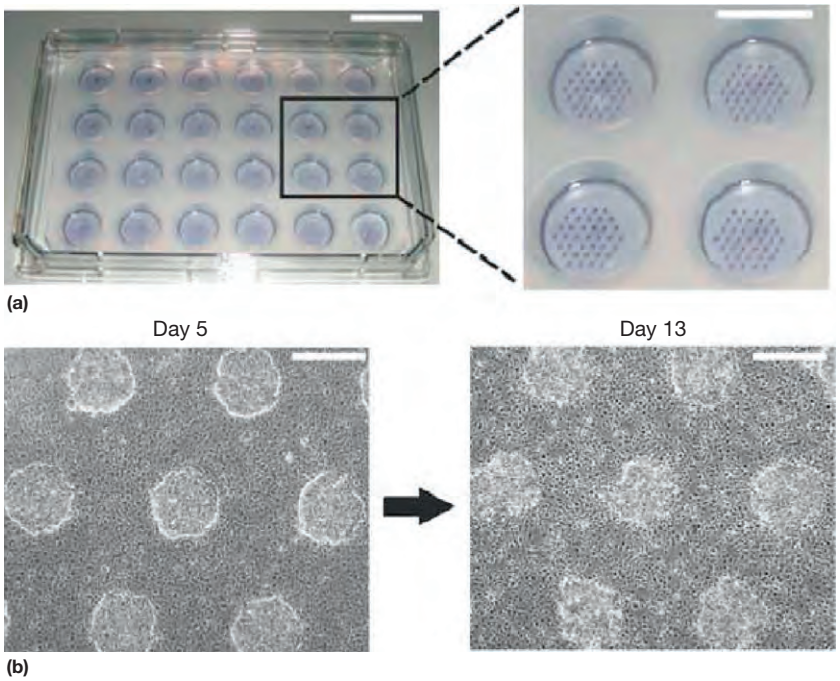

Figure 17 A PDMS microstencil was used to create 400 μm fibronectin islands to study the effect of the fibroblast's environment on the patterned hepatocyte cluster. (a) Photograph of a 24-well device with repeating PDMS microstencils, each with 37 microapertures (insert). (b) Phase-contrast micrographs of cocultures. Once the human hepatocytes adhere to the fibronectin-coated islands, fibroblasts are seeded onto the remaining areas. Images depict pattern fidelity over several weeks of culture. Scale bars are 500 μm. Adapted from Khetani, S. R.; Bhatia, S. N. *Nat. Biotechnol.* **2008**, *26*, 120–126, with permission from Macmillan Publishers Ltd.

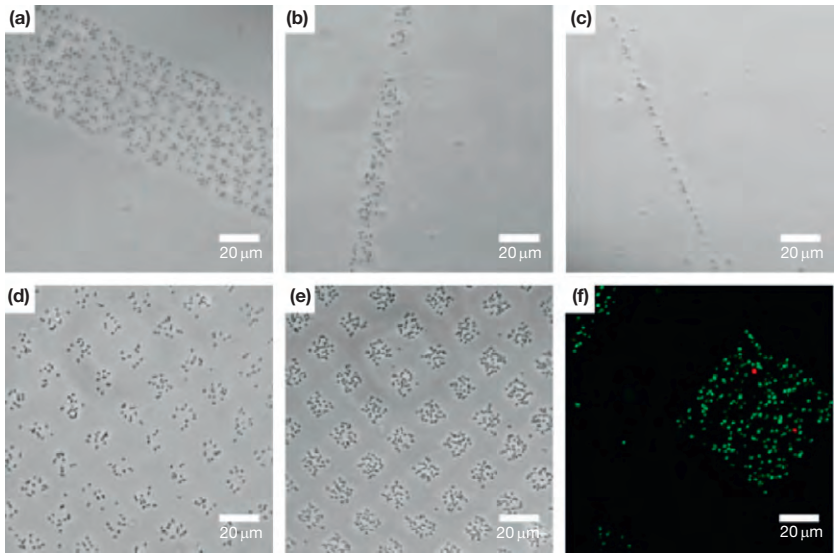

Figure 18 *Escherichia coli* bacteria patterned on PLL-*g*-PEG/PEG-mannoside patterns backfilled with PLL-*g*-PEG. (a–c) Bacteria attached to mannoside-patterned lines of 50, 10, and 2 μm width, respectively (culture time: 30 min). (d–e) The number of cells per patterned square varied depending on the type of mannoside present on the patterns (lower affinity monomannose and higher affinity trimannose, respectively). (f) Fluorescence image of live/dead-stained *E. coli* adhering to $60 \times 60\ \mu m^2$ patterned squares. Live bacteria appear green, dead bacteria red. Most of the bacteria remain alive upon immobilization. Reproduced from Barth, K. A.; Coullerez, G.; Nilsson, L. M.; *et al. Adv. Funct. Mater.* **2008**, *18*, 1459–1469, with permission from John Wiley and Sons.

mechanisms of bacterial colonization and biofilm formation are still poorly understood. For this reason, the study of the nonspecific and specific adhesion mechanisms of pathogens to precisely controlled interfaces has gained increased interest.

Bacterial adhesion to glycoproteins or glycolipids on the surface of eukaryotic cells via specific recognition by bacterial lectins is involved in a plethora of bacterial infections. Bacteria use different types of lectins to target host carbohydrates.[139] For

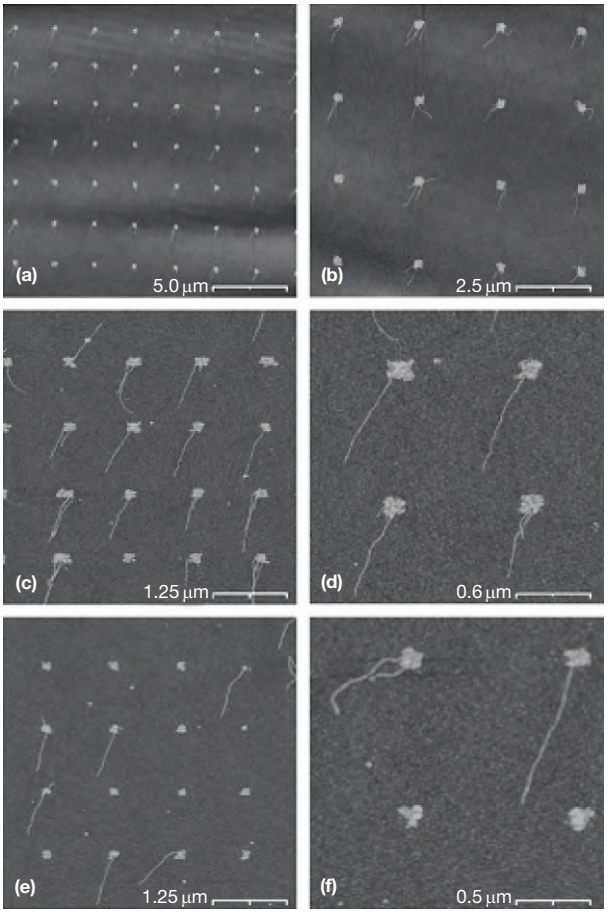

Figure 19 The number of viruses grafted to the antibody nanopatterns varies with the area of the islands. Feature sizes are 240 nm × 240 nm (a,b), 200 nm × 200 nm (c,d), and 90 nm × 90 nm (e, f). The bigger patterns see the majority of sites occupied by two or more phages, while the smaller patterns present only single-cell occupancy, at the cost of having only 20% of the features occupied. The intermediate size presents 21% of the features with two of more viruses and 41% with single virus occupancy. Reproduced from Solis, D. J.; Coyer, S. R.; Garcia, A. J.; Delamarche, E. *Adv. Mater.* **2010**, *22*, 111–114, with permission from John Wiley and Sons.

example, mannoside-containing N-linked glycoproteins are known to be the specific targets of bacterial FimH receptors in *Escherichia coli* bacteria. Barth *et al.*[140] produced surfaces containing PEG brushes presenting distinct oligomannosides (Figure 18), and studied the attachment of *E. coli* bacteria on those surfaces, with the aim of developing surfaces that model host tissues. Micropatterns of PEG-mannoside against a noninteractive background of nonfunctionalized PEG was produced via a resist-based photolithographic technique (MAPL, described in Section 4.413.2.1.1) and used to selectively generate bacteria colonies of different sizes and shapes. Such patterns of well-defined bacterial colonies are of potential interest as model surfaces to study the mechanistic aspects of bacteria communication and the formation of biofilms as well as to mimic controlled defects in antimicrobial coatings at the micron or submicron scale.

4.413.3.4. Viruses at Patterned Interfaces

Arrays of patterned viruses have recently attracted great interest. For example, using nanoscale patterns of antibodies directed against a phage coat protein can provide a strategy for arraying phages, irrespective of their biological diversity, as has been shown by Solis *et al.*[141] (Figure 19). The arrayed phages may subsequently serve as a platform for the presentation of bioligands of interest, and have the potential to elucidate the intricate relationships between spatial organization and resulting functionality in biological systems. Important potential future applications may, therefore, include advanced diagnostic or therapeutic systems. Solis *et al.*[141] used the subtractive printing technique (for details, see Section 4.413.2.1.4) to pattern antibodies directed against the M13 bacteriophage in square nanometric islands (with 90, 200, or 240 nm side length). Incubation of the patterns with bacteriophage suspensions resulted in arrays of viruses. The number of viruses grafted on each island depended on the phage suspension concentration and the size of the nanometric patterns. Using this strategy, large-scale arrays of single identical phages or different phages were created as a platform for the study of interactions with ligands of interest. One can foresee further enlightening studies using this strategy in association with fluorescence microscopy.

Glossary

Biomimetic To imitate or copy structure and function from biological macromolecules and assemblies.

Extracellular matrix Interlocking array of proteins and glycosaminoglycans present around cells that often provides anchorage for the cells.

Glycocalyx The carbohydrate-rich glycoprotein–polysaccharide layer that covers a cell surface.

Phosphorylcholine The functional group derived from phosphocholine (choline chloride *O*-(dihydrogen phosphate)).

Plasma coating A thin polymer film created using radiofrequency 'plasma' glow discharge technique.

Saccharide A small carbohydrate molecule such as glucose.

Steric repulsion Dynamic network of associated water molecules (surrounding hydrated molecules) that prevents penetration by large macromolecules such as proteins.

Zwitterion A molecule that contains both a negative and a positive charge on different atoms within the molecule.

Abbreviations

AFM	Atomic force microscopy
APC	Activated protein C
ATIII	Antithrombin III
Dex	Dextran
ePTFE	Expanded polytetrafluoroethylene
EC	Endothelial cell
ECM	Extracellular matrix
FA	Focal adhesion
Fg	Fibrinogen
FN	Fibronectin
G	Generation
GAG	Glycosaminoglycan
Hex	Hexanoyl or Hexanal
HSPG	Heparan sulfate proteoglycan
IC	Ion channel
ID	Internal diameter
MW	Molecular weight
OTS	Octadecyltrichlorosilane
PAI	Plasminogen activator inhibitor
PC	Phosphatidylcholine
PDMS	Polydimethlysiloxane
PEG	Poly(ethylene glycol)
PEO	Poly(ethylene oxide)
PG	Proteoglycan
PGI2	Prostaglandin I2
PLG	Plasminogen
PLM	Plasmin
PMMA	Poly(methyl methacrylate)
PPP	Platelet poor plasma
PRP	Platelet rich plasma
PSFP	Peptide fluorosurfactant polymer

PTFE	Polytetrafluoroethylene	**TAT**	Thrombin-antithrombin complex
PVam	Poly(vinyl amine)	**TF**	Tissue Factor
RGD	Arginine glycine aspartate	**TM**	Thrombomodulin
SEM	Scanning electron micrograph	**TPA**	Tissue plasminogen activator
SP	Surfactant Polymer		

4.414.1. Introduction

Biomaterials are used in biomedical devices that sustain, augment, or completely replace diseased human organs. These include vascular grafts, heart valves, and ventricular assist devices; orthopedic devices; drug delivery systems; extracorporeal systems; and a wide range of invasive treatment and diagnostic systems.[1–4] The use of synthetic materials for biomedical devices has increased considerably in recent years. The principal reasons for this proliferation have been (1) the increasing clinical demand for diverse, improved biomaterials for an aging population and (2) the increasing availability of materials, particularly polymers that possess the appropriate mechanical and physical properties. These materials range from delicate hydrogels for soft contact lenses and tissue engineering scaffolds to tough, ultrahigh molecular weight polyethylene for components of joint prostheses. However, current clinically used biomaterials are still largely based on commodity polymers introduced over 50 years ago, such as polyethylene, polyester fibers, silicones, and polyurethanes. Unfortunately, these and other biomaterials suffer from well-known problems including surface-induced thrombosis, excessive wound healing, and infection.[4,5–7] For example, small-diameter (<6 mm ID) vascular grafts are currently clinically impracticable as they are associated with consistent thrombotic occlusion and intimal hyperplasia.

The interface between a biomaterial and the biological environment is crucial to the solution of these problems because it affects protein and platelet interactions, thrombus formation, infection, fibrosis, calcification, tissue integration, and cell–surface interactions. Consequently, approaches that provide improved blood and tissue biocompatibility would favorably impact medical device performance and facilitate development of devices that are currently not feasible. This chapter considers approaches to the control of surface interactions, with particular emphasis on biomimetic approaches that utilize and adapt structural concepts from Nature to design new interfaces for biomaterials. Although the discussion emphasizes polymeric materials and cardiovascular applications, the approaches presented may be readily adapted to other materials and applications.

4.414.2. Biomaterials' Failure Mechanisms

The principal mechanisms of failure of implanted medical devices include surface-induced thrombosis, excessive wound healing including overproliferation of smooth muscle tissue (e.g., intimal hyperplasia) and fibrosis, calcification, and infection.[3,5–8] Examples are shown in Figure 1. A mechanical heart valve (Figure 1(a)) shows one leaflet completely closed

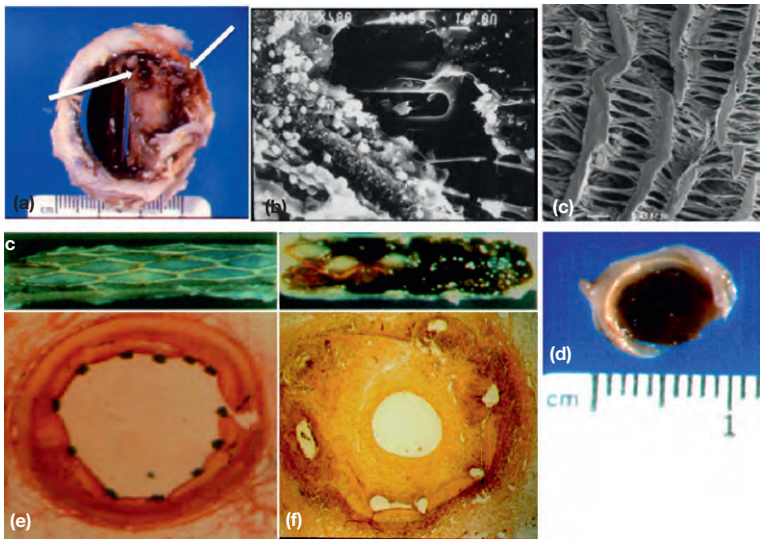

Figure 1 Examples of medical device failure. (a) A mechanical heart valve that shows one leaflet closed from the healing response (fibrous tissue deposition), along with thrombus deposits (arrow) and evidence of infection (arrow). (b) A chamber-type glucose biosensor covered by a thrombus after exposure to canine blood for 2 h *in vivo*. (c) Scanning electron micrograph (SEM) of expanded poly(tetrafluoroetheylene) vascular graft material. (d) Small-diameter vascular graft occluded by a thrombus. (e) Endovascular stent at the time of placement and (f) at 3–6 weeks postimplantation in which restenosis is clearly evident.

from the healing response (fibrous tissue deposition). The valve also shows thrombus deposits (arrow) and evidence of infection (arrow). Figure 1(b) shows a chamber-type glucose biosensor after exposure to canine blood *in vivo* for 2 h covered by a thrombus. Figure 1(c) shows an SEM of expanded poly(tetrafluoroetheylene) (ePTFE) vascular graft material and in Figure 1(d), a small-diameter graft occluded by thrombus. Figure 1 shows an endovascular stent at the time of placement (Figure 1(e)) and at 3–6 weeks postimplantation (Figure 1(f)), in which restenosis is clearly evident. While the majority of biomaterials implanted perform within approved standards, a minority suffer catastrophic failures requiring their removal, and many others do not perform as well as desired. There is substantial opportunity to improve the performance of biomaterials in patients.

4.414.2.1. Protein Adsorption and Thrombus Formation

The host response to biomaterials is largely determined by the surface or interfacial properties of the implanted material. Materials' surface properties have been consistently correlated with various measures of biological interaction such as protein adsorption, thrombosis, and cell and platelet adhesion in blood, and inflammation and wound healing in soft tissue. In addition, this knowledge has led to numerous studies on the application of surface modification methods to improve device and material biocompatibility.[9]

Figure 2 depicts the process of thrombus formation on a biomaterial. The initial adsorption of plasma proteins dominates subsequent coagulation responses (see also Chapter 4.406, Protein Interactions with Biomaterials).[10,11] The composition, conformation, and binding affinity of the adsorbed proteins are critical in determining events leading to thrombus formation, including activation and adhesion of blood platelets, activation of the coagulation cascade, and cell attachment.[10,11] Protein adsorption is governed by all the prevailing intermolecular forces, including van der Waals, electrostatic, and entropic (hydration) forces.[12,13] Many biomaterials are hydrophobic, so entropic forces are important to protein reactions. This invariably results in a net attraction and strong driving forces for protein adsorption from blood, where $>10^4$ different plasma proteins of total concentration $\sim$70 mg ml^{-1} and different individual protein concentration ranges over 10^{11} continually encounter the surface. Controlling these interactions is essential for the achievement of successful blood–materials interface, including the activation and spreading of platelets, and coagulation activation.[2,5,6] The 'ideal' blood–materials interface is the viable vascular endothelium: a typical vascular endothelial cell (EC) undergoes greater than 10^{10} collisions μm^{-2} with plasma proteins every second but is able to manage this barrage using its variety of interfacial structural and metabolic components. Thus, minimizing nonspecific protein adsorption and distinguishing between specific and nonspecific interactions are essential properties of EC function, seldom duplicated in biomaterials to date.

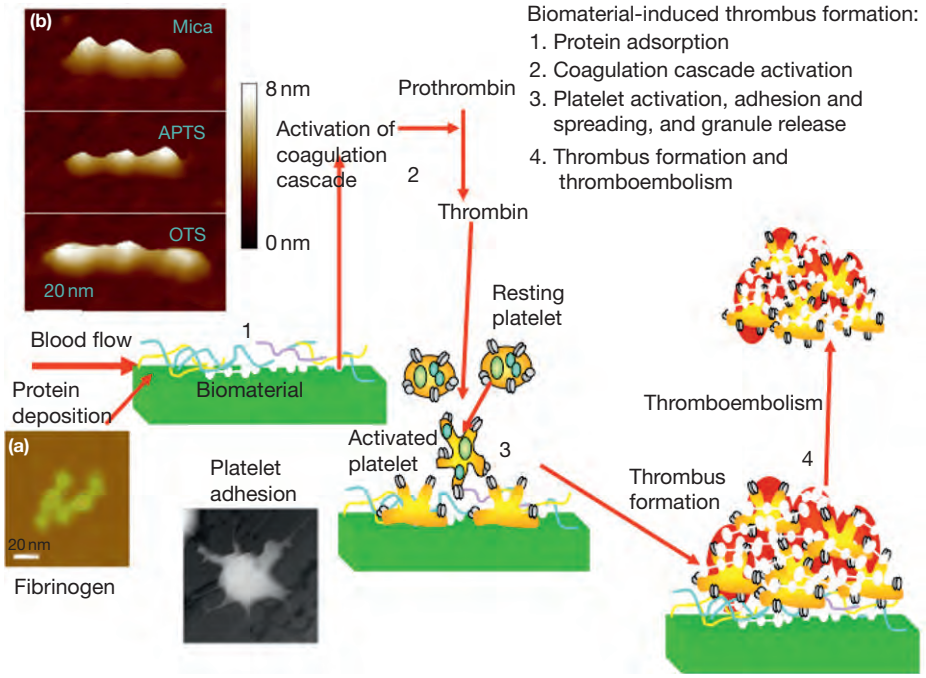

Figure 2 Biomaterial surface-induced thrombus formation is initiated by fast protein adsorption,[1] which will include the coagulation protein fibrinogen (Fg). The AFM image (a) shows Fg's three linked globular domains. The AFM image (b) shows Fg after adsorption on a hydrophilic surface (mica), a positively charged surface (APTS, aminopropyltrichlorosilane), and on a hydrophobic surface (OTS, octadecyltrichlorosilane). Fg undergoes maximum conformational change on the hydrophobic surface, although this actually reduces the ability of Fg to bind platelets. Protein adsorption is followed by the activation of the coagulation cascade[2] and platelet activation, adhesion and spreading, and granule release,[3] leading to thrombus formation, and possibly thromboembolism.[4]

4.414.3. Approaches for Controlling Surface Biological Interactions

Two general strategies are employed for controlling surface interactions with biomaterials: (1) surface modification designed to suppress undesirable protein and cell–surface interactions and (2) approaches designed to enhance favorable interactions such as surface attachment of ECs. This section focuses on approaches, particularly biomimetic approaches, designed to suppress undesirable protein and cell–surface interactions as a way of passivating biomaterials' surface so as to eliminate unwanted biological reactions. This includes surface modifications that passivate surfaces, such as preadsorption of plasma proteins like albumin or suppression of protein adsorption (e.g., use of oligosaccharide- or poly(ethylene oxide)-grafted surfaces). Other approaches, not covered here, include selective adsorption of certain proteins (e.g., plasminogen) with profibrinolytic or anticoagulation properties, or selective adsorption of certain proteins in preferred orientations that reduce platelet interactions.

The surface modification approach is widely used because it has direct applicability to clinical devices: through this strategy, biomaterial bulk and surface properties can be selected and/or modified separately. Numerous surface modification techniques have been developed for the modification of existing clinically used biomaterials.[9] They can be grouped into two broad categories: (1) chemical or physical alteration of the atoms or molecules in an existing biomaterial surface through chemical treatment methods such as wet or plasma etching and chemical modification, and (2) coatings prepared by methods such as solvent casting, covalent chemical grafting, radiation grafting, or thin film deposition by chemical vapor deposition or radiofrequency plasma film formation. Each technique has advantages and disadvantages, and none has completely eliminated surface challenges in biomaterial designs and device function. Surface modifications created by covalent chemical bonding are typically more stable, but usually less reliable or uniform coverage is obtained over surfaces receiving a physisorbed coating. Some materials are not amenable to covalent modification and must be physically coated. Many factors including clinical application and biocompatibility of the material and coating are best considered when choosing the most appropriate modification technique (see also **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing**; **Chapter 3.301, Surface Analysis and Biointerfaces: Vacuum and Ambient *In Situ* Techniques**; and **Chapter 3.303, Proteomic and Advanced Biochemical Techniques to Study Protein Adsorption**).

Preadsorbing albumin, a protein not involved in coagulation or platelet adhesion, on hydrophobic biomaterials is a simple method that passivates a surface by blocking most surface-binding sites for other adhesive proteins that may initiate adverse surface responses.[10,11] The major disadvantage of this method is that many other adhesive plasma proteins have higher surface affinities and will gradually surface-exchange with the preadsorbed albumin, so this method is not useful for long-term *in vivo* applications.[11] However, this method is very useful for *in vitro* experiments, where the duration of blood–materials interaction is relatively short (i.e., less than a few hours). Many surface modification methods are aimed at creating specific hydrophilic surfaces, such as those bearing carboxylate or hydroxyl groups, or functionalized for immobilization of small hydrophilic molecules. This is based on past observations that hydrophilic polymer surfaces adsorb reduced amounts of proteins.[16] However, proteins that do adsorb will frequently retain their biological functions, so simply making surfaces hydrophilic does not decrease, the risk of thrombogenicity and cell attachment, but increases it. One way to improve this approach is to increase the size of the hydrophilic group. For example, surface attachment of tetraethylene glycol dimethyl ether on polymer surfaces using radiofrequency glow discharge plasma-treated films typically shows very low adsorption of proteins,[14,15] although there is some concern regarding complement activation.[16]

4.414.3.1. Rods and Coils

The relative success of polyethylene oxide (also referred to as poly(ethylene glycol), PEG) as a protein-resistant coating for biomaterials[17–20] has been well explained on the basis of the entropic, or steric, repulsion unique to this tethered hydrated polymer. However, coating molecular architecture such as chain length, surface density, and substrate heterogeneity, all affect the efficacy of the PEG repulsion barrier.[21–25] Regular control of these interfacial coating molecular properties is difficult. An advantage of surface-grafting carbohydrates is that, unlike PEG, they have no amphiphilic or 'surface-active' character and do not exhibit entropic aggregation transitions in water (i.e., no cloud point in solutions).[22,26] Oligosaccharides have well-defined molecular configurations that lead to their molecular structural conformations modeled typically as rigid rods, whereas a PEG molecular structure is dominated by its polymer conformational freedom, modeled as a random coil (**Figure 3**). This one distinction has considerable impact for their different behaviors as coatings for biomaterials. Far greater surface-grafting precision is required in manipulating surface oligosaccharides to achieve an effective hydration barrier on biomaterials. Key properties of molecular architecture (configuration, conformation, chain length, branching, surface density, etc.) and thermodynamic factors that influence local interactions must be addressed to approach an effective glycocalyx-like hydration. At low surface density, the conformational freedom and 'surface activity' of PEG facilitate its spreading over a surface. The surface coating may be thin, but fractional surface defects or uncoated areas will be small due to this property. In contrast, if an oligosaccharide is attached in low density as a rigid rod, only a small fractional surface area will be covered, exposing numerous defect areas where proteins can adsorb. This is the most probable explanation for the wide variability observed for protein resistance of immobilized oligosaccharides.[27] If the immobilization density of oligosaccharides is increased, the observed differences in protein resistance should disappear, and, at high surface coverage, oligosaccharides should become superior in this performance, as PEG undergoes interfacial dehydration and becomes less effective at high density.[28] This hypothesis is difficult to prove because immobilization densities on biomaterials are not easily quantified precisely. However, one quantifiable example is with PEG-coated liposomes, which usually contain ~5 mol%

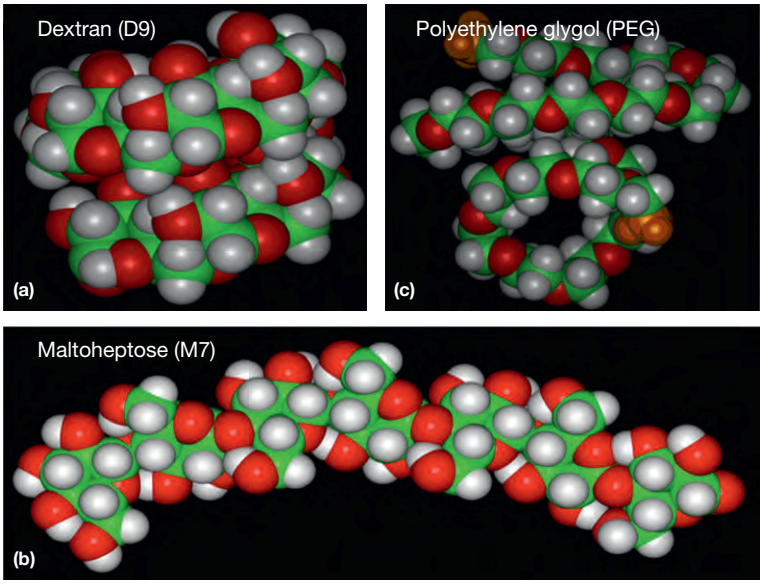

Figure 3 Molecular models of (a) dextran (α-1,6-D-glucose, 9 residues, MW = 1600), (b) maltoheptose (α-1,4-D-glucose, 7 residues, MW = 1152), and (c) poly(ethylene glycol) (PEG, MW= 1500). The 'shape' of the two oligosaccharides depends on their molecular configuration. In dextran, the glucose residues have a 1,6 linked configuration, which generates a helical structure that is relatively short and fat, while in maltoheptose, the glucose residues are 1,4 linked, which generates an extended helical structure. In contrast, PEG is a random coil; its $-CH_2CH_2O-$ repeat units have complete rotational freedom, so the overall molecular shape does not depend on configuration, but on its conformation that will change depending on local molecular and solvent interactions (i.e., the shape for the PEG shown in (b) is arbitrary).

PEG–lipid content. Incorporation of the PEG in liposome formulations increases their blood circulation half-life from 1 h up to ~12–24 h.[19,29] A red blood cell with its dense hydrophilic surface proteoglycan and glycoprotein glycocalyx has a circulation life time of ~120 days.[29] This surface design of the red blood cell glycocalyx has been exploited in synthetic colloids to extend the circulation time of cell–surface-attached polymer nanoparticles used for drug delivery.[31]

4.414.3.2. Biomimetic Surface Modifications

Biomimetic designs represent a common approach for the control of biomaterials' surface interactions. The approach involves the design of interface materials based on the mimicking of the synthetic materials found in Nature on biomaterial surfaces. In particular, the cell lipid membrane or its outer glycocalyx surface, or components of the extracellular matrix (ECM) are all common mimicry foci for biomaterial exploitation. The abundance of complex macromolecular and supramolecular structures within these related systems provides lessons in structural hierarchy that elicit functional efficiency useful as design motifs for creating new biomimetic materials.[30] Also, advances in materials' synthesis provide a scientific basis for the production and manipulation of new macromolecular structures, not just at the level of chemical composition, but at the higher level of structural creation of bioinspired constructs that assemble with hierarchy or supramolecular properties resembling natural systems.[31,32] Combining this knowledge of hierarchical assembly with the lessons from Nature has opened a wealth of new possibilities for new biomaterials and coatings combining both structural hierarchy and programmed biological function.

4.414.3.2.1. Cell membrane biomimetic surface modifications

Biomimetic designs have included utilization of organized phospholipid cell membrane-like coatings seeking to mimic simple cell lipid membrane chemistries, interfaces, and structures.[33–37] Monolayers of phosphatidylcholine (PC) molecules and diacetylene phospholipids, producing films of phosphorylcholine (PC) head groups coated on polymer surfaces, reduced protein adsorption, decreased platelet activation and adhesion, and decreased complement activation.[33,38] Polymers bearing the PC group have also been synthesized and used to modify a variety of hydrophobic polymers, such as polyethylene, showing significant reduction of protein adsorption and improvement in hemocompatibility.[33,38,39] A series of phospholipid polymers having methylene-or oxyethylene-bridging units between the PC group and the backbone was synthesized, and the effects on the mobility of the hydrated polymer chains and the structure of hydration in the polymers on the protein resistance of the polymer surfaces were studied. 2-Methacryloyoxyethyl PC polymers synthesized as biomimetics of the cell membrane structure were reported to reduce protein adsorption and cell adhesion *in vitro* when the polymer was placed in whole blood in the absence of anticoagulants.[39] Despite the observation that a PC lipid bilayer membrane alone is rarely found as a natural biological interface (i.e., actual cell membrane surfaces most often have dense carbohydrate glycocalyx layers), surface modification with PC chemistry and structure is promoted as a promising way to improve blood compatibility of biomaterials.

Polyampholytes – polymers with both positively and negatively charged groups or zwitterions – have been studied for their responsiveness to pH changes and their interactions with

proteins.[39–42] A protein-resistant surface can be achieved when the surface contains a nanometer-scale homogenous mixture of balanced charge groups derived from either zwitterionic or mixed charged groups, since they are strongly hydrated through ionic solvation.[41] Zwitterionic poly(sulfobetaine methacrylate) and poly(carboxybetaine methacrylate) surfaces show resistance to nonspecific fibrinogen adsorption.[42] Two charged compounds (11-mercapto-*N*,*N*,*N*-trimethylammonium chloride and 11-mercaptoundecylsulfonic acid) were shown to self-organize from a wide range of bulk concentrations to achieve a uniform distribution of mixed charged groups at the nanometer scale on a gold substrate, thus forming nonfouling mixed charged SAMs.[41] Another approach similar to creating a protein-resistant surface using balanced charge groups in a self-assembled film can be through the use of natural peptides that are negatively and positively charged such as glutamic acid or aspartic acid and lysine.[41] The protein resistance is reported to be comparable to that achieved with PEG-modified surfaces.[42]

4.414.3.3. Glycocalyx Biomimetic Models

Our own approach to this surface design problem, employing surface-assembling surfactant polymers,[43–48] has focused on biomimetic structures based on the cell's glycocalyx, rather than the lipid bilayer membrane components.

While the lipid bilayer is central to much biological membrane structure, the outer exposed surfaces of nearly all cell membranes bury their lipid headgroups (e.g., PC) beneath a thick layer of hydrated coated polymer – the cell's glycocalyx. The cell's surface is therefore the native glycocalyx (**Figure 4**), which can be as thick as 50 nm,[49,50] as a complex milieu of highly glycosylated molecules dominating the interface between the blood cell lipid bilayer membrane and the extracellular plasma environment.[51,52] An erythrocyte membrane contains ~500 000 glycophorin A proteins (**Figure 4(b)**), a transmembrane glycoprotein with 60% carbohydrate by mass, and ~100 extracellular O- and N-linked saccharides arranged as 16 short (1 nm) chains, facilitating high interfacial solvation.[51,52] Proteoglycans, including heparan sulfate proteoglycans (HSPGs), have received attention because of their roles in anticoagulation and leukocyte interaction.[53] HSPGs comprise a protein core decorated with highly charged polysaccharide side chains of sulfated glycosaminoglycans (GAGs), composed of 1,4 linked residues of uronic acid and glucosamine monomer repeats attached by a conserved tetrasaccharide to the protein core serine residues.[53] The potent anticoagulant properties of heparan sulfate, particularly in the form of its GAG, heparin, have been exploited extensively as a clinical anticoagulant and for immobilization on biomaterials including commercialized, clinically used products.[54]

To minimize nonspecific protein adsorption from more than 20 000 different plasma proteins and to prevent blood coagulation by interfacial activation, the EC glycocalyx relies on carbohydrates. Terminal anionic oligosaccharides produce complex three-dimensional (3D) charge distributions, facilitating an effective electrostatic repulsive (double layer) force. Additional specific ligand recognition sequences provide sufficient attractive forces to overcome the repulsive barrier to

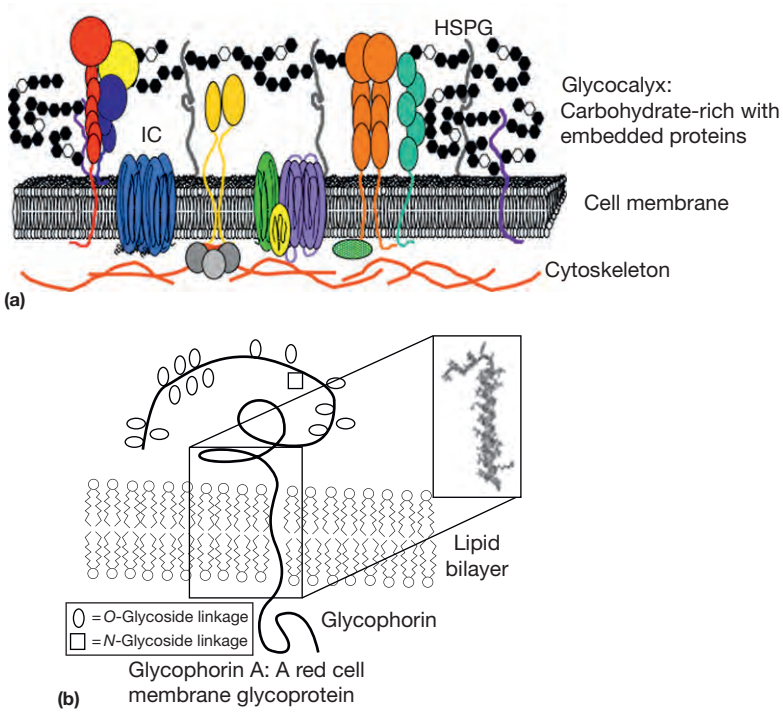

Figure 4 (a) Model of a cell surface glycocalyx that shows the carbohydrate-rich surface with embedded proteins linked to the cell's membrane and the underlying cytoskeleton. The glycocalyx is on the order of 50 nm thick, 10 times the thickness of the cell's bilayer membrane. All structures on the outer membrane surface are glycosylated. (HSPG: heparin sulfate proteoglycan, IC: ion channel). (b) Model of glycophorin A, which is a major red cell glycoprotein with many attached O- and N-linked saccharides.

achieve a highly evolved functional recognition specificity, while nonionic oligosaccharides provide a physical basis for maximizing entropic repulsion that minimizes nonspecific adhesion.[55–57] The glycocalyx is thus capable of both facilitating specific interactions with ligands and minimizing undesirable cell and molecular adhesions. Mimicking the general nonadhesive properties of the cell glycocalyx is a prerequisite for the successful development of biomimetic structures that incorporate bioactive components.

4.414.3.3.1. Glycocalyx-like biomimetic biomaterials

The ability to mimic the nonadhesive properties of the glycocalyx provides a conceptual approach to the solution of important problems with blood-contacting biomaterials related to nonspecific protein adsorption and platelet adhesion (e.g., device and materials thrombosis). An essential consideration in designing suitable modifications is to develop a materials application approach that is simple and inexpensive to implement, yet provides the desired interfacial properties. The commercial Carmeda™ anticoagulant coating represents such a model for biomaterials use.[58–60] The Carmeda coating represents the most successful method used clinically for heparin-based surface modification of blood-contacting medical devices. The innovative feature of this coating was the maximization of heparin's anticoagulant activity by end-point attachment to the biomaterial, rather than the 'side-on' attachment used previously. End-point attachment optimizes heparin's antagonistic interaction with coagulation factors, including thrombin, and involves reductive amination of the aldehyde on the reducing terminal of heparin with amino groups of a polymer layer coating on the biomaterial surface to facilitate covalent immobilization.[60]

Another successful design has been the comb-like surfactant polymer system (**Figure 5**), which provides multiple attachment sites that stabilize surface adhesion of an adsorbed coating.[45–48] The polymers consist of poly(vinyl amine) (PVAm) with both hydrophobic and oligosaccharide branches.[46] The same design may be extended to include different polar groups (carbohydrates, PEG, etc.) and/or peptides to achieve the desired coating interfacial functional properties. Surfactant polymers with glycocalyx-like glycodendrimer designs also have been developed.[47] The hyperbranched dendritic saccharides provide increased surface coverage due to the larger hydrodynamic size of the glycodendron compared with a single pendant saccharide. The spatial arrangement of the glycodendrimer provides a 'canopy' of protective carbohydrate over a biomaterial's surface.[47] Critical factors in the design revolve around two central issues: (i) surface stability and assembly (meaning effective kinetic irreversibility) under conditions expected in physiological environments and (ii) useful and enduring biological function. Multiple factors, both thermodynamic and kinetic, can affect surface stability, including the polymer molecular weight, hydrophobic side chain lengths and density, polar side chain composition and size, the hydrophobic/philic balance, and polymer–polymer and polymer–surface interactions. Given surface stability, biological interfacial function is then largely governed by the density, distribution, and properties of the polar side chains on the surface.

The adhesion stability of surfactant polymers on different biomaterials has been examined using a rotating disk system

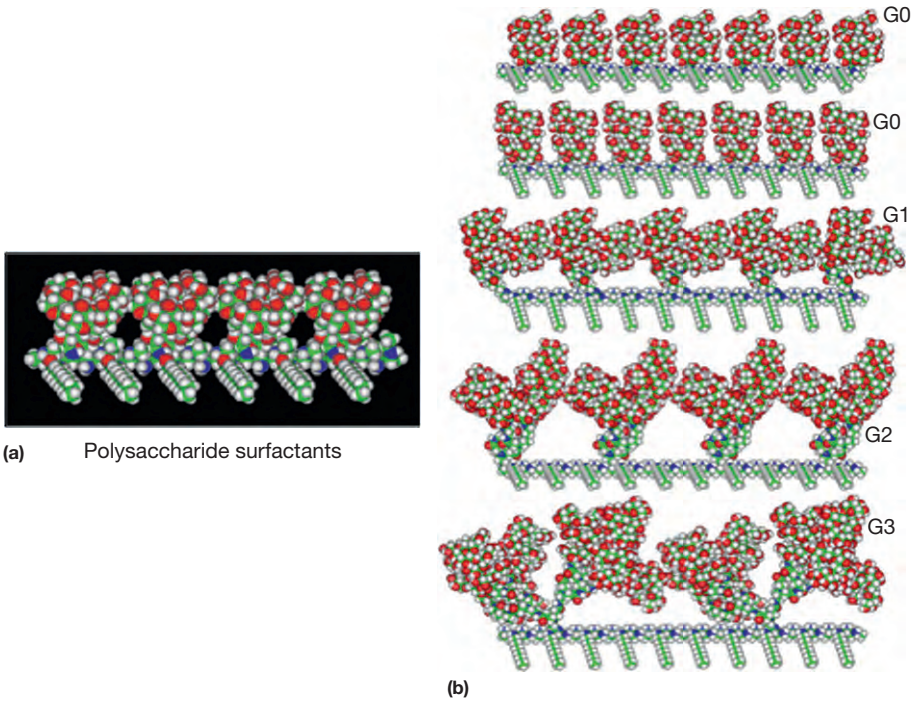

Figure 5 Space-filled model of (a) polysaccharide surfactant consisting of poly(vinyl amine) (PVAm) with both hydrophobic (hexanoyl) and oligosaccharide (dextran) branches (PVAm/hex-Dex). (b). Space-filled model of PVAm/Hex-Dex (top, same as in a) and PVAm/Hex with attached G0, G1, G2, and G3 generation dextran-dendrons (bottom). The number of dextrans/unit PVAm chain length is 16 for both the G2 and G3, even though the spatial arrangement changes.

immersed in PBS at 37 °C.[61] The surfactant polymers undergo spontaneous adsorption with stable adhesion on a diverse range of hydrophobic biomaterials including polyethylene (PE), polydimethylsiloxane (PDMS), polycarbonates, and some polyurethanes. These same surfactant polymers appeared less stable, however, on PTFE. Surfactant polymers readily adsorb on PTFE, but can be desorbed under an applied shear stress. However, if the hydrocarbon side chains are replaced by perfluorocarbons to introduce thermodynamic compatibility between the surfactant and the PTFE surface, stable adhesion on the latter can be achieved.[62]

4.414.3.3.2. Coating blood compatibility

The steric barrier provided by hydrated surface-grafted oligosaccharides is designed to suppress protein adsorption and to minimize platelet adhesion, while the high energy of desorption and low water solubility of the adsorbed surfactant polymer is designed to minimize possible exchange reactions with surface-active plasma proteins and lipids. Protein adsorption from human platelet poor plasma (PPP) and whole human blood is typically suppressed by more than 90% on modified biomaterial surfaces. Platelet interactions were examined for a range of surfactant-modified biomaterials under both static and dynamic flow conditions was reduced significantly.[46,47] For example, polycarbonate (used in blood pumps) was examined with and without a dextran surfactant polymer coating. The polycarbonate was covered by platelets ($>10^4/mm^2$) at 0 dyn cm^{-2}, which decreased at high shear stress with few platelets above ~65 dyn cm^{-2}. In contrast, few to no platelets were seen on the surfactant-modified polycarbonate at 0 dyn cm^{-2} or higher shear stresses. Similar results were obtained using whole human blood containing 3.8% sodium citrate (Figure 6) and a glycodendrimer surfactant polymer-coated octadecyltrichlorosilane (OTS)-glass surface (Figure 7).[47]

4.414.4. ECM Biomimetics

The ideal nonthrombogenic surface is a confluent layer of healthy ECs with a confluent glycoclayx. The EC (Figure 8)

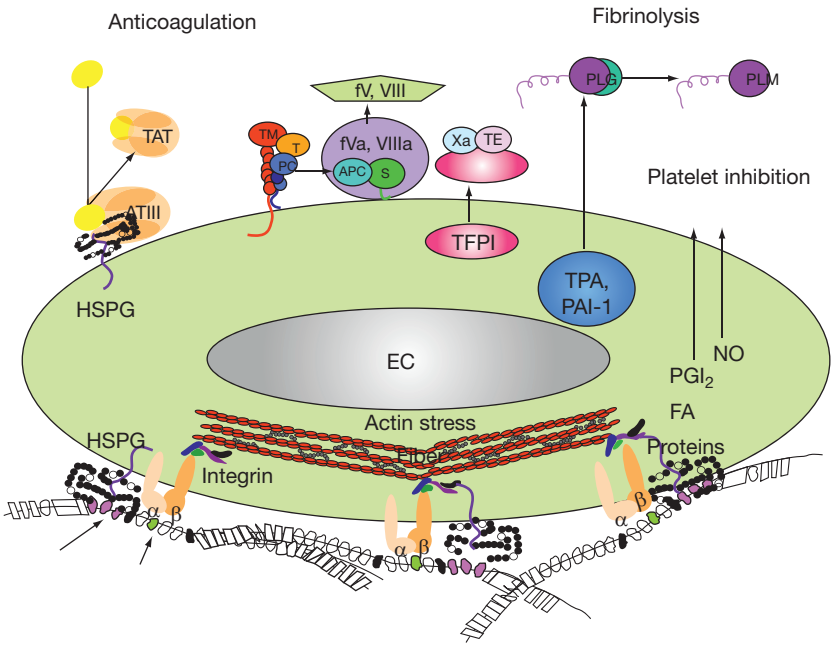

Figure 8 An endothelial cell (EC) with illustration of its anticoagulant functions, including anticoagulation, platelet inhibition, and fibrinolysis. EC integrin–extracellular matrix interactions are also illustrated. TAT, thrombin–antithrombin complex; ATIII, antithrombin III; HSPG, heparin sulfate proteoglycan; TM, thrombomodulin; T, thrombin; PC, protein C; APC, activated protein C; S, protein S; TF, tissue factor; fV, factor V; fVIII, factor VIII; Xa, activated factor X; TPA, tissue plasminogen activator; PAI-1, plasminogen activator inhibitor; PLG, plasminogen; PLM, plasmin; NO, nitrous oxide; PGI2, prostaglandin I2; FA, focal adhesion.

uses both metabolic and interfacial properties to provide several natural anticoagulant functions, regulate fibrinolysis and platelet function, prevent nonspecific adhesion, and interact closely with the ECM. Through its cytoskeletal network, the EC also responds and adapts to changes in shear stress of flowing blood. Consequently, EC seeding of biomaterials such as vascular prostheses has received intense interest as a means to improve thromboresistance with a natural living interfacial barrier.[63–73] Unfortunately, problems including shear stress and/or phenotype-dependent instability and species–species variation in EC seeding responses have limited success with human implants. One approach to addressing this problem in biomaterial surfaces that require cell seeding is creating an interface on these materials that mimics the structure–function properties of the native ECM in order to facilitate improved EC-biomaterial culture and integration (see also **Chapter 4.409, Surfaces and Cell Behavior**).

Like the glycocalyx, the ECM is a complex network of multifunctional biopolymers including collagens, proteoglycans (PGs), and glycosaminoglycans (GAGs) that interact mutually with cells and with each other.[74–76] Much effort has focused on developing biomaterial surfaces that mimic the cell-binding properties of the important ECM protein, fibronectin (FN) (**Figure 9**).[77–79] The central cell-binding domain that spans $FNIII_{8–10}$ is of particular interest because it contains an RGD (Arg-Gly-Asp) sequence, identified as the key cell integrin-binding site present in many ECM proteins including FN, vitronectin, laminin, osteopontin, thrombospondin, and many other ECM glycoproteins.[74–77] Most matrix-dependent cells including EC and smooth muscle cells bind to RGD through integrin interactions such as key EC cell membrane-based receptors, the $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrins. However, RGD peptide ligands of various forms will also bind the platelet membrane glycoprotein GPIIb/IIIa with high affinity to activate platelets, an important factor to appreciate in designing biomimetic surfaces and colloidal particles for cardiovascular applications.

Figure 9 shows that the RGD sequence is part of a random loop attached to the β-sheet secondary structure of the $FNIII_{10}$ domain. As the RGD sequence is part of a random loop, the small peptide does not require a particular secondary structure in order to maintain its integrin-binding specificity. This presents a significant advantage in using small RGD peptides in biomimetic designs for biomaterials because neither the entire FN domain nor the FN matrix protein is required to produce specific integrin–adhesive cell–surface interactions. However, cell–ligand binding affinity may be reduced relative to the intact whole protein. Two other sequences in FN – PHSRN ($FNIII_9$) and KNEED ($FNIII_8$) – act synergistically with the RGD sequence[80,81] to improve binding. The addition of $FNIII_9$ synergy domain to $FNIII_{10}$ results in ~50% increase in binding affinity, ~60–70% increase in cell adhesion, and ~60–70% increase in cell spreading, compared with $FNIII_{10}$ alone. The EC $\alpha_5\beta_1$ integrin that interacts with the central FN cell-binding domain is upregulated in migrating or shear-exposed EC and involved in early adhesion-dependent cell signaling events.[82–84] Another EC integrin ($\alpha_v\beta_3$) that binds to FN has a role in angiogenesis and shear-induced cytoskeletal alignment.[84,85] Therefore, producing ECM biomimetic surfaces that can bind certain integrin subfamilies and not cross-react with all cell membrane integrin subtypes, or activate platelet receptors represents an attractive area for new developments.

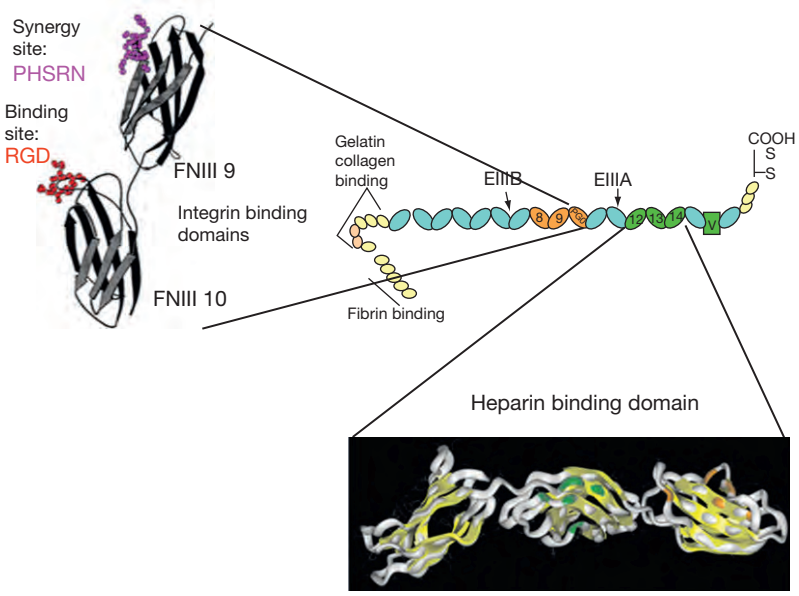

Figure 9 Structure and functional properties of fibronectin (FN). The FNIII 9 and 10 domains are shown expanded in which the RGD is seen located in the random coil loop attached to the β-sheet domain. Similarly, the PHSRN synergy site is located in a random coil loop on the β-sheet FNIII 9 domain. The β-sheet secondary structures in domains 12–14 encompass the heparin (HSPG)-binding region.

4.414.4.1. ECM-Like Biomimetics

Many biomimetic materials have been developed that mimic cell adhesive functions of the ECM, most often FN (*vide supra*), to support a healthy, confluent EC monolayer that remains stable under physiological shear stress conditions (see also **Chapter 2.208, Artificial Extracellular Matrices to Functionalize Biomaterial Surfaces**; **Chapter 4.411, Peptide- and Protein-Modified Surfaces**; **Chapter 4.412, Rational and Combinatorial Methods to Create Designer Protein Interfaces**; **Chapter 4.415, Surface Engineering Using Peptide Amphiphiles**; and **Chapter 4.416, Growth Factors and Protein-Modified Surfaces and Interfaces**). Specific molecular recognition is incorporated into ECM-like biomimetic materials' designs through inclusion of biologically important peptide sequences of many types. To be useful, a selected peptide sequence needs to retain its biological cell signaling specificity, even though it is no longer a part of its larger native protein structure from which it was derived and copied. RGD fulfills this requirement, and is by far the most frequently used ECM-derived peptide for improving the cell adhesiveness of biomaterials.[66,67,70,78,79] Other matrix-derived peptides, such as the REDV sequence derived from FN, or the laminin-derived peptides YIGSR or IKVAV, have also been explored extensively for similar utility on biomaterials.[66,68,69,78] The use of small adhesive peptides has the following advantages: (1) small peptides resist proteolysis from plasma and cellular proteases, (2) they are seldom immunogenic as short sequences, (3) they can be commercially sourced economically at high purity using solid-phase synthetic methods, (4) they enjoy versatile covalent surface tethering strategies with diverse chemistry, and (5) geometrically defined nanoscale peptide patterns can be designed at distinct surface densities that are significantly higher than those achieved with intact matrix proteins.

In designing biomaterials that direct cell behavior, known interactions between cell receptors and ECM protein domains need to be accounted for in designing ECM-like biomimetic surfaces for biomaterials. A wide range of approaches is used to attach RGD or other small peptides to solid surfaces and biomaterials.[86] Most surface grafting, immobilization, and attachment methods, including those using chemical and physical methods discussed previously in this chapter and in related chapters, can be used.[87] RGD-based peptides have been covalently linked to most of the common biomaterials including PLGA, polyacrylamides, titanium, gold, stainless steel, ceramics, and to polyurethanes as well as PTFE. Irrespective of the surface attachment method used, the key factors in any biomimetic design for controlling cell–surface interactions include maintenance of the peptide's biological function and its cell specificity; peptide density on the surface; elimination of nonspecific protein or cell adsorption interference; surface chemistry stability; cell attachment, growth, and migration promotional properties; and for vascular applications, the adherent cell's shear-dependent and phenotypic stability in the presence of flowing blood.

4.414.4.1.1. Integrin-dependent interaction of EC on biomimetic surfactant polymers

An important step in validating a biomimetic surface modification utilizing small peptides like RGD is a demonstration of cell integrin-dependent surface interaction. Importantly, this can be accomplished using a scrambled peptide control (i.e., RDG instead of RGD), excessive free RGD peptide in the assay milieu, or by replacement of a critical amino acid (i.e., RGE in place of RGD). To examine the ability to promote favorable interactions with human EC, RGD peptides were attached to

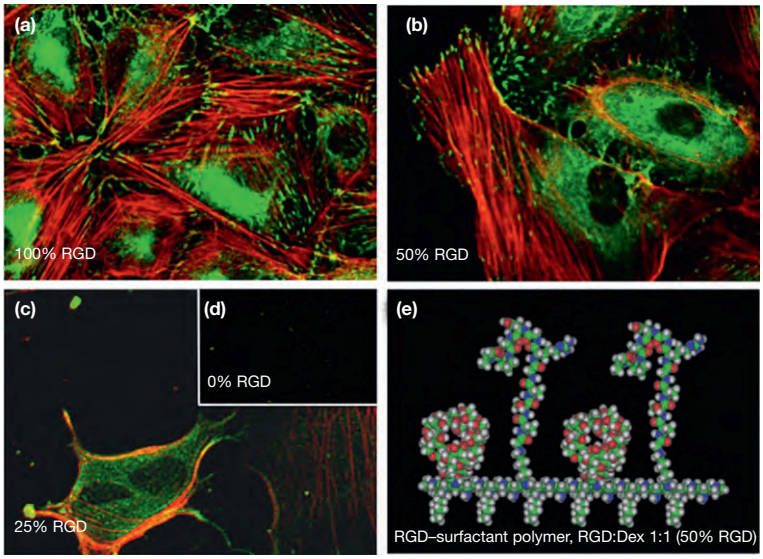

Figure 10 Human pulmonary artery endothelial cell (HPAEC) adhesion and formation of focal adhesions on RGD surfactant polymers (RGD-SP). (a) RGD-SP (100% RGD), (b) RGD-Dex-SP (50% RGD), (c) RGD-Dex-SP (25% RGD), and (d) Dex-SP (0% RGD). HPAEC seeded on these substrates were fixed and fluorescently stained for actin stress fibers (red) and vinculin (green) for focal adhesions after 3 h, and were examined by scanning confocal microscopy (60×). (e) Molecular model of RGD-Dex surfactant polymer (50% RGD), consisting of a poly(vinyl amine) with hexanal, dextran, and peptide branches. The full peptide sequence was –GSSSGRGDSPA–.

a biomimetic surfactant polymer (Figure 10(e)) adsorbed on an OTS-modified glass surface[88–90] *in vitro*. The ECM-like biomimetic polymers consist of a poly(vinyl amine) backbone with hydrophobic alkanal branches and varying ratios of cell adhesive peptide to dextran carbohydrate.[88–91] The RGD-containing peptide was –GSSSGRGDSPA–, in which the –GSSSG– was used as a hydrophilic flexible spacer to move the active cell-binding sequence away from the surfactant polymer backbone. The surfactant polymers (SP) contained increasing molar ratios of RGD:dextran of 0:1, 1:3, 1:1, 3:1, and 1:0, referred to as 0, 25, 50, 75, and 100% RGD, respectively, and were compared to a positive control of FN (1 $\mu g\,cm^{-2}$) coated on glass.[88,90] The pure polysaccharide, dextran (SP, 0% RGD), provided a negative control. After seeding human pulmonary artery ECs (5000 cells cm^{-2} in MCDB 131 basal medium), cell adhesion and growth were quantified by time-dependent phase-contrast microscopy and by a cell MTS proliferation assay. Maximal proliferation was observed with the FN positive controls (0.9 relative absorbance), but comparable results were obtained for surfactant polymers with high RGD content 100% RGD (0.8) > 50% RGD (0.75) >> 25% RGD (0.37) > OTS (0.35) – media only blank. No cells attached to the 0% RGD dextran-SP.

The RGD polymers stimulated EC responses in an integrin-dependent manner. The interaction was specific, as soluble GRGDSP, but not GRGESP, inhibited EC adhesion and spreading. At 3 h, EC attachment and spreading were rapid and comparable on FN and 100% RGD. The cells spread well with sharp spikes of vinculin localized at the termination point of actin stress fibers (Figure 10(a)–10(d)). Cell stress fibers and focal adhesions on the surfactant polymers correlated with the EC spreading pattern and with %RGD in the surfactant polymer. Adherent EC expressed $\alpha_5\beta_1$ integrins all along stress fibers and throughout the cytoskeleton. Substrates coated with a high dextran:RGD ratio (low overall RGD) content exhibited poor cell adhesion, consistent with suppressed protein adsorption, and ECs did not attach or grow on the carbohydrate surfactants. These data also showed the importance of RGD-ligand density in facilitating effective cell attachment and function.

4.414.4.1.2. Surface peptide ligand density

To examine the role of peptide specificity and ligand density, model substrates have been used to determine the dependence of cell adhesion on RGD-ligand density and clustering *in vitro*.[92–96] For the use of GRGDY coupled to glass, adhesion and maximal cell spreading required 6 RGD mm^{-2} or peptide spacing of 440 nm,[94] but a higher peptide density (60 RGD mm^{-2}) was required for focal adhesion formation. This peptide-only density was much lower than that (200–4500 RGD mm^{-2}) reported for FN, FN-fragments, RGD-polyacrylamide, or RGD-albumin.[93,97] Studies using clustered RGD constructs, attached to star-PEO or PMMA–PEO comb polymers, showed increased cell adhesion with increasing RGD cluster density.[12,93,95,96]

Cell migration requires adhesion followed by sufficient receptor/cytoskeleton interactions, cytoskeletal reorganization, and tail end detachment. Ligand-binding affinities, integrin expression levels, and ligand levels dictate cell migration speed, with the average speed displaying a biphasic dependence on adhesive strength, the maximum occurring at an intermediate cell–substrate adhesive strength.[92,98–101] Model surfaces altering substrate ligand density and distribution through use of peptides from the adhesive domains of ECM proteins have shown dependence of cell migration on ligand type and density.[92,101,102] For instance, glass-YIGSRG (derived

from laminin) with peptide clusters (6424 clusters mm^{-2}) showed greater EC locomotion than that on RGDS-glass.[99] Similar results were observed for fibroblasts with peptides at 10 nmol cm^{-2} (60 peptides nm^{-2}).[103] In addition, RGD clustering (1–9 ligands per cluster) with spacing of 6–300 nm enhanced cell motility, attributed to more efficient integrin clustering.[92] Smooth muscle cells showed decreased motility with increasing surface density of RGDS, VAPG, and KQAGDV from 0.2 to 2.0 nmol cm^{-2} (1.2–12 peptides nm^{-2}), providing evidence supporting decreased cell migration with increased adhesivity.[102] Similarly, we have shown decreased motility for human microvascular EC on RGD surfactant polymers with RGD density from 0.2 to 0.6 RGD nm^{-2}, with an inverse correlation between motility and adhesivity.[104] Peptide density affects cellular functions such as growth and migration, with the highest peptide density supporting the most proliferation, but the slowest migration, as determined using a Teflon fence migration assay.[104] Surface RGD peptide density was estimated from a 2D of lattice unit cell model for the surface-assembled surfactant polymer. Peptide surface density for the 100% RGD surfactant polymer was between 0.38 and 0.60 peptides nm^{-2} (i.e., 63–100 pM cm^{-2}). Similarly, surface densities for the 75, 50, and 25% RGD surfactant polymers were estimated to be 0.28–0.44, 0.19–0.30, and 0.095–0.15 peptides nm^{-2}, respectively.

