Widespread follicular keratosis is a striking feature of keratitis, ichthyosis, and deafness syndrome, a connexin/gap junction disorder, which is also characterized by alopecia of scalp, body, eyebrow, and eyelash hair, vascularizing keratitis, and a profound sensorineural hearing loss.[54]

Hereditary Mucoepithelial Dysplasia

The characteristic features of hereditary mucoepithelial dysplasia (HMD) are follicular keratosis, non-scarring alopecia with some coarse abnormal hairs remaining, fiery-red palatal and gingival mucosae, photophobia with demonstrable keratitis and corneal vascularization, and psoriasiform hyperkeratotic lesions in the perineal area and often also on the extensor limbs.[55–57] The condition occurs in both sexes, and family studies suggest both autosomal dominant and autosomal recessive patterns of inheritance may be possible. Light microscopic evaluation of skin and mucosae shows dyskeratotic cells in the spinous layer, vacuolated basal cells, and lack of epithelial maturation.[55,57] Electron microscopy shows paucity of desmosomes, cytoplasmic vacuolization, and presence of multilaminar bands and wheat sheaf–like collections of filamentous fibers in the cytoplasm, resembling gap-junction material, and suggesting a disorder of desmosomal or gap junction proteins.[55] Recent studies of several characteristic cases in one pedigree found normal expression of gap junction proteins (connexins 26, 32, and 43), desmosomal proteins (desmogleins 1 and 2, plakoglobin, desmoplakins I and II, and plakophilin 1), adherens junction proteins (β-catenin and E-cadherin), and cytoskeleton proteins (keratins, β-tubulin, vimentin, and actin).[57] Genetic analysis in the studied family excluded the desmosomal cadherins in chromosome 18q12 as candidate genes and ruled out a mutation in connexin 26.[57]

Ichthyosis Follicularis, Alopecia (Atrichia), and Photophobia Syndrome

The association of ichthyosis follicularis, alopecia, and photophobia was first reported as a syndrome by McLeod in 1909,[58] and for many years additional reported cases of what came to be designated *IFAP syndrome* occurred in males. Affected individuals demonstrate widespread, flesh-colored, spiny, follicular projections with minimal, if any, inflammation, severe alopecia, often total atrichia involving eyebrows and lashes as well as scalp hair, and severe photophobia, often with demonstrable corneal vascularization.[15,59–62] The condition was postulated to be inherited as an X-linked recessive trait, which is supported by the report of the mother and sister of a male patient with classical features of IFAP syndrome having linear lesions of hyperkeratosis, hypohidrosis, and atrophy and a patchy scalp alopecia, distributed along Blaschko's lines.[63] Many patients have only cutaneous features, but neurologic and skeletal anomalies and recurrent infections have occasionally been described.[60,62,64–66]

Atypical cases have included females with generalized involvement and transmission from mother to daughter[64,67–69]; psoriasiform patches,[62,68,69] particularly involving the perineal area; and hypotrichosis rather than complete atrichia.[69] Some patients with psoriasiform plaques lack the typical spiny follicular projections[62,66] and may represent a different entity,[70] or even a variant of HMD.[69] In support of the latter is the ultrastructural finding of reduced numbers of desmo-

TABLE 85-2
Syndromes with Follicular Atrophoderma as a Feature

CONDITION	INHERITANCE	MAIN FEATURES	COMMENTS
Bazex syndrome (Bazex-Dupre-Christol syndrome)[73]	X-linked dominant	Hypotrichosis, pili torti, hypohidrosis, milia, development of basal cell carcinomas in adolescence.	—
Rombo syndrome[74]	Autosomal dominant	Hypotrichosis, especially of eyelashes, peripheral cyanosis, basal cell carcinomas, and trichoepitheliomas.	—
X-linked dominant chondrodysplasia punctata (Conradi-Hünermann syndrome)[75]	X-linked dominant, lethal in males	Congenital Blaschko-distributed red scaly lesions that resolve in months, replaced by follicular atrophoderma. Cataracts, shortening of limbs, frontal bossing, saddle nose, low-set ears.	Mutation in emopamil binding protein gene, relevant in cholesterol biosynthesis
Congenital ichthyosis, follicular atrophoderma, hypotrichosis, and hypohidrosis[76,77]	Probably autosomal recessive	Congenital, diffuse ichthyosis, hypohidrosis, hypotrichosis. Woolly hair in one pedigree.	Only described in two families so far
Hereditary perioral pigmented follicular atrophoderma associated with milia and epidermoid cysts[78]	Autosomal dominant	Epidermoid cysts and milia.	Follicular atrophoderma limited to face, especially periorally
Nevus comedonicus[79]	Somatic mutation	Blaschko-distributed comedo-like plugs in dilated follicular orifices. Cribriform atrophy follows extrusion of comedones.	Due to somatic mutation of fibroblast growth factor receptor 2, identical to that, which, if present in the germline, causes Apert syndrome

somes in one patient with IFAP and psoriatic lesions, analogous to what is seen in HMD.[68] Treatment of IFAP is usually unsatisfactory, but there is a single report of temporary flattening of the follicular keratotic papules with oral acitretin.[72]

SYNDROMES ASSOCIATED WITH FOLLICULAR ATROPHODERMA

Follicular atrophoderma occurs as a feature of several rare syndromes[73–78] and in nevus comedonicus (Table 85-2).[79] As such, these conditions may come into the differential diagnosis of atrophoderma vermiculatum.

CHAPTER 86

Hair Growth Disorders

Ralf Paus
Elise A. Olsen
Andrew G. Messenger

Given their prominence in daily dermatologic practice, hardly any dermatologist can escape having to manage patients with hair growth disorders. These manifest as undesired hair loss (effluvium, alopecia) or as cosmetically disturbing, unwanted hair growth (hirsutism, hypertrichosis).

In this chapter, we sketch the biologic basis of hair growth disorders, explain key management principles, give definitions (Table 86-1), and provide practical advice on diagnosis and therapy. Throughout this chapter, we argue that, in order to offer our patients more effective hair therapy, it is essential to adopt a pathogenesis- and hair biology–based approach to hair growth disorders.

It is important to realize that the plight of patients with a hair growth disorder can be quite substantial, and is notoriously underestimated. The affected individual's "burden of disease" and the corresponding loss in the quality of life are easily missed (see eFig. 86-0.1 in online edition).[1,2] The clinical problem at hand is often trivialized by the consulted physician, and unrealistic patient expectations for hair restoration meet with a rather limited availability of effective medical therapy.

Despite the rather limited practical advances in the pharmacologic management of hair growth disorders during the past decade,[3–5] the cellular and molecular basis of hair growth disorders is becoming increasingly understood. However, there are now clear-cut, evidence-based

APPROACH TO THE PATIENT WITH HAIR GROWTH DISORDERS

AT A GLANCE

- Classify the hair disorder based on pathogenetic principles (see Table 86-2) and clinical pattern (see Table 86-4).
- Exclude or confirm the most common hair growth disorders based on pattern and diagnostic tools (see Table 86-3).
- Dispel misconceptions and educate the patient.
- Treat as appropriate for the confirmed or suspected diagnosis.
- Provide emotional support for patients who are adversely affected by the cosmetic effects.

guidelines for the assessment and management of patients with alopecia.[4,6,7]

PRINCIPLES OF HAIR FOLLICLE PATHOBIOLOGY

Hair growth disorders are best understood and managed if one recalls some basic concepts of hair follicle biology (for more details on hair follicle structure and function, see Chap. 84).

Clinically Relevant Hair Biology

Knowledge of the basic biology of hair enables essentially all hair growth disorders to become easily understandable as reflections of distinct pathogenetic mechanisms or combinations (Table 86-2).

Problems of the Hair Follicle Cycle

Disturbances of hair follicle cycling lie at the heart of most hair growth disorders, and have dramatic effects on visible hair growth and hair shaft shedding. If the anagen phase is prematurely terminated and catagen occurs too early, the affected skin shows largely catagen and/or telogen follicles, and loosely anchored club hairs that are eventually shed (i.e., the normal anagen/telogen ratio of approximately 4.5:1 changes in favor of telogen). Considering that our scalp skin alone has approximately 100,000 hair follicles, even relatively small shifts in the percentage of anagen versus telogen follicles have major effects on hair growth and shedding.

The resulting effluvium and alopecia is exemplified by drug- or hormonally induced telogen effluvium, or when inflammatory cells attack the anagen hair bulb in alopecia areata.[8,15] Alopecia areata offers a particularly instructive illustration of how crucial hair cycle disturbances are for hair loss: The hair-damaging inflammatory cell infiltrate almost exclusively attacks anagen hair bulbs; this immune attack then catapults anagen follicles into a dystrophic catagen, causing a major hair cycle disturbance and rapid shedding of the insufficiently anchored, improperly formed hair shafts.[22–24] As a result, the three most effective therapeutic strategies for hair loss therapy in the vast majority of patients that suffer from hair loss, in declining order of importance, are (see eFig. 86-0.2 in on-line edition):

1. To inhibit catagen development so as to prolong anagen.
2. To induce anagen in telogen follicles so as to increase the percentage of actively hair shaft-producing follicles.
3. To inhibit exogen so as to reduce hair shaft shedding.

Unfortunately, neither of the two currently available U.S. Food and Drug Administration–approved standard hair drugs (finasteride, minoxidil; see Treatment) are highly efficient and reliable catagen inhibitors or anagen inducers, and it is unknown whether they affect normal hair shedding ("exogen")[17] at all. Even 17β-estradiol, an important hair growth–modulatory hormone,[18] may inhibit catagen in human scalp hair follicles[25,26] more effectively than these standard "hair drugs." However, catagen inhibition can often simply be achieved by eliminating a catagen-inducing drug (e.g., β blockers, synthetic retinoids, anticoagulants, antithyroid drugs), by professional management of a catagen-inducing endocrine disorder (e.g., thyroid dysfunction, hyperandrogenism, hyperprolactinemia), or by adequate substitution therapy of a catagen-promoting deficiency (e.g., in iron, zinc, estradiol, or protein deficiency).[27–29]

Problems of Hair Follicle Transformation

Next to hair cycle abnormalities, the second most important cause of hair growth disorders involves the terminal-to-vellus or vellus-to-terminal transformation of hair follicles in a skin region where this does not normally occur spontaneously and/or is undesired. The former is the hallmark of patterned balding, which arises from the miniaturization of very large, well-pigmented

TABLE 86-1
Definitions

- Alopecia: Hair loss usually on the scalp
- Canities: Graying of hair
- Effluvium: Process of increased daily hair shaft shedding (normal: 25–100)
- Telogen hairs: Club hairs with depigmented rounded up proximal ends
- Anagen hairs: Hairs with pigmented malleable proximal ends
- Hair follicle cycle: Life-long cyclic transformations of the hair follicle, which begin in utero
- Catagen: Apoptosis-driven regression phase in between telogen and anagen phase
- Telogen: Period of relative quiescence, lasts variable periods of time depending on body site
- Anagen: Growth phase, lasts variable periods of time depending on body site
- Exogen: Active process of hair shaft shedding
- Hirsutism: Increased hair growth in male secondary sexual hair areas in a woman, restricted to strongly androgen-responsive hair follicles
- Hypertrichosis: Increased growth of terminal hairs in an area normally rich in vellus hairs
- Lanugo hair: Produced in utero, pigmented, in length and in form somewhere between vellus and terminal hair; occurrence in postnatal life (hypertrichosis lanuginosa) may indicate a serious problem
- Poliosis: Localized white hair
- Scarring alopecia: Cicatricial/permanent alopecia. Irreversible loss of hair follicles, with disappearance of follicular orifices, and potentially skin atrophy
- Terminal hair: Produced by large hair follicles located in the subcutis; hairs are generally > 0.03 mm in diameter
- Vellus hair: Produced by very small (but functionally fully active, cycling) hair follicles located in the dermis; thin (≤ 0.03 mm diameter), short, often depigmented, usually non-medullated hair shaft

TABLE 86-2
Pathogenesis Approach to Diagnosis

Pathogenetic Principle	Clinical Effect (Examples)
• Disturbed hair follicle cycling	Effluvium (telogen effluvium, alopecia areata, androgenetic alopecia, chemotherapy-induced alopecia)
• Unwanted hair follicle transformation	Patterned hair loss (androgenetic alopecia) Hirsutism Hypertrichosis
• Defective hair follicle regeneration	Cicatricial alopecia (lichen planopilaris, traction alopecia, radiation-induced alopecia, folliculitis decalvans, chronic discoid lupus erythematosus)
• Structural hair shaft defect	Hair shaft disorders (monilethrix, pili torti, trichothiodystrophy)
• Improper/missing hair follicle development	Aplasia cutis congenita Ectodermal dysplasias
• Combinations of the above	

Note that infectious or physical agents (e.g., staphylococci, dermatophytes, herpes–varicella zoster virus; ionizing radiation, trauma) or drugs that can lead to alopecia do so by inducing one or several of the above pathogenesis pathways (e.g., disturbed hair follicle cycling, structural hair shaft defect, defective hair follicle regeneration).

terminal hair follicles in androgen-sensitive scalp regions (i.e., vertex, temporofrontal skin) into minute, unpigmented, vellus hair follicles by dihydrotestosterone. This is usually, but not always, accompanied by telogen effluvium, due to the anagen-shortening effect of androgens (see eFig. 86-0.2 in on-line edition). The opposite transformation process underlies hirsutism, characterized by the excessive vellus-to-terminal transformation of androgen-dependent hair follicles in a male pattern, or as is seen in drug-, hormone-, or porphyrin-induced hypertrichosis.

Defects in Hair Follicle Regeneration

Permanent alopecia or cicatricial alopecia largely results from a defective capacity for hair follicle regeneration due to irreversible damage suffered by epithelial hair follicle stem cells. How exactly autoaggressive, inflammatory attacks on hair follicle stem cells are induced and regulated, how they may best be prevented, and how the recovery of these stem cells from immunologically or radiation-induced damage may be effectively promoted are all critically important, yet unanswered, questions.

Structural Hair Shaft Defects

Acquired or inherited defects in hair shaft production (e.g., from the expression of abnormal hair keratins or insufficient hair follicle supply with essential nutrients, trace elements, or vitamins) may lead to the generation of distorted, misshapen hair shafts during anagen. These structural changes may lead to hair fragility, with breakage soon after the hair penetrates the epidermal surface.

Alopecia Due to Improper or Missing Hair Follicle Development

Extremely rarely, as in aplasia cutis congenita (see Chap. 106) and in various forms of ectodermal dysplasias (see Chap. 143), hair follicles in defined regions of the integument have never developed properly. This must be distinguished from rare, inherited hair follicle abnormalities in which patients present with neonatal or early-onset alopecia, despite presumably normal intrauterine hair follicle development. This is true for the human equivalents of the well-known nude and hairless alopecia phenotypes seen in mutant mice. These conditions result from defined transcription factor defects that lead to improper hair shaft formation (nude/FOXN1)[36–38] or progressive hair follicle destruction with the onset of catagen (hairless)[39–42] after apparently normal hair follicle development.

DIAGNOSTIC TECHNIQUES

Hair loss confronts one with greater diagnostic challenges than disorders associated with excessive hair. It is optimal to follow established guidelines for considering and excluding the chief causes of effluvium and/or alopecia (Table 86-3; Fig. 86-1).[4,7] Using pattern recognition (Table 86-4) and focusing on pathogenic principles (see Table 86-2), one can use diagnostic procedures of increasing complexity (see Table 86-3) to reach a diagnosis. In general, the diagnosis is likely to be one of the four most common hair growth disorders [androgenetic alopecia (male or female pattern), telogen effluvium, alopecia areata, or hirsutism], rather than a rare diagnosis. The presence of "alarming hair signs" should be sought, and difficult differential diagnoses should be considered.

ALOPECIA: DIFFUSE (GLOBAL) HAIR LOSS

Reduced or absent hair growth in infancy may be the result of a failure of normal hair follicle development, and may be associated with other ectodermal defects (see Chap. 143). Many of these hereditary syndromes have other anomalies, most frequently bone, central nervous system, or eye. The features and mechanisms that underlie genetic disorders with hair abnormalities are discussed and regularly updated in the Online Mendelian Inheritance in Man website (http://www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM).[47]

The most common of the ectodermal dysplasias, hypohidrotic ectodermal dysplasia, which is characterized by sparse hair, abnormal teeth, and reduced or absent sweating, is due to mutations in the ectodysplasin signaling pathway.[48] This pathway is involved in the early embryogenic events in formation of the hair follicle placode.[21,49,50] Ectodermal dysplasias and genetic hair disorders for which genetic loci have been identified are listed in, and are largely discussed in other chapters, particularly Chap. 143.

HAIR SHAFT ABNORMALITIES

Hair shaft abnormalities can be primary and hereditary or secondary to external factors. Some hair shaft abnormalities represent common endpoints to various forms of trauma or inherent shaft weaknesses, and some are specific to a particular constellation of findings or inherent make-up of the hair shaft. Hair shaft abnormalities can be divided into those associated with hair breakage and those associated with unruly hair.

Hair Shaft Abnormalities Associated with Hair Breakage

TRICHORRHEXIS NODOSA The most common defect of the hair shaft leading to hair breakage is trichorrhexis nodosa.[51] Mechanical or chemical damage triggers this response, which can occur in nor-

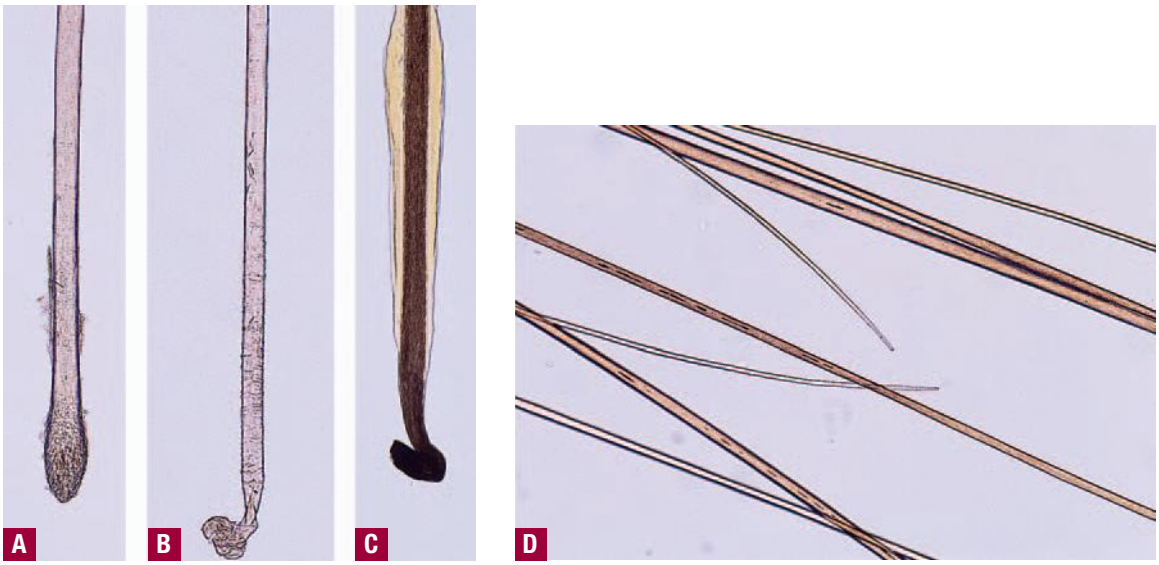
TABLE 86-3
Diagnostic Procedures

- Essential procedures
  - Hair pull test to assess scalp hair cycling
    - Manually grasp 50–100 scalp hairs and apply gentle traction from the base to the terminal ends, repeating in various areas of the scalp.
    - Shedding of more than two hairs/hair pull on multiple hair pulls is pathologic, if hair has been shampooed regularly.
    - To assess easy breakage or brittleness of hair if suspect structural hair shaft defect, hold hair shafts at both ends, and pull in opposite directions or rub hair between fingers.
  - Hair shaft microscopy
    - Align proximal portions of collected hairs on slide in a drop of cyanoacrylic glue, apply coverslip; alternative technique is to let hair shafts swell on glass slide in a drop of tap water under coverslip for 10 min before inspection.
    - Evaluate the proximal ends of pulled hairs for intact shaft and bulb, or hair breakage.
    - Assess if normal telogen club hairs (physiologic aberration; see Fig. 86-3A) versus dystrophic telogen or anagen hairs (pathologic process; see Fig. 86-3B).
  - Dermatoscope
    - Search for signs of scarring and a quick look at hair shaft details.
  - Biopsy (mandatory if scarring alopecia is suspected; insight into mechanism)
    - Take one to two 4-mm or one 6-mm punch biopsy in the direction of the follicle growth (oblique angle) and to a sufficient depth to contain the follicular bulbs in anagen located in the subcutis. The 6-mm punch should be bisected.
    - Vertical and horizontal sections have different uses: Vertical sectioning gives one a view of the epidermal/dermal interface, and horizontal sections allow quantitative assessment of the hair density.
- Additional useful tests
  - Trichogram (hair pluck test)
    - Rarely done today. Quick pull of 50–100 hairs en masse using a clamp or needle holder. Inspection of proximal hair bulbs allows determination of anagen/telogen ratio, but fraught with procedural artifacts, fails to give critical information about the type of hair being shed, and yields small sample size.
  - Phototrichogram (objective hair cycle assessment)[5]
    - To determine (1) the percentage of hairs in anagen, (2) the growth rate (with sophisticated cameras and computer software), and (3) shaft diameter requires locating the same precise target site at each time point, standardized photography, and standardized hair counting by image analysis.
    - Hairs are shaved in a demarcated target area and comparative photographs done at baseline and 2–3 days later. Only anagen hairs increase their length on follow-up (normal hair growth is ~ 1 cm/mo).
  - Global hair photography
    - Assesses the global cosmetic appearance of scalp hair in a defined area (vertex, frontotemporal, occipital) under precisely standardized conditions (constant distance, angle, and lighting) before, during, and after therapy. Optimal for independent, blinded assessments of therapeutic success or failure.
  - Hair shedding count
    - Standardized hair loss count before and 3 months after therapy.
    - Day 1: shampoo vigorously; days 2–4: no shampooing, comb only once a day. For these 3 days, have patient collect (1 envelope/day) and count only hair shafts lost during combing once daily.
  - Potassium hydroxide stain (for suspected fungal infection)
    - May reveal spores and hyphae in plucked proximal shafts. Complement with standard mycologic cultures.
    - Wood's lamp (see Chapter 5)
  - Laboratory tests
    - Most commonly performed for hair loss: complete blood cell count, ferritin or iron/total iron binding capacity, thyroid-stimulating hormone, and thyroxine
  - Additional tests as suggested by history and examination
    - Testosterone, dehydroepiandrosterone, sex hormone–binding globulin, prolactin, anti-nuclear antibody, double-stranded DNA, C-reactive protein, erythrocyte sedimentation rate, VDRL/treponemal hemagglutination.
  - Complementary techniques for hair shaft abnormalities
    - Most hair shaft abnormalities can be diagnosed by light microscopic examination, although some types require scanning electron microscopy to confirm findings suggested by light microscopy (e.g., longitudinal grooving), or to definitively rule out (e.g., monilethrix). Polariscopic examination should be performed if trichoschisis (a particular pattern of hair breakage) is seen under light microscopy to evaluate potential trichothiodystrophy (sulfur-deficient hair). The etiology of brittle hair can be further pursued by direct amino acid analysis of whole-hair hydrolysates and electrophoretic characterization of the main classes of proteins in hair (generally defined by their cysteine content, and designated ultrahigh-, high-, and low-cysteine or ultrahigh, high-, and low-sulfur proteins).

Data from Olsen EA: Current and novel methods for assessing efficacy of hair growth promoters in pattern hair loss. *J Am Acad Dermatol* **48**:253, 2003.

mal hair, but occurs much more readily in inherently weak hair. Microscopically, the affected hair develops a breach in the cuticle, with eventual separation and fraying of the exposed cortical fibers leading to a nodal swelling.[52] The fibers then fracture and the shaft breaks with the resultant appearance of a splayed paintbrush or fan-like array (Fig. 86-2). Trichorrhexis nodosa may be congenital or acquired.

Congenital trichorrhexis nodosa may be present at birth or may appear within the first few months of life. Although it might occur as an isolated defect or, rarely, with follicular hyperkeratosis or teeth/nail defects,[51] the occurrence of congenital trichorrhexis nodosa should lead to a search for an underlying metabolic disorder. Patients with argininosuccinic aciduria (see Chap. 131), primarily those with the late-onset form (occurring at more than 2 years of age),[15] have associated hair defects. In this condition, in which absence of the enzyme argininosuccinase leads to an accumulation of the nitrogenous waste precursor argininosuccinic acid, brittle lusterless hair develops along with psychomotor retardation and ataxia. The diagnosis is established by finding acidosis, hyperammonemia, and low serum arginine.[53] Citrulline (the normal precursor of argininosuccinic acid in the urea cycle) accumulates in the condition citrullinemia (see Chap. 131), which is caused by a defect in the enzyme argininosuccinic acid synthetase. In this condition, the hair is brittle and both trichorrhexis nodosa and pili torti (another common hair shaft defect) may be present.[51,54] Affected infants have an associated dermatitis that may be widespread but more pronounced in the perioral and diaper area. Patients with Menkes syndrome, caused by a defect in copper efflux,[55] and trichothiodystrophy (TTD; see Chap. 47), caused by a defect in the synthesis of the ultrahigh- and high-sulfur proteins integral to hair,[56] both have tri-



▲ **FIGURE 86-1** **A.** Telogen club hairs have a cornified, depigmented, rounded-up bulb without an attached root sheath. **B.** Loose anagen hair obtained by hair pull: Ruffled cuticle and no attached root sheath. Anagen hairs are recognized clinically by their pigmented, somewhat distorted, malleable bulb. Anagen hairs should not normally be found in a hair pull in patients with alopecia areata. **C.** Comparison with a normal anagen hair obtained by hair pluck. **D.** A newly growing anagen hair has a tapered distal tip rather than the blunt distal end of hairs that have been cut or trimmed or ends that are intrinsically broken.

chorrhexis nodosa apparent on microscopic examination of the associated brittle hair.

Acquired trichorrhexis nodosa, which is much more common than hereditary trichorrhexis nodosa, may be either distal or proximal. Proximal breakage appears most commonly in African American women, usually after repetitive chemical or hot-comb straightening.[51] Distal trichorrhexis nodosa is more commonly secondary to excessive brushing, back-combing, or sporadic use of permanent waves. Treatment of trichorrhexis nodosa, congenital or acquired, is by avoidance of chemical or physical trauma to the hair.

TRICHOSCHISIS The break in trichoschisis is a clean transverse fracture through the entire hair shaft at a location where there is a focal absence of cuticle (Fig. 86-3). Trichoschisis is usually, but not specifically, a marker for the sulfur-deficient hair of TTD, in which the hairs of the scalp, eyelashes, and brows are short and brittle.[51] The hair abnormality of TTD identifies a group of autosomal recessive disorders in which acronyms or eponyms identify particular constellations of extratrichologic neuroectodermal abnormalities (Table 86-5). In affected individuals, the hair cystine content is less than one-half normal, primarily from a major reduction and altered composition of the ultrahigh-sulfur matrix proteins.[56] Polariscopic examination of affected hairs characteristically shows alternating light and dark bands, presumably secondary to variations in sulfur content (see Fig. 86-3).[51] Various structural abnormalities can be detected by confocal and scanning electron microscopy, whereas Raman spectroscopy shows a larger contribution of energetically less favored disulfide conformers in TTD hairs. Taken together, these complex abnormalities make TTD hairs excessively prone to breakage and weathering.[57] Sulfur and/or amino acid analysis of the hair is diagnostic.

Patients with TTD, particularly the 50 percent with associated photosensitivity, may have a defect in excision repair of ultraviolet (UV) damage but without an increased risk of skin cancer.[58] Recent data support correlation of mutations in the DNA repair and transcription gene ERCC2 locus with the nucleotide excision repair characteristics of both TTD and xeroderma pigmentosum (see Chap. 140).[25] No treatment is currently available, but photosensitive patients should be tested for their cellular response to UV radiation and encouraged to practice sun protection.

PILI TORTI The short and brittle hairs in patients with pili torti, when viewed through a microscope, appear flattened and twisted through 90° to 360°.[51] The twisting must be differentiated from the normal twisting in the hair of black individuals and in the pubic/axillary hairs of other races; the hairs are distinguished by the multiple irregular intervals of twisting along an otherwise straight hair shaft (Fig. 86-4A). As with trichorrhexis nodosa, pili torti does not signify a particular abnormality but can be seen in many different syndromes and in the presence of other hair shaft abnormalities. Hereditary pili torti as an isolated finding, usually autosomal dominant, but potentially autosomal recessive or sporadic, is present at birth or develops over the first 2 years of life (see Fig. 86-4B). Clinically, the patient may have patchy alopecia with coarse stubble or longer broken hairs. The hair abnormality may improve after puberty. Pili torti, or a facsimile best characterized as "twisting hair dystrophy,"[26] may occur with other abnormalities. Particularly notable is the association of pili torti with Menkes syndrome (which results from inherited loss-of-function mutations in the gene encoding a copper-transporting adenosine triphosphatase (Atp7a) on the X chromosome[59] or trichopoliodystrophy. Infants with Menkes syndrome develop sparse, depigmented brittle hairs that show pili torti or trichorrhexis nodosa on microscopic examination.[51] The affected child characteristically has pale, lax skin, and mental and neurologic impairment secondary to degeneration of cerebral, cerebellar, and connective tissue.[60] In this X-linked recessive disorder, the defective gene, MKN or ATP7A, which maps to Xq13.3, encodes a copper-translocating membrane protein adenosine triphosphatase that prevents effective copper transport and leads to the accumulation of intracellular copper in

TABLE 86-4
Sorting Hair Growth Disorders by Clinical Pattern

- Alopecia
  - Localized, non-scarring
    - Alopecia areata
    - Trichotillomania
    - Traumatic alopecia, including traction[a]
    - Infection (tinea capitis)[a]
    - Alopecia psoriatica[a]
  - Localized, scarring
    - Lichen planopilaris
    - Frontal fibrosing alopecia (Kossard)
    - Cutaneous discoid lupus erythematosus
    - Morphea
    - Acne keloidalis nuchae
    - Infection (deep fungal infection, zoster, massive bacterial folliculitis, tinea capitis with kerion)
    - Folliculitis decalvans
    - Radiation-induced alopecia
    - Aplasia cutis congenita
    - Epidermolysis bullosa (junctional, dystrophic, or acquired)
  - Diffuse, non-scarring
    - Androgenetic alopecia
    - Telogen effluvium
    - Anagen effluvium
    - Alopecia areata
    - Androgen-induced alopecia
    - Loose anagen syndrome
    - Atrichia with papular lesions/hereditary vitamin D–resistant rickets
    - Ichthyosis follicularis, congenital atrichia and photophobia syndrome
  - Diffuse hair shaft disorders
    - Congenital papular atrichia
    - Alopecia with isolated hair shaft abnormality
    - Monilethrix
    - Trichorrhexis nodosa
    - Pili torti
    - Netherton syndrome
    - Trichothiodystrophy
    - Menkes syndrome
    - Ectodermal dysplasia syndromes
- Hypertrichosis
  - Localized: see Table 86-11
  - Generalized: see Table 86-10

[a]Can also be scarring.

some tissues.[55] The excessive intracellular copper inappropriately triggers the synthesis of metallothionein, whose normal function is to chelate copper to prevent cellular toxicity. This further deprives the copper-requiring enzymes of the copper needed for normal function.[61] A low serum level of ceruloplasmin is diagnostic. Copper replacement is ineffective in preventing the inevitable progressive and lethal neurologic decline, but

▲ **FIGURE 86-2** Trichorrhexis nodosa.

copper-histidine given immediately postpartum may prevent or ameliorate the severe neurodegeneration.[62]

TRICHORRHEXIS INVAGINATA ("BAMBOO HAIR") Bamboo hair is a distinctive hair shaft abnormality that may occur sporadically, either in normal hair or with other hair shaft abnormalities, or regularly as a marker for Netherton syndrome. The primary defect appears to be abnormal keratinization of the hair shaft in the keratogenous zone, allowing intussusception of the fully keratinized and hard distal shaft into the incompletely keratinized and soft proximal portion of the shaft.[63] This leads to the typical "ball-and-socket" deformity (Fig. 86-5) or, if fracture of the shaft occurs, a golf tee–shaped distal end of the shaft. Netherton syndrome (see Chap. 47) is an autosomal recessive–inherited disorder consisting of a triad of ichthyosis, atopic diathesis, and trichorrhexis invaginata.[51] Affected hairs are generally short and brittle and may be irregularly distributed over the scalp; this may lead to potential sampling errors on hair shaft evaluation.