Several studies have demonstrated that the spatial arrangement of cell adhesive peptides as well the surface density are important for controlling cell–surface interactions. When integrin-binding YGRDG peptides are tethered to star-shaped polymers of ~50 nm in size and arranged on inert PEG hydrogels individually or in clusters of between 1 and 9 peptides per cluster (each at low or high overall peptide density), cell adhesion and migration are observed to be supported on surfaces with only one YGRGD peptide per cluster; cell motility increases significantly at a higher peptide density per cluster, whereas nonclustered peptides support neither full spreading nor cell motility. This finding is in accordance with studies by Cavalcanti-Adam *et al.*[101] and supports the notion that peptide spatial arrangement as well as peptide density contribute significantly to the control of cell–surface behavior.

4.414.4.1.3. Shear stability of surface-attached cells

Vascular EC *in vivo* are subjected to physical forces related to blood flow.[104–107] Vascular ECs sense these forces and respond through phenotypic alterations in morphology and alignment, mechanical properties, and signal transduction.[106] Shear stability has also been related to integrin–ligand interaction, although the relationship plateaus at high adhesivity and does not exhibit bimodal behavior. One measure of shear stability is the shear stress at which 50% of cells are detached. This was shown to be greater for cyclic RGD (59 dyn cm^{-2}) than for linear peptide (39 dyn cm^{-2}).[108] It has also been shown that EC shear stability increases with increasing RGD surface density.[89,104] Interpretation of shear stability studies should take into account cell attachment time and the use or otherwise of low-shear preconditioning, its use being known to improve shear stability of attached cells.[109,110]

4.414.4.2. Biomimetic Modifications of Clinically Relevant Biomaterials

Beyond model assay systems, clinically used biomaterials are also modified using immobilized peptides to improve blood and tissue biocompatibility (see also **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing** and **Chapter 1.128, Fluorinated Biomaterials**). Examples include polyurethanes modified with YIGSR peptides.[68,69] Effective modification of ePTFE, commonly used for small-diameter vascular grafts, has presented a particular challenge. ePTFE is extremely hydrophobic and chemically inert. This makes quantitative modification of its surface very difficult to accomplish. To address this difficulty, a peptide fluorosurfactant polymer (PFSP) modification was developed to facilitate the adhesion and growth of EC on ePTFE vascular graft material.[111–113] The PFSP consisted of a poly(vinyl amine) backbone with integrin-binding RGD peptides for cell engagement, and perfluorocarbon pendant branches to facilitate adsorption and stable adhesion to underlying ePTFE. Aqueous PFSP solution was used to modify the surface of ePTFE fluorocarbon substrates. Following subconfluent seeding, EC adhesion and growth on PFSP were assessed at different time points. Quantification of adherent cell populations demonstrated reduced EC attachment efficiency but increased growth rate on RGD PFSP compared with FN on glass (**Figure 11**). Actin staining revealed a well-developed cytoskeleton for ECs on RGD PFSP indicative of stable adhesion. Uptake of acetylated low-density lipoprotein and positive staining for VE-cadherin confirmed the EC phenotype for adherent cells in these cultures. Production of prostacyclin, a potent antiplatelet agent, was equivalent between ECs on FN and RGD PFSP surfaces. The RGD PFSP provided a simple, quantitative, and effective approach to modify ePTFE and to encourage EC attachment, growth, and function.

4.414.4.2.1. Cell-selective peptides

A biomaterial surface modified with RGD peptides is not suitable as a blood-contacting surface, because in addition to many cell-based integrin receptors, RGD also readily binds the GPIIb/IIIa receptor on platelets, producing platelet binding and activation.[114] As there are many more platelets in blood ($(15–40) \times 10^4$ platelets per microliter) compared with ECs, an RGD-coated surface is essentially highly thrombogenic. To overcome this problem, autologous ECs obtained from the patient can be preseeded and cultured on the graft before implantation. An alternative approach that is much more appealing clinically is to modify the graft with a peptide selective for EC integrins that does not cross-react to bind platelet integrins. This has been shown using RGD-containing peptides with different flanking peptides or cyclic conformations that reduce (but do not eliminate) platelet receptor specificity. As an example, ePTFE was surface modified with an FSP bearing biologically active ligands, including both adhesive peptides and polysaccharide moieties. The goal was to improve graft hemocompatibility by promoting rapid surface endothelialization, while minimizing platelet adhesion. A direct comparison of platelet and EC adhesion to FSPs presents one of three cell adhesion peptides: cyclic Arg-Gly-Asp-D-Phe-Glu (cRGD),

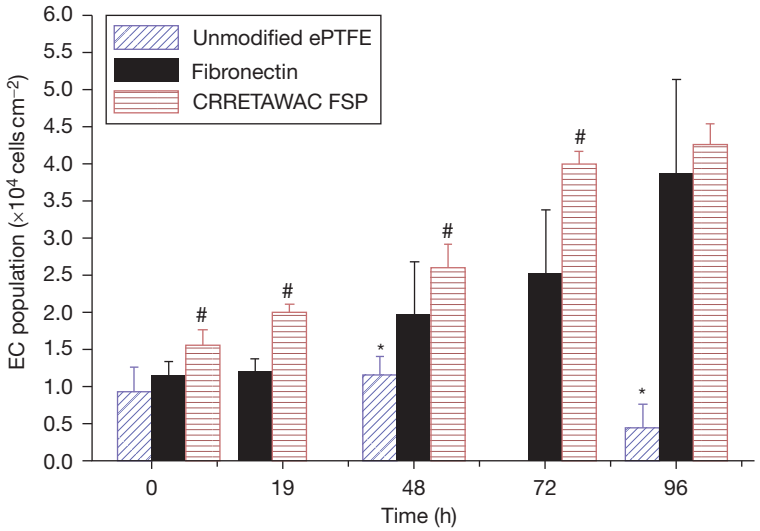

Figure 11 Endothelial cell (EC) attachment and growth on unmodified ePTFE, fibronectin (FN), and –CRRETAWAC– fluorosurfactant polymer (FSP)-modified ePTFE. Cell attachment and growth on CRRETAWAC FSP was higher than on FN and substantially greater than on unmodified ePTFE. #Significantly different ($p < 0.05$) cell population compared with FN and ePTFE surface at the same time point. Significantly different ($p < 0.05$) cell population compared with FN and CRRETAWAC FSP surfaces at the same time point. Bars represent standard deviation.

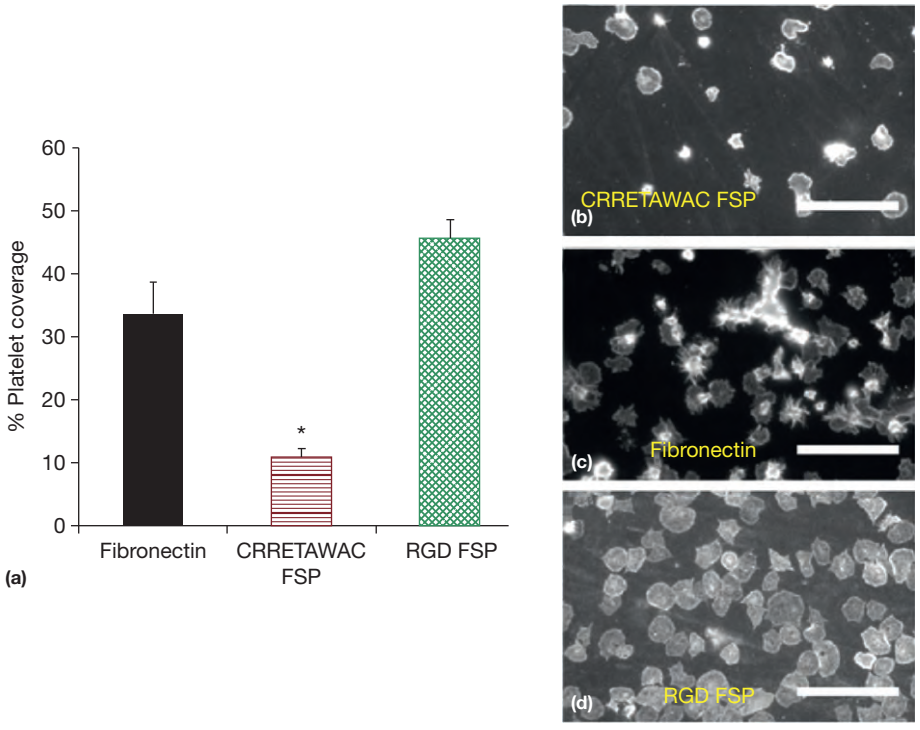

Figure 12 Human platelet adhesion/spreading with CRRETAWAC fluorosurfactant polymer (FSP) surface. (a) Platelet surface coverage on fibronectin (FN), CRRETAWAC FSP, and RGD FSP. Significantly different ($p < 0.05$) platelet surface coverage for CRRETWAC FSP compared with FN and RGD FSP. Bars represent standard deviation. (b) FITC-anti-CD41a-labeled platelets adherent to CRRETAWAC FSP-modified surface. Scale bars for all images are 30 mm. (c) FITC-anti-CD41a-labeled platelets adherent to FN-coated glass. (d) FITC-anti-CD41a-labeled platelets adherent to RGD FSP-modified FSAM.

cyclic *Cys-Arg-Arg-Glu-Thr-Ala-Trp-Ala-Cys* (cRRE, *disulfide bond cyclization), linear Gly-Arg-Gly-Asp-Ser-Pro-Ala (RGD), or simply a polysaccharide moiety, oligomaltose (M-7), the latter designed to prevent plasma protein adhesion. Measurements of soluble peptide–integrin binding indicated that cRRE exhibits very low affinity for the $\alpha_{IIb}\beta_3$ platelet fibrinogen receptor, but high binding affinity for the EC $\alpha_5\beta_1$ integrin.[112,113,115–118] Analysis of static and dynamic platelet adhesion on FSP-modified surfaces demonstrated that both M-7 and cRRE promote significantly less platelet

adhesion compared with RGD and cRGD FSPs, while EC adhesion was similar on all peptide FSPs and minimal on M-7 FSP (Figure 12). The results illustrate the potential for ECM-like peptide ligands presented using an FSP surface modification to selectively adhere ECs with limited platelet attachment.[112,113]

4.414.5. Summary and Outlook

The interface between biomaterial and the biological environment is crucial because it controls protein and platelet interactions, thrombus formation, cell–surface interactions, and the ability of an implant to integrate to perform its intended function in the host. The ability to use biomaterial coating strategies to mimic both the functional and nonadhesive properties of a cell glycocalyx and ECM provides an attractive route to addressing numerous clinical problems with the biomaterial–tissue interface and biocompatibility. ECM biomimetics are also an attractive model for bioadhesive modification for modulation of specific cell responses, in both *in vitro* and *in vivo* model systems. Select peptide sequences derived from ECM proteins, such as FN, laminin, and collagen, have been incorporated onto films, polymer coatings, surfactants, and immobilization methods onto biomaterials to provide versatile biomimetic materials designed to modulate cell functions and potentially guide tissue formation. Several challenges still remain to validate this approach for various scientific and technological goals, including the reliable control over peptide spatial organization and affinity, incorporation of adhesion peptides selective for specific cell types, and the design of different temporally inductive adhesion peptides for time-dependent modulation of cell adhesion or to adhere different cells at different times. For all such strategies, providing a surface that reliably eliminates nonspecific protein and cell interactions while promoting highly specific biological adsorption and cell engagement is critical. Coatings and surface modifications that mix cell-specific ligands into a highly nonfouling chemical matrix are attractive for this purpose. As the fundamental biology of the cellular microenvironment is often the inspiration for material design, the future directions for new biomimetic designs that control surface interactions include innovative strategies for the control of surface architectures, incorporating both spatial and temporal control of ligand presentations, ligand diversities, and subpopulations to target different cell types or phenotypes, controlled cell differentiation and other biofunctional aspects, and dynamic microenvironmental designs that are reliably altered in both space and time at biomaterial surfaces based on biological cues. Materials' design will continue to exploit new discoveries in cell biology (e.g., new peptide ligands, new cell signal molecules, and new cell–surface engagement processes) and tissue physiology (systems integration, cell–cell interactions, communication and differentiation, and cell coculture) to find creative hybrid approaches to biomimetic materials enabling these advanced functions.

Glossary

Angiogenesis Growth of new blood vessels from preexisting vessels.

ApoE-null mouse ApoE stands for plasma protein apolipoprotein E, binding to a specific receptor present in liver cells and peripheral cells. It is an essential protein for the normal catabolism of triglyceride-rich lipoprotein constituents. Mice that lack the ApoE gene are either called the ApoE-null or ApoE-knockouts (KO).

Apoptosis The process of programmed cell death involving characteristic changes related to cell morphologies such as blebbing, loss of cell membrane asymmetry, and cell shrinkage.

Astrogliosis An abnormal increase in the number of astrocytes due to the destruction of neurons.

Atherosclerotic plaques Fatty materials such as cholesterol buildup in the arterial wall.

Axon A long, slender projection of a nerve cell (i.e., neuron) that conducts electrical impulses away from the neuron's cell body or the soma.

Ball-and-stick model A molecular model of a chemical structure that aims to display both the 3D positions of the atoms and the bonds.

bFGF Basic fibroblast growth factor is present in the basement membranes and in the subendothelial extracellular matrix of blood vessels. bFGF is involved in the angiogenesis process and, in research, is a critical component in stem cell cultures.

Bioactive A material property based on its interacting ability with cellular organisms and tissues *in vitro* and *in vivo*.

Blastocyst A core–shell structure formed during the early embryogenesis of mammals. The shell is comprised of tropoblasts and the core contains the inner cell mass (ICM or embryoblast) and fluid-filled cavity (blastocoele). Blastocyst, in humans, begin formation 5 days after fertilization.

(Cell) Nucleus A membrane-enclosed cell organelle found in eukaryotic cells. The chromosome inside the nucleus is a complex structure made up of DNA and histone molecules. Gene expression control is done here in the nucleus.

Cell membrane A biological membrane comprised of a phospholipid bilayer with incorporated proteins.

Cell or cellular adhesion The binding of a cell to a surface (i.e., extracellular matrix) or a neighboring cell via adhesion molecules such as integrins, cadherins, and selectins.

Cell signaling A complex system of association that governs cellular activities and coordinates cell actions. The breakdown of the cell signaling pathways can lead to disease formation. Traditionally, focus has been given to exploring individual parts within a cell signaling pathway but, in recent times, systems biology approaches have allowed researchers to investigate multiple pathways and link them together to study a network of genes and proteins.

Centriole A barrel-shaped cell structure found in eukaryotic cells. Microtubules comprise the walls and are arranged perpendicular to the pericentriolar material – this associated pair is called the centrosome.
Circular dichroism (CD) CD refers to the differential absorption of left and right circularly polarized light and is exhibited by optically active chiral molecules such as proteins.
Collagen A family of fibrous proteins rich in glycine and contains hydroxyproline and hydroxylysine. It is found throughout vertebrates and is the most abundant protein in mammals. This protein is a major element in skin, bone, cartilage, teeth, blood vessels, etc.
COMPASS forcefield An *ab initio* forcefield optimized for condensed-phase applications. COMPASS stands for Condensed-phase Optimized Molecular Potentials for Atomistic Simulation Studies.
CREKA A pentapeptide with a sequence of Cysteine-Arginine-Glutamic acid-Lysine-Alanine that preferentially homes to tumor tissue. It was identified via *in vivo* phage display.
Cytoskeleton Internal proteinaceous framework of a eukaryotic cell composed of actin microfilaments, intermediate filaments, and microtubules and giving shape to a cell, and providing support for cell extensions such as villi and axons of nerve cells.
Cytosol The cytoplasm other than the various membrane-bound organelles.
DBU 1,8-Diazabicyclo[5.4.0]undec-7-ene, commonly used in organic synthesis as a nonnucleophilic base.
Dentin A calcified tissue constituting the interior hard part of vertebrate teeth between the enamel and the pulp gum, also written as dentine.
Differentiation (cellular) The cellular process of a less specialized cell transforming into a more specialized (thus differentiated) cell type.
DMEM Dulbecco-modified Eagle's medium utilized to maintain cells. It contains varying amounts of inorganic salts, amino acids, glucose, and vitamins. The most concentrated salt is sodium chloride. Specific media formulations are available from vendors.
DPC Dodecylphosphocholine, a single-C12-tailed phospholipid. CAS No. 29557-51-5.
DPPC 1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine, a double-C16-tailed phospholipid. CAS No. 63-89-8.
DPPE 1,2-Dipalmitoyl-*sn*-glycero-3-phosphoethanolamine, a double-C16-tailed phospholipid. CAS No. 923-61-5.
DPPG 1,2-Dipalmitoyl-*sn*-glycero-3-phospho-(1'-*rac*-glycerol) (sodium salt), a double-C16-tailed phospholipid. CAS No. 200880-41-7.
DSPE 1,2-distearoyl-sn-glycero-3-phosphoethanolamine, a double-C18-tailed phospholipid. CAS No. 1069-79-0.
Dynamic light scattering (DLS) A light-based physics technique used to determine the size distribution of small particles in liquid solutions undergoing Brownian motion. A monochromatic light source (e.g., fixed wavelength laser) is often utilized and the time-dependent fluctuation of the scattering intensity is monitored.
Endocytosis A membrane-based process for eukaryotic cells taking up foreign materials.
Endoplasmic reticulum (ER) Extensive, convoluted internal membrane in eukaryotic cells, continuous with the outer nuclear membrane and enclosing a continuous internal space (lumen); involved in the synthesis and transport of membrane proteins and lipids, and of proteins destined for secretion from the cell.
Extracellular matrix Macromolecular ground substance of connective tissue, secreted by fibroblasts and other connective tissue cells, generally comprised of proteins, polysaccharides, and proteoglycans.
FAM Carboxyfluorescein, a fluorescent dye molecule often utilized to tag proteins and incorporated into micelles and liposomes. Excitation/emission occurs at 492/517 nm.
Fluorescence Emission of light by a substance that has absorbed electromagnetic radiation often at a lower wavelength. It involves ground-state excitation via absorption, radiationless decay, and then a radiative transition back to the lower electronically excited state and ceases as soon as the source illumination is removed; it is different from phosphorescence.
Fmoc-chemistry 9-Fluorenylmethoxycarbonyl-based synthesis technique. The Fmoc-protecting group attaches to the amine-terminus of an amino acid and is selectively removed by bases such as piperidine and DBU.
Glial scar A reactive cellular process involving astrogliosis that occurs after injury to the CNS (central nervous system) and is the body's mechanism to protect and begin the healing process.
Globular protein A class of proteins that have metastable-folded spherical 3D structures and forms colloidal solutions after aqueous medium dissolution. The other class of proteins are fibrous proteins.
Glycolipid Lipids containing carbohydrate head groups and serving as cellular recognition sites.
Glycoprotein Proteins incorporating carbohydrate chains, ubiquitous in cell membranes and cellular secretions. If they become integral membrane proteins, they are involved in cell–cell interactions. An example is mucin.
Golgi apparatus Stacks of flattened membrane sacs present in eukaryotic cells and are involved in directing membrane lipids and proteins and secretory proteins to their correct destination in the cell.
Growth factor (GF) A general term for specific peptides and proteins required by particular cells for division and/or differentiation. Examples are epidermal growth factor, basic fibroblast growth factor, and nerve growth factor.
Heparin A highly sulfated glycosaminoglycan (polysaccharide) found in mast cells that has anticoagulant activity. This molecule will bind and activate the enzyme inhibitor antithrombin III which then inactivates thrombin and other proteases such as factor Xa.
Hirulogs A group of synthetic peptides designed to inhibit thrombin, leading to anticoagulation.
HOX Homeobox, a DNA sequence found within genes that are involved in the regulation of patterns of anatomical development (morphogenesis) in animals, fungi, and plants.

Hydrophobicity The physical property of molecular species (often nonpolar) being repelled from a mass of water, or forcing the structuring of water as a solvent around this molecule. The tendency to positively interact with or be dissolved by water will be referred to as hydrophilicity.
IKVAV A pentapeptide with a sequence of isoleucine-lysine-valine-alanine-valine that promotes cell adhesion, derived from the extracellular matrix protein laminin.
Inflammation or inflammatory response A complex host-initiated biological process following infection or tissue damage or after a particular immune reaction.
Integral protein A protein assembly that is permanently associated to the biological membrane and is difficult to isolate without the use of detergents or nonpolar solvents.
Integrin receptor (or Integrins) A class of cell receptor molecules that mediate the association between a cell and the surrounding environment (e.g., extracellular matrix, other cells). Integrins are involved in cell signaling processes that often define cell mechanics and regulate the cell cycle.
Ion channel A type of pore-forming integral membrane protein that allows selective flow of ions across the plasma membrane of the cell, thus controlling the electrochemical gradient formed inside and outside the cell.
Iron oxide Inorganic oxides composed of varying degrees of iron and oxygen. The most common iron oxide is Fe_2O_3, rust, and Fe_3O_4, paramagnetic magnetite.
IV-H1 A 15-mer peptide with a sequence of Gly-Val-Lys-Gly-Asp-Lys-Gly-Asn-Pro-Gly-Trp-Pro-Gly-Ala-Pro derived from the extracellular matrix protein collagen known to promote cancer cell adhesion and spreading.
Lipid bilayer A thin membrane composed of two layers of lipid. The cellular membrane is a phospholipid bilayer that incorporated multiple proteins, glycolipids, etc.
Lipidation A covalent addition process of a hydrophobic molecule (e.g., palmitic acid) onto a biomolecule (e.g., protein).
LyP-1 A cyclic nine-amino acid peptide, CGNKRTRGC, that can preferentially bind to tumors.
Lysosome A cellular organelle that contains acid hydrolases capable of breaking up cellular debris (e.g., worn-out organelles, food particles) and waste materials (e.g., engulfed viruses and bacteria). The organelle's pH is below 5.
Magnetic resonance imaging (MRI) A medical imaging technique utilizing an electromagnetic field that allows the visualization of soft tissue based on varying degrees of proton relaxation in different tissues and organs.
Mass spectrometry An analytical technique that measures the mass-to-charge ratio of ionized (thus charged) particles.
Metabolite The intermediates and products of metabolism and is often restricted to small molecules such as ethanol and glutamic acid.
Metallic alloy A partial or complete solid solution of one or more elements in a metallic matrix.
Metallic foam A porous (cellular) structure consisting of a solid metal that incorporates a large volume fraction of gas-filled pores (typically 70–95% porosity).
Micelle An aggregate of surfactant molecules dispersed in a liquid solution. This higher-order structure forms above the critical micelle concentration (CMC), often in the μM range.
Mitochondrion A membrane-enclosed organelle found in most eukaryotic cells and the main source of ATP (adenosine triphosphate), used as a chemical energy source. It also contains nucleic acids.
MSC (mesenchymal stem cell) Bone marrow stromal cells. A population of multipotent adult stem cell cultures discovered from the mesenchyme and the marrow that has been shown to differentiate into osteoblasts, chondrocytes, myocytes, and adipocytes. It is now also identified in nonmarrow tissue such as muscle and the dental pulp.
Nanoparticles Particles that are submicron, often 100 nm or below.
Nanostructure Structure exhibiting significant submicron features.
Native chemical ligation (NCL) A technique that reacts a C-terminal thioester with another peptide (or protein) containing an N-terminal cysteine residue.
Neural progenitor cell (NPC) Progenitor cells have a tendency to differentiate into a specific cell type with a limited amount of division possible. The term is sometimes used in place of neural stem cells, but (neural) stem cells can replicate indefinitely.
Neural stem cell (NSC) Self-renewing, multipotent adult stem cells able to generate the main phenotypes of the nervous system – neurons, astrocytes, and oligodendrocytes.
NiTi (nickel–titanium) A metallic alloy made up of nickel and titanium.
Nuclear magnetic resonance (NMR) A property that magnetic nuclei have in a magnetic field and applied electromagnetic (EM) pulse(s), causing the nuclei to absorb energy from the EM pulse and radiate this energy back out. The energy-radiated back out is at a specific resonance frequency that depends on the strength of the magnetic field and other factors.
Nuclear overhauser effect (NOE) The transfer of spin polarization from one spin population to another via cross-relaxation in NMR spectroscopy. NOE differs from spin coupling in the respect that it is a through-space observation rather than through bonds.
Nuclear transport Macromolecules such as RNA and proteins associate with karyopherins to enter and exit the cell nucleus via the nuclear pore complexes (NPCs), whereas small molecules can be transported without any regulatory process.
Osteogenic differentiation Cellular differentiation into fibroblast cells that, in addition, express the bone sialoprotein (or osteopontin) and osteocalcin.
PBX Pre-B cell leukemia homeobox refers to a family of transcription factors. They act as cofactors in the transcriptional regulation mediated by homeobox proteins during embryonic development and cellular development.
Peptide amphiphile (PA) A molecule that covalently links hydrophobic lipid tails together with hydrophilic peptide head groups. A linker segment (e.g., PEG) can be added in the middle.

Peripheral membrane protein A class of proteins that temporarily associate with the biological membrane either by attaching to integral membrane proteins or penetrating the peripheral region of the lipid bilayer.
Phospholipid A class of lipids comprising fatty acid chains (i.e., diglyceride), a phosphate group, and a small organic molecule such as choline.
Photocurable Polymerization occurring while exposed to a light source.
Posttranslational modification (PTM) The chemical modification of a protein after the translational process. Examples include phosphorylation, ubiquitination, palmitoylation, and acetylation.
Quantum dot A size- and shape-defined semiconductor whose excitons are confined in all three dimensions, often a few nanometers in size.
RGD A tripeptide with a sequence of Arginine-Glycine-Aspartic acid and is derived from the extracellular matrix protein, fibronectin. Peptide, proteins, and materials incorporating the RGD sequence have been shown to promote cellular adhesion.
Ribosome A component within the cell that associates with mRNAs and tRNAs in the cytosol to produce peptides and proteins enzymatically (the translation process).
SC4 A 12-mer bactericidal peptide that forms helical structures that have a sequence of KLFKRHLKWKII.
Self-assembly A term utilized to describe the processes in which a disordered system of preexisting components forms an organized structure or pattern as a consequence of specific, local, and cooperative interaction. If the components are molecules, the process is termed molecular self-assembly.
Self-renewal A cellular process that allows an unlimited number of cell divisions and replications.
Silanize or silanization Surface functionalization via silane molecules such as (3-aminopropyl)-triethoxysilane, (3-mercaptopropyl)-trimethoxysilane, and octadecyltrimethoxysilane.
Spinal cord injury (SCI) An injury to the spinal cord that causes myelopathy (loss of nerve function) or damage to nerve roots or myelinated fiber tracts that mediate signals to and from the brain.
Stem cells Cells that are able to self-renew and differentiate into multiple cell types. Mammalian stem cells are broadly categorized into either embryonic stem cells or adult stem cells.
Theranostic application An application that enables both medical diagnostics and treatment.
Transcription The process of single-stranded DNA being copied into the complementary RNA.
Translation Part of the protein biosynthesis process that involves the production of polypeptides via the association among mRNA, tRNA, and the ribosome.
Transplantation Instillation of an organ from one body to another for the purpose of replacing the recipient's damaged or absent organ. It can also involve the use of cell therapy sources such as stem cells and bone marrow cultures.
Vacuole A membrane-bound cavity in the cytoplasm of eukaryotic cells that contains air, water, cell sap, and digested food. It is present especially in plant and fungal cells while found to a lesser extent in animal and bacterial cells.
Vascular endothelial growth factor (VEGF) VEGF is a signal protein involved in the stimulation of new blood vessel production.
Vesicle A supramolecular assembly made up of lipid bilayers created by double-tailed lipid molecules such as phospholipids. Basically, it is a membrane-enclosed sack that has a hydrophilic core. Artificially prepared vesicles are referred to as liposomes.
Viscosity A measure of the resistance of a fluid being deformed by either shear stress or tensile stress.
W3K A 17-mer peptide with a sequence of WAAAAKAAAAKAAAAKA that is alanine-rich but water-soluble and forms worm-like micelles upon lipidation.
Wound healing An intricate and dynamic process in which tissues and organs repair themselves after sustaining injury.

Abbreviations

DMF Dimethyl formamide, a common solvent used in peptide synthesis.
PEG Poly(ethylene glycol)
SDS Sodium dodecylsulfate, a common anionic C12-alkylated surfactant molecule.
SEM Scanning electron microscopy
TEM Transmission electron microscopy
TFA Trifluoroacetic acid

4.415.1. Introduction

Biomaterials[1–20] can be divided into two different categories: one that exists in nature[21–25] or one that (favorably) mimics nature.[26–32] One facet of applications involving biomaterials is in the field of tissue and bio(medical) engineering. Bioengineers, on a regular basis, prepare biomaterials to influence biological events where genetic codes are transcribed and then translated within a dynamic environment in the *cell*. When taking into account the complexity involving biological systems, it is critical that surface properties are well understood all the way down to a single molecule or even an element. Multiple surface engineering techniques are available depending on the mode and degree of action, meaning the change of

physicochemical properties posttreatment (engineering). Surface cleaning, etching, and depth profiles are often done using radiation (beam) (i.e., plasma treatment[33–35]; electron beam lithography[36,37]; UV[38–41]; ultrasound[16,42]) (Mode 1). Synthetic chemistry-based techniques[43] are used when specific molecules need attachment (i.e., covalent bond formation; self-assembled monolayer) or a passivation of polymeric-networked materials (i.e., layer-by-layer technique[44–47]; core–shell material synthesis[15,48]; polymer coating on glass via photocuring[49,50]) is desired (Mode 2). Spatial positioning of molecules and nanoparticles on extended surfaces with nanometer-level precision can be achieved via printing methods (i.e., microcontact stamping[51–58]; dip-pen lithography printing[59,60]; ink jet printing[61–66] (Mode 3). Intermolecular associative and repulsive forces (interfacial phenomena)[67,68]-induced structuring can be useful as well to achieve well-defined nanostructured surfaces, and this is where self-assembly or cooperative assembly of molecules and (nano)materials[69–72] plays a critical role in the outcome of the final complex structure (Mode 4). (**Figure 1**)

In this chapter, we cover surface engineering efforts performed using peptide amphiphiles (PAs) (see **Chapter 2.205, Self-Assembling Biomaterials**). PAs provide a platform of bioactive nanostructured materials that provide biomaterials with a controlled display of functional and biologically responsive moieties on the periphery of the resulting biomaterial construct; PAs have the potential to mimic nature. The hierarchical two- and three-dimensional (3D) structures formed by PAs via self-assembly processes are spherical vesicles and micelles, lipid layers, and fibrous high-aspect-ratio structures (**Figure 2**).[17,18,74–80] The usual characterization methods for such higher-order structures involve dynamic light scattering (DLS), circular dichroism (CD), fluorescence spectroscopy, and microscopy. One of the key features of a lipidated peptide is that sequences incorporating a distinct secondary structure (i.e., α-helix) will often experience stabilization of the structure over a time domain compatible enough to elicit a cell (signaling) response (i.e., adhesion). We highlight work by several different groups over the past two decades reporting PAs' (nano)structural features as well as biological responses in cellular and animal models. We view 'surfaces' as critical components having unique spatial and temporal domains; they exist over multiple length scales and time domains often bioactive enough to interact with living systems undergoing dynamic changes with varied magnitudes and frequency depending on the type of biosystem. PAs can form surfaces that present bioactive subdomains and physicochemically unique properties that may architecturally and biochemically reproduce materials present in nature (i.e., the cell membrane, subcellular machinery, the extracellular matrix) (see **Chapter 4.406, Protein Interactions with Biomaterials** and **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**).

4.415.2. The Amphiphilic Nature of Life's Events

The cell membrane (shown in **Figure 3**) comprises multiple amphiphilic and hydrophobicity-controlled structures: lipids, proteins, polysaccharides, and nucleic acids.[15] Among the aforementioned biological entities, proteins interact with other biomolecules in a complex but intricate manner; most importantly, the role and the fate of proteins within a specific cell biology subsystem (i.e., receptor-mediated signaling pathway, cellular adhesion process, cytoskeleton rearrangement, endocytosis, inflammatory response, translation, transcription, ion channeling, posttranslational modification, apoptosis, nuclear transport, differentiation, self-renewal, etc.) will depend strongly on the dynamics associated with the protein's primary and secondary structures – for example, the hydrophobicity and the α-helical propensities will vary in accordance with the incorporated amino acid residue characteristics. We consider a cell membrane as a 2D soft surface that can be mimicked on flat surfaces. In living systems, however, the cell membrane exterior and interior are not interfaced to a hard surface (except in bone) and is, in fact, three-dimensionally responsive through multiple cellular and extracellular signaling pathways that play critical roles in the overall function of cells. In this respect, we can define self-assembly processes occurring in multiple biological systems constituting 3D structural cues and niches – meaning that coassembly of subcomponents are important to produce functionality (see **Chapter 4.401, The Concept of Biocompatibility**).

4.415.3. PAs: Synthesis, Physicochemical Characterization, and Self-Assembly

PAs (or lipopeptides; **Figure 2**) are a class of small molecules that link peptides (as the hydrophilic head group) together with hydrocarbons (hydrophobic tail). Unlike naturally occurring lipids, this platform of materials is synthetically prepared and usually has a molecular weight of 1000–3000. The use of PAs to address biomaterials and bioengineering questions has been developed since the mid-1990's. A highly efficient solid-phase synthesis method was employed by Tirrell and coworkers where dialkyl hydrocarbon chains were covalently bonded to bioactive peptide sequences such as Gly-Val-Lys-Gly-Asp-Lys-Gly-Asn-Pro-Gly-Trp-Pro-Gly-Ala-Pro (denoted as [IV-H1] from here on) derived from the extracellular matrix protein collagen, as shown in **Figure 4**.[80–85] The chemistry behind such PA synthesis is Fmoc-chemistry.[86–89] The motivation to utilize bioactive peptides displaying amphiphilic construct is to mimic aspects of native designs – for instance, the stem cell niche or the tumor microenvironment. The [IV-H1] sequence is a 15-mer biologically proved to promote cancer cell adhesion and spreading while physicochemically observed (via CD, NMR, etc.) to form a triple-helical structure, often the secondary protein structure naturally occurring in collagen (co)assembly.[80,83]

4.415.3.1. Synthesis and Characterization of PAs

The synthesis protocol outline for synthesizing a single-tailed PA is given below (**Figure 5**). Characterization generally involves mass spectrometry, CD, and NMR. Protocols developed by Tirrell and coworkers[80–85] can be easily applied to both dialkylated and monoalkylated PA synthesis.

4.415.3.2. Double-Tailed (Dialkylated) PAs

Double lipidation of cationic peptides often leads to potent antibiotic agents. In the context of surface engineering, double-tailed (low molecular weight) PAs displaying bioactive

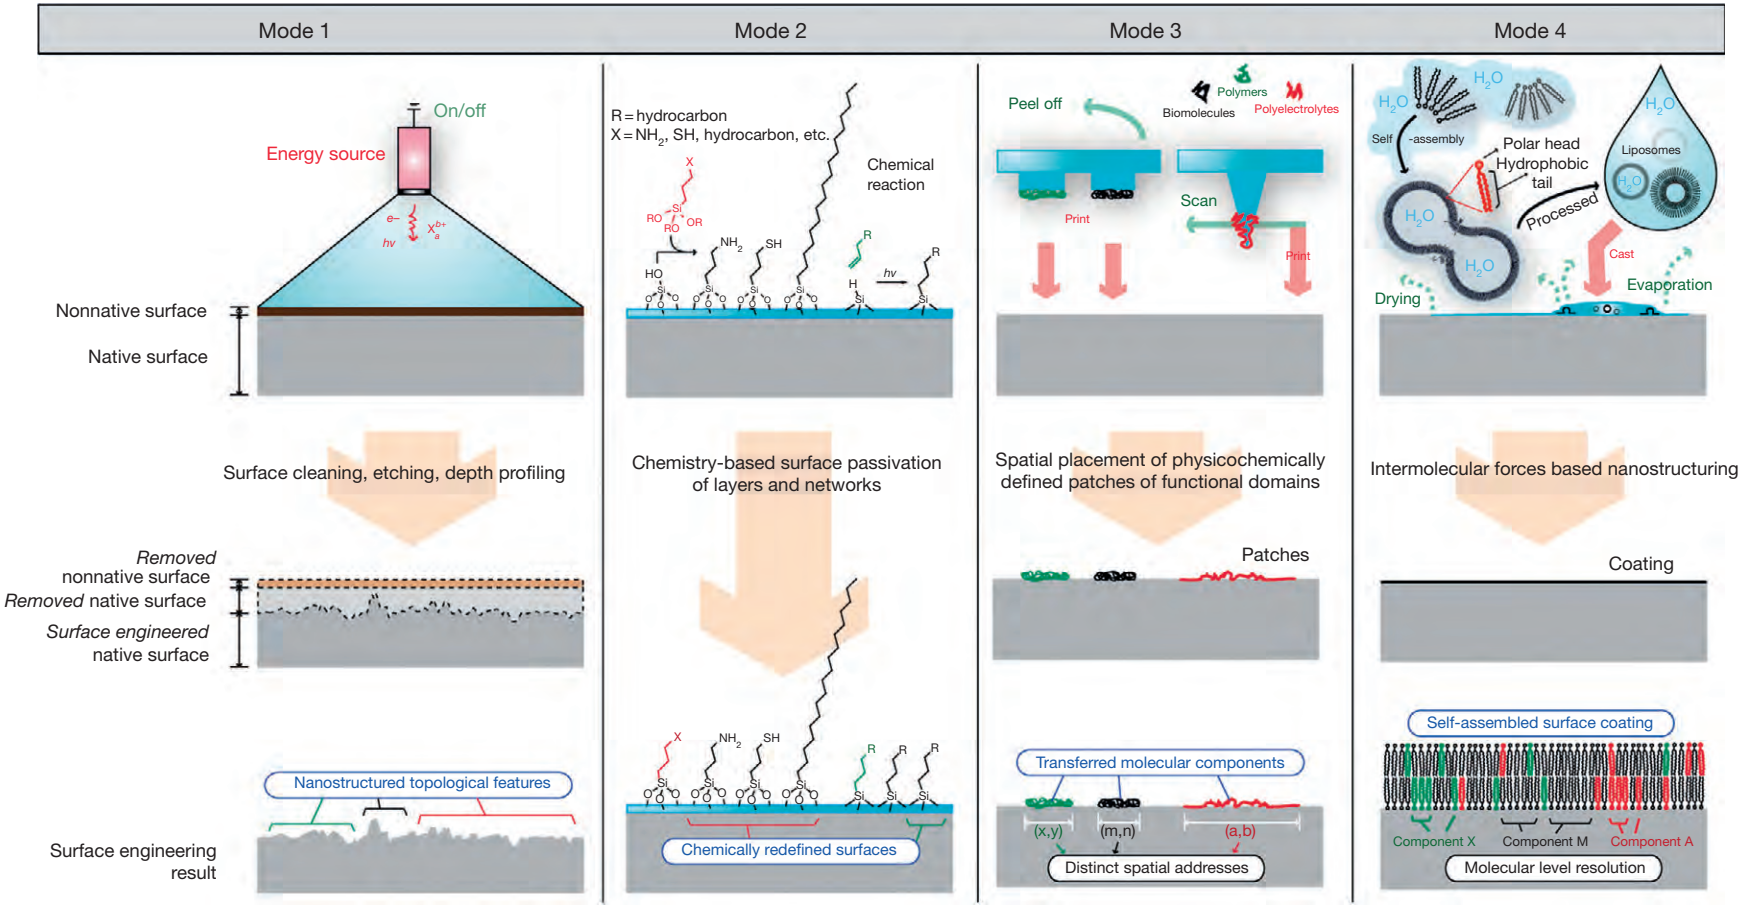

Figure 1 Modes of surface engineering. See main text for details. This review will cover mode 4, in depth. Various combinations of all four modes, however, can lead to unique surfaces with hierarchically, physicochemically, and biologically distinctive properties.

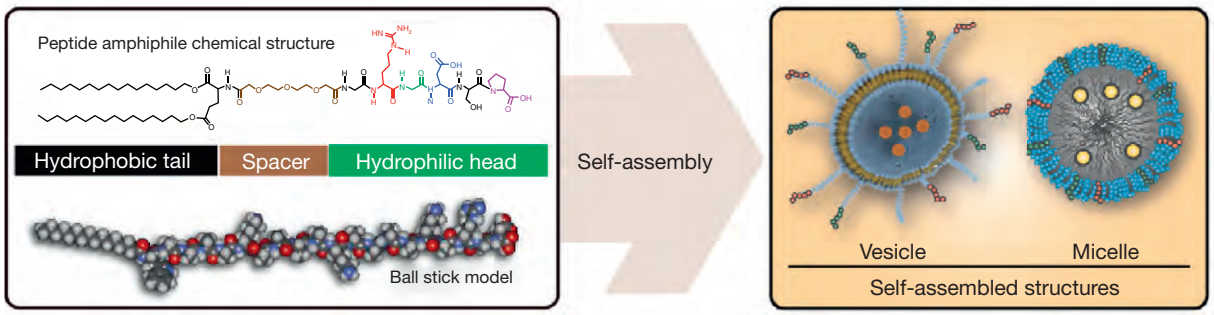

Figure 2 Self-assembled structures of peptide amphiphiles. Based on the degree of lipidation, peptide amphiphiles will form vesicles or micelles. The chemical structure represents the double-tailed peptide amphiphile $(C16)_2$-Glu-C_2-PEG-GRGDSP which is synthesized from covalent linkages among glutamate dialkyl ester 1',3'-dihexadecyl L-glutamate (two hexadecanols attached to glutamic acid; the hydrophobic tail), 3,6,9-trioxaundecanedioic acid (polyethylene oxide spacer), and a 6-mer peptide head group Glu-Arg-Glu-Asp-Ser-Pro (the hydrophilic head).[73] The ball-and-stick model represents the single-tailed peptide amphiphile C16-$WA_4KA_4KA_4$KARGD,[74] created using Accelrys DS Visualization software.

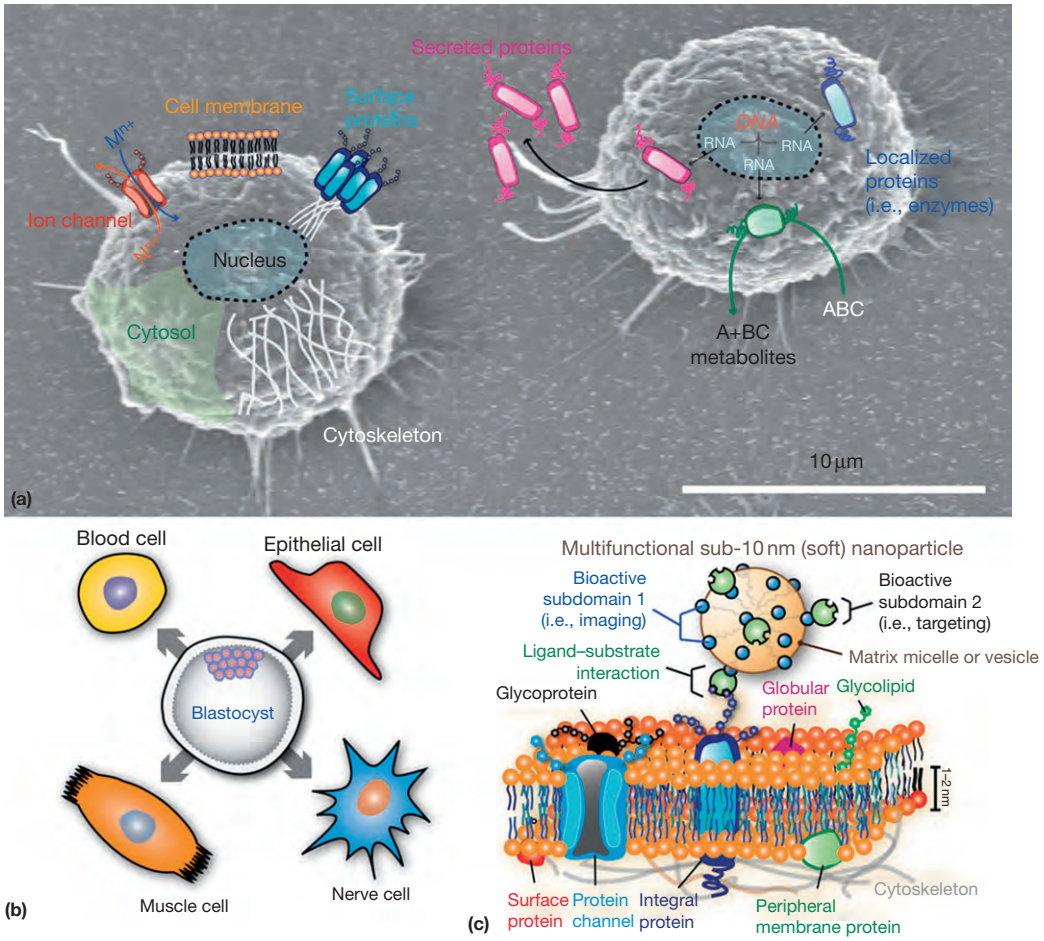

Figure 3 A cell as a multifunctional entity. (a) The breakdown of cellular machinery shows that a mammalian cell is essentially a multifunctional micron-sized particle comprised of internal and external components that function in coordination. The external components are (1) the cell membrane, (2) surface proteins/ion channels, and (3) the cytoskeleton, while the internal components are (4) the cytosolic organelles (i.e., ribosome, endoplasmic reticulum, golgi apparatus, mitochondrion, vacuole, lysosome, and centriole) and (5) the nucleus (which contains nucleic acids). Another major component in a living cell consists of the active biological processes that occur in a hierarchical and consistent fashion. These so-called biological pathways involve proteins, metal ions, nucleic acids, amino acids, external stimuli, and other biomolecules to work in concert with one another. The represented scanning electron microscopic (SEM) image shows two murine BV-2 microglia cells attached to a surface. (b) Multiple cell types exist differing in their function, shape, and size. (c) The cell membrane consists of many functional biomolecules, including multiple forms of functional proteins, displayed carbohydrates, and the lipid bilayer. A bioactive and nanometer-sized material (i.e., multifunctional micelles, liposomes, and inorganic nanoparticles) can directly interact with such biomolecules present on or inside a cell as shown in the illustration. It is important to precisely define the nature of such interactions in order to elicit a biologically definable process through certain types of surface engineering presented in **Figure 1**. Adapted from Suh, W. H.; Suh, Y. H.; Stucky, G. D. *Nano Today* **2009**, *4*, 27–36.

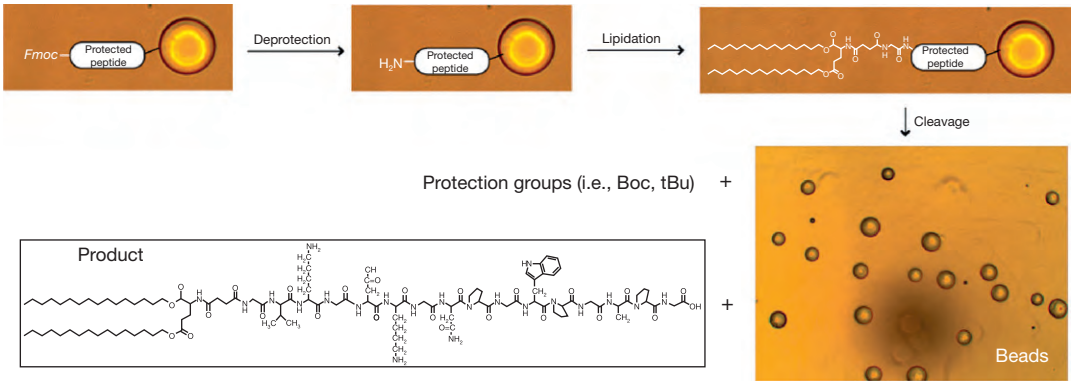

Figure 4 Synthetic outline of peptide amphiphile based on Fmoc-chemistry. A protected peptide is first prepared on a solid polymer bead using a standard peptide synthesizer. The amine-protecting Fmoc group is removed using base reagents (i.e., piperidine, piperidine/DBU, or 4-methylpiperidine in DMF), followed by lipid tail (or linker) addition. After the hydrocarbon tail addition process is complete, the peptide amphiphile and the protecting groups are cleaved under a mild acid condition (i.e., 95% TFA). Adapted from Berndt, P.; Fields, G. B.; Tirrell, M. *J. Am. Chem. Soc.* **1995**, *117*, 9515–9522.

sequences can be embedded into lipid bilayers created by phospholipids via vesicle fusion. This feature allows facile screening of functional molecules that play an intricate role in the cell adhesion process or to probe biomolecular forces in a controlled environment that may provide information crucial for our increased understanding of biological systems such as membrane protein trafficking and protein–biomolecule interactions.

Dialkylated hydrophilic moieties including PAs will form vesicles in liquid media (Figure 6).[91] Depending on the number of lipid bilayers formed and size of the soft spheres, such vesicles (often termed liposomes) can be categorized into small unilamellar vesicles (SUVs, < 100 nm diameter), larger unilamellar vesicles (LUVs, 100–1000 nm), multilamellar vesicles (MLVs, 100 nm to 20 μm), and multivesicular vesicles (MVVs, 100 nm to 20 μm). Generally, when PA-incorporated films are rehydrated and liposomes have formed, it is further purified via extrusion to predominately populate the working solution with SUVs before lipid bilayer experiments are conducted to minimize the heterogeneity of the surface being created (Figure 7) (see Chapter 1.124, Polymer Films Using LbL Self-Assembly).[92]

Peptide amphiphile $(C16)_2$-Glu-C_2-$(GPO)_4$-GVKGDKGNP GWPGAP (herein $(C16)_2$-Glu-C_2-$(GPO)_4$-[IV-H1], where O is hydroxyproline) was constructed by Tirrrell and coworkers and compared to poly(ethylene glycol) (PEG) lipids for its ability to promote melanoma cell adhesion, based on ligand accessibility as a means to control cell responses on a bioactive lipid bilayer.[93] The head group lengths for the studied lipids (neutron reflective data) were 8.8 nm for $(C16)_2$-Glu-C_2-$(GPO)_4$-IV-H1, while for DSPE-PEG-120, -750, -2000, and -5000, the lengths were 1.6, 3.5, 9.0, and 16.8, respectively. When the particular PA was mixed 50:50 with the PEG lipids and spread out as lipid bilayers, melanoma cells M14 clone #5 adhered to only 50% DSPE-PEG-120, -750, and -2000. For DSPE-PEG-5000, the head group length of the PEG lipid (16.8 nm) exceeds the PA head group length (8.8 nm) so the bioactive sequence IV-H1 – a known sequence to promote melanoma cell adhesion – was not accessible and PEG molecules are known antifouling agents,[94–97] hence no cell attachment and proliferation (see Chapter 3.320, Nanostructured Polymeric Films for Cell Biology).

4.415.3.3. Single-Tailed (Monoalkylated) PAs

Monoalkylated amphiphilic constructs self-assemble into spherical micelles with a hydrophobic core and hydrophilic head groups at the periphery of the soft nanoparticle (Figure 8). This is a contrasting feature compared to double-tailed (low molecular weight) amphiphile construct, as liposomes have a hydrophilic core surrounded by a lipid bilayer as mentioned earlier.

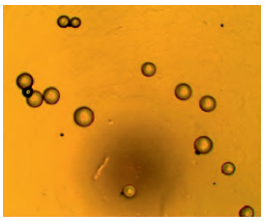
Tirrell and coworkers prepared an alanine-rich 17-mer peptide sequence containing single-tailed PA and profiled its conversion from spherical micelles into worm-like fibrous micelles based on modulation of physicochemical properties (i.e., shear induction).[74] The particular PA is C16-$WA_4KA_4KA_4KA$ (C16-W3K herein); above its critical micelle concentration (CMC), the PA molecules form spherical micelles or fibrous structures depending on shear, time, concentration, and temperature, and C16-W3K switches into fibrous structures. Multiple examples of monoalkylated PAs exist and we further examine their physicochemical and biological properties in the later sections of this chapter.

4.415.4. The Multifunctional (Soft) Nanoparticle Concept

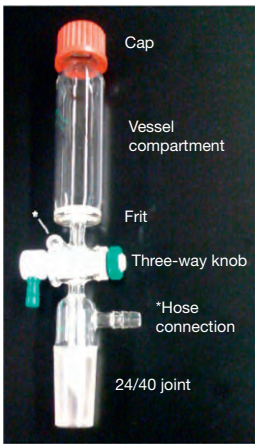
Multiple chemically distinctive PAs can comprise different higher-order structures such as liposomes and spherical micelles (Figure 9) with nanometer-scale precision (see Chapter 3.319, Characterization of Nanoparticles in Biological Environments; Chapter 3.319, Characterization of Nanoparticles in Biological Environments; and Chapter 4.429, Ordered Mesoporous Silica Materials). We describe some recent examples of molecular delivery and theranostic applications using multicomponent liposomes and spherical micelles.

4.415.4.1. Targeting-Enabled PA Spherical Micelles

Ruoslahti, Tirrell, and coworkers utilized a double-tailed PEG construct appended with a homing (targeting) peptide sequence (i.e., CREKA, LyP-1) for targeting atherosclerotic plaques or



Beads with protected peptides



Synthesis vessel

Peptide amphiphile synthesis protocol

0. Calculations (using excel is helpful) and preparation

a. Obtain a clean synthesis vessel.
b. Weigh peptide conjugated beads and calculate the mmol g^{-1}.
c. Calculate how much 4 equivalent carboxylic acid (lipid tail), 4 eq. HOBt (1-hydroxybenzotriazole), 4 equiv. HBTU (2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate), 8 equiv. DIEA (*N*,*N*-diisopropylethylamine) are needed.

Steps 1 through 12 should be done inside a chemical hood.

1. Swelling

a. Add the pre-weighed beads to the clean synthesis vessel.
b. Add 10–15 ml of DCM (dichloromethane).
c. Shake slowly for 30 min.

2. Washing

a. Stop shaking and empty DCM.
b. Add 10–15 ml of DMF (dimethylformamide) and shake to wash for 5 min.
c. Stop shaking and empty DMF.
d. Repeat step 2(b) and 2(c) twice more.

3. Deprotection (*Fmoc* to free amine)

a. Mix 2% piperidine, 2% DBU, and 96% DMF (recommended final volume 20–30 ml).
b. Add the deprotection solution to the emptied synthesis vessel from 2.
c. Shake moderately (beads are well dispersed during) for 1 h.
d. Stop reaction, empty the *Fmoc* deprotection solution; proceed to the wash step.
**Fmoc* = 9*H*-fluoren-9-ylmethoxycarbonyl

4. Washing

a. Wash 3× DMF (10–20 ml volumes; 5 min/ea).
b. Empty the final washing solution and proceed to either step 5 or 6.

5. (Optional) Amine test

6. Coupling

a. Coupling reagents from 0(b) are dissolved in 20 ml DMF, 2 ml DCM.
b. The coupling solution is added to the dried bead containing synthesis vessel from 4.
c. Shake moderately for, at least, 2–4 h but overnight reaction is also acceptable.
d. Stop reaction, empty the remaining coupling solution; proceed to the wash step.

7. Washing

a. Wash in the following order, first: 2× DMF, 2× DCM, 1× MeOH (10–20 ml volumes).
b. Do the final washing step: 1× DCM, 2× MeOH (also 10–20 ml volumes).
c. Dry under vacuum at room temperature.

8. Cleavage

a. Prepare a clean glassware (100 ml Erlenmeyer flask recommended) to receive the as-prepared peptide amphiphile solution.
b. Mix 2.5% water, 2.5% TIS (triisopropylsilane), and 95% TFA (trifluoroacetic acid) (final vol. 10–20 ml)
c. Add the cleaving solution to the dried bead containing synthesis vessel from 7.
d. Shake slowly for approximately 4 h.
e. Stop reaction and collect the crude PA solution into the precleaned glassware from 8(a) via vaccum filtration or nitrogen gas purging.

9. Evaporation

a. Transfer the collected crude PA in TFA (approximately 10–30 ml) to a 50 ml plastic tube.
b. Evaporate TFA via nitrogen gas purging.
c. After evaporation is complete (usually after overnight purging), the crude PA oil can be stored below −20 °C or undergo the final precipitation step.

10. Precipitation

a. Prepare a cold solution of ether (i.e., diethyl ether).
b. Add 20–30 ml of cold ether into the 50 ml plastic tube containing the PA oil.
c. Hand shake, vortex, and/or sonicate the PA-ether dispersion for approximately 5–10 min until white/ivory colored precipitates are visible.
d. Centrifuge at 1500 rpm for 5 min.
e. Empty the ether supernatant solution.
f. Repeat steps (a) through (e) twice more. Discard ether after product identification.

11. Drying

a. After the final precipitation (/wash) from 10, the collected crude PA pellet/particles are dried under nitrogen gas purging until the ether has visibly evaporated.
b. The crude PA solid is further dried under vacuum for 1–2 h (room temperature).
c. The crude PA is ready for HPLC separation. Store below −20 °C when appropriate.

12. Separation

13. Lyophilization

Figure 5 Peptide Amphiphile Synthesis Protocol. A macrophotograph of the synthesis vessel and the beads with protected peptides are shown on the far left. The optional amine test (Step 5) is usually done using the Kaiser test[90] in which the beads will turn blue if amine groups are exposed.

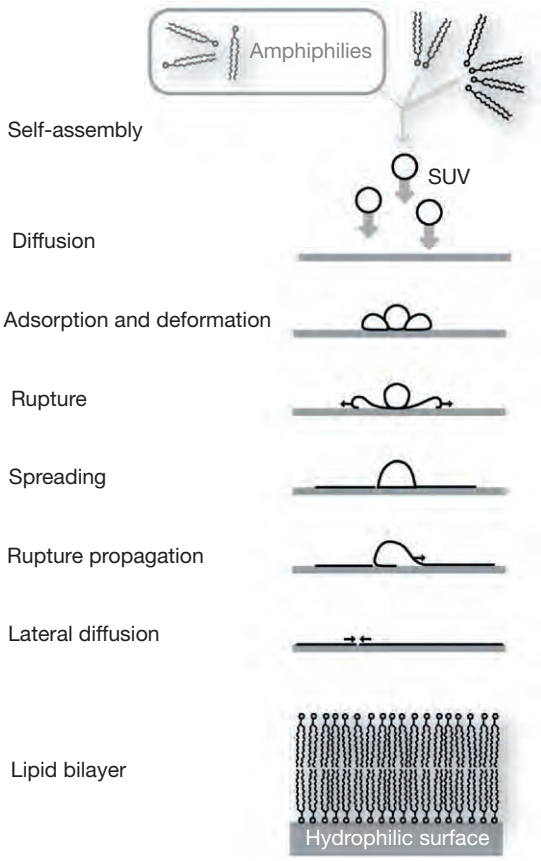

Figure 7 Vesicle fusion mechanism (hypothesis) on a hydrophilic surface. Adapted from Stroumpoulis, D.; Parra, A.; Tirrell, M. *AIChE J.* **2006**, *52*, 2931–2937.

tumors (see **Chapter 3.312, Cell Culture Systems for studying Biomaterial Interactions with Biological Barriers**).[76,98] The resulting spherical micelles have a diameter of ~25–35 nm and their *in vivo* circulation half-life time was 2–3 h. The added feature of the PA was the covalent linkage of either a bioimaging probe or a therapeutic agent; this makes them a multifunctional nanoparticle (type V MFNPS) (**Figure 9**). Synthesis-wise, the anticoagulant peptide hirulog[99] (CF*PRPGGGGNGDFEEIPEEYL where F* is D-Phenylalanine and a cysteine was added to the N-terminus of hirulog for functionalization), CREKA,[100] or LyP-1 (cyclic nine-amino acid peptide CGNKRTRGC)[101,102] were linked to DSPE-PEG2000-maleimide via Fmoc-chemistry methods (**Figure 10**). DSPE-PEG2000-CREKA spherical micelles, in particular, are able to home to the aortic tree of atherosclerotic mice within 3 h of injection (**Figure 10**). Thus, when CREKA-targeted hirulog micelles were injected into ApoE-null mice, the antithrombin activity was significantly higher compared to the wild-type mice or when nontargeted micelles were administered.

4.415.4.2. Single-Tailed PAs for Cancer Cell Biology Control

Hartgerink and coworkers[103] prepared C16-WYPWMKKHH, C16-RQIKIWFQNRRMKWKK, and C16-WYPWMKKHHRQI KIWFQNRRMKWKK to study their effects on cancer cell proliferation and inhibition of growth. The sequence WYPWMKKHH disrupts HOX/PBX/DNA complex formation, while the RQIKIWFQNRRMKWKK sequence allows cargo delivery into cells. The C16 hydrocarbon chain allowed the self-assembly process to occur; the resulting stable population of spherical micelles incorporated stable secondary structures (i.e., α-helix) when embedded in a micelle that predominantly comprised anionic surfactant molecules (i.e., SDS) (**Figure 11**).

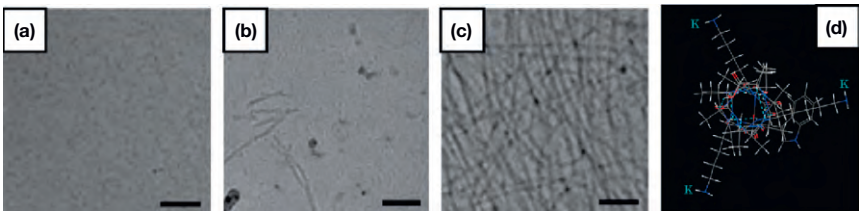

Figure 8 TEM of C16-W3K Peptide Amphiphile. (a) Spherical versus (b, c) fibrous micelles. C16-W3K initially forms spherical micelles (a). However, fibrous micelles are observed after 1 day (b) and highly cross-networked nanofibrous micelles dominate after 3 days (c). (d) Molecular mechanics method optimized W3K structure via the COMPASS Force Field produced by Accelrys Software Inc. The image shows that three lysine residues are evenly distributed along the peptide backbone, presenting no angular and longitudinal asymmetry around the α-helix. Adapted from Shimada, T.; Lee, S.; Bates, F. S.; Hotta, A.; Tirrell, M. *J. Phys. Chem. B* **2009**, *113*, 13711–13714.

4.415.4.3. *In Vitro* Binding Affinity Control via Native Chemical Ligation

Micelles and vesicles were prepared with a collagen binding protein CNA35 – 35 kDa collagen binding domain present in an adhesion protein from *Staphylococcus aureus* – displayed on the exterior of DSPE-PEG2000 that had moderate collagen binding affinities ($K_{micelle}$ ~0.5 μM, $K_{liposome}$ ~3 ± 1 nM) and allowed facile detection via fluorescence spectroscopy.[104,105] The native chemical ligation (NCL) method[106,107] was employed successfully to create covalent linkages between recombinant proteins and the PEG-conjugated vesicles and micelles; NCL exclusively occurs at the protein C-terminus – often not involved in any binding activities with high specificity. These examples (Figure 12) demonstrate a highly effective instillation of multiple functionalities (i.e., multiple collagen binding sites) into soft nanoparticles that may be necessary for targeting sites with multivalent architectures. The NCL method should be easily expanded to other nanoparticle systems (i.e., iron oxides and quantum dots) coated with peptide moieties.

4.415.5. Protein-Like Structures to 3D Hierarchical Nanostructures

Close to two decades ago, Yamada *et al.*[108] reported that dialkylated PAs made up of C12 and C16 tails along with 14 residues of L-glutamic acid (Figure 13) self-assembled into helical super structures (nanotubes) comprising single-walled PA bilayers. Transmission electron microscopic (TEM) and CD analysis suggested that the PAs formed tube-like nanostructures and also displayed α-helical secondary structures at ~0.1 wt% concentration (Figure 14). During the same period, Kunitake and coworkers also reported identical nanostructures formed from self-assembly of ammonium-based amphiphilic molecules in aqueous media.[109]

In the 1990s, Tirrell and colleagues[80,81,85] realized that controlling the mode of lipidation on PAs instilled with a collagen-model head group enabled the controlled mimicking of protein-like (secondary) structures by conducting an extensive investigation into the relationship between the degree of

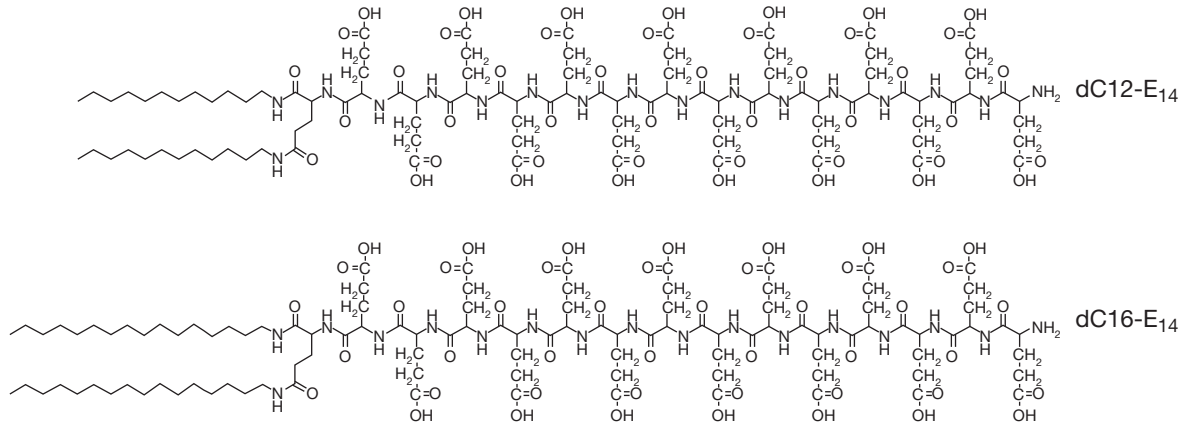

Figure 13 Double-tailed poly(L-glutamic acid) peptide amphiphile chemical structures. Adapted from Yamada, K.; Ihara, H.; Ide, T.; Fukumoto, T.; Hirayama, C. *Chem. Lett.* **1984**, 1713–1716.

alkylation (i.e., chain length, number of chains per molecule) and their secondary structure stabilization. The experiments involved the use of the peptide sequence $(GPO)_4$[IV-H1] $(GPO)_4$ where [IV-H1] is the alpha1(IV)1263-1277 collagen sequence (GVKGDKGNPGWPGAP) and C6, C8, C10, C12, C14, C16, and diC12 tails. Based on multiple CD and NMR analyses, C6-$(GPO)_4$[IV-H1]$(GPO)_4$ can form a triple-helix structure below 30 °C with the [IV-H1] region within the PA being in a triple-helical environment; the PA melting temperature is increased when the monoalkyl chain length is increased. The denaturation temperature for the C16 PA is comparable to the original $(GPO)_4$[IV-H1]$(GPO)_4$ sequence. However, the degree of stabilization differs between mono- (Tm = 55.0 °C) and dialkylated (Tm = 71.2 °C) PAs. All in all, whether a helix-forming peptide sequence is covalently linked to a single hydrocarbon tail or a double tail, synthesized PAs can oligomerize, self-assemble, and form various stable structures that may be crucial in positively (or negatively) influencing biological systems. More recently, Stupp and coworkers prepared 12 different PAs (Table 1) that self-assembled into fibrous structures made up of spherical micelles having exposed bioactive peptide sequences RGD and IKVAV. TEM was utilized as seen in the figures to unmistakably show amphiphilic constructs forming fibrous structures based on pH-tuning; this change in physical property allowed the formation of gel-like macroscopic materials (Figure 15). Table 1 lists single-tailed PAs that form fibrous worm-like 3D structures explored in this work. In Section 4.415.6, we highlight research that utilized mono-lipidated PAs in biomedical applications.

4.415.6. Applications in Biomedical Sciences: Tissue and Stem Cell Engineering

Mode 4 of surface engineering, mentioned earlier in this chapter (Figure 1), can be divided into three subcategories when

bioactive PAs are involved: (1) lipid bilayer embedded bioactive PAs, (2) fibrous PA incorporating bioactive PAs, and (3) 3D gel matrices displaying bioactive PAs and other biomolecules (**Figure 16**) (see **Chapter 4.409, Surfaces and Cell Behavior** and **Chapter 3.312, Cell Culture Systems for studying Biomaterial Interactions with Biological Barriers**).[111] In this section, we highlight the use of PAs to influence biological systems; we consider micelles with high-aspect ratios to be ideal for tissue engineering both on 2D surfaces and on 3D matrices.

4.415.6.1. Helical Structure and Antibacterial PAs

Tirrell, Mayo, and colleagues[112,113] studied single-tailed PAs for their antibacterial ability. In one instance, KLFKRHLKWKII-NH_2 (amidated C-terminus) was monoalkylated with C12 and C18 chains. The particular 12-mer peptide sequence (SC4)[114] is a potent antibacterial peptide that displays activity at nanomolar concentrations against Gram-negative bacterial species and micromolar concentrations against Gram-positive bacteria. SC4 also neutralizes endotoxins while displaying no hemolytic activity sub-100 μM. The bactericidal mechanism appears to be coming from the helix-forming nature of the peptide sequence that can permeabilize through the cell membrane. Lipidation of SC4 resulted in a 30-fold increase of biocidal activity against *Staphylococcus aureus*, *Steptococcus pyogene*, and *Bacillus anthracis* (Gram-positive), but there was little or no increase of antibacterial activity against *Escherichia coli* and *Pseudomonas aeruginosa* (Gram-negative) strains. In addition, lipidated SC4 PAs neutralized lipopolysaccharides (LPS) more than SC4 alone (~3–6 times increased inhibition of LPS activity). Red blood cells were observed to undergo lysis at micromolar PA concentrations (antibacterial activity induction occurs at the sub-1 μM to tens of nanomolar range), whereas endothelial cell toxicity was negligible. The molecular modeling representation based on 2D NMR data (i.e., Nuclear Overhauser Effect) suggests that the monoalkylated SC4 is helical in secondary structure and that has also been validated by CD experiments where the PAs were embedded in liposomes mimicking eukaryotic and bacterial cell membranes (**Figure 17**).

The next study by Tirrell and coworkers[112] showed that lauric acid (C12)-modified YGAA(KKAAKAA)$_2$ (termed AKK PA) had increased antibacterial activity, whereas YG(AKAKAAKA)$_2$ (termed KAK PA) did not in comparison to C12-SC4 PA. Here, the importance of helical structure was once again demonstrated; CD results as well as the helical wheel diagram analysis shown in **Figure 18** suggest that KAK PA does not share structural homology with SC4 PA. However, AKK PA displays a wider hydrophobic region, with cationic regions grouped on one side (similar to the SC4 PA) when an α-helical structure

Table 1 List of PA molecules that form nanofibers via pH control, divalent ion induction, and concentration. The chemical structure of C16-$C_4G_4S^{(PO4)}$RGD (PA 4) is shown in **Figure 15**.

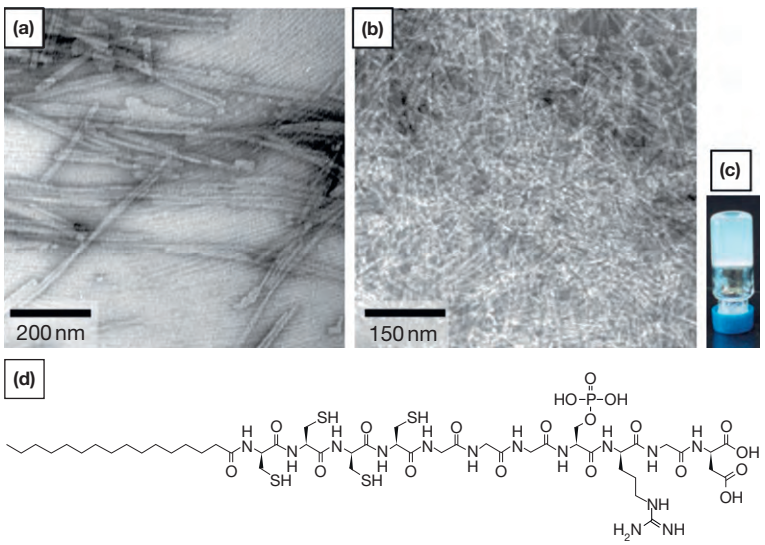

Figure 15 TEM images of nanofibers from PAs 6 and 7 from **Table 1**. Samples were (negatively) stained with phosphotungstic acid. (a) The aspect ratio of the nanofibers is much higher for C10–$A_4G_3S^{(PO4)}$RGD (PA 6) compared C16–$A_4G_3S^{(PO4)}$RGD (PA 7). (b) PA 7 will form a highly networked gel. Macrophotograph of PA 6 gel is provided on the far right (c). (d) Example chemical structure of PA 4 from Table 1. Adapted from Hartgerink, J. D.; Beniash, E.; Stupp, S. I. *Proc. Natl. Acad. Sci. USA* **2002**, *99*, 5133–5138.

is formed (embedded in a bacterial cell membrane mimic). AKK PA also shows reduced hemolytic activity, different from SC4 PA – although the AKK peptide sequence has a strong hydrophobic property, it is less than SC4 peptide. The structure–activity relationship, at least in cytotoxicity, is well demonstrated by Chu-Kung *et al.*[112]

4.415.6.2. Neural Stem Cell Engineering

Palmitic acid (C16) modified A_4G_3-IKVAV (IKVAV-PA) was utilized in Silva *et al.* to create an artificial 3D extracellular matrix (Figure 19) ideal for supporting murine neural progenitor cells (NPCs) at physiological conditions (see Chapter 2.209, Materials

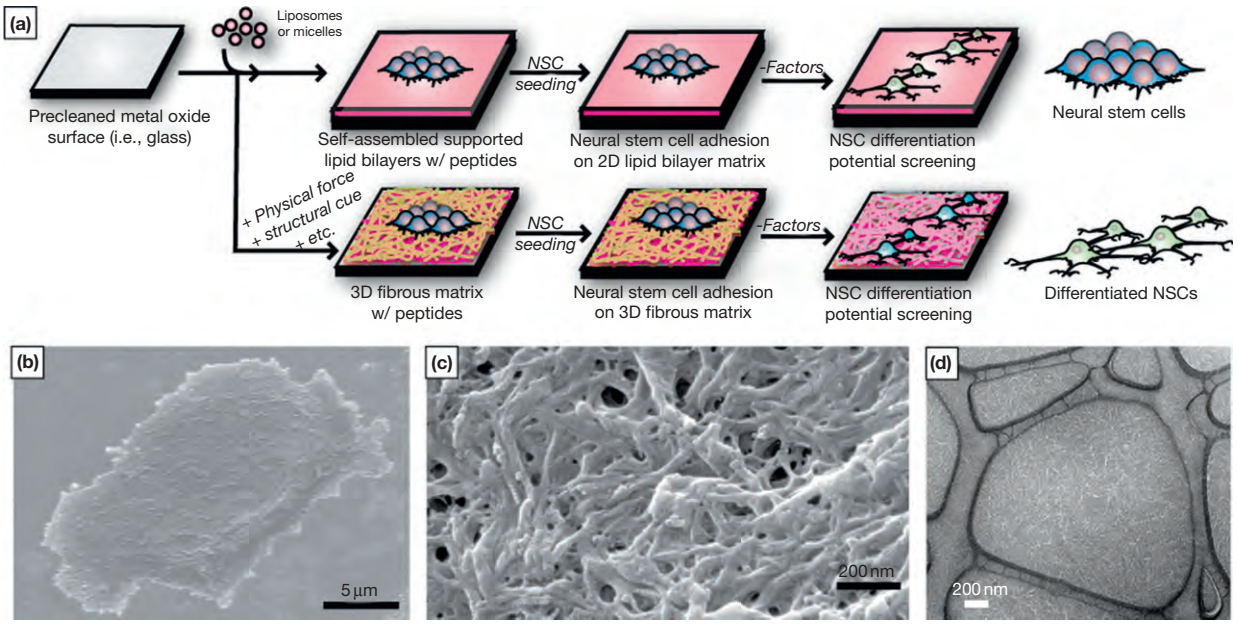

Figure 16 Surface engineering of surfaces using bioactive peptide amphiphiles for tissue engineering applications (schematic a). Electron microscopy images of a 3D peptide amphiphile gel matrix: SEM (b, c) and TEM (d) images. Adapted from Tirrell, M. WFPC Project 4.4.5: Modular, switchable, synthetic, extracellular matrices for regenerative medicine; In *AFIRM Annual Report*; Vandre, R., Ed.; 2009; pp II-53–II-56.

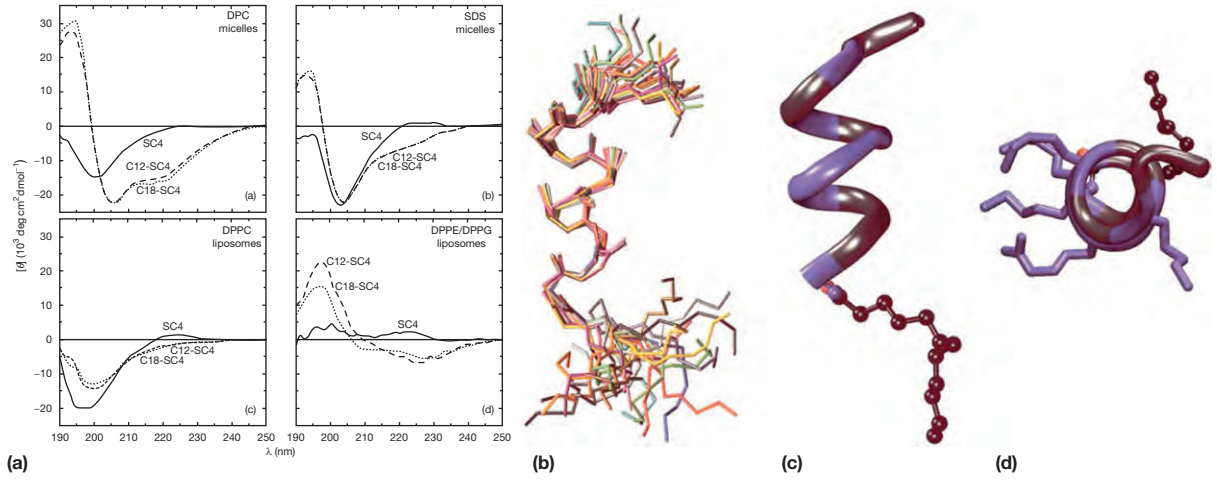

Figure 17 CD spectra of SC4 (unbroken lines), C12-SC4 (dashed lines), and C18-SC4 (dotted lines) in micelle and liposome membrane mimics. In micellar mimics, the SC4 amphiphiles showed spectra consistent with helical conformation in DPC (a-a) and somewhat less helix in SDS (a-b). Liposome membrane mimics showed spectra indicating little SC4 amphiphile structure in DPPC (a-c), the erythrocyte mimic, but a more structured state in bacterial-mimicking DPPE/DPPG liposomes (a-d). The SC4 peptide spectra indicate little structure under any condition. Spectra in water: NOE-derived structures of C12-SC4 in DPC micelles (b) Superposition of the 24 final structures, using residues Lys-1 through Trp-9 for alignment. (c) A ribbon backbone representation of one structure, showing the overall helical fold and a less-ordered C-terminus. Polar residues are shown in blue and apolar residues in gray. The fatty acid tail is shown as a ball-and-stick model. (d) An axial view of the average structure, demonstrating the distribution of charged side chains (arginine and lysine) in an amphipathic helix. The colors are as described in (c) looked similar to those in DPPC liposomes; results at 37°C were similar for all conditions. Adapted from Lockwood, N. A.; Haseman, J. R.; Tirrell, M. V.; Mayo, K. H. *Biochem. J.* **2004**, *378*, 93–103.

as Artificial Stem Cell Microenvironments).[115] The working concentration was 0.5 wt% of PA in NPC medium. The NPC experiment confirmed the utility of PA gels that allowed the survival of NPCs over a 3-week period encapsulated (three-dimensionally) – there was no abnormal cell behavior arising from the use of PA gels versus the poly(D-lysine) control. Differentiation profiling revealed that NPC grown inside the soft, nanofibrous PA gel scaffolds produced an increased population of cells identifiable as neurons compared to laminin and poly(D-lysine) controls; the underlying mechanism, however, is not clear. Additional 2D experiments using self-assembled IKVAV-PA coatings on substrates showed that the 2D PA matrix system works equally well compared to the 3D system in promoting the differentiation of NPCs into neurons; these findings suggested that the degree of bioactive sequence IKVAV displayed on the nanofibrous matrices influenced NPC biology rather than the dimensionality of the prepared extracellular matrices. Back-of-the-envelope calculations (2D surface approximated) show that the density of bioactive epitope IKVAV in the self-assembled nanostructures ($\sim 10^{14}$–$10^{15}\,cm^{-2}$) far exceeds the numbers for naturally occurring laminin ($\sim 10^{11}$–$10^{12}\,cm^{-2}$) by more than 1000-fold. It was also noted that injection of IKVAV-PA gels in animals resulted in no detrimental effects on the host.

Niece *et al.*[116] expanded on the aforementioned work and prepared 7 PAs with distinct functional subdomains: (1) lipid tail, (2) β-sheet inducer, (3) spacer, and (4) bioactive peptide sequence were systematically varied (Figure 20). Nanofibrous gels presenting the IKVAV sequence (highlighted PA box) had the highest NPC viability and, in addition, substantially outperforming the other PAs in promoting neuronal differentiation. The gelation of PAs was modulated by controlling the hydrophobicity instilled into the midpeptide region (subdomains 2, 3) – comparing the kinetic and the turbidity data, the viscosity and the speed of PA gelation was PA1>PA2>PA3.

Tysseling-Mattiace and coworkers[117] utilized the monoalkylated C16-AAAA-GGG-E-IKVAV peptide amphiphile (IKVAV-PA) (Figure 21) to study its efficacy and regenerative potential in a murine spinal cord injury (SCI) model (see Chapter 6.630, Biomaterials for Spinal Cord Repair). The injected PA gels biodegraded *in vivo* in ~4 weeks. Injection of PA gels (0.5 wt %) and controls were monitored up to several months for hindlimb functional recovery; the IKVAV-PA gel-injected mice had the best behavioral recovery – significant enough to categorize as a functional improvement. Immunohistochemical and biochemical analyses revealed that astrogliosis (i.e., glial scarring at the SCI site) and programmed cell death (i.e., apoptosis of oligodendroglial cells after SCI) were both attenuated. In addition, it was found that IKVAV-PA nanofibers foster the regeneration of sensory and motor axons, a goal of high clinical relevance (see Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration).

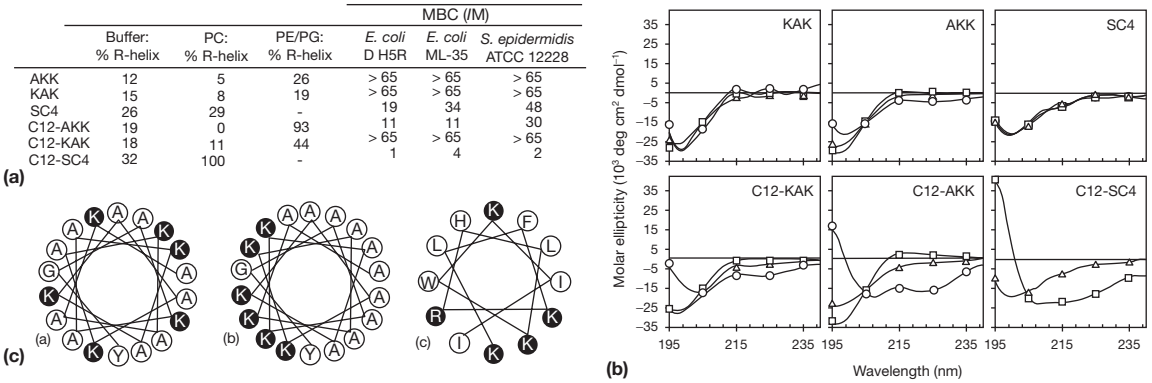

Figure 18 Physical and biological properties of AKK, KAK, SC4 peptides, and their respective peptide amphiphiles. (a) Helicity based on solvent/vesicle conditions and representative minimum bactericidal concentration (MBC) data based on different strains. More recently, Schaffer and coworkers[118] demonstrated that RGD-incorporating peptides could be readily prepared into 2D surfaces for stem cell tissue engineering. GGGNGEPRGDTYRAY (bsp-RGD(15)) and GRGDSP were lipidated and embedded into phospholipid bilayers at fixed mol%. Murine neural stem cells (NSCs) adhered to the RGD-functionalized surfaces and, for bsp-RGD(15) PA, the NSCs had a large fraction of single adherent cells, comparable to the laminin control (Figure 22). NSCs cultured on both 2D PA surfaces differentiated into both neurons and astrocytes.

4.415.6.3. Bone Marrow Mononuclear Cells

Webber *et al.* have demonstrated a dilution-based PA scaffolding approach by mixing bioactive C16-$V_3A_3K_3$RGDS with C16-$V_3A_3R_3$, C16-$V_3A_3K_3$, and C16-$V_3A_3E_3$ to determine the optimum ratio density of the bioactive PA[119] that promotes cell adhesion of bone marrow mononuclear cells (BMNCs) (Figure 23). This study reports that 10% (molar) doping of C16-$V_3A_3K_3$RGDS in C16-$V_3A_3E_3$ allows BMNCs to adhere effectively on fibrous PA structures *in vitro* (Figure 24) (see Chapter 4.411, Peptide- and Protein-Modified Surfaces). However, the degree of 2D surface adhesion that can be considered a dramatic increase was not observed, while the increase in proliferation of encapsulated BMNCs was 6 times more efficient compared to other controls.

4.415.6.4. Ameoblast Cell Engineering for Tooth Regeneration

Arg-Gly-Asp-incorporating PAs were self-assembled into nanofibers under physiological conditions at 1 wt% concentration;

ameoblast-like cells (LS8) and primary enamel organ epithelial (EOE) cells were grown inside the 3D PA matrix and injected into the enamel organ epithelia of murine embryonic incisors (*in vitro* organ culture model) **Chapter 6.619, Materials in Dental Implantology**. The peptide sequence is a branched RGD (BRGD-PA, **Figure 25**) and increased the cell proliferation and Ca^{2+} accumulation when cultured with LS8 cells and EOE cells. The microinjection of BRGD-PA into the enamel organ epithelia of incisors resulted in cell proliferation at the site of injection, with the eventual level of amelogenin and

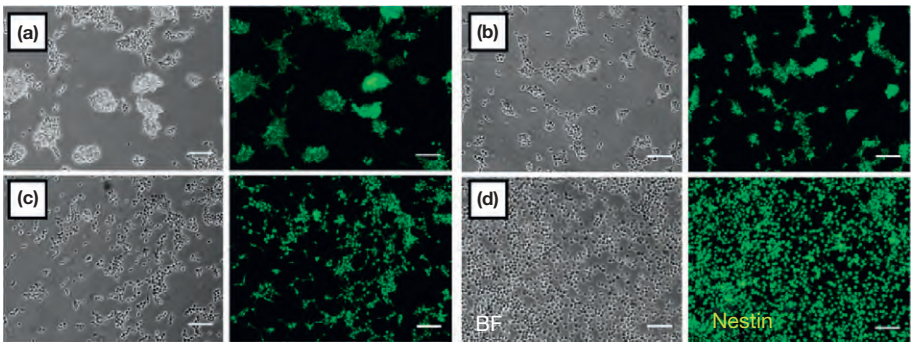

Figure 22 Bright field and immunofluorescence images of NSCs after 5 days. NSCs grown on (a) EggPC, (b) 40% GRGDSP PA, (c) 20% bsp-RGD(15) PA, and (d) Laminin treated surfaces. All NSCs expressed Nestin (green). Cells on EggPC and 40% GRGDSP PA surfaces formed loosely attached aggregates, whereas NSCs on laminin, and to a lesser extent, 20% bsp-RGD(15) PA, grew as monolayer adherent cells. Scale bar = 100 μm. Adapted from Ananthanarayanan, B.; Little, L.; Schaffer, D. V.; Healy, K. E.; Tirrell, M. *Biomaterials* **2010**, *31*, 8706–8715.

I. *Acta Biomater.* **2010**, *6*, 3–11.

ameloblastin protein expression (within the extracellular matrix) increasing, which is an indication that a population of cells is undergoing a differentiation process. In this study, multiple control PAs were utilized that consisted of D-amino acid RGD epitope and a rearranged terminal amino acid sequence (still displaying the same charge density) – the controls did not present significant positive responses via *in vitro* experiments.

4.415.6.5. Heparin-Binding PAs for Regenerative Medicine

Rajangam *et al.*[120] prepared two heparin-binding PAs (HBPAs) that self-assembled into bundles of nanofibers (Figure 26). The bioactivities of the PA gels were investigated using an *in vitro* angiogenesis assay using bovine pulmonary arterial endothelial cells sandwiched between two layers of either PA gel. The chemical structure of HBPA is C16-A_4G_3LRKKLGKA and the scrambled PA (SPA) is C16-A_4G_3LLGARKKK. Several different protein growth factors (GFs; i.e., angiogenic heparin binding growth factor, bFGF, VEGF) were supplemented to the PA–heparin gels prepared for *in vitro* assays. HBPA–heparin gel supplemented with GFs outperformed SBA-heparin gel's ability (with or w/o GFs) to form tubules in three dimensions with continuous lumens; this higher bioactivity of HBPA may be due to the stabilization of interactions among the exposed heparin-binding sequences (on the nanofiber matrix) and heparin via specific and nonelectrostatic interactions (Figure 27). *In vivo* angiogenesis studies conducted by Ghanaati *et al.* using HBPA confirmed the potential of HBPA–heparin sulfate nanostructures in vascularization and soft tissue regeneration.[121] Two rodent animal models were utilized that showed no harmful effects (i.e., inflammation, toxicity) arising from PA gel injections. These studies demonstrated that fibrous PA gels displaying bioactive subdomains on the nanofiber surface can potentially find usefulness in the area of wound healing and cell (transplantation) therapy.

4.415.6.6. Human Mesenchymal Stem Cell Engineering

PAs with photo-cross-linkable diacetylene units bearing a bioactive sequence RGD were utilized as silica surface-coating materials to influence human mesenchymal stem cell biology (Figure 28).[122] The studied PA is an extended version of the ones studied by Huang *et al.*[123] mentioned earlier. Peptide sequences KKLLA(K)-$(CH_2)_4$-NH_2 and RGDSKKLLA(K)-$(CH_2)_4$-NH_2 were linked to HOOC-C8-diacetylene-C12 monoalkyl chain. Soft lithography techniques were utilized to prepare nanofibrous PA (micron-sized) patterns that include channels and holes (see Chapter 4.413, Patterned Biointerfaces). The interesting observation noted in this particular study was that bioactive PA nanofibers that were aligned perpendicular to the micron-sized channels promoted hMSC attachment and subsequent alignment (nanofiber alignment:micron channel alignment = 35%:45%) to an identical degree (Figure 29). This example of surface bioactivity and architectural engineering

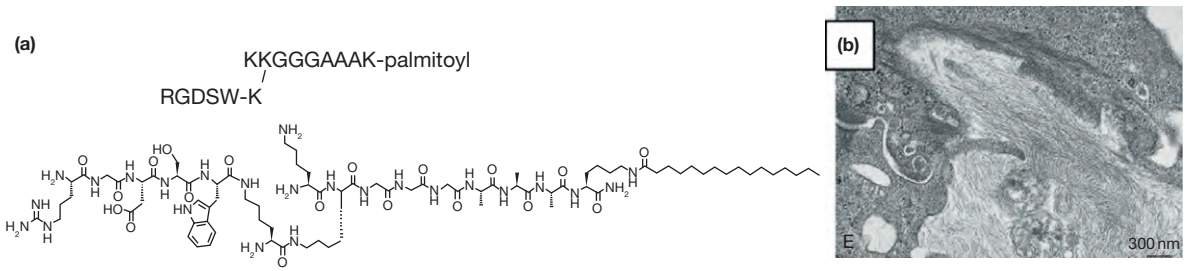

Figure 25 (a) Schematic chemical structure of the branched RGD peptide amphiphile (BRGD-PA). (b) TEM image of BRGD-PA injected incisor primordia 5 days after injection. The PAs assembled into nanofibers within the enamel organ epithelia, with cytoplasm extension into the nanofibers. Adapted from Huang, Z.; Sargeant, T. D.; Hulvat, J. F.; *et al*. *J. Bone Miner. Res*. **2008**, *23*, 1995–2006.

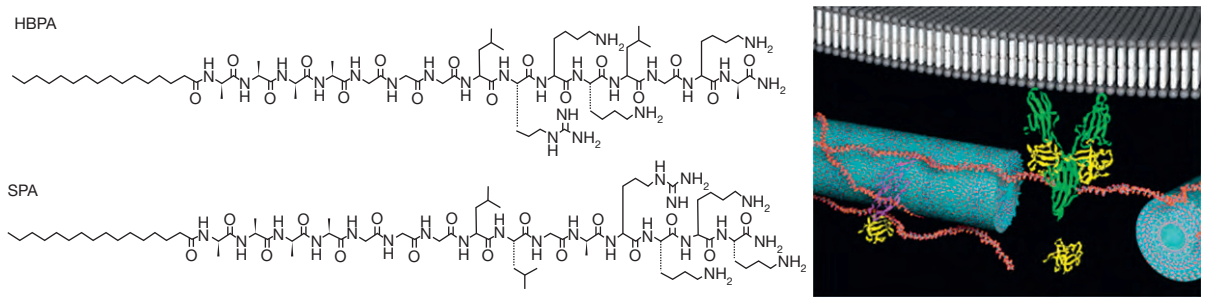

Figure 26 Molecular structures of heparin binding PAs and a schematic representation of heparin–nucleated HBPA nanofibers interacting with GF and receptors. The HBPA nanofibers (blue) are shown with adsorbed heparin chains on them (red). Heparin is known to bind and activate VEGF (purple), FGF-2 (yellow), and FGF receptor (green). The design proposes that the heparin–FGF-2–FGF receptor complex is further stabilized by their anchoring on HBPA nanofibers. For the control PA, it is possible that the absence of heparin stabilization by hydrophobic interactions and via the consensus format in the SPA nanofibers is responsible for the decreased bioactivity seen in SPA–heparin gels. Adapted from Rajangam, K.; Arnold, M. S.; Rocco, M. A.; Stupp, S. I. *Biomaterials* **2008**, *29*, 3298–3305.

via nanofibrous PAs may thus provide an excellent platform of biomaterials capable of influencing cytoskeleton organization and associated cell signaling pathways, leading to controlling key stem cell biology.

Jun and colleagues[124] subsequently reported five different C16-tailed PAs all incorporating (cell-mediated) proteolytically cleavable sequence GTAGLIGQ[125] which should prove useful in future cell encapsulation studies in a 3D nanofiber gel matrix (Figure 30); an additional 1–4-mer terminal head group dictated each PA's modular nature mediating and/or promoting integrin-receptor-based cellular responses by hMSCs. Among the PAs, C16-RGDS PA nanofibrous extracellular matrix (coating; 0.1 wt%) most successfully promoted hMSC adhesion and further osteogenic differentiation (i.e., mineral deposition). The same group further demonstrated that multiple different viscosity-controlled 3D PA gel matrices (1 wt%) (Figure 31) can be prepared via doping bioactive PAs into non-bioactive PAs (C16-GTAGLIGQS)[126] – an approach identical to the work done by Stupp and coworkers[119] to control the cell biology of BMNCs. The terminal 4–5-mer peptide sequences are derived from naturally occurring motifs associated with integrin-mediated binding architecture (RGDS), elastin (VAPG), collagen type I (DGEA), and laminin (YIGSR).

4.415.6.7. Dental Stem Cells

Galler *et al.*[127] prepared a single-tail C16-GTAGLIGQERGDS PA (Figure 32) to create a gel matrix (1 wt%) for dental stem cell (i.e., stem cells from human exfoliated deciduous teeth (SHED), dental pulp stem cells (DPSC)) engineering. Mineral deposition was observed for dental stem cells cultured with osteogenic supplements (i.e., beta-glycerophosphate (betaGP), dexamethasone (dex), KH_2PO_4 (KPh)) (Figure 33). As it turns out, the SHED-PA system showed promising tissue engineering results that suggest its potential application in soft dental tissue regeneration (i.e., dental pulp), whereas the DPSC-PA system may find utility in mineralized dental tissue engineering (i.e., bone, dentin) – mineral deposition tendency was far greater for DPSC than for SHED (see **Chapter 2.208, Artificial Extracellular Matrices to Functionalize Biomaterial Surfaces**).

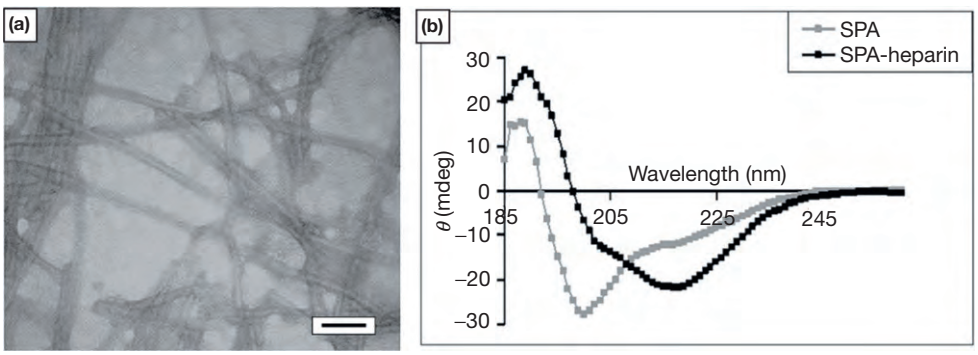

Figure 27 (a) TEM of SPA–heparin nanofibrous gel (stained) and (b) CD spectra showing predominant β-sheet formation for SPA in the presence of heparin (black) compared to predominantly helix formation without heparin (gray). The SPA–heparin spectra have been corrected for contribution by heparin alone. Adapted from Rajangam, K.; Arnold, M. S.; Rocco, M. A.; Stupp, S. I. *Biomaterials* **2008**, *29*, 3298–3305.

4.415.6.8. Bioactivation of Metallic Surfaces

Titanium-based metallic implants are popular choices for orthopedic, dental, and bone replacements possessing great biocompatibility and mechanical stability. Stupp and coworkers demonstrated that self-assembling bioactive PAs are suitable surface modifiers for Ti–6Al–4V metallic foams[128,129] and nickel–titanium (NiTi) shape memory metallic alloys (see **Chapter 2.201, Bio-inspired Silica Nanomaterials for Biomedical Applications**).[130] Branched PAs identical to those developed by Guler *et al.*[131,132] were utilized which contained the bioactive sequence RGD (**Figure 34**). NiTi metal sheets were first polished, cleaned, and silanized (using aminopropyltriethoxysilane (APTES)), then a 0.05 wt% PA solution was drop-cast onto the metallic surface. C16-A_3L_3K-ERGDS (BRGD-PA2), in particular, was used to achieve the bioactivation of nonbiologically responsive surfaces. Primary bovine pulmonary artery endothelial cells (CPAE) and mouse calvarial preosteoblastic cells (MC3T3-E1) were cultured on bioactivated metal surfaces to evaluate the efficacy of the surface engineering procedures. Proliferation assays indicated that MC3T3-E1 and CPAE cells grew best on TiNi surfaces silanized and then covalently modified with the branched PA (**Figure 35**).

4.415.7. Summary and Future Directions

Peptides amphiphiles are ideal molecular building blocks that self-assemble into hierarchical bioactive structures with controlled and defined physicochemical properties.[18,133] Two additional promising platforms of amphiphilic biomaterials involving bioactive moieties and nanosized structures described here can be used to explore biomedical applications[6] including regenerative medicine,[134] theranostics,[135] and drug delivery,[136,137] exploiting the stability of the final structures.

The utilization of *polymeric micelles* has been well investigated for multiple biomedical applications,[138–140] and here, we summarize a few recent excerpts. First, MacKay *et al.* formulated a recombinant production of ~62 kD polypeptide that self-assembles into spherical micelles consisting of a

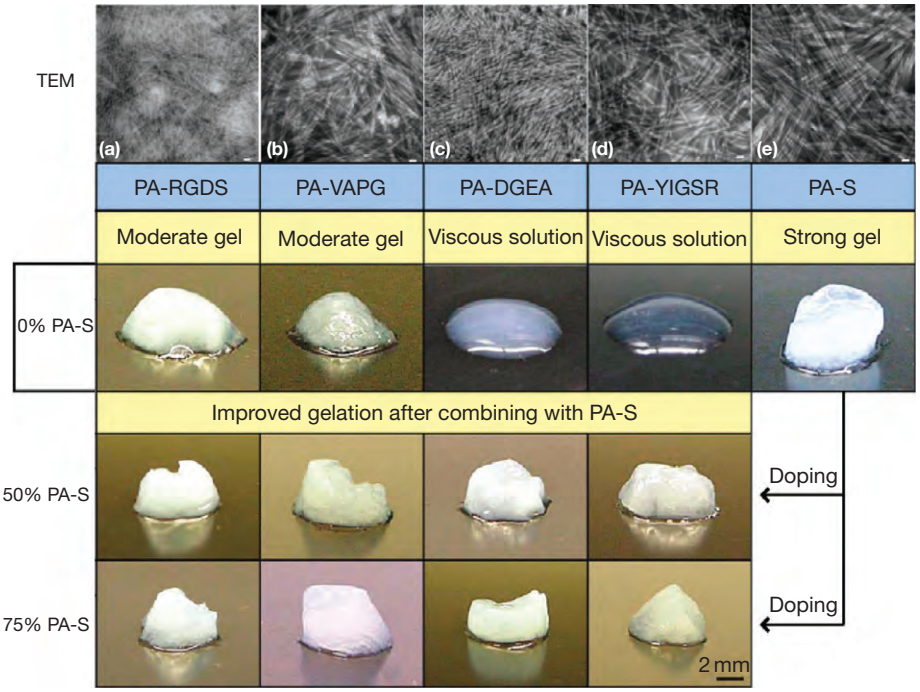

Figure 31 Macrophotographs of viscosity-controlled peptide amphiphile gels (hydrogels). Adapted from Anderson, J. M.; Andukuri, A.; Lim, D. J.; Jun, H. W. *ACS Nano* **2009**, *3*, 3447–3454.[126]

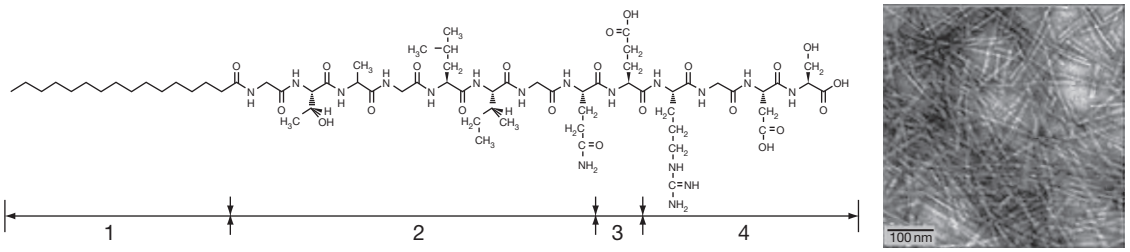

Figure 32 Chemical structure of C16-GTAGLIGQERGDS. The numbering refers to function: (1) hydrocarbon chain, (2) enzyme-cleavable site, (3) calcium binding, and (4) cell adhesion promoting sequence. A representative nanofibrous TEM is given. Adapted from Galler, K. M.; Cavender, A.; Yuwono, V.; *et al*. *Tissue Eng. A* **2008**, *14*, 2051–2058.

core–shell structure[141]; a hydrophobic core incorporating a hydrophobic drug (i.e., doxorubicin) covered with a hydrophilic corona shell made up predominantly of elastin-like protein sequence XGVPG (X = V,A,G) – herein, the PA will be referred to as CP-dox (chimeric polypeptide doxorubicin as coined by the original authors). The main feature of this particular system is that the self-assembled spherical micelles are sub-100 nm and the hydrophobic moiety can be any small molecule with aromatic groups. The second feature is that the attached therapeutic molecule was acid-labile which meant that the anticancer drug, doxorubicin, will release upon cellular uptake and endosomal or lysosomal processing (pH < 6). *In vivo* studies involving the treatment of malignant tumors with CP-dox revealed 96% tumor volume decrease compared to 50% decrease when only treated with doxorubicin. In addition, animal survival rate increased more than twofold when doxorubicin-only control increased 30%. This CP-dox also decreased the accumulation of doxorubicin in the animal's heart, important for overcoming any dose-limiting side effects that may result in cardiomyopathy. Second, Hubbell and coworkers,[142] more recently, developed a polymeric micelle system that incorporates carbon monoxide (CO)-releasing ruthenium (Ru) metal centers. The polymeric backbone comprises hydrophilic PEG, $Ru(CO)_3Cl$ instilled poly(ornithine acrylamide) and hydrophobic poly(*n*-butylacrylamide); it is a triblock copolymer system that self-assembles into 30–40 nm spherical micelles. The CO molecules release in a sustained manner *in vitro* after cysteine introduction (to 80% FBS cell medium) and effectively attenuated the LPS or Toll-like receptor ligand-induced NF-kB (proinflammatory transcription factor) activation of human acute monocytic leukemia cells, THP-1. Third, functional recovery after SCI was achieved via a diblock copolymer monomethoxy poly(ethylene glycol)-poly(D,L-lactic acid) self-assembled into 60 nm spherical micelles. The polymeric micelles, in this case, deterred the spreading of damage caused by the primary SCI process involving the neuronal cell membrane breakage and calcium influx. It is interesting to note that Stupp and coworkers reported the use

of a nanofibrous micellar matrix to promote functional recovery after SCI, as highlighted in **Section 4.415.6.2.**[117,143] It will be interesting to see how the SCI rescue process differs between the two micellar systems where one is spherical and the other fibrous. More up-to-date research involving polymeric micelles can be found in reviews by Bae and colleagues,[144] Bae and Kataoka,[145] Park and coworkers,[146] and Hennink and coworkers.[147]

The second platform involves *organic–inorganic nanocomposites* or *multifunctional nanoparticle systems* (MFNPS) (**Figure 9**).[15,148,149] In one example, Ruoslahti and coworkers[100,150] utilized inorganic oxide nanoparticles that were magnetic resonance imaging (MRI)-active and incorporating a targeting feature (i.e., CREKA) to home-in on tumor tissue. The core material is iron oxide, and the surface chemistry is such that different peptides and small molecules can be attached in a facile manner. Second, Labhasetwar and colleagues,[151] more recently, demonstrated image-guided drug therapy to treat xenograft breast tumors in mice utilizing iron oxide nanoparticles (10–25 nm magnetite particles) coated with oleic acid, Pluronic F127, and incorporating hydrophobic near-IR dye molecules (overall hydrodynamic diameter

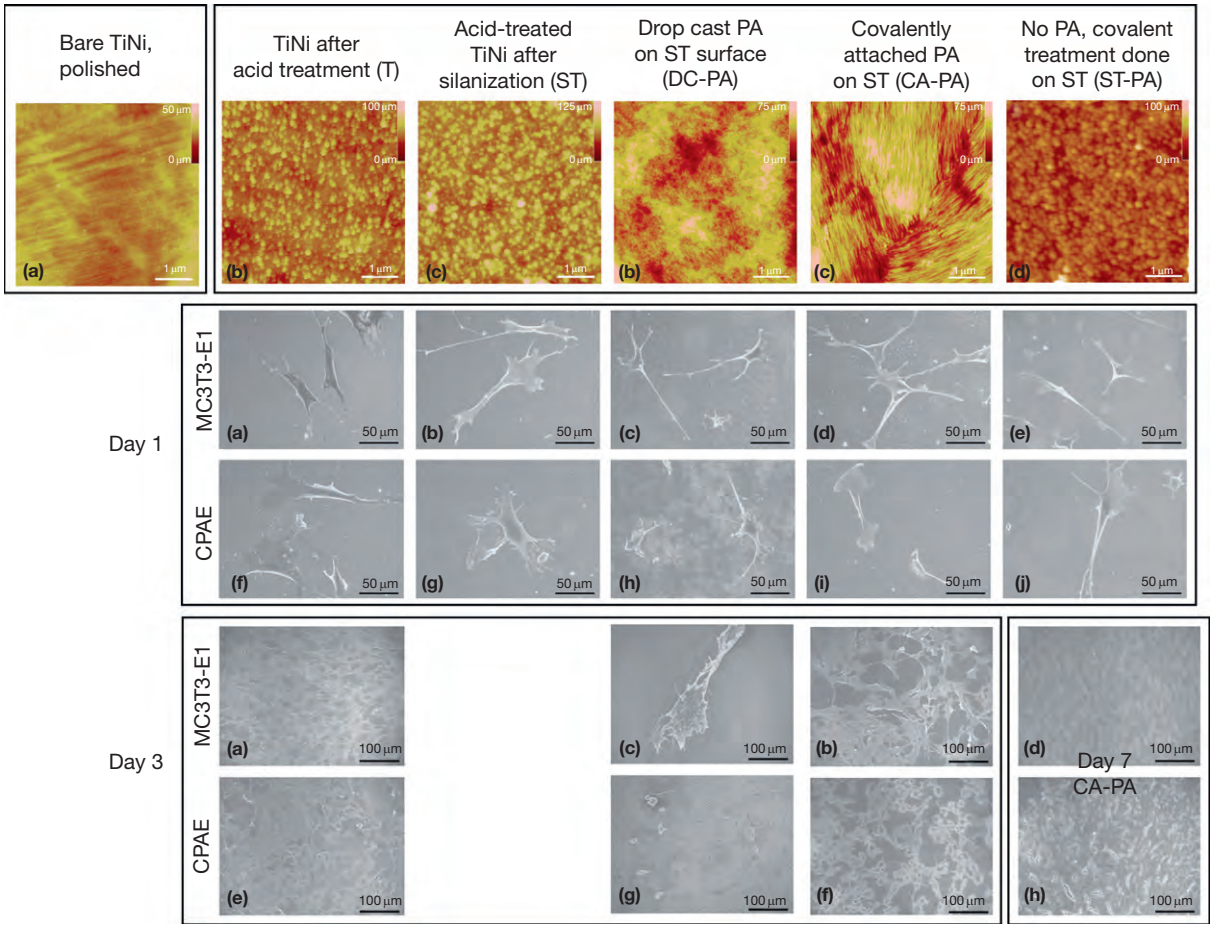

Figure 35 Atomic Force Microscopy analysis of TiNi surfaces with and without peptide amphiphiles (first row). D.; Rao, M. S.; Koh, C. Y.; Stupp, S. I. *Biomaterials* **2008**, *29*, 1085–1098.

determined via DLS was ~240 nm). *In vitro* toxicity testing using MCF7 breast cancer cells revealed no apparent toxicity from the prepared particle system. Inorganic species-incorporating nanomaterials will be useful for detecting small tumors in the body with high precision and sensitivity,[152–157] but the key obstacle will be the body's inability to process highly dense and essentially non-biodegrading inorganic structures[158–161] such as iron oxide, silicon dioxide, and titanium dioxide after prolonged accumulation. Biodistribution studies have shown nanoparticle accumulation in key organs such as the liver, spleen, and kidney[162–164] which can be long-term risk factors for patients. Of course, the patient-to-patient treatment response variations and dose-dependent-toxicity over multiple time domains will be difficult to extensively study on humans,[149] and so, it will be important and crucial to develop *in vitro* cell-based assessment models[163,165] with these particular platforms of biomaterials. Further examples of successful utilization of hard nanoparticles in biomedical applications are recently reviewed.[15,48]

The modulated stability of injectable self-assembled structures made up of amphiphilic constructs that include PAs and copolymers will be key for the development of new biomaterials for biomedical applications. Recently, Tirrell and coworkers[166] explored the internalization mechanism of PAs using an *in vitro* cancer cell model (i.e., SJSA-1). The particular PA consisted of a C16 tail and a peptide sequence derived from p53, a tumor suppressor protein (p5314-29, Pep; LSQETFSDLWKLLPEN). The results point to individual PA monomers (or unimers) being taken up by cells rather than the entire intact self-assembled spherical micelles (soft nanoparticles) being internalized, as often observed in solid inorganic (hard) nanoparticle endocytosis[46,48,161,167]; inorganic oxide nanoparticles, as mentioned earlier, are condensed solids (density of 2–5 g ml^{-1}),[168] and cellular organisms will not be able to process or degrade them using preexisting cellular machineries such as the lysosome or the lysozyme protein.[169–174] Aforementioned monomer dissociation/uptake mechanism will increase the instability of micelles introduced to the body, as multiple biological entities (i.e., proteins, ions, tissues, cells) undergoing dynamic changes are present *in vivo*. Park, Cheng, and colleagues[175] utilized an ~60-nm-sized block copolymer micelle system made from PEG-PDLLA (poly(ethylene glycol)-b-poly(D,L-lactic acid)) to demonstrate that the dynamic instability of polymeric micelles is important for the delivery of hydrophobic small molecules encapsulated inside the micelles to the cell cytosol via membrane-mediated

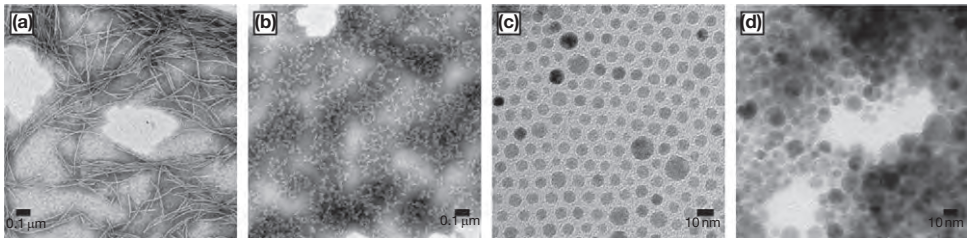

Figure 36 TEM images of C16-W3K-RGD and iron oxide nanoparticles. transportation. The challenge of self-assembled structure (i.e., micelles, vesicles) instability can be overcome by employing chemistry-based techniques such as cross-linking (via polymerization) of the hydrocarbon chains,[176,177] as demonstrated by Biesalski *et al.*,[178] or utilizing hard nanoparticles such as iron oxides and metallic particles that are magnetically susceptible[153,155,179–184] and surface-engineering the nanoparticles with bioactive functionalities. It will be important, however, to control the degree of polymerization, as extensive cross-linking or fixation will lead to the loss of self-assembling capabilities of PAs that may be crucial for bioactivity control (**Figure 36(a,b)**); moreover, the application-specific development of hybrid nanoparticles will be crucial as aggregations (**Figure 36(c,d)**), and oxidation of the core oxide nanoparticles may lead to decreased magnetic susceptibility and injectability for *in vivo* experiments.

The development of PA-based surface engineering of lipid bilayers, spherical micelles, and nanofibrous micelles has advanced in great quality and quantity in the past three decades, with continued increase in interest and work involving PAs (see **Chapter 5.531, Peripheral Nerve Regeneration** and **Chapter 5.532, Nerve Tissue Engineering**).[81,109,185–188] In particular, many research groups around the world developed multidisciplinary projects linked to translational medicine; regenerative medicine applications such as nerve/bone regeneration, wound healing, stem cell differentiation, and transplantation. In order for such practical applications to further advance the precise understanding of surface engineering principles, stability of assembled structures, biodistribution, and the cell–material interface created by peptide-based materials and living systems will be very important. Two key aspects of PAs' capabilities to control biological systems will be to control protein and nucleic acid function within and outside the cell[103,166,189–194] and to three-dimensionally mimic the naturally occurring extracellular matrices[7,11,73,115,118,195–197] – if these two functions are combined and well defined, then some of the undefined components pertaining to biomedical applications, such as stem cell tissue engineering and targeted drug delivery, can incorporate more quantitative subcomponents.

Acknowledgments

Glossary

Adhesion factors A class of membrane proteins comprising the outer surfaces of cell membranes in the developing nervous system that is thought to be intimately involved in guiding the development during embryonic life.

Autocrine A form of signaling in which a cell secretes a hormone or chemical messenger (called the autocrine agent) that binds to autocrine receptors *on the same cell*, leading to changes in the cell. This can be contrasted with paracrine signaling, intracrine signaling, or classical endocrine signaling.

Binding growth factor Juxtacrine mechanism of growth control and intercellular communication involving specific cell-to-cell contacts that are established by the interaction of membrane-bound forms of growth factors that are normally secreted with receptors on an adjacent cell and thus playing an important role in developmental processes that have spatial restrictions.

Down-regulation Densensitization. It means no response to further stimulation, rapid attenuation of receptor responsiveness due to agonist exposure, or weakening of the signal transmission under long lasting stimulation by hormones, neurotransmitters, or sensory signals. Modes of desensitization include ion channel regulation, ubiquitination, phosphorylation and dephosphorylation, endocytosis and recycling, GTP/GDP exchange, auto inhibition/feedback loop, or mRNA and protein synthesis regulation.

Endocrine A system of glands, each of which secretes a type of hormone into the bloodstream to regulate the body functions. It derives from the Greek words endo (Greek *ένδο*) meaning inside, within, and crinis (Greek *κρινής*) for secrete.

Extracellular matrix The extracellular part of animal tissue that usually provides structural support to the animal cells in addition to performing various other important functions. The extracellular matrix is the defining feature of connective tissue in animals.

Growth factor A naturally occurring substance capable of stimulating cellular growth, proliferation, and cellular differentiation. Usually it is a protein or a steroid hormone. Growth factors are important for regulating a variety of cellular processes. Growth factors typically act as signaling molecules between cells. Examples are cytokines and hormones that bind to specific receptors on the surface of their target cells. They often promote cell differentiation and maturation, which vary with growth factors.

Internalization Essentially three uptake mechanisms (phagocytosis, diffusion, and endocytosis) have been reported in the literature.

Intracrine A hormone that acts inside a cell. Steroid hormones act through intracellular (mostly nuclear) receptors and, thus, are considered to be intracrines. In contrast, peptide or protein hormones, in general, act as endocrines, autocrines, or paracrines by binding to their receptors present on the cell surface.

Juxtacrine A type of intercellular communication that is transmitted via oligosaccharide, lipid, or protein components of a cell membrane and may affect either the emitting cell or the immediately adjacent cells. It occurs between adjacent cells that possess broad patches of closely opposed plasma membrane linked by transmembrane channels known as connexons. Unlike other types of cell signaling (such as paracrine and endocrine), juxtacrine signaling requires physical contact between the two cells involved.

Matricrine Signal transduction of growth factors bound to extracellular matrix. Binding of the growth factors to ECM not only protects them from degradation but also concentrates the growth factors around the responding cells.

Multivalency Multivalency of ligand plays an important role in signal transduction. One unique determinant of effector function is the ability to dimerize or oligomerize receptors. Multivalent ligands can interact with the target receptors through multiple binding modes. The structure of a multivalent ligand determines the favored binding modes. In addition, after complex formation with receptors multivalent ligands prevent lateral diffusion of the activated receptors or complex in the plane of the cell membrane. This enhancement of clustering is considered to lead to a rapid and long-lasting effect.

Paracrine A form of cell signaling in which the target cell is near ('para' = near) the signal-releasing cell. Some signaling molecules degrade very quickly, limiting the scope of their effectiveness to the immediate surroundings.

RGD peptide The single letter code for arginine-glycine-aspartate. This tripeptide motif can be found in proteins of the extracellular matrix. Integrins link the intracellular cytoskeleton of cells with the extracellular matrix by recognizing this RGD motif. Without attachment to the extracellular matrix, cells normally undergo apoptosis ('anoikis'). Soluble RGD peptides induce apoptosis and might be used as drugs against angiogenesis, inflammation, and cancer mestastasis as small soluble peptides containing the RGD motif inhibit cell attachment and consequently induce apoptosis.

Signal transduction Signal transduction comes from the verb to 'transduce' meaning to 'lead across.' In biology, signal transduction is the process by which an extracellular signal molecule activates a membrane receptor that in turn alters intracellular molecules to create a response. Transmembrane receptors span the cell membrane, with part of the receptor outside and part inside the cell. The chemical signal binds to the outer portion of the receptor, changing its shape and conveying another signal inside the cell. Some chemical messengers, such as testosterone, can pass through the cell membrane, and bind directly to receptors in the cytoplasm or nucleus. Sometimes, there is a cascade of signals within the cell. With each step of the cascade, the signal can be amplified, so a small signal can result in a large response. Eventually, the signal creates a change in the cell, either in the expression of the DNA in the nucleus or in the activity of enzymes in the cytoplasm. These processes can take milliseconds (for ion flux), minutes (for protein- and lipid-mediated kinase cascades), hours, or days (for gene expression).