MONILETHRIX The hair abnormality of monilethrix is distinctive, with extremely short, brittle hairs emerging from keratotic follicular papules (see Fig. 85-5 and Chap. 85).[67] The onset may be delayed until patients are in their teens, and the loss may be localized or diffuse. Microscopically, hairs show elliptic nodes with a regular periodicity of 0.7 to 1.0 mm (Fig. 86-6).[51] Between the nodes, the hair shaft is constricted, and it is in these areas that the hair usually fractures. Monilethrix is caused by mutations of one of three of the genes encoding type II hair cortex keratins (KHb1, KHb3, and Khb6). Rare cases that clinically resemble monilethrix are autosomal recessive; the underlying gene, desmoglein 4 (DSG4), belongs to the desmosomal cadherin superfamily and is also expressed in the cortex of the hair follicle.[68,69]

Most cases of monilethrix are of autosomal dominant inheritance, with variable expressivity. In the mildest cases, the hair defect is localized to the occiput.[15,70] The hair defect may occur alone or in association with keratosis pilaris, physical retardation, syndactyly, cataracts, and nail/teeth abnormalities. Retinoids and topical minoxidil may be useful treatments, although this condition may also improve spontaneously with age.

LOCALIZED AUTOSOMAL RECESSIVE HYPOTRICHOSIS Localized autosomal recessive hypotrichosis results from a mutation in the gene for desmoglein 4 (dsg4), a desmosomal protein.[71] Patients present in early childhood with sparse broken hair involving scalp and eyebrows, and follicular hyperkeratosis (keratosis pilaris). The clinical presentation resembles monilethrix but the hair shafts do not show beading (Fig. 86-7).

Hair Shaft Abnormalities Associated with Unruly Hair

UNCOMBABLE HAIR SYNDROME The distinctive hair of patients with uncombable hair syndrome may present any time from infancy to puberty. The slow-growing, silvery blonde, "spun-glass" hair is generally unmanageable and disorderly but not unduly fragile (Fig. 86-8A).[15,72] The condition may be autosomal dominant or sporadic. Under light microscopy, the hair appears normal or may have some suggestion of a longitudinal groove or ribbon-like flattening (see Fig. 86-8B). Scanning electron microscopy confirms a longitudinal groove, and the hair may, if viewed on cross-section, show a kidney bean or triangular shape, which accounts for the alternate term of pili triangulati et canaliculi. The longitudinal groove in the hair shaft

is not specific to this syndrome but can be seen in normal hair, in other etiologies of unruly hair, and in several types of ectodermal dysplasia.[51] The defect may be secondary to an abnormal configuration of the inner root sheath, which keratinizes before the hair shaft and thus determines its shape.[72] Biotin supplementation has been advocated in one case report,[73] but generally there is no effective treatment for the syndrome.

WOOLLY HAIR Woolly hair is the presence of kinky, wavy hair on the scalp of persons of non-African or Negroid background. Microscopically, the hairs are tightly coiled. The unruly hair presents at birth or in infancy, usually as a solitary problem inherited in an autosomal dominant fashion.[74] Mutations in the genes for the desmosomal proteins plakoglobin (Naxos disease) or desmoplakin give rise to the triad of woolly hair, striate palmar-plantar keratoderma, and cardiomyopathy. Both recessive and dominant patterns of inheritance have been reported. Assessment of cardiac status should be performed in all children presenting with generalized woolly hair. A sporadic variant has been reported with fine, white-blond hair (Fig. 86-9). Diffuse partial woolly hair, a recently described autosomal dominant condition, presents in young adulthood with two distinct populations of scalp hair, one straight and the other very curly.[75] The curly hairs are thinner than normal hairs, which may contribute to the clinical appearance of a reduction in hair density. Woolly hair may also occur in a localized form (see Woolly Hair Nevus under Primary or Acquired Hair Shaft Abnormalities).

MARIA UNNA HYPOTRICHOSIS Maria Unna hypotrichosis, an autosomal dominant condition, is unusual in that the hair abnormality varies with age. The scalp hair in Maria Unna hypotrichosis is sparse or absent at birth, with variable coarse, wiry hair growth in childhood, affecting scalp and eyebrows. From late childhood, scalp hair is lost in a pattern resembling androgenetic alopecia (though both sexes are equally affected) with a scattering of coarse thickened hairs in the balding areas. Body hair is sparse to absent. Light microscopic examination of the hairs shows irregular twisting, and scanning electron microscopic examination shows longitudinal ridging and cuticle peeling. Diffuse follicular hyperkeratosis and facial milia-like lesions may be present. Marie Unna hypotrichosis maps to chromosome 8p21 close to the hairless (*hr*) gene, but the gene has not yet been identified.[76]

▲ **FIGURE 86-9** Sporadic recessive woolly hair.

Hair Shaft Abnormalities Unassociated with Breakage or Unruly Hair

The hair in pili annulati, an autosomal dominant (occasionally sporadic) condition, shows alternating light and dark bands both clinically and under light microscopy secondary to air-filled spaces in the cortex.[77] Cuticle folding and holes in the cortex are seen with electron microscopy.[51] The gene locus for pili annulati maps to chromosome 12q24.[78–80]

ABNORMALITIES OF HAIR FOLLICLE CYCLING

A wide variety of hair disorders, both genetic and acquired, relate to abnormalities or changes in the hair growth cycle. They may be associated with other changes in hair growth, particularly changes in hair follicle size as occurs in androgenetic alopecia.

Atrichia with Papular Lesions

Atrichia with papular lesions (APL), an autosomal recessive disorder, presents in infancy. Sparse hair is normally present at birth, but universal alopecia develops within the first year of life. Papular lesions, due to the formation of follicular cysts, appear later, generally 3 to 18 years after development of the alopecia.[81] The first mutation to be identified in APL was in the human homolog of the mouse hairless (*hr*) gene on chromosome 8p12.[82–84] The same clinical phenotype has been reported in some families with vitamin D–resistant rickets, in whom there is a mutation in the gene for the vitamin D receptor. Hair follicle development occurs normally in APL, but massive apoptosis in the hair bulb during the first catagen leads to separation of the dermal papilla from the base of the hair follicle and consequent failure to re-enter anagen. The follicular epithelium then undergoes a cystic change. Patients diagnosed with alopecia universalis (alopecia areata) at birth or during the first months of life may, in fact, have either APL or Vitamin D–resistant rickets particularly if the universal hair loss is persistent and/or familial.

Short Anagen Syndrome

The term *short anagen syndrome* has been applied to a poorly understood clinical presentation characterized by short fine but otherwise normal hair in children.[85] Hair density is normal, and there are no associated features. It is usually sporadic, although families showing autosomal inheritance have been described. Hair growth may improve after puberty.

Acute Telogen Effluvium

Acute telogen effluvium may occur at any age and represents a precipitous shift of a percentage of anagen hairs to telogen.[86] Telogen effluvium is a reaction pattern to a variety of physical or mental stressors[1,12,87,88]; the most common causative factors are given in Table 86-6. Although the clinical evidence that psychoemotional stress can cause telogen effluvium is still weak, the fact that defined stressors have very profound hair growth-inhibitory effects in mice[87,88] and that the central hypothalamic stress hormone, and the key stress-associated growth factor, nerve growth factor, both significantly inhibit human hair growth and prematurely induce catagen development in vitro[88,89] renders it likely that "stress" is also a negative hair growth modulator in humans. Any drug can potentially cause telogen effluvium, although some classes of drugs routinely do so.

TABLE 86-6
Causes of Telogen Effluvium

- Endocrine
  - Childbirth, miscarriage, abortion
  - Hypo- and hyperthyroidism
  - Discontinuation of estrogen-containing drugs
- "Stressful" events
  - Febrile illnesses
  - Catabolic illnesses (e.g., malignancy, "consumptive" chronic infection)
  - Major surgery
  - Major trauma
  - Acute or chronic psychological stress
- Nutritional
  - Rapid weight loss (e.g., "crash dieting")
  - Caloric or protein deprivation
  - Chronic iron deficiency
  - Excessive vitamin A ingestion
- Intoxication
  - Thallium
  - Mercury
  - Arsenic
- Drugs
  - Anticoagulants (including heparin)
  - β Blockers (propanolol)
  - Captopril
  - Cholesterol-lowering drugs
  - Colchicine
  - Cytostatic agents
  - Interferons
  - Lithium
  - Penicillamine
  - Retinoids
  - Selective serotonin reuptake inhibitors
  - Valproate
- Inflammatory scalp disease
  - Seborrheic dermatitis
  - Erythroderma

Normally, 50 to 100 hairs are shed per day. In telogen effluvium, a clinical increase in scalp hair shedding usually begins as the first group of anagen hairs that were thrown prematurely into telogen enter exogen 3 to 4 months after the inciting event. If the inciting cause is removed, the shedding resolves spontaneously over the next several months as the percentage of hairs in telogen return to normal; however, the hair density may take 6 to 12 months to return to baseline. In a significant number of patients, no obvious cause is found for telogen effluvium, and the increased shedding, and concomitantly the decreased density, of the scalp hair may become chronic.[90] Acute telogen effluvium is always potentially reversible and does not lead to total scalp hair loss, as the percentage of hairs in telogen rarely goes beyond 50 percent (Fig. 86-10). Persistent excess hair shedding after an acute episode may be an indication of other pathology, most commonly early female pattern hair loss and/or thyroid malfunction.

Chronic Telogen Effluvium

A persistent form of telogen effluvium, with loss of hair volume, lasting in excess of 6 months typically occurs in middle-aged women who may bring large amounts of shed hair for examination at a clinic visit.[91] Examination shows normal or high hair density, although there may be some rarefaction with short hairs along the frontotemporal regions. A simple method for evaluating shed hairs based on their length and the number of shed hairs per day has been proposed to help distinguish chronic telogen effluvium from androgenetic alopecia,[92] with the latter being associated with length less than 3 cm and fewer shed hairs per day. Underlying disorders, such as thyroid deficiency and systemic lupus erythematosus (SLE), should be excluded. Iron deficiency, with or without anemia, is often cited as a cause of chronic telogen effluvium,[93] although this is still controversial.[94,95] In one study, the mean ferritin level was significantly lower in patients with androgenetic alopecia than in normal controls without hair loss, but this was not seen in patients with telogen effluvium.[94]

▲ **FIGURE 86-10** Telogen effluvium.

In some women, chronic telogen effluvium is an early feature of androgenetic alopecia, and up to 60 percent of women with chronic telogen effluvium may show histologic evidence of pattern hair loss on biopsy.[96] In many women, however, no cause can be established and excess shedding may simply be the result of an age-related shortening of the hair cycle[97] that cannot reliably be distinguished from androgen-dependent anagen shortening, suggesting a relationship.[15] Retinoid-induced telogen effluvium has been the trigger for the development of androgenetic alopecia in older teenagers and young adults treated for acne.

Excessive hair shaft shedding and diffuse, non-scarring hair loss is a common feature of SLE (see Chap. 156), which occurs in 24 percent to 84 percent of SLE patients.[98–100] The degree of (telogen) effluvium is often associated with SLE activity, and patients with SLE may go on to develop cicatricial alopecia from chronic discoid lesions [see the section Cicatricial Alopecia (Destruction of the Follicle)].[101]

Anagen Effluvium

The daily loss of some telogen hairs is entirely normal, but it is always abnormal to shed anagen hairs. The term *anagen effluvium* is somewhat misleading because the abnormal anagen hairs in this condition are usually broken off rather than shed. The anagen hairs in

loose anagen syndrome and those of alopecia areata are generally shed in toto.

The classic and easily recognizable causes of anagen effluvium of the scalp are radiation therapy to the head and systemic chemotherapy, especially with alkylating agents (e.g., cyclophosphamide).[102,103] These agents can impair or totally disrupt the anagen cycle and cause varying degrees of hair follicle dystrophy.[104] The net result is either anagen hairs that break off within the follicle or at the level of the scalp (secondary to a weak point in the structurally inferior hair shaft) and are then shed without roots, or dystrophic anagen hairs that are easily dislodged from the usual follicular moorings. Replacement with a normal pelage usually occurs rapidly after discontinuation of chemotherapy, although high-dose busulfan as part of the preparatory treatment for bone marrow transplantation may lead to permanent alopecia due to irreversible damage to hair follicle stem cells.[5,105,106] Regrowth after radiation therapy depends on type, depth, and dose-fractionation, yet commonly leads to permanent follicular destruction, most likely as a result of irreversible hair follicle stem cell damage. In fact, scarring alopecia may progress long after radiation therapy has been discontinued, possibly due to persistent radiation-induced inflammatory changes that progressively damage hair follicle stem cells.[102] Lower dose cytostatic regimens or administration of less cytotoxic agents (e.g., methotrexate, dacarbazine) more often cause only telogen effluvium, because they induce premature catagen.

Cooling caps were previously advocated as a preventive measure for chemotherapy-induced alopecia,[107] but are relatively ineffective and poorly tolerated. The pharmacologic management of chemotherapy-induced alopecia has remained highly unsatisfactory.[5,103]

In the absence of obvious causes of anagen disruption such as cytostatic agents, one must consider exposure to toxic agents. Mercury intoxication, through either chronic industrial exposure, consumption of polluted water or seafood, or inadvertent exposure to mercury-containing antiseptics or fungicides, can lead to hair loss with or without other symptoms, especially neurologic ones.[111] Diagnosis is by documenting elevated mercury levels in hair, blood, or urine. Boric acid intoxication may be through exposure to household pesticides or ingestion of some common household products in which boric acid is a preservative. Patients may develop hair loss along with gastrointestinal, central nervous system, and renal symptoms; a hemorrhagic diathesis; and exfoliation or bullae.[102,112] Blood boric acid levels are elevated in affected patients.

Thallium poisoning leads to dramatic hair loss, with complete epilation occurring 2 to 3 weeks after intoxication.[113] Acutely, patients experience primarily neurologic symptoms including irritability, dysesthesia, ataxia, convulsions, and coma. Blood and urine levels are positive at the time of acute poisoning. Toxic exposure to colchicine and ingestion of certain plants can lead to anagen loss.[102] Severe protein malnutrition may also lead to anagen effluvium. Arsenic exposure does not cause hair loss; instead, arsenic is concentrated in the hair, which facilitates a diagnosis long after intoxication may have occurred.

Loose Anagen Syndrome

Loose anagen syndrome, a recently described, but not uncommon, syndrome has been primarily described in fair-haired children who have easily dislodgable hair (Fig. 86-11A).[114,115] However, loose anagen syndrome can occur in adults and may be familial. Families frequently report periods of greater scalp hair shedding or quiescence. The hair loss may be inapparent, except when traumatic pulling or extraction easily dislodges clumps of hair. Parents of affected children often show a mild form. The hair may also present with unruliness, especially at the occiput, which can be confused with uncombable hair syndrome or woolly hair (see Fig. 86-11B).[116,117] This condition can be misdiagnosed as telogen effluvium if the shed hair roots are not examined microscopically. Microscopically, the proximal shed hair shows a normal anagen bulb, with a ruffled cuticle but without the usual attached root sheath.[118] The unruly hair generally shows a longitudinal groove in the shaft as in uncombable hair syndrome. Given the disruption of the bulb structure by plucking of the hair, it is critical to gently run the fingers through the hair to collect samples, rather than plucking; obviously, hair is easier to obtain during a period of active shedding. A scalp biopsy, which is unnecessary for diagnosis, may show premature and abnormal keratinization of the inner root sheath, with clefts between the inner and outer sheath and the hair shaft. At least in some patients with loose anagen syndrome, this typical gap may result from hereditary keratin defects in the inner root sheath and/or the apposed companion layer (e.g., in families with diffuse partial woolly hair that can be associated with loose anagen hair syndrome).[119] The hair loss may improve with age, and gentle handling decreases shedding.

▲ **FIGURE 86-11** Loose anagen syndrome. **A.** Diffuse hair loss. **B.** Unruly hair. (From Olsen EA et al: The presence of loose anagen hairs obtained by hair pull in the normal population. *J Investig Dermatol Symp Proc* **4**:258, 1999, with permission.)

ALOPECIA AREATA

Epidemiology

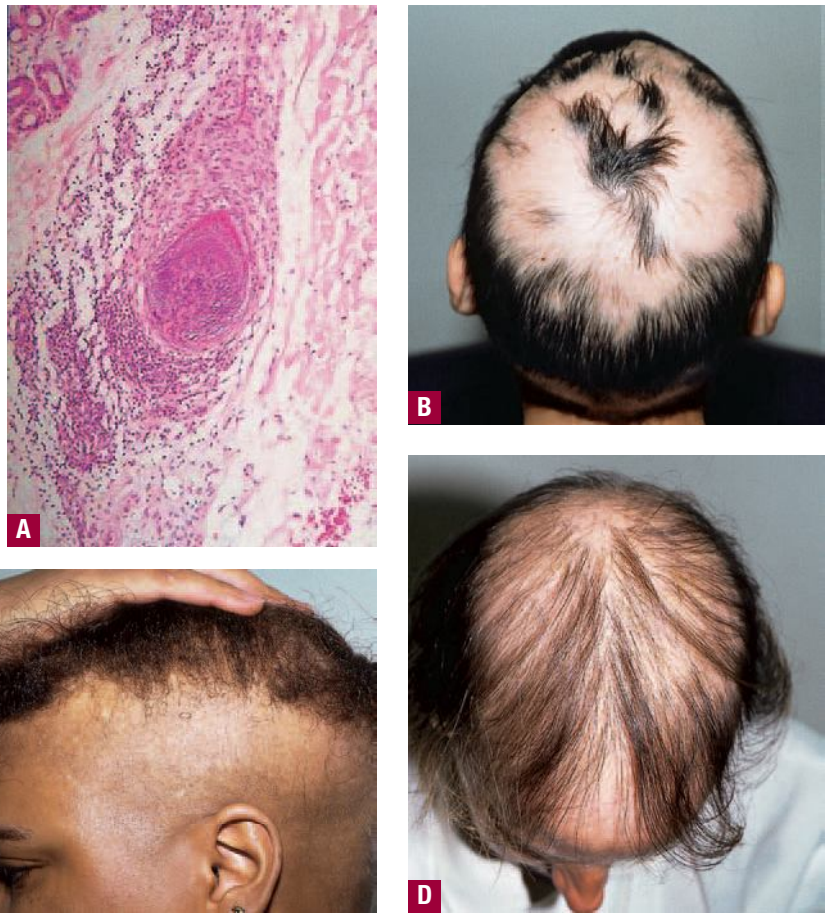
At any given time, approximately 0.2 percent of the population has alopecia areata and approximately 1.7 percent of the population experiences an episode of alopecia areata during their lifetime.[120,121] However, there are great geographic and ethnic variations in the incidence and prevalence of the disease; this is also seen with respect to the immunogenetic background of patients with alopecia areata.[24,43,76,122–127] In most patients, the onset is within the first three decades of life although alopecia areata can start at any age. The sex incidence is probably equal.

Etiology and Pathogenesis

Alopecia areata is a chronic, organ-specific autoimmune disease, probably mediated by autoreactive T cells, which affects hair follicles and sometimes the nails.[23,128–130] There is an increased frequency of other autoimmune diseases, notably autoimmune thyroid disease in affected adults, and of organ-specific autoantibodies in patients with alopecia areata.[129,131] Hair follicle autoantibodies are also found in some patients with alopecia areata[31,132] although it is unlikely that these autoantibodies are of importance in the primary pathogenesis of alopecia areata.[128,129,133]

Studies using human hair follicles transplanted into the skin of immunodeficient mice have provided convincing evidence for a cell-mediated etiology, with a key role for $CD8^+$ T cells, which may recognize a major histocompatibility complex class I–presented autoantigen (possibly expressed during anagen and/or anagen-associated melanogenesis).[129,134,135] These experimental data are in line with the concept that a (e.g., interferon-γ–induced) collapse of the normal immune privilege of the anagen hair bulb plays a key role on the primary pathogenesis of the disease.[128,130,133,136] Evidence in support of the concept that melanogenesis-associated autoantigens, which are normally sequestered from immune recognition by a functional hair follicle immune privilege, may be a key target of autoaggressive inflammation in alopecia areata[133] is slowly accumulating.[137,138] Histologically, alopecia areata is characterized by an inflammatory infiltrate, comprised mainly of T cells, in and around the bulbs of anagen hair follicles (Fig. 86-12A). The histopathologic features of alopecia areata, however, are stage-dependent, and the classic features may be missing in subacute and chronic lesions, rendering it prudent to include alopecia areata in the differential diagnosis whenever high percentages of telogen hairs or miniaturized hairs are present, even in the absence of a peribulbar lymphocytic infiltrate.[139]

Anagen follicles attacked by this inflammatory infiltrate move prematurely into catagen, followed by telogen, and then enter a dystrophic anagen status. Most follicles may continue to cycle but, while the disease remains active, are unable to progress beyond an early stage of anagen development and thus do not produce normal hair shafts.[140] An important feature of the pathology is that hair follicles are not destroyed in alopecia areata, possibly because the disease spares the follicular stem cell compartment in the mid-outer root sheath region.



▲ **FIGURE 86-12** **A.** Peribulbar lymphocytic infiltrate in alopecia areata. **B.** Extensive patchy alopecia areata. **C.** Ophiasis pattern of alopecia areata. **D.** Diffuse pattern of loss in alopecia areata. (**B-D** are reprinted with permission from Hordinsky MK: Alopecia areata, in *Disorders of Hair Growth: Diagnosis and Treatment*, edited by Olsen EA. New York, McGraw-Hill, 1994.)

The predisposition to alopecia areata is genetically determined.[141] Between 10 percent and 20 percent of patients with alopecia areata give a family history of the disease, and the true figure is probably higher because mild cases may pass unnoticed or are concealed.[124] There are several reports of alopecia areata in twins, some with concurrent onset. One small study of alopecia areata in twins found a concordance of 55 percent in monozygotic twins but none in dizygotic twins.[142] The genetic predisposition is polygenic in nature. To date, most genes found to be associated with alopecia areata are involved in regulating immune responses, yet there are substantial geographic/ethnic differences in the immunogenetics of alopecia areata.[76,122–127,141] The strongest associations have been with genes of the HLA-D region of the major histocompatibility complex locus.[143,144] There is also an association between severe forms of alopecia areata and polymorphisms in the autoimmune regulator gene on chromosome 21.[145] Alopecia areata is common in Down syndrome,[146] and there is also a high frequency of the disease (more than 30 percent) in autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia syndrome (also called *autoimmune polyglandular syndrome-1*), a usually autosomal recessive disorder in which there are mutations in the autoimmune regulator gene (see Chap. 144).[147]

A variety of environmental factors, including infection, drugs, trauma, and stress, have been suggested as triggering alopecia areata, although most patients with alopecia areata are unaware of any obvious precipitating factor. It is possible, though hard to prove, that a diversity of insults, physical or psychological, may trigger episodes of alopecia areata[128] but there is no evidence that they influence the prognosis.

Clinical Features

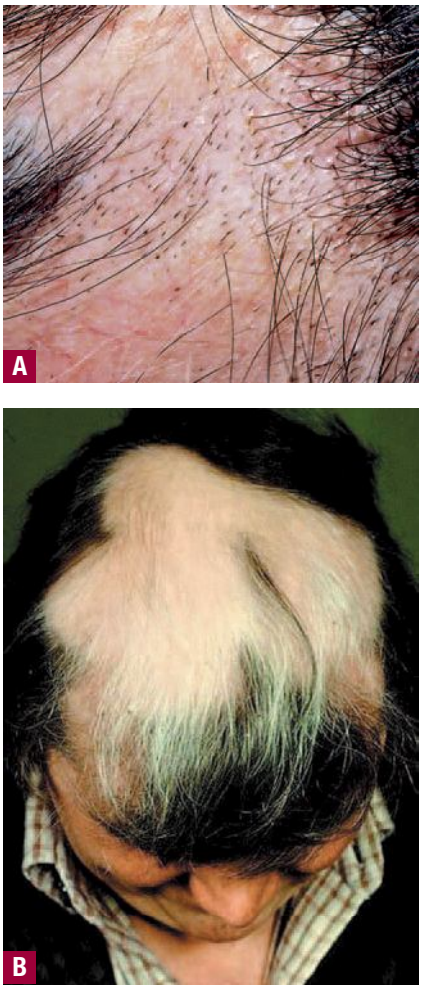
Alopecia areata typically presents with round patches of hair loss. Patches may be single or multiple, and may coalesce (see Fig. 86-12B–D). Although most obvious on the scalp, any hair-bearing skin can be affected, and is frequently found to involve the beard area. The term *alopecia totalis* is used to describe complete loss of terminal hair on the scalp and *alopecia universalis* to describe total loss of all terminal hair on the scalp and body.[148] *Ophiasis* refers to a band-like pattern of hair loss at the periphery of the scalp (see Fig 86-12C). The scalp usually appears normal. The pathognomonic "exclamation mark" hairs may be present, particularly at the periphery of areas of hair loss (Fig. 86-13A). These short broken hairs, whose distal ends are broader than the proximal ends, illustrate their inherent sequence of events: follicular damage in anagen and then a rapid transformation to telogen. White or graying hairs are frequently spared and probably account, in cases of fulminant alopecia areata, for the mysterious phenomenon of "going gray overnight" (see Fig. 86-13B). Nails in patients with alopecia areata may show fine pitting or, less commonly, mottled lunula, trachyonychia, or onychomadesis (see Chap. 87).

Differential Diagnosis

Though the clinical diagnosis is usually straightforward, other conditions that typically need to be considered are:

- Tinea capitis. Obvious inflammation (e.g., scaling, pustules) in association with patchy hair loss suggests a diagnosis of tinea capitis and excludes alopecia areata.
- Trichotillomania. This can be difficult to distinguish from alopecia areata (and may, in fact, be associated with it, especially in children). However, here the hair loss is rarely complete and the broken hairs are usually firmly anchored in the scalp, unlike exclamation point hairs. A biopsy may be needed.
- Early scarring alopecia.
- Syphilis (alopecia areolaris).

Diffuse alopecia areata can be difficult to differentiate from other causes of diffuse hair loss, and may be associated with them (e.g., thyroid abnormalities, other autoimmune diseases and syphilis). Diffuse alopecia areata usually progresses rapidly and the diagnosis becomes clear with time, but a biopsy may be necessary to clarify remaining uncertainties.



▲ **FIGURE 86-13** **A.** Exclamation mark hairs of alopecia areata. (From Olsen EA: Clinical tools for assessing hair loss, in *Disorders of Hair Growth: Diagnosis and Treatment*, edited by Olsen EA, New York, McGraw-Hill, 2003, with permission.) **B.** Sparing of white hair in alopecia areata.

Prognosis

Spontaneous remission can be expected in the majority of cases where hair loss is limited to a few small patches (possibly, up to approximately 80 percent within 1 year), although most patients experience recurrences at some stage.[149] The prognosis in extensive alopecia areata, particularly alopecia totalis and universalis, is less favorable and fewer than 10 percent of patients in the latter two groups recover spontaneously. The ophiasis pattern of alopecia also tends to be recalcitrant. Other features pointing to a poor prognosis include onset in childhood, loss of body hair, nail involvement, atopy, and a positive family history for alopecia areata.

Management

Counseling of patients on the nature of alopecia areata, its prognosis, and the treatment options is essential. For the majority of patients, alopecia areata is a cosmetic issue. Occasionally, it causes physical disability (e.g., when there is eyelash involvement or marked nail dystrophy). Nevertheless, the cosmetic importance of hair is such that alopecia areata can cause severe emotional problems, particularly in children and young women, though by no means restricted to these groups.[2] In view of the limited efficacy of current forms of treatment, the physician has an important role in helping patients adapt to their lack of hair. This is not an easy task and input from other health professionals, such as a clinical psychologist, may be needed. Many patients are helped by involvement in patient support groups. With children, it is often the parents whose reactions must be addressed for the child to adjust to the hair loss. The National Alopecia Areata Foundation (http://www.naaf.org) is an excellent source of information for patients.

Treatment

There is relatively little evidence from well-designed clinical trials, and so treatment recommendations are based mainly on case series and clinical experience (Box 86-1).[150] Helpful guidelines for managing alopecia areata have been developed.[4,6]

Box 86-1

Treatment of Alopecia Areata

- Patchy alopecia
  - Intralesional corticosteroids: Up to 2 mL injected/session and repeated at intervals.
  - Potent topical steroid 1–2×/day.
  - Topical anthralin 0.1%–2.0% once daily. Wash off after 10–20 min, steadily increase contact duration, switch to higher dose if no significant irritation.
  - Minoxidil lotion (5%) twice daily.
- Extensive or rapidly progressive alopecia.
  - Contact immunotherapy.
  - Systemic corticosteroids. Benefits are uncertain and must be weighed against risk of systemic corticosteroid therapy.
  - Wig or hairpiece.
- Alopecia totalis/universalis
  - Contact immunotherapy.
  - Topical/systemic steroids.
  - Wig or hairpiece.

CONSERVATIVE MANAGEMENT All of the currently available treatments for alopecia areata have a high failure rate and none alters the natural history of the disease. After discussion of the options patients may therefore opt not to be treated, other than to wear a wig if appropriate. 'No treatment' is a legitimate option in patients with a short history and limited disease, in view of the high rate of spontaneous remission in this group.

TOPICAL CORTICOSTEROIDS Topical corticosteroids are widely used to treat alopecia areata. There is some evidence of efficacy if potent corticosteroids are used under occlusion,[151] but less aggressive treatment regimens are probably ineffective.

INTRALESIONAL CORTICOSTEROIDS Intralesional corticosteroids are the most effective approach for treating patchy alopecia areata. Hydrocortisone acetate (25 mg/mL) and triamcinolone acetonide (5 to 10 mg/mL) are commonly used, either by subdermal injection or using a needle-less device.[152,153] Multiple injections repeated monthly are usually necessary, limited by patient discomfort. Intralesional corticosteroids are not appropriate in rapidly progressive or extensive disease. Especially with triamcinolone injections, there is a significant risk of inducing skin atrophy, which may increase exponentially with each repeated injection.