Abbreviations

α_2-PI	α_2-Plasmin inhibitor
aFGF	Acidic FGF
ALK	A peptide sequence ALKRQGRTLYGF
ALK1	Activin receptor-like kinase 1
ALP	Alkaline phosphotase
Ang1	Angiopoietin 1
AV	Arteriovenous
BDNF	Brain-derived neutrotrophin factor
bFGF	Basic FGF
BMHSCs	Bone marrow hematopoetic stem cells
BMP	Bone morphorgenic protein
BMSCs	Bone marrow-derived mesenchymal stem cells
BSA	Bovine serum albumin
BSP	Bone sialoprotein
C2C12	A typical pluripotent mesenchymal precursor cell line
cAMP	Cyclic adenosine monophosphate
CAMs	Cell adhesion molecules
CBD	Collagen-binding domain
CBF-1	C promoter binding factor
CCMBM	Collagen-containing mineralized bone-derived matrix
CD31	Cluster of differentiation 31
CD34	Cluster of differentiation 34
CD44	Cluster of differentiation 44
c-fos	A cellular proto-oncogene belonging to the immediate early gene family of transcription factors
CHO	Chinese hamster ovary
CMCS	Carboxymethyl chitosan
CMP	Collagen mimetic peptide
CNTF	Ciliary neutrophic factor
CSF-1	Colony stimulating factor 1
CT	Computed tomography

CTLL-2	A clone of cytotoxic T cells derived from a C57BL/6 mouse
CXCR3	$G\alpha_i$ protein-coupled receptor in the CXC chemokine receptor family
DBM	Demineralized bone matrix
DGR	A peptide sequence DGRGDSVAYG
DLL4	Delta-like protein 4
DM-GRASP	Dorsal funiculus, ventral midline immunoglobulin-like restricted axonal surface protein
DRG	Dorsal root ganglion
ECM	Extracellular matrix
ECs	Endothelial cells
EDC	Ethylcarbodiimide hydrochloride
EGF	Epidermal growth factor
EGFR	EGF receptor
ELISA	Enzyme-linked immunosorbent assay
Eph	Ephrin
Epo	Erythropoietin
ERK	Extracellular signal-regulated kinase
ES	Embryonic stem
F9	Embryonal carcinoma cell
FXIIIa	Coagulation factor XIII
FAK	Focal adhesion kinase
FBD	Fibrin-binding domain
FGF	Fibroblast growth factor
FGFR	FGF receptor
Flk-2/Flt-3	Fetal liver kinase-2/fetal liver ligand-3
FN	Fibronectin
FP6	Receptor chimeric protein
GDF	Growth differentiation factor
HA	Hydroxyapatite
HB-EGF	Heparin binding-epidermal growth factor
HC-DBM	Heparin-cross-linked DBM
HEK293	Human Embryonic Kidney 293
HEMA	2-Hydroxyethyl methacrylate
HER2	Human EGFR-related 2
HGF	Hepatocyte growth factor
HSCs	Hematopoietic stem cells
HUBECs	Human umbilical vein ECs
IFBMs	Interfacial biomaterials
IFN-γ	Interferon-γ
IgCAM	Immunoglobulin CAM
IGF-1	Insulin-like growth factor
IGFBP	IGF binding proteins
IgG Fc	Immunoglobulin fragment c
IL-2	Interleukin-1
IL-2R	IL-2 receptors
IL-1ra-ELP	Fusion protein of recombinant human IL-1 receptor antagonist and elastin-like peptide
IPN	Interpenetrating polymer network
JNK	c-jun N-terminal kinase
K1	Fibrin-binding peptide Kringle 1
KGF	Keratinocyte growth factor
LCST	Lower critical solution temperature
LIF	Lukemia inhibitory factor
LOCSs	Linear ordered collagen scaffolds
MAPK	Mitogen-activated protein kinase
MBP	Maltose-binding protein
MC3T3-E1	A well-studied osteoblast-like murine-derived cell line
MDCK	Madin-Darby canine kidney
MEF	Mouse embryonic fibroblast
MG-63	Human osteosarcoma cell line
MSCs	Mesenchymal stem cells
mShh	N-terminal Shh
NCAM	Neural CAM
NCD	Nanocrystaline diamond
NGF	Nerve growth factor
NHS	N-hydroxysuccimide
NIH3T3	NIH Swiss mouse embryonic fibroblast cell line. The name 3T3 is from(3 days, transfer, inoculum 3×10^5 cells/50 mm dish)
NMuMG	Mammary gland cell
NSPCs	Neural stem/progenitor cells
NT	Neurotrophin
OCT-1	Osteoblast cell derived from osteocalcin promoter-driven SV-40 T-antigen transgenic mouse calvarias
OP9	A stromal cell line
OPDs	Osteopromotive domains
OPN	Osteopontin
P19	Embryonal carcinoma cell
PC12	A cell line derived from a pheochromocytoma of the rat adrenal medulla
PCL	Poly(ε-caprolactone)
pDCs	Plasmacytoid dendric cells
PDGF	Platelet derived growth factor
PDL	Periodontal ligament
PEG	Polyethylene glycol
PEGDA	Poly(ethylene glycol) diacrylate
PEG-TGF-β2	PEG-attached TGF-β2
PET	Polyethylene terephthalate
PHSRN	A peptide sequence
PLGA	Poly(lactide-*co*-glycolide)
PLA	Polylactide
PPDAs	OPD peptide-amphiphiles
PPy	Polypyrole
PRG	A peptide sequence PRGDSGYRGDS
PSCs	Pancreatic stem cells
PTH(1–34)	Parathyroid hormone (1–34)
Rac 1	Ras-related C3 botulinum toxin substrate 1
RGD	Arginine-glycine-aspartic acid
rhBMP3-C	Recombinant human BMP3 fusion protein
RT-PCR	Reverse transcription-polymerase chain reaction
SAM	Self-assembled monolayer
SCF	Stem cell factor
SCI	Spinal cord injury
SCID	Severe combined immunodeficient
SEM	Scanning electron microscopy
Shh	Sonic hedgehog
SMC	Smooth muscle cell
SPR	Surface plasmon resonance
SRCs	SCID repopulating cells

SRK	A proto-oncogenic tyrosine kinase
STO	A mouse fibroblast cell line (S, SIM; T, 6-thioguanine resistant; O, ouabain resistant)
TGF-β	Transforming growth factor-β
TGFβRII	TGF-β type II receptor
TG-pI-BMP-2	Fusion protein of N-terminal transglutaminase substrate (TG) domain, plasmin substrate (pI) domain, and BMP-2
Ti6Al4V	An α/β titanium base alloy
TKKTLRT	A peptide sequence
TNF-α	Tumor necrosis factor-α
TrkA	A protein that in humans is encoded by the *NTRK1* gene
UT-7/Epo	UT-7 is a cell line established from the bone marrow of a patient with acute megakaryoblastic leukemia. UT-7/Epo is a subline of UT-7 cells established from UT-7 cells maintained for more than six months in the presence of Epo
VCAM	Vascular CAM
VEGF	Vascular endothelial growth factor
vWF	von Willebrand factor
XTT	2,3-bis(2-methoxy-4-nitro-5-sulfony)-2H-tetrazoline-5-carboxanilide

4.416.1. Introduction

Engineering of cellular environments is a valuable tool for guiding cellular activities such as differentiation, spreading, motility, proliferation, or apoptosis, all of which together regulate tissue development in a complex manner. In the field of biomaterials research, the rational control of these cell functions is very important. These functions of cells are considered to be generally regulated by three types of interactions as shown in Figure 1. They are the interactions between cell and extracellular matrix (ECM), between cell and cell (e.g., cadherin), and between cell and soluble biosignals (e.g., cytokines and growth factors). Considering the role of proteins in these interactions, the surface immobilization of proteins is important for the rational engineering of bioactive materials with cells.

Here, various proteins used for surface immobilization to regulate cell functions on biomaterials are reviewed, and various approaches for material designs using immobilization of proteins for regulation of cell functions are discussed.

4.416.2. Proteins for Surface Immobilization

4.416.2.1. Cell Adhesion

Cell adhesion is mediated by cell adhesion molecules (CAMs) located on the cell surface and they are involved in the binding with ECM or with other cells.[1] These proteins are typically transmembrane receptors and are composed of three domains: an intracellular domain that interacts with the internal skeleton, a transmembrane spanning section, and an extracellular domain that interacts either with CAMs of the same kind (homophilic) or with other CAMs or the ECM (heterophilic binding). CAMs account for cell-to-cell or cell-to-ECM interactions and are divided into four major groups: the integrins, the cadherins, the selectins, and the members of the immunoglobulin superfamily as shown in Table 1. These molecules are of paramount importance in the establishment of normal tissue structure and function and participate in a variety of physiological processes such as morphogenesis, embryogenesis, organogenesis, immunological function, wound healing, and inflammation.

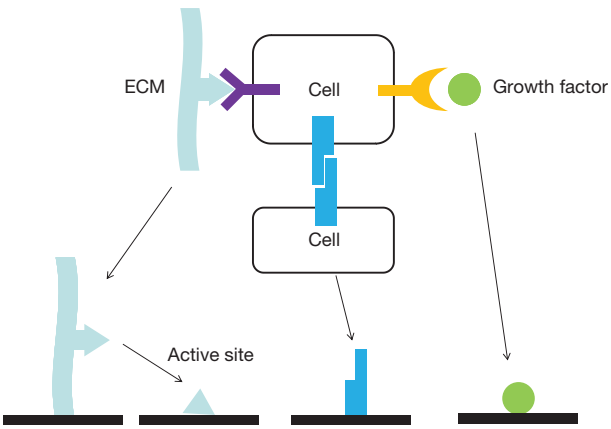

Figure 1 (Top) three types of interactions (cell–ECM, cell–cell, and cell-growth factor) of cells and (bottom) applications for biomaterials.

4.416.2.1.1. ECM–cell interactions

ECM is primarily composed of a complex meshwork of fibrous protein surrounded by space-filling molecules such as glycosaminoglycans as well as mineral deposits in hard tissues such as bone. Many of these components are secreted by resident cells and primarily provide support and anchorage and they also play important roles as tissues boundaries and in the modulation of intracellular and intercellular communication.[2] Moreover, the ECM is not only made but also organized and remodeled by the cells within it. Formation and remodeling of this ECM network is vital for tissue responses such as cell

Table 1 Primary families of cell adhesion molecules (CAMs)

CAMs	*Members*	*Interactions*
Integrins	Heterodimers of α- and β-subunits	Cell-to-ECM and cell-to-cell
Cadherins	Classic: N-, P-, E-, R-, B-cadherin Nonclassic: desmosomal, protocadherins	Homophilic cell-to-cell
Selectins	L-, E-, P-selectin	Heterophilic cell-to-cell
IgCAM superfamily	NCAM, VCAM, ICAM, Mad CAM, PECAM, CD146, CD2, CEA	Homophilic and heterophilic cell-to-cell

migration during tissue formation and repair, growth, wound healing, and fibrotic responses. Cell–matrix interactions can directly modulate cell morphology, survival, proliferation, and differentiation in multiple cell systems. Many of the fibrous proteins that make up the ECM, including collagen, fibronectin (FN), elastin, tenascin, and laminin, have both structural and adhesive functions and are secreted in specific tissues by specialized cells, including fibroblasts (present in most connective tissues), chondroblasts (cartilage), and osteoblasts (bone).

The collagens are the most abundant proteins in mammals, constituting about 25% of the total protein mass. They contribute significantly to the integrity and mechanical properties of tissues such as bone, skin, cartilage, and tendon.[3–5] So far, about 25 distinct collagen α-chains have been identified, each encoded by a separate gene. Different combinations of these genes are expressed in different tissues. Although in principle more than 10 000 types of triple-stranded collagen molecules could be assembled from various combinations of the 25 or so α-chains, only about 20 types of collagen molecules have been found. The main types of collagen found in connective tissues are types I, II, III, V, and XI, type I being the principal collagen of skin and bone and by far the most common. These are the fibrillar collagens, or fibril-forming collagens, with the rope-like structure. After being secreted into the extracellular space, these collagen molecules assemble into higher order polymers called collagen fibrils, which are thin structures (10–300 nm in diameter), many hundreds of micrometers long in mature tissues and clearly visible in electron micrographs. Collagen fibrils often aggregate into larger, cable-like bundles, several micrometers in diameter, which can be seen under the light microscope as collagen fibers.

FN is a complex, multifunctional protein with multiple domains, each with specific binding sites for other matrix macromolecules and for receptors on the surface of cells. FN therefore contributes to both organizing the matrix and helping cells attach to it.[6,7] Among the ECM proteins, FNs as a family of structurally related soluble and matrix glycoproteins have been extensively studied in numerous biological processes including cell adhesion, wound healing, and organogenesis. Following tissue injury, fibroblasts invade the fibrin clot in the wound space where they are activated. This activation to accelerate the wound healing process appears to initiate a switch of the fibroblast cell surface receptors from binding type I collagen to those that bind provisional matrix proteins such as fibrin and FN. Cells producing a sufficient amount of FN can spread on material surfaces in a serum-free medium, whereas cells that do not secrete adequate levels of FN cannot spread even with added FN in the medium. This is one of the many examples showing the important role of FN in mediating the interaction between cells and biomaterials surface.

Elastin is the dominant ECM protein in elastic fibers, a major component of arteries, lungs, and skin.[8,9] Laminin is the major noncollagenous component of the basal lamina, playing a critical role as the 'glue' that holds many body structures together. Osteopontin (OPN) is a soluble protein found in all body fluids; it stimulates signal transduction pathways (via integrins and CD44 variants) similar to those stimulated by components of the ECM. This appears to promote the survival of cells exposed to potentially lethal insults such as ischemia/reperfusion or physical/chemical trauma. OPN is chemotactic for many cell types including macrophages, dendritic cells, and T cells; it enhances B lymphocyte immunoglobulin production and proliferation. In inflammatory situations, it stimulates both pro- and anti-inflammatory processes, which on balance can be either beneficial or harmful depending on what other inputs the cell receives.

Most of these structural proteins also play fundamental roles in promoting cell adhesion and mediating intracellular signals critical to tissue function. In particular, cell adhesion to the ECM is essential for controlling such complex biological processes as embryonic development, wound healing, immune responses, and tissue organization and repair. For example, cell-adhesive interactions with specific ECM proteins regulate bone cell survival, cell cycle progression, differentiation, and matrix formation; at the tissue level, these interactions can play crucial roles in bone remodeling, maintenance, and formation. Moreover, ECM-mediated cell adhesion plays critical roles in animal development, as evidenced by the embryonic lethality of mice that have genetic deletions for particular ECM ligands and receptors. Proteins such as FN are important in guiding cell movements during organism development, including migration of mesodermal cells at different embryonic stages. These ECM components regulate cell behavior by interacting with cell surface receptors to activate particular intracellular signaling pathways, resulting in tissue-specific alterations in cell spreading, migration, cell–cell communication, and differentiation. Hynes[10] reviewed many effects beyond providing structural support.

Although there are many types of cell receptors that facilitate cell–ECM interactions, cells recognize and adhere to ECM ligands primarily via integrins, a widely expressed class of cell surface receptors. Integrins are transmembrane, heterodimeric proteins consisting of a particular combination of two noncovalently associated subunits (α and β), of which 24 specific combinations have been currently identified in humans.[11,12] Integrins interact with the ECM through their extracellular domains, and are linked to cytoskeletal elements and signaling molecules through their intracellular domains, functioning primarily as a bridge between the ECM environment and the cell. Different α and β subunit combinations have the capacity to bind to one or more ECM ligands, whereas many ECM proteins can act as ligands for more than one integrin. For example, FN is a ligand of $\alpha_5\beta_1$, laminin, $\alpha_6\beta_1$, $\alpha_7\beta_1$, $\alpha_6\beta_4$, fibrinogen, and $\alpha_2\beta_3$. Moreover, a wide array of integrins can be expressed, typically in tissue- and development-specific patterns. For example, osteoblasts and osteoprogenitor cells express multiple integrins, including $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_4\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_8\beta_1$, $\alpha_v\beta_3$, and $\alpha_v\beta_5$, that can vary in degree of expression with the stage of the osteoblast and bind to numerous ECM components.

4.416.2.1.2. Cell–cell interactions

4.416.2.1.2.1. Cadherins

Cadherins are integral transmembrane single-chain glycoproteins that mediate intercellular cell–cell adhesion thorough homotypic interactions (between molecules of the same types, that is, neural cell adhesion molecule (NCAM) to NCAM in the presence of extracellular Ca^{2+}). The first three cadherins discovered were named according to the main tissues in which they were found: E (epithelial)-cadherin is present on many types of epithelial cells; N (neural)-cadherin on

nerve, muscle, and lens cells; and P (placental)-cadherin on cells in the placenta and epidermis. More than 300 different cadherins have been reported.[13] All are also found in various other tissues; N-cadherin, for example, is expressed in fibroblasts, and E-cadherin is expressed in parts of the brain. These and other classical cadherins are related in sequence throughout their extracellular and intracellular domains. There are also a large number of nonclassical cadherins, with more than 50 expressed in the brain alone. The nonclassical cadherins include proteins with known adhesive function, such as the desmosomal cadherins discussed earlier and the diverse protocadherins found in the brain. The classical and nonclassical cadherin proteins constitute the cadherin superfamily. Tissue-specific expression of cadherin molecules is required for cell sorting and recognition during embryogenesis and for preserving tissue architecture.

4.416.2.1.2.2. Selectins

Selectins are a family of transmembrane proteins containing an amino-terminal lectin domain for binding to ligands, an epidermal growth factor (EGF)-like domain, 2–9 regulatory protein repeats, a transmembrane domain, and a short cytoplasmic tail. This class of CAMs consists of three proteins, namely, E (endothelial)-, L (leukocyte)-, and P (platelet)-selectin, which mediate the adhesion between endothelial cells (ECs), leukocytes, and platelets. Selectins have received considerable attention because of their importance in inflammatory and immune trafficking as well as their role in diseases such as atherosclerosis and cancer metastasis.[14]

4.416.2.1.2.3. Immunoglobulin superfamily

Immunoglobulin CAMs (IgCAMs) are a large group of cell surface glycoproteins, which contain an immunoglobulin-like extracellular domain. Several members of this family have been implicated in malignancies, such as NCAM, vascular CAM (VCAM), intracellular CAM, platelet-endothelial CAM, mucosal addressin CAM, and carcinoembryonic antigen. These molecules are capable of both homotypic and heterotypic (between different types of molecules, i.e., VCAM to $\alpha_4\beta_1$ integrin) adhesions. IgCAMs play multiple roles in many biological processes, including nervous system development and immune response. In some cases, their expression is induced by cytokines, such as tumor necrosis factor α (TNF-α), interleukin-1 (IL-1), and interferon-γ (IFN-γ) and this suggests a link between inflammation and tumorigenesis.

4.416.2.1.2.4. Others

In addition to cadherin, selectins, and immunoglobulin superfamily, other cell–cell interactions include Notch signaling and sonic hedgehog (Shh) as components for stem cell niches.

4.416.2.1.2.5. Notch

Notch proteins are involved in cell–cell signaling pathways essential during embryonic development and in adult self-renewal systems. The molecules involved in the Notch pathway are highly conserved across species and are vital in developmental cell fate decisions such as neural development, epithelial-to-mesenchymal transitions, vascular development, keratinocyte differentiation, as well as hematopoietic and T cell differentiation.[15] The Notch receptor is a single-pass transmembrane protein that is a heterodimer of two subunits. The first subunit consists of a large extracellular segment with EGF repeats – a common repeat found in growth factors and ECM proteins. The second subunit consists of a short extracellular domain, a transmembrane domain, and an intracellular domain.

4.416.2.1.2.6. Sonic hedgehog

Shh signaling is a well-known cell-signaling pathway conserved in many mammals. Shh is one of the best-studied ligands that regulate proliferation and differentiation in many cell types.[15] Shh, upon binding to the Patched-1 receptor, initiates a cascade of molecular signaling involving other molecules. The cascade regulates the receptor transcription and also transcriptional effectors of the Gli family.

4.416.2.1.3. Cell adhesion peptides

Active regions in signal proteins, ECMs and CAMs, or peptides that essentially interact with integrins are known. They are listed in **Table 2**.[35,36]

Most integrins recognize specific binding sites, typically small peptide sequences motifs, such as the ubiquitous arginine–glycine–aspartic acid (RGD) motif present in a variety of ECM proteins.[37–39] Integrin binding to ligands is a dynamic and highly regulated process that requires 'activation' of the integrin and mechanical coupling to the ligand. This activation changes the conformation of the extracellular proteins of the receptor into a more 'high-affinity' structural orientation for ligand binding, although divalent metal ions are also typically needed for functional binding. After integrin–ligand binding, integrins associate with the actin cytoskeleton and begin to aggregate together in clusters forming focal adhesions, distinct structures that form intracellular scaffolds of structural and signaling molecules. Focal adhesion mediates stable adhesion by providing structural links between ECM and cell

Table 2 Peptide sequences concerned with integrin-mediated cell adhesion

Peptide	*Protein*	*Integrin*	*References*
RGD	Collagen, fibronectin, vitronectin, PECAM (IgG superfamily), fibrinogen	$\alpha_1\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_6$, $\alpha_{IIb}\beta_3$, $\alpha_3\beta_1$, $\alpha_5\beta_1$	16,17
KQAGDV	Fibrinogen	$\alpha_{IIb}\beta_3$	18,19
RYD		$\alpha_{IIb}\beta_3$	20
KGD		$\alpha_{IIb}\beta_3$	21
RHD	Amyloid peptide	$\alpha_5\beta_1$	22,23
NGR		RGD-directed integrin	24
(S)DGR		RGD-directed integrin	24,25
LDV	Fibronectin	$\alpha_4\beta_1$, $\alpha_4\beta_7$	26–28
DGEA	Collagen I	$\alpha_2\beta_1$	29
YGYYGDALR	Laminin	$\alpha_2\beta_1$	30
FYFDLR	Type IV collagen	$\alpha_2\beta_1$	30
KRLDGS	Fibrinogen	$\alpha_M\beta_2$ (CD11b/CD18)	31
R and D	Type I collagen	$\alpha_1\beta_1$	32
L/IET	ICAMs	β_2	33,34

skeleton to regulate force-associated cell functions such as adhesion, spreading, morphology, and migration. These adhesive structures also activate discrete signaling pathways (mitogen-activated protein kinase (MAPK), c-jun N-terminal kinase (JNK), extracellular signal-regulated kinase (ERK) through accumulation and activation of signaling mediators, such as focal adhesion kinase (FAK) and sarcoma (Src) that can ultimately regulate transcriptional factor activity and direct major cell functions such as migration, proliferation, and differentiation. For example, $\alpha_2\beta_1$-mediated cell attachment to type I collagen stimulates the tyrosine phosphorylation of FAK and, subsequently, the activation of ERK, an MAPK implicated in the control of osteoblast-specific gene expression and matrix mineralization.

On the other hand, many synthetic peptides, especially RGD-containing peptide, have been prepared. Potential to develop RGD-based therapeutics that function either as agonists to promote the interaction of cells and tissues with artificial matrices or as antagonists to control the nature of cell–cell and cell–ECM interactions exists.[40] Many types of linear and cyclic RGD peptides have been developed and also peptidemimetics are chemically investigated.[41]

4.416.2.2. Cell Growth

There are two general types of cells: anchorage-dependent and anchorage-independent. In the case of the former, the cell destiny is determined after adhesion to ECM. In the case of the latter, the density is not dependent on cell adhesion. However, the growth, differentiation, apoptosis, transformation, etc. of both types of cells are regulated by soluble growth factors or cytokines. Advances in developmental molecular and cell biology, biochemistry, and medicine have identified various chemical compounds such as growth factors, cytokines, and chemokines that are produced by cells; these agents act as biosignals in their respective microenvironments, provide essential cues, and regulate crucial events that are necessary for tissue development, repair, and regeneration at the cellular and molecular levels. Such contributions elucidate the fundamental aspects of biology and physiology in both health and disease; research in relevant fields is continuing and breakthrough developments are forthcoming.

4.416.2.2.1. Mechanisms

Development and homeostasis of tissues and organs depend on a fascinating, but complex, interplay and function of their constituent cells with their microenvironment. It is known that there are many types of growth factors, for example, insulin, EGF, nerve growth factor (NGF), bone morphogenic protein (BMP), vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), insulin-like growth factor 1 (IGF-1), transforming growth factor β1 (TGF-β1), hepatocyte growth factor (HGF), and platelet-derived growth factor (PDGF). The action mechanisms of growth factors are summarized as shown in Figure 2. Diffusible interactions, such as endocrine, paracrine, autocrine, and intracrine, and nondiffusible interactions such as juxtacrine and matricrine are generally known.[42–44] It is also known that each growth factor does not have just one mechanism but multiple mechanisms to act upon cells.

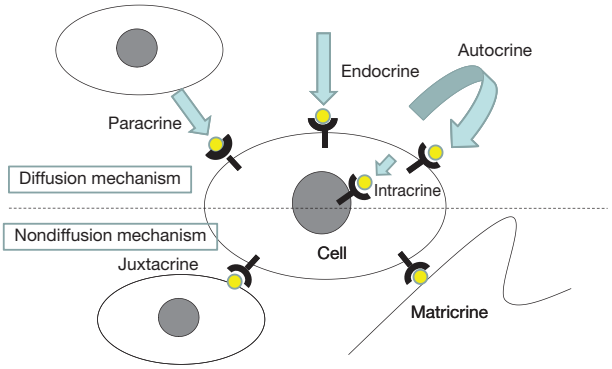

Figure 2 Various action mechanisms of growth factors.

4.416.2.2.2. Growth factors for immobilization on surfaces

Growth factors can be immobilized on solid surfaces for medical applications using different techniques.

4.416.2.2.2.1. Insulin

Insulin is a peptide hormone composed of 51 amino acids and has a molecular weight of 5808 Da. It is produced in the islets of Langerhans in the pancreas. The action of insulin on the human metabolism level includes control of cellular intake of certain substances, most prominently glucose in muscle and adipose tissue (involving about two-thirds of body cells), increase of DNA replication and protein synthesis via control of amino acid uptake, and modification of the activity of numerous enzymes. Many types of nonserum cell culture media include insulin as a supplement.

4.416.2.2.2.2. Insulin growth factor 1

IGFs have high sequence similarity to insulin and are part of a complex system that cells use to communicate with their physiologic environment. The complex system consists of two cell-surface receptors (IGFR1 and IGF2R), two ligands (IGF-1 and IGF-2), a family of six high-affinity IGF binding proteins (IGFBP 1–6), as well as associated IGFBP-degrading enzymes, collectively referred to as proteases. IGF-1 is important for both the regulation of normal physiology and a number of pathological states, including cancer. IGF has been shown to play roles in the promotion of cell proliferation and the inhibition of cell death (apoptosis). IGF-2 is thought to be a primary growth factor required for early development while IGF-1 expression is required for achieving maximal growth. While IGF-2 may be primarily fetal in action, it is also essential for development and function of organs such as the brain, liver, and kidney.

4.416.2.2.2.3. Epidermal growth factor

EGF, a peptide composed of 53 amino acids with a molecular weight of 6045 Da, promotes cellular proliferation, differentiation, and survival. EGF was first purified from the mouse submandibular gland, but since then has been found in many human tissues including submandibular gland and parotid gland. Salivary EGF, which seems also regulated by dietary inorganic iodine, also plays an important physiological role in the maintenance of oroesophageal and gastric tissue

integrity. The biological effects of salivary EGF include healing of oral and gastroesophageal ulcers, inhibition of gastric acid secretion, stimulation of DNA synthesis, as well as mucosal protection from intraluminal injurious factors such as gastric acid, bile acids, pepsin, and trypsin and protection to physical, chemical, and bacterial agents. EGF acts by binding to the EGF receptor (EGFR) on the cell surface and stimulating the intrinsic protein–tyrosine kinase activity of the receptor. The tyrosine kinase activity, in turn, initiates a signal transduction cascade that results in a variety of biochemical changes within the cell – a rise in intracellular calcium levels, increased glycolysis and protein synthesis, and increases in the expression of certain genes including the gene for EGFR – that ultimately lead to DNA synthesis and cell proliferation.

4.416.2.2.2.4. Nerve growth factor

NGF was discovered more than 50 years ago and is one of the neutrophic factors important for neuron survival and neurite growth. NGF 7S is a 130 kDa protein composed of five noncovalently linked subunits (2α, 1β, 2γ). From proteolytic fragmentation studies, the β-subunit is understood to be responsible for the neutrophic activity in the NGF 7S.[45] Studies showed that NGF plays a critical role in nerve injury repair.[46] It is also a factor with chemotactic effects on nerve growth cones. When presented with a concentration gradient of NGF, growth cones guide growing axons to their proper innervating target. In a proof-of-concept study, a well-defined linear concentration gradient of soluble NGF of at least 133 ng (ml mm)$^{-1}$ was required to guide neurites of PC12 cells and/or dorsal root ganglion (DRG) neurons up to 7.5 mm toward the higher end of the concentration gradient.[47] Other members of the neurotrophin (NT) family that are well recognized include brain-derived neurotrophic factor (BDNF), NT-3, and NT-4/5.

4.416.2.2.2.5. Bone morphogenic protein

BMPs consisting of more than 20 isoforms are members of the TGF superfamily. BMPs are powerful stimulators of bone formation and effectors of mesenchymal cell differentiation into bone cells. BMPs are primarily secreted by osteoblasts. There are two types of BMP receptors in cell membranes, both of which are serine–threonine kinases. BMP binding to the type II receptor leads to dimerization of that receptor with a type I receptor and phosphorylation of the type I receptor, which then activates downstream signaling.[48] BMP-2, BMP-4, BMP-6, BMP-7, BMP-9, and BMP-13 growth differentiation factor-6 (GDF-6) are the most important BMPs in promoting the differentiation of pluripotent mesenchymal cells into osteoblasts and lead to increased bone formation. Both *in vitro* and *in vivo*, BMPs promote the fusion of mononuclear hematopoietic cells of the macrophage–granulocyte lineage; this process results in osteoblast formation and activation, leading to increased bone turnover and remodeling in the late stages of bone repair and development.

4.416.2.2.2.6. Vascular endothelial growth factor

VEGF, the most widely studied stimulator of EC migration, proliferation, and differentiation, plays a role in nearly every phase of vascular tissue development and maintenance. The VEGF family (a subset of the PDGF superfamily) includes VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor, and VEGF is the primary regulator of vasculogenesis and angiogenesis. The effect of VEGF is conveyed by its interaction with pertinent receptors on the cell membrane. There are two important VEGF receptors expressed on ECs, VEGF-1 (Flk-1) and VEGF-2 (Flk-2).

VEGF is involved in the organization of primitive blood vessel development, guidance of capillary extension, proliferation of ECs, recruitment and commitment of EC precursors, wound healing, and maintenance of healthy blood vessels. Because VEGF critically affects almost every stage of vascular tissue development, repair, and expansion, it is the most important candidate among growth factors for the development of vascular tissue and of vascularized, engineered constructs of other tissues and organs. VEGF alone, even in high doses, is unlikely to lead to functional blood vessel formation: VEGF must be used in conjunction with other important factors.

4.416.2.2.2.7. Fibroblast growth factor

FGFs are secreted by many cells, especially macrophages and tumor cells. There are more than 20 FGFs, but most pertinent to the vasculare are the acidic fibroblast growth factor (aFGF or FGF-1) and basic fibroblast growth factor (bFGF or FGF-2). These growth factors act by activating the tyrosine kinase receptors, FGF receptor 1 (FGFR-1) and FGFR-2, on target cell membranes. FGF affects angiogenesis through both direct and indirect pathways that involves upregulation of receptors specific to other important angiogenetic factors such as VEGF. bFGF stimulates expression of VEGF in ECs and stromal cells. When combined with VEGF, bFGF acts synergetically to increase EC migration and proliferation.

4.416.2.2.2.8. Transforming growth factor β

TGF-β is an important regulator of early vascular development and angiogenesis. The TGF-β superfamily consists of nearly 30 proteins including the BMPs. There are two types of TGF-β receptors on cells, both of which are serine–threonine kinases; type II receptors (such as TGF-βRII) bind the growth factors and then phosphorylate type I receptors (such as activin receptor-like kinase 1 (ALK1)), which activate intracellular signaling cascades. Of all the growth factors and receptors in the TGF-β family, TGF-β1 interacting with TGF-βRII and ALK1 are the most pertinent ones to vascular tissue and fibrosis.

4.416.2.2.2.9. Hepatocyte growth factor

HGF, a mesenchymal-derived protein, has been found to play a central role in liver development and regeneration after injury. As a pleiotropic morphogen, it has been shown to have mitogenic, motogenic, and antiapoptic effects. In addition, HGF is being explored as an antifibrotic agent and may have applications in the treatment of liver fibrosis.[49]

4.416.2.2.2.10. Platelet-derived growth factor

PDGFs, members of the same superfamily as VEGF, are potent mediators of smooth muscle cell (SMC) and pericyte proliferation, migration, and recruitment. There are five PDGFs: PDGF-AA, PDGF-AB, PDGF-BB, PDGF-C, and PDGF-D. The PDGFs act via two receptors, PDGFR-α and PDGFR-β, located in cell membranes. The most prevalent *in vivo* interaction

of PDGFs and PDGFRs pertinent to the vascular system is that of PDGF-BB and PDGFR-β.[48] PDGF regulation of SMCs and pericytes is critical to the formation of blood vessels, as these cell types form the supportive mural layer around mature vessels.

4.416.2.3. Cell Adhesion and Growth

The formation of complex organs, the organization of cells within them, and the expression of tissue-specific genes require a combination of spatial instructions from the ECM and intercellular adhesion, together with temporal signals from soluble factors such as growth factors, hormones, and cytokines. The precise integration of the resulting intracellular signaling networks drives the principal cellular processes of suppression of apoptosis, cell cycle, migration, and differentiation, which are all keys to the morphogenesis and function of tissues. Eliceiri[50] described the importance of crosstalk between integrins and growth factor receptors in signaling mechanism to provide specificity during normal development and pathological processes in vasucular biology. It was shown that integrins directly associate with growth factor receptors and regulate the capacity of integrin–growth factor receptor complexes to propagate downstream signaling. The crosstalk occurs during cell growth, migration, and invasion as well as in ECs during angiogensis. Streuli and Akhtar[51] reviewed the pathways, both activated and coordinated by the integrin class of cell–matrix receptors and other receptor systems. They discuss (1) how β_3 and β_1 integrins work together with growth factors to control angiogenesis; (2) how $\alpha_6\beta_4$ integrin cooperated with receptor tyrosine kinases in normal epithelial function and cancer; (3) the interplay between β_1 integrins and EGFR; (4) signal integration connecting integrins and cytokine receptors for ILs, prolactin, and IFNs; and (5) how integrins and syndocans cooperate in cell migration.

Ivaska and Heino[52] review the present information concerning the role of integrins as assisting growth factor receptors and the interplay between the receptors in cell signaling and in the orchestration of receptor recycling. They summarize some forms of collaboration between integrins and growth factor receptors as follows: (1) Integrins directly bind to latent growth factors and activate them. Subsequently, activated growth factors bind to their signaling receptors. (2) The binding of integrins to ECM proteins activates the same signaling pathways as binding to the receptors does. (3) Receptors can signal when located either on the cell surface or in endosomes. Coendocytosis of integrins and growth factors regulates cellular signaling at multiple levels. (4) Integrins activate growth factor receptors in a collaborative manner. Integrins create an environment in which growth factor receptors can properly interact with the downstream signaling molecules. In the collaborative mechanism, the binding of growth factors to their receptors precedes receptor activation. (5) Integrins activate growth factor receptors in a direct manner. Integrins create an environment in which growth factor receptors can properly interact with the downstream signaling molecules. In the direct mechanism, the growth factor receptors are activated without receptor activation. (6) Integrins activate protein tyrosine phosphatase and suppress signaling by growth factor receptors.

4.416.3. Protein Immobilization (Chapter 2.209, Materials as Artificial Stem Cell Microenvironments; Chapter 4.411, Peptide- and Protein-Modified Surfaces; and Chapter 5.508, Scaffold Materials for hES Cell Culture and Differentiation)

4.416.3.1. Immobilization for ECM–Cell Interactions (Chapter 2.207, Extracellular Matrix: Inspired Biomaterials; Chapter 2.208, Artificial Extracellular Matrices to Functionalize Biomaterial Surfaces; and Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration)

4.416.3.1.1. Extracellular matrices

Surface modification can modify the interaction between the biomaterials surface and the biological environment and yet preserve the mechanical properties of the base biomaterials.[53] Design of functionalized polymer surfaces for biomaterial applications often relies on immobilization of ECM proteins or peptides to control the integrin-mediated cell attachment. Given the central roles of integrins in cellular processes, ongoing biomaterials research has focused on identifying material surface characteristics that modulate the type, strength, and degree of ECM–integrin binding. Cell adhesion to ECM components or ECM-derived ligands on engineered surfaces governs host responses to implanted devices, integration of biomedical prostheses and tissue-engineered constructs, and the performance of biotechnological supports.

The coating of various biomaterial substrates with full-length ECM proteins modulates integrin-mediated cell function to varying degrees.[2] For instance, FN coatings on polystyrene increase osteoblast expression of α_3 and α_5 and reduce expression of α_2, α_6, and α_v subunits compared with uncoated polystyrene. Stromal cell, calvarial osteoblast, and osteoblast-like cells exhibit enhanced β_1-mediated adhesion, proliferation, and differentiation on FN-coated and type I collagen-coated surfaces compared with that on uncoated glass, polystyrene, or titanium surfaces. It has been postulated that plasma FN-coated implants enhanced early bone formation because of a chemotactic attraction of osteoprogenitors near the ECM-coated implant surface. Although there are conflicting data regarding the functional effects of collagen coating on polystyrene and titanium for various cell types, there is evidence of cell type-specific distinct integrin expression profiles on collagen versus noncollagen-coated surfaces. Osteoblasts upregulate α_3 expression over α_6 on type I collagen-coated polystyrene, whereas type IV collagen coatings mediate greater α_1, α_2, α_3, and β_1 expression and activation. Other bone-specific matrix proteins, including bone sialoprotein (BSP) and OPN, have also been explored as bioactive surface coatings to control β_3-mediated binding and signaling for human osteoblasts and stromal cells. BSP is an acidic, noncollagenous glycoprotein abundantly expressed in mineralized tissues. BSP bound to type I collagen was found to orient in a bioactive orientation that augments β_3 binding and subsequent osteoblast adhesion and differentiation over unmodified interfaces. Implants coated with BSP were found to be fairly osteoconductive *in vitro*, yet supported only minimal functional integration and mechanical fixation *in vivo*.

Vitronectin is another ECM protein that dominates serum-exposed adsorption to polystyrene. Coating vitronectin on polystyrene not only enhances mouse osteoblast expression of $\alpha_v\beta_3$,

but has also been shown to weaken adhesion of murine cells compared with uncoated polystyrene. However, for human osteoblasts, adhesion to vitronectin was found to be primarily $\alpha_{v\beta5}$-mediated and more robust than adhesion to uncoated surfaces. These studies highlight cell type-dependent effects on integrin binding and cell function that surface modifications using natural ECM proteins may elicit.

The ECM adsorption approach is nevertheless highly sensitive to materials surface chemistry. Grinnell and Feld[54] first showed that plasma FN would be adsorbed in higher content but with lower bioactivity on hydrophobic compared to hydrophilic surfaces, a finding subsequently confirmed by other studies[55,56] FN has been immobilized to surfaces using covalent coupling chemistries via the amine, thiol, and aldehyde groups.[57–60] Covalent coupling or conjugation presumably would be more efficient and stable against detachment. A critical issue of the covalent strategy is the conservation of the desired bioactivity of the immobilized FN. The degree of activity depends on the binding procedure and the substrate.[60] A combination of conjugation and adsorption can sometimes produce optimal results. By conjugating FN to the terminals of Pluronic™ F108 adsorbed on polystyrene, Biran *et al.*[58] concluded that the FN was more bioactive than the FN adsorbed directly onto polystyrene as revealed by the neurite adhesion and outgrowth assays.

Zhang *et al.*[61] investigated the bioactivity of FN immobilized on polyethylene terephthalate (PET), one of the most widely studied biomaterials surfaces, using both conjugation and adsorption methods. In the first case, FN was covalently conjugated to an aminated PET surface via glutaraldehyde cross-linking, and then the surface was blocked by ethanolamine. In the second case, FN was physically adsorbed to the ethanolamine-blocked aminated-PET surface without FN conjugation. Adsorption methods preserved the compact conformation of FN, reaching saturation when a monolayer of FN was formed. Covalent conjugation induced FN unfolding and fibrillogenesis, forming multiple layers of FN. Adsorption maintained a more active RGD domain, thereby promoting cell adhesion, whereas conjugation induced fibrollogenesis and blocked the access to RGD, consequently suppressing cell adhesion as the surface density of FN increased. On the other hand, Bramfeldt and Vermette[62] demonstrated that covalent immobilization of FN, fibrinogen, or fibrin resulted in significantly enhanced cell adhesion of poly(ε-caprolactone) (PCL)-polyethylene-glycol (PEG) block copolymers. In addition, they reported that the cell growth was also more enhanced on the covalently immobilized surface than on the one with physisorbed proteins.

Recently, Kohen *et al.*[63] examined the property of some substrata coated with Matrigel™, a blend of ECM proteins derived from murine tumor cells, by culturing human embryonic stem (ES) cells. They observed that human ES cells attached and grew poorly on Matrigel adsorbed on polystyrene, while they proliferate when exposed to Matrigel adsorbed onto glass or oxygen plasma-treated polystyrene (e.g., 'tissue culture' treated polystyrene). Furthermore, human ES cells grown on the Matrigel-coated tissue culture polystyrene are less likely to differentiate than those grown on the Matrigel-coated glass. Matrigel formed a viscoelastic multilayer with similar thickness on all three surfaces; however, the network structures were different, as the adsorbed proteins formed a globular network on polystyrene and fibrillar networks on the hydrophilic substrates. Matrigel networks on glass were denser than those on oxygen plasma-treated polystyrene, suggesting that the density and structure of the Matrigel network affected stem cell differentiation, whereas a denser network promoted uncontrolled human ES cell differentiation and did not maintain the self-renewal phenotype.

OPN, an ECM molecule involved in wound-healing processes, was immobilized onto poly(2-hydroxyethyl methacrylate) (poly(HEMA)) by Martin.[64] The immobilization was confirmed by electron spectroscopy for chemical analysis and time-of-flight secondary ion mass spectroscopy. Iodination of OPN yielded quantitative data supportive of dose-dependent immobilization. Enzyme-linked immunosorbent assay (ELISA) was also used to investigate the presence of OPN on poly(HEMA). The cell-adhesive properties of immobilized OPN were also confirmed by using a bovine aortic EC adhesion assay. Martin *et al.*[65] covalently attached OPN to type I collagen and they confirmed the attachment using surface plasmon resonance (SPR). Radio-iodination of OPN showed that binding to collagen was dose-dependent and maximal in basic conditions. Principal component analysis of time-of-flight secondary ion mass spectrometry data identified differences in OPN immobilized. They showed that adhesion of bovine aortic ECs on immobilized OPN using the affinity coating was significantly enhanced compared to controls.

4.416.3.1.2. Biomimetic peptides (Chapter 4.415, Surface Engineering Using Peptide Amphiphiles)

For promoting cell-specific functions, the functionalization of biomaterials with natural matrix proteins has several drawbacks. As many full-length matrix proteins contain multiple integrin and other biomolecule binding sites, it is likely that these proteins may induce significant binding of more than one integrin, and hence, do not truly support an 'integrin-specific' surface. Moreover, immunogenic and pathogen transmission concerns across species limit widespread use of these ECM-derived protein ligands as bioactive coatings for implants in humans. Furthermore, processing issues including scale-up difficulties and long-term stability may reduce the widespread application of these matrix-functionalized surfaces.

Synthetic biomimetic strategies to promote cell adhesion have primarily focused on presenting short bioactive motifs derived from ECM components onto biomaterial or implant surfaces.[66–70] ECM-derived ligands to control cell adhesion were comprehensively reviewed by Petrie and Garcia[2] and Raynor *et al.*[71] A number of adhesion motifs from ECM components that can be subsequently incorporated in a small synthetic peptide have been identified. These motifs consist of a short linear sequence of amino acids, typically no more than a dozen amino acids in length, that one or more integrin receptors can recognize and bind. These short sequences (**Table 2**) can be easily incorporated into adhesion oligopeptides that can be strategically immobilized in numerous ways on a biomaterial support to promote integrin-mediated adhesive and functional responses. These immobilization schemes include covalent tethering directly onto a biomaterials substrate, using plasma treatment to increase the functional groups on the substrate, or tethering onto polymer coatings functionalized on an underlying substrate. Nonbiofouling

supports (i.e., PEG or alginate) are often used to isolate the activity of these motifs better by utilizing a background with minimal nonspecific protein adsorption.[72]

Carrico *et al.*[73] reported microbial expression of artificial proteins bearing the photosensitive noncanonical amino acid para-azidophenylalanine. The recombinant proteins, designated artificial ECM proteins with aryl azides, belong to a family of engineered proteins designed to exhibit mechanical properties similar to those of native elastin and to support adhesion of mammalian cells through cell-binding domains (CS5 or RGD) derived from FN. Liu and Tirrell[74] presented a method for preparing cross-linked artificial ECM films that are suitable for cell studies, and they demonstrated that cells recognized the RGD sequence within cross-linked, PEG-conjugated (PEGylated) protein films. They varied the density of adhesion ligands by mixing artificial ECM-RGD and artificial ECM-RDG prior to cross-linking, and they examined the role of RGD density in modulating the adhesion, spreading, and migration of human umbilical vein ECs. Zhe *et al.*[75] reported rational design and synthesis of a new type of bioactive poly(ethylene glycol) diacrylate (PEGDA) macromonomers, cyclic RGD-PEGDA, to mimic the cell-adhesive properties of ECM, aiming to create biomimetic scaffolds with controlled spatial organization of ligands and enhanced cell binding affinity for tissue engineering. Petty *et al.*[76] used microfluidic networks to establish a gradient of RGD peptide in contact with a monolayer that presented meleimide groups among tri(ethylene glycol) groups. Foillard *et al.*[77] prepared tetrameric RGD-containing peptide for highly efficient cell adhesion on beads. Perlin *et al.*[78] reviewed RGD functional materials including both synthesis and design strategies. Robertus *et al.*[79] reviewed recent development in the cell adhesion of mammalian cells to RGD-modified self-assembled monolayer (SAM)-modified surfaces, the physical properties of which can be controlled by an external stimulus, for example, by light, electrochemistry, etc.

Hwang *et al.*[80] designed and constructed a hybrid of the mussel adhesive protein with RGD peptide. Meyers *et al.*[81] created multidomain peptides for use as coatings to endow material surfaces with desired biological activities. They termed such peptide-based functional coatings as 'interfacial biomaterials' (IFBMs). Especially, IFBM is a modular peptide containing at least one material binding domain and at least one bioactive functionality. They combined polystyrene-binding peptide with RGD, yielding a bifunctional IFBM; they created spatially resolved patterns of cells on substrates and the patterns retained the border in culture.

Self-assembly of peptides has also been investigated by many researchers. Rexeisen *et al.*[82] showed that single-tailed peptide-amphiphiles formed nanofibers in solution and gels after screening of their electrostatic charges and those containing cell-binding motifs. FN-mimetic peptide sequences were developed, containing both the primary binding domain RGD and the synergy binding domain Proline-Histidine-Serine-Arginine-Asparagine (PHSRN), which has shown superior cell adhesion properties over simple RGD sequences and FN in two-dimensional (2D) culture. Cryo-transmission electron microscopic images of a 100 μM peptide-amphiphile solution showed individual nanofibers with a diameter of ~10 nm and lengths on the order of several micrometers. The peptide-amphiphile gel was monitored by parallel-plate rheometry, and the elastic modulus (G') was greater than the viscous modulus (G''), which indicates that the peptide forms a gel. The shear modulus for a 2-day-old gel was measured to be ~500 Pa, which is within the modulus range for living tissue. Cejas *et al.*[83] also prepared collagen-related peptides which were self-assembly of short, single strands into functional biomaterials of micrometer scale. Horii *et al.*[84] showed a class of self-assembling peptide nanofiber scaffolds having an excellent biological material for three-dimensional cell culture and stimulating cell migration into the scaffold, as well as for repairing tissue defects in animals. They designed a pure self-assembling peptide scaffold RADA16-I by direct coupling to short biologically active motifs. The motifs included osteogenic growth peptide ALK (ALKRQGRTLYGF) bone-cell secreted-signal peptide, OPN cell adhesion motif DGR (DGRGDSVAYG), and 2-unit RGD binding sequence PRG (PRGDSGYRGDS). Compared to pure RAD16 scaffold, they found that these designer peptide scaffolds significantly promoted mouse preosteoblast MC3T3-E1 cell proliferation. Moreover, alkaline phosphatase (ALP) activity and osteocalcin secretion, which are early and late markers of osteoblastic differentiation, were also significantly increased. They demonstrated that the designer, self-assembling peptide scaffolds promoted the proliferation and osteogenic differentiation of MC3T3-E1. Under the identical culture medium condition, confocal images unequivocally demonstrated that the designer PRG peptide scaffold stimulated cell migration into the 3D scaffold. Their results suggest that these designer peptide scaffolds may be very useful for promoting bone tissue regeneration.

The density or spacing of plasma membrane proteins is thought to be crucial for their function; clear-cut experimental evidence, however, is still rare. Therefore, Jaehrling *et al.*[85] examined nanopatterns biofunctionalized with cell adhesion molecule neural CAM DM-GRASP (dorsal funiculus, ventral midline immunoglobulin-like restricted axonal surface protein) with respect to their impact on neuron attachment and neurite growth. Data analysis/modeling revealed that these cellular responses improve with increasing DM-GRASP density, with the exception of one spacing, which does not allow for the anchorage of a cytoskeletal protein (spectrin) to three DM-GRASP molecules.

4.416.3.2. Immobilization for Cell–Cell Interaction

In order to control cell–cell interaction, the investigations on immobilization of CAM proteins such as cadherin, selectin, Notch ligand, Shh, etc. have been reported.

4.416.3.2.1. Cadherin

Nagaoka *et al.*[86] prepared a cadherin-immobilized surface for ES cell culture. Gelatin-coated plates or feeder layers form tight aggregated colonies by the E-cadherin-mediated cell–cell adhesions. They showed that murine ES cells do not make cell–cell contacts or form colonies when cultured on the plate coated with a fusion protein of E-cadherin and IgG fragment crystallizable Fc domain. The cells in culture retain all ES cell features including pluripotency to differentiate into cells of all three germ layers and germ-line transmission after

extended culture. Furthermore, they show a higher proliferative ability, lower dependency on leukemia inhibitory factor (LIF), and higher transfection efficiency than colony-forming conditions. Their results suggested that aggregated colony formation might inhibit diffusion of soluble factors and increase cell–cell communication, which may result in a heterogeneous environment within and between surrounding cells of the colony. This method should enable the more efficient and scalable culture of ES cells, an important step toward the clinical application of these cells.

Nagaoka *et al.*[87,88] also used the E-cadherin fusion protein as an adhesion matrix for the culture of F9 embryonal carcinoma cells which usually form colonies when cultured on gelatin or FN matrices. F9 cells cultured on the E-cadherin fusion protein matrix formed a scattered distribution with a different cytoskeletal organization and E-cadherin-rich protrusions that were regulated by Rac1 activity. The same scattering activity was observed in P19 embryonal carcinoma cells. In contrast, three types of differentiated cells, mouse, NAMRU, mammary gland (NMuMG) cells, Madin-Darby canine kidney (MDCK) kidney epithelial cells, and mouse primary isolated hepatocytes, did not show the scattering activity observed in F9 and P19 cells. These results suggest that migratory behavior on an E-cadherin-immobilized surface is only observed in embryonic cells and that the regulatory mechanisms underlying E-cadherin-mediated cell adhesion vary with the state of differentiation.

4.416.3.2.2. Selectin

Koike *et al.*[89] immobilized P-selectin purified from human platelets to induce monocytes to release TNF-α. The induction of TNF-α release was dependent on the concentration of P-selectin used for the immobilization, and the maximal stimulation was observed when the plate was coated with $0.3\,\mu g\,ml^{-1}$ of P-selectin. Use of either a higher or a lower concentration of P-selectin for the plate-coating was found to elicit less TNF-α release, although the higher concentration of P-selectin caused a stronger adhesion of HL-60 leukemic cells. The expression of mRNA of TNF-α roughly paralleled the TNF-α secretion, as assessed by reverse transcription-polymerase chain reaction (RT-PCR). These results indicate that monocytes are activated by immobilized P-selectin in a density-dependent manner.

Cell rolling is an important physiological and pathological process used to recruit specific cells in the bloodstream to a target tissue. This process may be exploited for biomedical applications to capture and separate specific cell types. A commonly studied protein that regulates cell rolling is P-selectin. P-selectin has been covalently immobilized on glass substrates by Hong *et al.*[90] By coating surfaces with this protein, biofunctional surfaces that induce cell rolling were prepared. Although most immobilization methods have relied on physisorption, chemical immobilization has obvious advantages, including longer functional stability and better control over ligand density and orientation. The chemistry was categorized on the basis of the functional groups on modified glass substrates: amine, aldehyde, and epoxy. The prepared surfaces were first tested in a flow chamber by flowing microspheres functionalized with a cell surface carbohydrate (sialyl Lewis(x)) that binds to P-selectin. Adhesion bonds between P-selectin and sialyl Lewis(x) dissociate readily under shear forces, leading to cell rolling. P-selectin immobilized on the epoxy glass surfaces exhibited enhanced long-term stability of the function and better homogeneity as compared to that for surfaces prepared by other methods and physisorbed controls. The microsphere rolling results were confirmed *in vitro* with isolated human neutrophils. This work was essential for the future development of devices for isolating specific cell types on the basis of cell rolling, which may be useful for hematologic cancers and certain metastatic cancer cells that are responsive to immobilized selectins. Schmidt *et al.*[91] constructed a biophysical simulation of the motion of a rigid microsphere coated with selectin in shearing flow undergoing thermal motion.

Plasmacytoid dendritic cells (pDCs) recognize microbes, viruses in particular, and provide unique means of innate defense against them. The mechanism of pDC tissue recruitment remained enigmatic because the ligands of CXCR3, the cardinal chemokine receptors on pDCs, have failed to induce *in vitro* chemotaxis of pDCs in the absence of additional chemokines. Kohrgruber *et al.*[92] demonstrated that CXCR3 is sufficient to induce pDC migration, however, by a migratory mechanism that amalgamates the features of haptotaxis and chemorepulsion. To mediate 'haptorepulsion' of pDCs, CXCR3 requires the encounter of its cognate ligands immobilized, optimally by heparan sulfate, in the form of a negative gradient. This is the first report of the absolute requirement of chemokine immobilization and presentation for its *in vitro* promigratory activity. The paradigmatic example of pDC haptorepulsion described here may represent a new pathophysiologically relevant migratory mechanism potentially used by other cells in response to other chemokines.

4.416.3.2.3. Notch ligand

Cell–cell interactions mediated by Notch and its ligands are known to affect many cell fate decisions in both invertebrates and vertebrates. However, the mechanisms involved in ligand-induced Notch activation are unknown. Recently, it was shown that, in at least some cases, endocytosis of the extracellular domain of Notch and ligand by the signaling cell is required for signal induction in the receptive cell. These results imply that soluble ligands, (ligand extracellular domains) although capable of binding Notch, would be unlikely to activate it. To test the potential activity of soluble Notch ligands, Varnum-Finney *et al.*[93] generated monomeric and dimeric forms of the Notch ligand Delta-1 by fusing the extracellular domain to either a series of myc epitopes (Delta-1(ext-myc)) or to the Fc portion of human IgG-1 (Delta-1(ext-IgG)). Notch activation, assayed by inhibition of differentiation in C2 myoblasts and by HES1 transactivation in U20S cells, occurred when either Delta-1(ext-myc) or Delta-1(ext-IgG) was first immobilized on the plastic surface. However, Notch was not activated by either monomeric or dimeric ligand in solution (nonimmobilized). Furthermore, both nonimmobilized Delta-1(ext-myc) and Delta-1(ext-IgG) blocked the effect of immobilized Delta. These results indicate that Delta-1 extracellular domain must be immobilized to induce Notch activation in C2 or U20S cells and that nonimmobilized Delta-1 extracellular domain is inhibitory to Notch function. These results imply that ligand stabilization may be essential for Notch activation.

Konno *et al.*[94] immobilized Notch ligand by photoimmobilization and showed that immobilized Notch ligand maintained growth of Notch ligand-dependent cells, such as soluble Notch ligand. The Notch signaling pathway was identified as a key regulator of epithelial differentiation. Utilizing this knowledge, Beckstead *et al.*[95] applied an affinity immobilization scheme designed to attach and orient the Notch ligand, Jagged-1, in an active conformation on a biomaterial surface. When epithelial stem cells were plated on the bound ligand, the Notch/CBF-1 signaling pathway was stimulated and the cells were upregulated by both intermediate- and late-stage differentiation markers. In addition, the ligand promoted tight clustering and extensive stratification. Soluble Jagged-1 showed no Notch/CBF-1 signaling and very little, if any, cell differentiating activity. The high potency of bound Jagged-1 suggests that modification of a surface with a Notch ligand presents a powerful method to control stem cell differentiation at the cell–biomaterial interface.

Thymocyte development takes place in a complex milieu of supportive cells and ECM that are responsible for the proliferation, adhesion, migration, and selection processes that these cells undergo before reaching maturity. In recent years, the role of Notch signaling in lymphocyte development, specifically T cell development, has been extensively characterized. Although Notch-ligand-mediated signals have been shown to be a necessary component of T cell generation from stem cells, high-throughput, synthetic biomaterial-based systems for Notch-directed stem-cell differentiation into lymphocytes are yet to be reported. Taqvi *et al.*[96] reported a microbead-based, artificial Notch signaling system to study stem-cell differentiation into the T cell lineage. Magnetic microbeads were functionalized with the Notch ligand DLL4 using streptavidin-biotin binding and antibody–antigen coupling. Immunohistochemistry and flow cytometry analysis indicated ~65% conjugation efficiency. Efficient Notch signaling through these functionalized microbeads was demonstrated through a myotube inhibition assay in C2C12 myoblasts. Thy1.2(+) early T cells were successfully generated from mouse bone marrow hematopoietic stem cells (BMHSCs) using DLL4 functionalized beads using both insert-based and mixed stromal cell (OP9) coculture conditions, indicating that stem cell–stromal cell physical contact is not necessary for DLL4-directed T cell differentiation. In coculture studies, bead-to-cell ratios of 1:1 generated higher T cell differentiation efficiencies compared to bead-to-cell ratios of 5:1. They demonstrated the promising potential of this biomaterial-based Notch signaling system to generate T cells from stem cells and to elucidate the molecular interactions in T cell development.

Suzuki *et al.*[97] demonstrated efficient *ex vivo* expansion of hematopoietic stem cells (HSCs) measured by long-term severe combined immunodeficient (SCID) repopulating cells (SRCs) from human cord blood CD133-sorted cells using a soluble form of Delta-1. After a 3-week culture on immobilized Delta-1 supplemented with stem cell factor (SCF), thrombopoietin, Flt-3 ligand, IL-3, and IL-6/soluble IL-6 receptor chimeric protein (FP6) in a serum- and stromal cell-free condition, we achieved approximately sixfold expansion of SRCs when evaluated by limiting dilution/transplantation assays. The maintenance of full cell multipotency and self-renewal capacity during culture was confirmed by transplantation to nonobese diabetic/SCID/gammac(null) mice, which showed myeloid, B, T, and natural killer cells as well as CD133(+)CD34(+) cells, and hematopoietic reconstitution in the secondary recipients. Interestingly, the CD133-sorted cells contained ~4.5 times more SRCs than the CD34-sorted cells. The present study provides a promising method to expand HSCs and encourages future trials on clinical transplantation.

Kertész *et al.*[98] showed that prolonged *in vitro* culture (14 days) of murine bone marrow lineage negative cells in a medium supplemented with three early acting cytokines (SCF, Flk-2/Flt-3 ligand, thrombopoietin) and with immobilized Notch ligand, Jagged-1, resulted in robust expansion of serially transplantable HSCs with long-term repopulating ability. They found that the absolute number of marrow cells was increased ~8–14-fold in all cultures containing recombinant growth factors. However, the frequency of high quality stem cells was markedly reduced at the same time, except in cultures containing growth factors and Jagged-1-coated Sepharose-4B beads. The absolute number of hematopoietic cells with long-term repopulating ability was increased ~10–20-fold in the presence of multivalent Notch ligand. These results supported the idea of the role of the combinatorial effects of Notch and cytokine-induced signaling pathways in regulating HSC fate and the potential role of Notch ligand in increasing cell numbers in clinical stem cell transplantation.

4.416.3.2.4. Ephrin B2

Zisch *et al.*[99] developed the natural hydrogel matrix fibrin as platform for extensive interactions and continuous signaling by the vascular morphogen ephrin-B2 that normally resides in the plasma membrane and requires multivalent presentation for ligation and activation of ephrin (Eph) receptors on apposing EC surfaces. Using fibrin and protein engineering technology to induce multivalent ligand presentation, a recombinant mutant ephrin-B2 receptor binding domain was covalently coupled to fibrin networks at variably high densities. The ability of fibrin-bound ephrin-B2 to act as ligand for ECs was preserved, as demonstrated by a concomitant, dose-dependent increase of EC binding to engineered ephrin-B2-fibrin substrates *in vitro*. The therapeutic relevance of ephrin-B2-fibrin implant matrices was demonstrated by a local angiogenic response in the chick embryo chorioallontoic membrane evoked by the local and prolonged presentation of matrix-bound ephrin-B2 to tissue adjacent to the implant. This new knowledge on biomimetic fibrin vehicles for precise local delivery of membrane-bound growth factor signals may help to elucidate specific biological growth factor function and serve as starting point for the development of new treatment strategies.

4.416.3.2.5. Sonic hedgehog

The signaling domain of Shh, a potent upstream regulator of cell fate, has been implicated in osteoblast differentiation from undifferentiated mesenchymal cells in its endogenous form. Therefore, an immobilized form as a means for accelerating differentiation of uncommitted cells to the osteoblast phenotype was investigated by Ho *et al.*[100] A recombinant cysteine-modified N-terminal Shh (mShh) was synthesized, purified, and immobilized onto interpenetrating polymer network

(IPN) surfaces and also grafted with a BSP-derived peptide containing the RGD sequence (BSP-RGD), at calculated densities of 2.42 and 10 pmol cm^{-2}, respectively. The mitogenic effect of mShh was dependent on the mode of presentation, as surfaces with immobilized mShh and BSP-RGD had no effect on the growth rate of rat bone marrow-derived mesenchymal stem cells (BMSCs), while soluble mShh enhanced cell growth compared to a similar surface without mShh supplementation. In conjunction with media supplemented with bone morphogenetic protein-2 and -4, mShh and BSP-RGD-grafted IPN surfaces enhanced the ALP activity of BMSCs compared with tissue culture polystyrene and BSP-RGD-grafted IPN surfaces supplemented with soluble mShh, indicating enhanced osteoblast differentiation. The adhesive peptide BSP-RGD was necessary for cell attachment and proliferation, as well as differentiation in response to immobilized mShh. The addition of immobilized Shh substantially improved the differentiation of uncommitted BMSCs to the osteoblast lineage, and therefore warrants further testing *in vivo* to examine the effect of the stated biomimetic system on peri-implant bone formation and implant fixation.

4.416.3.3. Surface Immobilization of Growth Factors

The effect of immobilized growth factors is expected to be different from immobilized adhesion factors because of intrinsic differences in their cell interaction mechanisms (**Chapter 4.427, Cell-Demanded Release of Growth Factors** and **Chapter 4.412, Rational and Combinatorial Methods to Create Designer Protein Interfaces**).

4.416.3.3.1. Mechanisms

Figure 3 shows the possible cell interaction mechanisms for both diffusible and nondiffusible growth factors. First, growth factor interacts with cognate receptors on cell surfaces to form complexes. Second, the complex moves on the cell surface to be aggregated. At the same time, the interaction induces phosphorylation of intracellular domains of receptors and triggers cell signal transduction within the cell. In the case of diffusible interactions, the aggregates of formed complexes are internalized through clathrin-dependent or -independent mechanisms. The internalized complexes are partially decomposed in lysosomes and are partially recycled back to the cell membrane. In the case of intracrine mechanisms, although the internalization mechanism is not known, the receptor is considered to be located in the cell, but not on the cell membrane. In diffusible actions, with the exception of intracrine functions, the number of factor-specific cell receptors determines the sensitivity of the cell. Internalization of receptors by complex formation downregulates numbers on the cell membrane. This critical downregulation mechanism for cell desensitization reduces excess response to excess exogeneous stimulation.

Nondiffusible mechanisms (juxtacrine) are enabled by discovery of cell membrane-bound growth factors in 1990s. Heparin-binding epidermal growth factor (HB-EGF), TGF-β, TNF-α, colony stimulating factor 1 (CSF-1), and c-kit ligand are known as juxtacrine growth factors as reviewed by Massague and Pandiella[101] and Iwamoto and Mekada.[102]

In the 1990s, chemically immobilized growth factors were devised and investigated (reviewed by Ito[103,104]). The effect of immobilized growth factors has been investigated as either artificial juxtacrine or matricrine. Comparison between diffusible and nondiffusible cell stimulations by growth factors is important to design the combination of growth factor with scaffold and cells. Immobilization of growth factors onto scaffolds is considered to induce some characteristic phenomena with cellular cognate receptors, as shown in Figure 4. Immobilized growth factors stimulate cells with increased potency over soluble factors. It has also been also demonstrated that immobilized growth factors exhibit increased and effective distinct soluble factors because their interaction is not only a ligand–receptor complex formation. These effects of immobilized growth factors are considered to be due to complex, multiple mechanisms.

One difference is the high local density and multivalency on surfaces. The interaction of immobilized biosignal molecules from the substrate due to local density is extremely high and constant. In addition, the importance of mutivalency of immobilized biosignal molecules has been discussed by many researchers. Recently, Kiessling *et al.*[105] considered synthetic multivalent ligands as probes of cell signal transduction. Multivalent ligands can bind avidly to multiple receptors on the cell surface, a process facilitated by the cell's fluid lipid bilayer and the 2D diffusion of membrane receptors. Multivalent ligands can activate signaling pathways if they can cluster signaling

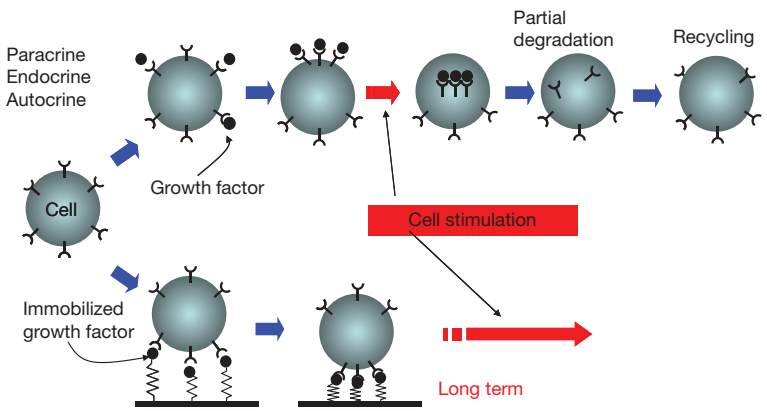

Figure 3 Cell interaction mechanisms with diffusible and nondiffusible growth factors.

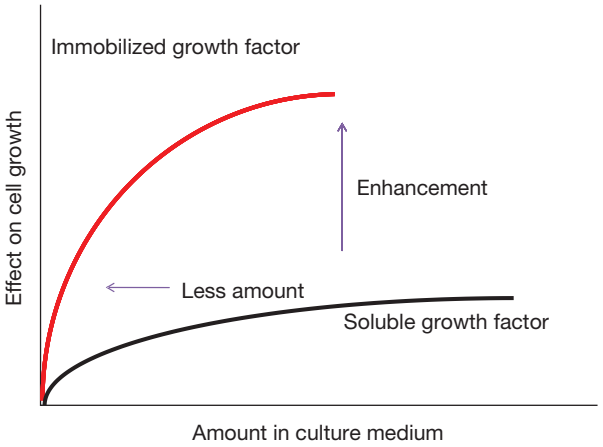

Figure 4 Schematic comparison of the mitogenic effect of immobilized growth factor with that of nonimmobilized growth factor. Immobilized growth factor induces a greater effect than nonimmobilized growth factor. A smaller amount of immobilized growth factor is considered to induce the effect as a result of multivalency and high local concentration. Potentiation of mitogenic effects is considered to be caused by inhibition of downregulation and other factors.

receptors. They discussed the three major concepts critical for application of multivalent ligands as effective probes of signal transduction: (1) Signal transduction cascades are mediated by receptor–receptor interactions and promoting receptor assembly is critical for signaling. (2) Multivalent ligands can interact with the target receptors through multiple binding modes. (3) The structure of a multivalent ligand will determine the favored binding modes. Thus, the structure can be optimized to elicit the desired biological response.

In addition to high local concentration and multivalency, prevention of lateral diffusion of the activated receptors or the receptor–ligand complexes in the plane of the cell membrane must be considered. This equates to stabilization of the aggregates of complexes and thus leads to a long-lasting effect. Inhibition of the cell internalization process should also be considered as shown in Figure 3. In general, cells decompose these biosignal molecules within the cells to reduce their stimulation by a process called downregulation. Factor immobilization inhibits this downregulation and as a result, cell stimulation continues for a long time without reduction. In addition, differences in stimulation between the cells in medium and at the cell–matrix interface should also be distinguished. The specific situation differentially affects various cell functions at surfaces.

4.416.3.3.2. Examples of immobilized growth factors

4.416.3.3.2.1. Insulin

Insulin was immobilized and the effect was investigated by Ito *et al.*[66,67] They immobilized insulin, transferrin, and collagen on the surface of hydrolyzed poly(methyl methacrylate) films using ethylcarbodiimide hydrochloride (EDC) chemistry, and cultured mouse STO (S, SIM; T, 6-thioguanine resistant; O, ouabain resistant) fibroblasts on the protein-immobilized films. They found that insulin remained immobilized without detachment and accelerated cell growth in a more potent manner than free or adsorbed insulin. Subsequently, Ito *et al.*[106] compared the effects with those of proteins such as a cell-growth factor insulin, cell adhesion factors fibrinogen and FN, and serum proteins albumin and γ-globulin. As a result, the insulin-immobilized poly(methyl methacrylate) membrane strongly accelerated the growth and slightly accelerated the adhesion of fibroblast cells and immobilized FN and fibrinogen enhanced cell adhesion and the former also accelerated the cell growth. Immobilized albumin and γ-globulin influenced the adhesion and growth of cells very little. It was found that various proteins specifically influence the adhesion and growth of cells in an immobilized state. Liu *et al.*[107] revealed that cell growth was enhanced by the addition of immobilized insulins that were not internalized. It appears that insulin–receptor binding is enough for the transmission of the cell growth signal to the cell nucleus. The enhanced cell growth by the immobilized insulins compared with free insulin molecules is ascribable to suppression of the cell downregulation, a consequence of intracellular decomposition of the insulin–receptor complex. Liu *et al.*[108] also reported that the growth acceleration by immobilized insulin was enhanced by the introduction of a spacer arm between insulin and the immobilization matrix. The amount of receptor proteins present on the biological membrane of fibroblast cells after culture with insulin immobilized on nondegradable polymer membrane was much higher than that after culture with free insulin, implying suppression of downregulation by immobilized insulin. It was demonstrated that the effects of immobilized growth factors overcome the effect of multivalent soluble growth factors.[109,110]

In order to investigate the signal transduction of immobilized insulin, Chinese hamster ovary (CHO) cells overexpressing human insulin receptors were cultured on polymer film in the absence of serum or soluble proteins.[111,112] Small amounts of immobilized insulin (1–10% of the required amount of free insulin) were sufficient to stimulate cell proliferation. In addition, the maximal mitogenic effect of immobilized insulin was greater than that of free insulin. Immobilized insulin activated the insulin receptor and downstream signaling proteins, and this activation persisted for longer periods than that obtained with free insulin, probably explaining the greater mitogenic effect of the immobilized insulin. In addition, the immobilized-insulin film was usable repeatedly without marked loss of activity. Repeated utilization provides evidence indicating the stable activity of immobilized growth factors. If the immobilized growth factor was released from the surface because of proteolysis or incompleteness of immobilization, the biological activity of surface is not considered to be maintained. Repeated utilization is an advantage of immobilized enzymes for bioreactors useful for mass cell culture.

If the concept of immobilization was applied to other materials[113–119] or to a protein-free cell culture,[120–122] the activity was enhanced by coimmobilization with cell adhesion proteins[113,123–132] for other cells.[122,131–133] Heparin was coimmobilized for enhancement by Kim *et al.*[134] and Sasmazel *et al.*[135] On the other hand, Ito *et al.*[111,112] developed a photoimmobilization method and Ito *et al.*[125,126,128] succeeded in visualization of the cell signal transduction. Spatial regulation of the cell functions was performed on

micropattern-immobilization of insulin. When cell culture was performed on micropatterned growth factors, cell growth was accelerated only on the growth factor-immobilized areas.

In addition to spatial control, temporal control using a temperature-sensitive polymer poly(*N*-isopropylacrylamide) was performed by Chen *et al.*[136] and Hatakeyama *et al.*[137–139] Insulin was immobilized and a thermoresponsive polymer was grafted onto a substrate. They investigated the effect of insulin coupling under lower critical solution temperature (LCST) of the thermoresponsive polymer film, poly(*N*-isopropylacrylamide-*co*-acrylic acid), using polymers that were either ungrafted or coupled with insulin. The insulin conjugates were precipitated from an aqueous solution at high temperatures, but they were soluble at low temperatures. The LCST was not significantly affected by the insulin coupling. The thermoresponsive polymer was grafted to glow-discharged polystyrene film and covalently conjugated with insulin. The surface wettability of the conjugate film was high at low temperatures and low at high temperatures. The amounts of immobilized insulin required to stimulate cell growth were 1–10% of the amount of free insulin required to produce the same effect. The maximal mitogenic effect of immobilized insulin was greater than that of free insulin. About half of the viable cells were detached from the film only by lowering the culture temperature. The recovered cells proliferated normally on new culture dishes.

4.416.3.3.2.2. Insulin-like growth factor 1

Adult stem cells exhibit a much higher differentiation potential than previously expected and the sources within the adult organism seem to be surprisingly abundant. Brose *et al.*[140] investigated adult stem cells isolated from mouse and rat pancreas and showed their potential to differentiate into osteoblasts, chondrocytes, and adipocytes and they also showed that pancreatic stem cells (PSCs) differentiated spontaneously into cell types of all three germ layers. In addition, it was demonstrated that a directed differentiation is also possible and a variety of cytokines are compared as inducers. They applied the soluble differentiation factors for the use of immobilized cytokines. They immobilized IGF-1 to amino- or epoxy-silanized glass or affinity binding of the biotinylated cytokine to neutravidin-coated surfaces. The immobilized IGF-I induced adipogenic differentiation of mouse PSCs. At day 18, the cell cultures were analyzed by Oil red O staining and showed clear formation of oil vesicles. The results show that cytokines could be immobilized functionally, retaining their biological activity to effectively induce stem cell differentiation in long-term cell culture experiments. Miller *et al.*[141] developed an inkjet printing methodology for creating solid-phase patterns of unmodified growth factors on native biological material substrates. They demonstrated this approach by printing gradients of fluorescently labeled BMP-2 and IGF-II bio-inks on fibrin-coated surfaces. Concentration gradients were created by overprinting individual substrate locations using a dilute bio-ink to modulate the surface concentration of deposited growth factor. After inkjet printing, cell culture was performed to evaluate the effect of immobilized growth factors.

Stefonek-Puccinelli and Masters[142] demonstrated cell migration control by coimmobilization of gradient-patterned growth factors. Growth factors, including IGF-1 and EGF, are known to be deficient in chronic wounds; unfortunately, traditional delivery of soluble growth factors to wounds is expensive and complicated by their degradation. Therefore, they attempted to direct and accelerate keratinocyte migration by creating immobilized gradients of EGF. In addition, they optimized EGF gradients for cell migration, synthesized and characterized gradient patterns of IGF-1, and tested for migration synergy upon combination of EGF and IGF-1 patterns. An optimal EGF concentration and pattern was identified, resulting in migration that was almost tenfold of that achieved on unpatterned controls. Immobilization of IGF-1 gradients also accelerated and directed keratinocyte migration ($p < 0.05$); however, no difference in migration was found across various IGF-1 concentrations or gradient patterns. Although combining EGF with IGF-1 patterns did not accelerate migration beyond levels achieved using EGF alone, these methods can be applied to create other types of multicomponent gradients that may ultimately be utilized to create bioactive wound dressings.

Van Lonkhuyzen *et al.*[143] produced a chimeric protein of IGF-1 and vitronectin, the protein associated with IGF-I-binding protein. The complex of fusion protein and IGF-binding protein bound to both the IGF-1 receptor and integrin (thus binds to cells), and stimulated receptor-mediated and integrin-mediated pathways. As a result, the fusion protein complex exhibits a higher cell proliferation activity compared with the nonfusion protein complex.

4.416.3.3.2.3. Epidermal growth factor

Early work by Kuhl and Griffith-Cima[144] covalently tethered EGF to aminosilane-modified glass via star PEG, which allows the ligand to retain significant mobility and active conformation. The tethered EGF was as effective as soluble EGF in eliciting DNA synthesis and cell rounding responses of primary rat hepatocytes under different surface conditions. Ito *et al.*[125,126,128] considered the effect of immobilized EGF as artificial juxtacrine stimulation. Chen *et al.*,[145,146] Ogiwara *et al.*,[147] and Woo *et al.*[148] performed photo-immobilization of EGF and they clearly showed growth enhancement by the immobilized EGF. Coimmobilization of EGF and cell adhesion proteins or peptides was also investigated by Park *et al.*[149] and Tigli and Gumusdereliglu.[150] In addition, to further investigate the interaction of immobilized growth factor, CHO cells overexpressing the cognate receptors were cultured on plates immobilized with growth factors in narrow stripe patterns less than cell size.[151] The contact area (stripes 2 μm in width) between the cells and the immobilized growth factor was stained by antiphosphotyrosine antibody. As free lateral diffusion and internalization of the bound growth factor and the receptor complex were prohibited by immobilization of growth factor, only signal proteins in the interaction regions were activated. This finding also indicates that the biological signal was transduced only to the cell that interacted with immobilized growth factor. Utilization of microbeads immobilized with growth factors is also one of the tools to probe the interaction of cellular receptors with immobilized growth factor. Ichinose *et al.*[152] quantitatively investigated the interaction between immobilized growth factor and cellular receptors at the single molecular level. When immobilized density was only slightly lower than that of receptor dimers, cellular response was dramatically decreased. Receptor molecules bound with the immobilized growth factor were prevented

from lateral diffusion and internalization and maintained their initial surface position and density.

Chen and Ito[153] succeeded in the preparation of gradient micropattern immobilization of EGF to investigate the effect of artificial juxtacrine stimulation. Wang and Bohn[154] prepared surface composition gradients of EGF by adaptating an electrochemical gradient technique. Stefonek and Masters[155] synthesized surfaces covalently modified with gradients of EGF to create a platform that promotes directed cell migration. Under serum-free conditions, human epidermal keratinocytes on immobilized EGF gradients preferentially migrated in the direction of higher EGF concentrations and exhibited unidirectional migration speed and distance that were over fivefold greater than that observed on control surfaces. Treatment of migrating cells with an inhibitor of the EGFR resulted in immediate cessation of migration, thus verifying that the observed migration trends were directly attributable to keratinocyte interactions with immobilized EGF. EGF was also immobilized on polydimethylsiloxane,[156] silica nanoparticles,[157] silicone rubber,[158] and chitosan.[159]

Interestingly, Ito *et al.*[160] found that cellular gene expression is affected by both the kind and mode of growth factor stimulation (diffusive vs. nondiffusive). EGF was pattern-immobilized on a polystyrene plate. Although the growth of the rat phaeochromocytoma cell line PC12 is stimulated by diffusible EGF, and differentiation is stimulated by diffusible NGF, immobilized (nondiffusible) EGF stimulated PC12 differentiation. Immobilized EGF caused a long-lasting stimulation of intracellular signal protein, MAPK (also known as ERK), and p38 (a subfamily of the MAPK superfamily) in cells, as did diffusible NGF. The switching between growth stimulation and differentiation is considered to be due to the duration of the stimulus. The function of the biosignal conjugate was regulated using conjugation methodology.

Fan *et al.*[161] found that immobilized EGF provides a survival advantage to mesenchymal stem cells (MSCs). It is known that MSCs can act as a pluripotent source of reparative cells during injury and therefore have great potential in regenerative medicine and tissue engineering. However, the response of MSC to many growth factors and cytokines is unknown. Therefore, they investigated cellular responses of MSC on a biomaterial surface covalently modified with EGF. They found that surface-tethered EGF promotes both cell spreading and survival more strongly than saturating concentrations of soluble EGF. By sustaining MAPK kinase-extracellular-regulated kinase signaling, tethered EGF increases the contact of MSC with an otherwise moderately adhesive synthetic polymer and confers resistance to cell death induced by the proinflammatory cytokine, Fas ligand. It was concluded that tethered EGF may offer a protective advantage to MSC *in vivo* during acute inflammatory reactions to tissue engineering scaffolds.

Signaling by the EGFR plays a role in cell survival and has been implicated in bone development and homeostasis. Providing EGF in a scaffold-tethered format may sustain local delivery and shift EGFR signaling to prosurvival modes compared to soluble ligand. Marcantonio *et al.*[162] therefore examined the effect of tethered EGF on osteogenic colony formation from human bone marrow aspirates in the context of three different adhesion environments using a total of 39 donors. They found that tethered EGF, but not soluble EGF, increased the numbers of colonies formed regardless of the adhesion background, and that tethered EGF did not impair early stages of osteogenic differentiation. It is known that EGFR-mediated signaling helps regulate bone development and healing through its effects on osteogenic cells. Platt *et al.*[163] showed how EGFR activity and osteogenic differentiation responses in primary human MSCs were influenced by presenting covalently immobilized EGF on the culture substratum, a presentation mode that reduced EGFR internalization and restricted signaling to the cell surface. In both the absence and presence of immobilized EGF, MSCs increased the expression levels of EGFR and its heterodimerization partner HER2 during the course of osteogenic differentiation. Immobilized EGF increased levels of phosphorylated EGFR and phosphorylated ERK compared to control substrata, and these elevations were associated with a twofold enhancement of MSC ALP activity at day 7 and matrix mineralization at day 21. Surprisingly, addition of soluble EGF to cells cultured on immobilized EGF substrata reduced osteogenic differentiation, even though EGFR signaling is more strongly activated in an acute, short-term manner by sEGF treatment than by immobilized EGF treatment. A striking concomitant result of the soluble EGF effects was near-complete downregulation of EGFR and HER2, demonstrating that the immobilized EGF–EGFR interaction was dynamically reversible even though temporally sustained. Taken together, their results showed that enhanced MSC osteogenic differentiation corresponds to a sustained combination of receptor expression and ligand presentation, both of which were maintained by immobilized EGF.

Parallel screening was investigated by many researchers. For example, Nakajima *et al.*[164] prepared parallel and rapid screening of composite biomaterials through assays using cell-based arrays to optimize matrix–growth factor combinations. They employed photo-assisted patterning of an alkanethiol SAM to achieve site-addressable combinatorial immobilization of natural and synthetic matrices incorporated with growth factors including EGF, ciliary neurotrophic factor (CNTF), NGF, and NT-3. Neural stem cell obtained from the rat embryonic striatum was cultured directly on the array to screen for cell adhesion, proliferation, and promotion of neuronal and glial specification. The results showed that a significant number of cells adhered to laminin-1, FN, ProNectin, and poly(ethyleneimine). They found that cells proliferated most extensively on a spot with immobilized EGF among the spots with different matrix–growth factor combinations.

Protein engineering has been employed for the immobilization of growth factors. Nishi *et al.*[165] produced fusion proteins using the collagen-binding domain (CBD) motif from bacterial collagenase fused to EGF and FGF. Both were retained for 5–10 days when subcutaneously injected into rats (5–7 days), which suggests their tight binding to collagen or other ECM components. The EGF fusion protein exhibited only 1/10 of the original EGF activity, while the bFGF fusion protein showed an activity comparable with that of the native molecule. The CBD used may affect the activity of the fusion protein or its binding to the receptor, depending on the growth factors being fused. Hall *et al.*[166] incorporated a high affinity CBD derived from coagulation von Willebrand factor (vWF) to specifically target EGF to colonic lesions. The CBD-EGF fusion proteins bound tightly to collagen matrices under conditions

in which native nontargeted EGF was washed away. In biologic assays, the CBD-EGF fusion protein stimulated NIH3T3 cell proliferation with near wild-type biological activity. *In vivo* binding studies showed that the collagen-targeted EGF, but not the nontargeted EGF, accumulated at areas the where collagen on the luminal surface of the inflamed colon was exposed. A single colonic instillation of the collagen-targeted EGF induced a more rapid regeneration of intestinal crypts 24 h after treatment. These findings indicated that intracolonic delivery of collagen-targeted EGF represents a potentially effective therapeutic strategy for acute or chronic inflammatory bowel disease.

Ishikawa *et al.*[167] established another type of collagen-binding growth factor (CBD-EGF) consisting of EGF and FN CBD. A typical yield of CBD-EGF was $\sim 200\,\mu g\,ml^{-1}$ culture in an *Escherichia coli* expression system. This fusion protein bound to gelatin and fibrillar collagen sponges, and the bound protein was not effectively eluted even with 2 M NaCl. In addition, CBD-EGF bound to type I, II, III, or IV collagen-coated plates, and the specificity of binding was confirmed by competitive inhibition using FN. CBD-EGF substantially stimulated cell growth after binding to collagen-coated culture plates, whereas EGF had no effect, indicating that this fusion protein acted as a collagen-associated growth factor. In an animal model of impaired wound healing, CBD-EGF, but not EGF, was retained with collagen sponges at wound sites 4 days after implantation, and repair of epidermis was observed underneath the sponges. These results suggested that the fusion protein with high collagen affinity would be useful for wound healing. Ishikawa *et al.*[168] investigated the concept that CBD moiety with high collagen affinity may enhance the effective local concentration of EGF at the site of administration in the following tissues: skin wounds, catheter-injured arteries, and hind limb muscles. In an animal model of impaired wound healing, application of CBD-EGF in combination with collagen gel induced granulation tissue formation in the intractable skin wounds of diabetic mice (db/db) because of its sustained retention. It was also shown that CBD-EGF binds to type IV collagen (basement membrane, BM) exposed on the inner surface of blood vessels after balloon-catheter injury. In the injured artery, infused CBD-EGF remained bound to collagen exposed on the injured tissues even after blood circulation was restored. Injection of the fusion protein into the hind limbs revealed that our delivery system was effective for direct administration to muscular tissue. Native EGF did not exhibit these wound healing effects. Kato *et al.*[169] also developed collagen-growth factor composites for use in tissue engineering; chimeric proteins consisting of EGF and collagen binding domains derived from vWF or FN were synthesized by means of recombinant technology. Hall *et al.*[166] showed that collagen-binding EGF (CBD-EGF) dosed into an injured colon without a carrier promotes the repair of the inflamed luminal surface.

Fibrin-binding growth factor was reported by Kitajima *et al.*:[170] a chimeric protein of the FN fibrin-binding domain (FBD) and EGF. This fusion protein (FBD-EGF) binds to fibrin in the absence of the cross-linking enzyme (FXIIIa) and may be suitable for the preparation of fibrin-based scaffolds with EGF activity. The wound-healing potential of FBD-EGF was examined using an *in vitro* culture model of keratinocyte sheets; repair of the injured sheet was enhanced by fibrin-bound FBD-EGF, but not by EGF alone. *In vivo* evaluation of EGF-immobilized material was performed by Choi *et al.*[171] They immobilized human EGF on electrospun nanofibers composed of biodegradable polymers for the purpose of treating diabetic ulcers. Wound healing effects of the EGF nonofibers were confirmed in diabetic animals with dorsal wounds. The expression of keratinocyte-specific genes significantly increased with the application of EGF-conjugated nanofibers. The EGF-nanofibers exerted superior *in vivo* wound healing activities compared to control groups or EGF solutions. Furthermore, immunohistochemical-staining results showed that EGFR was highly expressed in the EGF nanofiber group. This study showed that EGF-conjugated nanofiber could potentially be employed as a novel wound healing material by increasing proliferation and phenotypic expression of keratinocytes.

Ogiwara *et al.*[172] produced an EGF fusion protein coupled with the Fc region of IgG. The Fc region is often used as a fusion tag to allow extracellular domains of large membrane proteins or receptor molecules to adhere nonspecifically to solid surfaces. These authors used the hydrophobicity of the Fc region as a binding domain for hydrophobic artificial substrates, although this type of fusion protein is not considered as a binding growth factor. Similarly, Nakaji-Hirabayashi *et al.*[173–176] demonstrated that human epidermal growth factor carrying a hexahistidine sequence at the C-terminus (hEGF-His) could be anchored to the Ni-chelated surface by coordination and they investigated the immobilization state in detail. Boucher *et al.*[177] immobilized EGF by a new capture system based on *de novo* designed peptides, that is, the E and K coils. The influence of the type of coil (E or K) upon EGF bioactivity, assessed in an *in vitro* cell assay, was compared to that of the Fc domain of immunoglobulin G by monitoring phosphorylation of EGFR upon chimeric EGF exposure. They demonstrated that the type and the location of the tag have a strong impact on growth factor bioactivity (EC50 ranging from 5.5 to 63 nM). Additional SPR-based biosensor experiments were conducted to test the ability of captured chimeric EGF to bind to its receptor ectodomain *in vitro*. These experiments indicated that the oriented coiled-coil-mediated immobilization of EGF was significantly more efficient than a random approach as coil-tagged EGF displayed enhanced affinities for artificially dimerized EGFR ectodomain when compared to Fc-tagged EGF (apparent KD of 5 pM vs. 16 nM). Altogether, they suggested that coil-tagged chimeras represent an attractive avenue for the oriented immobilization of growth factors for tissue engineering applications and that HEK293 cells offer a robust platform for their expression in a bioactive form. In addition, Boucher *et al.*[178] demonstrated that immobilized EGF provided a sustained phosphorylation of A-431 cell surface EGFRs.

Cell-binding growth factors were developed by Kawase *et al.*[179] and Hashi *et al.*[180] by employing the FN cell-binding domain ($\sim$30 kDa, including the RGD sequence). The EGF fusion protein promoted the proliferation of rat kidney fibroblasts. Another type of cell-binding EGF (containing an RGD sequence) was generated via the incorporation of hydrophobic linker sequences[181] and collagen-binding sequences.[182] They constructed a new multifunctional protein that can be easily immobilized onto hydrophobic surfaces, and at the same time can help enhance specific cell adhesion and proliferation onto collagen substrates.

Hayashi *et al.*[183] developed a recombinant technology to confer a mitogenic activity on type III collagen by fusing it to EGF at the collagen's N-terminus. The chimeric protein of EGF-collagen was synthesized in insect cells by the baculovirus-insect cell expression system. The fusion protein was shown to hold the triple helical conformation of collagen and the mitogenic activity of EGF. It was also demonstrated that the chimeric protein can be immobilized on tissue culture dishes as a fibrous form and on collagen fibrils without abolishing the original mitogenic activity of EGF. This fusion protein can be utilized as a biocompatible, biodegradable, and adhesive fibrous mitogen for a variety of purposes in the area of tissue engineering.

4.416.3.3.2.4. Nerve growth factor

Neurons are highly affected by the components of their environment including bioactive molecules such as neutrophic factors, electrical signals, ECM molecules, and cell-to-cell interactions. As a consequence, neuron tissue engineering has focused on how to produce optimal scaffolds by integrating multiple cues to mimic natural nerve tissue. Immobilization of NGF on polystyrene was reported by Ito[184] for the first time. He immobilized NGF on polystyrene to regulate the neurocite growth of pheochromocytoma PC12 cell line. Chen *et al.*[185] immobilized NGF on a gelatin–tricalcium phosphate membrane. Yu *et al.*[47] immobilized NGF on chitosan films either at indistinct areas or as concentration gradients. They found that when neurons were plated on a chitosan film that has distinct immobilized NGF-pattterned areas surrounded by unmodified chitosan, the neurons remained predominantly as single cells in the NGF-patterned regions, but formed aggregates outside of these patterns on the plain chitosan film. The immobilized NGF influenced neuron behavior and can be used to further probe mechanisms of other neuron behaviors such as axon guidance.

Neurotrophic factors that present as concentration gradients are neurotropic cues that direct axonal growth toward their targets. Multiple factors work together *in vivo* to ensure that axons reach the proper targets, likely interacting with one another via intracellular signaling pathways. NGF and NT-3 are NTs known to guide axons as well as promote axonal growth following injury to both the spinal cord and peripheral nerve. These molecules interact with neurons through different tyrosine kinase receptors. Kapur and Schoichet[186,187] immobilized NGF to guide neurite outgrowth. Moore *et al.*[188] showed that the receptors for these growth factors were colocalized on E10 chick DRG cells, providing an opportunity for synergism. Well-defined concentration gradients of NGF and NT-3 were immobilized for the first time in a cell-penetrable, cell-adhesive scaffold of poly(hydroxyethyl methacrylate) PHEMA and poly(L-lysine). An NGF concentration gradient of 310 ng ml^{-1} mm^{-1} was required to guide chick DRG neurites. A lower concentration gradient of 200 ng ml^{-1} mm^{-1} of NGF was shown to elicit guidance when an NT-3 concentration gradient of 200 ng ml^{-1} mm^{-1} was also present, indicating a synergistic response in the DRG neurons. These gradient scaffolds may be useful for guided regeneration following injury to the spinal cord or peripheral nerve and may also elucidate the mechanism for intracellular signaling of neurotrophic factors.

Shibata *et al.*[189] demonstrated that NGF-receptor complexes had two distinct diffusive states, characterized as mobile and immobile phases. The transition between the two diffusive states occurred reversibly with time durations determined by a single rate limiting process. The abrupt transition to the immobile phase often occurred simultaneously with the clustering of NGF-receptor complexes. Immobilization depended on the phosphorylation of the TrkA NGF-receptor. Using dual-color imaging, it was demonstrated that the membrane recruitment of the intercellular signaling protein occurred with NGF-receptor complexes in the immobile phase indicating that signal transduction occurs during this phase. Thus, it was considered that NGF signaling was performed through a repetitive random process to induce formation of signaling complexes.

Bhang *et al.*[190] reported that NGF immobilization on a culture substrate reduced the amount of NGF required for the PC12 cell culture dramatically. They considered several mechanisms explaining the enhancement of immobilized NGF. First, NGF immobilized on substrates bound receptors on cultured cells more efficiently than NGF added to culture media, and triggered signals more efficiently with less or no loss of bioactivity. NGF added to culture medium was evenly distributed throughout medium, so only a small portion reached the cell microdomains to trigger NGF signaling. In addition, NGF suspended in the culture medium may lose bioactivity by denaturing more easily than NGF bound to the surface. Second, downregulated signaling due to NGF internalization into cells may be inhibited by immobilization. Immobilized NGF was considered to sustain the signal protein phosphorylation, which activates signal transduction.

Numerous therapeutic interventions have been also tested to enhance functional recovery after sciatic nerve injuries. NGF was employed to treat the nerve injury repair. Sun *et al.*[46,191–193] constructed a collagen-binding human NGF-β and a polypeptide TKKTLRT as a CBD which could bind to the native collagen utilized. They reported that CBD-NGF-β bound to endogenous collagen on the rat sciatic nerve and maintained NGF activity both *in vitro* and *in vivo*. In the rat sciatic nerve crush injury model, they found that collagen-binding NGF could be retained and concentrated at the nerve injured site to promote nerve repair and enhance function recovery following nerve damage. CBD-NGF-mediated nerve fiber density was approximately twice as much as that observed for native NGF. It also enhanced healing of rabbit dermal ischemic ulcers. Han *et al.*[194,195] constructed an efficient delivery system including collagen-binding BDNF and linear ordered collagen scaffolds (LOCSs). *In vitro* activity assay showed that CBD-BDNF had similar bioactivity in neurite outgrowth of dorsal root ganglia and the survival of PC12 cells. CBD-BDNF was shown to have specific binding activity to collagen. Using the rat hemisection in spinal cord injury model, they found that LOCS loaded with CBD-BDNF significantly improved the recovery evaluated by the Basso, Beattie, and Bresnahan scale and immunohistochemical staining with antineurofilament antibody. Thus, this targeting drug delivery system consisting of CBD-BDNF and LOCS could be an effective strategy for the repair of spinal cord injury (SCI). Nakaji-Hirabayashi *et al.*[175,176] also prepared BDNF carrying histidine groups at the C-terminus by recombinant DNA technology for enhancing cell survival in a hydrogel composed of hyaluronic acid.

Fibrin is an abundant protein present on the surface of injured tissues. In addition, it has been studied as a material for tissue engineering scaffolds. Therefore, growth factors with fibrin-binding affinity are considered useful for tissue regeneration. Sakiyama-Elbert *et al.*[196] produced a fusion protein between NGF and a short polypeptide of the α_2-plasmin inhibitor (α_2-PI); the activated coagulation factor XIII (FXIIIa) mediated the cross-linking of this sequence to fibrin. In addition, a plasmin cleavage sequence was inserted between the α_2-pI sequence and the growth factor. The fusion protein (TG-P-NGF) was incorporated into fibrin clots by FXIIIa and was then released by plasmin when the tissues started to heal. TG-P-NGF was designed to be released 'when cells demand.' The activity of the fusion protein was ~40% of that of native NGF, when assayed by neurite extension in PC12 cells. Unlike collagen-binding growth factors, this fusion protein bound to fibrin covalently. This may relate to the reduced activity observed in an *in vitro* assay. Fibrin-binding NGF (TG-P-NGF) mixed with fibrin gel enhanced neurite extension from chick embryo DRG (organ culture) by 50%, compared to native NGF, and by 350% relative to the fibrin gel alone, in spite of the reduced activity of the fusion construct.

Electrical stimulation plays an important role in inducing cell adhesion and differentiation and reducing inflammation. Incorporating neuroactive molecules, such as neurotrophic factors, ECM components, and topographical features for contact guidance, into electroconductive materials is a key goal in nerve tissue engineering. Polypyrrole (PPy) is known as a conductive polymer that has been widely studied for biomedical applications such as biosensors, drug delivering vehicles, and nerve tissue engineering. Therefore, Lee *et al.*[197–199] incorporated neuroactive molecules into PPy via a specific and stable method. They demonstrated that application of an external electrical potential to NGF-immobilized PPy films did not cause a significant release of NGF nor reduce their neurotrophic activity. The novel scaffold provided electroconductive and neurotrophic activities. Gomez *et al.*[200] reported that immobilized NGF and microtopography had distinct effects on polarization versus axon elongation in hippocampal cells in culture.

Coimmobilization of NGF and ECM proteins was performed by Achyuta *et al.*[45] to enhance neural adhesion and proliferation on surfaces for application in nerve tissue engineering and neuroprosthetic devices. They reported that in the absence of immobilized NGF, neurite growth of PC12 cell line is influenced strongly by the presence of NGF in solution and unaffected significant increases in laminin surface density (18.7–93.5 ng mm^{-2}). However, when both laminin and NGF were immobilized together, the surface density of laminin was an important factor in determining whether or not the neurite outgrowth-promoting effect of NGF can be obtained. Immobilized laminin was shown to play a synergistic role in the induction of neurite extension by NGF. It was considered that this approach may eventually be utilized to engineer surfaces that promote primary neuronal adhesion and proliferation on neural implant surfaces or on nerve tissue engineering scaffolds.

4.416.3.3.2.5. Bone morphogenic protein

Bone formation is one the most widely explored areas of tissue engineering.[201] A variety of biomaterials have been used as scaffolds for bone growth *in vitro* and *in vivo*, ranging from inorganics such as metals and ceramics to natural polymers such as collagen. Osteogenic factors and particularly members of the TGF-β superfamily have a key role in bone formation and repair. BMP-2 is one the most potent members of the BMP family for the induction of bone formation *in vivo*. BMP was immobilized on a variety of biomaterials, ranging from inorganics such as metals and ceramics to organics such as natural and synthetic polymers. Immobilization of BMP on metal surface was performed by several researchers. Adden *et al.*[202] prepared alkyl phosphonic acid monolayer films for immobilization of BMP-2 on titanium (Ti) surfaces. They employed (11-hydroxyundecyl)phosphonic acid or (12-carboxydodecyl)phosphonic acid to the metal surface. For coupling reaction, the former used carbonyldimidazole and the latter *N*-hydroxysuccinimide. Puleo *et al.*[203] immobilized BMP-4 on titanium alloy. Shi *et al.*[204] and Lim *et al.*[205] reported that the surfaces of Ti alloy substrates were functionalized by first covalently grafting carboxymethyl chitosan (CMCS), followed by the conjugation of BMP-2 to the CMCS-grafted surfaces. The modified substrates significantly promoted attachment, alkaline phosphatase activity, and calcium mineral deposition of both osteoblast and BMSCs. On the other hand, Kashiwagi *et al.*[206] created artificial proteins that contained three copies of a Ti-binding motif, and fused them to the N-terminal of BMP-2. The engineered BMP-2 showed reversible binding to Ti surfaces and induced BMP signaling activity.

Schuessele *et al.*[207] immobilized BMP-2 on hydroxyapatite (HA) disks. They employed a novel method using aminobisphosphonate, pamidronate, and alendronate, which are strong calcium ion chelating agents compared with the established silanization technique. Osteoblastic differentiation of C2C12 cells was efficiently induced by immobilized BMP-2. They concluded that the bisphosphonate-based surface modification represented a safe and easy alternative for the attachment of protein to HA surfaces. Kloss *et al.*[208] immobilized BMP-2 on nanocrystaline diamond (NCD). They demonstrated that coating of endosseous implants with NCD allowed stable functionalization by means of physisorption with BMP-2. Strong physisorption was shown to be directly related to the unique properties of NCD, and BMP-2 in its active form interacted strongly when NCD was oxygen-terminated. They indicated that the technical advancement is application in clinical therapies with regard to bone healing, as primary human mesenchymal stromal cells strongly activated the expression of osteogenic markers, while being cultivated on NCD physisorbed with physiological amounts of BMP-2.

BMP was also immobilized onto natural biopolymeric materials. For example, Karageorgiou *et al.*[209] immobilized BMP-2 onto silk fibroin films using carbodimide chemistry. Using cell culture inserts, it was demonstrated that differentiation was induced by the immobilized BMP-2 and not by BMP-2 released into the culture medium. Culture of cells in a medium, apart from immobilized growth factor, is one evidence indicating the activity of immobilized growth factors. Transwell™ substrates composed of semipermeable polyester membranes are a convenient medium-permeable but growth factor-impermeable tool to study the cell stimulating effects of released growth factors. If cell growth on the semipermeable membrane was not enhanced and the growth of cells on

immobilized surface is enhanced, this demonstrates that the immobilized growth factor is active without release. Comparison with similar amounts of medium-supplemented BMP-2, where no additional BMP-2 was added with medium changes, showed that delivery of BMP-2 immobilized on the biomaterial surface was more efficient than soluble delivery. They concluded that BMP-2 covalently coupled on silk biomaterial matrices retained biological function *in vitro* on the basis of the induction of osteogenic markers in seeded bone marrow stromal cells.

Tsujigiwa *et al.*[210,211] and Yamachika *et al.*[212] immobilized BMP-2 on succinylated type I atelocollagen and the immobilized BMP enhanced the osteoblastic differentiation. In addition, the phosphorylation of receptor-activated Smads, part of the signaling pathway activated by BMP-2, was prolonged by immobilized BMP-2. Implantation of immobilized BMP-2 into the backs of rats promoted the formation of mature bone-like structure. They demonstrated that immobilized BMP-2 had higher bioactivity than nonimmobilized BMP-2. Park *et al.*[213] immobilized BMP-2 on nanofibrous chitosan membranes used for guided bone regeneration. The BMP-2-conjugated surface increased osteoblastic cell attachment proportional to the amount of BMP-2 conjugated. In addition, the BMP-2-conjugated chitosan membrane significantly promoted cell proliferation, ALP activity, as well as calcium deposition when compared with BMP-2 adsorbed membrane, indicating a stable localization of BMP-2 at the surface of the chitosan membrane.

Chen *et al.*[214] and Zhao *et al.*[215,216] developed collagen-binding BMP-2. They explored a collagen-containing mineralized bone-derived matrix (CCMBM) from bovine bone tissues, which not only maintains proper mechanical strength but also binds to the collagen-binding recombinant human collagen-binding bone morphogenetic protein-2 (CBD-BMP-2). By analyzing its morphology and composition, they found that CCMBM was porous and mainly composed of calcium compounds. CCMBM could provide mechanical support for bone injury repair. It also showed good biocompatibility and proper degradation rate helpful for bone regeneration. In addition, the intentionally preserved collagen allowed the specific binding of CBD-BMP-2 to CCMBM and resulted in significantly increased osteogenesis *in vivo*. The results indicated that the combination of CCMBM with collagen-binding BMP-2 could emerge as an effective medical device for bone repair. Chen *et al.*[214] subcutaneously implanted demineralized bone matrix (DBM) combined with CBD-BMP-2 and showed ectopic bone formation in rats. They also showed that BMP-2-loaded DBM was effective in the repair of rabbit mandible bone defects, with an efficiency that was 10–20% higher than that of native BMP-2/DBM. Lin *et al.*[217] employed DBM, collagen-based viscous scaffold, but its low mechanical strength and limited BMP-2 binding ability restrict its application in bone repair. They cross-linked heparin to DBM to increase its BMP-2-binding ability. The mechanical strength of DBM was dramatically increased. The compression modulus of heparin-cross-linked DBM (HC-DBM) was improved (sevenfold increased) under wet conditions, which would allow the scaffolds to keep specific shapes *in vivo*. As expected, HC-DBM showed specific binding ability to BMP-2. Additional studies showed that the bound BMP-2 exerted its function to induce cell differentiation on the scaffold. Subcutaneous implantation of HC-DBM carrying BMP-2 showed higher ALP activity (2 weeks), more calcium deposition (4 and 8 weeks), and more bone formation than that of control groups. It was concluded that HC-DBM has increased mechanical properties as well as specific BMP-2 binding ability.

Schmoekel *et al.*[218] prepared fibrin-binding BMP-2 (TG-pI-BMP-2) and its mediated elevation of ALP activity in C3H10T1/2 cells was comparable with that observed for native BMP-2, while its retention in a fibrin gel was higher than that of the native protein (60% vs. 25% of added amount). They examined the effects of TG-pI-BMP-2 in a rat craniotomy defect model and revealed that the healing area was 76% larger than that observed for native BMP-2. In addition to craniofacial bones, this study was extended to the repair of long bones, as assessed by bone bridging.

Immobilization onto synthetic polymers has also been reported. Edlund *et al.*[219] immobilized BMP-2 onto polylactide (PLA) or PCL which were the most commonly used degradable polymers and have been extensively studied for temporary supports. They prepared heparin covalently bonded surfaces and BMP-2 was immobilized in the heparin layer. The coupling scheme involved functionalization of surfaces by grafting in the vapor phase with PLA and PCL films. The biocompatibility of functionalized surfaces was verified by a much improved attachment and proliferation of MSCs. Shen *et al.*[220] reported immobilization of BMP-2 onto polylactone-type polymer scaffolds via plasma treatment. To introduce proper functional groups on the surface of poly(lactide-*co*-glycolide) (PLGA) matrix, PLGA films were treated under different atmospheres. Oxygen plasma-treated PLGA has the strongest binding ability to BMP-2. When mouse OCT-1 cells were cultured on the BMP-2-immobilized PLGA, the immobilized BMP-2 stimulated differentiation of OCT-1 cell and accelerated process of mineralization of OCT-1 cell in the scaffolds. Liu *et al.*[221] used heterobifunctional acrylate-*N*-hydroxysuccinimide PEG as a spacer to tether BMP-2 onto a PLGA scaffold. Use of PEG-tethered BMP-2 was feasible because BMP-2 retained its activity after covalent conjugation. The PEG-tethered BMP-2 conjugate sustained stimulation and retained its mitogenic activity, notably affecting pluripotent stem cell proliferation and differentiation. They seeded the scaffolds with bone marrow-derived mesenchymal stromal cells as progenitor cells to evaluate their morphology and phenotypic expression. They also created bilateral, full-thickness cranial defects in rabbits to investigate the osteogenic effect of cultured mesenchymal stromal cells on bone regeneration *in vivo*. Histomorphometry and histology demonstrated that the PEG-tethered BMP-2 conjugate enhanced *de novo* bone formation after surgery. Winkler *et al.*[222] reported that heating of BMP-2 depots on various materials to 100 °C augmented the intensity of local ALP induction. They considered that the heat treatment generated both soluble pool of BMP-2 and a materials-bound layer of BMP-2 in which the protein is protected against degradation and it appeared useful to locally immobilize BMP-2 on various implant surfaces.

BMP-3 is also a potent osteoinductive growth factor belonging to the TGF-β superfamily. Han *et al.*[223] engineered a recombinant BMP-3 protein to include an auxiliary collagen-targeting domain derived from vWF. The renatured rhBMP3-C fusion protein bound tightly to collagen matrices and inhibited

DNA synthesis in normal rat calvaria cells and in two out of three human osteosarcoma cell lines tested. ALP activity was increased in rat calvarial cells and was decreased in osteosarcoma cells *in vitro* in a dose-dependent manner. Collagen sponges impregnated with rhBMP3-C and implanted subcutaneously in Fischer-344 rats induced dose-dependent dystrophic calcification of the collagen matrix, with no evidence of ectopic bone formation. However, local injection of rhBMP3-C infused in a collagen suspension induced new bone formation on the periosteal surface of rat calvaria. In a rat cranial defect model, surgical implantation of rhBMP3-C arrayed on either collagen sponges or on porous ceramics coated with type I collagen exhibited marked osteoinductive properties. Taken together, these results demonstrate the feasibility of engineering and manufacturing targeted-BMPs, which exhibit an integral gain-of-function that may be exploited to therapeutic advantage in (1) the enhancement of effective local concentrations, (2) the prevention of systemic biodistribution and side effects, and (3) the design of improved osteoinductive matrices.

Oligopeptides derived from BMP-2 and BMP-7 were immobilized on alginate hydrogels and glass, respectively. Suzuki *et al.*,[224] Saito *et al.*,[225] and Kirkwood *et al.*[226] prepared synthetic oligopeptide derived from BMP-2 and demonstrated osteoinduction in immobilized alginate. Recently, Sharon and Puleo[227,228] attempted to control the orientation of bioactive molecules immobilized on a biodegradable substrate to improve their accessibility for binding to cell surface receptors and, therefore, to increase bioactivity. The osteotropic peptide, parathyroid hormone (1–34) (PTH(1–34)) was used to demonstrate the approach. The intrinsic N-terminal serine residue was oxidized to create an aldehyde group that specifically bound to hydrazide-derivatized PLGA under neutral conditions to form a hydrazone bond. Use of dihydrazide spacers significantly increased the amount of peptide immobilized compared to simple adsorption or direct, random attachment. In probing the accessibility of immobilized PTH(1–34), attachment using longer dihydrazide spacers enhanced the binding of an antibody against an epitope in the N-terminal region of the peptide. The longest spacer also increased binding of a C-terminal antibody. Furthermore, substrates with peptide tethered via spacers stimulated intracellular synthesis of cAMP, with activity increasing with dihydrazide length. PTH(1–34) immobilized using the longest spacer was significantly more effective than both random binding and adsorption. Site-directed binding of bioactive peptides to surfaces presents biomolecules for binding with cells so as to enhance interaction with receptors, and therefore the approach may be useful for obtaining preferred localized tissue responses.

Lee *et al.*[197–199] showed that self-assembled nanostructures consisting of BMP receptor-binding peptides, termed osteopromotive domains (OPDs), and hydrophobic alkyl chains were fabricated with the aim of developing 3D scaffolding materials for osteoblastic differentiation. OPD peptide was identified from BMP-2 and had an affinity for BMP receptors thereby inducing differentiation of human bone marrow stromal cells into osteoblastic cells. The peptide-hydrophobic alkyl chain amphiphiles were designed to mimic nanofibrous extracellular structures and to add osteogenic ligands to enhance osteoblastic cell function. The OPD peptide-amphiphiles (OPDAs) that end with the alkylation of the N-terminus of the OPD peptide were synthesized by standard solid phase chemistry. The self-assembly was triggered by mixing OPDA solution with calcium ions. Observation using scanning electron microscopy (SEM) revealed the formation of nanofibrous structures with extremely high aspect ratios and high surface areas. The FT-IR and circular dichroism spectrophotometry demonstrated that self-assembled nanofibers have a β-sheet structure. The activation of Smad, an osteoblastic differentiation marker, was obtained in the cell culture gel of self-assembled OPDA; therefore, they concluded that the intracellular signal transduction for osteogenesis was performed in the same manner as it was done for an OPD peptide. Cell survival was supported in the OPDA gel for 10 days, and osteoblastic differentiation of human BMSCs was evident as demonstrated by calcein staining and ALP activity measurement. These results revealed that self-assembled OPDA maintained osteogenic activity through the surface-exposed OPD peptide. Taken together, the self-assembled OPDA nanofibrous gel can be utilized as a cell culture scaffold in bone regeneration.

4.416.3.3.2.6. Vascular endothelial growth factor

Tissue engineering and tissue regeneration approaches presently suffer from oxygen and nutrient delivery constraints because of the inability of current scaffolds to rapidly and reliably guide the formation of stable and long lasting vascular networks. Cell seeded or residing in the middle of the tissue construct has a limited supply of oxygen and nutrients as blood vessels do not infiltrate at an appreciable rate and the diffusion limit of oxygen is only a few hundred microns. VEGF is a key component in the signaling cascade to form new blood vessels from existing vessels and can trigger proliferation, migration, and survival of cells through a single growth factor–receptor binding event. It is known that VEGF exists as many different isoforms with different affinities for ECM because of alternative splicing.

Immobilization of VEGF has been reported by Taguchi *et al.*[229] They immobilized VEGF onto poly(arylic acid) grafted polyethylene films using (*N*-(3-dimethylaminoprophyl)-*N*′-enthylcarbodiinide hydrochloride) EDC chemistry and found that VEGF and FN coimmobilized surface greatly promoted the growth of human umbilical vein ECs (HUVECs). Ito *et al.*[230] photoimmobilized VEGF with gelatin and showed that the immobilized VEGF greatly enhanced the proliferation and surface coverage of HUVECs. They demonstrated that the specific interaction of immobilized growth factor with the cognate receptor was examined by the antibody against immobilized growth factor. If the effect of immobilized growth factor was inhibited by the antibody, the specific interactions were certified. They showed that adsorption of antibody against immobilized VEGF reduced the effect of immobilized VEGF.

Shen *et al.*[231,232] immobilized VEGF by EDC onto collagen scaffolds. They also found that immobilized VEGF (relative to soluble VEGF) promoted the penetration and proliferation of ECs in the collagen scaffold on the basis of the results of cell density analysis in histological sections, immunehistochemistry, 2,3-bis(2-methoxy-4-nitro-5-sulfony)-2H-tetrazoline-5-carboxanilide (XTT) proliferation assay, glucose consumption, and lactate production. Sharon and Puleo[227,228] employed another chemistry to immobilize VEGF on

biodegradable polymer PLGA. Exposed carboxy groups on acid-terminated PLGA were modified with dihydrazide spacer molecules. The number of hydrazide groups available for subsequent attachment of protein was dependent on dihydrazide length, with shorter molecules presenting a significantly greater surface density. Immobilized VEGF enhanced EC proliferation, with surfaces having the shortest and longest spacers stimulating greater effects.

Anderson *et al.*[233] designed another covalent immobilization of VEGF using its heparin-binding domain to orient the molecule (bind) and secondary functional group to mediate covalent binding (lock). This bind-and-lock approach aimed to allow VEGF to assume a bioactive orientation before covalent immobilization. Surface density of immobilized VEGF was determined by SPR and ELISA. The electrostatically and covalently bound VEGF successfully phosphorylated the receptor VEGFR-2.

Wang *et al.*[234] designed a synthetic collagen mimetic peptide (CMP) $((ProHypGly)_x$; Hyp: hydroxyproline) in contact with collagen and discovered CMP's structure-dependent binding affinity to type I collagen. Therefore, the CMP architecture consisting of multiple anionic charges at peptide's N-terminus is designed to attract VEGF by charge–charge interactions and bind to collagen by CMP–collagen interaction. By VEGF binding, the morphological features of ECs, indicative of tubulogenesis but not equivalent to functional angiogenesis, were enhanced.

Protein engineering for binding VEGF was performed using the $VEGF_{121}$ isoform lacking the fibrin-binding sequence found in the major isoform ($VEGF_{165}$) as reported by Sahni and Francis.[235] Fusion with the α_2-PI sequence enabled the incorporation of $VEGF_{121}$ into a fibrin gel by Zisch *et al.*[236] and Ehrbar *et al.*[237] In addition, the fusion protein (α_2-PI_{1-8}-$VEGF_{121}$) stimulated the growth of ECs on the gel in a dose-dependent manner. Fibrin-binding $VEGF_{121}$ (α_2PI_{1-8}-$VEGF_{121}$) mixed with fibrin exhibits efficacious angiogenic properties, as assessed using a chorioallantoic membrane assay by Ehrbar *et al.*[237]: the blood-vessel density in the presence of fibrin-binding $VEGF_{121}$ was $\sim$1.5 times higher than that induced by native $VEGF_{121}$. In addition, α_2PI_{1-8}-$VEGF_{121}$ induced the formation of nonleaky vessels on a Teflon chamber coated with fibrin and subcutaneously implanted. Backer *et al.*[238] engineered a cysteine tag into VEGF, then conjugated VEGF onto FN-coated surfaces via the cysteine-tag, and observed growth stimulation of VEGFR-2 overexpressing cells. The maltose-binding protein (MBP), which possesses a large number of exposed hydrophobic zones, was used as a link for the immobilization of VEGF by Han *et al.*[194,195] Cell adhesion onto the VEGF-immobilized surface was enhanced and the phosphorylation of VEGFR in cells was observed on the immobilized surface. Ishikawa *et al.*[239] prepared collagen-binding VEGF using CBD found in FN.

In addition to VEGF, the other growth factor coimmobilization has also been carried out. Arkudas *et al.*[240,241] quantitatively assessed the angiogenic effects of different concentrations of VEGF and bFGF immobilized in a fibrin-based drug-delivery system in the arteriovenous (AV) loop model. An AV loop was created in the medial thigh of 60 rats. The loop was placed in a Teflon isolation chamber and embedded in 500 µl of fibrin gel loaded with VEGF and bFGF in four different concentrations (no growth factor, 100 ng ml^{-1} of VEGF, 25 ng ml^{-1} of VEGF and bFGF, 100 ng ml^{-1} pf VEGF and bFGF). The explanation intervals were 1, 2, and 4 weeks after the initial operation for all groups. Specimens were investigated using micro-CT and histological and morphometrical techniques. After 2 weeks, the cross-section area and construct weight were significantly lower with the use of 100 ng ml^{-1} of VEGF and bFGF. Micro-CT and histology showed significantly greater vascular density and number of vessels of the constructs at 2 and 4 weeks when 100 ng ml^{-1} of $VEGF_{165}$ and bFGF were applied than in the growth factor-free specimens. The angioinductive effects were dose-dependent, with best results when 100 ng ml^{-1} of $VEGF_{165}$ and bFGF were used. The greater tissue formation was accompanied by faster resorption of the fibrin matrix.

Chiu and Radisic[242] coimmobilized VEGF and angiopoietin 1 (Ang1) onto 3D porous collagen scaffolds using EDC chemistry. Over both 3 and 7 days *in vitro*, seeded ECs had increased proliferation on scaffolds with immobilized VEGF and/or Ang1 compared to that on unmodified scaffolds with soluble growth factor controls. Notably, the group with coimmobilized VEGF and Ang1 showed significantly higher cell number, higher overall lactate production rate, and higher overall glucose consumption rate at day 3 than its corresponding soluble control for which growth factors were added to culture medium. By day 7, hematoxylin and eosin, live/dead, CD31, and vWF staining all showed improved tube formation by ECs when cultivated on scaffolds with coimmobilized growth factors. Interestingly, scaffolds with coimmobilized VEGF and Ang1 showed increased EC infiltration in the chorioallantoic membrane assay, compared to scaffolds with independently immobilized VEGF/Ang1. They presented an alternative method for promoting the formation of vascular structures, via covalent immobilization of angiogenic growth factors that are more stable than soluble ones and have a localized effect.

Leslie-Barbick *et al.*[243] investigated strategies to facilitate vascularization in scaffold materials, in their case, PEG hydrogels. The hydrogels are hydrophilic and resist protein adsorption and subsequent nonspecific cell adhesion, but can be modified to contain cell-adhesive ligands and growth factors to support cell and tissue function. In addition, the hydrogel matrix can include proteolytically degradable peptide sequences in the backbone of the structure to allow cells to control scaffold biodegradation, allowing 3D migration. VEGF, a potent angiogenic signal, and the cell-adhesive peptide arginine-glysine-aspartic acid-serine (RGDS) were covalently attached to PEG monoacrylate linkers. PEGylated RGDS and VEGF were then covalently immobilized in PEGDA hydrogels in 2D and 3D. Immobilized VEGF increased EC tubulogenesis on the surface of nondegradable PEGDA hydrogels fourfold compared to controls without the growth factor. EC behavior in 3D collagenase-degradable hydrogels modified with RGDS and VEGF was observed using time-lapse confocal microscopy. Bulk immobilization of VEGF in 3D collagenase-degradable RGDS-modified hydrogels increased EC motility 14-fold and cell–cell connections 3-fold. Covalent incorporation of PEGylated VEGF in PEG hydrogels can be a useful tool to promote EC migration, cell–cell contact formation, and tubulogenesis in an effort to produce vascularized tissue-engineered constructs.

4.416.3.3.2.7. Fibroblast growth factor

DeLong *et al.*[244] immobilized bFGF to hydrogel scaffolds with the retention of mitogenic and chemotactic activity. The bFGF was functionalized to incorporate it covalently within PEG hydrogel scaffolds by reaction with acryloyl-PEG-NHS. Hydrogels were formed by exposing aqueous solutions of PEGDA, acryloyl-PEG-RGDS, and acryloyl-PEG-bFGF to long-wavelength ultraviolet light in the presence of a photoinitiator. These bFGF-modified hydrogels with RGD adhesion sites were evaluated for their effect on vascular SMC behavior, and it was found that SMC proliferation increased by ~41% and migration by ~15%. A covalently immobilized bFGF gradient was formed using a gradient maker to pour the hydrogel precursor solutions and then photopolymerizing to lock in the concentration gradient. Silver staining was used to detect the bFGF gradient, which increased linearly along the hydrogel's length. Cells were observed to align on hydrogels modified with a bFGF gradient in the direction of increasing tethered bFGF concentration as early as 24 h after seeding. SMCs also migrated differentially, up the concentration gradient, on bFGF-gradient hydrogels compared to control hydrogels with and without a constant bFGF concentration. These hydrogel scaffolds may be useful for studying protein gradient effects on cell behavior and for directing cell migration in tissue-engineering applications.

Ito *et al.*[160] micropattern-immobilized heparin on a polystyrene plate for adsorption of bFGF and demonstrated that the growth of NIH3T3 cells was enhanced only in the heparin-immobilized regions. This result indicated that gradient-micropattern-immobilized heparin activated bFGF for cell growth. In addition, the growth of cells was found to be affected by the surface density of immobilized heparin. The surface density was regulated by a gap length of 2 μm-width stripes immobilized with heparin. Although a high density (a region having short gap length) of immobilized heparin suppressed the cell growth in the absence of bFGF, it enhanced cell growth in the presence of bFGF. The dependence of cell function on the density of immobilized heparin was visualized by gradient-micropattern-immobilization. Christman *et al.*[245] prepared a heparin-mimicking polymer and micropattern-immobilized the polymer for bFGF or VEGF micropatterned adsorption.

Watanabe *et al.*,[246] Campbell *et al.*,[247] and Miller *et al.*[248] investigated cell behavioral responses to inkjet printed spatial patterns of hormones biologically immobilized on biomimetic substrates, by using the example of preosteoblastic cell response *in vitro* to FGF-2 printed on fibrin films. Concentration-modulated patterns of FGF-2, including continuous concentration gradients, were created by overprinting dilute FGF-2 bioinks with a custom inkjet printer. The immobilized FGF-2 was biologically active and the printed patterns persisted up to 10 days under cell culture conditions. Cell numbers increased in register with printed patterns from an initial random uniform cell distribution across the patterned and nonpatterned fibrin substrate. Pattern-immobilized FGF-2, not cell attachment, directed cell organization because the fibrin substrate was homogeneous. The capability to engineer arbitrary and persistent hormone patterns was relevant to basic studies across various fields including developmental biology and tissue regeneration. MG-63 cells were uniformly seeded onto patterned substrates. Cells were exposed to defined spatial FGF-2 surface concentrations of 1–22 pg mm^{-2}. Cell numbers were observed to increase in register with the printed FGF-2 patterns from an initial random uniform cell distribution across the patterned and nonpatterned regions. Higher surface concentrations did not result in increased cell density. In addition, the cells on the FGF-2 patterns survived longer than the cells off patterns. They demonstrated that the inkjet printing approach permits the systematic study of cellular responses to defined spatial surface concentrations of immobilized growth factors.