SYSTEMIC CORTICOSTEROIDS Oral corticosteroid therapy can induce short-term hair regrowth in patients with alopecia areata; however, hair regrown is usually lost after treatment is discontinued.[154] Newer regimens that involve pulsed oral corticosteroids (e.g., prednisolone 200 mg once weekly for 3 months or dexamethasone 5 mg daily for 2 consecutive days/week for 3 months) may also induce hair regrowth in some patients. No significant side effects have been reported in published series but cannot be ruled out, and long-term benefits have not been shown.[150,155,156]

TOPICAL MINOXIDIL SOLUTION There is limited clinical trial evidence that topical minoxidil solution (TMS) stimulates hair regrowth in some patients.[3,157] Minoxidil is ineffective in alopecia totalis/universalis.

ANTHRALIN Data from small case series suggest that treatment with anthralin cream is helpful in some cases, but the overall response rate is low.[158] However, especially in children where steroids or contact immunotherapy are decided against, this is a reasonable and safe treatment option.

PHOTO(CHEMO)THERAPY Phototherapy using UVB has been widely used, but there is no convincingly documented evidence of efficacy. Some case series have reported success using psoralen and UVA light (local or whole body), but there have been reports of high relapse rate when treatment is discontinued. Retrospective reviews have suggested that the response is no better than that expected from the natural history.[159–161] The deleterious long-term effects of phototherapy-induced premature skin aging and photocarcinogenesis argue against this treatment option, especially in children.

CONTACT IMMUNOTHERAPY In addition to intralesional glucocorticoid injections, this is the only form of therapy for which efficacy has been convincingly documented. This may be the most effective treatment for patients with extensive alopecia areata, although it is not widely available. Also, there is insufficient comprehensively comparative analysis with alternative treatment options. The patient is sensitized to a potent allergen [usually diphenylcycloprenone (DPCP) or squaric acid dibutylester (SADBE)] and then a solution of DPCP or SADBE is painted on the scalp once weekly. The concentration of DPCP or SADBE is adjusted to induce a mild dermatitis reaction. Published response rates vary widely (9 percent to 85 percent),[5,162] but clinical experience suggests that approximately 30 percent of patients with extensive alopecia areata achieve a cosmetically worthwhile response after 6 months of treatment. Continuous or intermittent treatment is needed to maintain the response in most patients. Alopecia totalis/universalis is less likely to respond to contact immunotherapy, and it is unclear whether patients with rapidly progressive disease profit.

Risks include severe dermatitis, urticaria, and pigmentary abnormalities including vitiligo (an important consideration in racially pigmented skin). Sensitization of health care workers and relatives handling the immunogen is also a significant hazard. Contact immunotherapy has been in use since the early 1980s, and no long-term side effects have been reported.

COSMETIC MEASURES Female patients with extensive alopecia areata often choose to wear a wig or hairpiece. Hair weaves can give good results if sufficient hair remains, although they are expensive to maintain. Locks of Love (http://www.locksoflove.org) is an organization that collects human hair and provides hairpieces to financially disadvantaged children younger than age 18 years with alopecia areata and other chronic forms of alopecia. Wigs are generally less successful in men where other hair styles, such as shaving the scalp, are often a more acceptable approach. Temporary tattooing can be helpful for loss of eyebrows.

NON-SCARRING HAIR LOSS: PRODUCTION DECLINE

Triangular (Temporal) Alopecia

Triangular alopecia may be congenital but usually appears in childhood as a focal patch of hair loss at or just behind the frontotemporal hairline. The hair loss either may be complete or fine vellus hairs may remain.[46,163] The underlying scalp is normal. The hair loss may be uni- or bilateral (Fig. 86-14). Histologically, the affected area shows a transition from terminal to vellus hair. The alopecia is usually persistent. Hair transplants are a reasonable approach. Congenital triangular alopecia may occur within families as a paradominant trait.[164]

Hypotrichosis Simplex

Hypotrichosis simplex, an autosomal dominant disorder, is characterized by progressive global loss of scalp hair

▲ **FIGURE 86-14** Triangular alopecia.

▲ **FIGURE 86-15** Hypotrichosis simplex in a 35-year-old woman.

from early/mid childhood onward. Both sexes are equally affected. The eyebrows and body hair are unaffected and there are no associated features. The pathogenesis has not been studied, but may involve a process of follicular miniaturization resembling pattern hair loss. A mutation in the gene for the adhesion protein corneodesmosin has been reported in some families with hypotrichosis simplex (Fig. 86-15).[165,166]

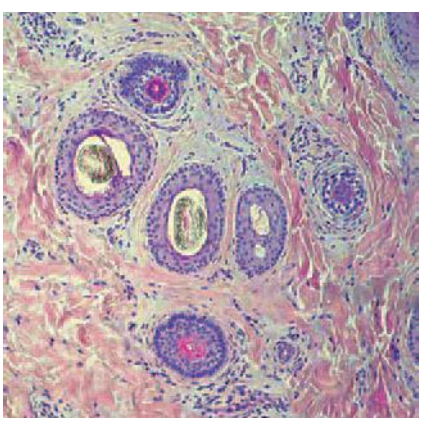
Pattern Hair Loss

Pattern hair loss is by far the most common type of hair loss in both sexes. Male pattern hair loss (also known as *male androgenetic alopecia, male balding*) is an androgen-dependent, genetically determined trait. Female pattern hair loss has also been termed *androgenetic alopecia*, in the belief that it is the same entity as in men, but the requirement for androgens is less clearcut than in men and the distribution of hair loss is generally different.[167,168] However, in both men and women, pattern hair loss is characterized by a progressive decline in the duration of anagen, an increase in the duration of telogen, and miniaturization of scalp hair follicles, indicating a final common pathway of follicular regression (Fig. 86-16).[169]

Pattern hair loss is a biologically normal trait. Nevertheless, the high value our societies place on maintaining a full head of hair means that loss of hair can have a significant adverse effect on quality of life. Both sexes are affected though, in general, the impairment of psychosocial well-being is more frequent and more severe in women.

EPIDEMIOLOGY ***Men.*** Almost all Caucasian men develop some recession of the hair line in the frontotemporal region following puberty. More advanced balding may start at any time after puberty and its frequency and severity in the population increase with advancing age.[170] Approximately 80 percent of men have some degree of balding by the age of 70 years, and approximately 50 percent show Norwood-Hamilton VI/VII balding (Fig. 86-17). The frequency has been reported to be lower in African American men.[171] Although it is generally thought that the prevalence of androgenetic alopecia in Asian men is much lower than in Caucasians, it is probably higher than often suspected.[172] Interestingly, in Finnish men aged 63 years androgenetic alopecia was significantly associated with insulin-linked disturbances, such as hypertension and diabetes,[173] and patients with a large prostate reportedly show a higher prevalence of androgenetic alopecia.[174,175] In a recent autopsy study, baldness (as well as hair growth in the external auditory canal) were positively associated with coronary artery disease and sudden cardiac death, which revives the long-standing controversial debate of whether and how balding and cardiovascular disease are associated.[176,177]

Women. Female pattern hair loss is less common than male balding but shows a similar age-related increase in population frequency and severity. Similar to male balding, the onset may be as early as the peripubertal period but in the great majority it is later. By the age of 30 years, 2 percent to 5 percent of Caucasian women show some thinning of their scalp hair rising to nearly 40 percent at age 70 years.[167,178] Although there is a popular view that late-onset female pattern hair loss is related in some way to post-menopausal changes, this is not apparent from the published epidemiologic data. Similar to male pattern baldness, female pattern hair loss may be associated with coronary artery disease, at least in women under the age of 55 years.[179] Female pattern hair loss is less common in Asian women.[180]



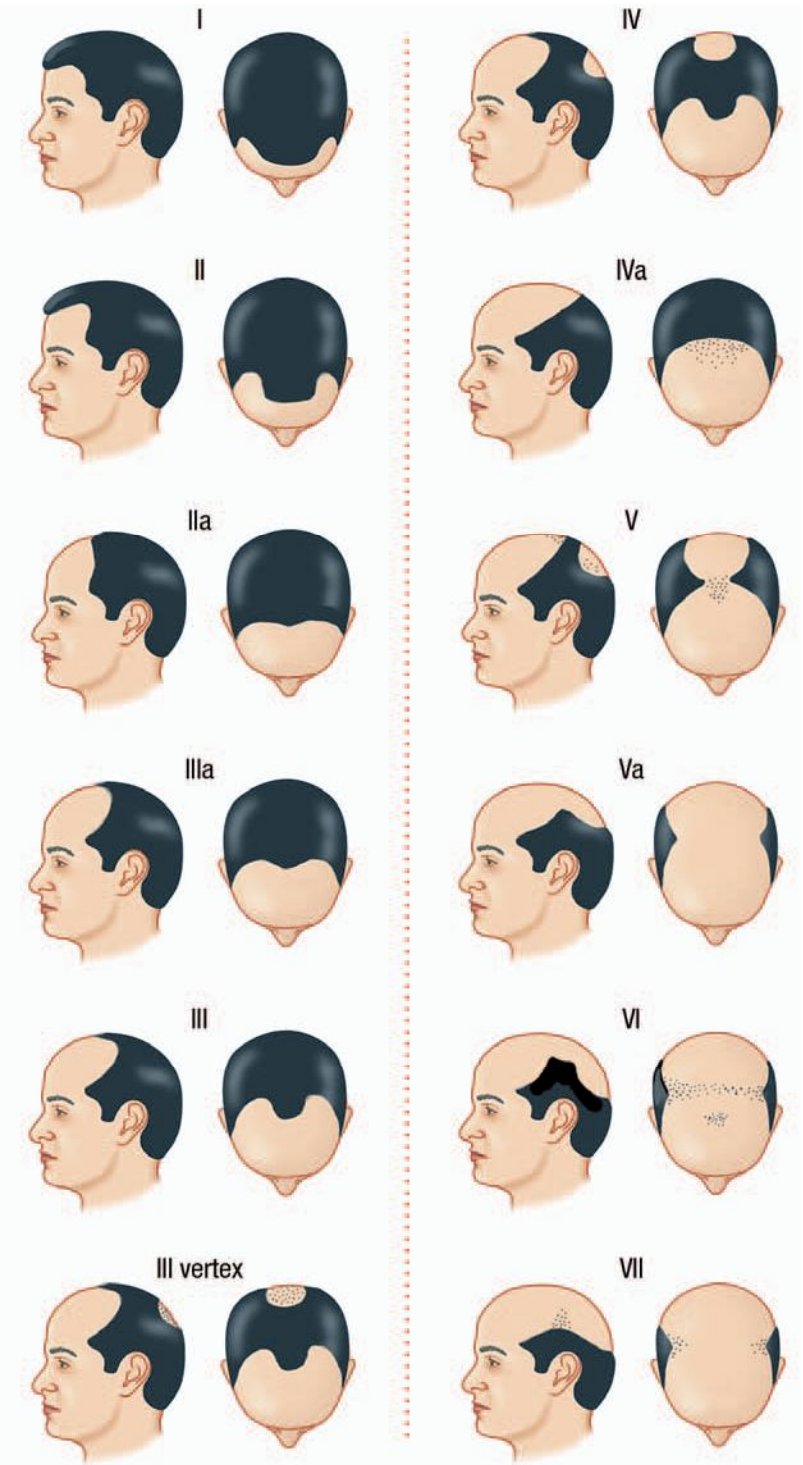
▲ **FIGURE 86-16** Histology of female pattern hair loss. There are two terminal and three vellus follicles in this field of a biopsy from female pattern hair loss.

ETIOLOGY ***Men.*** Male balding is undoubtedly an androgen-dependent trait. Men castrated before puberty do not develop balding unless subsequently treated with testosterone.[181] Balding also does not occur in XY individuals who fail to express androgen receptors due to a mutation in the androgen receptor gene (complete androgen insensitivity syndrome), despite male levels of circulating testosterone.[182] Although testosterone is the major circulating androgen in men, the balding process is driven by its metabolite dihydrotestosterone, which has greater affinity and avidity for the androgen receptor.[183]

Although testosterone is necessary for its development, it has long been recognized that male balding runs in families, and it is clear that a genetic predisposition is also required. Twin studies show a high level of concordance in monozygotic twins (80 percent to 90 percent),[187] and there is a higher frequency of balding in the fathers of bald men than in the fathers of non-bald men.[188] Osborn proposed that male balding is an autosomal dominant trait,[189] but more recent evaluation of the published data suggests that it has a polygenic basis.[190] Three studies have shown an association between male balding and variant regions in the androgen receptor gene.[191–193] However, this does not explain the paternal influence on male balding, as the locus for the androgen receptor gene is on the X chromosome and is therefore inherited exclusively from the mother.

Recent experimental evidence suggests that, in androgen-sensitive hair follicles, hair growth-inhibitory secreted factors (e.g., transforming growth factor-β) released from androgen-stimulated fibroblasts of the follicular dermal papilla may be at least one key factor in mediating hair growth inhibition and hair follicle miniaturization, at least in male pattern balding.[194–196]

Women. Scalp hair loss is a feature of hyperandrogenism in women and rapidly progressive pattern hair loss, particularly when accompanied by other signs of androgen excess such as hirsutism, amenorrhoea, and a raised circulating testosterone level, should prompt a search for an androgen-secreting tumor. Some studies,[197,198] though not all,[199] have reported that, as a group, women with slowly progressive female pattern hair loss show modest elevations of cir-



▲ **FIGURE 86-17** Hamilton-Norwood classification of pattern hair loss in men. (From Olsen EA: Female pattern hair loss. *J Am Acad Dermatol* **45**:S70, 2001.)

culating androgen levels and an increased frequency of polycystic ovaries.[200] Many women with pattern hair loss do not exhibit other biochemical or clinical signs of androgen excess, however, and do not respond to anti-androgen treatment, suggesting that androgens do not play a role.[201] No genetic loci associated with female pattern hair loss have yet been identified.

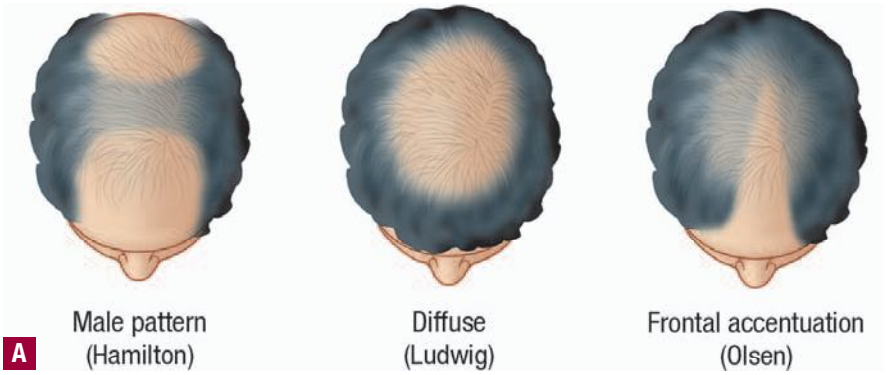
CLINICAL FEATURES Clinical diagnosis, based on male or female pattern recognition, is usually very straightforward. However, hyperprolactinemia may mimic androgenetic alopecia,[199,203,204] and androgenic alopecia due to hyperandrogenism must be distinguished from classic androgenetic alopecia.[7] In addition, a female pattern of hair loss may be seen in males, and vice versa.

Men. The two major features of male pattern hair loss are recession of the frontal hair line and balding of the scalp vertex. Eventually, hair loss may coalesce leaving a rim of normal hair growth at the sides and back of the scalp. The changes that occur during the progression of male balding were first classified by Hamilton,[205] to be later modified by Norwood.[170] Nevertheless, male balding is a continuum rather than a series of distinct stages and individual patterns can vary quite widely (see Fig. 86-17). Hairs within the balding areas may become progressively shorter and finer in caliber, eventually disappearing completely, or show a more diffuse reduction in hair density with maintenance of normal hair diameter in the remaining hairs. In a small proportion of Caucasian men (less than 5 percent), balding assumes a more diffuse distribution over the crown and frontal scalp, with retention of the frontal hair line, resembling female pattern hair loss. This pattern is more common in Asian men.[180]

Women. Female pattern hair loss is usually a more diffuse process than male balding. Typically, there is a reduction in hair density involving the crown and frontal scalp, with maintenance of the frontal hair line (Fig. 86-18).[206] There may be miniaturized hairs in the frontotemporal region but deep recession of a well-demarcated hair line is uncommon. Unlike men, the parietal regions may also be involved. Female pattern hair loss may present with excessive hair shedding and loss of hair volume, before there is an obvious reduction in hair density. Differentiation from chronic telogen effluvium can be difficult. In such cases, the diagnosis may be established by the presence of a high proportion of miniaturized follicles on biopsy. A small proportion of women display a "male" pattern of hair loss. It should be emphasized that the distribution of hair loss in women is not a reliable guide to androgen status.

Investigations are probably unnecessary in men and in most women with typical pattern hair loss. However, if the hair loss is diffuse and not localized to typical patterns, it is appropriate to check thyroid stimulating hormone and iron in men on an iron-deficient diet or in whom blood loss could be an issue. Authorities generally recommend the following tests for women with pattern hair loss:

- Serum ferritin (a measure of iron stores): The role of low iron stores in



▲ **FIGURE 86-18** Pattern hair loss in women. **A.** Different phenotypic expressions. **B.** Characteristic frontal accentuation (widened hair part).

female pattern hair loss is uncertain, but there is some evidence that women with serum ferritin less than 40 μg/L respond poorly to anti-androgen treatment.[207] In women with chronic disease in whom ferritin levels may be elevated due to inflammation, iron and total iron binding capacity should be investigated. Of note, iron-containing medications (including vitamins) should be discontinued for these measurements.

- Thyroid-stimulating hormone: Hair loss is traditionally regarded as a feature of thyroid deficiency although there are few formal published data.[208]
- Serum androgens: The majority of women with female pattern hair loss have no clinical or biochemical evidence of androgen excess.[197] However, screening laboratory testing should be considered, especially in women with concomitant evidence of hirsutism, moderate to severe adult acne, acanthosis nigricans, irregular menses, and/or galactorrhea. Screening studies, at a minimum, should include free and/or total testosterone with or without dehydroepiandrosterone sulfate. Patients with raised serum testosterone levels should be referred for specialist endocrinologic evaluation[7] to consider the presence of a tumor or endocrinologic disorder, such as congenital adrenal hyperplasia.

MANAGEMENT Broadly speaking, patients presenting with pattern hair loss fall into three overlapping groups—those who wish to be reassured that their hair loss is not a manifestation of a serious underlying disease, those who are concerned by it and wish to be treated (Box 86-2), and those with a body dysmorphic disorder. The latter group is important to identify as these patients are unlikely to be satisfied with treatments aimed at restoring hair growth and involvement of other health care professionals, such as a clinical psychologist, may be needed.[1,209] Treatments for pattern hair loss are available, but patients should be counseled that none will restore hair growth to its prepubertal density and that, although some recovery of hair growth is possible, the main aim, at least for medical treatments, is to prevent further progression (see Box 86-2).

Men. Two medical treatments, TMS and oral finasteride, are licensed for the treatment of male pattern hair loss,[3,7,186] and can be used in combination. A trial of at least 6 months of therapy is needed to assess efficacy, and treatment must be continued to sustain the response.

Box 86-2

Treatment of Androgenetic Alopecia

- Caution against unrealistic expectations; primary goal is to halt progression.
- Male pattern hair loss
  - 5% topical minoxidil solution or foam twice daily.
  - Oral finasteride, 1 mg daily.
  - Combination of the above: Use for at least 6 mo to assess response, and continue treatment to maintain response.
  - Surgery (e.g., hair transplantation). Most useful for restoring frontal hair loss.
- Female pattern hair loss
  - 2%–5% topical minoxidil solution twice daily.
  - Topical 17β-estradiol (e.g., estradiol benzoate, 20–25 mg/mL isopropanol).
  - Oral anti-androgens (spironolactone, cyproterone acetate).
  - Combination of the above: Use for at least 6 mo to assess response, and continue treatment to maintain response.
  - Maintain serum ferritin > 40 μg/L.
  - Hair transplantation in selected cases.

MINOXIDIL. Clinical trials using a variety of endpoints, including hair counts, hair weight, and global photography, have shown that up to 60 percent of men show improvement in vertex balding using 5 percent TMS with a mean increase in hair density of 10 percent to 12 percent. The response rates with 2 percent TMS are lower.[211] Treatment has to be continued to maintain the response, and any hair gained is lost within 4 to 6 months of stopping treatment.[3] Minoxidil is not effective in treating frontotemporal recession. Minoxidil lotion occasionally causes scalp irritation, most commonly due to the propylene glycol in the vehicle.

FINASTERIDE. Finasteride is an inhibitor of type 2 5α-reductase. Taken orally in a dose of 1 mg daily it prevents the progression of hair loss in most men and, after 2 years of treatment, approximately two-thirds show some improvement in hair growth.[186] In an extended trial, men taking finasteride subsequently showed some loss of hair after 5 years of treatment, but hair loss progressed more rapidly in untreated men.[212] There is a marginally higher frequency of sexually related problems, such as impotence, in men taking finasteride, but otherwise it is generally well-tolerated. Any positive benefit is lost within 12 months if treatment is discontinued. It is unclear how exactly finasteride exerts its beneficial effects in those patients that respond to treatment. One recent study suggests that the reversal of apparent "hair loss" by finasteride reflects some kind of reactivation of "hypotrophic" terminal hair follicles on the basis of faster re-entry into and longer duration of anagen, but not a genuine vellus-to–terminal hair conversion.[213] Despite the absence of formal clinical studies on the efficacy of this combination, topical minoxidil and systemic finasteride are often combined

in clinical practice. A combination of 5α-reductase 1 and 2 inhibition may be beneficial in the treatment of male pattern hair loss.[214]

SURGERY. A variety of surgical techniques have been developed for treating male pattern hair loss, of which hair transplantation is the most widely used.[7,215] All involve redistributing terminal hair to the balding areas so the number of terminal hairs remains the same. In skilled hands, and with careful patient selection, good cosmetic results can be obtained. Surgery is the only treatment that can improve hair coverage on totally bald scalp, and quickly restore hair.[215] Surgery is most effective for restoring frontal hair loss (see Chap. 250).

Women. As with male pattern hair loss, a trial of at least 6 months of therapy is needed to assess efficacy, and treatment must be continued to sustain the response. Combinations of agents may be used.

MINOXIDIL. Clinical trials of topical minoxidil solution in female pattern hair loss have reported a mean increase in hair density of 10 percent to 18 percent. One large trial found no significant difference in response to the 2 percent and 5 percent formulations, although there was a trend toward superiority of the higher concentration.[216] At present, only the 2 percent formulation is licensed for women by the U.S. Food and Drug Administration. As in men, a better response is obtained when treatment is used at an early stage of hair loss. Continued treatment is necessary to maintain the response.

ANTI-ANDROGENS. Anti-androgens have been widely used to treat female pattern hair loss, but there is little clinical trial evidence to demonstrate efficacy and none is licensed for this indication. One controlled trial showed a small response to cyproterone acetate but only in those women with clinical evidence of androgen excess.[217] Uncontrolled studies of cyproterone acetate and spironolactone have reported benefit in some patients.[207,218] Generally, 100 to 200 mg/day of spironolactone is needed for response. Potentially fertile women should take contraceptive measures during antiandrogen treatment because of the risk of feminizing a male fetus.

FINASTERIDE. The final verdict on whether or not systemic finasteride may also be a treatment option in post-menopausal women with androgenetic alopecia is still out.[219] A controlled trial of finasteride in post-menopausal women did not demonstrate efficacy,[220] although small case series have reported improvement in hair growth in women with hyperandrogenism[221] and in younger women.[222] Potentially fertile women should take contraceptive measures during treatment with finasteride because of the risk of feminizing a male fetus.

TOPICAL ESTROGENS. Even though convincing clinical trials in support of topical estrogens, a long-practiced, empirical treatment regime for female androgenetic alopecia, are still lacking, topical 17β-estradiol (e.g., estradiolbenzoate, 20 to 25 mg in 70 percent isopronol) is frequently used to counteract androgenetic alopecia-related telogen effluvium in these patients.[5] Notably, estradiol prolongs the duration of anagen, at least in human scalp hair follicle organ culture.[223,224]

SURGERY. Surgical treatment of pattern hair loss is less widely used in women because of the usual diffuse nature of the condition and often poor hair quality in the donor area. However, good results can be obtained in selected cases, particularly in those women with pronounced frontal loss and good hair density in the occipital (donor) region (see Chap 257).[7]

TRAUMATIC HAIR LOSS

Exogenous trauma may cause hair loss, either temporary or permanent, by several different mechanisms, including follicular destruction, hair breakage, and changes in hair follicle cycling.

Pressure Alopecia

There are numerous reports of localized hair loss, usually affecting the occipital scalp, after prolonged surgery or ventilation. The hair loss may be permanent and is presumably due to ischemia from pressure injury.[225,226] In neonates with a history of a capus succedaneum, a "halo scalp ring" may occur, characterized by an annular alopecia that presents as a circumferential ring around the scalp from pressure necrosis; hair loss may be permanent.

Trichotillomania

Trichotillomania (Greek, hair pulling madness) manifests as a compulsive desire or habit to pull out the hair. It occurs in 0.6 percent to 3.4 percent of adults.[227] In young children, trichotillomania is usually a habit akin to thumb sucking, and most recover spontaneously. In teenagers and adults, though, trichotillomania is a more serious and often intractable psychiatric problem. Childhood trichotillomania is more common in boys, but in the adult form, women outnumber men 7:1. This cause of focal scalp hair loss is classified as an impulse control disorder,[228,230,231] and several different underlying psychopathologies can underlie this clinical sign.[229–231]

The clinical presentation is usually quite distinctive, with a confluence of very short sparse hairs within an otherwise normal area of the scalp (Fig. 86-19A,B). Microscopic examination of the ends of cut or plucked hairs generally reveals either the tapered tips of newly regrowing anagen hairs or bluntly broken hairs. (A hair pull here is usually negative because the telogen hairs have generally all been dislodged). The most difficult differential diagnosis is from alopecia areata,[234] but the absence of complete hair loss within affected sites and the firmly anchored nature of broken hairs usually permits the distinction to be made. Where doubt remains, a scalp biopsy can be diagnostic, showing the characteristic increase in the number of catagen hairs (rarely seen in biopsies of normal scalp), trichomalacia, and melanin within the follicular canal secondary to traumatic hair removal and the absence or sparsity of a perifollicular inflammatory infiltrate.[235,236] A vertically oriented hair shaft split, which contains proteinaceous material and erythrocytes ("hamburger sign") has been proposed as an additional, novel histologic pointer to trichotillomania.[237]

Treatment of these patients is difficult. In children, the habit can often be broken by mere acknowledgement of the problem or behavior modification. Adolescents and adults with this condition present a more challenging problem. In those patients who admit to pulling their hair cognitive behavioral therapy is probably the most effective form of treatment, although there is a high failure rate.[238,239] Psychotropic drugs, such as clomipramine or sertraline, may also help. The combination of behavioral therapy (habit reversal training) and medication may be more efficacious in the treatment of trichotillomania than either approach alone.[240] Patients who deny the self-inflicted nature of their

▲ **FIGURE 86-19** Trichotillomania. **A.** Bizarre pattern of localized hair loss in a boy. **B.** Extensive hair loss in a woman.

hair loss usually refuse referral to a psychiatrist or clinical psychologist.

Traction Alopecia

Traction alopecia is caused by inadvertent prolonged traction on the scalp by the physical pressure of hair styling (e.g., pony tail, tight braids, foam rollers, etc.; Fig. 86-20). There is often a cultural element, such as braiding in African American girls[241] or the "topknot" in Sikh boys.[242] The distribution of hair loss reflects that of maximal traction, but is most commonly seen at the scalp margins. Although potentially reversible in its early stages, loss of hair follicles leads to permanent hair loss if the traction is unrelenting over months to years.[243,244]

Tinea Capitis (See Chap. 188)

Tinea capitis is a very common cause of hair breakage or loss, particularly in children. It typically presents with patchy hair loss associated with inflammation of the affected scalp. The degree of inflammation varies from severe pyodermatous swellings (kerion) to barely detectable. It may also present as noninflammatory "black dot ring-worm" presentation, with broken hairs filling, but not projecting from, follicular orifices (see eFig. 86-20.1 in on-line edition).

Treatment of tinea capitis must be by the systemic route, and contacts must be sought and treated to prevent re-infection (see Chaps. 188 and 233).[247]

PRIMARY OR ACQUIRED HAIR SHAFT ABNORMALITIES

Acquired localized trichorrhexis nodosa may be seen in hair that is subject to repetitive rubbing, such as with lichen simplex chronicus or trichotillomania (see the section Trichotillomania). It may also present in focal areas secondary to trauma from chemical or heat processing of hair. Acquired pili torti may present as a focal patch of fragile hair. This is usually secondary to trauma or some underlying, potentially scarring scalp abnormality.[51] Hypervitaminosis in patients with anorexia nervosa or retinoids has also been associated with acquired pili torti.[248] Bubble hair is a recently recognized and very distinctive abnormality of the hair shaft and is characterized by rows of bubbles seen microscopically within localized areas of brittle hair.[250,251] Exposure to prolonged high temperatures from curling irons or hair dryers applied to wet or damp hair are the usual causative factors, and the defect is completely reversible.

◀ **FIGURE 86-20** Traction alopecia.

Unruly Hair

WOOLLY HAIR NEVUS Woolly hair nevus is a non-hereditary focal condition that usually appears within the first 2 years of life but can occur as late as adolescence.[252] Fifty percent of cases have an associated epidermal, verrucous, or pigmented nevus, although not necessarily immediately under the affected hair.[51] There may be associated ocular abnormalities, such as persistent papillary membrane or retinal abnormality. Spontaneous improvement in the hair may occur with age. Both woolly hair and ulerythema ophryogenes have been associated with Noonan syndrome and cardiofaciocutaneous syndrome (see Chap. 85) so that the presence of woolly hair also raises several genodermatoses as differential diagnosis.[253]

ACQUIRED PROGRESSIVE KINKING Acquired progressive kinking has been primarily reported in postpubescent males with androgenetic alopecia.[254] It presents with gradual curling and darkening of the frontal, temporal, auricular, and vertex hairs. Microscopically, affected hairs show kinks and twists, with or without longitudinal grooving.[255]

Abnormality of Cycling

ALOPECIA AREATA Alopecia areata most frequently presents as focal hair loss (see the previous section Alopecia Areata).

SYPHILIS (See Chap. 200) Hair loss may be one or the sole cutaneous manifestation of secondary syphilis.[256] This may present as a patchy "moth-eaten" alopecia (alopecia areolaris) or as generalized thin-

◀ **FIGURE 86-21** Alopecia of secondary syphilis.

ning (Fig. 86-21). If this clinical picture is seen in children, congenital syphilis is to be considered.[257] A scalp biopsy may show either a superficial and deep perivascular mixed lymphocytic/macrophage/plasma cell infiltrate, a peribulbar perifollicular lymphocytic infiltrate mimicking alopecia areata, or a noninflammatory telogen effluvium picture.[258,259] Serologic testing should be positive, and treatment with appropriate antibiotics reverses the hair loss.

Scalp Conditions Associated with Focal Hair Loss

Most eczematous conditions of the scalp do not cause hair loss, the exceptions being pityriasis amiantacea, severe scalp psoriasis or seborrheic dermatitis, scalp involvement with dermatomyositis, and malignancies such as cutaneous T-cell lymphoma or Langerhans cell histiocytosis. In pityriasis amiantacea, thick, tenaciously adherent scale infiltrates and surrounds the base of a group of scalp hairs (Fig. 86-22).[260] The condition may mimic psoriasis clinically, but, in contrast to psoriasis, the hair in involved areas is dislodged on attempts to physically remove the scale. Removal of the scale in this manner can lead to scarring alopecia. The condition usually presents in children, is best treated with the combination of keratolytics and topical corticosteroids, and usually improves with age. Pityriasis amiantacea represents a particular reaction pattern of the scalp to various inflammatory scalp diseases, most frequently seborrheic dermatitis or psoriasis. However, tinea capitis must be excluded in every case, and topical antibiotics can be a helpful adjuvant therapy if recalcitrant.[261]

CICATRICIAL ALOPECIA (DESTRUCTION OF THE FOLLICLE)

The term *cicatricial* or *scarring alopecia* implies the potential of permanent destruction of the hair follicle,[262] most likely as a result of irreversible damage to epithelial hair follicle stem cells in the region of the bulge.[263,264] Clinically, there is effacement of follicular orifices, always in a patchy or focal distribution. A biopsy is confirmative, showing replacement of follicles with fibrotic stellae and either fibrosis or hyalization of surrounding collagen.[265–268] Although some cases of cicatricial alopecia are due to physical causes (e.g., pressure or chronic traction) or to the hair follicle being secondarily involved in a destructive process (e.g., "kerion" fungal infection, necrotizing zoster, metastatic/primary neoplasm) or as the result of a developmental defect (aplasia cutis congenita), most patients seeking medical attention have a primary cicatricial alopecia. Although these conditions have a common endpoint (irreversible alopecia), they have varied clinical and histologic features and virtually no therapies (Table 86-7) are able to turn the process completely off.

A new classification system has been proposed by the North American Hair Research Society to identify and evaluate significant differences among these entities.[271] The primary cicatricial alopecias are presented in keeping with this classification system (see Table 86-7).[262] The power of routine histology to allow definitive distinctions between various types of cicatricial alopecia is disputed, but direct immunofluorescence may help to make such distinctions.[272,273]

Primary Cicatricial Alopecia

LUPUS ERYTHEMATOSUS (See Chap. 156) Chronic cutaneous lupus erythematosus may present in the scalp, usually with erythema, atrophy, and variable hypopigmentation and/or follicular plugging (see eFig. 86-22.1 in on-line edition).

LICHEN PLANOPILARIS Areas of active alopecia in lichen planopilaris are clinically distinguished by perifollicular erythema and/or a violaceous discoloration of the scalp. Keratotic follicular papules may be evident. Evidence of lichen planus may be present elsewhere, and this should be sought to help confirm the diagnosis (see Chap. 26).

Graham-Little Syndrome. Graham-Little syndrome is characterized by lichen planus–like lesions and a follicular "spines"/keratosis pilaris-like picture that develop in areas of alopecia on the scalp, eyebrows, axillary, and pubic areas (see Chap. 26).[265]

Frontal Fibrosing Alopecia. *Frontal fibrosing alopecia* is a term given to the frontotemporal hairline recession and eyebrow loss in post-menopausal women that is associated with perifollicular erythema, especially along the hairline.[277] Scalp biopsy is largely indistinguishable from lichen planopilaris, although frontal fibrosing alopecia may show more prominent apoptosis and less inflammation than lichen planopilaris, along with spared interfollicular epidermis.[276] Topi-

◀ **FIGURE 86-22** Pityriasis amiantacea. Note area of patchy alopecia after manual removal of adherent scale.

Entity	**Epidemiology**	**Scalp**	**Non-Scalp**	**Therapy[a,b]**
Lymphocytic[c]				
Discoid lupus erythematosus	Women > men	Symptomatic, erythematous scaly plaques with follicular plugs; telangiectases, atrophy and depigmentation with time; activity in center of alopecic patch	May be present; rule out systemic lupus erythematosus	• Topical ± intralesional steroid • Hydroxychloroquine, prednisone; topical tacrolimus, tazarotene, imiquimod • Isotretinoin
LPP (classic)	Women > men	Pruritic, multifocal, or central alopecic patches with follicular hyperkeratosis and erythema at hair-bearing margin	May be present (especially as lichen ruber mucosae)	• Topical ± intralesional steroid • Oral retinoid, prednisone, hydroxychloroquine, oral cyclosporine
Frontal fibrosing alopecia	Post-menopausal women	Frontotemporal recession often with classic LPP at hair-bearing margin	May be present (eyebrows)	• Topical ± intralesional steroid • Anti-androgens, finasteride
Graham-Little syndrome	Adults	Patches with follicular hyperkeratosis	May be present (non-scarring in axillae, pubic area)	See text
Graft-versus-host disease	See Chap. 28	Usually presenting like LPP, hyperpigmentation may be present	See Chap. 28	• Prednisone • Calcineurin inhibitors • Topical steroid, psoralen and ultraviolet A light, etretinate
Pseudopelade of Brocq	Adults	Asymptomatic, noninflamed ivory-white or flesh-colored small oval-round confetti-like, reticulate, or large, irregular patches, ± atrophy	Rarely present (beard); separate entity, or end-stage variant of LPP?	• Topical ± intralesional steroid • Prednisone, hydroxychloroquine, isotretinoin
Central centrifugal cicatricial alopecia (previously also known as *follicular degeneration syndrome*, *pseudopelade* in African Americans)	Especially black women	Central scalp; noninflamed late stage; flesh-colored symmetric patch	Absent	• Cease traumatic/chemical hair-care practices • Topical steroid + oral tetracycline
Keratosis follicularis spinulosa decalvans	Onset in childhood	Patchy, follicular hyperkeratosis ± perifollicular erythema	Present; photophobia, keratosis pilaris	• Topical and intralesional steroid • Isotretinoin
Alopecia mucinosa	All ages	Polymorphous disease (e.g., erythematous plaques with patulous ostia): alopecia areata-like, diffuse, or complete alopecia	May be present; rule out malignancy, because this is a classic presenting symptom of cutaneous T-cell lymphoma (see Chap. 146)	For primary form: • Topical steroid, intralesional steroid • Minocycline, isotretinoin • Phototherapy
Neutrophilic[c]				
Folliculitis decalvans	Adults	Usually central scalp; grouped follicular pustules, miliary abscesses at hair-bearing margin	Generally absent; may represent scalp variant of hidradenitis suppurativa/acne inversa (see http://www.hs-foundation.org)	• Antibiotic ± topical steroid • Rifampin + second antibiotic • Fusidic acid + zinc • Isotretinoin
Mixed				
Acne keloidalis	Especially black men	Occipital scalp; firm red-brown papules, papulopustules, nodules and keloidal plaques	Absent	• Intralesional steroid ± antibiotics • Excision (plaque form), cryotherapy, isotretinoin
Erosive pustular dermatosis	Especially elderly women	Asymptomatic, crusted purulent plaque	Absent	• Topical steroid, calcipotriol • Zinc

LPP = lichen planopilaris.
[a]Therapy of cicatricial alopecia is severely hampered by the paucity of evidence-based medicine. Most treatment regimes are based on anecdotal reports or small study series; double-blind, randomized, placebo-controlled, prospective studies in a sufficiently large cohort of patients are virtually non-existent.
[b]The main aim of treatment is to prevent progression, and patients should be advised that significant recovery of hair growth is unlikely.
[c]Histologically, it is relatively easy to distinguish the lymphocytic and neutrophilic groups of cicatricial. However, currently it is exceedingly difficult, if not impossible, to distinguish clinically distinct primary cicatricial alopecias within these two groups.
Adapted from Ross EK, Tan E, Shapiro J: Update on primary cicatricial alopecias. *J Am Acad Dermatol* **53**:1, 2005.

▲ **FIGURE 86-23** Frontal fibrosing alopecia.

cal and intralesional steroids, topical and systemic retinoids, and hormone replacement therapy do not prevent the hair loss progression (Fig. 86-23).

PSEUDOPELADE OF BROCQ In clinical terms, pseudopelade of Brocq[278] implies flesh- to pink-colored, irregularly shaped alopecia that may begin in a "moth-eaten" or characteristic "footprints-in-the-snow" pattern with eventual coalescence into larger patches of alopecia (Fig. 86-24).[43,278] There is no follicular erythema or hyperkeratosis, yet the disease may progress inexorably. There has been considerable debate as to the specificity of this diagnosis versus an assignation of the term to describe all noninflammatory scarring alopecias, including the end-stage of a variety of initially inflammatory conditions. Histologically, the lesions are characterized by a perifollicular and perivascular lymphocytic infiltrate primarily at the level of the follicular infundibulum, loss of sebaceous epithelium, and fibrotic streams into the subcutis without interface or follicular plugging changes.[279] Elastin stains may distinguish pseudopelade (persistent elastic fibers around the midshaft of the follicle) from lichen planopilaris and lupus erythematosus (loss of elastic fibers in this location).[280] Direct immunofluorescence is negative in the majority of cases. However, in general, the histology is similar, if not identical, to that of lichen planopilaris.[273] It is unclear whether any treatment helps.

Other Forms of Scarring Alopecia

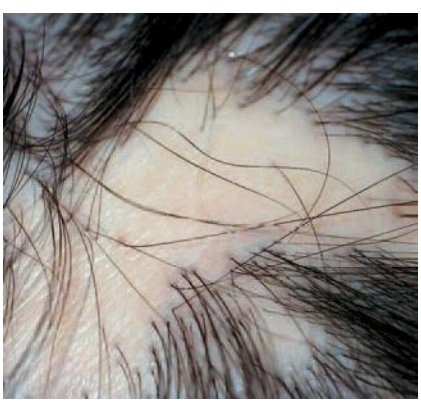
Central centrifugal cicatricial alopecia (CCCA) is a form of cicatricial alopecia that affects adults of African orgin.[43,271] This condition has also been called *hot comb alopecia* or *follicular degeneration syndrome*. This starts at the crown or midline vertex and spreads slowly in a centrifugal fashion. Inflammation has been reported more commonly in affected men than in affected women.[282] Histologically, the earliest and most distinctive change is premature desquamation of the inner root sheath with later changes through the outer root sheath (including migration of the hair shaft), a mononuclear infiltrate primarily at the isthmus, and, finally, loss of the follicular epithelium and replacement with fibrous tissue.[282] Although tight braiding, hot combs, and hair straightening agents are often invoked as causative or at least contributory factors and their use discouraged in CCCA, this has not been definitely proven. The distribution of CCCA overlaps that of pattern hair loss but the sex distribution is tremendously skewed toward women.

Alopecia mucinosa , also known as *follicular mucinosis*, generally presents as erythematous, alopecic papules, plaques, or flat patches on the scalp and face.[267] Biopsy reveals prominent follicular, epithelial, and sebaceous gland mucin, and perifollicular lymphohistiocytic infiltrate, which may be associated with follicular lymphocyte exocytosis, without concentric lamellar fibrosis.[265,267,283] In adults, alopecia mucinosa almost invariably represents follicular mycosis fungoides (see Chap. 146).[283] It is controversial whether a self-limited variant exists in children.

Keratosis follicularis spinulosa decalvans is a rare, usually X-linked disorder with the gene located at Xp22.13–p22.2 (see Chap. 85).[284,285]

Folliculitis decalvans is an inflammatory disease characterized by pustular folliculitis leading to scarring hair loss. Surviving hairs may group so that multiple hairs are seen emerging from a single follicular orifice (tufted folliculitis) (Fig. 86-25). *Staphylococcus aureus* is usually cultured from these pustules, but whether this is a primary or secondary process is unclear. Histologically, early lesions show an acute suppurative folliculitis with neutrophils and eosinophils, later mixed with lymphocytes and histiocytes.[265,266] Loss of sebaceous epithelium and perifollicular fibrosis is common.[265] Systemic antibiotics, particularly in combination with rifampin, systemic and/or topical steroids, and systemic retinoids may also be helpful.[289]

Dissecting folliculitis or perifolliculitis capitis abscedens et suffodiens is another inflammatory condition of the scalp that can lead to scarring alopecia. African Americans are particularly affected. This condition begins with deep inflammatory nodules, primarily over the occiput, that progress to coalescing regions of boggy scalp (Fig. 86-26). Sinus tracts may form and dislodge purulent material. As in folliculitis decalvans, *S. aureus* is the most common bacterial isolate. Biopsy of early lesions shows follicular plugging and suppurative follicular or perifollicular abscesses with a mixed inflammatory infiltrate of neutrophils, lymphocytes, plasma cells, or eosinophils.[265–267] Later, foreign-body giant cells, granulation tissue, and, finally, scarring with sinus tracts occur. Control is difficult to attain, but small case series have reported success with oral isotretinoin, systemic antibiotics (using similar regimens to folliculitis decalvans), systemic steroids, and dap-



▲ **FIGURE 86-24** Pseudopelade of Brocq.

◀ **FIGURE 86-25** Folliculitis decalvans.

◀ **FIGURE 86-26** Dissecting folliculitis.

sone.[262,290] Surgical incision and drainage, excision with grafting, and/or x-ray epilation are occasionally used for refractory cases.

Acne keloidalis (nuchae) is a destructive scarring folliculitis that occurs mostly on the occipital scalp of African Americans, primarily men (Fig. 86-27). The clinically distinctive lesions begin as follicular pustules and papules and progress to persistent firm papules or coalesce into hairless keloid-like plaques.[291] On histopathologic examination of an early lesion, there is follicular dilatation and a mixed peri-infundibular infiltrate that goes into follicular rupture and foreign body granulomas, loss of sebaceous glands, and lamellar fibroplasia. Mild forms of the disease may be treated with topical or intralesional corticosteroids, or systemic antibiotics, and/or cryotherapy. Surgical excision of the affected skin the most effective treatment for severe acne keloidalis.[262]

The primary lesion in acne necrotica is a pruritic or painful erythematous follicular-based papule that develops central necrosis and crusting and heals with a varioliform scar.[292,293] The lesions are concentrated on the nose, forehead, and anterior scalp, but may spread, primarily to the trunk. The course is chronic. Histologically, acne necrotica is a lymphocytic necrotizing folliculitis.[292] Possible treatments include systemic antibiotics and oral isotretinoin.[262,292]

Erosive pustular dermatosis of the scalp is predominantly a disease of the elderly, mainly women, although pediatric cases do occur.[294] It presents as chronic boggy crusted plaque on the scalp overlying exudative erosions and pustules, eventually leading to scarring alopecia (Fig. 86-28).[295,296] A history of preceding trauma may be obtained,[294,297] and there are several reports of onset after treatment for actinic keratoses.[262] On biopsy, there is a lymphoplasmacytic infiltrate with or without foreign body giant cells and pilosebaceous atrophy. Multiple organisms, both bacterial and fungal, have been cultured, but these probably represent secondary colonization; patients do not generally respond to antibacterial or antifungal drugs. No single treatment is uniformly successful, but potent topical steroids, topical tacrolimus,[298] or isotretinoin may be helpful.[297]

Secondary Cicatricial Alopecia

Cicatricial alopecia may present as a hereditary or development problem, alone or as part of a syndrome. Examples of the latter are Conradi-Hünermann chondrodysplasia punctata; incontinentia pigmenti; ankyloblepharon, ectodermal defect, cleft lip or palate syndrome; Hallermann-Streiff syndrome; and generalized atrophic benign epidermolysis bullosa.[46]

Congenital Cicatricial Alopecia

The most common congenital cicatricial alopecia is aplasia cutis congenita, which is the congenital focal absence of epidermis with or without absence of other layers of the skin.[46] Hair follicles in the involved areas are variably affected. The condition may present at birth as an ulceration, crust, scar, or parchment-like membrane (see Chap. 106).

EXCESS HAIR

Hirsutism refers to hair growth in women in areas of the body where hair growth is under androgen control and in which normally only postpubescent males have terminal hair growth. These areas include the moustache, beard, chest, escutcheon, and inner thigh.

Hypertrichosis specifically refers to hair density or length beyond the accepted limits of normal for a particular age, race, or sex. The excess hair may be generalized or localized and may consist of lanugo, vellus, or terminal hair.

Hirsutism

EPIDEMIOLOGY What constitutes significant hirsutism is difficult to define, as it depends on a variety of cultural and racial factors, media-driven perceptions of normality, and the perceptions of the individual physician and patient.[299] Not surprisingly, therefore, estimates of the frequency of hirsutism in the female populations have varied widely. In Lon-

▲ **FIGURE 86-27** Acne keloidalis.

◀ **FIGURE 86-28** Pustular dermatosis of the scalp.

don, 1.2 percent of women were significantly hirsute.[300] Other studies have reported frequencies of up to 18 percent.[299] The frequency and distribution of female androgen-dependent hair growth also varies with age; terminal hair growth in the pubic and axillary regions declines with age, whereas facial hair growth increases. These difficulties have led to the use of the patient-determined term *unwanted hair* to influence therapeutic decision making. Nevertheless, the physician may still have to make a value judgment as to when patient concerns really represent a body dysmorphic disorder, rather than a problem solvable by hair removal.

PATHOGENESIS Terminal hair growth in a "male" pattern is undoubtedly due to the effect of androgens, and reflects the conversion of vellus to terminal hair follicles. In many women, hirsutism is associated with raised levels of circulating androgens (54 percent in one series).[301] However, in some, androgen levels are within the normal range, suggesting in these individuals that hair growth is especially sensitive to androgen stimulation. Recent evidence suggests that testosterone increases 5α-reductase gene expression in dermal papillae from lower abdominal skin of women with hirsutism; theoretically, this may raise the dihydrotestosterone-generating potency of these hair follicles.[302] Also, only certain 5α-reductase type 1 haplotypes are reportedly associated with hirsutism,[303] which further raises the question of whether inherited, constitutive abnormalities in intrafollicular dihydrotestosterone synthesis are an important element in the pathogenesis of hirsutism. Other clinical features of hyperandrogenism include oligo- or amenorrhea, sub- or infertility, acne, acanthosis nigricans, and female pattern hair loss to frank virilization with male pattern balding and clitoromegaly.[304] Table 86-8 lists causes of hyperandrogenism, of which polycystic ovary syndrome is by far the most common.[304,305]

INVESTIGATION Whether and how to investigate hirsute women depends on a number of factors, including the presence of clinical features of increased androgen production, the duration of the history, and the concerns of the patient. In fertile women with normal menses and a long history of relatively mild hirsutism, it is debatable whether investigation is necessary at all. In women with moderate to severe hirsutism, particularly when accompanied by other signs of androgen excess, further evaluation is warranted (Table 86-9). Women with hyperprolactinemia may have an increase in functional androgens through adrenal overproduction and through a decrease in sex hormone–binding globulin caused by a diminution of ovarian estrogen production.[306]

TABLE 86-8
Hirsutism

- Androgen-secreting tumors
  - Adrenal
    - Adenoma
    - Adenocarcinoma (rare)
    - Ectopic adrenocorticotropic hormone–secreting tumor (rare)
  - Ovarian
    - Gonadal stromal tumor
    - Thecoma
    - Lipoid tumor

Functional androgen excess

- Adrenal enzyme deficiencies (congenital adrenal hyperplasia)
  - Early onset 21-hydroxylase deficiency
  - Late-onset 21-hydropxylase deficiency
  - 11β-hydroxylase deficiency
  - 3β-ol dehydrogenase deficiency
- Cushing syndrome
- Polycystic ovarian disease
  - With or without adrenal contribution
  - Hyperthecosis
- "Idiopathic" hirsutism
- Medication/drug use

Hughes CL: Hirsutism, in *Disorders of Hair Growth: Diagnosis and Treatment*, edited by Olsen EA. New York, McGraw-Hill, 1994, p 344, Table 14-2.

TABLE 86-9
Recommended Investigation for Hirsutism

- Serum testosterone (if > 200 ng/mL, exclude androgen-secreting tumor)
- Serum-free testosterone and dehydroepiandrosterone (more sensitive; most women with moderately elevated androgen levels have polycystic ovarian syndrome)
- 17-hydroxyprogesterone (raised level suggests congenital adrenal hyperplasia; confirm diagnosis by repeat measurement after adrenocorticotropic hormone stimulation)
- Serum prolactin (hyperprolactinemia due to macro- or microprolactinoma or treatment with neuroleptic drugs[331]; may have associated menstrual abnormalities, infertility, and galactorrhea)

Box 86-3
Treatment of Hirsutism

Remove existing terminal hair and prevent further vellus-to-terminal transformation

- Temporary hair removal
  - Shaving, plucking, depilatory creams
  - Topical eflornithine (slows growth; does not remove hair)
- (Potentially) permanent hair removal
  - Electroepilation[332]
  - Laser hair removal[307]
- Anti-androgen measures
  - Weight loss
  - Oral anti-androgens (spironolactone, cyproterone acetate)
  - Oral contraceptives
  - Finasteride

TREATMENT The approach is two-pronged: the removal or reduction of existing unwanted terminal hair, and the reduction of the androgen drive toward further vellus-terminal transformation. The latter approach (e.g., using anti-androgens) may also help to reduce hair growth but, on its own, is unlikely to eliminate it (Box 86-3). Shaving, plucking, and use of depilatory creams are temporary means of hair removal that can be irritating and painful. The topically applied inhibitor of ornithine decarboxylase, eflornithine 13.9 percent, is approved for the reduction of unwanted facial hair in women when applied twice daily.

Laser epilation is less permanent than often suspected, is most effective when applied repetitively, and patients should be discouraged from unrealistic expectations. The mechanism of laser epilation is the selective photothermolysis of melanized hair through absorption of light energy.[307] The combination of the topically applied eflornithine with laser therapy may decrease the growth after hair removal.[308]

Weight loss may be helpful in obese patients because obesity increases free testosterone levels by reducing sex hormone–binding hormone and contributes to insulin resistance.

There are marginal differences in efficacy between systemically administered agents, but all generally take 6 to 12 months for sufficient miniaturization of terminal hairs to be clinically significant. These include oral anti-androgens (such as spironolactone, 100 to 200 mg daily) or cyproterone acetate,[309–312] oral contraceptives, and finasteride.[309,313] Oral contraceptives inhibit androgen synthesis by inhibiting the output of gonadotropins and are most effective if combined with anti-androgens. Treatment of congenital adrenal hyperplasia may also be accom-

plished through the use of low-dose dexamethasone.[314] Hyperprolactinemia may be treated directly with either medical (bromocriptine) or surgical treatment of the hyperprolactinoma, possibly combined with an anti-androgen.

Hypertrichosis

Congenital hypertrichosis lanuginosa presents as a confluent, generalized overgrowth of silvery blonde to gray lanugo hair at birth or in early infancy.[315] It is rare (1 in 1 billion) and thought to occur as an autosomal dominant trait with variable expressivity. In most cases, other than possibly anomalous dental eruptions, children are otherwise healthy. The hair may persist, increase, or decrease with age.[316–318]

There are several other congenital disorders associated with generalized hypertrichosis, but none that are so evenly distributed as congenital hypertrichosis lanuginosa (Table 86-10).[43] Patients with the autosomal dominant Ambras syndrome or hypertrichosis universalis congenita present with much longer, thicker hair, with accentuation over the entire face, ears, and shoulders.[319–321] Associated facial dysmorphism and dental anomalies are common. Members of the five-generation family described with congenital generalized hypertrichosis also have excess terminal hair on the face and upper body, more severe in men than women in keeping with the X-linked dominant inheritance.[318,322] Patients with the autosomal dominant (rarely autosomal recessive) gingival fibromatosis frequently have hypertrichosis, mostly on the face, eyebrows, limbs, and upper back, along with seizures and oligophrenia.[43,315] Hypertrichosis may be delayed until puberty, although gingival fibromatosis in this situation usually appears with the emergence of the primary, versus secondary, teeth.

ACQUIRED GENERALIZED HYPERTRICHOSIS

There are few more ominous signs in dermatology than the onset of generalized hypertrichosis without an obvious drug-related explanation. Generalized acquired hypertrichosis lanuginosa almost always signals an underlying malignancy or is a harbinger of one to develop in the near future (Fig. 86-29 and see eFig. 86-29.1 in on-line edition; see Table 86-10 and Chap. 154).[323,324] However, an association with autoimmune hepatitis has also been reported.[325] More frequently, extensive acquired hypertrichosis is a common feature of porphyria cutanea tarda, variegate porphyria, and congenital erythropoietic porphyria (see Chap. 132).

▲ **FIGURE 86-29** Acquired hypertrichosis lanuginosa. (From Olsen EA: Hypertrichosis, in *Disorders of Hair Growth: Diagnosis and Treatment*, edited by Olsen EA. New York, McGraw-Hill, 2003.)

There are several drugs that routinely cause generalized hypertrichosis (see Table 86-10).[43,315] Oral minoxidil, a piperidinopyramidine derivative that is a potassium channel opener and antihypertensive agent when used systemically, causes hypertrichosis in 80 percent of patients, most prominently over the face, shoulders, and extremities.[210] Diazoxide, a benzothiadiazine used primarily in malignant hypertension or idiopathic hypoglycemia of infancy, leads to lanugo-like hypertrichosis of the face, trunk, and extremities in 1 percent to 20 percent of adults but in almost 100 percent of children. Dilantin use leads to terminal hair hypertrichosis in 5 percent to 12 percent of patients, again first over the extremities, trunk, and face. The immunosuppressive immunophilin ligand, cyclosporine A, causes terminal hair hypertrichosis in 40 percent to 95 percent of patients, with a more diffuse distribution of ex-

▲ **FIGURE 86-30** Cyclosporine-related hypertrichosis.

cess hair, but primarily over the upper body (Fig. 86-30).[326–328] Based on findings in the mouse, the underlying mechanism likely reflects premature anagen induction as well as catagen inhibition by cyclosporine A,[133,329] which may contribute to the vellus to terminal hair conversion that leads to hypertrichosis.

LOCALIZED HYPERTRICHOSIS Table 86-11 lists the conditions associated with localized hypertrichosis. These are generally inherited, developmental, or secondary to irritation or trauma.

TREATMENT Removal of the inciting cause should be the prime approach to treatment and usually leads to regression of the hypertrichosis. However, in situations in which this is not possible, one must either help the patient deal psychologically with the physical anomaly and/or use means of either temporarily or permanently removing the hair. The same methods of hair removal described for hirsutism management may be used for hypertrichosis as well, except for the anti-androgenic approaches (see Box 86-3).

CHAPTER 87

Biology of Nails and Nail Disorders

Antonella Tosti
Bianca Maria Piraccini

BIOLOGY OF NAILS

The nail apparatus consists of a horny "dead" product, the nail plate, and four specialized epithelia: the proximal nail fold, the nail matrix, the nail bed, and the hyponychium (Fig. 87-1A). The nail apparatus develops during the ninth embryonic week from the epidermis of the dorsal tip of the digit as a rectangular area, the nail fold, which is delineated by a continuous groove.[1] The proximal border of the nail fold extends downward and proximally into the dermis to form the nail matrix primordium. By the fifteenth week the nail matrix is completely developed and starts to produce the nail plate, which will continue to grow until death. The nail apparatus lies immediately above the periosteum of the distal phalanx. The intimate anatomic relationship between the nail and the bone is responsible for the common occurrence of bone alterations in nail disorders and vice versa. The shape of the distal phalangeal bone also determines the shape and the transverse curvature of the nail.

Fingernails usually present a longitudinal major axis and toenails a transverse major axis. The ratio between length and width is important for the aesthetic appearance of the nails. The size of the nails varies in the different digits. The biggest nail is that of the first toe, which covers approximately 50 percent of the dorsum of the digit.

Nails have numerous functions. Fingernails not only contribute to the pleasing appearance of the hands, but are very important in protecting the distal phalanges and enhancing tactile discrimination and the capacity to pick up small objects. They are also widely used for scratching and grooming and are an efficient natural weapon. Toenails protect the distal toes and contribute to pedal biomechanics.

Nail Plate (See Fig. 87-1A)

The nail plate is a fully keratinized structure that is continuously produced throughout life (see Fig. 87-1B). It results from maturation and keratinization of the nail matrix epithelium and is firmly attached to the nail bed, which partially contributes to its formation. Proximally and laterally the nail plate is surrounded by the nail folds, which cover its proximal third and lateral margins. At the tip of the digit, the nail plate separates from the underlying tissues at the hyponychium. The nail plate is rectangular, translucent, and transparent. It is curved in both the longitudinal and transverse axes, especially in the toes. The nail plate surface is smooth but frequently shows mild longitudinal ridges that increase with aging. The pattern of these ridges can be used for forensic identification. The bottom of the nail plate shows longitudinal ridges that correspond to the rete ridges of the nail bed. The nail plate is homogeneously pink, except for its free edge, which is white. The pink color of the nail plate is due to the nail bed blood vessels.

The proximal part of the fingernails, especially of the thumbs, shows a whitish, opaque, half-moon–shaped area, the lunula, that is the visible portion of the nail matrix. In this area the nail plate attachment to the underlying epithelium is loose. More than 90 percent of fingernails show a thin distal transverse white band, the onychocorneal band, which marks the most distal portion of firm attachment of the nail plate to the nail bed.[2] This area represents an important anatomic barrier against environmental hazards, and its disruption produces nail plate detachment with onycholysis. The onychocorneal band is separated from the nail plate white free edge by a 1.0- to 1.5-mm pink band called the *onychodermal band*.

In transverse sections, the nail plate consists of three portions: dorsal nail plate, intermediate nail plate, and ventral nail plate.[3] The dorsal and the intermediate portions of the nail plate are produced by the nail matrix, whereas its ventral portion is produced by the nail bed. Above the lunula the nail plate is thinner and consists only of the dorsal and intermediate portions. There is a natural line of cleavage between the dorsal and the intermediate nail plate.

The nail plate progressively thickens from its emergence to its distal margin. The mean toenail thickness at the distal margin is 1.65 ± 0.43 mm in men and 1.38 ± 0.20 mm in women. Fingernails are thinner; the mean thickness is 0.6 mm in men and 0.5 mm in women. There is an increase in nail thickness with age, particularly in the first two decades. Nail thickness depends on the length of the nail matrix and nail bed.[4] Thinning of the nails is usually a sign of nail matrix disorders, whereas nail thickening is most commonly a consequence of nail bed disorders.

Proximal Nail Fold (See Fig. 87-1A)

The proximal nail fold is a skinfold that consists of a dorsal and a ventral portion. The dorsal portion is anatomically similar to the skin of the dorsum of the digit but thinner and devoid of pilosebaceous units. The ventral portion, which cannot be seen from the exterior and proximally continues with the germinative matrix, covers approximately one-fourth of the nail plate. It closely adheres to the nail plate surface and keratinizes with a granular layer. The limit between the proximal nail fold and the nail matrix can be histologically established at the site of disappearance of the granular layer.

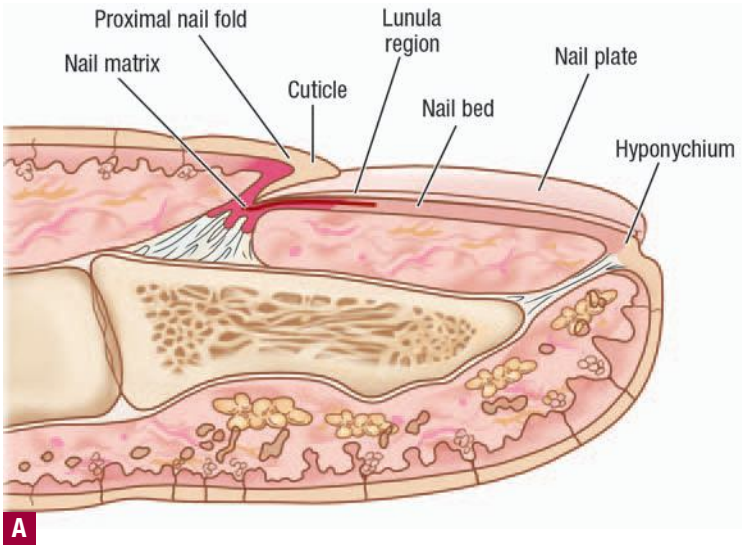
The horny layer of the proximal nail fold forms the cuticle, which is firmly attached to the superficial nail plate and prevents the separation of the plate from the nail fold. The integrity of the cuticle is essential for maintaining the homeostasis of this region.