Activation of FGFRs requires the formation of a ternary complex between FGFs, FGFRs, and heparan sulfate proteoglycans, which are all located on the cell surface and the BM/ECM. Heparan sulfate proteoglycans appear to stabilize FGFs by inhibiting the rapid degradation of FGFs normally observed in solution. Because of the pivotal role of FGFs in proliferative and developmental pathways, a number of recent studies have attempted to engineer microenvironments to stabilize growth factors for use in applications in tissue culture and regenerative medicine. Nur-E-Kamal *et al.*[249] demonstrated that covalent linkage of FGF-2 to nanofibrillar surfaces (defined as covalently bound FGF-2) composed of a network of polyamide nanofibers resulted in the maintenance of the biological efficacy of FGF-2 when stored dry for at least 6 months at 25 or 4 °C. Moreover, covalently bound FGF-2 was more potent than FGF-2 in solution when measured in cellular assays of proliferation and viability using a variety of cell types. Covalently bound FGF-2 also strongly activated FGFR, ERK1/2, and c-fos. Hence, cell-signaling molecules can be incorporated into synthetic nanofibrillar surfaces, providing a novel means to enhance their stability and biological activity.

Shen *et al.*[231,232] immobilized bFGF on carbon dioxide plasma-treated PLGA films. They found that adhesion and growth of cells on PLGA scaffolds were greatly improved by immobilization of bFGF on them. Mori *et al.*[250] and Ijiri *et al.*[251] immobilized growth factors such as FGF in stable infectious microcrystals called polyhedra which function to protect a certain insect virus after the death of infected larvae. They showed that FGF-2, FGF-7, and EGF immobilized on polyhedra were functional, inducing the growth of fibroblast cells and keratinocytes. In addition to these organic materials, FGFs have been immobilized on metals and ceramics. Ohyama *et al.*[252] immobilized bFGF onto a platinum microcoil to enhance tissue organization in intracranial aneurysms. Ultrathin multiorganic layers were assembled on a platinum coil through successive deposition of cationic polyethylenimine and anionic heparin, and then bFGF was immobilized through an affinity interaction with heparin. bFGF was effectively immobilized on the surface of the platinum coil without deterioration of the coil's mechanical properties. Coil embolization of aneurysms constructed using a canine common carotid artery was performed via the endovascular approach. The aneurysms together with parent arteries were harvested 2 weeks after coil embolization. Platinum coils unmodified, coated with heparin, or immobilized with heparin and bFGF were examined. The percentage of occlusion at the aneurysm orifice in animals treated with bFGF-immobilized coils was significantly greater than that in animals treated with heparin-coated coils or unmodified coils. The histological score of the aneurysms

treated with bFGF-immobilized coils was also significantly greater than the scores in the control group. They indicated that bFGF-immobilized microcoils may be beneficial in the obliteration of aneurysms. Peelen *et al.*[253] immobilized bFGF on gold film for the specific capture of mammalian cells by FGF receptor binding. Kokubu *et al.*[254] investigated the behavior of rat periodontal ligament (PDL) cells cultured on FGF-2-immobilized titanium surfaces treated by oxygen plasma. They used cell disks (15 mm in diameter), and 35-mm culture dishes sputter-coated with titanium. These were treated with oxygen plasma and dipped in FGF-2 solution. The PDL cells were obtained from rat incisors. Proliferation ratio, ALP activity, and expressions of type I collagen and VEGF mRNAs were evaluated. Proliferation ratio and expressions of type I collagen and VEGF mRNAs were significantly higher, whereas ALP activity was significantly lower in FGF-2-immobilized cells than in the control group. These findings suggested that oxygen plasma modification can immobilize FGF-2 onto a titanium surface. Immobilized FGF-2, although inferior to culture medium with FGF-2, influenced the proliferation of PDL cells and might have promoted collagen and vascular synthesis.

Sogo *et al.*[255] reported formation of a FGF-2 and calcium phosphate composite layer on HA ceramic for promoting bone formation. To avoid the risk of FGF-2 denaturation, FGF-2 immobilization was carried out at 25 °C. FGF-2 was successfully immobilized on HA ceramic surfaces by deposition with calcium phosphate to form an FGF-2 and calcium phosphate composite layer. A maximum of $2.72 \pm 0.01\ \mu g\,cm^{-2}$ of FGF-2 was immobilized in the composite layer formed on the HA ceramic under the optimum condition. An FGF-2-immobilized HA ceramic is likely to have the ability to release sufficient amount of FGF-2 to promote bone formation. FGF-2 released from an FGF-2-immobilized HA ceramic maintained its biological activity, as the proliferation of fibroblastic NIH3T3 was promoted. Therefore, the FGF-2-immobilized HA ceramic is expected to be a useful material for promoting new bone formation.

Lee *et al.*[197–199] prepared two synthetic peptides derived from FGF-2, namely residues 36–41 (F36; PDGRVD) and 77–83 (F77; KEDGRLL), and their N-termini were further modified for ease of chitosan surface immobilization. The adhesion of MSCs to the peptide (F36 and F77)-immobilized chitosan membrane was increased in a dose-dependent manner and completely inhibited by soluble RGD (Arg-Gly-Asp) and antiintegrin antibody, indicating the existence of an interaction between F36/F77 and integrin. Peptide-immobilized chitosan supported human bone-marrow-derived mesenchymal-stem-cell differentiation into osteoblastic cells, as demonstrated by alkaline phosphate expression and mineralization.

Andrades *et al.*[256] showed that collagen-binding bFGF dissolved in collagen solution accelerates wound healing, both in normal and in diabetic rats. Implantable scaffolds combined with collagen-binding growth factors have also been studied. Brewster *et al.*[257] generated another collagen-binding bFGF of which the bFGF part was an engineered one that has thrombin resistance. These authors used SPR analysis to show that the binding affinity of the fusion protein was fourfold higher than that of native FGF and the engineered bFGF part alone. collagen binding-bFGF stimulated EC angiogenesis in fibrin gel. However, the advantage of the collagen-binding affinity of the fusion protein during angiogenesis was not clearly shown via comparison with unfused bFGF.

Zhao *et al.*[258,259] developed a fibrin-binding FGF. To endow bFGF with fibrin-targeting ability, a fibrin-binding peptide Kringle1 (K1), derived from human plasminogen, was fused to human bFGF. The recombinant K1bFGF showed high fibrin and plasma-clot-binding ability. When applied to the wound sites with plasma clots, K1bFGF induced robust neovascularization and improved wound healing. To extend the application of K1bFGF to other cases where no plasma clots exist, they developed a fibrin-scaffold/K1bFGF system. This system could induce localized neovascularization by delivery of K1bFGF in a sustained and site-targeting manner, and provide a microenvironment promoting cell growth and tissue regeneration. They successfully used the pathologic environment of fibrin clot as the target for bFGF, on the basis of which bFGF was designed into a targeting agent by the introduction of a fibrin-binding peptide. This provided a potential approach to improve therapeutic neovascularization and wound repair. Zhao *et al.*[258] compared a short polypeptide sequence of vWF with that of human collagenase as the fusion partner for bFGF and found that the latter provides a higher binding affinity to collagen. Considering that the same growth factors fused with different partner polypeptides were synthesized, the properties of these factors were compared by Zhao *et al.*[259] They demonstrated that vessel migration into collagen scaffolds was enhanced by CBD-bFGF, although the collagen-binding affinity did not vary much between native bFGF and CBD-bFGF. The difference in the angiogenic effect between native and engineered bFGFs was apparent at 7 days, but not at 4 days, after implantation.

4.416.3.3.2.8. Transforming growth factor β

TGF-β represents a superfamily of over 30 protein growth factors. Ti and Ti alloys are often used for orthopedic and dental implants. Osseointegration of Ti6Al4V may be improved not only by precoating of the surface with ECM proteins like type 1 collagen but also by additional immobilization of growth factors. Fischer *et al.*[260] immobilized TGF-β, which is known as an inducer of collagen synthesis. It was immobilized adsorptively on uncoated and type 1 collagen coated Ti6Al4V surfaces. TGF-β was found immobilized slightly faster to type 1 collagen-coated than to uncoated Ti6Al4V and released slower from the collagen-coated material. Immobilized TGF-β was biologically active for at least 3 weeks storage at 4 °C. Sterilization by ethylene oxide inactivates immobilized TGF-β. In osteoblasts cultured on implants with adsorptively immobilized TGF-β, mRNA level and specific catalytic activity of ALP as well as accumulation of calcium and phosphate were found reduced, whereas procollagen α1(I) mRNA level and the rate of collagen synthesis were increased.

The downgrowth of corneal epithelial cells at the interface of an artificial cornea and the host eye tissue poses a significant problem to be overcome in developing a successful implant. As a means of inhibiting the proliferation of corneal epithelial cells on the stromal surface of the implant, Merrett *et al.*[261] examined the immobilization of TGF-β2 via a bifunctional PEG spacer to poly(dimethylsiloxane) surfaces.

Biomaterials developed for tissue engineering and wound healing applications need to support robust cell adhesion, yet also need to be replaced by new tissue synthesized by

those cells. In order to maintain mechanical integrity of the tissue, the cells must generate sufficient ECM before the scaffold is degraded. On the other hand, Mann *et al.*[262] found that TGF-β1 can be used in scaffolds to dramatically increase ECM production. Matrix production by vascular SMCs grown on adhesive ligand-modified glass surfaces and in PEG hydrogels containing covalently bound adhesive ligands was increased in the presence of 0.04 pmol ml^{-1} (1 ng ml^{-1}) TGF-β1. TGF-β1 can counteract the effect of these adhesive ligands on matrix production; matrix production could be increased even above that observed in the absence of adhesive peptides. Further, TGF-β1 covalently immobilized to PEG retained its ability to increase matrix production. Tethering TGF-β1 to the polymer scaffold resulted in a significant increase in matrix production over the same amount of soluble TGF-β1.

To overcome rapid diffusion and clearance from the implant site and to increase stability, recombinant TGF-β2 was covalently bound to injectable bovine dermal fibrillar collagen and its activity compared to admixed TGF-β by Bentz *et al.*[263] Covalent binding was achieved in a two-step procedure: First, TGF-β2 was made to react with the difunctional PEG linker, and then the PEG-attached TGF-β2 (PEG-TGF-β2) was bound to the fibrillar collagen. After reaction with injectable fibrillar collagen, extraction of unbound PEG-TGF-β2 and Western blot analysis, using a TGF-β-specific antibody, demonstrated that at least 85% of the TGF-β2 was bound to the fibrillar collagen. The activity of PEG-TGF-β2 was fully stable in phosphate-buffered saline at 4 and 37 °C for at least up to 4 weeks. Unmodified TGF-β2 mixed with fibrillar collagen was completely inactivated after 1 week of incubation, as measured by the mink lung epithelial cell growth inhibition assay. TGF-β2-containing formulations showed the TGF-β typical fibroblastic response at the day 7 time-point. Covalent binding of TGF-β2 to collagen with both difunctional PEG cross-linkers resulted in a significantly stronger and longer lasting TGF-β2 response than that observed with admixed formulations of collagen and TGF-β. The TGF-β response with bound PEG-TGF-β2 lasted up to day 42 but was not seen after day 7 for TGF-β2 admixed to fibrillar collagen. The findings clearly demonstrated that TGF-β2 remains fully active after being covalently bound to collagen via difunctional PEG. In addition, covalent binding potentiates and prolongs *in vivo* TGF-β responses and stabilizes the TGF-β *in vitro*. Their results suggest that this method of formulation could be useful to stabilize and deliver similar peptide growth factors or biologically active agents.

Tuan *et al.*[264] reported biologically active TGF-β1 tripartite fusion proteins consisting of (1) a purification tag, (2) a protease-sensitive linker/collagen binding domain, and (3) a cDNA sequence encoding the active fragment of human TGF-β 1. Purified collagen-binding TGF-β exhibited antiproliferative activities comparable to purified platelet TGF-β1, but at lower specific activities. Coupling of proteins was achieved with TGF-β on collagen gels by the addition of an auxiliary collagen binding domain (WREPSFMALS) by Andrades *et al.*[256] They showed that the result was better access of the protein to the cells because of a longer half-life and slower release, resulting in more potency than TGF-β1 supplied directly in medium.

Chou *et al.*[265] immobilized TGF-β1 onto the surface of the tri-*co*-polymer sponge to suppress undesired cell differentiation during the cartilage growth *in vitro*. Tri-*co*-polymer with the composition of gelatin, hyaluronic acid, and chondroitin-6-sulfate has been used to mimic the cartilage ECM as scaffold for cartilage tissue engineering. The scaffold was synthesized with a pore size in the range of 300–500 μm. TGF-β1 was immobilized on the surface of the tri-*co*-polymer scaffold with EDC as a cross-linking agent. Tri-*co*-polymer scaffolds with and without TGF-β1 were seeded with porcine chondrocytes and cultured in a spinner flask. After culturing for 4 weeks, chondrocytes expressed S-100 protein, Alcian blue, and type II collagen for the scaffold with TGF-β1 immobilization. There was no observed type I and type X collagen expression in the scaffolds by observation of RT-PCR. In addition, in the scaffold without TGF-β1 immobilization, type X collagen could be detected after culture for 2 weeks. Type I collagen was progressively expressed after 4 weeks. They concluded that TGF-β1-immobilized scaffold suppressed chondrocytes toward prehypertrophic chondrocytes and osteolineage cells. TGF-β1 immobilization was considered to be of great potential in cartilage tissue engineering.

On the other hand, Bhatnagar *et al.*[266] reported another type of immobilization for TGF-β. They prepared cross-linked hydrogel features patterned using subtractive lift-off of polymerized hydrogel film. Projection lithography and oxygen plasma etch were used to pattern parylene C polymer film. Molecular self-assembly of polymerizable monolayer was obtained in solution-phase and acrylamide-based hydrogel was polymerized using free-radical polymerization on this substrate. Parylene C film was mechanically lifted off to remove the blanket hydrogel film and microhydrogel features were obtained attached to the predefined patterns in the range from 1 to 60 μm. The microhydrogels were functionalized with aldehyde functional groups, and proteins were coupled to them using Schiff base chemistry followed by reductive amination. Interaction of MSCs with TGF-β1 functionalized features was studied and TGF-β1-was found to retain its tumor suppression activity.

4.416.3.3.2.9. Hepatocyte growth factor

Immobilization of HGF was reported by Kitajima *et al.*[267] for the first time. They prepared a fusion protein consisting of HGF (an angiogenic factor) and CBD polypeptide of FN. The fusion protein (CBD-HGF), produced by a baculovirus expression system, exhibited much stronger collagen binding activity than native HGF in the range of 0.4–6.4 μg ml^{-1}. Its binding at the lowest concentration exceeded that of HGF at the highest concentration. In addition, the collagen-bound CBD-HGF promoted growth of ECs to a greater degree at least 4 days longer than HGF added to the culture medium, and afforded about fivefold greater increase in cell number after 10 days. These findings suggest that the fused CBD moiety not only helped immobilize HGF on collagen but also helped stabilize the fusion molecule, resulting in prolonged activity. The angiogenic activity of CBD-HGF in animal tissues was examined by subcutaneously implanting collagen sponges containing bound CBD-HGF. Blood vessel formation in the sponges after 7 days was 4–6-fold more extensive than in the control sponges without modification. Implanted sponges with native HGF did not show significant differences from control. These results indicate that CBD-HGF is suitable for *in vitro* culture of ECs and that this fusion protein can be used to confer HGF activity on biomaterials for use in tissue engineering.

Jones *et al.*[49] also investigated solid-phase presentation of HGF on microarrays of ECM proteins. In their experiments, HGF was mixed in solution with ECM proteins (types I and IV collagen or laminin) and robotically printed onto silane-modified glass slides. Primary rat hepatocytes were seeded onto HGF–ECM protein microarrays and formed cellular clusters that corresponded in size to the dimensions of individual protein spots (500-μm diameter). Analysis of liver-specific products, albumin and α1-antitrypsin, revealed several fold higher levels of expression of these proteins in hepatocytes cultured on HGF–ECM microarrays compared to cells cultivated on ECM proteins alone. In addition, cultivation of hepatocytes on HGF/ECM protein spots led to spontaneous reorganization of cellular clusters from a monolayer into 3D spheroids. They investigated the effects of surface-tethered HGF on hepatocytes cocultivated with stromal cells and observed a significantly higher level of albumin in cocultures where hepatocytes were stimulated by HGF–ECM spots compared to cocultures created on ECM protein islands without the growth factor. They demonstrated that incorporation of HGF into ECM protein microarrays has a profound and long-lasting effect on the morphology and phenotype of primary hepatocytes.

A recombinant HGF fused to an IgG Fc region was constructed by Azuma *et al.*[268] Almost similar amounts of HepG2 cells adhered to the fusion protein-coated surface compared to collagen-coated controls with large morphological changes. Immobilized fusion protein continuously activated Akt in HepG2 cells whereas Akt activation induced by soluble HGF rapidly decreased with time, indicating that immobilized fusion protein followed different signal transduction pathways from that followed by soluble HGF.

HGF is known to stimulate EC proliferation. However, reendothelialization is not enhanced when the native protein is administered to the injured artery, probably because of the short half-life of HGF at the site of injury. Therefore, the effects of an HGF fusion protein having CBD-HGF on reendothelialization and neointimal formation were studied in the balloon-injured rat carotid artery by Ohkawara *et al.*[269] The left common carotid artery of male Sprague-Dawley rats was injured with an inflated balloon catheter, and then treated with CBD-HGF ($10\,\mu g\,ml^{-1}$), HGF ($10\,\mu g\,ml^{-1}$), or saline (control) for 15 min. After 14 days, the rats were injected with Evans blue and sacrificed. The reendothelialized area was significantly greater in the CBD-HGF-treated rats than in the control or HGF-treated rats. Neointimal formation was significantly more pronounced in the CBD-HGF-treated rats than in other rat groups. Both HGF and CBD-HGF stimulated proliferation of vascular SMCs as well as ECs *in vitro*. Consistent with this, cultured SMCs were shown to express the HGF receptor (c-Met). It was concluded that CBD-HGF accelerates reendothelialization and neointimal formation *in vivo*. CBD fusion protein is a useful vehicle to deliver vascular growth factors to injured arteries.

Ota *et al.*[270] sought to promote myocardial repair using urinary bladder matrix incorporated with a fusion protein CBD-HGF in a porcine model. Urinary bladder matrix incorporated with CBD-HGF was implanted into the porcine right ventricular wall to repair a surgically created defect. Linear local shortening was significantly improved in the CBD-HGF-treated matrix compared with controls, whereas it was inferior to the normal myocardium. Mean electrical activity was statistically greater in the CBD-HGF-treated matrix than that in the control groups and less than in the normal myocardium. Histologic examination showed predominant α-smooth muscle actin positive cells with the CBD-HGF-treated matrix showing the thickest layer, with an endocardial endothelial monolayer. Scattered isolated islands of α-actinin positive cells were observed only in the CBD-HGF-treated matrix, but not in the controls, suggesting the presence of cardiomyocytes. It was concluded that CBD-HGF/urinary bladder matrix patch demonstrated increased contractility and electrical activity compared with urinary bladder matrix alone or Dacron and facilitated a homogeneous repopulation of host cells. Urinary bladder matrix incorporated with CBD-HGF was considered to contribute to constructive myocardial remodeling.

4.416.3.3.2.10. Platelet-derived growth factor

There is a great interest in adult stem cells and their resulting progenitors because of inherent capacity to self-renew and differentiate into multiple cell types, providing promising cell-based therapeutic strategies after tissue loss due to disease or injury. For example, neural stem/progenitor cells (NSPCs) hold great promise in regenerative medicine. However, controlling their differentiation into a desired phenotype within a defined matrix is challenging. To guide the differentiation of NSPCs, Aizawa *et al.*[271] first created a cell-adhesive matrix of agarose modified with glycine-arginine-glycine-aspartic acid-serine and then demonstrated the multipotentiality of NSPCs to differentiate into the three primary cell types of the central nervous system on this matrix: neurons, oligodendrocytes, and astrocytes. They examined whether immobilized PDGF-AA would promote differentiation in a manner similar to the same soluble factor and found similar percentages of NSPCs differentiated into oligodendrocytes. They found that the gene expression of the differentiated oligodendrocytes was similar for 2′, 3′-cyclic nucleotide 3′-phosphodiesterase but different for myelin oligodendrocyte glycoprotein in the presence of soluble PDGF-AA versus immobilized PDGF-AA. Their observation demonstrated for the first time that it is possible to control the differentiation of NSPCs, and specifically to oligodendrocytes, in cell-adhesive matrices with immobilized PDGF-AA.

A short polypeptide sequence of the human collagenase CBD was also employed to construct collagen-binding fusion proteins of PDGF-BB by Lin *et al.*[272] Sun *et al.*[191,193] used the rabbit dermal ischemic ulcer model to study the effects of CBD-PDGF loaded on collagen membranes. Their results revealed that this system maintained a higher concentration and stronger bioactivity of PDGF-BB on the collagen membranes and promoted the reepithelialization of dermal ulcer wounds, the collagen deposition, and the formation of capillary lumens within the newly formed tissue area. It was demonstrated that collagen membranes loaded with collagen-targeting human PDGF-BB could effectively promote ulcer healing.

4.416.3.3.2.11. Keratinocyte growth factor

Exogenous keratinocyte growth factor (KGF) significantly enhances wound healing, but its use is hampered by a short biological half-life and lack of tissue selectivity. Geer *et al.*[273] used a biomimetic approach to achieve cell-controlled delivery

of KGF by covalently attaching a fluorescent matrix-binding peptide that contained two domains: one recognized by factor XIII and the other by plasmin. Modified KGF was incorporated into the fibrin matrix at high concentration in a factor XIII-dependent manner. Cell-mediated activation of plasminogen to plasmin degraded the fibrin matrix and cleaved the peptides, releasing active KGF to the local microenvironment and enhancing epithelial cell proliferation and migration. To demonstrate *in vivo* effectiveness, they used a hybrid model of wound healing that involved transplanting human bioengineered skin onto athymic mice. At 6 weeks after grafting, the transplanted tissues underwent full thickness wounding and treatment with fibrin gels containing bound KGF. In contrast to topical KGF, fibrin-bound KGF persisted in the wounds for several days and was released gradually, resulting in significantly enhanced wound closure. A fibrinolytic inhibitor prevented this healing, indicating the requirement for cell-mediated fibrin degradation to release KGF. In conclusion, this biomimetic approach of localized, cell-controlled delivery of growth factors may accelerate healing of large full-thickness wounds and chronic wounds that are notoriously difficult to heal.

4.416.3.3.2.12. Leukemia inhibitory factor

For the maintenance of pluripotency, mouse ES cells are cultured on a feeder layer of mouse embryonic fibroblast (MEF) or incubated with LIF that is produced by MEF. LIF is a pleiotropic cytokine, which induces the differentiation of leukemia cell lines into macrophages and the expression of acute phase proteins in hepatocytes, as well as inhibits proliferation of ECs. Makino *et al.*,[274] Cetinkaya *et al.*,[275] and Alberti *et al.*[276] reported that chemically immobilized LIF can be effective for the maintenance of mouse ES cells.

On the other hand, Nagaoka *et al.*[87,88] prepared an immobilizable fusion protein composed of LIF and IgG-Fc region, which was used as a model for the matrix-anchored form of LIF to establish a novel system for ES cell culture and to investigate the effect of immobilized LIF on maintenance of ES cell pluripotency. Mouse ES cells maintained their undifferentiated state on the surface coated with LIF-Fc. Furthermore, when cultured on the coimmobilized surface with LIF-Fc and E-cadherin-Fc, mouse ES cells showed characteristic scattering morphologies without colony formation, and they could maintain their undifferentiated state and pluripotency without additional LIF supplementation. The activation by LIF signaling was sustained on the coimmobilized surface. They indicated that immobilized LIF and E-cadherin maintained mouse ES cells efficiently.

4.416.3.3.2.13. Stem cell factor

In vivo, SCF exists in both a bound and soluble isoform. It is believed that the bound form is more potent and fundamentally required for the maintenance of HSCs. This theory is supported by the observation that steel-Dickie mice lacking the bound isoform of SCF are unable to maintain hematopoiesis and by the fact that bound SCF displayed on the surface of transgenic cells is better able to maintain c-kit activation than soluble SCF. Further work has shown that recombinant SCF molecules, which include a surface-binding domain, are more potent than their soluble equivalent. It is generally assumed that such an elegant approach is necessary to provide the correct molecular orientation and avoid the pitfalls of random cross-linking or the denaturation associated with the adsorption of proteins to surfaces. Doran *et al.*[277] demonstrated that SCF physisorbed to tissue culture plastic was not only bioactive, but also more potent than the soluble equivalent.

Cellulose-binding domain-fused protein technology facilitated the binding of bioactive cytokines to cellulose materials and has permitted the analysis of several aspects of cell stimulation by surface-localized growth factors. Doheny *et al.*[278] reported the synthesis and initial characterization of a fusion protein comprising a cellulose binding domain and murine SCF. A significant advantage of the cellulose-binding domain fusion protein system is that it permits the stimulation of factor-dependent cells with localized growth factor, essentially free of nonfactor-derived interactions between the cell and matrix. The long-term stability and bioactivity of cellulose binding SCF adsorbed to microcrystalline cellulose under cell culture conditions were demonstrated by Jervis *et al.*[279] Cellulose-bound SCF was shown to stimulate receptor polarization in the cell membrane and adherence to the cellulose matrix. In addition, cellulose-surface presentation of the cellulose-bound SCF fusion attenuated c-kit dephosphorylation kinetics, potentially modulating the overall response of the cell to the SCF signal.

4.416.3.3.2.14. Erythropoietin

Erythropoietin (Epo) was immobilized on a culture plate and the Epo-dependent human leukemia cell line UT-7/Epo was then cultured upon the plate.[280] A photo-reactive gelatin was mixed with Epo and the mixture was cast on a plate. The plate was then irradiated with ultraviolet light in the presence or absence of a photo-mask. After washing with water, a micropatterned or unpatterned surface was formed. A leukemia cell line dependent on Epo, UT-7/Epo, was cultured on the sample plate. On the micropatterned surface, apoptosis of cells was induced on the surface without Epo, but was not observed on the Epo-immobilized surface. This result demonstrated that Epo stimulated the cells even after immobilization. Although the activity of immobilized Epo was low, the activity was slightly higher than that achieved by soluble Epo at higher concentration. In addition, the immobilized Epo could be repeatedly used for culture of UT-7/Epo cell. The present study provided a convenient immobilization method and indicated that immobilization of cytokines will be useful for creating an artificial cell culture device.

4.416.3.3.2.15. Interleukins

The mouse T cell line cytotoxic T lymphocyte lines-2 (CTLL-2) is known to be dependent on IL-2 for both growth and viability. These cells possess high affinity IL-2 receptors and have been shown to internalize IL-2 after binding. To determine if internalization of IL-2 is required for the mediation of its signal, IL-2 was covalently coupled to an insoluble matrix via glutaraldehyde cross-linking and CTLL-2 cells were incubated with the immobilized lymphokine matrix.[281] This covalent cross-linking prevents the free lateral diffusion and internalization of the bound IL-2 receptors (IL-2R) while still permitting specific binding between the cells and the immobilized ligands. Although only very limited proliferation was observed during the incubation as assessed by ^{3}H-thymidine

incorporation, the viability of the CTLL-2 cells on the immobilized IL-2 matrix was preserved. Cells incubated on the immobilized IL-2 surface could proliferate in response to exogenous soluble IL-2 that was added to the cultures after 36 h whereas control cultures incubated with an immobilized bovine serum albumin (BSA) matrix had died. This indicates that immobilized IL-2 can mediate some of the activity of soluble IL-2 and that internalization of the IL-2 receptor may not be required for at least part of the IL-2-mediated effect.

The expansion of CD34+ HSCs on 2D and 3D polymeric scaffolds, surface-immobilized with hematopoietic growth factors, was investigated by Chai *et al.*[282] The polymeric scaffolds were prepared by functionalizing polyethylene terephthalate film disks and nonwoven disks with carboxy groups by oxidation. SCF and IL-6 were covalently immobilized individually or concomitantly into amide bond formation. It was observed that immobilized IL-6 on 2D PET induced drastic expansion of CD34+ cells, contributed largely by expansion of progenitor cells with multilineage potential.

Kim *et al.*[283] investigated whether immobilized anti-inflammatory cytokines will signal changes in the inflammatory profile of cultured monocytes. A fusion protein of recombinant human IL-1 receptor antagonist and elastin-like peptide (IL-1ra-ELP) was expressed in *E. coli*. THP-1 human monocytes were cultured on either carboxyl-terminated SAMs, or SAMs with either covalently immobilized or soluble IL-1ra-ELP. LPS-stimulated monocytes exposed to either soluble or immobilized IL-1ra-ELP were prevented from cell differentiation, showed attenuated expression of proinflammatory cytokines, and had increased production of anti-inflammatory and pro-wound healing cytokines. These results suggest that immobilized anti-inflammatory cytokines have the potential to be immunomodulatory biomaterials. Novak *et al.*[284] reviewed biomimetic strategies based on viruses and bacteria for the development of immune evasive biomaterials.

4.416.3.3.2.16. Tumor necrosis factor α

TNF-α is a cell-derived inflammatory factor with potent antitumor activity. Photoactive arylazide-4-azidobenzoic acid was modified to TNF-α by Guan *et al.*[285] By photo-immobilization, the modified TNF-α was immobilized on cell culture polystyrene. Both the relation between the amount of TNF-α in the feed and immobilized TNF-α and the influence of different UV irradiation time on photo-immobilization are discussed. In addition, Guan *et al.*[286] coimmobilized TNF-α and interferone γ (IFN-γ) on polystyrene membranes for cell culture to prepare biomaterials and they showed that coimmobilization of IFN-γ and TNF-α had significant inhibitory effect on growth of Hela cells, with inhibitory rates up to 82%, and IFN-γ showing synergistic activity.

4.416.4. Summary and Future Directions

To endow biofunctionality to materials, protein immobilization is a very promising methodology.[287,288] The surfaces of various materials including metals, ceramics, and organics can be modified with proteins and biomimics. In the case of metal and ceramics, organic functional groups or organic layers were introduced and the modified surfaces were further functionalized with bioactive molecules (reviewed here) to render the surfaces bioactive.[289–292] For Ti, its alloys, and stainless steel, surfaces were first functionalized by silane derivatives or stable coating[293–295] by phosphonic acid molecules,[202,296–298] and electrodeposition,[299] electrochemical treatment,[300] or photo-modifications[301,302] were performed before immobilization of biological molecules.

In addition to these methods, as a universal modification method, an unusual amino acid, 3,4-dihydroxyphenylalanine, contained in mussel adhesive protein, was incorporated into surface modifiers for inorganic sufaces directly or as its derivatives.[303–307] The utility of combinatorially selected peptides through viral- or bacterial-displayed peptide libraries has recently proven to be an effective technique for generating polypeptide sequences with specific affinities to a variety of inorganic surfaces.[308–311] In this approach, a pool of random amino acid sequences displayed on the surface of a host organism is exposed to a target inorganic substrate and mutant organisms displaying specific binding sequences are selected. Several groups have applied this approach successfully to identify inorganic binding peptides and utilized them for various applications including making templated conjugates.

Various methods to couple with organic surfaces have also been developed with the progress in protein microarray technologies,[312–317] enzyme immobilization technology,[318,319] and surface grafting technology.[70,71] Not only chemical binding structure but also the spatio-temporal control of immobilized proteins is reported. Recently, in addition to biomedical materials or usual cell culture substrates, niche substrata for stem cells have become important.[320–323] Although the structure of this niche is considered to be very complex, precise spatio-temporal control of specific signal proteins and coimmobilization techniques will enable new capabilities to control cell-surface behaviors of improved biomaterials. Successful extension of many *in vitro* approaches to modifying cell-materials responses to actual *in vivo* scenarios has not yet been undertaken but must be used to validate the utility of immobilized growth factors, cytokines, and proteins for possible clinical applications.

Glossary

Aminopropyltriethoxysilane (APTES) This chemical ideally forms three siloxy bonds (Ti–O–Si–) with the Ti-oxide surface to result in stable linkage of the moiety and exposure of a primary amine for further chemical coupling reactions.

Biofilm bacteria Bacteria adherent to a surface and encased in a polysaccharide matrix; bacteria in this state display reduced metabolism and sensitivity to antibiotics.

Interleukin 1, 6 (IL-1, 6), etc. Cytokines released by osteoblastic cells as inflammatory mediators.

Microbial surface components recognizing adhesive matrix molecules (MSCRAMM) One of the proteins on the bacterial surface used to attach to the extracellular matrix of the host tissue.

Nuclear factor-κB (NF-κB) A transcription factor mediating, among others, signaling through RANK.

Osteoprotegerin (OPG) A soluble RANK inhibitor that binds to RANKL.

Passivation Formation of a metal oxide layer through acid etching or through hydrothermal aging.

Phosphate-buffered saline (PBS) 137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM NaH_2PO_4, pH 7.4 in water (Fisher Scientific).

Planktonic bacteria Rapidly proliferating, nonadherent bacteria.

Polyethylene glycol (PEG) A common substance used in drug formulations. PEG linkers are available commercially for use in peptide synthesis reactions to provide space between different components.

Prostaglandin E2 (PGE2) An arachidonic acid derivative important in inflammatory responses.

Quorum sensing An interbacterial communication mechanism dependent on population density and associated with marked (more than 50%) changes in protein expression patterns.

Receptor activator of NF-κB (RANK) A TNF-α superfamily transmembrane receptor expressed on osteoclast precursors and mature osteoclasts.

Ti6Al4V A titanium alloy frequently used in the manufacture of orthopedic devices.

Tryptic soy broth (TSB) A dextrose, casein, and soybean meal containing buffered salt medium for growing aerobic bacteria.

Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) A protein that can block OPG effects and induce osteoclastogenesis.

Vancomycin (VAN) A glycopeptide antibiotic against species of gram-positive bacteria.

Vancomycin coupled to the Ti-oxide surface (VAN-Ti) The actual structure would be Ti–O–APTES–PEG–PEG–VAN. In this case, PEG is 2-(2-amino-ethoxy)-ethoxy-acetic acid (AEEA).

Abbreviations

AEEA	2-[(ethoxy)ethoxy]acetic acid
APTES	Aminopropyltriethoxy silane
CFU	Colony forming units
Chromic acid	H_2SO_4/HNO_3
D-Ala-D-Ala	The D conformation of Alanine in a dipeptide
DNA	Deoxyribonucleic acid
HATU	*O*-(7-azabenzo-triazole-1-yl)-1,1,3,3-tetramethyluronium hexafluoride
IL-1, 6, etc.	The cytokines interleukin-1, 6, etc.
MALDI-TOF	Matrix-assisted laser desorption/ionization time of flight mass spectrometry
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant *staphylococcus aureus*
MSCRAMM	Microbial surface components regulating adhesive matrix molecules
MW	Molecular weight
NF-κB	Nuclear factor κB
OPG	Osteoprotegrin
PBS	Phosphate buffered saline
PEG	Polyethylene glycol
PGE2	Prostaglandin E2
Piranha Acid	H_2O_2/H_2SO_4
RANK	Receptor activator of NF-κB
RANKL	Ligand for RANK
RGD	The cell binding motif arginine-glycine-aspartic acid
RNA	Ribonucleic acid
SAM	Self-assembled monolayer
Ti6Al4V	The metal alloy 6% aluminium, 4% vanadium with the remainder titanium
TNF	Tumor necrosis factor
TRAIL	Tumor necrosis factor-related apoptosis-inducing ligand
TSB	Tryptic Soy Broth
VAN	Vancomycin
VAN-Ti	Vancomycin bonded to Ti
VRSA	Vancomycin resistant *S. aureus*
VSSA	Vancomycin sensitive *S. aureus*

4.417.1. Implant-Associated Infection in Orthopedic Materials

Perhaps the most insidious complication associated with implants in general, and orthopedic implants specifically, is infection. Approximately 50–70% of all hospital-acquired infections are associated with indwelling biomedical devices.[1] In the context of the skeletal system, such infections can have devastating consequences. The implantation of any foreign material, whether consisting of cadaverous or allogenic tissue or an inert biomaterial of a chemistry or composition, increases the probability of infection.[2] The very properties of material that allow close juxtaposition of bone tissue with the implant to facilitate bone ingrowth are also those that predispose the implant to establishment of infection.[3] When an orthopedic implant is placed, it becomes quickly coated with serum proteins. Poor perfusion and clot formation limit immune system accessibility to the foreign surface. Ideally, as the clot dissolves, new tissue either forms around the implant (spinal fusions, joint arthroplasty) or begins to replace the implant (allograft and autograft). However, if any bacteria are present, a 'race for the surface' begins where both bacteria and osteoblasts attempt to colonize the surface.[4] Unfortunately, bacteria have perhaps an unfair advantage due to their proliferative potential and ability to survive under less than ideal circumstances. Bacterial adhesion and propagation quickly progresses from individual microorganisms to formation of a polysaccharide-rich biofilm that subverts immune surveillance and limits antibiotic efficacy. Importantly, while blood-borne bacteria are readily cleared by a healthy immune system or antibiotic therapy, implant-associated bacteria protected in a biofilm can survive to become a continuing nidus of infection.[5]

4.417.1.1. The RANKL Pathway and the Pathogenesis of Osteomyelitis

Once established, bacterial colonization of an orthopedic implant, whether biomaterial or harvested graft material, results in high local concentrations of bacteria and their released factors/metabolites. These bacterial products can interact with resident cells to result in osteomyelitis and eventually, osteolysis.[6] Osteomyelitis, from the Greek osteon (bone), myelo (marrow), and the suffix -itis (inflammation), is defined as an infection of bone characterized by progressive inflammation and bone destruction (osteolysis). Independent of cause, all factors involved in the pathogenesis of osteolysis are known to act through the regulation of the RANK–RANKL pathway.[7] Receptor activator of NF-κB (RANK) is a TNF-α superfamily transmembrane receptor expressed on osteoclast precursors and mature osteoclasts. Activation of RANK by its ligand, RANKL, initiates a signaling cascade resulting in osteoclast precursor differentiation and mature osteoclast activation. Competitive inhibition of RANK is achieved by the binding of a soluble protein, osteoprotegerin (OPG), secreted by bone marrow stromal cells and osteoblasts, to RANKL.[8] It has also been shown that injections of OPG can block osteoclast-mediated osteolysis.[7]

During an immune response, neutrophils first reach the infectious locus and destroy bacteria via phagocytosis.[9] These neutrophils reside at the infectious locus until macrophages and other inflammatory cells arrive (hours–days), at which point the neutrophils undergo apoptosis. As macrophages and immune cells are recruited to the infected bone area, they, in turn, produce mediators that act on stromal cells and osteoblasts to regulate the RANK–RANKL–OPG pathway. With the infiltration of such immune cells, osteoblasts secrete an array of inflammatory cytokines, colony-stimulating factors, and chemokines.[10,11] One particular proinflammatory cytokine, IL-6, plays a key role in the osteolysis associated with infection.[12] Finally, cytokines such as TNF and IL-1 and IL-6 have also been theorized to play a direct role in osteomyelitis since they are known to regulate RANKL and OPG levels.[13] Cytokines released by interactions between bacteria and resident osteoblasts can amplify the immune response and increase the number of the bone-resorbing osteoclasts. *Staphylococcus aureus*,

responsible for 48.6% of all surgical site infections,[14] is a potent inducer of membrane-bound RANKL. In osteoblasts resident in infected bone, this induction seems to be mediated by a 5–30-fold upregulation of prostoglandin E2 (PGE2); this induction is not observed in cases of aseptic loosening.[15] Importantly, PGE2 induces RANKL expression.[15] When infected by *S. aureus*, osteoblasts also increase tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) expression.[16] TRAIL can bind OPG, blocking its inhibitory effect on RANK, and increasing osteoclast formation and thus bone resorption. In addition, by production of cytokines such as IL-6 and IL-12, bacterially challenged osteoblasts can direct immune responses by infiltrating leukocytes.[17] Finally, the inflammatory process itself leads to tissue destruction, as many inflammatory processes result in compression and obliteration of vascular channels leading to ischemia and bone necrosis. The responsive hyperemia at the infarction edge is associated with increased osteoclastic activity, bone loss, and localized osteoporosis.[18,19] Overall, the role of the RANK–RANKL–OPG pathway in the mediation of osteoclastogenesis and osteoclast activation is one that is manipulated by invading bacteria to alter bone responses.[19,20]

4.417.1.2. Biofilm Development

Despite a robust immune response, implant-associated bacteria still survive. The key to this survival is the formation of biofilm. Biofilms are ubiquitous in the natural world and their control has posed significant challenges not only in medicine but also in geology, the petroleum industries, water distribution systems, and naval and aviation technologies.[21] Biofilm formation on medical devices and transplanted tissues reduces resident bacteria accessibility to immune surveillance, local cellular defense mechanisms, and antibiotic treatment.[5,22–25] The majority of bacterial infections currently treated by physicians in the developed world are considered to involve biofilm formation (**Chapter 4.418, Engineering Interfaces for Infection Immunity**).[5,24]

Establishment of a biofilm is a multistep process involving not only the microorganism, but also the implant and host tissue (**Figure 1**). The initial attachment of a bacterium to the surface of an implant is usually very rapid and mediated by nonspecific surface conditions (e.g., surface tension, hydrophobicity, electrostatic forces), presence of host tissue ligands (e.g., fibronectin, fibrinogen, collagen), and specific bacterial surface proteins.[3] Bacteria express and upregulate several adhesins (e.g., microbial surface components recognizing adhesive matrix molecules (MSCRAMMs)) on their surfaces that facilitate adhesion to elements of the host extracellular matrix and to biomaterials;[2,27] each MSCRAMM interacts with specific extracellular matrix proteins.[28] For example, one MSCRAMM is autolysin that exhibits a vitronectin-binding site and may also have a role in adherence to hydrophobic surfaces.[29] Once attached to the surface, adherent bacteria can commence formation of biofilm. Structural examination of biofilms shows that they are complex structures composed of cells (±15% by volume) embedded in matrix material (±85% by volume).[30,31] The biofilm-embedded, sessile bacteria grow in matrix-enclosed microcolonies interspersed with porous regions important for metabolism and nutrient access. The high level of biofilm organization suggests that these communities are regulated by

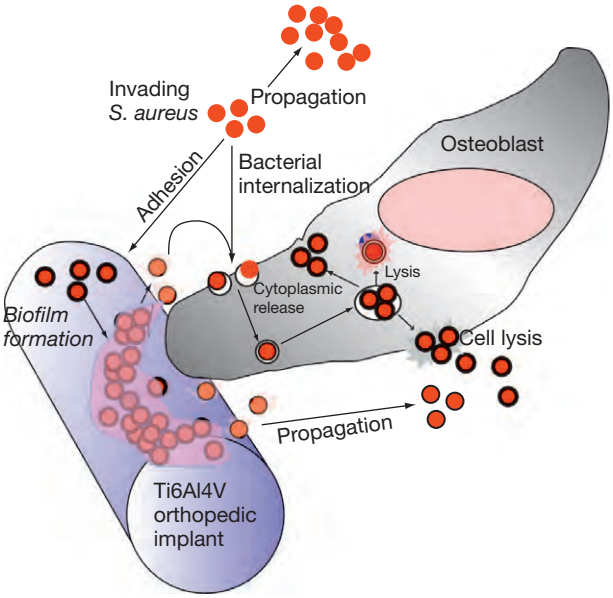

Figure 1 Cartoon of the mechanisms for establishment of infection around an implant. Invading *S. aureus* either continue to propagate or adhere to a surface. The surface can either be the resident bone cells (osteoblasts) that internalize the bacteria and establish intracellular infection,[17] thought to be one of the causes of latent infection, or the bacteria can adhere to the implant surface and make it inhospitable for continued osteoblastic cell growth.[26] Once adherent, metabolic changes occur in the bacteria that make the adherent bacteria relatively insensitive to bathing antibiotics (indicated by thickened black lines on the implant surface). These adherent bacteria propagate and encase themselves in a biofilm slime, further protecting themselves from immune surveillance, as well as bathing antibiotics. This organized biofilm community exists in a protected niche that, upon maturation, can slough off bacteria into the surrounding space. These sloughed off bacteria can then propagate, and exactly akin to the initial invasion, either propagate, seed new areas of the implant, or become internalized into the surrounding bone.

signals analogous to hormones and pheromones that regulate multicellular eukaryotic tissues. This signal system, referred to as 'quorum sensing,' is an interbacterial communication mechanism dependent on population density and associated with marked (i.e., more than 50%) changes in protein expression patterns.[32] During this process of biofilm maturation, bacteria begin to bud from the biofilm, allowing continued seeding of new sites, adherence and internalization of bacteria by adjacent cells, and propagation of infection. The survival of the biofilm is dependent on convective flow through channels that carry bulk fluid into the community, thereby keeping resident bacteria alive; depletion of nutrients and accumulation of waste products in biofilms still occurs. Metabolic waste accumulation induces resident bacteria to enter a slow growth state, or even senescence, rendering them up to a 1000 times more resistant to most antimicrobial agents than their rapidly proliferating, nonadherent planktonic counterparts.[22,33–35]

During maturation, adhesion-associated resistance in biofilm-embedded bacteria does not seem to stem from the familiar mechanisms of antibiotic resistance, such as efflux pumps, modifying enzymes, and target mutations.[35] Even sensitive bacteria without any known genetic basis for resistance can exhibit profoundly reduced susceptibility within a biofilm. For example, a β-lactamase-negative strain of *Klebsiella*

pneumoniae, with a minimum inhibitory concentration of 2 μg ml^{-1} ampicillin in aqueous suspension, is scarcely affected (66% survival) by 5000 μg ml^{-1} ampicillin when entrenched in a biofilm.[36] Even more importantly, when resilient biofilm-encased bacteria are dispersed, they usually rapidly become susceptible to antibiotics. Currently, several hypotheses exist for this resistance to antibiotics imparted by biofilms, including limited penetration of antibiotics in biofilms, partial differentiation of bacteria into a protected phenotypic state, and the altered microenvironment within the depths of the biofilm.[34] Thus, formation of a biofilm on an implant results in a complex microenvironment that cannot be effectively treated by normal pharmacological therapies. The surgical remedy therefore is removal of the infected component. Unfortunately, many treatments that make these implants suitable for osteoblast adhesion could also foster bacterial adhesion.

4.417.2. Bacterial Responses to Orthopedic Implants

4.417.2.1. Metallic Implants

Metal implants have made fracture fixation, joint replacement, and spinal surgery possible and significantly bettered the quality of life for millions of patients. Metal implants have numerous strengths and weaknesses as biocompatible surfaces within a bony environment. However, we focus on their interaction with bone and conditions under which they are colonized by pathogens. In general, any surface that can foster extracellular matrix molecule attachment to induce osteoblast cell population, and by inference, osseointegration, also fosters bacterial adhesion. The consequences of this ready implant colonization have been countered through stringent sterilization procedures and the use of clean-room technology to improve the sterility of the operating field. Some safeguards associated with these measures have decreased surgical infection rates. However, because of perioperative bacterial contamination, patient infection still remains a significant issue for metallic implants.[37–40]

The surfaces of many metallic implants are modified in order to enhance tissue integration. Different levels of microtexturing are used, ranging from anodization of screws, nails, and fracture plates to the creation of deliberate roughness and porosity of hip and knee implants to foster bone ingrowth.[41–44] Additional coatings, including hydroxyapatite, can be applied to foster osseointegration.[45,46] While many studies have addressed the effects of roughness on bacterial colonization, the data remain variable (e.g., Raulio *et al.*,[47] Duarte *et al.*,[48] Riedewald[49]). An examination of the dental literature suggests that surface roughness may retard bacterial colonization (e.g., Yoshinari *et al.*,[50] Duarte *et al.*,[48] Harris and Richards[51]). It appears that the most important determinant is surface hydrophobicity.[52–54] Thus, bacterial colonization, at least *in vitro*, can be lessened, to some degree, by alterations in surface chemistry. However, such modifications can be complicated by the addition of hydroxyapatite. The elevated porosity seen in a hydroxyapatite coating opens up the potential for use as a controlled release system.[55–57] In one application, adsorption of gentamicin to hydroxyapatite results in sufficient antibiotic release to allow short-term prophylaxis.[58,59]

Unfortunately, once infected, the most successful means of eradicating infection is surgical removal of the implant. This removal is accompanied by debridement of the surrounding bone to remove any possible infection, and either replacement (with aggressive antibody treatment)[60] of the infected component or implantation of an antibiotic-eluting spacer to eliminate residual infection followed by subsequent insertion of a new implant, a process that can require up to 6 weeks of antibiotic treatment.[61,62] With both treatments, recurrence of infection after replacement of the implant can occur, with arthrodesis or amputation the only options in difficult cases.[60] This propensity for reinfection underscores the importance of preventing the establishment of infection. Importantly, metal surfaces are prone to bacterial colonization, whether in medical applications or in applications related to their industrial use.[63–66] This propensity for colonization, considering the adaptability of bacteria, is best circumvented by a combination of approaches. While the maintenance of the sterile operating field continues to be the first defense to prevent perioperative contamination, combinations of controlled release systems with implant designs that retard bacterial colonization hold the greatest potential for preventing establishment of implant-associated infection.

4.417.2.2. Bone Allograft

Allograft bone, often used in repairing large bone defects and fostering bone growth around the new implant,[67–70] is also prone to bacterial colonization and biofilm formation.[71–74] These bone grafts are porous, avascular foreign bodies whose porosity provides a haven for bacterial colonization, while their lack of vascularization leads to low perfusion, limited immune surveillance, and inadequate penetration of systemic antibiotics. Furthermore, bacteria often associated with graft infections are notoriously efficient biofilm producers and encase themselves in a thick biofilm matrix that further protects them from environmental challenges. Multiple attempts have been made to combat this problem, and one of the most popular solutions possibly is antibiotic impregnation of grafts to deliver local high concentrations.[75–82] These elution systems, however, are limited by variable elution kinetics, short-term protection, local tissue toxicity,[83] and by the possibility of an increased incidence of microbial resistance.

Despite the clinical success seen with the use of allograft bone,[84–88] there remain a number of complications associated with its use, including infection rates which can reach 20% in massive allograft surgeries.[89–92] Once infection is established, treatment is similar to that of the metal implant. The grafts are removed, the surgical site is extensively debrided, and long antibiotic regimens are administered. Despite all these measures, also complicated by an immunocompromised host or adjuvant chemotherapy, complete eradication of the infection can fail, leading to limb amputation or even death.

4.417.3. Antibiotic Prophylaxis and Treatment of Surgical Infection

Infection rates after orthopedic surgery depend on the surgeon, the patient comorbidity, the procedure, and the implanted material.[90] Risk of perioperative infection is mitigated by routine administration of prophylactic systematic antibiotics intravenously for 2–14 days and orally for up to 16 weeks.[90,93] In an

attempt to ensure therapeutic doses of antibiotics, numerous systems have been designed to locally deliver antibiotics and prevent bacterial attachment.[94] One early attempted local antibiotic delivery system used cancellous bone as an antibiotic carrier in which bone pores were filled with penicillin.[95] Similar systems that depend on passive adsorption/loading have been used in collagen sponges and other porous materials as an adjunct to implantation.[96] In an attempt to ensure that eluting antibiotics kill bacteria before they initiate biofilm, these techniques rely on adsorption of antibiotics prior to implantation akin to the procedure for mixing antibiotic-bearing polymethylmethacrylate cement.[97–101] Other procedures rely on formation of a drug-release coating of a device or formation of an antibiotic-impregnated spacer. Antibiotic release is then achieved through passive diffusion or elution as the biomaterial degrades.

Unfortunately, all drug elution systems suffer shortcomings. Specifically, initial release of high local antibiotic concentrations quickly drops, rendering these implants unprotected beyond a few days. As an example, in an allograft system, ~75% of the adsorbed vancomycin (VAN) and ~99% of netilmicin eluted within 120 h, independent of initial concentrations and the time of impregnation.[102] When release patterns of eight antibiotics impregnated into cancellous bone were assessed by two different *in vitro* methods, agar diffusion and broth elution, only rifampicin (out of benzylpenicillin, dicloxacillin, cephalotin, netilmicin, clindamycin, VAN, ciprofloxacin, and rifampicin) maintained MIC or higher for longer than 21 days.[103] As the majority of periprosthetic infections occur within 4 months of surgical transplantation, this short-term elution may be insufficient to combat infection.[90,92] Thus, even though release of antibiotic from a controlled release system might effectively combat acute infection, biofilms can reestablish as local antibiotic dissipates into the tissue immediately surrounding the implant; this tissue serves as an important reservoir of additional viable bacteria.[104–106] Furthermore, exposure of bacteria to subinhibitory concentrations of antibiotics at the tail end of elution runs the risk of fostering development of resistant strains of bacteria.[5,107] Importantly, after use of gentamicin-loaded beads in patients undergoing two-stage exchange arthroplasty, resistant bacterial subpopulations with extremely high MICs were detected, suggesting that the use of these gentamicin-loaded beads may contribute to the occurrence of reinfection with resistant variants.[107] No consensus exists to date on the ideal concentration of the impregnation solution or the incubation time and drug bioavailability, bioactivity, elution kinetics, and maximum concentration required for efficacy in the postoperative period for any procedure or antimicrobial agent. The duration of antibiotic elution and more importantly the time it takes to reach sub-MIC concentrations can vary significantly and depends on pH, porosity, degradation characteristics, and many other parameters that influence elution.[102] These release parameters can be further complicated *in vivo* by patient and surgical factors such as vascular health, perfusion, local implant site, trauma, and inflammatory conditions.

In combating bacterial infection, the antibiotic itself can have deleterious effects in the bone environment. Specifically, topically applied antibiotic powder (chloramphenicol and methicillin) was detrimental to osteogenesis in fresh corticocancellous isograft;[78] gentamicin also showed toxicity toward osteoblast-like cells *in vitro*.[108] One of the most important antibiotics in clinical use today is the antibiotic VAN. Because of the prevalence of deep infections due to *S. aureus* and the increase in numbers of MRSA, VAN has become the antibiotic of choice in the treatment of deep infections (prior to typing) associated with implants. Since high doses of VAN have been shown to decrease the rate of osteoblast replication and even cause cell death,[109] controlled-release technologies with VAN are less frequent and await more thorough studies to ascertain local and systemic toxicity. *In vitro* studies show that ciprofloxacin at a dose greater than 100 $\mu g\,ml^{-1}$ and VAN and tobramycin at doses greater than 2000 $\mu g\,ml^{-1}$ severely decreased osteoblast-like cellular proliferation.[83] Cytotoxicity has also been demonstrated *in vivo* where 100 g of antibiotic-impregnated cancellous bone impacted in a rabbit femur condyle eluted more than 7000 mg of netilmicin, a dose that can be toxic in humans.[102]

4.417.3.1. Structure of VAN

VAN was first isolated from a *Streptomyces* species, found in soils obtained from Borneo and India. This antibiotic was developed in the 1950s and is the first glycopeptide antibiotic; it has since been synthetically diversified to represent several analogous drugs.[110–112] This class of glycopeptide antibiotics generally comprises a relatively conserved heptapeptide backbone of five to seven aromatic rings and different sugars.[113] VAN specifically contains two hexoses and five aromatic rings.[114] Today, it is commercially produced in cultures of *Amycolatopsis orientalis* (previously designated as *Nocardia orientalis* and *Streptomyces orientalis*). VAN is used as the more soluble hydrochloride salt, and because it is not readily absorbed by the gastrointestinal tract, must be administered intravenously.[115] Over the past 30 years, VAN has been used to treat deep-seated gram-positive bacterial infections and remains the drug of choice for infections caused by *S. aureus*, especially those caused by the increasing numbers of strains resistant to methicillin (MRSA). Its human nephrotoxicity starts at 90 $\mu g\,ml^{-1}$ but many initial accounts of serious nephrotoxicity have been since attributed to early production impurities.[116] Importantly, even many staphylococci responsible for prosthetic infections are now resistant to gentamicin[117] and the reports of VAN-resistant staphylococci remain few;[116,118,119] unfortunately, reports of VAN-resistant organisms are increasing.[120–123]

Importantly, VAN is very well characterized both in terms of its clinical actions and its structure–function relationship.[109] Specifically, its chemical structure, ligand-binding site, and the results of its functionalization on antimicrobial activity have been reported.[124] VAN is stable as a powder, which makes it convenient for use in diverse new delivery formulations and is effective against most gram-positive organisms (especially *S. epidermidis* and *S. aureus*, including MRSA) which are the main culprits in orthopedic infections.[14,125,126] VAN can be coupled to a surface through its carboxylic acid group and through its amines, allowing retention of activity.[127–129]

4.417.3.1.1. VAN's mechanism of action

VAN preferentially targets gram-positive bacteria that typically have a relatively simple external structure. The outer surfaces of these bacteria consist of diverse surface adhesins or

MSCRAMMs (microbial surface components recognizing adhesive matrix molecules), which are used to attach to the extracellular matrix, other bacteria, host cells, and foreign surfaces. Below this layer, a thick peptidoglycan wall gives the cell structural integrity and protects it from internal turgor pressure. This cross-linked peptidoglycan wall terminates in the interior cytoplasmic lipid bilayer membrane. The overall biosynthetic pathway of the bacterial cell wall occurs in three stages: first, the monomeric glycan wall precursors are synthesized with peptides in the cytoplasm; second, peptidoglycan wall monomers are packed in mobile lipid carriers (undecaprenylphosphate) that are transferred to the outer surface of the growing membrane; and finally, monomers are attached to the growing glycan chains in enzymatically controlled processes. Two enzymes located in the cytoplasmic membrane are critical: the first, glycosyltransferase, polymerizes murein (or peptidoglycan) monomers between their amino-sugar moieties to produce nascent peptidoglycan chains; the second, transpeptidase, also known as penicillin-binding protein (PBP), links the newly formed nascent peptidoglycan chains to preexisting peptidoglycan layers of the *S. aureus*, stabilizing both chemistry and membrane mechanical structure.

In contrast to penicillin which directly binds to and inhibits the bifunctional transglycosylases/transpeptidases involved in cell wall biosynthesis, VAN competes with these enzymes for their native substrates.[130] In *S. aureus*, these substrates fall into two classes: the D-alanyl-D-alanine (D-Ala-D-Ala) residues in either the completed peptidoglycan layers or on the nascent peptidoglycan chain, and peptidoglycan monomers located in the cytoplasmic membrane that serve as the substrates for glycosyltransferase. When VAN interacts with a sensitive (dividing) bacterium, large amounts first interact with the ~20 peptidoglycan layers of the cell wall. In this context, the wall acts as an ion-exchange resin where eventually all of the binding sites of the wall become saturated with VAN.[124] As VAN molecules penetrate through the wall, they encounter their second (and most important) target on the outside surface of the membrane: the lipid intermediates containing the disaccharide–pentapeptide wall subunit as it is extruded through the cell membrane.[131] VAN encases the D-Ala-D-Ala terminus of the lipid–PP–disaccharide–pentapeptide, burying it into a cleft of the antibiotic molecule. This large antibiotic–peptidoglycan complex can no longer interact with the transglycosylase enzyme, preventing transfer of the peptidoglycan precursor disaccharide to the growing glycan polymer chain, thereby inhibiting cell wall synthesis.[113]

Inhibition of the transglycosylation reaction results in accumulation of lipid intermediates in the cytoplasm due to the continued biosynthesis of cell wall constituents. With cell wall formation inhibited, the cell cannot increase in diameter, and DNA, RNA, and protein synthesis ultimately cease. Importantly, since gram-positive bacteria have a high osmotic pressure ($10–20 \times 10^5$ Pa), synthesis of this rigid cell wall is vital to prevent the cells from rupturing.[132] In the presence of VAN-mediated inhibition of these enzymes, autolytic enzymes continue to function. In the absence of wall growth, the continued autolytic activity causes lowered cell wall rigidity and these bacteria become susceptible to osmotic lysis.[113,131] Although VAN has been reported to be bactericidal, bacteria are not necessarily killed directly but rather cell death ensues because of the inhibition of cell wall growth. Therefore, this lysis is unlikely to occur as rapidly as with other true bactericidal agents such as β-lactam antibiotics. Furthermore, the stoichiometric 1:1 complex that VAN forms with the peptidoglycan precursor UDP–*N*-acetylmuramylpentapeptide is mediated by weak, multiple hydrogen bonds,[115] making its affinity for its substrate low.

4.417.3.1.2. Antibiotic resistance to VAN

Inevitably, there are reports of gradual reductions in VAN susceptibility among *S. aureus* isolates.[133] The possible mechanisms of resistance to glycopeptide antibiotics include inactivation of antibiotic, modification of the target site, altered accessibility of the target site, and sequestration of antibiotic. Many studies on mechanism of VAN resistance have been performed on the first clinical isolate of VAN-resistant *S. aureus* (VRSA) strain, Mu50.[134–138] A thickened cell wall seems to be the cardinal feature of all the VRSA clinical strains isolated so far. The cell walls of 16 VRSA strains isolated from seven countries are significantly thicker (mean 31.3 nm, SD 2.6 nm) than the average of VAN-susceptible *S. aureus* (VSSA) strains (mean 23.4 nm, SD 1.9 nm). Fundamentally, there are two main ways to increase the thickness of the cell wall peptidoglycan layers. The first is to produce excess amounts of peptidoglycan, as seen in Mu50, and the second is to reduce peptidoglycan turnover. Normally, new peptidoglycan layers are produced on the surface of the cytoplasmic membrane, displacing the older layers outwards so that they are eventually cast off from the cell surface. Autolytic enzymes (peptidoglycan hydrolyzing enzymes) are involved in these shedding processes and have also been found to have a remarkably reduced autolytic activity in certain strains. Overall, it appears likely that recently reported resistance in coagulase-negative staphylococci results either from a *change* in the accessibility of the target site or from a *decreased* amount of antibiotic available at the target site due to its sequestration in a modified wall structure.[134,135]

4.417.4. Surface Tethering of Antibiotics to Prevent Bacterial Adhesion

Overall, the strategy to combat implant-associated infection is complex. Two key considerations are involved: (1) prevent bacterial adhesion and biofilm formation and (2) avoid therapies likely to foster pathogen resistance. Review of the literature shows that the most successful means of combating infections have been achieved using controlled release systems that attain sufficient antibiotic concentrations to eliminate soft-tissue/bone infection. While a large body of literature describes the effects of different surfaces on bacterial colonization, experience suggests that the ideal surface must resist colonization over the long term (months to years). However, as previously stated, these controlled release systems, even without their other drawbacks, have a very finite drug-release life span, and the establishment of hematogenous or reestablishment of homologous infection can occur. To overcome these limitations, one alternative is the use of tethered antibiotics. We have hypothesized that if bacterial adhesion can be minimized, then biofilm formation can be prevented, allowing either immune surveillance or an adjunct-controlled release system to clear the surrounding tissue of infection. Research supports this idea

while emphasizing the importance of a multipronged attack to combat infection without fostering antibiotic resistance.

4.417.4.1. Device Surface Preparations for Tethering

The first consideration in deciding to modify the implant is the existing engineered design of the implant. For metal implants, the shape is critical for function and the surface is highly engineered to influence its interaction with bone. Without further surface complexities resulting from coatings such as hydroxyapatite, the same implant can display different degrees of roughness so as to enhance strength, longevity, and, of course, osseointegration.

Immobilization of substrates on devices has been explored for different metals, as well as bone allograft. Specifically, the adhesion peptide RGD was immobilized to glass,[139] quartz,[140–142] gold,[143] silicone,[144] silica,[145] and titanium[146–148] surfaces, among others to allow enhanced cell adhesion and, by implication, osseointegration.[146] Different linkages have been used on titanium surfaces including phosphonates,[149,150] plasma amination,[151] silanization to reveal active amines,[127,148,152] surface photopolymerization of PEG-acrylamide groups,[153] reaction with *p*-nitrophenyl chloroformate to activate the surface,[154] and, interestingly, titanium-binding peptides to allow PEGylation.[155] Modifications have also been introduced to the titanium surface to allow enhanced physisorption and release of antibiotics.[156–162] Covalent modification of these titanium surfaces with antibiotics has to date focused predominantly on VAN.[153,163–165]

One immobilization strategy relies on initial formation of an amine-rich, reactive surface to allow chemical coupling of linkers and antibiotics. Initially, both Ti and Ti6Al4V, common orthopedic metal materials, were explored, including powdered Ti, Ti and Ti6Al4V wires, and Ti6Al4V foils of different sizes for derivatization, as well as using a modified procedure for bone allograft. On the basis of the properties of titanium in aqueous environments, stable tethering to the implant surface must rely on formation of a covalent bond with Ti oxide, the naturally occurring ambient surface. While a variety of agents that form bonds with this amphoteric Ti oxide have been used (e.g., dopamine[166,167] and phosphonate[168]), aminopropyltriethoxy silane (APTES) that ideally can form three siloxy bonds to the titanium oxide in a self-assembled monolayer (SAM), and can be further cross-linked for added stability,[169] was used. Thus, to allow stable metal oxide bonding of APTES, a rich metal oxide layer is required. Formation of the oxide layer (or passivation) could be achieved either through cleaning of the surface using oxidizing solutions that strongly etched the metal (e.g., chromic acid (H_2SO_4/HNO_3), or piranha acid (H_2O_2/H_2SO_4)) or by other means of oxidation, such as hydrothermal aging.[163,170,171] Both methods yield a very water-wettable polar surface. Importantly, a gentle piranha acid (50:50 H_2O_2/H_2SO_4, 4 °C) increased surface pitting as visualized by scanning electron microscopy; surface pitting was not increased with hydrothermal aging.[170] Hydrothermal aging of the metal surfaces also resulted in increased surface wettability, with little change in surface features as determined by surface angles (**Figure 2**). Therefore, production of a surface oxide layer suitable for further coupling with APTES could be produced with retention of topography.

Production of the APTES layer results in addition of primary amines. These amines can be used to monitor success through either labeling with fluorescamine, followed by imaging with confocal laser scanning microscopy[128,170] (**Figure 3**), or

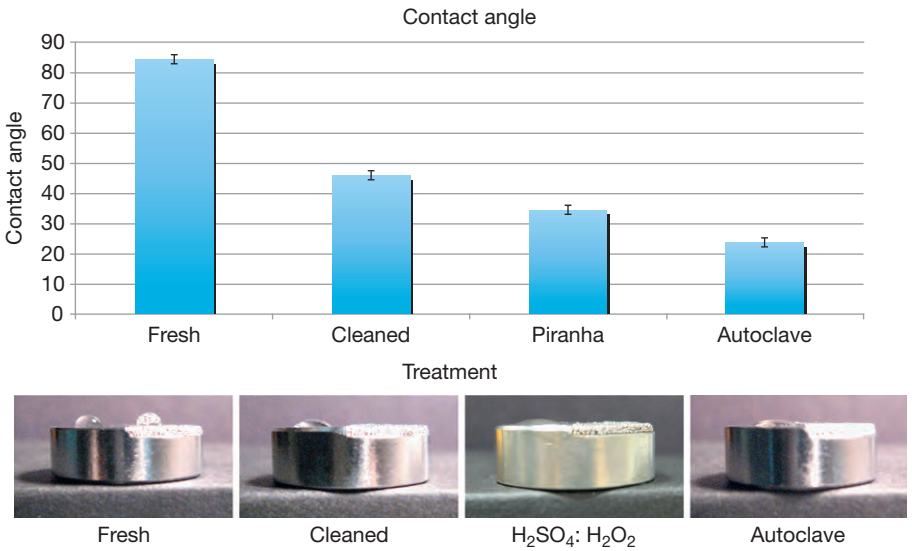

Figure 2 Changes in hydrophobocity as a function of cleaning and passivation. Surface hydrophobicity was assessed as a function of treatment, by placing a 10-μl water drop on disks that were untreated, cleaned, passivated by H_2SO_4/H_2O_2, or passivated by autoclaving. The top panel presents the contact angles measured from pictures of droplets on surfaces; statistical *p*-values between groups are as noted (n.s. = not significant). Representative pictures of the droplets on the surfaces are presented in the bottom panel. The decreasing contact angles obtained for the H_2SO_4/H_2O_2 and autoclaved conditions suggest that these treatments are successful in creating a robust oxide layer. Contact angles measured between all treatments were significantly different ($p < 0.05$). Reproduced from Ketonis, C.; Parvizi, J.; Adams, C. S.; Shapiro, I. M.; Hickok, N. J. *Clin. Orthop. Relat. Res.* **2009**, *467*(7), 1678–1687, with permission from Springer.

measuring spectrophotometrically after performance of the ninhydrin reaction.[127,163] Milligram quantities of powder have sufficient surface area to fall within the detectable range of the assay; with 1-mm wires, 5–10 wires 1.5-cm in length were required.[127,163]

Antibiotics typically target cell wall synthesis, cell wall cross-linking, protein synthesis, and DNA repair. Therefore, any surface-bound antibiotic needs to have an ability to dissolve and extend into the bacterial cell. To achieve this, we sequentially coupled two Fmoc-[2-(2-amino-ethoxy)-ethoxy]-acetic acid (Fmoc-AEEA) linkers to the APTES surface in the presence of *O*-(7-azabenzo-triazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU). After deprotection of the second linker, we coupled VAN to the primary amine in the presence of HATU.[163] Others have used a similar scheme with the addition of multiple PEG arms to result in a high density of VAN coupled to the underlying surface.[129,153,164]

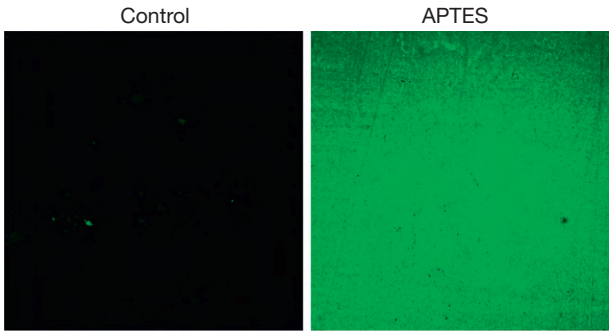

Figure 3 Amine coverage of Ti foil as visualized by staining with fluorescamine. The surface amine content of a control foil or a foil that had been cleaned, passivated, and reacted with APTES was visualized by epifluorescence after reaction with fluorescamine. Control foils showed little fluorescence, whereas the APTES foil showed a bright green fluorescent signal, indicative of a rich surface amine content.

4.417.4.2. Properties of Surface-Tethered VAN

To certify efficacy as an immobilized drug, the antibiotic must be truly bonded to the surface and must remain stable. In initial studies, this question was answered through deliberate bond cleavage at the APTES, collection of the cleaved material, and analysis by MALDI-TOF. The array of molecular ions detected consisted of the predicted structure of vancomycin-Ti (VAN-Ti) illustrated in Figure 4.[163,172] However, it would be possible that, in addition to the necessarily small quantities of surface-bound VAN, larger quantities of physisorbed antibiotic would remain on the surface. To exclude that possibility, VAN-coupled rods were routinely incubated in phosphate-buffered saline for at least 24 h to remove any easily desorbed material. Prolonged elution is sometimes required to solubilize antibiotic adsorbed during the initial synthesis; this elution was complete in the days to several weeks time frame, leaving only surface-coupled antibiotic for analysis as determined by analysis of eluted VAN activity.[173]

In order for the metal surface-coupled antibiotic to retard bacterial adhesion, sufficient antibiotic must be immobilized to the surface to affect bacterial adhesion and proliferation. Surface coupling of antibiotics has been achieved either directly through APTES using short PEG linkers,[163,172] or through multifunctional PEG acrylate linkers;[129,153] other methods of coupling agents and peptides to Ti surfaces have not been used for coupling of antibiotics. VAN that was directly coupled through the APTES via two PEG linkers was visualized through indirect immunofluorescence using a polyclonal anti-VAN antibody. A bright, uniform fluorescence was visible over the surface; this coverage appeared to largely recapitulate that already observed for detection of the APTES using fluorescamine, that is, a uniform, bright coverage that was easily distinguishable from control surfaces (Figure 5).[127,170,174,175] Because VAN (MW 1547.3) comprises multiple rings and thus is larger than the basically straight chain structure for APTES

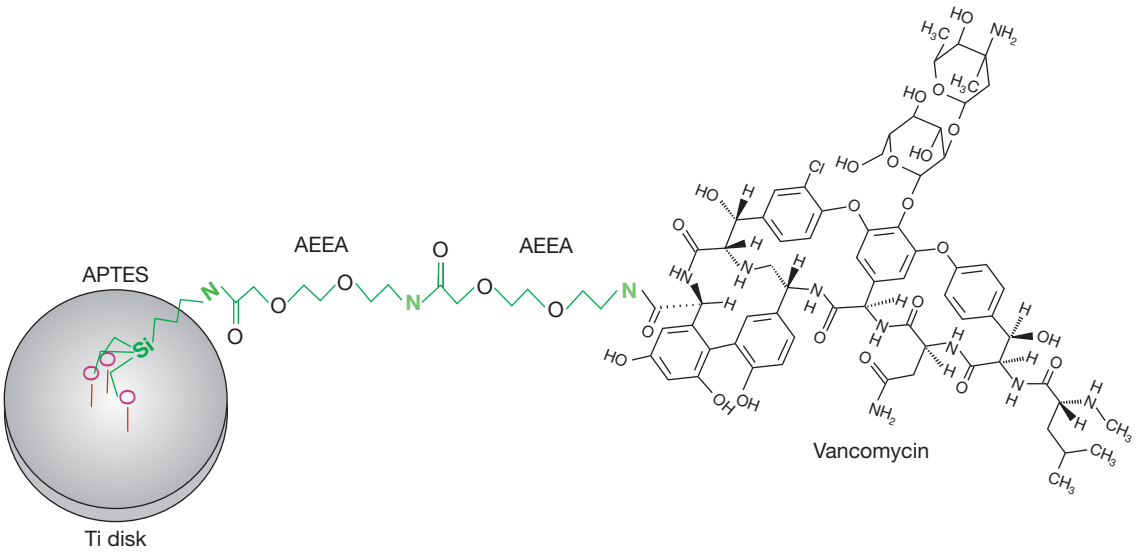

Figure 4 Predicted structure of the vancomycin-modified Ti surface. Vancomycin is bonded to the Ti surface via aminopropylation, followed by the addition of two AEEA linkers. Vancomycin coupling is then achieved through coupling of the carboxylic acid of vancomycin to the exposed linker primary amine. Adapted from Jose, B.; Antoci, V., Jr.; Zeiger, A. R.; Wickstrom, E.; Hickok, N. J. *Chem. Biol.* **2005**, *12*, 1041–1048.

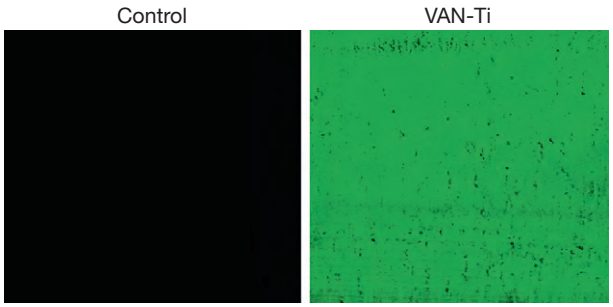

Figure 5 Vancomycin (VAN) can be detected tethered to the surface of Ti. After coupling VAN to the surface of Ti, any adsorbed antibiotic was removed by a 24-h incubation in PBS. Presence of VAN on the surface of the pin was tested by incubation with an anti-VAN antibody, followed by reaction with an Alexafluor488 secondary antibody. Fluorescence was visualized by confocal laser scanning microscopy. Control surfaces (cleaned Ti with reaction with primary and secondary antibody) showed no fluorescence, whereas the VAN-Ti surface showed a bright fluorescence, with some out-of-plane areas showing a darker signal.

(MW 221.37), it is likely that because of steric hindrance, only a subset of the available amines could be used for coupling the much larger VAN. Therefore, VAN coverage was also estimated through recovery of fluorescent antibodies (as compared to a treated, uncoupled surface that underwent the same blocking and incubation with VAN antibodies) and estimated to be 1.8 ng VAN per 1 mm × 1.5 cm Ti6Al4V rod.[175]

Having an estimation of antibiotic amounts on a surface begged the next question – how much antibiotic is sufficient on a two-dimensional surface, when minimum inhibitory concentrations (MIC) for antibiotics are defined on the basis of three-dimensional tests? This question will remain unanswered until more antibacterial surfaces and their accompanying control surfaces are assayed so that a standard can be developed.

The final question associated with any surface derivatization is that of long-term stability. The other major studies of polymerized VAN on surfaces have not measured longevity.[129,153,164] Longevity was measured on the VAN-Ti surfaces as a function of time at 37 °C. For short-term experiments, the surfaces were incubated for 7 days, at 37 °C, in PBS, 10% fetal bovine serum in Dulbecco's modified essential medium, and in the presence of *S. aureus* cultured in tryptic soy broth (TSB). For long-term experiments, antibiotic-modified surfaces were either kept dry or in PBS, at 37 °C for months to years. No changes in VAN coverage of Ti pins were apparent after incubation under any of these conditions for times out to 2 years.[127,174] A similar modification of native allograft bone was stable for at least 10 months by antibody staining and at least 2 months on the basis of activity determinations.[173]

4.417.4.2.1. Properties of surface-tethered antibiotics

Many previous studies for bioimmobilization indicate that it is clearly possible to attach PEG-like linkers to solid supports,[129,155,176–179] and these PEG linkers have the potential to be used for tethering VAN to those linkered supports.[128,163,172] In order to be of utility, however, these tethered antibiotics must retain their ability to either inhibit bacterial proliferation (bacteriostatic) or cause bacterial lysis (bactericidal). The tethering chemistry described for VAN uses the only carboxylic acid

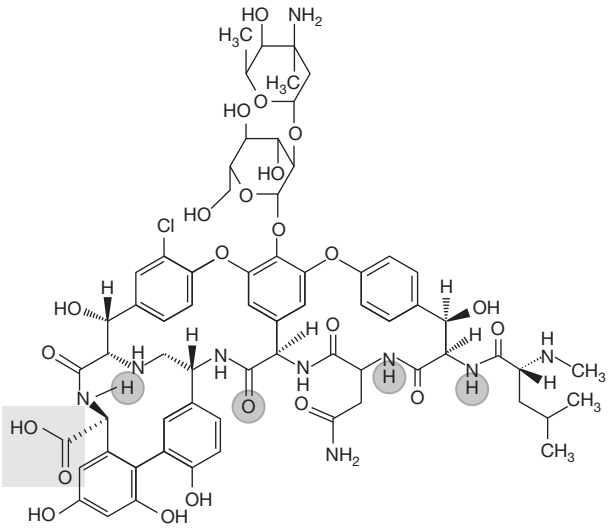

Figure 6 Vancomycin (VAN) structure with substrate interaction sites indicated. The structure of VAN is shown, with the Lys–D-Ala-D-Ala hydrogen bonding sites indicated by circles. The carboxylic acid used for coupling to the Ti surface is indicated by a square.

group present in VAN. Importantly, this carboxylic acid group is not directly part of the substrate interaction site that binds the D-Ala-D-Ala peptidoglycan to inhibit cross-linking of the gram-positive bacterial cell wall[180] (**Figure 6**). On that basis, alone, VAN should retain at least some of its antibacterial activity. Furthermore, the chemistry of VAN is well known and many modifications to its parent structure have been described,[124] as well as their effects on its activity. On the basis of literature reports, addition of chemical moieties to this sole carboxylic acid group appeared to retain bioactivity.[124] Others have used the amines on VAN for tethering with retention of activity.[153,164] Furthermore, it appeared that membrane-anchoring of VAN increased its activity against a VAN-insensitive strain.[181] Interestingly, addition of the AEEA linkers was to facilitate bacterial membrane solubility of the VAN[163] and perhaps increase the efficacy of the antibiotic in the tethered stage. This remains to be tested.

For a surface-bound VAN, antibiotic activity is expected to be only effective against those bacteria in the process of adhering to the surface; as antibiotic elution does not occur from a tethered surface, nonadherent bacteria distal to the surface are expected to be able to continue to proliferate. Measurement of the effects of these tethered antibiotics can be performed by visualization of the adherent bacteria or by recovery of the adherent bacteria through gentle sonication in the presence of detergent, followed by plating and enumeration. Both methods yield important and somewhat different information. Importantly, the magnitude of the effects using the two methods is not necessarily compatible, although both show the same trends.

Adherent bacteria and biofilms can be fluorescently visualized using the commercially available Live/Dead BacLight™ kit (Invitrogen) which relies on the differential membrane permeability of two fluorescent dyes to allow discrimination between viable bacteria and those that have sufficient membrane damage to no longer be viable.[182] Syto9, the first of the

two dyes, is able to enter all bacteria and bind to its DNA, thus causing both viable and nonviable bacteria to fluoresce green. The second dye, propidium iodide, is excluded by the intact membrane of viable bacteria, whereas nonviable bacteria readily allow its internalization and subsequent binding to DNA.[182] Thus, only nonviable bacteria fluoresce red. In examining fields of bacteria, viable bacteria will fluoresce green, whereas nonviable bacteria will fluoresce both red and green. Because the polysaccharide matrix of biofilms can contain free DNA as well as cause retention of dye, biofilms can show staining with both dyes. On VAN-modified surfaces, usually no red fluorescence is apparent, suggesting that nonviable bacteria do not remain sticky.[127,128,174,175,183]

When VAN-modified metal or allograft surfaces are examined using the Live/Dead BacLight™ dyes, little fluorescence is apparent. In contrast, control surfaces (surfaces that have been washed but not taken through subsequent synthetic steps; this surface most closely mimics actual smooth Ti surfaces used clinically), depending on the time of incubation and the bacterial strain used, tend to be heavily colonized by bacteria and show intense green fluorescence with some structures that reproduce those apparent in other published reports of biofilms.[174] The magnitude of this inhibition of bacterial adhesion (which may be the result of facilitated killing of bacteria attempting to adhere, although this analysis cannot distinguish between killing and inhibition) appears to be dependent on the inocula.[184] Importantly, even after incubation with *S. aureus* or *S. epidermidis* for 24 h, when bathing bacterial concentrations are expected to exceed 10^7–10^8 cfu ml^{-1}, statistically fewer bacteria are observed on the VAN-coupled surfaces than on the control, untethered surface (metal or bone allograft).[127,173,174,184] The ability to retard bacterial colonization appears to be stable to exposure to bacteria as the activity of the VAN-coupled Ti rods appears to be retained for at least four to five 24-h rechallenges with *S. aureus*.[127,174,175] *S. aureus*, the major causative organism in deep infections,[14] and *S. epidermidis*, a second frequent contaminant,[185] are studied in this fashion. Because the lab strains adapt fairly quickly to liquid culture *in vitro*, adhesion can be lost and become difficult to regain in strains that are not virulent.

Because these microscopy methods only provide a snapshot of small areas of the surface, the only means to assign a magnitude to the effect of the VAN-coupled surface is through direct recovery of the adherent bacteria from the rod surface. These numbers were determined by incubating either clean, unmodified surfaces or VAN-modified surfaces with *S. aureus* in TSB in static cultures for times out to 24 h. Static cultures allow bacterial adhesion, although some viability may be sacrificed in quickly growing cultures that remain static. It is important to note that bacterial adhesion and biofilm formation occur under both flow conditions and static conditions, although the strength of the adhesion may be different, depending on the fluid stress to which the culture is exposed.[186,187] At the end of the incubation period, surfaces are gently washed approximately six times with PBS to remove loosely adherent bacteria and any nucleic acid contamination from the culturing medium. Again, this washing step is crucial and is probably one of the least defined steps in the procedure. Washing must be gentle enough to not generate sufficient shear force to remove chunks of biofilm, but thorough enough to remove nonadherent bacteria. When examining the surfaces after Live/Dead staining, insufficient washing will result in the appearance of many free-floating bacteria; plating of washes to determine bacterial content as a function of wash conditions and numbers can help to standardize the conditions for the particular laboratory.

After this washing, removal of the bacteria from the surface straddles the fine line between (a) complete removal with accompanying bacterial lysis of at least a subset of the adherent bacteria and (b) partial, reproducible removal, with the remaining adherent bacteria visualized using the Live/Dead stain as described previously. Many papers have detailed methods for sonication in Triton-X, Tween-20, or Tween-80 detergents for amounts of time varying from 5 to 10 min.[188,189] Sonication with PBS containing 0.3% Tween-80 for 5 min was used, and numbers of recovered cfu were statistically lower on the VAN-modified surfaces.[127,173,174,184]

In parallel with these experiments, tethered VAN was assayed to determine if the spectrum of bioactivity described for the parent antibiotic was reproduced, using both the Live/Dead assay and direct colony counting. Specifically, as VAN inhibits cell wall synthesis, a process important for the viability of gram-positive but not gram-negative microorganisms, VAN has little gram-negative coverage.[190] Therefore, if the VAN tethered to the surface retains its native activity, gram-negative organisms ought to be relatively unaffected by its presence. The gram-negative organism *E. coli* readily adhered to the control surfaces (both metal and allograft) at all times tested. When the VAN-coupled surfaces were examined, they were indistinguishable from the control rods, as were the counts retrieved from them.[174,184]

A problem in quantification of adherent bacteria can arise, however, in the characterization of these antibacterial surfaces. If the surfaces are performing as expected, that is, inhibiting bacterial adhesion, then the strength of adhesion may, in fact, be lower on the antibacterial surface than it is on the control surface. Because sonication does not completely remove adherent bacteria, differences in strength of adhesion will skew the results. Specifically, assuming that adhesion is stronger on the control surface than on the antibacterial surface, the difference between numbers of bacteria recovered from the control and from the antibiotic-modified surfaces is smaller than that actually observed with representative fields of Live/Dead staining. Adhesive measurements relying on shear force to detachment or on the force required to remove individual cells using atomic force microscopy could certainly determine if adhesive strength was decreased on antibacterial surfaces.

If these surfaces are to have clinical utility, they must retain their antibacterial character in a physiological environment, that is, in the presence of full plasma, which also contributes to biofilm formation. While *in vitro* modeling necessarily requires a reductionist approach that cannot begin to recapitulate the complexity of the *in vivo* situation, coating with serum or with fibrin can begin to address the effect of host protein adhesion on antibacterial surface and MSCRAMM binding activity. During the performance of all *in vitro* adhesion imaging studies described earlier, 10% fetal bovine serum was routinely used to block the surfaces for prevention of nonspecific antibody binding, suggesting that the VAN remains accessible even with protein coating.[127,174] The final proof was whether or not the surface retained antibacterial activity after serum

coating. This was tested by first coating pins with 10% fetal bovine serum, followed either by confirmation of the presence of serum proteins, specifically fibronectin by immunohistochemistry, or by incubation with *S. aureus*. The tethered VAN continued to inhibit bacterial adhesion, even in the presence of serum proteins.[174]

To determine if these surfaces withstand multiple bacterial challenges, the antibiotic-tethered pins were repeatedly challenged for 24 h with *S. epidermidis* in TSB, followed by removal of the adherent bacteria with sonication in sodium dodecyl sulfate.[127] After washing to remove the residual detergent, the rods were stained again to make certain that adherent bacteria were removed, washed, and incubated with *S. epidermidis* for 24 h. Again, rod colonization was assessed by Live/Dead staining, followed by washing, restaining, etc. By the fifth rechallenge in TSB, some variability was apparent not only in the resistance of the VAN pin to colonization, but also in the ability of the bacteria to colonize the control pins probably due to the presence of the residual detergent.[174] Thus, the presence of the tethered VAN should endow the implant with the ability to resist bacterial colonization not only for the first bacterial assault, but also for several subsequent assaults.

Finally, in dealing with a permanent antibiotic surface, the question of antibiotic resistance must be raised. *S. aureus* was cultured in the presence of VAN-Ti pins for up to 2 months. In order to ensure that any adherent bacteria had sufficient nutrients, the VAN-Ti pins were sterilely moved to fresh TSB medium every 2–3 days. Adherent bacteria were recovered by sonication and antibiotic sensitivity was measured. No changes in the susceptibility of the parent *S. aureus* strain to VAN was detected at the end of the incubation.[175] Of course, this selection for resistance is only being tested under essentially selective metabolic pressure. Resistance often arises in mixed populations of bacteria, especially in biofilms, where transfer of plasmid elements can cause transfer of traits.[191,192] While this most important test will rely on clinical conditions, resistance was not fostered under these ideal conditions. Firstly, bacterial resistance arises because the resistant organism has a selective growth advantage over the growth-suppressed organisms that are sensitive to the drug. This condition of growth advantage is one of the concerns of the controlled release systems because this scenario typically happens as the antibiotic levels deplete to levels near the MIC. In the case of the tethered VAN pin, the level of antibiotic at the surface of the implant is expected to remain fairly constant so that the bacteria that attempt to adhere to the surface will continue to encounter bactericidal levels of antibiotic, thus effectively preventing development of resistance by this mechanism. Importantly, as biofilm formation appears to be retarded on these surfaces, the ability to horizontally transfer plasmids is limited, thus also minimizing the possibility of resistance. Finally, antibiotic resistance is not a frequent event and generally arises in the gut due to the large numbers of bacteria that are actively proliferating at any time. In the infected implant, numbers of bacteria that will see the surface are limited so that the probability of a resistant organism is small. As the bulk of the bacteria (i.e., those not in contact with the surface) will not be experiencing a metabolic pressure, an incidental resistant organism, which is typically slow growing,[191,192] will not have a selective growth advantage and is likely to lose out in the struggle for nutrients. While all of these predictions suggest that resistance due to surface-tethered antibiotics will be very rare, only the simple conditions have been tested to date.

4.417.4.3. Biocompatibility of Tethered VAN

As noted in the introduction, high concentrations of antibiotics can have deleterious effects on bone cell viability. Thus, on an osseointegrating implant surface, even low levels of attached antibiotics can affect host tissue biocompatibility. When osteoblast-like cells are cultured on either Ti or VAN-Ti surfaces, similar morphology, size, and density of cells are apparent (**Figure 7**).[175] In other studies, we have explicitly tested biocompatibility. To date, we have found no significant differences in cell number, viability, or levels of osteoblast maturation markers associated with culturing on VAN-modified allograft surfaces.[173,184] On the basis of these cell adhesion data, we would expect that use *in vivo* would be feasible, with standard tests such as pullout tests determining the strength of the bone-modified implant interface.

4.417.4.4. Coupling with Other Technologies

When describing these antibiotic-coupled surfaces, their strength is also their weakness. Specifically, while the tethered antibiotic may keep the implant from becoming the nidus for future infection, it cannot control infection in the tissue surrounding the implant. The surgeon always tries to minimize the impact of the previous infection by removal of the infected bone by debridement; however, latent infection does exist and is probably due to (1) hematogenously sourced microbes, (2) biofilm formation on bone or adjacent soft tissue surfaces distant from the implant insertion site, or (3) equally challenging, due to the presence of internalized phagocytosed but viable bacteria that can lyse the host cells to reestablish infection.[5,6,193] Any of these possibilities require effective antibiotic therapy. Systemic antibiotic administration is always a possibility, but due to poor penetration into the bone, is often problematic – although in the presence of an implant that actively resists infection, these therapies may become more efficacious. The most successful means to treat infection to date has been through the controlled release systems, especially release of antibiotics from cement spacers used to treat infection.[37,194,195] The ultimate therapy for prevention of

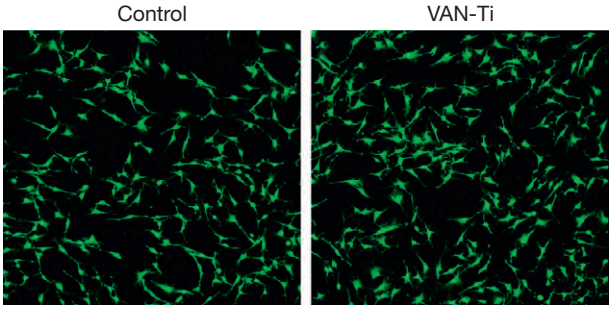

Figure 7 Osteoblastic MC3T3-C1 cells cultured on control or vancomycin (VAN)-Ti surfaces. Cells plated on either control or VAN-modified surfaces for times out to 24 h showed no differences in cell morphology or number as a function of surface modification.

implant-associated infections may well lie with combination therapies. The tethered antibiotic surface could serve as a platform for the application of a controlled release system, such as a sol–gel, for delivery of two therapies over a defined therapeutic window. Similarly, orthopedic implant placement is often accompanied by the use of allograft bone to foster osseointegration – this allograft bone is not only compatible with the tethering chemistry,[128] but is also available as a simple antibiotic elution system.[82,173,196] Together, these combination therapies could better minimize the incidence of implant-related infection and ensure that the costs, pain, repeated surgeries, and sometimes dire consequences of these infections become a less frequent event.

Acknowledgments

The authors thank Stephanie Barr for excellent technical help throughout the work described. They also thank the Musculoskeletal Transplant Foundation for providing samples for this work and for their generous support for these studies. Further, the authors thank the NIH (grants DE-13319, DE-10875, AR-051303, DE019901, and HD061053) and the Department of Defense (grant DAMD17-03-1-0713) for funding these studies. Results presented are not the statement or policy of the funding agencies.

Glossary

Adaptive immune response It is composed of highly specialized, systemic cells and processes that eliminate or prevent pathogenic challenges. The adaptive immune response provides the vertebrate immune system with the ability to recognize and remember specific pathogens (to generate immunity), and to mount stronger attacks each time that specific pathogen is encountered.

Adjuvants A pharmacological or immunological agent that modifies the effect of other agents (e.g., drugs, vaccines) while having few if any direct effects when given by itself. Adjuvants are often included in vaccines to enhance the recipient's immune response to a supplied antigen.

Antibiotics Broad category of antimicrobial compounds that kill bacteria or inhibit their growth.

B cells Lymphocytes that make antibodies against antigens, perform the role of antigen-presenting cells (APCs), and develop into memory B cells after activation by antigen interaction.

Bacteriophage Any one of a number of viruses that infect bacteria.

Biofilms Adherent bacteria can secrete mostly insoluble gelatinous exopolymers that form a three-dimensional cell: polymer matrix known as a biofilm.

C3b C3b is the larger of two elements formed by the cleavage of complement component 3. C3b covalently bonds to microbial cell surfaces upon invasion of a host. This leads to the production of surface-bound C3 convertase and thus more C3b components. Bound C3b also aids in opsonization of the microbe preparing the microbe for phagocytosis.

Cathelicidins Antimicrobial peptide is a family of polypeptides found in lysosomes in macrophages and polymorphonuclear leukocytes (PMNs).

CD+4 T cell (Th 2 response) A subgroup of lymphocytes that are unusual in that they have no cytotoxic or phagocytic activity. CD4+ T cells are generally treated as having a predefined role as helper T cells within the immune system, although there are known rare exceptions.

CD+8 T cell (Th 1 response) A cytotoxic T cell (also known as TC, CTL, T-Killer cell, cytolytic T cell, CD8+ T cells, or killer T cell) belonging to a subgroup of T lymphocytes (a type of white blood cell) that are capable of inducing the death of infected somatic or tumor cells; they kill cells that are infected with viruses (or other pathogens), or are otherwise damaged or dysfunctional.

CpG Regions of DNA where a cytosine nucleotide occurs next to a guanine nucleotide in the linear sequence of bases along its length. Unmethylated CpG sites can be detected by Toll-like receptor 9 on dendritic cells and B cells in humans; this is used to detect intracellular viral, fungal, and bacterial pathogen DNA.

CR1 Erythrocyte complement receptor 1; in primates, CR1 serves as the main system for processing and clearance of complement opsonized immune complexes.

Cross-presentation (cross-priming) The ability of certain APCs to take up, process, and present extracellular antigens with MHC class I molecules to CD8+ T cells (cytotoxic T cells). Cross-priming describes the stimulation of naïve cytotoxic CD8+ T cells by this process.

DC-SIGN Dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; DC-SIGN on macrophages recognizes and binds to mannose-type

carbohydrates commonly found on viruses, bacteria, and fungi.

DEC-205 A type I cell surface protein expressed primarily by dendritic cells (DC).

Defensins Small cysteine-rich cationic proteins found in both vertebrates and invertebrates; active against bacteria and fungi; consist of 18–45 amino acids including six to eight conserved cysteine residues.

Disinfectants Chemicals that kill microorganisms.

Endocytosis Process by which cells absorb molecules (such as proteins) by engulfing them.

F(ab′) Fragment antigen-binding (Fab fragment) is a region on an antibody that binds to antigens. It is composed of one constant and one variable domain of each of the heavy and the light chain.

Fc region Fragment crystallizable region (Fc region) is the tail region of an antibody that interacts with cell surface receptors called Fc receptors and some proteins of the complement system.

FimH Mannose-binding adhesin, FimH, component of the Type 1 pili produced by all members of the Enterobacteriaceae family.

Gingipains Extracellular cysteine proteinases of *Porphyromonas gingivalis* constitute the major virulence factor of this periodontopathogenic bacterium.
They are the product of three genes, two coding for an Arg-specific (RgpA and RgpB) and one for a Lys-specific proteinase (Kgp).

Granulocyte–macrophage colony-stimulating factor (GM-CSF) Stimulates stem cells to produce granulocytes (neutrophils, eosinophils, and basophils) and monocytes.

Histatins A group of electrophoretically distinct histidine-rich polypeptides with antimicrobial activity found in human parotid and submandibular gland secretions.

IL-1; IL-10 Fifteen different types of interleukin proteins are known, and they are designated numerically, IL-1 through IL-15.

Immunoglobulin G (IgG) IgG antibodies are large molecules of about 150 kDa composed of four peptide chains. It contains two identical heavy chains of about 50 kDa and two identical light chains of about 25 kDa, thus tetrameric quaternary structure.

Innate immune response Innate immune response comprises the cells and mechanisms that defend the host from infection by other organisms, in a *nonspecific* manner. This means that the cells of the innate system recognize and respond to pathogens in a generic way.

J774 macrophage-like cells An immortalized murine macrophage cell line that exhibits many of the responses of primary acquired macrophage.

Langerhans cells (LCs) Dendritic cells in the epidermis. LCs are normally present in lymph nodes and other organs, including the stratum spinosum layer of the epidermis.

M cells Microfold (M) cells located in the epithelium overlying follicles of the mucosa-associated lymphoid tissue.

Macrophage Phagocytic cells acting in both nonspecific defense (innate immunity) and in specific defense mechanisms (adaptive immunity) of vertebrate animals. Their role is to phagocytose (engulf and then digest) cellular debris and pathogens.

Macropinocytosis A form of endocytosis that accompanies cell surface ruffling. It is distinct in many ways from the better-characterized micropinocytosis, which includes clathrin-coated vesicle endocytosis and small uncoated vesicles. Because macropinosomes are relatively large, they provide an efficient route for nonselective endocytosis of solute macromolecules.

MHC-I Major histocompatibility complex (MHC) I; function of the MHC-I is thus to display to cytotoxic T cells (CTLs), the endogenous (from host cell) antigen fragments.

MHC-II MHC (major histocompatibility complex) class II; antigens presented by class II molecules are derived from extracellular, endogenous proteins.

MyD88 Myeloid differentiation primary response gene (88); a universal adapter protein as it is used by all TLRs (except TLR 3) to activate the transcription factor NF-κB.

Neutrophils A type of white blood cell, specifically a form of granulocyte, that help the cell to kill and digest microorganisms it has engulfed by phagocytosis. The neutrophil has a life span of about 3 days.

Nuclear factor kappa-light-chain-enhancer of activated B cells (NF-KB) A protein complex that controls the transcription of DNA.

Nosocomial infections Infections that are a result of treatment in a hospital or a health-care service unit. Infections are considered nosocomial if they first appear 48 h or more after hospital admission or within 30 days after discharge.

Opsonization An opsonin is any molecule that acts as a binding enhancer for the process of phagocytosis, for example, by coating the negatively charged molecules on the membrane.

OVA Ovalbumin is the main protein found in egg white, making up 60–65% of the total protein.

Phagocytosis Process in which phagocytes engulf and digest microorganisms and cellular debris.

PRRs Proteins expressed by cells of the innate immune system to identify pathogen-associated molecular patterns, or PAMPs, which are associated with microbial pathogens or cellular stress.

Quorum sensing A type of decision-making process used by decentralized groups to coordinate behavior. Many species of bacteria use quorum sensing to coordinate their gene expression according to the local density of their population.

RhII The opportunistic human pathogen *Pseudomonas aeruginosa* possesses two cell density-dependent genetic regulatory systems that control expression of a number of secreted virulence factors. These two systems, the *lasI–lasR* and *rhII–rhIR* gene pairs, are members of the *luxI–luxR* family of quorum-sensing signal generators and signal receptors. The *rhII* gene in *P. aeruginosa* encodes a 201-amino-acid protein that catalyses the synthesis of an autoinducer, butyrylhomoserine lactone.

T cells Belong to a group of white blood cells known as lymphocytes, and play a central role in cell-mediated immunity. They can be distinguished from other lymphocyte types, such as B cells and natural killer cells (NK cells), by the presence of a special receptor on their cell surface called T cell receptors (TCR).
TLRs A class of proteins that play a key role in the innate immune system. They are single, membrane-spanning, noncatalytic receptors that recognize structurally conserved molecules derived from microbes.
TNF-α A cytokine involved in systemic inflammation and is a member of a group of cytokines that stimulate the acute phase reaction.
Transforming growth factor beta (TGF-β) A protein that controls proliferation, cellular differentiation, and other functions in most cells.

Abbreviations

APCs	Antigen-presenting cells (e.g., macrophage, dendritic cells)
BiFPs	Bispecific fusion proteins; used as artificial opsonins
CF	Cystic fibrosis
CT	Cholera toxin
CTL	Cytotoxic T cell
DC	Dendritic cell
ECM	Extracellular matrix
FBGCs	Foreign body giant cells
FcR	Fc receptor on a APC
Lamp1	Lysosomal-associated membrane protein 1
LPS	Lipopolysaccharides
MALT	Mucosa-associated lymphoid tissue
MDP	Synthetic muramyl dipeptide
MPL	Monophosphoryl lipid A
PBMCs	Peripheral blood mononuclear cells
pDNA	Plasmid DNA
PLG	Poly(D,L-lactide-*co*-glycolide)
PLGA	poly(lactic acid-*co*-glycolic acid)
PMNs	Polymorphonuclear leukocytes

4.418.1. The Problem

4.418.1.1. Nosocomial Infections

Biofilms cause a significant amount of all human microbial infections and are particularly problematic in medical device infections. Nosocomial (hospital acquired) infections are the fifth leading cause of death in the United States with 2 million cases annually (or ~10% of American hospital patients) leading to more than $5 billion in added medical cost per annum.[1] About 60–70% of nosocomial infections are associated with some type of implanted medical device, and it is estimated that over 5 million such devices or implants are used per annum in the United States alone. Regardless of the sophistication of the biomedical implant (i.e., catheters vs. a three-dimensional (3D) stem cell-containing polymer scaffold), all medical devices or tissue engineering constructs are susceptible to microbial colonization and infection.[2,3]

Upon adhesion to a surface (inanimate material or tissue), replicating adherent bacteria can secrete mostly insoluble gelatinous exopolymers that form a 3D cell:polymer matrix known as a biofilm (Figure 1). From a medical perspective, both commensal and pathogenic microorganisms form biofilm-like conglomerates that are either associated with the epithelial or endothelial lining; embedded in the lung, intestinal, or vaginal mucus layer; attached to the teeth or medical implant surfaces, or formed intracellularly. Biofilm formation and persistence has profound implications for the patient because microorganisms growing as biofilms are significantly less susceptible to antibiotics and host defenses than are planktonic forms of the same microorganisms. Many biofilm infections are notoriously difficult to resolve and they commonly manifest as chronic or recurrent infections. Biofilm infections constitute a number of clinical challenges, including diseases involving uncultivable species, chronic inflammation, impaired wound healing, rapidly acquired antibiotic resistance, and the spread of infectious emboli.

On account of space constraints, we urge readers to explore the many excellent recent literature reviews of medical biofilms that are directed at such special topics as overall biofilm formation and infection,[4–8] biofilm diagnosis and treatment,[9] general survival strategies of infectious biofilms,[10,11] biofilm antibiotic/antimicrobial resistance,[12–14] quorum-sensing control of biofilm formation,[15–17] and biofilm issues related to specific infections, such as cystic fibrosis (CF),[18] osteomyelitis,[19,20] otitis media,[21,22] dental caries and oral infections,[23–26] and infection immunotherapy.[27]

4.418.1.2. Current Anti-infective Biomaterials Strategies

Since native immunity can be circumvented or compromised (by drugs or disease), the medical profession has naïvely attempted to eradicate biofilm-based infections by resorting to disinfectants and antibiotics. These are mostly synthetic compounds selected primarily for their ability to inactivate or kill *suspended* bacteria but exhibit little efficacy when applied to *biofilm* infections.[14,28] Biofilm-bound bacteria are significantly less susceptible to antibiotics and antimicrobial stressors than planktonic organisms of the same species.[14,29] Recent studies have shown that sublethal doses of antibiotics can actually enhance biofilm formation. Bagge *et al.*[30] report that genes coding for alginate biosynthesis were induced by exposure to the β-lactam antibiotic, imipenem. Exposure to subinhibitory concentrations of imipenem caused structural changes in the biofilm, for example, an increased biofilm mass and alginate polymer matrix. Increased levels of alginate matrix production may be an unintended adverse consequence of imipenem

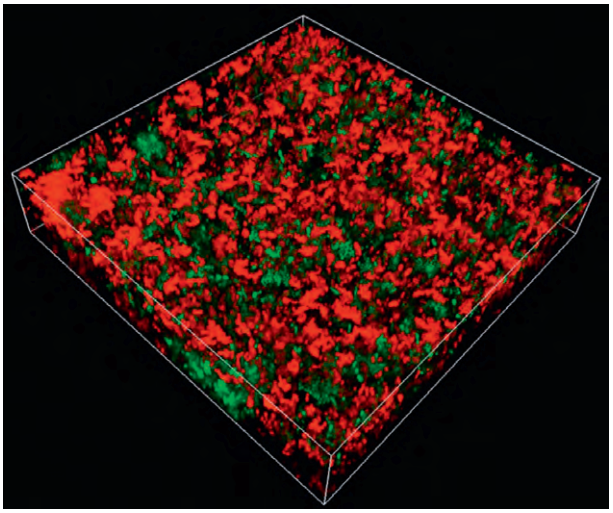

Figure 1 Three-dimensional reconstructed image of a binary culture biofilm collected by confocal laser scanning microscopy. Biofilm *z*-direction 'height' is 15–20 μm. The biofilm comprises the bacterial species, *Klebsiella pneumoniae* (green) and *Psedomonas aeruginosa* (red), which have been visualized using species-specific monoclonal antibody-conjugated quantum dots. Unlike traditional fluorochrome stains, quantum dot luminescence is photostable and size-tunable, allowing for multicolor emitted light from QDs of varying size all with a single excitation wavelength. Here, *K. pneumoniae* is labeled with monoclonal antibody conjugated to CdSe-core, ZnS-shell nanocrystals (green 560 nm emission maxima), and *P. aeruginosa* (red) monoclonal antibody conjugated to CdSe/ZnS nanocrystals (red 600 nm emission maxima).

treatment in CF patients. Similarly, Hoffman *et al.*[31] report that subinhibitory concentrations of aminoglycoside antibiotics (e.g., tobramycin) induced biofilm formation in *Pseudomonas aeruginosa* and *Escherichia coli*. Hoffman's results along with those of Bagge *et al.*, suggest that enhanced biofilm formation in the presence of antibiotics may be one universal defense mechanism of bacteria in avoiding the lethal effects of antibiotics.

The biomaterials community over the past 30 years has attempted to produce anti-infective devices or implants by either (1) designing device alternatives (liquid:air breaks, skin cuffs, antibiotic fills, all for indwelling catheters), (2) tethering anti-infective agents, bound directly to the surface of the material (silver coatings, tethered quaternary ammonium, synthetic antibiotics), or (3) releasing soluble toxic agents (chlorhexidine, antibiotics) into the adjacent surroundings. Mechanical design alternatives have had only marginal success and are applicable for short-term indwelling catheters. Tethered anti-infective agents are inhibitory only to the initial wave of incoming bacteria and provide little residual effects once layers of dead cells accumulate, which are also inflammatory. Finally, regardless of the type of 'drug-release' method used (passive vs. sustained or responsive control), release of a toxic agent from a biomaterial of a soluble anti-infective agent will inevitably stop once the entrapped agent is depleted. Further, as shown earlier, delivery of sublethal dosages of antibiotics can lead to accelerated biofilm formation and induced virulence factor expression.

4.418.1.3. Bacterial Evasion of Host Immune Defenses

The primary defense against infection is the innate immunity provided by neutrophils, macrophages, and dendritic cells (DCs) particularly by activating the complement system. The role of complement activation is to control infections by eliminating microorganisms by opsonization and then clearance from the bloodstream.[32] Components of the complement system also interact with B and T cells to coordinate the adaptive immune response by regulating antigen presentation, promoting the formation of specific antibodies, and maintaining immunological memory.[33,34] Complement evasion by many Gram-positive bacteria involves incorrect binding of complement recognition factors by bacterial cell wall proteins (protein A, G, M).[35] Gram-negative bacteria have also evolved secretory proteins that can degrade complement factors or their binding components, or that prove antichemotactic or toxic to immune cells. For example, *S. aureus* has the ability to thwart neutrophils and macrophages by (a) inhibiting chemotaxis (blocking formylated peptide recognition, blocking C5a binding, secreting leukotoxins, and blocking LFA1-ICAM1-mediated extravasation), (b) negating opsonization (via protein G binding IgG antibody molecules by way of their Fc segments, plasmin degradation of bound IgG and C3b, and blocking C3b binding), and (c) thwarting phagocytosis (cell wall modifications to resist low endosomal pH, enzymatic degradation of endosomes).[10] *Staphylococcus epidermidis*, another Gram-positive bacteria and the main species isolated in the majority of nosocomial infections, avoids the immune system through adhesion and biofilm formation.[36,37] Otto and coworkers[38] have documented that Gram-positive bacteria actually sense antimicrobial peptides released by neutrophils and macrophage and can coordinate a directed defensive response. They discovered an antimicrobial peptide sensor system that controls major specific resistance mechanisms; the sensor contains a classical two-component signal transducer and an unusual third protein, all of which are indispensable for signal transduction and antimicrobial peptide resistance.

Some pathogens obviate the immune response by specifically targeting C-type lectin receptors, particularly DC-specific ICAM-3-grabbing nonintegrins and mannose receptors, which benefits the pathogen by downregulating intracellular signaling, inhibiting maturation, and cytokine secretion.[39] For example, entry of the Gram-negative oral pathogen, *Porphyromonas gingivalis*, into monocyte-derived DCs *in vitro*, leads to suboptimal DC maturation. This process requires *P. gingivalis* to express the major fimbriae, FimA.[40,41] *P. gingivalis* also expresses unique immunosuppressive lipopolysaccharides (LPS)[42–44] and proteolytic gingipains.[45] The lipopolysaccharides of *P. gingivalis*, relative to those of *E. coli*, stimulate DCs to secrete IL-10, but not IL-12 *in vitro*[43] and *in vivo*.[44] These two factors (suboptimal DC maturation and truncated cytokine expression) lead to the induction of a Th2-effector response, which suggests that *P. gingivalis* may target DC C-type lectin receptors (e.g., DC-specific ICAM-3-grabbing nonintegrins) for entry, and for blunting DC maturation.

4.418.1.3.1. Biofilm–immune cell interactions

As indicated above, freely suspended microorganisms have evolved a multitude of ways to avoid the immune system.

One of these mechanisms is to form biofilms. Historically, there have been few studies that have focused on biofilm-bound bacterial cell interactions with the immune system, but this is changing.

For years, one explanation behind a biofilm's resistance to the immune system was that immune cells could not penetrate into the biofilm. However, Leid *et al.*[46] documented such penetration in an *in vitro* study with freshly isolated human leukocytes contacting 2-day-old (early, maturing) and 7-day-old (fully developed) *S. aureus* biofilms under static and flowing fluid conditions that mimic physiological shear. Leukocytes penetrated 7-day-old *S. aureus* biofilms under laminar-shear conditions but do not penetrate 2-day-old *S. aureus* biofilms grown under static conditions. Leukocytes produced a Th1-type response to both the 7-day-old shear and 2-day-old static *S. aureus* biofilms. That leukocytes were able to penetrate biofilms but unable to phagocytose bacteria suggests that other mechanisms may inhibit normal leukocyte function. Leid *et al.*[47] continued this investigation to report that the exopolysaccharide alginate matrix protects *P. aeruginosa* biofilm bacteria from interferon-γ (IFN-γ)-mediated leukocyte killing.

Jesaitis *et al.*[48] exposed *P. aeruginosa* biofilms to neutrophils and then measured *in vitro* oxygen consumption, cell morphology, and host defensive processes. They report that the consumption of oxygen increases in both the bacteria and neutrophils, but with little accumulation of H_2O_2 when leukocytes settled on established biofilm. Neutrophils did not exhibit significant motility or the characteristic polarized morphology of motile cells, but were still able to engage in phagocytosis while retaining a roughly spherical shape and modest membrane ruffling. However, bacteria exhibited increased oxygen consumption and initiated a detachment response that released a cloud of bacteria from the biofilm that eventually enveloped and obscured the settled neutrophils.

Walker *et al.*[49] report that human neutrophils may serve to enhance the initial development of *P. aeruginosa* biofilms. The mechanism of biofilm enhancement by neutrophils was attributed to neutrophil-generated polymers containing actin and DNA. The bacteria bind to F-actin and the free DNA promotes biofilm matrix stability. Disruption of the polymers with DNase results in dispersion of the bacteria and a reduction in biofilm development. The presence of these actin–DNA polymers, with colocalization of *P. aeruginosa*, was confirmed in both neutrophil lysates and CF sputum. Introduction of additional neutrophils after 24 and 48 h further enhanced *P. aeruginosa* biofilm development, while exposure to fewer neutrophils resulted in a lesser degree of biofilm enhancement.

Similarly, Chandra *et al.*[50] showed that peripheral blood mononuclear cells (PBMCs) enhanced the ability of the yeast, *Candida albicans*, to form biofilms and that the majority of PBMCs were localized to the basal and middle layers of the biofilm. They also found that only viable PBMCs enhanced *Candida* biofilm formation and that PBMCs cell surface components did not contribute to this biofilm enhancement; the biofilm-enhancing effect is mediated by a soluble factor released into the medium, and that the supernatant collected from cocultures contained differential levels of pro- and anti-inflammatory cytokines.

Zimmermann *et al.*[51] report that the quorum-sensing molecule *N*-(3-oxododecanoyl)-L-homoserine lactone (3OC12-HSL) synthesized by *P. aeruginosa* induces directed migration (chemotaxis) of neutrophils in an *in vitro* assay. They proposed that this early attraction of polymorphonuclear leukocytes (PMN) could contribute to prevention of biofilm formation, which may be an inaccurate conclusion. It could be possible that these bacterial signals are actually used by adherent bacteria to stimulate an immune cell response that enhances biofilm formation and virulence. In a mini-review, Wagner *et al.*[52] discusse the topic of communication between adherent bacteria and host immune cells. Wu *et al.*[53] demonstrate that IFN-γ binds to an outer membrane protein in *P. aeruginosa*, OprF, resulting in the expression of a quorum-sensing-dependent virulence determinant, the PA-I lectin. To determine whether IFN-γ induced PA-I by activation of the QS signaling system, they measured *rhlI* gene expression in response to IFN-γ. *rhlI* is the gene required for the synthesis of C4-HSL (C4-homoserine lactone), a core QS signaling molecule that plays a central role in the expression of PA-I. IFN-γ induced *rhlI* transcription in PAO1 and C4-HSL synthesis increased significantly after exposure to IFN-γ. Activation of the QS system by IFN-γ also led to the increase of pyocyanin production, which is another quorum-sensing-dependent virulence product. The results by Wu *et al.* and others[17] suggest that adherent bacteria not only actively sense but can also manipulate host immune response.[17,54]

Mittal *et al.*[55] reports that strains of *P. aeruginosa* vary in their ability to induce macrophage response, which affects the composition of secreted products (cytokines, chemokines). Concomitantly, these different compositions of macrophage-secreted products influenced overall biofilm formation and upregulated expression of a litany of virulence factors in a cytokine composition-dependent manner, again indicating the need to study macrophage response to biofilm not planktonic bacteria.

4.418.1.4. Thinking Outside the Cube

Most emerging alternatives to commercial antibiotics are still based upon some mechanism of killing or terminating the target bacteria, for example, bacteriophage,[56] bacteriophage lytic enzymes,[57] probiotics,[58,59] and human antimicrobial peptides such as defensins, cathelicidins, and histatins.[60] This 'kill' philosophy preordains the potential development of resistance in bacteria. An alternative approach is to develop therapies that specifically inhibit bacterial virulence or enhance immune response. Such 'antipathogenic' drugs, in contrast to antibacterial drugs, do not kill bacteria or stop their growth and are assumed not to select for resistant strains. The very elegant 'antivirulence' strategy seeks to inhibit regulatory systems that govern the expression of bacterial virulence phenotype such as antiadhesion therapy (passive antibody therapy[61,62] and synthetic peptide vaccine and antibody therapy[63]), inhibiting or negating cell–cell signaling[64] and upregulation of biofilm detachment promoters (rhamnolipids).[65]

Here, we highlight the prospects and remaining obstacles to generating both a short-term (innate) and a life-long (adaptive) infection immunity that originates from the biomedical device itself. Technologies described here could also have implications outside infection defense in the area of cancer immunotherapy, where current commercial techniques employ *ex vivo* transfection of DCs collected from patients by a tedious

apheresis protocol. Our approach of a surgical implant releasing *in vivo* transfection vectors could also dramatically improve cancer immunotherapy delivery (see Section 4.418.3).

4.418.2. Innate and Adaptive Immune Responses

4.418.2.1. Immunology 101

The immune system has evolved to protect the host from infection in two ways: *innate* and *adaptive* immunity. *Innate immunity* is the ability to produce a response within minutes or hours after infection through the recognition of molecules expressed by pathogens (e.g., bacterial cell wall components, bacterial nucleic acids, formylated peptides, and viral double-stranded RNA). Such molecules are recognized by specialized receptors on cells of the innate immune system, which include DCs, macrophages, neutrophils, natural killer cells, and γ–δ T cells. Binding of microbial components to innate immune cell receptors triggers signaling cascades within the cells that induce phagocytosis and the production of antimicrobial products (Figure 2). Phagocytes also produce growth factors that can regulate adaptive immune responses. While innate immune responses are immediate (and may induce cross-protective immunity[66]), they are typically short-lived.

Although macrophages can eliminate invading pathogens by phagocytosis and then present various antigens, macrophages are not potent activators of naïve T cells. In contrast, DCs are bone marrow-derived leukocytes that are specialized for the uptake and presentation of antigens to naïve T cells.[67–69] In fact, only one DC is required to activate 100–3000 naïve T cells.[70] DCs rapidly circulate the peripheral tissues in their 'immature' form but accumulate very rapidly at sites of injury, device implantation, or infection,[71] suggesting that circulating DC precursors are recruited in response to local inflammatory cues. Immature DCs – characterized by their high phagocytic activity and lack of surface costimulatory B.7 molecules (CD80, CD86)[72] – can capture exogenous antigens via several pathways; including macropinocytosis, receptor-mediated endocytosis, and phagocytosis of particles such as necrotic cell fragments and microbes.[71] DCs can be activated to mature DCs via several different signals (Figure 2), such as interaction with pathogen-related molecules (e.g., LPS), stimulation by cytokines in the local microenvironment (e.g., tumor necrosis factor (TNF), IL-1, IL-10, transforming growth factor beta (TGF-β)), and engagement of other receptors (e.g., mannose receptors, complement receptors).[71,72] Upon capture of antigen, DCs go through phenotypic changes in which their rate of antigen uptake briefly increases and then almost completely stops. DCs then morphologically change, downregulate expression of chemokine receptors responsible for the migration of other immune cell types to the inflammation site, and upregulate expression of receptors that mediate DC translocation to the lymph nodes (LNs). Surface expression by DCs of 'costimulatory' molecules is also upregulated. These costimulatory molecules are required for the activation of T cells, together with presentation of the antigen on major histocompatibility complexes (MHC) Class I and II, which are also upregulated upon 'maturation.' Once in the LNs, where most T cells reside, surface costimulatory and secreted cytokine signals communicate structural information about the antigen that was captured between the DC and T cell. T cells, specific to the peptide–MHC complex, will then proliferate into clones capable of either destroying a target cell that

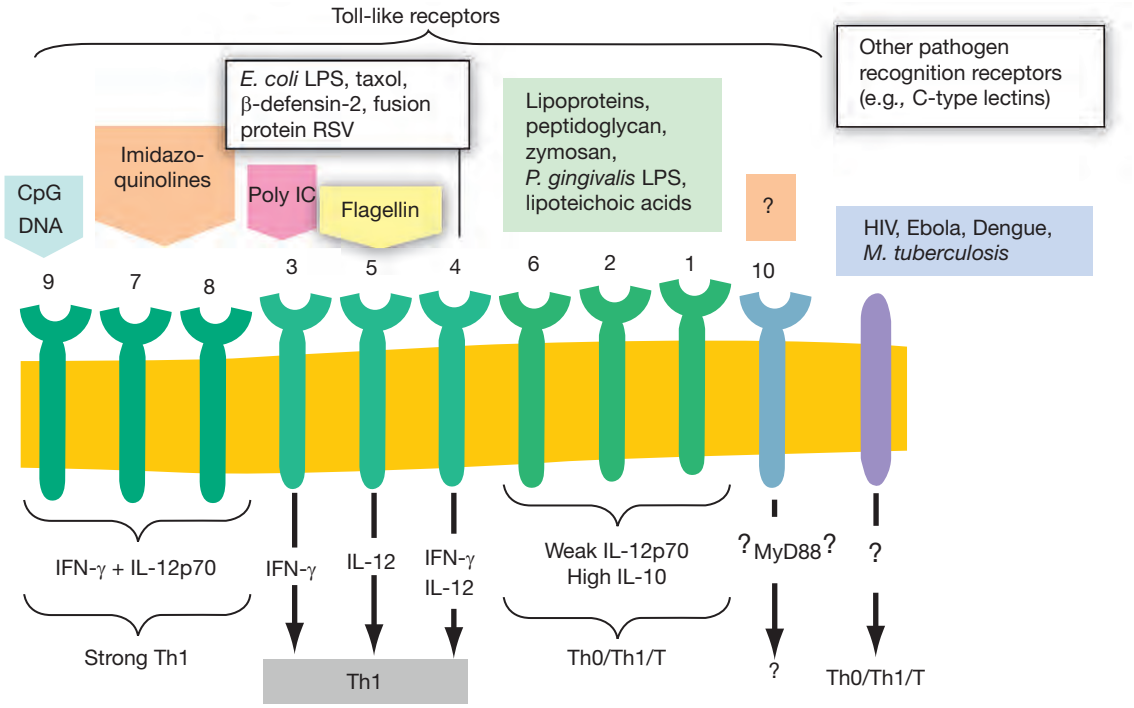

Figure 2 Triggering dendritic cell response through TOL-like receptors and other adaptor proteins results in distinctive dendritic response depending on signal and activated receptor. Adapted from Pulendran, B.; Kumar, P.; Cutler, C. W.; Mohamadzadeh, M.; Van Dyke, T.; Banchereau, J. *J. Immunol*. **2001**, *167*, 5067–5076.

expresses that same complex on its surface (CD8+ T cell) or, in the case of helper T cells (CD4+ Th), capable of secreting soluble signals to B and T cells that direct the immune response required. Cell signaling between lymphocytes can shift the immune response to either a cytotoxic cell-mediated response, called a Th1 response (characterized by secretion of cytokines such as IFN-γ, IL-2, and IL-12 along with IgG2a antibody) or to B cell secretion of antibody, called a Th2 response (characterized by secretion of IL-4 and IL-10 along with IgG1 antibody).