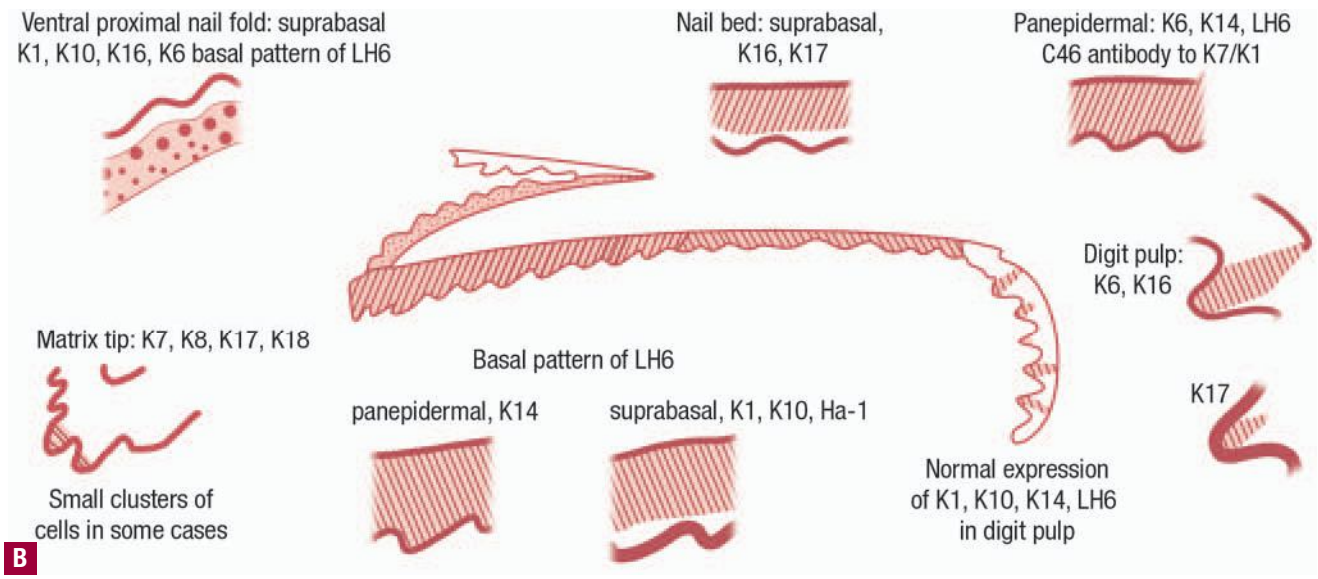
The dermis of the proximal nail fold contains numerous capillaries that run parallel to the surface of the skin and may easily be observed in vivo by capillary microscopy (Fig. 87-2). This permits the observation of both the arterial and the venous limbs of the capillaries, which are arranged in parallel rows and appear as fine regular loops with a small space between the afferent and efferent limbs. The morphology of proximal nail fold capillaries is typically altered in connective tissue diseases.[5–8]

Nail Matrix (See Fig. 87-1A)

The nail matrix is a specialized epithelial structure that lies above the mid portion of the distal phalanx. After elevation of the proximal nail fold, the matrix appears as a distally convex crescent with its lateral horns extending proximally and laterally.

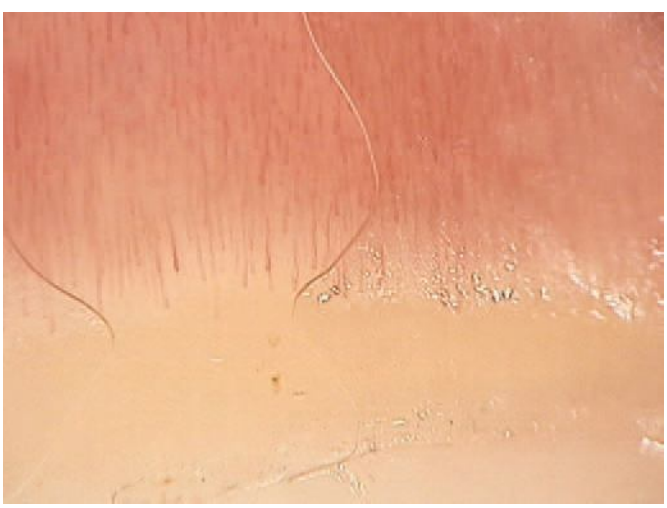
In longitudinal sections the matrix has a wedge-shaped appearance and consists of a proximal (dorsal) and a distal (ventral) portion. Nail matrix keratinocytes divide in the basal cell layer and keratinize in the absence of a granular zone. The site of keratinization (keratogenous zone) of nail matrix ony-





◀ **FIGURE 87-1** **A.** Diagrammatic drawing of a normal nail. **B.** Keratin gene expression at different locations within the nail. (From De Berker D et al: Keratin expression in the normal nail unit: Markers of regional differentiation. *Br J Dermatol* **142**:89, 2000, with permission.)

chocytes can be clearly distinguished in histologic sections as an eosinophilic area where cells show fragmentation of their nuclei and condensation of their cytoplasm.[1] In this area, nuclear fragments are destroyed by deoxyribonuclease and ribonuclease enzymes. In some conditions nuclear fragments may persist within the intermediate nail plate, producing leukonychial spots. These, however, frequently disappear before reaching the nail free edge, due to the persistence of active DNA and RNA lytic enzymes within the horny nail plate.



▲ **FIGURE 87-2** Capillary microscopy of the proximal nail fold showing the longitudinally oriented capillary loops.

Maturation and differentiation of nail matrix keratinocytes do not follow a vertical axis, as in the epidermis, but occur along a diagonal axis that is distally oriented. For this reason, keratinization of the proximal nail matrix cells produces the dorsal nail plate and keratinization of the distal nail matrix cells produces the intermediate nail plate.

In some fingers the distal matrix is not completely covered by the proximal nail fold but is visible through the nail plate as a white half-moon–shaped area, the lunula. The white color of the lunula results from two main anatomic factors: (1) the keratogenous zone of the distal matrix contains nuclear fragments that cause light diffraction; (2) nail matrix

capillaries are less visible than nail bed capillaries because of the relative thickness of the nail matrix epithelium.[9]

NAIL MATRIX KERATINOCYTES (See Fig. 87-1B) The nail matrix cells are able to synthesize both "soft" or skin-type and "hard" or hair-type keratins.[10–12] Evaluation of keratin expression in the different constituents of the nail apparatus showed that the nail matrix is the sole site of expression of hard keratin proteins, particularly Ha1 keratin.[13] Data indicate that fibroblasts derived from the nail matrix may induce hard keratin expression in non–nail matrix keratinocytes.[14]

MELANOCYTES (See Chap. 70) Nail matrix melanocytes are usually quiescent and therefore not detectable in pathologic sections. They possess the key enzymes that are necessary for melanin production, however, and may become activated by a large number of physiologic and pathologic conditions.[15] Nail matrix melanocyte activation produces diffuse or banded nail pigmentation and is more common in blacks and Japanese than in Caucasians. DOPA-negative (inactive) melanocytes are sparsely present in the nail matrix and in the nail bed.[16] DOPA-positive, activated melanocytes are especially seen in the distal nail matrix, where they are frequently arranged in small clusters among the suprabasal layers of the nail matrix epithelium.[17]

LANGERHANS CELLS (See Chap. 10) Langerhans cells are more numerous in the proximal than in the distal nail matrix. As in normal epidermis, Langerhans cells are predominantly found in the suprabasal layers. However, they may occasionally be seen within the basal layer of the nail matrix epithelium.

MERKEL CELLS The presence of Merkel cells in the nail matrix has been demonstrated. Their density is possibly influenced by age, with these cells being more numerous in fetus than in adult nails.[18]

Nail Bed (See Fig. 87-1A)

The nail bed extends from the distal margin of the lunula to the onychodermal band and is completely visible through the nail plate. The nail bed epithelium is so adherent to the nail plate that it remains attached to the undersurface of the nail when the latter is avulsed.

The nail bed epithelium is thin and consists of two to five cell layers. Its rete ridges, which are longitudinally oriented, interdigitate with the underlying dermal ridges in a "tongue-and-groove"–like fashion. Nail bed keratinization produces a thin horny layer that forms the ventral nail plate. Nail bed contribution to nail plate formation corresponds to approximately one-fifth of the terminal nail thickness and mass.[19] In pathologic sections, the ventral nail plate is easily distinguishable because of its light eosinophilic appearance. Nail bed keratinization is not associated with the formation of a granular layer. This may appear, however, when the nail bed becomes exposed after nail avulsion.[1]

Hyponychium

The hyponychium marks the anatomic area between the nail bed and the distal groove, where the nail plate detaches from the dorsal digit (see Fig. 87-1A). Its anatomic structure is similar to that of plantar and volar skin, and keratinization occurs through the formation of a granular layer. The horny layer of the hyponychium partially accumulates under the nail plate free margin. The hyponychium is normally covered by the distal nail plate, but it may become visible in nail biters.

Basement Membrane Zone

The antigenic structure of the basement membrane zone of the nail is identical to that of the epidermis, and there are no differences in the antigenic composition of the basement membrane zone in the different portions of the nail apparatus.[16,20] This may explain the involvement of the nails in conditions characterized by mutations of basement membrane–associated genes as well as in autoimmune skin diseases involving the basement membrane zone antigens.[21]

Dermis (See Fig. 87-1A)

The nail apparatus is devoid of subcutaneous tissue, and its dermis does not contain pilosebaceous units. The arrangement of the rete ridges varies in the different portions of the nail apparatus. The dermis beneath the proximal nail matrix consists of condensed connective tissue that forms a tendon-like structure connecting the matrix to the periosteum of the proximal phalangeal bone (posterior ligament). A small amount of subdermal fat tissue is present close to the periosteum of the base of the phalanx.[22] The close connection between the lateral horns and the periosteum is possibly responsible for the nail plate's lateral convexity. The rete ridges of the dermis underneath the nail matrix are characteristically long and root-like in shape. The dermis under the distal matrix consists of a loose network of connective tissue containing numerous blood vessels and rare glomus bodies.

The dermis of the nail bed has a unique arrangement with longitudinal grooves and ridges that run from the lunula to the hyponychium.[1] The longitudinal orientation of the capillary vessels within the nail bed grooves explains the linear pattern of nail bed hemorrhages (splinter hemorrhages). The nail bed dermis contains abundant connective tissue networks with connective tissue bundles radiating to the phalangeal periosteum. It contains numerous glomus bodies.

Blood and Nerve Supply

The nail apparatus has an abundant blood supply provided by the lateral digital arteries (see Fig. 87-2). These run along the sides of the digits and produce both branches that supply the matrix and the proximal nail fold and arches that supply the matrix and the nail bed. The nail matrix, therefore, has two different sources of blood supply. The nail bed is richly supplied (10 to 20 cm^2) by incapsulated neurovascular structures containing one to four arteriovenous anastomoses and nerve endings. These glomus bodies may be involved in the regulation of the blood supply to the digits in cold weather. The cutaneous sensory nerves, which originate from the dorsal branches of the paired digital nerves, run parallel to the digital vessels.

Chemical Properties (See Fig. 87-1B)

The nail plate, like hair, consists mainly of low-sulfur filamentous proteins (keratins) embedded in an amorphous matrix composed of high-sulfur proteins rich in cysteine. Other nail constituents include water, lipids, and trace elements. Nail keratins consist of 80 percent to 90 percent hard hair-type keratins and 10 percent to 20 percent soft skin-type keratins. Hard keratins have been identified as the acidic 44K/46K and basic 56K/60K keratins. Soft keratins have been identified as the 50K/58K and 48K/56K keratin pairs.[23] Keratin filaments have a transverse orientation that is parallel to the nail surface. This explains why the nail plate is more

susceptible to transverse fractures than to longitudinal fractures. Specific keratins are expressed only in some compartments of the nail unit; for instance, K6a and K6b, K16, and K17 are not expressed in the nail matrix.[13,24,25] Mutations of the genes encoding for these keratins are associated with nail thickening due to nail bed hyperproliferation, as is seen in pachyonychia congenita (PC).[26,27]

Under normal conditions the water content of the nail plate is 18 percent, and most of the water is in the intermediate nail plate.[28] This may vary significantly, however, because of the high porosity of the nail plate, which allows it to be rapidly hydrated and dehydrated. Dehydration is faster when the nails are kept long. When the water content decreases below 18 percent, the nail becomes brittle; when it increases above 30 percent, it becomes opaque and soft.[29]

The nail contains less than 5 percent lipids, mainly cholesterol; the nail plate lipid content is under hormonal control and decreases after menopause.[30] The nail plate also contains traces of several inorganic elements, particularly iron, zinc, and calcium. These, however, do not contribute to nail hardness.

Physical Properties

The nail plate is hard, strong, and flexible. The hardness and strength of the nail plate are due to its high content of hard keratins and cysteine-rich high-sulfur proteins, whereas its flexibility depends on its water content and increases with nail plate hydration.[31] The double curvature of the nail plate along its longitudinal and transverse axes enhances nail plate resistance to mechanical stress.[32]

The physical properties of the nail also depend on the arrangement and adhesion of onychocytes in the different portions of the nail plate, as well as on the orientation of the keratin filaments within the nail plate onychocytes.[32] At the ultrastructural level, the corneocytes of the dorsal nail plate are flat, with their shorter diameter perpendicular to the nail plate surface. The average sizes of these cells are 34 μm in length, 64 μm in width, and 2.2 μm in height.[33] Cell adhesion is strong. This portion of the nail is responsible for nail plate hardness and sharpness. The onychocytes of the intermediate nail plate show multiple interdigitations of their cell membranes. The average dimensions of these cells are 40 μm in length, 53 μm in width, and 5.5 μm in height. Cell adhesion is provided by desmosomes. This part of the nail plate is responsible for nail pliability and elasticity. The ventral nail plate is thin and consists of soft keratins. It provides adhesion to the underlying nail bed.

Nail Growth

The nail plate grows continuously throughout life. Fingernails grow faster than toenails, with a mean growth of 3 mm/month for fingernails and 1 mm/month for toenails. Complete replacement of a fingernail requires 100 to 180 days (6 months). When the nail plate is extracted, it is approximately 40 days before the new fingernail first emerges from the proximal nail fold. After a further 120 days it will reach the fingertip.[29] The total regeneration time for a toenail is 12 to 18 months. As a consequence of the slow nail growth rate, diseases of the nail matrix only become evident a considerable time after their onset and require a long time to disappear after treatment.

Nail growth rate varies among different individuals and among the different digits of the same individual. It depends on the turnover rate of the nail matrix cells and is influenced by several physiologic and pathologic conditions. Nail growth rate is slow at birth, increases slightly during childhood, and usually reaches its maximum between the second and the third decades of life. It sharply decreases after the age of 50 years.[34]

Conditions that have been associated with a slow growth rate include systemic illness, malnutrition, peripheral vascular or neurologic diseases, and treatment with antimitotic drugs. Nails affected by onychomycosis frequently exhibit a slow growth rate. An arrest of nail growth is a typical feature of yellow nail syndrome. Conditions that have been associated with accelerated nail growth include pregnancy, finger trauma, psoriasis, and treatment with oral retinoids or itraconazole. Accelerated nail growth may cause longitudinal ridging of the nail plate (nail beading).

Due to their slow growth rate, the nails may provide information on pathologic conditions that have occurred up to several months before the time of observation. Drugs, chemicals, and biologic substances accumulate in nails, where they can be detected and measured. Advantages of analyzing nail samples include the ease and non-invasiveness of their collection, the small sample size required for analysis, and the ease of storage at room temperature. The nail of the big toe is the best site for investigation because of its size and slow growth rate.[35]

NAIL SIGNS AS A FUNCTION OF THE SITE OF PATHOLOGY[1,29] (Table 87-1)

Beau's Lines and Onychomadesis (Nail Shedding)

Beau's lines result from a temporary arrest of proximal nail matrix proliferation and appear as transverse grooves, often deeper in the central nail plate, that move distally with nail growth. Onychomadesis also results from a temporary arrest in nail matrix activity, and the proximal nail plate is detached from the proximal nail fold by a whole-thickness sulcus. Causes of onychomadesis are the same as those for Beau's lines but are more severe (Table 87-2). Multiple Beau's lines or onychomadesis in the same nail indicates repetitive insults. The time of the insult leading to Beau's lines can be dated by measuring the distance of the groove from the proximal nail fold. Local trauma, such as from manicures or onychotillomania, or related to local cutaneous disease, particularly dermatitis, periungual erythema, and paronychia, are causes of Beau's

TABLE 87-1

lines (Fig. 87-3). Beau's lines at the same levels in several nails suggest a systemic cause. Most common among these are drugs (especially chemotherapy), high fever, viral illness,[36,37] surgery, and peripheral ischemia. Onychomadesis in children often relates to recent coxsackievirus infection.[36]

Pitting

Pits result from small areas of abnormal keratinization of the proximal nail matrix that produce foci of parakeratotic cells in the superficial nail plate. They appear as small punctate depressions of the superficial nail plate, which progress distally and often become more evident with nail growth (Fig. 87-4). Deep and irregularly distributed pits are seen in psoriasis and atopic dermatitis; geometric and superficial pits are typical of alopecia areata (see Chaps. 18, 14, and 86).

▲ **FIGURE 87-3** Beau's lines and toenail onychomadesis due to trauma by footwear.

▲ **FIGURE 87-4** Pitting. Note small punctate depressions of the superficial nail plate. In this patient, the presence of onycholysis surrounded by an erythematous border suggests a diagnosis of psoriasis.

Onychorrhexis (Longitudinal Striations and Fissuring)

Onychorrhexis results from diffuse defective keratinization of the proximal nail matrix. The nail plate is usually thinned and presents multiple longitudinal ridges and fissures. Onychorrhexis is typical of lichen planus (see Chap. 26).

Longitudinal Grooves

Longitudinal grooves are usually single and appear as a longitudinal depression of the nail plate (1 to 2 mm large) due to compression of the nail matrix by tumors of the proximal nail fold (Fig. 87-5).

Trachyonychia

Trachyonychia results from multiple foci of defective keratinization of the proximal nail matrix. The nails are rough due to excessive longitudinal ridging.

True Leukonychia

True leukonychia results from defective keratinization of the distal matrix with persistence of parakeratotic cells in the ventral nail plate. The superficial nail plate is structurally normal, but the nail presents opaque white patches or striae, which often disappear before reaching the distal edge of the nail. Punctate leukonychia is due to microtrauma and is typically seen in the fingernails of children. Striate leukonychia of fingernails is a consequence of aggressive manicure. Total or subtotal leukonychia is usually hereditary (Fig. 87-6).

▲ **FIGURE 87-5** Irregular longitudinal groove of the nail plate due to matrix compression by a myxoid cyst of the proximal nail fold.

Koilonychia

In koilonychia the nail plate is thin and spoon shaped. Koilonychia is physiologic in the toenails of children. In adults it can be a sign of iron deficiency or occupational factors.

Melanonychia[38]

Melanonychia is due to the presence of melanin in the nail plate. It can be caused by activation or proliferation of nail matrix melanocytes. In most cases melanonychia appears as a single or longitudinal brown to black band. Multiple bands of melanonychia are usually due to melanocyte activation, as is seen in darker-skinned individuals, pregnant women, those with inflammatory nail

- Trauma

disorders or Laugier-Huntziker syndrome, those taking certain medications (Table 87-3), and individuals with a variety of systemic disorders, particularly human immunodeficiency virus infection and Addison syndrome. In Laugier-Huntziker syndrome, melanonychia is associated with the presence of lip and/or genital pigmented macules and usually affects several digits; it begins during adolescence[39,40] (see Chap. 73). A single band of melanonychia may be a sign of a nail matrix nevus or melanoma (see Chaps. 122 and 124). Melanonychia affecting the fourth and/or fifth toenail is usually due to trauma. Longitudinal melanonychia of a single nail often deserves biopsy.

Longitudinal Erythronychia[41]

Longitudinal erythronychia reflects a nail bed disorder. A single longitudinal red line extending from the proximal nail to the distal edge is most commonly caused by onychopapilloma or other benign subungual tumors. Multiple bands of longitudinal erythronychia are seen in Darier disease (see Chap. 49).

▲ **FIGURE 87-7** Distal splinter hemorrhages (*arrow*).

▲ **FIGURE 87-8** Schematic drawing showing pattern of exogenous pigmentation (*left*) and endogenous pigmentation (*right*).

Onycholysis

Onycholysis is detachment of the nail plate from the nail bed and can be caused by traumatic, inflammatory, infectious, or neoplastic nail bed disorders. See Onycholysis under Environmental Nail Disorders later.

Splinter Hemorrhages

Splinter hemorrhages appear as red to black small thin longitudinal lines under the nail plate. They are more commonly located in the distal nail plate and represent rupture of the longitudinally oriented nail bed capillaries (Fig. 87-7). Causes include trauma and inflammatory nail disorders, such as psoriasis.

Apparent Leukonychia

In apparent leukonychia the nails are pale white due to nail bed discoloration that fades with pressure.

Subungual Hyperkeratosis

Subungual hyperkeratosis is due to inflammatory disorders that cause an abnormal keratinization of the distal nail bed and hyponychium with accumulation of scales under the distal nail plate. The most common causes include psoriasis, onychomycosis, trauma, and atopic dermatitis (see Chaps. 18, 188, and 14).

Paronychia

Paronychia is inflammation of the proximal nail fold and presents as painful periungual erythema, sometimes with associated purulence. Acute paronychia is usually caused by infection (see Infectious Nail Disorders). Chronic paronychia is most commonly due to mechanical or chemical factors. If the periungual area is fluctuant or shows purulence, it should be drained to avoid matrix damage. Topical and/or systemic antibiotics should be administered if bacterial infection is suspected.

Nail Pigmentation

Nail pigmentation is most commonly due to exogenous staining of the nail plate. In this case the proximal margin of the pigmentation follows the shape of the proximal nail fold. Exogenous nail pigmentation is most commonly due to occupational exposures or nail cosmetics. Nail pigmentation due to endogenous causes is rare. The proximal margin of the pigmentation follows the shape of the lunula (Fig. 87-8). Possible causes include drugs, argyria, hemochromatosis, alkaptonuria, and Wilson disease.

HEREDITARY AND CONGENITAL NAIL DISORDERS[42] (Table 87-4)

Ectodermal Dysplasias (See Chap. 143)

Nail changes may be associated with hypotrichosis, hypodontia, and hypohidrosis. Most common are short, thickened, hypoplastic nails.

Epidermolysis Bullosa (See Chap. 60)

In all sub-types of epidermolysis bullosa nail changes are common and may be the first or the only symptom of the disease. Junctional and dermolytic epidermolysis bullosa may produce anonychia.

Pachyonychia Congenita (See Chap. 48)

PC is a group of autosomal dominant disorders characterized by severe nail thickening due to massive nail hyperkeratosis[42] (Table 87-5). Type 1 PC is associated with

TABLE 87-4
Hereditary and Congenital Nail Disorders

Ectodermal dysplasias	• Atrophy/thickening
Epidermolysis bullosa	• Partial or total anonychia • Pachyonychia • Subungual/periungual hemorrhagic blisters
Pachyonychia congenita	• Onychogryphosis • Severe thickening • Yellow-brown discoloration
Iso-Kikuchi syndrome	• Micronychia/anonychia • Hemionychogryphosis
Nail patella syndrome	• Hypoplasia/aplasia • Triangular lunulae
Congenital malalignment of the hallux	• Lateral deviation of the nail plate • Lateral/distal embedding of nail • Nail thickening • Yellow-brown discoloration • Transverse ridging

TABLE 87-5

    - Natal teeth
    - Pili torti
    - Hoarseness

mutations of K6a and K16 genes,[43] whereas type 2 PC is caused by mutations of K6b and K17.[44,45] In PC both fingernails and toenails are thickened, yellow-gray, and transversely overcurved with marked subungual hyperkeratosis most notable at the distal portion of the nails (Fig. 87-9). Nail trimming is impossible, because the nails are extremely hard. The abnormalities usually develop during childhood, but a late-onset variety of PC has been described.[46] Focal palmo-plantar keratoderma is associated with the nail changes in 60 percent of patients or may result from mutations without detectable nail changes.[47] Up to 75 percent of patients have oral leukokeratosis; hyperhidrosis of the palms and soles, follicular keratoses, and acral bullae (especially during warmer months) are common. Patients with type 2 PC also tend to have cystic lesions (steatocystoma multiplex, vellus hair cysts), which reflects the expression of K6b and K17 in adnexal structures. The cystic lesions begin during childhood and progressively appear. Coarse or twisted hair, early primary tooth loss, and natal teeth are other occasional features of type 2 PC, reflecting expression of the affected genes in the hair follicle apparatus and teeth.

Nail Patella Syndrome

Nail abnormalities in nail patella syndrome may involve all fingernails or may be limited to the thumbs, which are always the most severely affected digits (Fig. 87-10). Nail hypoplasia is usually more marked in the medial portion of the nail. The shape of the lunula is typically triangular.[42]

Congenital Malalignment of the Hallux

Congenital malalignment of the hallux is the most common cause of ingrowing (ingrown) nails and is usually diagnosed when the child starts to walk. The great toenail shows a lateral deviation that produces embedding of the lateral side of the nail plate. The digit is painful and the toenail often shows Beau's lines and onycholysis (Fig. 87-11). Congenital malalignment may be unilateral or bilateral. Spontaneous improvement may occur, and most children do not have symptoms by the age of 2 years.[48] Inflammation due to lateral ingrowing can be managed by daily massaging of the lateral nail fold with creams containing steroids, antibiotics, and urea. Surgical treatment is invasive and usually not necessary.[49]

▲ **FIGURE 87-10** Nail patella syndrome: nail hypoplasia and triangular lunula.

INFECTIOUS NAIL DISORDERS (Table 87-6)

Acute paronychia is most commonly due to *Staphylococcus aureus* infection and typically affects a child's fingernail. Predisposing factors include nail biting or sucking and occupational traumas. The proximal nail fold is painful, erythematous, and swollen. Pus may be discharged after pressure (see Chap. 177).The differential diagnosis includes herpes simplex virus infection (see Chap.

◀ **FIGURE 87-9** Pachyonychia congenita of the fingernails in an adult (**A**) and of the toenails in a 4-year-old boy (**B**). Note the severe nail thickening and transverse hypercurvature due to compact nail bed hyperkeratosis.

▲ **FIGURE 87-11** Congenital malalignment of the big toenail. The longitudinal axis of the nail is deviated laterally. Note Beau's lines and mild lateral ingrowing.

193) and Hallopeau acrodermatitis (see Chap. 21), both of which have a typical relapsing course. Suspicion of herpes simplex virus infection should arise when the pain intensity is disproportionate to the clinical symptoms and the disease is recurrent. Most commonly, cephalosporins are initiated as therapy. However, any purulent material should be drained if possible and cultured to ensure choice of the optimal antibiotic.

Green Nails

Bacteria are not capable of attacking a healthy nail plate. The Gram-negative bacterium *Pseudomonas aeruginosa* may colonize the dorsal or ventral nail plate under propitious conditions, such as chronic paronychia or onycholysis. The presence of *Pseudomonas* is revealed by a characteristic green-black nail pigmentation due to pyocyanin staining (Fig. 87-12). Topical application of a few drops of diluted bleach or chlorhexidine solution two or three times a day clears the pigmentation in a few weeks. Administration of systemic antibiotics is unnecessary.

▲ **FIGURE 87-12** Onycholysis with green discoloration due to *Pseudomonas* colonization.

Onychomycosis[50,51]

For a detailed description of the onychomycoses see Chap. 188. Onychomycosis is a common toenail disease, and its prevalence increases with age.

Clinical features depend on type of nail invasion (Table 87-7). The possibility of mold onychomycosis should be suspected when proximal subungual onychomycosis is associated with periungual inflammation (Fig. 87-13) or when white superficial onychomycosis is severe and involves the entire nail plate (Fig. 87-14). Nondermatophytic onychomycoses are becoming more frequent worldwide and represent a clinical problem, because they usually respond poorly to systemic treatment.

DSO = distal subungual onychomycosis; PSO = proximal subungual onychomycosis.

ONYCHOMYCOSIS AT A GLANCE

- Fifteen percent of the general population and 40 percent of individuals older than 60 years are affected.
- Clinical presentation reflects the route of nail invasion.
- Dermatophytes account for 85 percent of cases, nondermatophytic fungi for 15 percent.
- Infection with human immunodeficiency virus should be suspected with proximal subungual onychomycosis (PSO).
- Mold fungal infection should be suspected when PSO is associated with acute periungual inflammation or when white superficial onychomycosis involves most of the nail plate.
- *Candida* sp. are the causative agents only in immunosuppressed individuals.
- Toenails are involved in most cases; tinea pedis is usually associated.
- The cure rate for toenail onychomycosis is approximately 80 percent with the use of systemic antifungals, but recurrences are frequent (up to 20 percent). Mold infections respond poorly to systemic treatment.

ENVIRONMENTAL NAIL DISORDERS

Nail Fragility[52] (Table 87-8)

With nail fragility, the nails are brittle and show distal lamellar splitting (onychoschizia). Several nails are usually affected. The nail plate margin is irregular due to distal splitting. Idiopathic nail fragility usually affects middle-aged women who are exposed to water and chemicals that dehydrate the nail plate. Aging also is associated with increased nail fragility. The risk of nail fragility from trauma is increased by manicures, onychotillomania, and certain occupations, especially those that involve frequent exposure to water and chemicals. Fragile nails can be a feature of several

TABLE 87-7
Clinical Presentations of Onychomycosis (see Chap. 188)

Distal subungual onychomycosis[a]	*Trichophyton rubrum, Trichophyton interdigitale*	Onycholysis associated with subungual hyperkeratosis, patchy or linear yellow discoloration
Proximal subungual onychomycosis	*T. rubrum*[b]	Proximal leukonychia with normal nail plate surface

[b]Possible marker of human immunodeficiency virus infection.

dermatologic disorders, among them lichen planus, alopecia areata, psoriasis, and onychomycosis. In addition, nutritional deficiency, peripheral neuropathies, peripheral vascular disease, and use of certain medications increase the risk of nail fragility. Management includes protection of the hands by the use of cotton gloves under rubber gloves and frequent application of topical moisturizers. Oral biotin, 5 mg/day, can be helpful.[53]

Chronic Paronychia[54,55]

Chronic paronychia is an inflammatory disorder that almost exclusively involves the fingernails of adult women. Mechanical or chemical trauma damages the cuticle and permits penetration of irritant and allergenic environmental substances, which cause an inflammatory reaction of the proximal nail fold and nail matrix. Secondary colonization with *Candida* sp. and/or bacteria occurs in most cases, causing self-limited episodes of painful acute inflammation (see Chap. 189). Chronic paronychia most commonly affects the first, second, and third fingers of the dominant hand. Clinically the proximal and lateral nail folds show mild erythema and swelling, and the cuticle is absent. The nail plate may show superficial abnormalities and green discoloration due to *Pseudomonas* invasion.

▲ **FIGURE 87-13** Proximal subungual onychomycosis due to *Aspergillus niger*. Note severe periungual inflammation.

Onycholysis

Idiopathic onycholysis usually affects the fingernails of women and is a consequence of mechanical and chemical damage of the onychodermal band (Table 87-9). The detached nail plate is white due to the presence of air and frequently presents areas of green-brown discoloration due to bacterial colonization. The use of sharp tools to clean the nail plate free margin produces roller coaster onycholysis (manicure onycholysis). Traumatic onycholysis of the fingernails is usually occupational and is more commonly observed in butchers, slaughterhouse workers, chicken processing workers, and workers lifting heavy bags. Traumatic onycholysis of the toenails most frequently affects the big toe, often bilaterally. It is usually a consequence of anatomic abnormalities

▲ **FIGURE 87-14** White superficial onychomycosis due to *Aspergillus flavus* with diffuse and deep nail plate invasion.

CHRONIC PARONYCHIA AT A GLANCE

- Occurs most commonly in food handlers and housecleaners.
- Associated with mechanical or chemical cuticle damage.
- Characterized by eczematous inflammation of the proximal nail fold and matrix.
- Secondary colonization by bacteria and yeasts usually occurs.
- First, second, and third digits of the dominant hand are most often affected.
- Management includes protective measures, topical and/or systemic steroids, and topical antimicrobials.
- Systemic antifungals are not effective.

TABLE 87-8

  - Peripheral vascular diseases
  - Peripheral neuropathies
  - Nutritional deficiencies

IDIOPATHIC ONYCHOLYSIS AT A GLANCE

- Occurs in homemakers and those in certain occupations.
- Caused by mechanical or chemical damage.
- Follows asymptomatic and slowly progressive nail plate detachment.
- Management includes taking protective measures, trimming the onycholytic nail plate, and applying topical antiseptics.

(overlapping of the second toe on the first toe) or poorly fitting shoes. Subungual hematoma is frequently associated. Secondary onycholysis is seen in several dermatologic disorders. When only one nail is affected, it is important to explore the nail bed after cutting the onycholytic nail to rule out a nail tumor. Patients with idiopathic onycholysis should be instructed to keep the nail dry, trim the onycholytic nail plate, and wear cotton gloves under rubber gloves. Application of topical 4 percent thymol in chloroform solution on the exposed nail bed can accelerate cure.

NAIL TUMORS[56]

Tumors of the nail usually affect one digit and are often associated with nail plate furrows or grooves or localized onycholysis. In some situations nail pigmentation is altered.

Benign Tumors

FIBROMA/FIBROKERATOMA Fibroma/fibrokeratoma appears as a nodular or filiform growth that often has a keratotic surface. Most fibromas originate in the proximal nail fold and extend to the nail plate surface, where the tumor presents as a longitudinal furrow or groove (Fig. 87-15). Subungual lesions are uncommon. Tuberous sclerosis should be considered, especially if multiple lesions are present (see Chap. 141).

SUBUNGUAL EXOSTOSIS[57] Subungual exostosis appears as a subungual hard nodule that detaches and lifts the nail plate (Fig. 87-16). The toenails of young adults are usually affected, and a history of trauma is not unusual. Radiography confirms the diagnosis.

MYXOID CYST[58] Myxoid cyst appears as a nodule of the proximal nail fold associated with a longitudinal groove in the correspondent nail plate. Because the cyst often drains spontaneously, the shape of the groove is irregular (see Fig. 87-5). Myxoid cysts usually affect the fingernails of middle-aged women and are associated with osteoarthritis of the interphalangeal joints.

▲ **FIGURE 87-15** Fibrokeratoma of the proximal nail fold. Note the longitudinal groove of the nail plate due to matrix compression.

▲ **FIGURE 87-16** Subungual exostosis.

GLOMUS TUMOR Glomus tumor may hardly be seen, appearing as a small red patch under the nail plate and usually affecting the hand (Fig. 87-17). The minimal clinical appearance is disproportionate to the intense pain, which is usually accentuated by cold and radiates to the limb.

ONYCHOMATRICOMA[59] The clinical presentation of onychomatricoma is typical: the affected nail is thickened, whitish, and overcurved with longitudinal tunnels (hollows), which are evident at the frontal view (Fig. 87-18).

NAIL MATRIX NEVI[60,61] Nail matrix nevi appear as a band of longitudinal melanonychia and are usually diagnosed in childhood (Fig. 87-19). The color and width of the band are variable, and modification of the pigmentation with aging is common. Although the rate of progression of nail matrix nevi to melanoma is probably low, some advise excision of these lesions after puberty.

▲ **FIGURE 87-17** Glomus tumor of the nail bed, appearing as a violaceous subungual patch.

▲ **FIGURE 87-18** Onychomatricoma: nail overcurvature with white longitudinal striations corresponding to nail plate tunnels.

Malignant Tumors

SQUAMOUS CELL CARCINOMA (See Chap. 114) In situ squamous cell carcinoma (Bowen disease) usually manifests in fingernails with a lesion that clinically closely resembles a wart. Associated melanonychia or paronychia may be a diagnostic clue. Squamous cell carcinoma presents as a slowly growing subungual nodule that eventually ulcerates (Fig. 87-20) or a warty periungual growth. The underlying bone is commonly involved. Oncogenic human papillomavirus may be isolated in the lesion. Surgical excision with Mohs surgery is the best treatment for squamous cell carcinoma without bone involvement.

MELANOMA[62–64] (See Chap. 124) Nail melanoma most commonly affects the thumb or great toe and is usually an acral lentiginous melanoma. Most patients are middle-aged or elderly and dark skinned (one-third of nail melanoma occurs in African Americans, Asians, and Native Americans). Longitudinal melanonychia is the most common sign. The band is usually dark and has an irregular border. Periungual pigmentation (Hutchinson nail sign) indicates superficial spreading of the tumor. Amelanotic melanoma is often misdiagnosed as a pyogenic granuloma because it appears as a nail bed growth that first detaches the nail plate and then destroys the epithelium with erosion and bleeding (Fig. 87-21). The low survival rate of patients with nail melanoma is related mainly to the delay in diagnosis.

Although dermoscopy is helpful in evaluating nail pigmentation, because it distinguishes pigmentation due to hematoma from melanocytic pigmentation, dermoscopic criteria for distinguishing melanonychia due to melanocyte activation or nail matrix nevi are still not well defined and reliable. A pathologic study is recommended in all cases of longitudinal melanonychia showing suspicious features (Table 87-10).

▲ **FIGURE 87-19** Nail matrix nevus: melanonychia and periungual pigmentation.

▲ **FIGURE 87-20** Subungual squamous cell carcinoma: ulcerated nodule.

▲ **FIGURE 87-21** Amelanotic melanoma of the nail bed.

MELANOMA AT A GLANCE

- Involvement of nails is rare (0.7 percent to 3.5 percent of melanomas).
- Thumb or hallux is most often affected.
- Longitudinal melanonychia and Hutchinson sign are classic.
- Lesion is amelanotic in 25 percent of cases.
- Only 15 percent of patients survive 5 years or longer.

NAIL PSORIASIS[66] (See Chap. 18)

Psoriasis can be limited to the nails and produce nail signs that mimic those of a large number of other nail disorders. Pitting is considered by dermatologists to be the typical symptom of psoriasis. Psoriatic pits are limited to the fingernails, are large, deep, and irregular (see Fig. 87-4), and represent psoriatic involvement of the proximal nail matrix.

Onycholysis, salmon patches, and subungual hyperkeratosis are additional clinical signs of nail bed psoriasis. Onycholysis is actually the most common manifestation of nail psoriasis and may affect both fingernails and toenails. In fingernails the presence of an erythematous border along the onycholytic area is diagnostic for nail psoriasis (Fig. 87-22). In toenails onycholysis is usually combined with subungual hyperkeratosis and may closely resemble onychomycosis.

TABLE 87-10
Clinical Signs That Require Histologic Evaluation of Longitudinal Melanonychia

- Periungual pigmentation
- Adult age
- Change in color/width of the band
- Hyperpigmented lines within the band
- Proximal portion of the band wider than distal
- Thumb, index finger, or toe involvement
- Blurred margins
- History of trauma (negative prognostic factor)[65]

NAIL PSORIASIS AT A GLANCE

- Present in up to 50 percent of patients with skin psoriasis and up to 83 percent of those with psoriatic arthritis.
- Isolated nail psoriasis is not rare.
- Nail matrix and nail bed are most commonly affected.
- Most often precipitated or worsened by trauma.
- Most common signs are onycholysis, salmon patches, subungual hyperkeratosis, and irregular pitting.
- Fingernails and/or toenails may be affected. Several nails are involved in most cases.
- Treatment is often unsatisfactory.

Salmon patches (oil drop sign) are also diagnostic for nail psoriasis.[67] They are seen in fingernails and appear as yellow-red areas of discoloration in the center of the nail or bordering an onycholytic area (Fig. 87-23). Rarely, nail psoriasis may produce severe nail plate abnormalities such as trachyonychia or crumbling. Other common but rather aspecific signs include splinter hemorrhages and paronychia.

Differential Diagnosis

The differential diagnosis of nail psoriasis is summarized in Box 87-1.

▲ **FIGURE 87-22** Nail psoriasis: onycholysis surrounded by an erythematous border.

▲ **FIGURE 87-23** Nail psoriasis: salmon patches of the nail bed.

Treatment

Treatment of psoriasis affecting only the nails is often unsatisfactory and should be limited to patients who experience functional impairment or severe cosmetic problems. It is important to instruct patients to avoid trauma and to refer the patient to a rheumatologist if digital pain is described.

Systemic treatments for skin and joint psoriasis are generally effective for nail psoriasis (methotrexate, cyclosporin A, biologics). Phototherapy is not effective.

Intralesional steroids (triamcinolone acetonide 2.5 to 5.0 mg/mL in saline) are the best treatment for nail matrix psoriasis limited to a few fingernails, for which they can be injected in the proximal nail fold every 4 to 8 weeks. Acitretin at low dosages (0.3 mg/kg/day) for 4 to 6 months may also be an effective option in severe nail psoriasis. In nail bed psoriasis, topical treatment with calcipotriol or tazarotene reduces subungual hyperkeratosis.[68,69]

Box 87-1

Differential Diagnosis of Nail Psoriasis

- Onycholysis
- Onychomycosis (usually associated with subungual hyperkeratosis): up to 21% of psoriatic nails have secondary onychomycosis
- Idiopathic onycholysis (fingernails): usually seen with other nail changes
- Trauma (toenails): psoriasis usually affects several nails, not just halluces
- Pitting
- Eczema: often has periungual scaling and Beau's lines
- Alopecia areata: different morphology of pits

▲ **FIGURE 87-24** Hallopeau acrodermatitis continua.

PUSTULAR PSORIASIS (See Chaps. 18 and 21)

The diagnosis of Hallopeau acrodermatitis is suggested by a clinical history of relapsing periungual and subungual pustules with onycholysis. The patient is most commonly seen when the acute episode has subsided; at this time the affected digit shows onycholysis with nail bed and periungual erythema and scaling (Fig. 87-24). Low-dose acitretin (0.3 mg/kg/day) may be useful.

LICHEN PLANUS[66] (See Chap. 26)

Nail lichen planus is serious, because it may destroy the nails. It is therefore important to diagnose and treat the disease as soon as possible. Although lichen planus often affects both the nail matrix and the nail bed, clinical suspicion should be aroused by nail matrix signs, particularly nail thinning with longitudinal ridging and fissuring. Dorsal nail pterygium formation is not common (Fig. 87-25). It results from nail matrix destruction and appears as a V-shaped extension of the skin of the proximal nail fold that adheres to the nail bed. Idiopathic atrophy of the nails is a rare variety of nail matrix lichen planus characterized by acute and progressive nail destruction leading to diffuse nail atrophy with and without pterygium. Onycholysis is quite frequent in both fingernails and toenails. Severe toenail involvement causes features that resemble yellow nail syndrome, with thickened, yellow-brown toenails.

Differential Diagnosis (Box 87-2)

In patients with brittle nails, the nail abnormalities are milder. The nails are thin and ridged, but fissuring at multiple sites

▲ **FIGURE 87-25** Nail lichen planus: dorsal nail pterygium.

is not observed. Onychoschizia is frequently associated. Trauma that produces damage to the matrix in an area wider than 3 mm causes permanent thinning and fissuring. Only one nail is usually affected, and it may show a single fissure.

NAIL LICHEN PLANUS AT A GLANCE

- Nail lichen planus is seen in approximately 10 percent of patients with skin lichen planus.
- Nail involvement is not associated with oral, skin, or scalp lesions in most cases.
- Nail matrix lichen planus produces nail thinning, with longitudinal fissuring, dorsal pterygium, and trachyonychia. Nail bed lichen planus is frequent, especially in toenails, but clinical signs are not specific.
- Several nails are involved in most cases. Scarring of the nail matrix with nail atrophy is a possible sequela.
- Diagnosis should be confirmed by nail biopsy, and systemic treatment is necessary to avoid scarring.

Box 87-2

Differential Diagnosis of Lichen Planus

LONGITUDINAL FISSURING

- Brittle nails
- Trauma (single fissure)
- Systemic amyloidosis
- Lichen striatus
- Graft-versus-host disease

PTERYGIUM

- Trauma
- Bullous diseases
- Digital ischemia
- Dyskeratosis congenita
- Graft-versus-host disease

Nail abnormalities may be the first sign of systemic amyloidosis, with nail thinning, ridging, and fissuring closely resembling mild nail matrix lichen planus. In amyloidosis, nail bed hemorrhages are common. Diagnosis depends on nail biopsy. Lichen striatus may manifest as nail thinning and fissuring limited to one or two adjacent digits. Skin changes that course from the affected nail in a linear configuration are typical. Inherited (epidermolysis bullosa) and acquired (e.g., bullous pemphigoid) bullous diseases can produce pterygium. Skin and mucosal lesions are usually present. Digital ischemia is distinguished in that the digit is cold and shows skin signs of impaired vascular skin supply.

Treatment

Nail matrix lichen planus requires oral or intramuscular treatment with systemic steroids, which induce remission of the disease in most cases. Intralesional (vs. systemic) corticosteroid injections should be considered in patients with involvement of fewer than three digits. Dorsal pterygium is not reversible and when the sole manifestation, should not be treated. Solitary nail lichen planus presenting as trachyonychia does not lead to nail scarring and therefore does not necessarily require treatment.

PARAKERATOSIS PUSTULOSA

Parakeratosis pustulosa is a rather common condition that occurs only in children. The disease is limited to one nail in most cases (usually the thumb or index finger) with a clinical picture that closely resembles that of psoriasis (Fig. 87-26). Characteristics are distal onycholysis, fingertip desquamation, and mild subungual hyperkeratosis. Spontaneous regression usually occurs after puberty.

▲ **FIGURE 87-26** Parakeratosis pustulosa: psoriasiform nail changes limited to one digit in a child.

TRACHYONYCHIA (TWENTY-NAIL DYSTROPHY)

Trachyonychia (twenty-nail dystrophy) is a nail sign that can be caused by several inflammatory disorders that produce a mild disturbance of nail matrix keratinization. These include alopecia areata, psoriasis, lichen planus, and eczema. The nail is rough and opaque due to excessive longitudinal ridging. The disease occurs most commonly in children. Trachyonychia does not produce nail scarring, even in cases due to lichen planus.

TRACHYONYCHIA (TWENTY-NAIL DYSTROPHY) AT A GLANCE

- Idiopathic but likely reflects alopecia areata, psoriasis, dermatitis, or lichen planus of the nail. More common in children.
- Characterized by nail roughness due to excessive longitudinal ridging (sandpaper nails).
- Several nails are involved in most cases; involvement of 20 nails is not necessary for diagnosis.
- Nail changes often regress spontaneously.
- Treatment is not required.

▲ **FIGURE 87-27** Nails in Darier disease.

DARIER DISEASE[1] (See Chap. 49)

The nail abnormalities noted in Darier disease are diagnostic but are not seen in all patients (Fig. 87-27). Key features are longitudinal erythronychia, longitudinal leukonychia associated with distal nail plate nicking (V shaped), and subungual hyperkeratotic papules.

ALOPECIA AREATA (See Chap. 86)

Nail involvement is seen in approximately 20 percent of adults and 50 percent of children with alopecia areata and is most common in male patients with severe involvement. Geometric pitting is most typical (Fig. 87-28). Pits are small, superficial, and regularly distributed in a geometric pattern along longitudinal and transverse lines. Trachyonychia is quite common in children affected by alopecia totalis or universalis. Nail abnormalities may improve with systemic steroid treatment or spontaneously; they respond poorly to application of topical medications.

▲ **FIGURE 87-28** Alopecia areata: geometric pitting.

ATOPIC DERMATITIS (See Chap. 14)

Nail abnormalities associated with atopic dermatitis are non-specific in most cases. Manifestations are most commonly Beau's lines, irregular pitting, and chronic paronychia. The condition is often mistaken for candidal onychomycosis. Onycholysis and subungual hyperkeratosis are seen in severe cases, especially those triggered by occupational exposure.

YELLOW NAIL SYNDROME

Yellow nail syndrome may or may not be associated with a systemic disorder and is occasionally familial.[70,71] However, it is important to refer patients to a pneumologist to exclude respiratory tract involvement. Other conditions that may be associated with yellow nail syndrome include rheumatoid arthritis and internal malignancies. The history is the most important clue to diagnosis, because patients always claim that their nails have stopped growing.

The nail changes may benefit from treatment with high oral dosages of vitamin E. Spontaneous improvement is possible. Topical vitamin E and systemic antifungal medications (itraconazole, fluconazole) do not appear to be effective.[70–72]

YELLOW NAIL SYNDROME AT A GLANCE

- In the typical syndrome, nail changes are associated with respiratory disorders and lymphedema.
- Arrested nail growth is diagnostic.
- Nails are overcurved and thickened, the cuticle is absent, and nail color varies from pale yellow to green. Onycholysis is often associated.
- Most or all nails are usually involved.

NAIL SIGNS OF SYSTEMIC DISEASES (Table 87-11)

In systemic diseases, nail manifestations usually involve most or all nails. The diagnosis is suggested by clinical history, morphology, and distribution of the nail abnormalities.

Beau's lines located at the same level in all digits or onychomadesis occurring simultaneously in all digits is strongly diagnostic for nail matrix damage from a systemic cause. Examination and capillaroscopy of the proximal nail fold are very important for the diagnosis of connective tissue diseases (Fig. 87-29). Patients with scleroderma and dermatomyositis show enlarged capillary loops with reduced capillary density and avascular areas (see Fig. 87-29). In systemic lupus erythematous periungual erythema and telangiectasia are typical; although periungual vessels can be tortuous, the capillary density tends to be normal. Cuticular hyperkeratosis and hemorrhages are seen in systemic lupus erythematous and dermatomyositis. Pterygium inversus unguium is typical of scleroderma; in this condition the nail plate adheres to the fingertip skin, which makes nail trimming very painful. The diagnosis of systemic amyloidosis can be suggested by nail involvement, which sometimes precedes skin and mucosal changes. The nails are thinned, longitudinally fissured, and show subungual hemorrhages. Mild leukonychia is often seen in normal individuals and therefore does not represent a specific sign of systemic disorders. Clinical patterns include half-and-half nails (leukonychia affects the proximal half of the nail bed), Terry's nails (leukonychia affects the entire nail bed except for its 2-mm distal margin), and Muehrcke's lines (narrow paired transverse bands parallel to the lunula) (Fig. 87-30). Clubbing may or not be associated with cyanosis (Table 87-12). In clubbing the angle between the proximal nail fold and nail plate is greater

TABLE 87-11
Nail Signs of Systemic Disease

Beau's lines/onychomadesis	See Table 87-2

[c]Associated with hypertrophic osteopathy.

than 180 degrees (Fig. 87-31). The digit has a bulbous appearance, and the nail plate is enlarged and excessively curved. Melanonychia can be associated with a variety of systemic disorders and conditions, particularly human immunodeficiency virus infection, adrenal disease, pregnancy, and certain drugs (Fig. 87-32 and Table 87-13).

DRUG-INDUCED NAIL ABNORMALITIES[73]

A few nail abnormalities are highly likely to have resulted from administration of medication (see Table 87-13). Pyogenic granulomas involving several nails are an occasional side effect of treatment with retinoids, indinavir (Fig. 87-33), and anti–epidermal growth factor receptor chemotherapeutic agents, often leading to drug discontinuation. Retinoids have also been associated with nail fragility and paronychia. Taxanes (docetaxel and paclitaxel) frequently induce painful onycholysis with subungual hemorrhage and abscess formation. The nail lesions resemble a subungual infection and are reversible after drug discontinuation. Both β blockers and bleomycin may lead to digital ischemia. Therapy with psoralen plus ultraviolet A light has been associated with photo-onycholysis and with melanonychia. Photo-onycholysis is a rare phototoxic condition observed after intake of tetracycline derivatives, psoralens, and fluoroquinolones and subsequent exposure to sunlight or ultraviolet A light. It may be associated with a photosensitivity reaction in the skin and typically affects the central part of the nail plate of one or more fingernails. Onycholysis is painful and often hemorrhagic. Thumbnails are often spared.[74]

▲ **FIGURE 87-29** Proximal nail fold capillaroscopy in dermatomyositis: avascular areas and enlarged capillary loops.

▲ **FIGURE 87-30** Muehrcke's lines.

TRAUMATIC NAIL DISORDERS

Nail Biting

Nail biting is common in children and may encourage spreading of subungual warts.

When nail biting is associated with picking and chewing of the cuticle and periungual skin, the nail plate often shows superficial abnormalities and melanonychia due to melanocyte activation.

Habit Tic Deformity (Onychodystrophia Mediana Canaliformis)

In habit tic deformity the thumb shows a central longitudinal furrow with multiple transverse parallel lines (Fig. 87-34). The nail deformity is due to the nervous tic of pushing back the cuticle and the proximal nail fold of the thumb with the index finger.

▲ **FIGURE 87-31** Clubbing.

▲ **FIGURE 87-32** Longitudinal melanonychia involving several nails in a patient undergoing polychemotherapy.

Subungual Hematoma

Subungual hematoma may be caused by a single acute trauma or by repeated microtraumas (see Chap. 98). Nail hematomas last several months because part of the blood is incorporated into the nail plate. Very dark lesions require differentiation from melanic pigmentation. Dermoscopy shows rounded red-black globules.[63,64] Acute hematomas require immediate drainage to avoid matrix compression.

Onycholysis

Traumatic onycholysis of the great toenails is frequent in athletes, in women wearing high-heeled shoes, and in individuals with podiatric abnormalities. Nail detachment is not associated with nail bed hyperkeratosis.

  - Paronychia

▲ **FIGURE 87-33** Multiple pyogenic granulomas in a patient treated with indinavir.

Onychogryphosis

Onychogryphosis is common in the elderly and neglected individuals (Fig. 87-35). The nail is thickened, distorted, opaque, and yellow-brown, and tends to have an oyster shell appearance.

Pincer Nails

Pincer nails is a painful abnormality that usually affects the toenails and may be associated with subungual exostosis. The distal nail plate is overcurved and compresses the subungual soft tissues.

Ingrowing Toenails

Ingrowing toenails most commonly affect young adults with congenital malalignment of the great toenails. Improper nail cutting may lead to embedding of a nail edge, causing inflammation and granulation tissue formation. Hyperhidrosis is frequently associated. The aim of treatment for ingrowing toenails is to extract the nail edge that is ingrowing and prevent further penetration of nail fragments into the lateral folds. To accomplish this, the lateral nail plate can be lifted by using a cotton pack or by inserting a gutter splint along the lateral nail margin.[75] The width of the nail plate can also be reduced by surgical or chemical (phenolization) removal of the lateral nail matrix.[76]

▲ **FIGURE 87-34** Longitudinal furrow of the nail plate due to habit tic.

SECTION 16

DISORDERS DUE TO ULTRAVIOLET RADIATION

CHAPTER 88

Fundamentals of Cutaneous Photobiology and Photoimmunology

Irene E. Kochevar
Charles R. Taylor
Jean Krutmann

Knowledge of the interaction of sunlight with the skin is fundamental to understanding the pathogenesis, diagnosis, and treatment of more than 100 cutaneous disorders. Whenever ultraviolet (UV) or visible radiation is used to diagnose or treat a skin condition, important principles of photophysics involving absorption and emission of light underlie the success of the therapy. Sunscreen recommendations rely on an understanding of solar UV radiation and the ways in which the causative wavelengths can be minimized. Skin cancer is an epidemic clinical problem, whose pathophysiology necessitates comprehension of the photophysical, photochemical, and photobiologic events described in this chapter.

Almost every ancient civilization worshipped a god of the sun whose healing powers were believed to be broad reaching. Even today, sun exposure is widely felt to induce a sense of well-being. In addition, sunlight is important for the synthesis of vitamin D_3 and the setting of internal clocks. On the negative side, sunlight causes deleterious acute and chronic inflammatory skin reactions, skin cancer, and photoaging, and can elicit adverse reactions to certain drugs (see Chaps. 89, 90, 91). Although the sun is a major source of the UV and visible radiation that interacts with human skin, UV and/or visible radiation are also emitted from common sources such as fluorescent lights, incandescent bulbs, photocopy machines, and phototherapy lamps. Tanning salons are another familiar example. Dentists use UV for hardening of acrylates, as do nail salon estheticians. Thus, UV and visible radiation are a constant part of the human environment and play a role in health, disease, and therapy. Photodermatology is the study of this interaction between human skin and UV and visible radiation. To understand the responses of skin to UV and visible radiation, it is essential to be acquainted with the principles governing the interaction of these wavebands with biomolecules in the skin.

When UV and visible light photons reach the skin surface, a series of steps must occur to transform the energy of the radiation to an observable response as shown schematically in Fig. 88-1. First, the radiation must penetrate to the appropriate level in the skin where it is absorbed by molecules in the skin, termed *chromophores*. Photochemical reactions then convert the chromophores into new molecules, the photoproducts. These photoproduct molecules stimulate cellular signal transduction pathways leading to biochemical changes that culminate in cellular effects, such as the proliferation, secretion of cytokines, and apoptosis that are observed as acute skin responses. For example, in the case of the patient who has ingested tetracycline and is then sun exposed, one might see exaggerated sunburn as a classic example of a phototoxic reaction. A similar series of steps are also responsible for responses to chronic exposure to UV radiation such as actinic keratoses and wrinkles (photoaging).

▲ **FIGURE 88-1** Generalized steps from ultraviolet (UV) and visible radiation hitting the skin to observation of clinical responses.

ULTRAVIOLET AND VISIBLE RADIATION

UV radiation and visible light are portions of the electromagnetic (EM) spectrum, which includes a wide range of wavelengths, from high-energy x-rays to low-energy microwaves and radiowaves (Table 88-1; Fig. 88-2). The short-

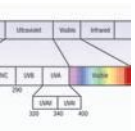
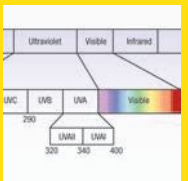
FUNDAMENTALS OF CUTANEOUS PHOTOBIOLOGY AND PHOTOIMMUNOLOGY AT A GLANCE





- When radiation enters the skin, it is scattered or absorbed. Only light absorbed by molecules (chromophores) in the skin can cause a photobiologic response.
- Electromagnetic radiation can be conceptualized either as a wave or as packets of energy called *photons*.
- The energy in a photon is inversely proportional to the wavelength of radiation.
- Irradiance (W/cm^2) × Time (seconds) = Exposure dose or Fluence (J/cm^2)
- The action spectrum indicates which wavelengths produce a photobiologic response most effectively and is plotted as the reciprocal of the minimum effective fluence versus wavelength.
- After absorbing energy of a photon the chromophore is in an "excited state."
- During a photochemical reaction of an excited state molecule, the chromophore is transformed into a stable "photoproduct."
- When certain drugs absorb ultraviolet (UV)/visible light, inflammation ensures. This is called *photosensitization*.
- Photosensitivity responses are usually mediated by reactive oxygen species.
- UV radiation is immunosuppressive. Local and systemic immunosuppression are recognized.
- Pyrimidine dimers, reactive oxygen species and urocanic acid are involved in UV-induced immunosuppression.
- Other molecules are interleukin 10, tumor necrosis factor-α, platelet-activating factor, and platelet-activating factor–like lipids.
- The major cellular players in UV immunosuppression are Langerhans cells, keratinocytes, macrophages, and T cells.
- UV radiation impairs T helper 1–mediated cellular immune response.

TABLE 88-1
Electromagnetic Radiation According to Wavelength

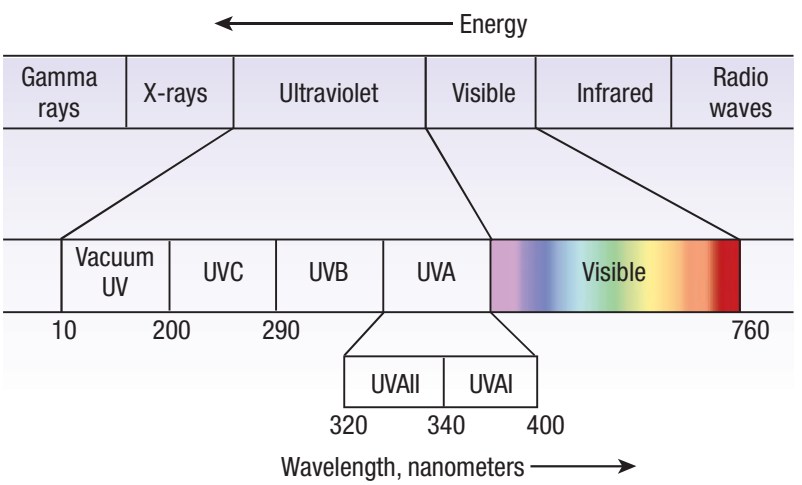
WAVEBAND	WAVELENGTH RANGE (NM)
X-ray	0.1–10
Vacuum ultraviolet	10–200
Ultraviolet C	200–290
Ultraviolet B	290–320
Ultraviolet A (UVA)	320–400
UVAI	340–400
UVAII	320–340
Visible	400–760
Violet	400
Blue	470
Green	530
Yellow	600
Red	700
Near infrared	760–1000
Far infrared	1000–100,000
Microwaves and radiowaves	$> 10^6$

est wavelengths are associated with the highest energy radiation and the longest wavelengths with the lowest energy radiation. The UV waveband is of special interest because dozens of skin disorders are aggravated by these wavelengths and many popular therapies, such as UVB phototherapy (see Chap. 238) and psoralen and ultraviolet A light (PUVA) photochemotherapy (see Chap. 239), use sources emitting UV radiation. Visible light encompasses those wavelengths perceived as color by the human eye and is also frequently used in therapies, such as blue-light aminolevulinic acid–photodynamic therapy (PDT; see Chap. 239), and is emitted by several lasers intended to target pigmented (colored) targets within the skin (e.g., pulsed dye and Q-switched ruby) (see Chap. 240).

Ultraviolet Radiation

For medical photobiology, the UV range (200 to 400 nm) is subdivided into UVA, UVB, and UVC (see Table 88-1 and Fig. 88-2). A division was made at 290 nm because wavelengths from the sun shorter than 290 nm are absorbed by ozone in the stratosphere and do not reach the earth's surface at sea level. Wavelengths in the range of 200 to 290 nm are referred to as *UVC* or *germicidal radiation*. These wavelengths are strongly absorbed by DNA and therefore can be lethal to viable cells of the epidermis or to bacteria. UVC lamps emit at 254 nm and are used for air and water purification. Care must be taken to avoid exposure of eyes and skin to UVC radiation because of the danger of UV keratitis and mutation.