DCs choreograph the innate and adaptive immune systems in response to pathogen invasion. Although DCs and other antigen-presenting cells (APCs) traffic throughout almost every tissue in the body, the sites for strong immunosurveillance activity are concentrated primarily in epithelial and mucosal tissues.[73] These sites form the barriers to the outside world and are the portals of entry for many pathogens. When a pathogen breaches the skin or mucosal barrier, it encounters a phenotypically distinct population of immune cells in a physiological environment that is unique to the route of entry. Therefore, the site of initial antigen challenge sets the stage for the immune response in which DCs play a directing role. Resident DCs at these sites act as immunological sensors that receive signals from microbial components and their local cellular environment to activate and then regulate immunity. In the skin, Langerhans cells (LCs), other DCs, and macrophages are the first to respond to the danger signals and antigens presented by an invading pathogen. Secretion of chemokines attract other immune cells to the site of infection and activated APCs then migrate to draining LNs to condition the adaptive immune response. Most traditional vaccines that are delivered subcutaneously or intramuscularly target these first responders and the resulting immune response consists primarily of IgG antibody and central memory lymphocytes that are disseminated throughout the peripheral lymphatic organs.[74,75] In contrast, antigens presented in the airways, digestive tract, and vagina are collected by microfold (M) cells found in specialized mucosa-associated lymphoid tissues (MALT).[76] Priming the immune response by mucosal antigen delivery leads primarily to production of secretory IgA in mucosal secretions. Locally produced immunoglobulin M (IgM) and IgG, and mucosal cytotoxic T cell (CTLs) can also contribute significantly to mucosal immunity.[73,77] In general, systemic vaccination does not typically induce strong mucosal immunity.[73,78–80] Identifying the signals that promote DC development and function as educators of T and B lymphocytes will lead to improved vaccines and other immunotherapies. Understanding how to modulate the tropism and effectiveness of the adaptive immune response by antigen delivery and presentation to specific DC subsets is particularly important.

4.418.2.2. Innate Immune Responses to Biomaterials: 'Anger Management'

The host response to biomaterials follows a cascade of events initially similar to, but ultimately diverging from, normal wound healing. The initial injury (a wound or the implantation of a medical device) causes a perturbation of the homeostatic mechanisms, setting off the process of healing.[81] The classic view of the host response to biomaterials divides the response into several overlapping phases: blood–material interactions, acute inflammation, chronic inflammation, foreign body reaction, and fibrous encapsulation. The various different cell phenotypes participating in the immune and inflammatory host response are depicted in **Figure 3**.

Inflammatory cell recruitment requires enhanced leukocyte chemotaxis to the implant site, as well as leukocyte transmigration through the endothelium. Various molecular signals at the implant site can act as chemoattractants for the initial recruitment of inflammatory cells. Initial injury from the implantation procedure induces injured cells to release a variety of distress signals such as ATP, uric acid, and bioactive lipids. Activated platelets release several growth factors and activated mast cells likewise release various degranulation products (e.g., histamine, proteoglycans, proteases) and cytokines (e.g., TNF-α and interleukin IL-16).[82] Mast cells can also initiate the production of various other cytokines and chemokines, such as granulocyte–macrophage colony-stimulating factor (GM-CSF), IL-4, IL-6, IL-10, IL-13, macrophage inflammatory protein (MIP)-α, and monocyte chemotactic protein (MCP)-1. As leukocytes arrive at the site of injury, they, too, begin to produce various growth factors and cytokines that attract more inflammatory cells. MIP-1α and MCP-1 have been implicated in phagocyte chemotaxis toward the implant.[83]

Following their chemotaxis toward the medical implant and transmigration through the endothelium, leukocytes adhere to the implant surface and become activated to carry out their functions. Since neutrophils arriving first at the implant site are 'spent' within hours to less than a day,[84] the focus of most cell–biomaterial interaction studies has been the next incoming cell line, macrophages. Macrophages are widely considered the central cell type in directing and determining the outcome of the host response against implanted materials, because they are the predominant cell type found at the tissue–material interface in the later stages of the host response.[85] It is commonly hypothesized that host cells interact with surface-adsorbed proteins, rather than with the biomaterial surface itself.[86,87] Macrophage function is a dynamic process, which is dependent on the modulation of their activation states by either the changing local microenvironment[88,89] or by the macrophages themselves, as they release a wide variety of cytokines, extracellular matrix (ECM) proteins, and growth factors. Presence of adherent infecting bacteria can lead to a chronic inflammatory situation at the device interface. Chronic inflammation is associated with macrophages, lymphocytes, proliferation of connective tissues, deposition of matrix proteins, and capillary neogenesis.[90] Ultimately, macrophages may form foreign body giant cells (FBGCs) in an attempt to 'wall off' the implanted device leading to fibrous encapsulation by recruited fibroblasts.

Monocyte-derived macrophages are key mediators of the inflammatory response, as evidenced by changes in wound healing exhibited by animals with altered macrophages.[91,92] In the setting of inflammation, macrophages can be activated in a polarized manner by local factors such as cytokines and microbial organisms (for review, see Mantovani *et al.*[93] and Mosser[94]). The classic form of the activated macrophages (termed M1) is elicited by cytokines including IFN-γ and TNF, as well as by Gram-negative bacterial cell wall LPS. M1 macrophages generate large amounts of reactive oxygen species and inflammatory cytokines, all of which serve to augment killing of phagocytosed

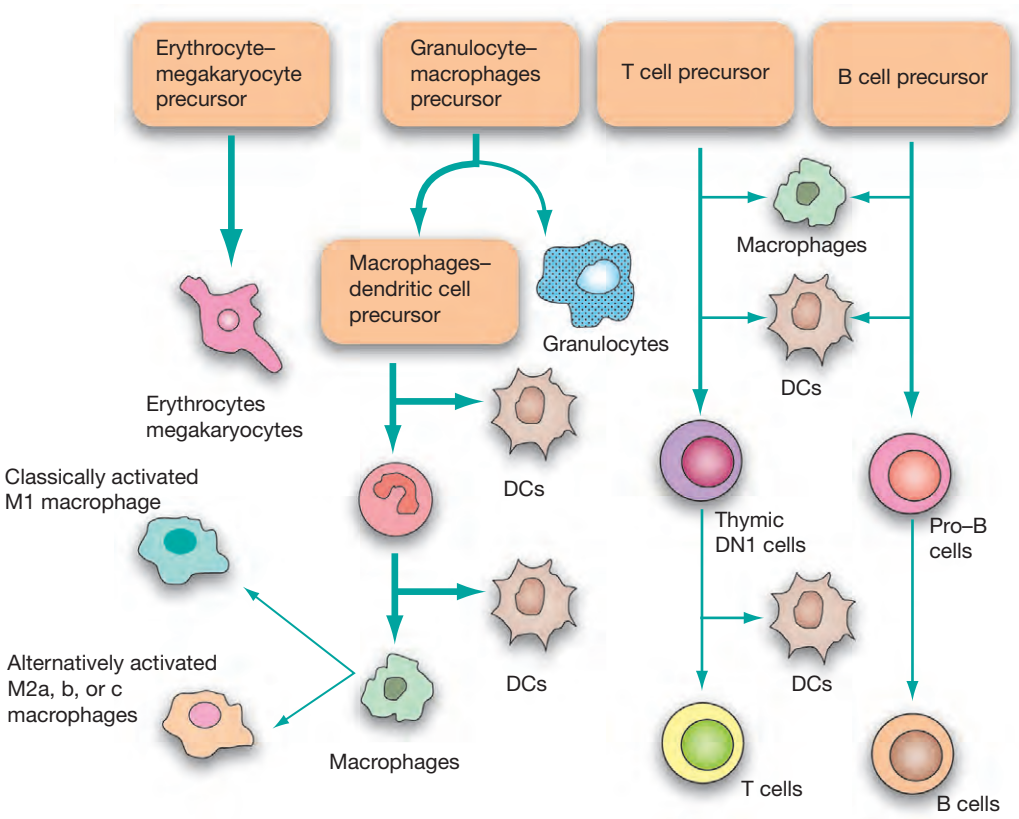

Figure 3 Phenotypes of cells comprising the immune system.

intracellular parasites and local cell-mediated immune response (the Th1 response). While M1 macrophages are critical for the early response to injury and infection, prolonged or aberrant activation of M1 macrophages can also result in undesired tissue destruction and chronic inflammation.

Designation of M2 macrophages is a broad category that encompasses macrophages activated in a manner different from the classic M1 macrophages, and includes macrophages activated by IL-4 and IL-10, immune complexes, and glucocorticoids.[95–97] M2 macrophages promote angiogenesis, tissue remodeling, parasite encapsulation, and can act as immunoregulators by suppressing the inflammatory response. M2 macrophages are generally characterized by low levels of IL-12 and IL-23 along with high levels of IL-10. M1 macrophages can be distinguished from M2 macrophages by the expression of distinct sets of chemokines and chemokine receptors.[97] Polarization of macrophages toward the M2 form can create an environment that is favorable toward wound healing, tissue regeneration, and implantable biomaterials. Consequently, the identification of pathways that can be modified to regulate macrophages polarization will be extremely beneficial for harnessing inflammation in pathologic states.

Wagner and Bryers[98] developed poly(ethylene glycol):poly (acrylate) PEG-*g*-PA copolymers (inherently nonfouling) covalently modified with either cell adhesion peptides (YRGDS, YRGES (negative control), or YEILDV) or F(ab′) fragments of monoclonal antibodies (Mabs) to monocyte integrin receptors (anti-VLA4, anti-β1, and anti-β2, anti-CD64) known to enhance macrophage adhesion and modulate inflammation activation. Monocyte adhesion, phagocytic response (oxidative burst), and cytokine expression were determined for each material. Monocyte/macrophages cytokine expression (TNF-α, IL-1β, IL-6, and IL-8) in response to control, base, and modified materials, was also determined. Tissue culture poly (styrene) (TCPS) mediated the greatest number of adherent monocytes. Both YRGDS and YEILDV peptides tethered to PEG-*g*-PA increased macrophage adhesion versus PEG-*g*-PA controls by a factor of two. However, F(ab′) fragments of all four antibodies promoted enhanced monocyte adhesion (7×) versus PEG-*g*-PA controls. Monocytes adhering to F(ab′) modified surfaces exhibited a lower oxidative burst without the addition of exogenous stimuli (LPS) versus peptide-modified surfaces. Cytokine expression and phagocytosis response by surface adherent macrophages to *S. epidermidis* and *P. aeruginosa* bacteria were also quantified on a per macrophages cell basis. Upon bacterial challenges, peptide-modified materials predisposed adherent macrophages to overexpressed proinflammatory cytokines and exhibited a significant immediate phagocytic response that diminished within 1 h. Conversely, bacterial challenge of materials modified by F(ab′)s exhibited 'per cell' cytokine expression levels that were significantly reduced compared to peptide-modified PEG-*g*-PA. Efficiency of adherent macrophages to ingest and kill both species was determined using radiolabeled and fluorescently labeled bacterial cell ingestion studies as a function of the PEG-*g*-PA surface modification. Macrophages adhering to F(ab′) modified

surfaces exhibited sustained enhanced phagocytic response (>3 h) and 3× higher bacterial killing efficiencies when compared with macrophages on peptide-modified materials.

The Wagner study indicates that signal molecules, either 'surface-decorated' on or 'released from' a biomaterial can directly influence macrophage inflammatory response and subsequent interactions with invading bacteria. In addition, this work may indicate that biomaterial signals could direct the local differentiation of monocytes into either M1- or M2-type macrophages.

4.418.2.3. Adaptive Immune Responses to Biomaterials: Biomaterial Vectors for Transfecting DCs

4.418.2.3.1. Phenotype/characteristics of peripheral versus LN DCs

DCs *in vivo* are present in peripheral tissues and secondary lymphoid organs (i.e., spleen, LNs), and also circulate within the blood. Within these compartments, DCs are composed of subsets with specialized functions and unique MHC class I or MHC class II processing capabilities. Particular DC subsets are dedicated to establishing protective responses against viral infections, whereas other subsets are involved in eliminating bacterial, fungal, and parasitic infections.[99] Priming of T and B cells also requires different DC subsets, as does the induction of immunity versus tolerance.[75] LCs are a DC subset populating mucosal-stratified squamous epithelium and skin epidermis, and overlie interstitial DC (intDC) present in the dermis.[100] LC and intDC are located ideally to capture pathogens that infect humans through the skin or mucosa, and bridge the innate and adaptive immune responses to tailor microbe-specific immunity. LC and intDC show different phenotypes and perform different biological functions. For example, they express distinct pathogen pattern-recognition receptors (PRRs) and exhibit different responses to chemokines. Epidermal LCs express CD1a, Langerin, and E-cadherin, whereas dermal intDCs express DC-SIGN, CD11b, factor XIIIa, and CD14.[101] It has been proposed that LCs preferentially induce cellular immunity, whereas intDCs more efficiently prime humoral immunity.[75] This is based on observations that LCs are particularly efficient at inducing cytotoxic high-avidity CD8+ T and induce CD4+ T polarization into Th1 and Th2 cells.[75] In contrast, intDCs are inefficient at priming CD8+ cells but rather secrete IL-6 and IL-12 to induce differentiation of naïve B cells into IgM-secreting plasma cells.[102] Dermal intDCs are also strong activators of naïve CD4+ T cells but polarize their development to help immunoglobulin production from B cells (Tfh).[103]

Sexually transmitted mucosal pathogens such as HIV, human papillomavirus (HPV), and herpes simplex virus (HSV) – all interact with LC during initial infection of the female genital tract but generate different immune responses depending on the antigens presented and the receptors involved. In human mucocutaneous herpes simplex, HSV infection is typically confined to the stratified squamous epithelium.[104] Langerin receptors on LCs are involved in initial HSV uptake; however, infected keratinoctyes also play a key role in the immune response by secreting specific chemokines, and cytokines proposed to cause apoptosis of infected LCs at the site of infection.[105,106] This outcome is thought to facilitate transfer of HSV antigens to other DC subtypes responsible for activation of HSV-specific CD8+ T cells in the draining LNs.[107] In the sexual transmission of HIV-1, cervicovaginal LCs also play an important but different role. For example, vaginal epidermal DCs express Langerin receptors that bind efficiently to HIV, but the virus largely bypasses this receptor in favor of alternative endocytic routes of LC entry.[108] The result is a distinct fate for the endoctyosed virion. Langerin receptors expressed by epidermal LCs can direct HIV-1 to Birbeck granules for degradation, but Langerin-independent LC entry may protect the virus by trafficking it to endocytic compartments where antigens are preserved for cross-penetration.[109] As a consequence, vaginal LCs migrating into the submucosa have been shown to transmit intact virions to CD4+ T cells,[110] and the *de novo* production of HIV-1 in infected LCs has also been proposed.[111] It is evident that the interaction between LCs and HSV or HIV-1 results in markedly different immune responses. Therefore, knowing the route of pathogen transmission and understanding the mechanisms underlying pathogen infection will lead to the development of novel immunotherapies based on targeting DCs.

Infectious diseases are caused by a broad array of pathogens with differing etiologies. Despite the formidable challenge this poses for vaccine development, pathogens share some commonalities that can be exploited to develop immunotherapies against many types of infections. For example, all viruses and some bacterial and protozoan pathogens are considered *obligate intracellular pathogens*. Therefore, activation of a cellular immune response that identifies and eliminates infected host cells is critical (i.e., MHC class I antigen presentation). However, targeting antigen delivery to DC subsets that will prime specific T cell immunity is a complex problem that requires antigen transport to DC-rich areas (e.g., site of biomedical device implantation, antigen binding to and uptake by DCs, and antigen processing and presentation. Antigen-loaded *ex vivo*-generated DCs and *in vivo* DC targeting are the two approaches being pursued for DC-based immunocancer therapies (e.g., Dendreon's Sipuleucel-T™). *Ex vivo* strategies consist of exposing immature DCs isolated from a patient's blood to specific antigens or other stimuli and then returning the maturated DCs to the donor. This approach has shown that DCs matured with a cocktail of proinflammatory cytokines can induce broad T cell immunity.[112–114] However, the high complexity associated with this procedure makes it economically prohibitive and will possibly prevent its impact on diseases of the developing world. In contrast to *ex vivo* strategies, novel approaches are being developed to target antigens directly to DCs *in vivo*. Multiple DC surface molecules have been identified and used for antigen internalization and processing by MHC I and MHC II pathways. Effective *in vivo* results have been observed using heat-shock proteins, pseudovirions, or protein antigens conjugated to DC-specific antibodies that can lead to DC activation. In the absence of DC activation, studies in mice have shown that antigen targeting to DCs induces tolerance.[115,116] Complete success of this strategy depends on overcoming biological delivery challenges and the weak immunogenicity of many antigens. These challenges are being addressed by biomaterial vectors, which are the next generation of immunotechnologies that target antigen delivery to DCs and are tailored to the specific immunopathology of the pathogen (see **Section 4.418.3**).

4.418.2.3.2. Vaccine Adjuvant Design

Adjuvants are molecules, compounds, or macromolecular formulations that boost the potency and longevity of specific immune response to antigens, but cause minimal toxicity or long-term immune effects themselves. Addition of adjuvants to a vaccine enhances and directs the immune cell response to the antigens, thus reducing the amount of antigen or number of immunizations required and improving the vaccine's efficacy. Traditional 'live vaccines' based on attenuated pathogen cells do not require the addition of adjuvants. Likewise, vaccines based on inactivated viruses or bacteria are often sufficiently immunogenic without added adjuvants, although some are formulated with adjuvants to further enhance the immune response. By contrast, current-generation vaccines increasingly consist of highly purified recombinant proteins or protein subunits, synthetic peptides, or plasmid DNA (pDNA). Such vaccines possess defined compositions and are less reactogenic, making them less toxic and safer but also poorly immunogenic compared to traditional vaccines.[117,118] Therefore, these new vaccines increasingly require a combination with adjuvants that can enhance the quality and magnitude of the adaptive immune response produced from using the specific antigen alone.

Adjuvants can be classified according to their component sources, physiochemical properties, or mechanisms of action. Two main classes of adjuvants commonly found in modern vaccines are the following: (1) *immunostimulants* that directly act on the immune cells to increase responses to antigens (e.g., Toll-like receptor (TLR) ligands, cytokines, saponins, and bacterial exotoxins) and (2) *vehicles* that present vaccine antigens to the immune system in an optimal manner, including controlled release and depot delivery systems to increase the specific immune response to the antigen, for example, mineral salts, emulsions, liposomes, virosomes (nanoparticles made of viral proteins such as influenza hemagglutinin and phospholipids), biodegradable polymer microspheres, and so-called immune-stimulating complexes (i.e., ISCOM™, ISCOMATRIX™). Vehicles can also serve to deliver the aforementioned immunostimulants.

To date and despite decades of research, aluminum-based mineral salts, collectively referred to as 'Alum,' are the only adjuvant approved for human use in the United States by the FDA.[119] Alum is classified among the first generation of adjuvants, which also includes emulsions (e.g., MF59 and Freud's adjuvant), polymeric particles, and liposomes.[120] These first-generation adjuvants are particulate-based and are naturally targeted for uptake by phagocytic macrophage and DCs, because their physical structure and dimensions closely mimic the size and geometry of pathogens. The primary mode of action of particulate adjuvants is to adsorb or encapsulate vaccine antigens to enhance persistency and improve delivery.[117,120] For example, antigens adsorbed onto alum exhibit enhanced stability and persist longer at the site of injection.[120] Alum and MF59 are good vaccine adjuvants for induction of antibody and TH2 responses.[118,121] However, as is the case with all first-generation particulate adjuvants, they only weakly stimulate antibody production to protein subunit antigens and are poor adjuvants for cell-mediated immunity.[122]

Second-generation adjuvants were developed 40–50 years after Alum and MF59. These adjuvants consist of more than one adjuvant component and arise from the addition of immunostimulants to first-generation adjuvants.[120] The most potent immunostimulants often take the form of pathogen-associated molecular patterns and include bacterial products (e.g., LPS), toxins (e.g., cholera toxin, CT), or bacterial nucleic acids (e.g., unmethylated bacterial CpG DNA). These specific immunostimulants induce DC maturation by binding to PRRs on DCs inducing the expression of the costimulatory molecules required to shape the adaptive immune response.[75,123] However, these natural pathogen-associated signals can lead to systemic inflammation and shock, and are considered too toxic for human clinical use.[124] Derivatives of natural immunostimulants, such as the synthetic muramyl dipeptide (MDP) and monophosphoryl lipid A (MPL), are less toxic and are showing promise in second-generation adjuvants. For example, the combination of alum with MPL is licensed in a significant number of countries for use as a vaccine component against HPV[125] and hepatitis B virus.[126] MPL is a TLR4 agonist and its addition to alum has been shown to increase antibody titers and to induce potent and focused T cell responses.[117,120,127] A multicomponent adjuvant that consists of two immunostimulants (MPL and QS21) combined with an oil-in-water emulsion has been shown to induce potent TH1 cellular immune responses and has promise for use as a malaria vaccine candidate.[128]

The components of an ideal adjuvant formulation will include immunostimulants to stimulate the innate immune system and provide the costimulatory signals that shape adaptive immunity, the antigen against which the adaptive immune responses are elicited, and a delivery system that can combine these two components at the place and time to elicit optimal stimulation. Biomaterials are an integral component to the design of these formulations because they can be engineered for localized and targeted delivery of antigens through specific intracellular pathways to control the presentation of antigens to key immune cells.[73] In addition, biomaterials can be designed to control the cytokine environment and influence how T cells perceive antigens.[73,74] Biomaterials that contain hydrophobic domains have been shown to exhibit natural adjuvant behavior.[124,129] For example, the adjuvant activity of block copolymers containing a higher proportion of hydrophobic poly(propylene glycol) compared to hydrophilic poly (ethylene glycol) improved antibody formation against BSA in mice.[130] The hydrophobic portions of these materials might function as danger signals that trigger activation of PRRs, in particular, TLRs. For example, TLR4 binds to a variety of ligands that possess hydrophobic domains such as LPS and bacterial fimbriae.[123,124] Hydrophobic biomaterials have also been shown to induce greater inflammatory responses.[74] In particular, micro- and nanoparticles formulated from biodegradable poly(lactic-*co*-glycolic acid) have been shown to cause lysosomal damage and activate the NAPL3 inflammasome, which stimulates caspase-1 activation and promotes secretion of proinflammatory cytokines.[131] These inflammatory responses are the first indication of pathogen invasion and lead to recruitment of cells to the sites of infections and coordination of systemic immune defenses.[132] Other groups have also demonstrated that the chemical composition of biomaterials can lead to DC maturation. Uto *et al.*[133] showed that γ-PGA nanoparticles induce DC maturation through MyD88-mediated NF-κβ and activation of the p38 MAPK pathways,

which is similar to LPS-mediated maturation of DCs. Poly (lactic acid-*co*-glycolic acid) (PLGA) microparticles and films have also been shown to promote maturation of bone marrow-derived DCs.[134,135] Yoshida and Babensee[136] directly compared DC maturation phenotype reporting that PLGA was a stronger stimulus of DC maturation than agarose, and this maturation was not affected by microparticle phagocytosis. However, agarose-treated DCs showed higher activation of NFκB 24 h after the initial stimulation of DCs.

Although the chemical composition of certain biomaterials may intrinsically provide adjuvant activity, encapsulation or presentation of immunostimulants within or conjugated to the surface of the biomaterials can provide stronger signals required to activate sustained immunity.[73,124] Codelivery of a tumor antigen with LPS or IFN-γ was shown to provide improved immunotherapy and lead to disease-free survival versus delivery of the antigen alone.[137] Other studies show that incorporation of synthetic analogs of bacterial and mycoplasmal lipoproteins within liposomes or conjugated to the surface of lipid vesicles provides highly potent immunoadjuvant activities by binding to TLRs and triggering cell activation and adaptive immune responses.[138,139] Demento *et al.*[140] showed that a recombinant envelope protein antigen incorporated into PLGA nanoparticles, with their surfaces modified with LPS, could provide protection from a lethal challenge from West Nile virus. Recent work by Ali and Mooney demonstrate the potential for designer vaccine and adjuvant formulation using biomaterials. Their work describes the use of porous poly(D,L-lactide-*co*-glycolide) (PLG) matrices engineered to incorporate a combination of inflammatory cytokines, immune potentiators, and antigens as an immunotherapy against large invasive tumors.[141,142] These PLG matrices were formed into discs and engineered to present CpG DNA and corelease both cytokines and tumor antigens. When implanted into tumor-bearing mice, the PLG constructs coordinated the response of multiple DC subtypes that led to a sustained and potent tumor-specific CD8+ CTLs response and inhibition of immunoregulatory pathways.[141] Finally, biomaterials can be engineered to selectively activate aspects of the complement system, which is a series of enzyme-signaling cascades that promote inflammation, macrophage phagocytosis, anaphylaxis, B cell maturation, and T cell responses, and can also enhance antigen presentation by follicular DCs present in lymphoid tissue.[33,129] Polyhydroxylated nanomaterials have been shown to activate LN-resident DCs in mice by stimulating the C3b component of the complement cascade.[129] Complement activation by nonspecific adsorption of complement proteins, antibodies, and opsonins onto polymer particles has also been shown to enhance phagocytosis by macrophages and monocytes.[143,144]

4.418.2.3.3. Biomaterial vectors for targeted antigen delivery in vivo

Biomaterials used commonly for drug delivery are experiencing a new role as antigen delivery vehicles. Drug delivery biomaterials have historically sought to minimize immunological interactions with materials. In contrast, biomaterials for immunotherapy exploit advantages of immunological properties of certain materials for designing new biomaterial vectors that induce specific and desired immune responses. Liposomes, micelles, and polymer micro- and nanoparticles are the commonly used platforms for the design of new DC-based vaccines and immunotherapies. These biomaterials are specifically designed to (1) protect the antigen against degradation before they reach DCs; (2) prolong antigen presentation to DCs by delivering effective and sustained doses; (3) traffic antigens intracellularly into MHC class I or II pathways to induce specific T cell responses; and (4) increase antigen targeting to stimulate LN or peripheral DC maturation. The biomaterial itself can also function as a synthetic adjuvant to enhance the immunogenicity of the delivered antigen. In general, biomaterial vectors provide protracted presentation of intact antigens to increase the opportunity for DC uptake and processing.

Immature DCs sample their antigenic environment and readily internalize exogenous solutes, particles, and necrotic or apoptotic cells by macropinocytosis, receptor-mediated endocytosis, and phagocytosis.[145] The mechanism for antigen uptake by DCs affects the subsequent processing of antigen through MHC class I or MHC class II pathways for presentation to CD8+ and CD4+ T cells, respectively. Cellular immunity is mediated primarily by CD8+ T cells, CD4+ Th1 cells, and natural killer T cells that recognize pathogen-derived antigens presented by MHC class I molecules or CD1-lipid antigen complexes.[74,75,146] However, most exogenous antigens are internalized within endosomes and are processed into the MHC class II pathway to stimulate CD4+ T cell humoral immunity. Cross-presentation, or the presentation of exogenous antigens on MHC class I molecules, is challenging and can limit the quality and magnitude of the cellular immune response achieved by DC-based vaccines. Cross-presentation pathways for antigen presentation by MHC class I molecules can also be exploited to elicit both CD4+ and CD8+ T cell immunity.[147] Therefore, many efforts have focused on enhancing cross-presentation of exogenous antigens delivered by biomaterial vectors. These methods include targeting DC subsets that actively cross-present antigen,[148] employing pH-responsive polymers that facilitate escape of antigens into the cytosol from the endosome,[149] and delivering pDNA encoding the expression of antigens that can be loaded onto MHC class I molecules for presentation.[150]

Several studies have confirmed that liposomes and polymer particles are readily internalized by DCs, and that the physicochemical and biochemical properties of the biomaterial can be altered to control DC uptake and presentation. For example, antigen molecules contained within liposomes coated with mannose are internalized to a greater extent by DCs via receptor-mediated endocytosis and induce a twofold higher proliferation of primed T cells compared to uncoated liposomes or free antigen.[151] Enhancing cellular immunity is improved by targeting specific DC surface receptors such as the C-type lectins DC-SIGN and DEC-205.[152–154] Mouse CD8α+ DCs uniquely express DEC-205 and are specialized to efficiently cross-present antigens via the MHC class I pathway.[147,155] Microparticles surface-modified with a DEC-205 targeting ligand show threefold enhanced uptake *in vivo* by CD8α+ DCs compared to control particles.[148] Inducing cellular immunity through the MHC class I pathway by delivering exogenous antigens formulated within particles can be challenging, since particles are often internalized initially within

endosomes that are then rapidly trafficked to lysosomes, where the particle and antigen can be degraded before being processed and presented. Or, the antigen is processed into the MHC class II pathway to stimulate CD4+ T cell humoral responses. Employing acid-degradable polymers to deliver oligonucleotide and peptide antigens has been shown to evade lysosomal trafficking by destabilization of endosomes and release of the antigens into the cytosolic compartment where they can be processed by the MHC class I pathway.[156–159] Release of DNA inside the cell cytosol of DCs has also been achieved with poly(ortho ester) microspheres and acid-degradable microparticles.[160] Gene delivery of antigen-encoding pDNA promotes processing and presentation by the MHC class I pathway, since gene products are naturally processed to the cytoplasm and endoplasmic reticulum. Therefore, biomaterial vectors that facilitate intracellular gene delivery can enhance the cellular immune response.

Biomaterial vectors have been designed primarily to target peripheral immature DCs, particularly LCs found in the epidermis. However, new approaches in biomaterial technology are being developed to target LN DCs. This has the advantage of avoiding premature antigen presentation by peripheral DCs that can lead to antigen tolerance.[161,162] To overcome the challenge of targeting peripheral DCs, biomaterial vectors are being designed to delay the intracellular bioavailability of their antigen load until DCs reach a LN. The stringency for DC-targeting specificity is also reduced because of the high tissue concentration of phagocytically active DCs present in LNs. Therefore, although the requirement for DC-targeting ligands, such as anti-Dec205, may be necessary to compensate for the low LC numbers in skin, these targeting ligands may not be needed to deliver antigens to LN DCs.[124] Targeting antigen delivery to microfold (M) cells located in the epithelium overlying follicles of the MALT is also an active area of biomaterials design for mucosal vaccines. For example, antigens targeted to M cells present at immune inductive sites located in the nasopharyngeal duct can elicit antigen-specific T and B lymphocyte responses in the respiratory and reproductive tissues by way of the common mucosal immune system.[76] A DNA vaccine against HIV glycoprotein gp160 conjugated to σ1 protein for M cell-targeting was delivered intranasally and effectively produced gp160-specific CTL responses in various mucosa-associated and systemic immune compartments.[163,164]

The targeting challenge then becomes designing biomaterial vectors small enough to be taken into lymphatic vessels and be retained in draining LNs. Several studies have examined the size-dependent trafficking of particles to the draining LNs. In a recent study by Manolova *et al.*,[165] 20–200 nm diameter particles readily migrated to the draining LNs after intradermal injection in mice. These particles were subsequently internalized by the LN-resident DCs. In contrast, the same study showed that LC present in the epidermis internalized 500–2000 nm-diameter particles. These trafficking patterns have consequences of the immune response, since CD8α+ DCs in the LNs more efficiently prime cellular immunity.

A final strategy has been to conjugate molecules to the particle surface that will preferentially interact with DCs. For example, liposomes have been coated with antibodies specific to DCs (e.g., anti-CD11c and anti-DEC-205), which improved DC uptake and resulted in immunity against the surrogate tumor antigen (OVA).[137,166] Similarly, mannose has been used to target receptor-mediated gene delivery to DCs; mannose was coupled to polyethylenimine DNA transfer complexes[167] and chitosan/DNA nanoparticles[168] to improve transfection.

4.418.3. Engineering Infection Immunity

4.418.3.1. Enhanced Innate Response

Opsonization is the process where microorganisms and inanimate colloids (e.g., liposomes, particulates) are coated with host-produced proteins and lipids (immunoglobulins, complement factors), facilitating the binding of the opsonized bacteria or particle to specific receptor molecules present on phagocytes (i.e., neutrophils, macrophage, DCs). IgG antibodies bind to their antigens on the surface of bacteria through coupling of the variable binding sites in the Fab region of the antibody, leaving the Fc region exposed. Phagocytes possess Fc γ receptors and therefore can bind to the Fc-coated bacteria or particles and internalize them. Complement fragment, C3b, also specifically binds to surface proteins or polysaccharides on microorganisms, thus mediating binding to C3b receptors on the phagocytes. Unfortunately, bacteria have evolved numerous ways to avoid opsonization by IgG and complement and thus avoid phagocytic elimination.

An alternative antibiofilm biomaterials defense is one where the biomaterial would release factors that enhance macrophage phagocytosis of bacteria. Currently, we are developing small molecules, called 'artificial opsonins,' that are designed to uniquely bind to both target bacteria and macrophage, thus enhancing phagocytosis. There are a number of reports of synthetically derived 'opsonins' enhancing bacterial phagocytic clearance.

Whitesides' group[169] describes the application of a bifunctional polyacrylamide molecule containing both vancomycin and fluorescein groups, which recognized the surfaces of four species of Gram-positive bacteria (*S. aureus*, *S. epidermidis*, *Streptococcus pneumoniae*, and *Enterococcus faecalis*). The vancomycin group binds to replicating bacterial cell wall component peptides terminated in D-Ala–D-Ala. Fluorescein groups allow for the imaging of the bound opsonin, plus the fluorescein group is recognized by antifluorescein Mabs, the Fc portion of which promotes binding to macrophage. Flow cytometry revealed that bifunctional polyacrylamide molecule-labeled *S. aureus* and *S. pneumoniae* were opsonized by antifluorescein Mabs 20-fold more than were untreated bacteria and promoted subsequent *in vitro* phagocytosis of *S. aureus* bacteria by cultured J774 macrophage-like cells ~twofold more efficiently than in control groups.

The Taylor group, in a series of elegant papers, reports the use of several different *bispecific fusion proteins* (BiFPs) that enhanced phagocytosis by macrophage of various pathogens, including *E. coli*,[170] *P. aeruginosa*,[171] and *S. aureus*.[172] In all cases, BiFPs consisted of (1) a molecule that recognizes a surface marker on the pathogen that was chemically coupled with (2) a Mab that is specific to the complement receptor 1 (CR1) present on primate erythrocytes. In *in vitro* and *in vivo* studies, a series of works from the Taylor group has shown that BiFPs promote binding of the target pathogen first to

circulating erythrocytes, which then enhances macrophage phagocytosis of the bacteria. BiFP-mediated phagocytosis did not apparently harm the erythrocyte, as verified in both *in vitro* and *in vivo* experiments.[170]

Kobayashi *et al.*[173] reports improved *in vivo* and *in vitro* phagocytosis of a periodontal pathogen, *P. gingivalis*, using a BiFP composed of two monoclonal antibody fragments; one against (a) the hemagglutinin domain of *P. gingivalis* (anti-r130k-HMGD antibody) and (b) the PMN FcαRI (CD89) receptor (FcR). The Kobayashi work selectively targeted Fc receptors that were dominant on PMNs collected from gingival crevicular fluid of chronic periodontitis patients versus Fc receptors dominant on peripheral blood PMNs. Data show that PMNs exhibited a higher capacity to phagocytose and kill *P. gingivalis* opsonized with the BiFP targeting *P. gingivalis* r130k-HMGD to leukocyte Fc RI as compared to opsonizing the bacteria with only the anti-r130k-HMGD antibody.

A novel biomedical device would thus release artificial opsonins upon implantation to exploit the surge in macrophage numbers at the site of injury, thus promoting a short-term enhanced innate immune response. The bacterial or macrophage recognition moieties forming the BiFP opsonin could be a variety of different molecules, including synthetic cell structure recognition molecules (vancomycin, lectins), complete poly- or monoclonal antibodies, $F(ab')_2$ or $F(ab')$ fragments of antibodies, genetically constructed diabodies, or surface structure recognizing aptamers. Note, however, that the aforementioned examples use entire Mabs or fragments of Mabs and are very specific to their target bacterium. Thus, multiple BiFPs would need to be generated to protect against mixed strain or species infections. Currently, we are developing a class of small molecules as the bacterial-recognition portion of BiFPs that would provide broad-spectrum protection against any Gram-positive species.

4.418.3.2. Biomaterials that Vaccinate

While artificial BiFP opsonins may enhance an innate short-term immune response against device-colonizing microbes, literature indicates that most indwelling biomedical devices are susceptible to infections sometimes decades after implantation (e.g., late-stage endocarditis of heart valves).

The goal of any vaccine is to produce a long-term protective immune response against a pathogen. For most bacteria, initial attachment to a eukaryotic cell surface or ligand-coated biomedical device leads to biofilm formation, and then upregulation of virulence factors leads to infection. Both an innate and an induced adaptive antibody response could prevent attachment and abrogate pathogen colonization. The ideal antigens to promote both levels of immune response would be the very surface proteins (i.e., bacterial 'adhesins') that mediate specific bacterial cell adhesion to ligands present on host tissue or device surfaces.[174] Given that bacterial-specific adhesion can trigger expression of many virulence factors leading to acute and chronic inflammation, a vaccine approach that effectively blocks bacterial adhesion would have multiple advantages.

Our research group is developing a biomaterial platform to engineer infection immunity by releasing in multiple waves, vaccines that have as antigen target those bacterial surface structures used for bacterial-specific adhesion. Recent research has greatly expanded the molecular details of the specific adhesin: ligand couples (Table 1) employed by Gram-positive bacteria (*S. epidermidis*, *S. aureus*, Group A and B *Streptococcus*, *E. faecalis*), Gram-negative bacteria (*P. aeruginosa*, *Klebsiella pneumoniae*, *P. gingivalis*, *E. coli*), and yeast (*Candida* spp.) to colonize and infect living tissue and implanted biomedical devices.[174] Thus, the concept of biomaterials designed to engineer infection immunity, targeting specific adhesins, could be applied to numerous situations. Many of these cell-bound molecules have served as antigens in vaccines that have been evaluated *in vivo* (Table 2) for their ability to prevent systemic infections.

There are essentially three ways to activate a DC to present antigen, with the subsequent immune response being dependent upon the form of the antigen (Figure 4): direct antigen presentation (e.g., whole attenuated pathogen, isolated antigen molecule, recombinant protein), DNA vaccine (i.e., pDNA encoding for the antigen protein), and mRNA vaccine (i.e., RNA encoding for the antigen protein). Exogenously acquired protein antigens are processed by late endosomes into MHC-II complexes that initiate CD+4 T cell activation and then activate B cell antibody secretion. Endogenously acquired antigen (e.g., viral infection; DNA/mRNA vaccine) is tagged with ubiquitin, then partially degraded in the proteosome, transported next to the endoplasmic recticulum, and presented on the DC's surface as a MHC-I complex, thus activating an immediate (but short-lived) cytotoxic CD8+ T cell response. In contrast to protein vaccines, DNA- or RNA-based vaccines can provide the ability to potentially generate both a strong CTL response and humoral response.

Upon internalization of a pDNA vaccine carrier by DCs, the carrier must escape endosomal entrapment or be degraded, the carrier must release the pDNA into the cytoplasm, and finally, the pDNA must be incorporated into the DC nucleus for expression. Subsequently expressed antigen can be processed as aforementioned into MHC-I complexes to initiate priming of CD8+ T cell, or the antigen can be secreted. The secreted antigen can be taken up exogenously by the same or other DCs and presented by the MHC-II pathway to CD4+ T cells, which can secrete soluble cytokine signals in T or to B cells to induce antibody secretion. In DCs, in a process known as 'cross-priming,' endogenously expressed antigen could be routed to the MHC-II complex.

DNA vaccines have certain advantages over protein antigens, including (a) DNA can serve as a natural adjuvant by including unmethylated CpG motifs; (b) by coding for multiple gene expression, DNA vaccines can also induce costimulatory molecules; (c) pDNA can target expression to certain cellular locations, thus fine-tuning the immune response; and (d) pDNAs allow the possibility of multiple antigen expression. Disadvantages of DNA vaccines include (a) incorporated CpG motifs can lead to overstimulation and toxicity;[192,193] (b) the required large amounts of highly characterized pDNA require processing with antibiotics and antibiotic-resistance markers; (c) pDNA contain sequences meant to control gene expression (e.g., promoters, polyA signals, introns) that may deregulate gene expression after integration into the genome; and (d) genome-incorporated pDNA can result in uncontrolled duration and strength of antigen expression.

RNA vaccines offer the same advantages as DNA vaccines versus protein antigens, but RNA vaccines have several added

Table 1 Potential targets for anti-infection immunotherapy

Microbial species	*Common venue of infection*	*Molecular target/role*	*Molecule (accession no.; Swiss-Prot. no.)*	*Molecule gene (GeneID; Locus Tag)*
Staphylococcus epidermidis	Cardiovascular biomaterials, intravascular catheters, vascular prostheses, pacemaker leads, defibrillator systems, prosthetic heart valves, and left ventricular assist devices	AltE and Aae; autolysins, mediate adhesion	YP-188221; Q5HQB9	GeneID: 3241348; SERP0636
		SdrG; fibronigen (FGN)-binding protein	YP-187803; Q5HRI6	GeneID: 3242987; SERP0207
		GehD; collagen-binding protein	YP-189935.1; Q5HKF8	GeneID: 3241026; SERP2388
	Ventriculoperitoneal cerebrospinal fluid shunts and continuous ambulatory Peritoneal dialysis	icaC; polysaccharide intercellular adhesin (PIA)	YP-189846.1; Q5HKP7	GeneID: 3242232; SERP2296
		Aap; accumulation association protein	YP-189945.1; Q5HKE8	GeneID: 3242404; SERP2398
Staphylococcus aureus	Cardiovascular biomaterials; contact lenses; intraocular lenses, breast implants, indwelling catheters; fracture-fixation devices, ventricular shunts, inflatable penile implants; orthopedic devices	SAR2040 autolysin	YP-041411.1; Q6GFB1	GeneID: 2861487; SAR2040
		fnbA and fnbB; fibronectin (FN) receptors	fnbA [YP-495075.1; Q2FE03] fnbB [YP-495074.1; Q2FE04]	fnbA [GeneID: 3913735; SAUSA300-2441] fnbB [GeneID: 3913823; SAUSA300-2440]
		SdrD, SdrE, SdrG; FGN-binding protein	YP-493249.1; Q2FJ79	GeneID: 3914310; SAUSA300-0546
		CnA; collagen-binding receptor	YP-042111.1; Q6GDB2	GeneID: 2859239; SAR2774
		Bap; biofilm-associated protein		
		icaC; polysaccharide intercellular adhesin (PIA)	YP-042088.1; Q6GDD5	GeneID: 2859657; SAR2750
Candida albicans	Catheters; hemodialysis grafts; peritoneal dialysis Catheters; VADs; penile implants	Ala5 adhesin	XM-712914.1 → XP-718007.1; Q5A8L3	GeneID: 3640334; CaO19.13158
Pseudomonas aeruginosa	Contact lenses; intraocular lenses; urinary catheters; orthopedic implants; tracheal lavage tubes	lecB fucose-binding lectin PA-IIL	NP-252051.1; Q9HYN5	GeneID: 882528; PA3361
		oprF, major porin and FN-binding protein	NP-250468.1; P13794	GeneID: 878442; PA1777
		Adhesin LapA	NEWENTRY 175	GeneID: 3760128; NEWENTRY 176
		Asialo GM1		
Enterococcus faecalis	Cardiovascular materials; cardiovascular devices; intravascular catheters; transjugular intrahepatic portosystemic shunt devices; urinary catheters	Collagen type 4 binding Ace	NEWENTRY	GeneID: 2828057
		Endocarditis- and biofilm-associated pilus (ebp) genes (ebpA,B, and C)	NP-814823.1; Q836L8	GeneID: 1199995; EF1093
		Sortase A (SrtA)	NP-816668.1; Q82ZJ9	GeneID: 1201902; EF3056
		Alt autolysin	NP-814543.1; P37710	GeneID: 1199693; EF0799
Porphyromonas gingivalis	Dental biomaterials	Arg-specific (RgPA) proteases	YP-001930085.1; B2RM93	GeneID: 6330747; PGN-1970
		Lys-specific (KgP) proteases	YP-001929844.1; B2RLK2	GeneID: 6330196; PGN-1728

Microbial cell surface molecules involved in cellular adhesion or adherent cell biofilm formation.

benefits versus DNA vaccines.[194] Owing to RNA's smaller size, a larger amount can be delivered per carrier, thus in general being more efficient. Since RNA does not require nuclear incorporation, expression of antigen in transfected cells occurs much faster than with pDNA. Potentially dangerous side effects are reduced, since eukaryotic promoters needed for pDNA are not present in RNA constructs. mRNAs are relatively easy to manufacture in high amounts, to purify to homogeneity, and to characterize. Finally, RNA does not persist in the organism, and RNA is not incorporated into the genome.

One main drawback of both DNA and RNA vaccines is that the efficiency of naked oligonucleotide transfection is very low (compared to viral systems) due to lack of protection from systemic nucleases, inability to migrate through cell membranes, or entrapment and degradation within endosomes. Consequently, nonviral gene constructs typically require some type of polymer delivery system. The reader is directed to a number of excellent reviews on the subject of polymer gene delivery.[195–199]

Currently, we are developing a platform of polymer constructs that would release condensed RNA vaccines meant to transfect DCs arriving upon implantation of a biomedical device. Our polymer constructs will release nanoparticles of condensed DNA or mRNA vaccine that will target a selected adhesion protein employed by the microorganism to initiate colonization. Such targets could be the fibronectin-binding

Table 2 Existing vaccines that target microbial adhesin or biofilm formation virulence factors (**Table 1**)

Microbial species	*Antigen selected*	*Results*	*References*
Staphylococcus aureus	Immunization with four antigens (iron-regulated surface determinant protein = IsdA, iron-regulated heme-iron binding protein = IsdB, SdrD, and SdrE)	In contrast to individual protein antigens, immunization with the combined vaccine afforded complete protection against a lethal challenge with *S. aureus* Newman. Survival analysis revealed that the combined vaccine afforded significant protection against lethal challenge (10^9 cfu ml^{-1}) with any one of the five clinical *S. aureus* isolates	177
	Collagen-binding protein (CNA); CNA-based DNA vaccine	Vaccine produced hi titer (64 000) antibody and evidence of a cell-mediated immune response (CMI). The anti-CNA antibodies recognized intact bacteria and prevented binding to collagen *in vitro*. However, the vaccination did not protect against bacterial challenge using the intraperitoneal route of infection	178
	Multivalent polyprotein DNA vaccine; vaccines expressed clumping factor A (ClfA), fibronectin-binding protein A (fnbA), and the enzyme Sortase (Srt) as single proteins or combined as a polyprotein	All animals produced mixed Th1 and Th2 response including functional antigen-specific, mostly IgG2a antibodies, sustained production of IFN-γ, and a predominantly CD8+ T cell response. Upon virulent *S. aureus* isolate challenge, after 21 days, 55% of the multigene vaccinated mice survived infection compared to only 15% of control groups	179
	Four adhesion factors (fibrinogen-binding protein-SdrD), fnbA, clumping factor A-ClfA, and collagen adhesin-CnA as targets in a DNA vaccine	Intranasal immunization with a pDNA mixture coding the four adhesins, triggered significant levels of specific serum and mucosal Ig that inhibited *S. aureus* adhesion to cow mammary gland epithelial cells *in vitro*. Splenocytes of immunized mice challenged *in vitro* with *S. aureus* extracts showed a strong proliferative response. Finally, immunized mice were significantly protected against intramammary challenge with *S. aureus*	180
	Aurexis® (tefibazumab), a humanized monoclonal antibody anti- to clumping factor A, ClfA	Preclinical *in vivo* testing revealed that a single administration of Aurexis® significantly protected against an IV Challenge with a methicillin-resistant *S. aureus* (MRSA) strain in murine septicemia and rabbit-infective endocarditis (IE) models	181
	Surface polysaccharide poly-*N*-acetyl-β-(1-6)-glucosamine (PNAG) and a deacetylated form of the antigen (dPNAG; 15% acetylation) were conjugated to the carrier protein diphtheria toxoid (DT) and used to immunize animals	Immunization of animals with a conjugate vaccine of dPNAG elicit antibodies that mediated opsonic killing and protected against *S. aureus* infection	182
Staphylococcus epidermidis	mAbs against Aap and against surface-exposed lipoteichoic acid (LTA) were used for passive immunization of mice	Neither anti-Aap nor anti-LTA mAbs showed protection *in vivo*, although *in vitro*, anti-Aap, and anti-LTA did show binding to *S. epidermidis*	183
	Active immunization (AI) using a major immunogenic polysaccharide determinant of slime (20-kDa PS) as antigen, and passive immunization (PI) after administration of specific antibodies toward 20-kDa PS	Clinical grading showed that both AI and PI rabbits had a significantly less corneal damage as compared with infected nontreated rabbits	184
Enterococcus faecalis	Enterococcal aggregation substance (AS) is a large (137-kDa) surface-expressed protein encoded by pheromone-responsive, conjugative plasmids	Antibodies specific for AS were opsonic for *E. faecalis* expressing AS *in vitro*. New Zealand White rabbits immunized with AS were challenged intravenously with *E. faecalis* cells constitutively expressing AS in the rabbit model of experimental endocarditis. Highly immune animals did not show significant differences in clearance of organisms in comparison with nonimmune animals	185
Porphyromonas gingivalis	Immunized BALB/c mice with rgpA DNA vaccine via the abdomen with a Gene Gun or via the nasal cavity weekly for 6 weeks	Immunization elicited IgG responses against *P. gingivalis* in both groups. Nasal immunization also induced sIgA against *P. gingivalis*, although Gene Gun immunization did not. Reduction of alveolar bone loss was observed in both groups at 42 days following initial infection	186

(*Continued*)

Table 2 (Continued)

Microbial species	*Antigen selected*	*Results*	*References*
	An unnamed 40-kDa outer membrane protein of *P. gingivalis* (40-kDa OMP) was nasally administered with a nontoxic chimeric adjuvant (combination of A subunit of mutant cholera) Toxin and pentameric B subunit of heat-labile enterotoxin *E. coli*	Mice given nasal OMP adjuvant showed a significant reduction of alveolar bone loss caused by oral infection with *P. gingivalis* even 1 year after the immunization compared to unimmunized mice	187
	The ability of eight recombinant protein fragments corresponding to domains/regions of the RgpA–Kgp proteinase–adhesin complex to attenuate *P. gingivalis* infection, when used as a vaccine, in the murine lesion model was determined	The A1 adhesin portions of either the RgpA or Kgp complexes gave the best protection. Immunization with catalytic portions of the RgpA–Kgp proteinase–adhesin complex had no effect on *P. gingivalis* infection	188
Porphyromonas gingivalis	IgG generated by immunization with plasmids encoding for either the catalytic domain of Kgp or Arg-gingipain (Rgp) used to vaccinate mice	Immunized mice were challenged by intraperitoneal inoculation with *P. gingivalis*. All nonimmunized mice died within 72 h. Vaccination with either pDNA prevented inflammatory responses and prolonged the survival rate of immunized mice by 43 and 27%, respectively	189
	RgpA–Kgp complex and synthetic ABM and proteinase active site peptides conjugated to diphtheria toxoid	Protected against *P. gingivalis* induced periodontal bone loss in a murine periodontitis model. When RgpA–Kgp complexes or active site peptides are used as a vaccine, they induce a Th2 response that blocks function of the RgpA–Kgp complex	190
Pseudomonas aeruginosa	Compared the formation of antibodies in lower airways induced by systemic and mucosal vaccination strategies. Immunized 48 volunteers in six vaccination groups with either a systemic, a nasal, or four newly constructed oral live vaccines based on attenuated live *Salmonella* strains, followed by a systemic booster vaccination. All vaccines were based on a recombinant fusion protein of the highly conserved *P. aeruginosa* outer membrane proteins OprF and OprI as antigen	While systemic and mucosal vaccines induced a comparable rise of serum antibody titers, a significant rise of IgA and IgG antibodies in the lower airways was noted only after nasal and oral vaccinations	191

receptors on *S. aureus* used to bind to surface-immobilized fibronectin; cell surface Arg-specific (RgpA) and Lys-specific (Kgp) proteinases (designated the RgpA–Kgp complex) used by the oral pathogen, *P. gingivalis*, the major cause of chronic periodontitis; Group B *Streptococcus* to immobilized fibronectin; *Steptococcus mutans* and *S. sangiuns* to mucin-coated dental devices; *P. aeruginosa* binding to a G4 glycolipid on cornea and contact lenses; or *E. coli* FimH binding to mannose-coated catheters.

One distinct advantage of nucleotide transfection of DCs (vs. direct antigen protein) is that one can modify the DNA or mRNA with targeting signals to better control MHC class I and class II presentation. For example, incorporation of ubiquitin mRNA with the target antigen will result in an enhanced formation of peptides for MHC class I presentation,[200–202] whereas targeting sequences from the invariant chain (Ii) or lysosome-associated membrane protein (Lamp1) will lead to presentation of the antigen in the context of both MHC class I and class II, thus providing antigen-specific help.[203–206] Currently, we are developing mRNA vaccines against the *S. epidermidis* fibronectin-binding receptors used to colonize fibronectin-coated cardiovascular devices. *S. epidermidis* upregulate these fibronectin-binding receptors once exposed to serum at high shear stresses, which distinguishes infecting strains from benign *S. epidermidis* skin flora.

One might ask "Why transfect DCs from the medical device rather than simply vaccinate the patient prior to implantation?" Why not vaccinate patients systemically with antigen or mRNA vaccines coupled with a proven adjuvant? As reported previously, most systemic vaccine formulations consist of the antigen or a nucleotide molecule destined to express the antigen plus an adjuvant concoction meant to stimulate and heighten immune response. Typically, vaccine formulations seek to capitalize on immune cell phagocytosis by employing adjuvants in particulate form with or without additional immunostimulants. Even proven vaccine adjuvant formulations require multiple doses to achieve protective immunity.

Circumstantial evidence is emerging that biomedical implants may serve as the ideal vaccine adjuvant when designed properly. Classical vaccine/adjuvant combinations are notoriously inefficient at transfecting DCs. While the injection of naked pDNA in mice can induce an immune response, including the generation of antibodies and CTLs, high doses of DNA were needed to reach protective titers. Adjuvants have reduced the required DNA dose, but their design is mostly art. Only recently, because of the needs of cancer immunotherapies, has the biomaterials/gene delivery community begun to develop new strategies for adjuvant engineering. Bennewitz and Babensee[207] incorporated a model protein

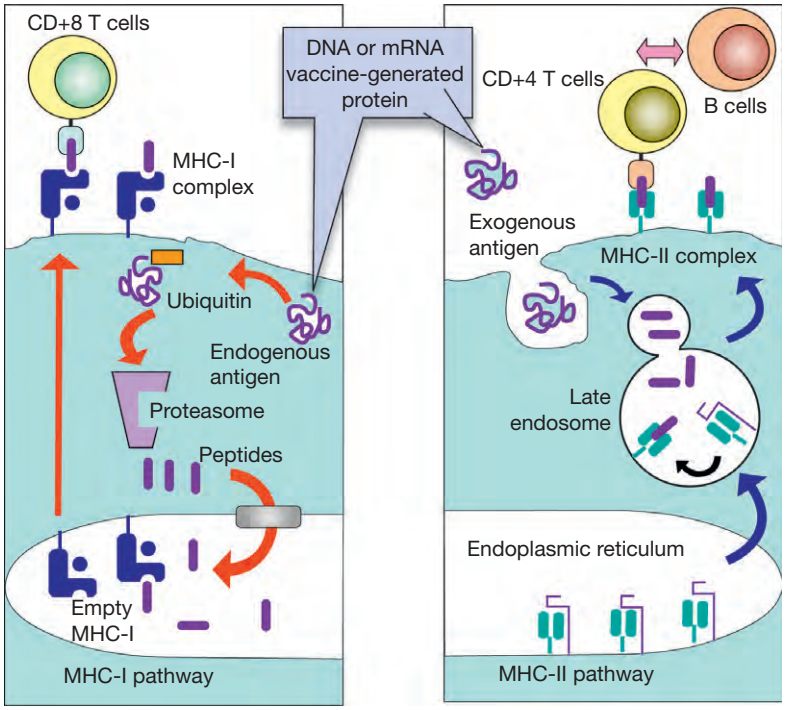

Figure 4 Antigen presentation and pathways of vaccine response. Plasmid DNA or mRNA is taken up by dendritic cells for intracellular expression of antigen. Antigen can be secreted (not shown) and subsequently taken up by other DCs as an exogenous antigen. Antigen expressed intracellularly by a dendritic cell or taken up through cross-priming is presented by MHC-I to CD8+ T cells (cytotoxic leukocytes; CTLs). Antigen taken in exogenously or directed by DNA or mRNA trafficking signals are processed by the MHC-II pathway and presented to CD4+ TH cells, which can subsequently secrete soluble cytokine signals (e.g., IL-12) back to the dendritic cell, proliferative signals (e.g., IL-2 and IFN-γ) to Tc cells, or signals directed toward B cells (e.g., IL-4) to induce B cell proliferation and antibody secretion.

antigen ovalbumin (OVA) into PLGA carriers; carriers were either microparticles (diameter = 3.5 μm) or porous scaffolds (0.7 cm dia. × 0.2 cm thick discs; pores ~400 μm). Carriers with antigen were then injected (particles) or surgically implanted (scaffolds) into mice and the resulting systemic humoral immune response to the released OVA was assessed by following the OVA-specific IgG concentration and isotypes. The total amount of polymer and antigen delivered was kept constant, as well as the antigen release rates. Humoral immune response was higher and sustained for antigen released from implanted scaffolds with associated tissue damage but was lower and transient when the same amount of polymer/antigen was delivered by particles, which were minimally invasively delivered by injection. Results implicate 'danger signals' associated with the implantation of the scaffolds because of tissue injury, and may prime the system for an enhanced immune response. Localized DC cell counts reported were significantly higher around the surgically implanted scaffolds versus particle injections.

Ali *et al.*[141,142] developed porous poly[lactide-*co*-glycolide] polymeric scaffolds to first release a cytokine (GM-CSF) to recruit and house host DCs, and subsequently present cancer antigens (melanoma tumor lysates) and danger signals (bacterial CpG oligonucleotide sequences) to activate the resident DCs and markedly enhance their homing to LNs. The ability of the scaffolds to recruit DCs and program an immune response was evaluated *in vivo* in a murine melanoma tumor model. The vaccine provided significant protection, with the level of protection correlating with CpG dose. Animal survival increased from 23 to 50% and 90% at CpG doses of 0, 10, and 100 μg, respectively. Scaffolds presenting CpG-ODN with antigen alone resulted in only a 20% survival, indicating the benefit of recruiting DCs with GM-CSF. The failure of vaccine formulations consisting of bolus systemic injections of antigen, CpG-ODN, with and without 3000 ng of GM-CSF, demonstrated the benefit of the scaffold, providing a local residence for recruited DCs while they are programmed with CpG. Similar to the work of Bennewitz and Babensee[207] earlier, injecting GM-CSF-loaded PLG nonporous microspheres that provided sustained GM-CSF delivery but not porous structure to provide a residence for recruited cells, with bolus injections of CpG-ODN and tumor lysate, resulted in little immune protection, and animals did not survive past 35 days.

4.418.4. Concluding Remarks

As engineered biomaterials and tissue regenerative medicine advance, an increasing portion of the population will receive one or multiple biomedical devices, ranging from disposable contact lenses, dental implants, orthopedic implants, and vascular grafts to tissue-engineered livers, small-diameter vascular grafts that promote stem cells differentiation into endothelial cells, and a polymer transfection system that delivers microRNA knockout therapy to control chronic inflammation. Current biomaterials approaches to prevent infections of such

implants will do little to reduce the current nosocomial infection epidemic, thus seriously compromising the use of the advanced devices and tissue constructs currently under development. Newer approaches are required to prevent device-based infections; approaches that, like tissue engineering, direct the human immune system against biofilm-forming microorganisms with biologically specific programming.

Here, we have highlighted the prospects and remaining obstacles to generating both a short-term (innate) and a lifelong (adaptive) host infection immunity that originates from the biomedical device itself. Technologies described here could also have implications outside infection defense; in the areas of vaccine delivery or cancer immunotherapy.

Glossary

Adjuvant Any material used to augment the immune response to an antigen during vaccination.
Antigen Molecule derived from a pathogen that is the molecular target of a T cell or antibody response.
Antigen-presenting cells (APC) Cells capable of displaying peptide antigens bound to major histocompatibility complex (MHC) molecules on their surface, enabling the activation of antigen-specific T cells.
Chemokine Host protein secreted by stromal or immune cells to attract immune cells (or other cells) to a tissue site by the process of chemotaxis.
CpG DNA Short single-stranded oligonucleotides containing specific patterns of unmethylated C-G motifs, which are PAMP signatures of bacterial DNA and ligands for TLR9.
Cross-presentation Process of APC internalization of extracellular antigens, and processing and loading of these antigens onto class I MHC molecules for presentation to $CD8^+$ T cells.
DAMPs Danger-associated molecular patterns; endogenous molecular signatures of tissue damage/cell death, which are recognized by immune cells as 'danger' signals.
DNA vaccine Vaccine based on the delivery of nucleic acids that encode for antigens of interest, enabling *in situ* production of antigen in tissue to drive an immune response.
PAMPs Pathogen-associated molecular patterns; conserved molecular motifs that the immune system has evolved to recognize as signatures of pathogenic microbes.