The range 290 to 320 nm is known as UVB and is often referred to as *mid-UV* or *sunburn spectrum*. It includes the biologically most active wavelengths reaching the earth's surface. Also, ordinary window glass transmits only longer wavelengths. Most sunscreens efficiently reflect or absorb these wavelengths, and the sun protection factor (SPF) is based on testing against this waveband. However, it is important to note that different wavelengths within these subdivisions can elicit greatly varying biologic responses. For example, consider the response of skin to two wavelengths in the UVB range, 297 and 313 nm. Radiation at 297 nm is nearly 100 times more erythemogenic than 313-nm radiation[1] and more effectively causes DNA damage and photocarcino-



▲ **FIGURE 88-2** Electromagnetic spectrum divided into major wavelength regions. The lower band emphasizes the ultraviolet (UV) and visible bands that are important for photobiologic responses in human skin.

genesis.[2] An example relevant to phototherapy is that narrowband UVB (312 nm) and excimer laser (308 nm) are used to treat psoriasis because these wavelengths are more effective than other portions of the UVB spectrum.[3,4] UVB constitutes only approximately 5.0 percent of the UV and 0.5 percent of total radiation reaching the earth's surface; the exact amount varies markedly with the time of day, season, cloud conditions, and other factors.

Long-wave UV or UVA (320 to 400 nm) is sometimes referred to as *black light* because it is not visible to the human eye but causes certain substances to emit visible fluorescence. Approximately 95 percent of the UV radiation reaching the earth's surface is UVA. As described for UVB radiation, the response of skin to UVA is not constant across all wavelengths from 320 to 400 nm.[3] In fact, UVA has been divided into UVA I (340 to 400 nm) and UVA II (320 to 340 nm) because the latter band is more damaging to unsensitized skin than the longer wavelengths. Although most sunscreens offer their greatest protection against UVB wavelengths, those products said to be "broad-spectrum" indeed have considerable ability to protect against UVA wavelengths, although no formal measure equivalent to the SPF rating yet exists. Generally, the higher the SPF, for example, 45 or greater, the more likely one is going to find some UVA protection inherent in that preparation. Newer sunscreen agents enhance protection against damaging UVA rays (see Chap. 223). Because approximately 95 percent of the UV radiation reaching the earth's surface is UVA, protection against this waveband is quite important for minimizing adverse cutaneous effects such as photoaging and carcinogenesis.

Visible Radiation

The visible spectrum (400 and 760 nm) is defined by the wavelengths that are perceived as color by the retina. Some people can see wavelengths slightly shorter than 400 nm and others wavelengths longer than 760 nm. Specific colors are associated with different wavelengths, as shown in Fig. 88-2. Skin responses to visible light generally require photosensitization. For example, in PDT, a dye absorbing long wavelength visible light (red) is used and for aminolevulinic acid PDT, a prodrug is applied that is converted into a blue-absorbing protoporphyrin IX (see Chap. 239). Intense pulsed light sources, usually lasers, are used to treat vascular, pigmented and other lesions without application of a photosensitizing dye (see Chap. 240).

Other Wavebands of Electromagnetic Radiation

X-rays and γ rays occupy the short wavelength (high energy) end of the EM spectrum, and infrared radiation is found at longer wavelengths (lower energy) than visible radiation (see Table 88-1). X-ray and γ ray radiations ionize molecules (remove electrons) indiscriminately and are known as *ionizing radiation*, the subject of radiobiology (see Chap. 95). In radiation therapy of tumors, these wavelengths kill tumor cells by ionizing water molecules and producing free radicals that damage DNA. Infrared radiation (IR) has lower energy than visible light.[5,6] It is subdivided into IR-A (760–1440 nm), IR-B (1440–3000 nm), and IR-C (3000 nm–1 mm). In contrast to IR-B and IR-C, IR-A penetrates into the dermis and exerts biological effects. IR-B and IR-C are felt as heat. Recent studies suggest that IR-A wavelengths can damage skin, but might also be therapeutically useful although for both effects the mechanisms are still unclear.[5,6]

PROPERTIES OF ELECTROMAGNETIC RADIATION

Certain principles are better illustrated by conceptualizing EM radiation as waves, whereas others are better understood by thinking of it as packets of energy called *photons*. These two descriptions are complementary.

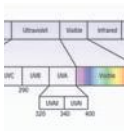
Waves consist of periodic motion or oscillations that travel through a medium. When the motion is perpendicular to the direction of propagation, such as waves traveling down a length of rope, the waves are called *transverse waves*. EM radiation considered as a wave consists of oscillating electric and magnetic fields at right angles to each other and to the direction of propagation. Consequently, it may be described either by its frequency (number of oscillations per second) or by its wavelength (distance traveled per oscillation). Because all EM radiation propagates at the same velocity through space, frequency and wavelength have an inverse relationship, which is expressed as: $\nu = c/\lambda$, where ν = frequency of oscillations per second, c = velocity of radiation (the speed of light, 3×10^8 m/s), and λ = wavelength in meters. When light is considered as a wave, specific colors of UV and visible radiation are associated with specific wavelengths of the EM spectrum. For example, red light is associated with wavelengths around 700 nm, whereas blue light is associated with wavelengths around 470 nm (see Table 88-1).

In addition to its wave character, EM radiation may be described as a stream of discrete packets of energy known as *quanta* or *photons*. The amount of energy in a photon (quantum) is directly proportional to the frequency of the radiation and inversely proportional to the wavelength of radiation, as expressed by Planck's law: $E = h\nu = hc/\lambda$, where E = the energy of the photon in joules (J), h = Planck's constant (6.626×10^{-34} J/s), ν = frequency of oscillations per second, c = velocity of radiation (3×10^8 m/s), and λ = wavelength in meters. This relationship shows that the energy of the photon increases when the wavelength is shorter and decreases when the wavelength is longer. In other words, radiation of shorter wavelength has greater energy per photon. For example, a 300-nm photon has twice the energy of a 600-nm photon. Because they have lower energy, photons associated with wavelengths longer than the visible range usually do not cause photochemical reactions.

SOURCES OF ULTRAVIOLET AND VISIBLE RADIATION

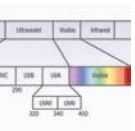
Sunlight

The shortest wavelength of the solar spectrum reaching the earth's surface at sea level is approximately 290 nm, although slightly shorter wavelengths have been detected at high altitudes.[7] The shorter UV wavelengths emitted by the sun are filtered out by the ozone layer and molecular oxygen of the stratosphere. Depending on the geographic location and the season, it has been estimated that sunlight produces between 2 and 6 mW/cm^2 of UV radiation between 290 and 400 nm. Filtering of wavelengths less than 290 nm by ozone is a very important process because the shorter UVC wavelengths are highly damaging to animals and plants. Ozone present in the stratosphere is constantly being generated and degraded. Because the transmission of solar UVC and UVB through the atmosphere varies exponentially with ozone concentration, small changes in the ozone layer may result in hazardous increases in UV irradiance at the earth's surface.[8] For example, calcula-



tions of the effects of ozone depletion predict a doubling of skin cancer incidence by 2100 even if the Montreal Protocol restrictions on ozone-depleting substances are followed.[9]

The UV Index developed by the National Weather Service and the U.S. Environmental Protection Agency represents an attempt to quantify the risks attendant with solar radiation at a given time and place. Among other factors, the effects of altitude, latitude, season, and clouds are considered. The scale goes up to 15, and any UV Index greater than 10 is considered a high-risk day for possible overexposure in that locale.



Artificial Sources of Ultraviolet and Visible Radiation

Skin is exposed to UV and visible radiation from a wide variety of sources in daily life and from a different set of light sources for therapy and diagnosis. The following is a general discussion of UV and visible light sources. Specific information should be obtained from the manufacturer before using a new light source.

INCANDESCENT SOURCES Incandescent light sources include electric lightbulbs, flood lamps, and some quartz iodide bulbs. In these lamps, an electric current passing through a metal filament heats the filament, causing it to emit EM radiation. Most of the radiation emitted is in the visible and infrared spectrum. Only the occasional patient with solar urticaria, chronic actinic dermatitis, or some porphyrias is bothered by the output of ordinary incandescent sources. Wavelengths shorter than 360 nm are usually not emitted because the hot filaments are encased in glass envelopes that transmit only UVA and visible radiation. Tungsten-halogen incandescent lamps, often used as flood lamps, emit UVA and visible radiation. Some quartz iodide incandescent lamps produce significant UVA and some UVB emission.

ARC SOURCES Arc sources include xenon lamps, medium- and high-pressure mercury (hot quartz) lamps, fluorescent lamps, and halide lamps. In arc lamps, electrons are driven through a gas by a potential difference between two electrodes. The gaseous molecules between the electrodes are ionized and subsequently release EM radiation. Radiation is emitted preferentially at specific wavelengths (emission lines) as well as in a continuum of wavelengths. The wavelengths and relative power at each wavelength depend on the gas used, the arc temperature, the pressure within the lamp, and the lamp wall material.

Xenon arc lamps emit both UV and visible radiation and are now the most common sources used in solar simulators. Photoprovocation testing for polymorphic eruption is often done with such sources. Filters are used to limit the wavelengths for phototesting with solar simulators. Xenon arcs are also used in some phototherapy and photobiologic research applications. In a xenon lamp, xenon gas under 20 to 40 atmospheres (atm) of pressure is heated to a high temperature in a rigid quartz envelope to produce intense visible and UV radiation. At these pressures, the xenon spectrum becomes a continuum—that is, all wavelengths are emitted rather than just specific wavelengths.

The wavelengths emitted by mercury arc lamps are strongly influenced by the pressure of the gas within the envelope. Low-pressure mercury germicidal lamps emit 85 percent of the radiant energy at 254 nm. Because the operating temperature is low, they are also known as *cold quartz lamps*. With increasing pressure (1 atm), the primary 254-nm emission is absorbed by other mercury atoms within the lamp and re-emitted at longer wavelengths (297, 302, 313, 334, and 365 nm, and visible wavelengths). With further pressure increases (2 to 100 atm), these spectral lines broaden and decrease relative to the intensity of the continuous spectral background. In medical practice, medium- and high-pressure mercury (hot quartz) lamps are generally used as sources of UVB, although their spectral power distribution is mainly in the UVA and visible range.

The commonly used UVB sunlamps (see Chap. 238) and UVA lamps for PUVA therapy (see Chap. 239) are fluorescent lamps. They are, in essence, modified low-pressure mercury arc lamps consisting of a glass tube containing the mercury gas with electrodes at both ends. The inner surface of the glass tube is coated with a phosphor, which absorbs the 254-nm radiation and re-emits the energy at longer wavelengths. The chemical composition of the phosphor determines which wavelengths are re-emitted. In general, fluorescent lamps have a relatively wide, bell-shaped emission spectra, with spectral emission lines of mercury superimposed, and are referred to as *broadband light sources*.

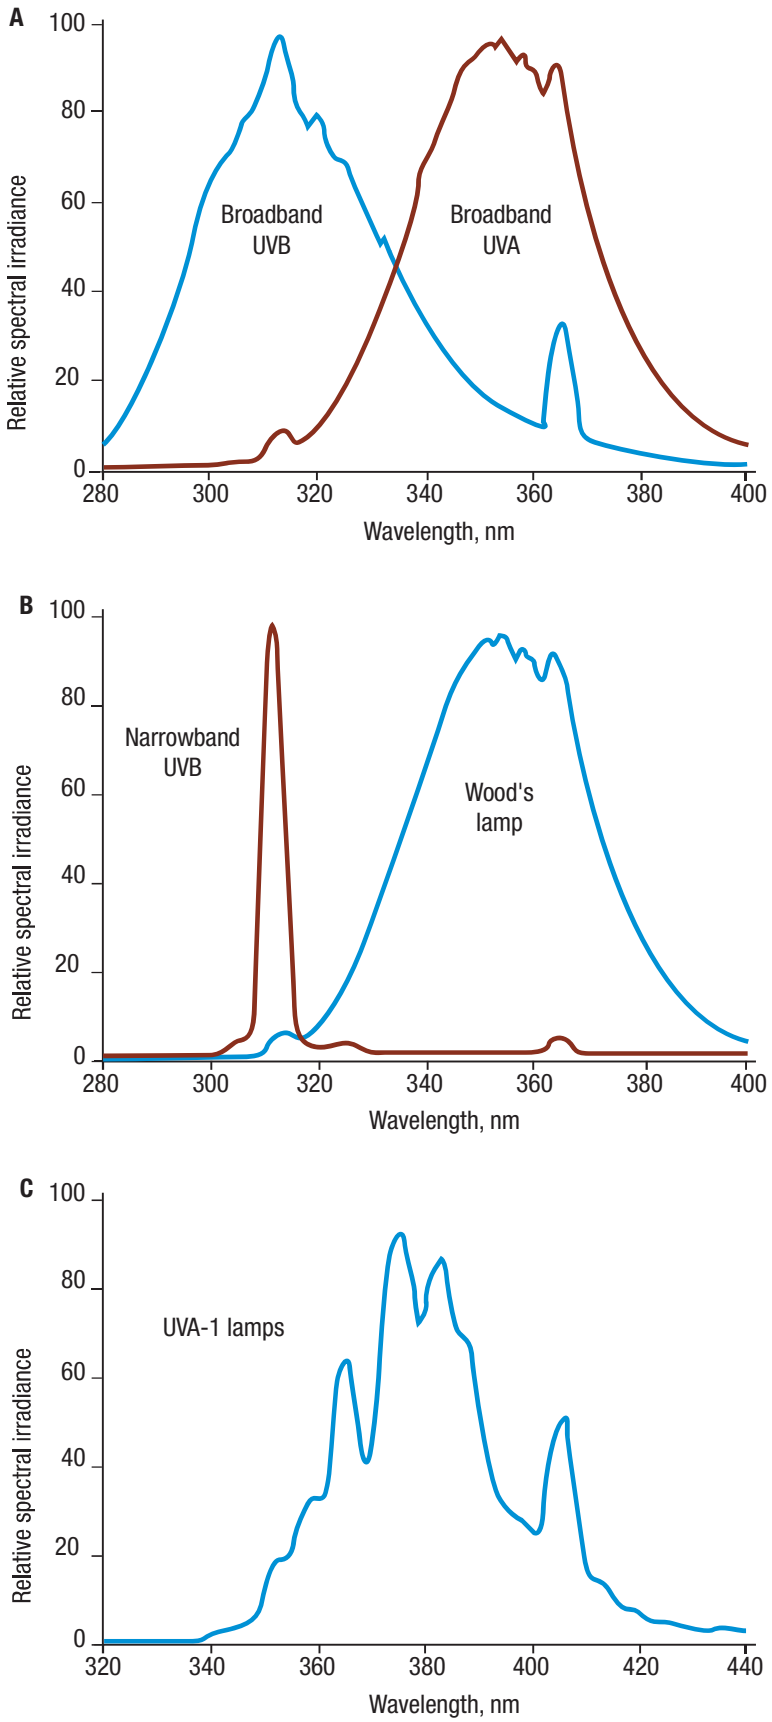
Fluorescent sunlamps (type FS) emit mainly in the UVB range (Fig. 88-3). They are often referred to as *UVB lamps*, even though they emit a portion of UVA radiation, because the therapeutically significant radiation is in the UVB range (Table 88-2). A fluorescent lamp with a major emission peak at 311 nm (Philips TL01) was developed for use in phototherapy (see Fig. 88-3).[10,11] This lamp is an efficient source for psoriasis phototherapy because, compared to a conventional UVB lamp, the energy emitted almost entirely overlaps with the action spectrum for clearance of psoriasis.[3] Interestingly, this lamp has also been successfully used for the treatment of vitiligo, atopic dermatitis, and polymorphic light eruption, all of whose action spectra are unknown and may possibly differ from that for psoriasis.

High-intensity, UVA-emitting fluorescent lamps are most often used in PUVA therapy of psoriasis, vitiligo, and other skin diseases. The most efficient UVA source for PUVA therapy would maximize the emission of 320- to 360-nm radiation for photoactivation of psoralen molecules, while minimizing the UVB emission. Table 88-2 shows the percentage of total emission that is in the 320- to 360-nm range from several UVA-emitting light sources that are used in phototherapy units.

Wood's lamps are small, low-pressure, UVA-emitting fluorescent lamps with a UVA-transmitting, visible-absorbing glass envelope. They are useful in clinical practice because, after UVA absorption, the fluorescent emission from normal and abnormal components of skin, hair, teeth, and urine may be diagnostic (e.g., in porphyria, vitiligo, and fungal infection).

Halide lamps emit a high-intensity continuum in the UVB and especially the UVA range. With appropriate filters, this lamp is used increasingly as a UVB, as well as a UVA, source for phototherapy (in particular, UVA1 therapy) and photochemotherapy. The metal halide lamp usually consists of a high-pressure mercury lamp with metal halides as additives. The continuous range of wavelengths emitted from halide lamps differentiates them from medium-pressure mercury arc lamps that emit in narrow wavelength ranges. Approximately 20 percent of the emission spectrum can be UVA radiation.

LASERS (see Chap. 240) Laser is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. Lasers produce intense beams of monochromatic radiation. The laser operates by exciting



▲ **FIGURE 88-3** Emission spectra of some of the fluorescent lamps used in phototherapy. **A.** Broadband ultraviolet B (UVB) fluorescent lamps and UVA (black light) fluorescent lamps. **B.** Narrowband (Phillips TL01) fluorescent lamp with a maximum at 311 nm and a fluorescent lamp with a Wood's glass filter. **C.** UVA-1 halide lamps (Sellamed 24000 bed system). Emission spectra were measured with a Luzchem Model SPR-4001 Spectroradiometer.

TABLE 88-2
Approximate Spectral Power Distribution of Ultraviolet B (UVB) and UVA Radiation Expressed as Percentage of Total Emission in the UV Waveband in Common Phototherapy Sources

	% UVB	% UVA
Broadband UVB (Westinghouse Sunlamp)	60	40
Narrowband UVB[a] (Phillips Fluorescent UVB, TL01, 311 nm)	80	20
Broadband UVA (Houva Lite; Black Light by Sylvania, Westinghouse, and General Electric; Sylvania Puva Life Line; Dermalight Metal)	2	98
UVA-1[b] (Dermalight UltrA1, Dr. K. Hönle Medizintechnik GmbH)	0	100
Wood's light[c] (RA Fisher; Spectronics)	0	100
Halide lamps[d] (Dermalight Systems; Dr. K. Hönle Medizintechnik GmbH)	0	100

[a]Most (~95% of the UVB emission of the typical narrowband UVB source is centered around 311 nm).
[b]This UVA emission is above 340 nm.
[c]The filter used (so-called *Wood's filter*) is glass with nickel oxide phosphor. Consequently, UVB is screened. A moderate amount of visible light is produced.
[d]The actual amount depends on the model purchased and the filters used (glass vs. quartz). Some models allow the operator to change the filters readily and thus increase the amount of UVB to > 50% of the irradiance.

molecules to a metastable excited state from which photon emission is stimulated by a subsequent photon incident on the excited molecule. The emitted photon and the stimulating photon are then each capable of stimulating emission of yet other excited molecules, eventually producing an avalanche of photons of the same wavelength, phase, and direction of propagation. Lasers emit UV, visible, or infrared wavelengths and may operate as either continuous or pulsed sources. Applications of lasers in dermatology use their capacity to concentrate large amounts of energy in a small volume of tissue.

ULTRAVIOLET AND VISIBLE RADIATION DOSIMETRY

To treat patients with the appropriate amount and wavelengths of UV or visible radiation, it is important to become acquainted with how the radiation is quantified and related to the exposure

time. The basic unit of EM energy is the joule (J). Power is the rate of energy flow, joules per second (J/s). In the case of UV and visible radiation, power is the rate of radiant energy emission and is given in watts (W), with the units of J/s. The rate at which the radiant energy is delivered to a surface, such as skin, is expressed as the power delivered per unit area of surface (Power/area; W/cm^2). This quantity is called *irradiance*. The total radiant energy delivered per unit area of skin surface is called the *exposure dose* or *fluence* and is the product of irradiance and time:

$$\text{Irradiance } (W/cm^2) \times \text{Time (sec)} = \text{Exposure dose or Fluence } (J/cm^2)$$

For most responses to UV and visible radiation, it is the exposure dose at a particular wavelength that determines the magnitude of the response. The energy delivery rate of the radiation source generally does not affect the response using conventional light sources, in contrast, laser radiation effects are often influenced by the irradiance (see Chap. 240).

The irradiance delivered by a source as a function of wavelength is called the *spectral irradiance* and is expressed as units of irradiance per nanometer [(W/cm^2)/nm]. A spectroradiometer is used to measure the spectral irradiance of a light source. When measuring a light source's irradiance over a given spectral region, a detector weighted to the wavelengths of interest is most useful. For example, a broadband radiometric measurement of wavelengths less than 315 nm provides a rough indication of the erythemally effective wavelengths emitted by a source of UV radiation.

There is, however, no substitute for knowing the full spectral irradiance delivered by a source, as determined by a spectroradiometer. For example, in phototesting, only the wavelengths of interest should be used. To assess endogenous UVA sensitivity, the UVB portion of a source's emission, if present, must be filtered out so that the more erythemogenic UVB wavelengths do not lead to a falsely lower determination of erythema threshold in the UVA range. The spectroradiometer is critical in defining the full spectral output of a light source.

OPTICAL PROPERTIES OF SKIN

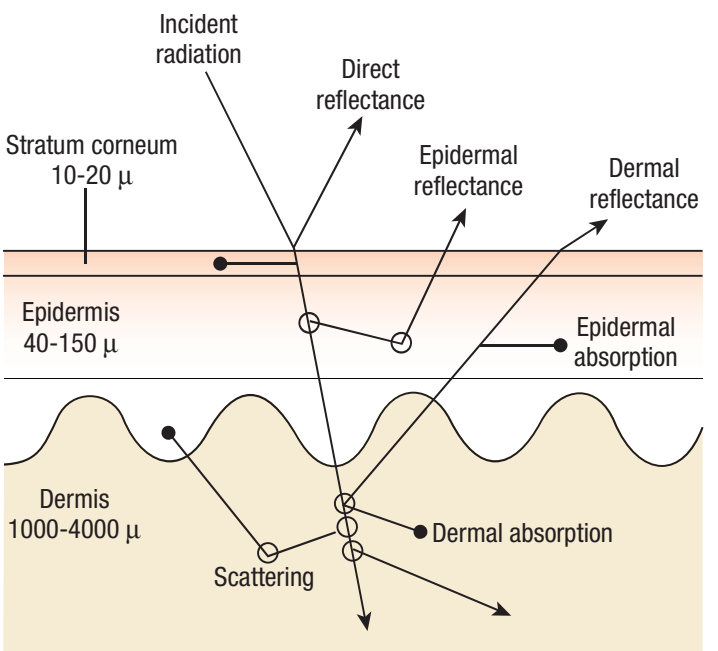
When UV and visible radiation strike the skin, part is remitted (reflected and scattered), part is absorbed by chromophores in various layers, and part is transmitted inward to successive layers of cells until the energy of the incident beam has been dissipated (Figs. 88-4 and 88-5). A very small fraction of the absorbed radiation is absorbed and then re-emitted at longer wavelengths as fluorescence. The two major processes limiting the penetration of UV and visible radiation into skin, absorption and scattering, vary with wavelength.[12]

UV wavelengths less than 320 nm are readily absorbed by proteins, DNA, and other components of epidermal cells. Along with scattering, this absorption accounts for the low penetration of these wavelengths into skin (see Fig. 88-4). For example, approximately 50 percent of 300-nm radiation and 10 percent of 350-nm radiation reaches the dermal–epidermal junction. Between 5 percent and 10 percent of incident light is reflected by the outer surface of the stratum corneum. This surface or so-called *specular reflectance* is relatively constant for all visible wavelengths and accounts for the surface appearance of skin, which is especially glossy if the surface is smooth, wet, or oily. In contrast, if the surface is irregular, the light is scattered and the skin appears dull or "rough." Moisturizers applied to the skin reduce this rough appearance by smoothing out the many air-surface interface irregularities, thus reducing specular reflectance and making the skin look shinier.

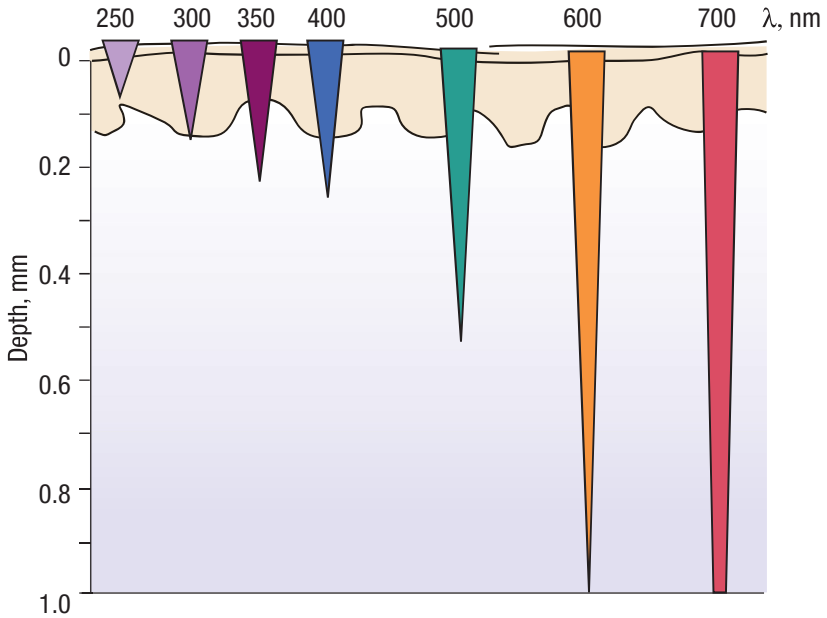
Scattering includes any process that deflects the path of optical radiation. For example, skin with scales, as in psoriasis, scatters more light than does normal skin. During phototherapy, application of emollients to the psoriatic plaques helps reduce the scattering of UVR and allows more of the effective wavelengths to penetrate into the viable tissue. In fair, white skin, the bulk of the visible remittance, approximately 50 percent of the incident radiation, is light that has penetrated the epidermis and has been scattered from various depths within the dermis back through the epidermis and skin surface.

Melanin, which absorbs relatively uniformly over the visible wavelengths and is normally present only in the epidermis, acts largely as a neutral density filter to diminish dermal remittance. Melanosomes in darker-skinned individuals are larger and singly dispersed as compared to those of fairer-skinned individuals. The greater overall melanin content in darker skin absorbs more visible light and therefore causes the skin to appear darker as there is less light reflected back to the observer.

Blood (hemoglobin) within the dermis absorbs the shorter (blue) visible wavelengths, diminishing these spectral regions of the dermal remittance component, and giving a reddish hue to our perception of the total remittance. Abnormal location and quantity of these or other pigments account for the appearance of the skin in pathologic conditions



▲ **FIGURE 88-4** The interaction of ultraviolet and visible radiation with skin. The incident radiation is reflected from the surface, scattered (*circles*), and absorbed (*black dots*) as it travels through the skin.



▲ **FIGURE 88-5** Illustration of the approximate penetration of ultraviolet and visible radiation into skin. λ = wavelength.

(e.g., melasma with extra pigment in the epidermis and/or dermis; vitiligo with an absence of epidermal melanin).

ABSORPTION OF ULTRAVIOLET AND VISIBLE RADIATION BY MOLECULES IN SKIN

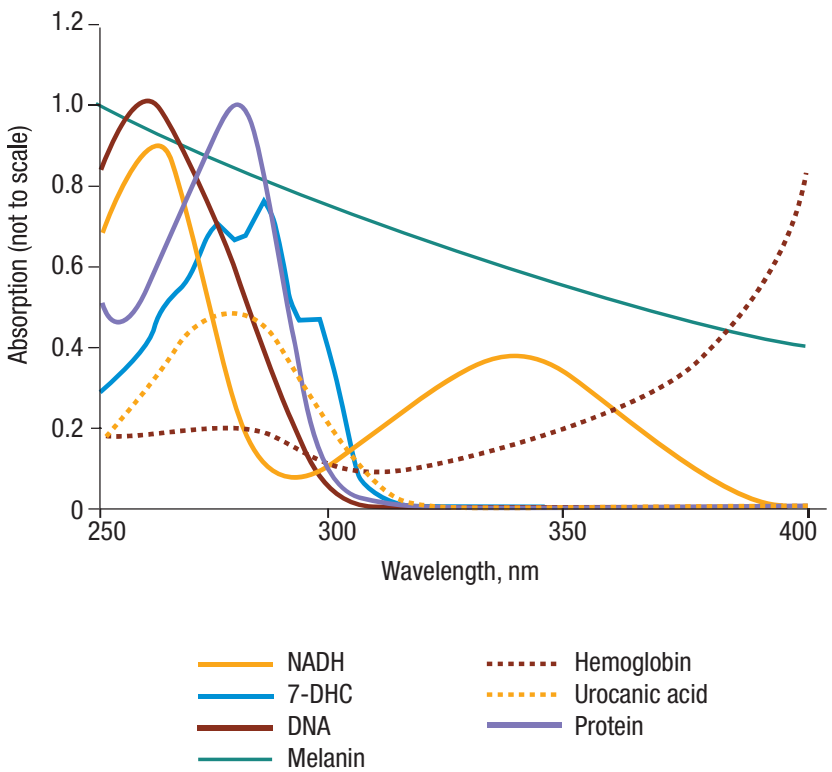
When a photon is taken up by a chromophore, it is said that absorption has occurred. After absorption, the molecule contains extra energy and may be altered to form a new molecule called a *photoproduct*. These new molecules initiate responses in skin cells. Thus, absorption is the first step in a photobiologic response.

Skin is composed mainly of water; organic molecules, such as proteins, lipids, and nucleic acids; and inorganic ions, including Na^+, Ca^{2+}, and Cl^-. The organic molecules absorb photons in the UVA, UVB, and visible spectral regions. The specific wavelengths absorbed by each molecule (called an *absorption spectrum*) are determined by the structure of the molecule (i.e., the arrangement of the electrons). Only absorbed radiation can initiate biologic responses. The first law of photochemistry, set forth by Grotthus and Draper in 1818, states that only absorbed light can cause a photochemical change.

The absorption spectrum of a compound is a plot of the probability of absorption of photons of a specific wavelength on the Y-axis against wavelength on the X-axis (Fig. 88-6). The wavelengths that have the highest probability of absorption are called *absorption maxima*, λ_{max}, and can be used to target (e.g., DNA, λ_{max} = 260 nm; porphyrins, λ_{max} = 400 to 410 nm). Many of the biomolecules that absorb in the UVB spectrum actually have absorption maxima at shorter wavelengths in the UVC range (see Fig. 88-6). These include the purine and pyrimidine bases in DNA and RNA (λ_{max} ~ 260 nm), urocanic acid (UCA; λ_{max} = 280 nm), aromatic amino acids in proteins (λ_{max} ~ 280 nm), and 7-dehydrocholesterol (λ_{max} = 285 nm). However, within skin the absorption maxima occur at longer wavelengths because these shorter wavelengths do not penetrate sufficiently. Similarly, most photosensitizing drugs have effective action spectra in the UVA range although in solution outside the body they may have absorption maxima at shorter wavelengths. Many endogenous cutaneous chromophores absorb UVA [e.g., reduced nicotinamide adenine dinucleotide phosphate (340 nm)]. Others absorb both UVA and visible radiation, including hemoglobin (λ_{max} = 410 nm), bilirubin (λ_{max} = 450 nm), and β-carotene (λ_{max} = 460 nm). Melanin absorbs throughout the UV and visible spectrum without a distinct absorption maximum wavelength.

PHOTOCHEMICAL REACTIONS LEADING TO SKIN RESPONSES

After absorbing the energy of a photon, the chromophore is in an "excited state,"



▲ **FIGURE 88-6** Absorption spectra of cutaneous chromophores absorbing ultraviolet radiation. Note that the relative amounts of ultraviolet radiation absorbed by these chromophores in skin depends on the heights of the absorption peaks as shown in this figure, the amount of each chromophore in skin, and the penetration of each wavelength into skin. 7-DHC = 7-dihydrocholesterol, NADH = reduced nicotinamide adenine dinucleotide.

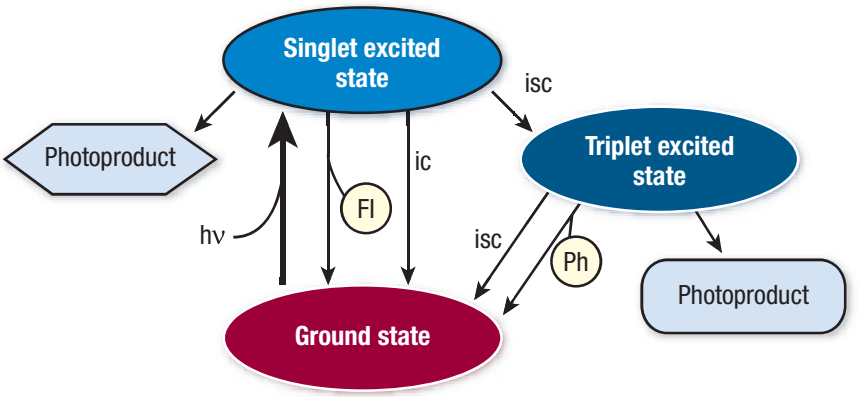
which exists for only a very short time before reacting with nearby molecules. The products of these reactions initiate signal transduction processes that lead to the observed responses in skin.

Excited State Molecules

Normally, molecules are in the so-called *ground state* and have a certain distribution of electrons in space around the nuclei of their atoms. For each molecule, a series of electronic states with higher energies and different distributions of electrons also exist; these are called *excited states*. When a molecule in the ground state absorbs the energy of a UV or visible photon, the molecule is promoted to an excited electronic state (Fig. 88-7). According to quantum mechanics, only certain energy gaps are allowed to exist between electronic states. Consequently, a molecule can absorb photons only with certain energies; this results in a unique absorption spectrum for each molecule.

A molecule exists in this first excited state formed for a very brief period. It is called a *singlet excited state* and exists for a few nanoseconds. The molecule may return to the ground state by emitting light (fluorescence) or releasing the energy as heat, a process called *internal conversion* (see Fig. 88-7). Alternatively, the singlet excited state may undergo a chemical reaction to form a photoproduct, or it may convert into another excited state with lower energy, the triplet excited state, by a process called *intersystem crossing* (see Fig. 88-7). Singlet and triplet excited states differ in the spins of a pair of electrons in an orbital. If the spins are opposite, they are called *singlet states*. If the spins are the same, they are called *triplet states*. The ground state is almost always a singlet state. The triplet excited state may exist for a longer time (i.e., a few microseconds). It may emit light (phosphorescence), undergo a chemical reaction, or return to the singlet ground state by intersystem crossing (see Fig. 88-7). Formation of photoproducts by reactions of the excited states is of greatest interest to us because the photoproducts initiate photobiologic responses.

These excited state processes are responsible for the effectiveness of light for diagnosis and therapy. For example, fluorescence occurs every time a Wood's light is used. UVA emitted from this lamp causes autofluorescence of dermal collagen fibers. To the examining physician, this fluorescence is viewed through the overlying epidermis. Thus, any epidermal lesions such as lentigines tend to have their borders accentuated by contrast because the fluorescence is observed most brightly around the lesion. The heat generated by internal conversion is responsible for the denaturation of proteins and other effects of pulsed lasers (see Chap. 240). In this case, many photons are absorbed in a small volume of tissue over a very brief time, and the excited singlet state molecules release their energy to the water in the tissue, causing a rapid increase in temperature. Other phototherapies and adverse responses to UV (i.e., drug phototoxicity and photosensitivity diseases) result from the photoreactions of the excited singlet and triplet states with cellular molecules.



▲ **FIGURE 88-7** Absorption of ultraviolet and visible radiation (hν) by molecules and the dissipation of the absorbed energy by fluorescence (Fl), internal conversion (ic), intersystem crossing (isc), phosphorescence (Ph), and photochemistry to form photoproducts.

Photoproducts

During a photochemical reaction of an excited state molecule, the chromophore may be transformed into a new, stable molecule called the *photoproduct*. Often, the photoproduct molecule is produced when the chromophore forms covalent bonds with another molecule in the cell. These reactions are termed *bimolecular*. An important example is the formation of covalent adducts between psoralen and DNA.[13] The phototherapy of diseases such as psoriasis makes use of this photochemical reaction (see Chap. 239). The mechanism for formation of psoralen-DNA photoproducts has several steps. The psoralen molecule enters the cell nucleus and intercalates between the stacked nucleic acid bases. When the skin is exposed to UVA, the psoralen molecule absorbs a photon. If the neighboring base is a pyrimidine (cytosine or thymine), the excited state psoralen may covalently bond to the base, forming a photoadduct. The photoadduct may then absorb another UVA photon and link to a pyrimidine base on the opposite DNA strand thereby cross-linking the two DNA strands. DNA-psoralen cross-links are particularly toxic to cells and are important for the phototherapeutic effect of PUVA.

Photoproducts are also important for many UVB-induced responses in skin. When a thymine or cytosine absorbs UVB, the excited state may covalently bond to an adjacent thymine or cytosine, forming a four-membered ring structure called a *cyclobutyl pyrimidine dimer* (CPD). Additional products with somewhat different structures, but still resulting from new covalent bonds, are formed and called *6-4 photoproducts*. Both of these products lead to mutations and the sites on the DNA strands where they are formed are related to sites of mutation in nonmelanoma skin cancers.[14]

7-Dehydrocholesterol is a chromophore in skin that absorbs UVB radiation (see Fig. 88-6). The excited state molecule is converted by a bond rearrangement into previtamin D_3 without requiring another molecule, an example of a unimolecular reaction. The previtamin D_3 thermally isomerizes to vitamin D_3, enters the circulation, and is ultimately hydroxylated in the liver and the kidney to form the active hormone, 1,25-dihydroxyvitamin D. In this case, UVB-induced photochemistry in the skin is beneficial to the organism.[15]

Photochemical reactions vary in efficiency. Each chromophore molecule that absorbs a photon undergoes a photochemical reaction because, as described above, several pathways are available to molecules in excited states (e.g., fluorescence, internal conversion). The term

quantum yield is used to define the likelihood that one of these processes occurs. For example, the quantum yield for forming a certain photoproduct is:

$$\text{Photoproduct Quantum Yield} = \frac{\text{Number of photoproduct molecules formed}}{\text{Number of photons absorbed}}$$

Photosensitization

When certain drugs (tetracyclines, quinolones, psoralens) and dyes absorb UV and/or visible radiation, delayed erythema or inflammation is observed (see Chap. 91). This phenomenon is called *photosensitization*, and the dyes and drugs are called *photosensitizers*. In most cases, oxygen is required for photosensitization to occur. The exception is the phototoxicity of psoralens, which does not require oxygen in the photosensitization mechanism. Molecular level studies have shown that photosensitivity responses are mediated by reactive oxygen species (ROS), which are small molecules and free radicals that rapidly oxidize cellular molecules. Examples of ROS include singlet oxygen, hydrogen peroxide, superoxide anion, hydroxyl radical, and nitric oxide. These ROS oxidize unsaturated lipids, certain amino acids in proteins (histidine, methionine, tryptophan, cysteine), and nucleic acids. The products formed initiate signal transduction processes, leading to production of inflammatory mediators such as prostaglandin E_2 (PGE_2) and cytokines [e.g., tumor necrosis factor (TNF)-α, interleukin (IL)-1β].

When a photosensitizer absorbs a UV photon of the appropriate wavelength, changes in electron energy may create a "triplet excited state." The photosensitizer can then react with ground state oxygen (O_2). The energy transfer returns the photosensitizer to its ground state while generating highly reactive singlet oxygen ($^1O_2$). Singlet oxygen is unique among the ROS because it is an excited state molecule. It has a short lifetime in cells (< 4 microseconds) because it reacts with many cellular molecules.[16] The skin photosensitization produced by PDT drugs and by protoporphyrin IX, the porphyrin that accumulates to abnormally high levels in red blood cells of patients with erythropoietic protoporphyria (EPP), involves initial formation of singlet oxygen. Oxidation of membrane lipids is believed to initiate the signal transduction processes, leading the wheal and flare response observed in EPP photosensitivity. Singlet oxygen is also involved in the phototoxicity mechanisms for some phototoxic drugs. However, the observed skin phototoxicity responses often differ from that seen in EPP photosensitivity, possibly because of the presence of the photosensitizing agents in different tissue locations (e.g., epidermis, dermis, or vasculature). The photosensitizers may also be in different locations in the cells (i.e., nucleus, mitochondria, or cell membranes), which would influence the photoproducts formed and the subsequent cutaneous effect observed. Endogenous UVA-absorbing chromophores are believed to generate singlet oxygen in keratinocytes and fibroblasts.[17,18]

Other ROS are also produced in skin cells after photon absorption by photosensitizers and endogenous chromophores.[19] For example, hydrogen peroxide and superoxide anion are produced after photosensitized and direct photon damage to mitochondria. They are also produced by redox active enzymes in keratinocytes and fibroblasts that are stimulated in cells exposed to UVB or UVA radiation.[20,21] UVA-induced responses in normal skin and in photosensitivity conditions are generally dependent on production of ROS. Recent studies suggest that some UVB-initiated responses also involve ROS.[22] Antioxidants act by quenching (i.e., chemically reacting with and removing) ROS and other free radicals before they can damage cellular molecules.

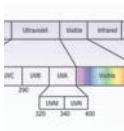
Action Spectra

The action spectrum for a photobiologic response indicates which wavelengths produce the response most effectively. Knowing the action spectrum of a patient's photosensitivity is helpful in determining the treatment plan, as phototherapy is most efficient when the emission of the lamp matches the action spectrum for the beneficial response. In an ideal case, the action spectrum corresponds to the absorption spectrum for the chromophore. Determination of an action spectrum is, therefore, a powerful tool for identification of the putative chromophore for a given photobiologic reaction. An action spectrum is most accurately plotted as the reciprocal of the number of incident photons required to produce a given effect (Y-axis) against wavelength (X-axis). Conventionally in dermatology, the reciprocal of the minimum fluence (exposure dose) is plotted versus wavelength. Such an action spectrum for wheal formation in a patient with EPP showed a maximum at 400 nm, close to the maximum of protoporphyrin IX, which supports biochemical evidence for this porphyrin as the chromophore for the photosensitivity.[23]

Lack of correspondence between an experimentally determined action spectrum and the absorption spectrum of the actual chromophore may occur due to tissue optics. Light that impinges on a tissue is usually absorbed by other chromophores in the tissue; it is also reflected and scattered (see Fig. 88-4). These effects decrease the amount of light transmitted to a specific depth in tissue and vary with wavelength. One familiar example is that of psoralen, which has absorption maxima around 295 and 330 nm, with slight absorption extending into the longer UVA waveband in vitro. However, determinations of the psoralen photosensitization action spectrum in vivo show that maximum responses occur with wavelengths greater than 320 nm, possibly due to skin optical properties.[24,25] Whenever possible, decisions about which wavelengths to use for a treatment should be based on action spectra rather than on the in vitro absorption spectrum of the photochemotherapeutic drug.

PHOTOIMMUNOLOGY

Skin cancer is caused largely by direct damage to DNA, leading to specific gene mutations. However, for the development of clinically apparent skin cancer, a second UVB-induced mechanism is required, namely, UVB-induced immunosuppression.[26,27] The connection between sun exposure and skin cancer was realized first in the beginning of the last century when physicians observed skin tumors that grew preferentially at sites that had been extensively sun exposed. This was followed in the 1970s by a seminal study by Kripke,[28] who discovered a connection between immunosuppression and photocarcinogenesis. In a series of experiments, she demonstrated that UV-induced tumors, which had been transplanted onto syngeneic recipient mice, were rejected if the recipient mice had not been exposed to UVB. This result implies that UV-induced tumors have a highly antigenic phenotype[28] and can be rejected by a functioning immune system. Treatment with known immunosuppressive drugs, or—this was the novel finding—with low doses of UVB, led to failure of tumor rejection.[29,30] Both aspects (i.e., the strong antigenicity of UV-induced tumors and the immunosuppression by UVB) have triggered vigorous research



activities in the field now termed *photoimmunology*. Numerous studies tried to clarify the cellular and molecular mechanisms.[31] These have turned out to be highly complex (see Fig. 88-9). Results sometimes appear contradictory, likely due to use of various experimental approaches and model systems.

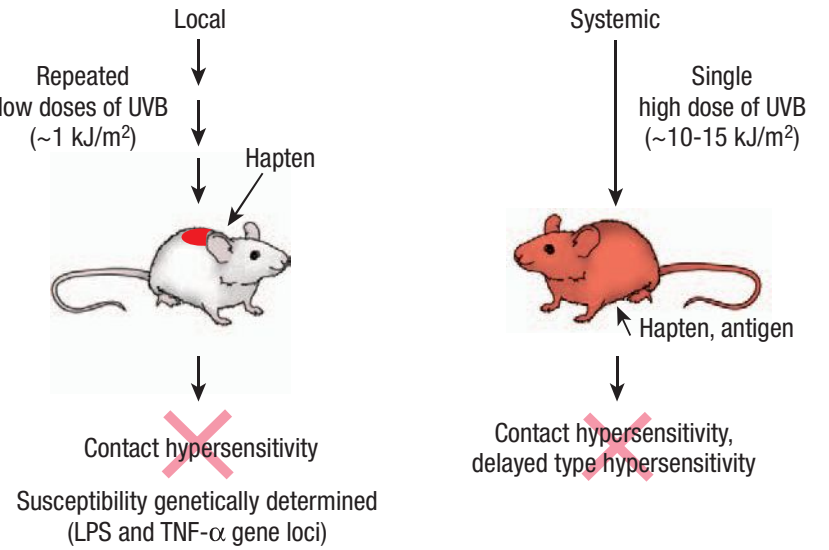
Model Systems for Ultraviolet B–Induced Immunosuppression

The standard model for studying UVB-induced immunosuppression is the delayed-type hypersensitivity (DTH) to antigens and the contact hypersensitivity reaction (CHS). The ability of UVB irradiation to block either induction or elicitation of allergic sensitization can then be quantified; typically a hapten such as dinitrofluorobenzene or oxazolone is applied to the skin as the stimulus and intensity of the subsequent immune response is measured as tissue swelling. DTH responses have become the model of choice to study the immunosuppressive effects of UVB radiation, as the tumor-associated antigens of UVB-induced tumors are only poorly characterized and testing DTH responses is less time-consuming and less laborious than examining photocarcinogenesis. UVB radiation has also been shown to affect immune responses involved in the pathogenesis of viral, parasitic, fungal, and bacterial infections. UVB-mediated immunosuppression is of two types: (1) local immunosuppression in which the immune response to antigens applied at the irradiated site is abrogated, and (2) systemic immunosuppression in which the immune response to antigens applied to unexposed sites is impaired (Fig. 88-8).[32] Of note, however, some mice are more susceptible to UVB-induced immunosuppression than others, with the genetic loci for lipopolysacharide, *Lps*, and tumor necrosis factor, *Tnf*, strongly influencing the response.[33]

Molecular Targets in Photoimmunosuppression

DNA is a chromophore for UVB radiation and can be a direct target (see Fig. 88-6). UVB radiation generates a variety of photoproducts, most commonly CPDs and (6-4) photoproducts. Pyrimidine dimer formation is a direct cause of UV-induced immunosuppression (Fig. 88-9). The cells of the opossum *Monodelphis domestica* contain endogenous photoreactivating enzymes, which are capable of repairing CPDs, and UVB does not induce immunosuppression in these animals on exposure to photoreactivating light immediately after irradiation.[34] Also in mice, a correlation between CPDs and UVB-induced systemic immunosuppression exists.[35] UVB irradiation leads to CPDs in antigen-presenting cells (APCs) and impairment of their antigen-presenting capacity. The damage persists for several days, and the damaged cells migrate from the skin to lymph nodes. Treatment at the site of UVB irradiation with liposomes containing the DNA repair enzyme T4 endonuclease V prevents the impairment in antigen presentation.[36] The role of DNA damage in UVB-induced immunosuppression was also confirmed in human skin, in which topical application of photolyase-containing liposomes to UVB-exposed sites prevents UVB-induced immunosuppression.[37]

In addition to direct DNA damage, the generation of ROS is likely to be involved in photoimmunosuppression (see Fig. 88-9). Accordingly, topical application of a polyphenolic fraction isolated from green tea before and after UVB irradiation to mouse skin protects against UV-induced immunosuppression,[38] an effect most likely mediated by the antioxidant epigallocatechin-3-gallate, the component of extract that has the ability to reduce oxidative stress, inflammatory responses, and skin cancer. It should be noted that such secondary plant metabolites affect cell signaling, however, so that protection against UVB-induced events may not exclusively be explained by antioxidant effects.



▲ **FIGURE 88-8** Ultraviolet B (UVB) radiation–induced immunosuppression: Local versus systemic. TNF = tumor necrosis factor.

The cell membrane of immunocompetent skin cells is another target for UV radiation. An important function of the cell membrane is to transfer signals from outside into the cell via membrane receptors. UVB exposure leads to clustering and internalization of cell surface receptors for epidermal growth factor, TNF, and IL-1 in the absence of the respective ligands. Clustering results in strong activation of stress-induced c-Jun NH2-terminal kinases, which are members of the mitogen-activated protein kinase family[39] (see Fig. 88-9). Conceivably, such aberrant receptor clustering may subvert signaling pathways normally used by growth factors and cytokines, eventually contributing to the immunological response.

UVB radiation can lead to lipid peroxidation, including cell membrane lipids. Phosphatidylcholine, an important membrane lipid, can be oxidized to platelet-activating factor (PAF)–like lipids that bind to PAF receptors and activate cytokine synthesis. A role of UVB-induced PAF formation in photoimmunosuppression is suggested by the observation that comparable immunosuppression can be induced in mice when they are irradiated with UVB, injected with carbamyl-PAF, or injected with phosphatidylcholine that had been exposed to UVB under atmospheric oxygen. The immunosuppressive properties of all three treatments were equally blocked by specific PAF receptor antagonists, indicating that UVB-induced PAF-like lipids can trigger the PAF receptor in a way similar to PAF. In turn, PAF receptor activation stimulates a variety of downstream effects, including the activa-

tion of mitogen-activated protein kinase pathway and synthesis of immunosuppressive cytokines (see Fig. 88-9).[40]

An extracellular chromophore that mediates UVB-induced immunosuppression is UCA (see Fig. 88-6).[41] UV radiation isomerizes *trans*-UCA to *cis*-UCA dose-dependently until a balanced photostationary state is reached. A number of independent studies confirmed the importance for *cis*-UCA in UVB-induced immunosuppression, although the exact mechanism of action is not clear at present.

Cellular Events Involved in Photoimmunosuppression

UVB radiation of keratinocytes alters their expression of surface molecules and induces the synthesis and secretion of a whole set of immunomodulatory soluble factors, including IL-1, IL-6, IL-8, TNF-α, and PGE_2 (see Fig. 88-9).[42] Evidence for keratinocyte-derived soluble factors with immunosuppressive function came from experiments showing that either serum factors from UVB-exposed mice or supernatants from UVB-irradiated murine epidermal cells suppressed hypersensitivity reactions in mice. Subsequently, it was found that TNF-α and IL-10, two potent immunosuppressive cytokines, are produced by UVB-irradiated keratinocytes as well.[42,43] IL-10 is also released by $CD11b^+$ macrophages in human skin.[44] Injection of TNF-α mimics UVB-induced alterations on Langerhans cells (LCs). The administration of a neutralizing antibody to TNF-α before irradiation abrogates partially UVB-induced accumulation of dendritic cells (DCs) in draining lymph nodes (DLNs) and suppression of contact hypersensitivity. The release of TNF-α is of special importance for local immunosuppression, and, as mentioned above, the *Tnfa* gene locus contributes to UVB susceptibility.

IL-10 is a T-helper cell type 2 (Th2) cytokine and abrogates the production of Th1 cytokines, in particular interferon-γ (IFN-γ). UVB-induced IL-10 production by keratinocytes in murine or macrophages in human skin[47] shifts the immune response from a Th1 to a Th2 type. This can explain why Th1-mediated cellular immune reactions are impaired by UV radiation.

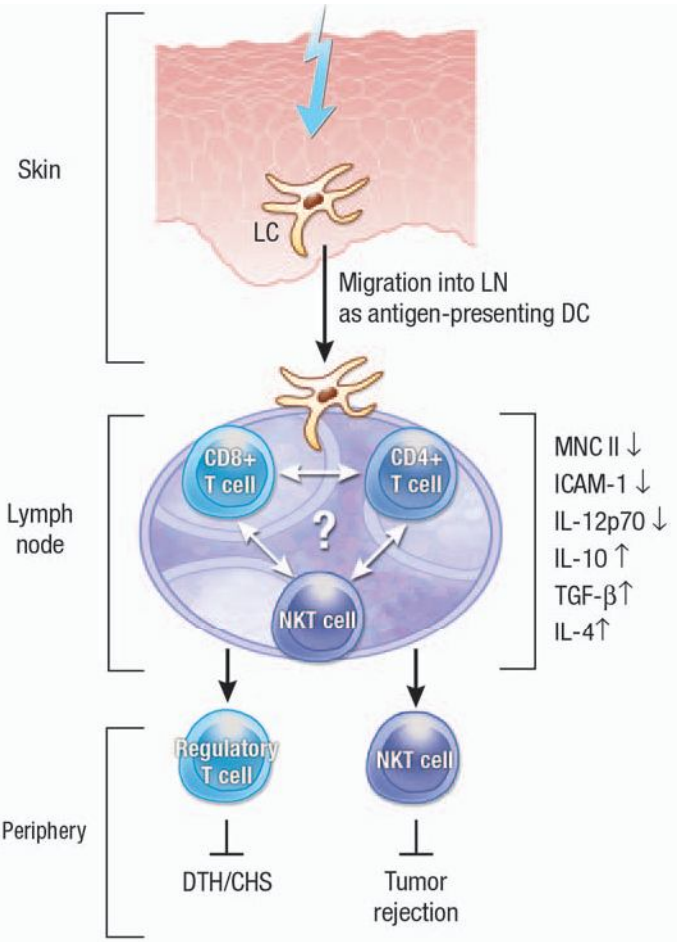
The interactions between the different cytokines are not fully understood, but IL-10 certainly is a major player. For instance, anti–IL-10 antibodies neutralize the suppressive effects of supernatants from UVB-irradiated keratinocytes on DTH in mice.[45] The main mechanism of IL-10 is probably inhibiting the antigen-presenting capacity of LCs. In parallel, UV-exposed keratinocytes release PAF and PAF-like lipids which trigger the PAF receptor, as described in Molecular Targets in Photoimmunosuppression.[40] Presumably, PAF and its receptor enhance the production of cyclooxygenase-2, PGE_2, IL-4, and IL-10. IL-10 production can be reversed by IL-12. Incidentally, IL-12 can restore UV-impaired CHS.[46] Injection of mice with IL-12 after UVB exposure prevented UVB-induced immunosuppression and suppressed partially UVB-induced tolerance obtained by resensitization 14 days after the UV irradiation. This IL-12 effect is most likely

linked to the capacity of this cytokine to enhance the repair of UVB radiation–induced DNA photoproducts, which form the molecular basis for IL-10 production by irradiated keratinocytes.

Cellular Mediators of Photoimmunosuppression: Langerhans Cells, Macrophages, and T Cells

LCs, 2 percent to 5 percent of epidermal cells, are a DC subset that originates from bone marrow precursors and populates the epidermis. They are the professional skin-specific antigen-presenting cells and ingest antigen locally in the skin, but lack co-stimulatory capacity. After antigen uptake, LCs migrate to the DLN, where they mature to potent stimulators for antigen-specific T cells, expressing high levels of major histocompatibility complex molecules and co-stimulatory molecules B7.1 and B7.2 and intercellular adhesion molecule-1 on their cell surface (see Chap. 10).

In the 1980s, it was demonstrated that epidermal LCs play a pivotal role in the induction and regulation of CHS reactions. LC density is an important factor for the induction of CHS responses, and UV radiation leads to the disappearance of LC from irradiated sites.[48] In these studies, mice were sensitized with the hapten dinitrofluorobenzene either on skin with typical amounts of LC or on LC-deficient skin. A significantly impaired CHS response was observed when the mice were sensitized on LC-deficient skin. The capacity to deplete LCs temporarily from the skin appears to be an important feature of UVB irradiation. Moreover, UV exposure results in reduced surface expression of co-stimulatory molecules Ia, B7.1, B7.2, and intercellular adhesion molecule-1 (see Fig. 88-9).[49,50] The depletion of these molecules might account for or contribute to immunosuppression. The loss of LCs in the skin is accompanied by an increase in DCs in the DLN.[51] Fluorescein isothiocyanate+ Ia+ CPD+ cells in the DLNs were found after painting the skin with fluorescein isothiocyanate and irradiating subsequently with UV. This demonstrates that LCs indeed leave the skin after UV exposure. UVB possibly induces LC migration in the absence of exogenous antigen, although the migratory effect is enhanced by sensitization with antigen. The ultimate fate of chronically irradiated LCs remains to be examined. UVB-induced LC migration was also observed in human skin in vivo.[52]



▲ **FIGURE 88-10** Ultraviolet B radiation–induced immunosuppression: Illustration of the presumed cellular interplay in skin-draining lymph nodes (LNs). CHS = contact hypersensitivity reaction; DC = dendritic cell; DTH = delayed-type hypersensitivity; ICAM = intercellular adhesion molecule; IL = interleukin; LC = Langerhans cell; MHC = major histocompatibility complex; NKT = natural killer type; TGF = transforming growth factor.

In addition to reducing the number of LCs in the skin, UVB radiation affects LC function by impairing the antigen-presenting capacity in DTH and CHS. UVB-irradiated LCs activate preferentially CD4+ Th2 cells.[53] In contrast, they do not activate CD4+ T cells of the Th1 subset, but induce clonal anergy.[54] Another cellular player in UV-induced immunosuppression is CD11b+ macrophages, which infiltrate UVB-irradiated human skin (see Fig. 88-9). These cells produce IL-10, and their deletion by antibodies makes UV-irradiated mice permissive again for CHS.[55]

In addition to immunologic unresponsiveness to haptens applied after irradiation, UVB exposure–induced hapten-specific tolerance (i.e., resensitization with the same hapten at later time points) likewise fails.[56] In adoptive transfer experiments, it was shown that UVB induces T-suppressor cells.[57] Elmets at al.[57] prepared single cell suspension of the spleen and lymph nodes from UVB-exposed and hapten-treated mice, injecting the cell suspension into naive mice. When the recipient mice were sensitized and challenged with the same hapten that was used for the donor mice, they showed significantly impaired CHS responses.

The phenotype of the regulatory T cells and their mechanism of action are not well understood (Fig. 88-10). Results obtained so far are difficult to compare. Different experimental set-ups yielded partly contradictory results. There is evidence to suggest that CD8+ T cells are important mediators of UVB-induced immunosuppression in the local immunosuppression.[58] In addition, T cells (not defined by CD4 or CD8) that express cytotoxic T lymphocyte antigen (CTLA)-4 on their surface transfer UV-induced tolerance.[59] CTLA-4 appeared to be of functional relevance, because in vivo injection of anti–CTLA-4 antibodies blocked transfer of suppression. The physiologic function of

CTLA-4 is to end immune responses by shutting down activated T cells, so CTLA-4 is an important molecule in immune regulation. On stimulation with antigen-bearing DCs, CTLA-4$^+$ T cells secrete high levels of IL-10, transforming growth factor-β, and IFN-γ, but low levels of IL-2 and no IL-4. Other studies showed that CD4$^+$ T cells from UV-exposed mice are capable to suppress CHS when injected into untreated recipient mice.[60] These CD4$^+$ T cells produce IL-10, but no IL-4 and IFN-γ on APC co-culture and inhibit IL-12 production by APCs.

Apart from CD4$^+$ regulatory T cells, natural killer T cells with regulatory capacities were found in UVB-induced systemic immunosuppression (see Fig. 88-10). In particular, CD3$^+$, CD4$^+$, and DX5$^+$ CD1-restricted natural killer T cells have been described, which secrete IL-4 and can adoptively transfer suppression of tumor rejection as well as DTH responses.[61]

Photoimmunology: Concluding Remarks

UV radiation is a permanent environmental threat, and adaptive responses against its damaging effects have been developed in all living organisms. From a theoretic point of view, it is therefore tempting to speculate that photoimmunosuppression serves a physiologic role as an adaptive response of the skin to UV-induced modifications of proteins and an immunologic response to so-called *neo-antigens* and, as a consequence, chronic inflammation. Under these conditions, the higher risk of skin cancer that appears to accompany UV-induced immunosuppression appears of less significance in evolutionary terms, as skin cancers occur principally in late life, after the reproductive period. From a practical point of view, however, photocarcinogenesis poses a serious health problem. Accordingly, modern approaches to prevent UV-induced immunopsuppression include broad-spectrum UV filters, liposomally encapsulated DNA repair enzymes, antioxidants, and osmolytes.[62]

CHAPTER 89

Acute and Chronic Effects of Ultraviolet Radiation on the Skin

Antony R. Young
Susan L. Walker

THE SKIN AND ULTRAVIOLET RADIATION: AN OVERVIEW

Sunburn and tanning are the most obvious acute clinical effects of ultraviolet radiation (UVR). Photoaging and skin cancer are the consequences of chronic exposure. It has been useful to describe sun-sensitivity according to skin phototype, as shown in Table 89-1. It is widely assumed that sensitivity to UVR is primarily related to pigmentation or tanning ability. However, the relationship between skin phototype and sensitivity to sunburn still holds on vitiliginous patches,[1] indicating that other factors are important, such as differences in DNA repair capacity.

ULTRAVIOLET RADIATION

UVR represents approximately 5 percent of terrestrial solar radiation and is officially divided into UVA (315 to 400 nm), UVB (280 to 315 nm), and UVC (100 to 280 nm), though other definitions are widely used (e.g., a UVB/UVA division at 320 nm). UVA is sometimes subdivided into UVAI (340 to 400 nm) and UVAII (315/320 to 340 nm). Sea-level solar UVR is approximately 95 percent to 98 percent UVA and 2 percent to 5 percent UVB. UVC is completely absorbed by stratospheric ozone (O_3) that also attenuates UVB. A given solar UVR spectrum varies with the solar zenith angle (the angle between an imaginary perpendicular line and a line from its base to the sun), which is dependent on time of day, season, and latitude. The highest UVB content is found when the sun is directly overhead with the shortest path (e.g., noon at the equator at high altitude).

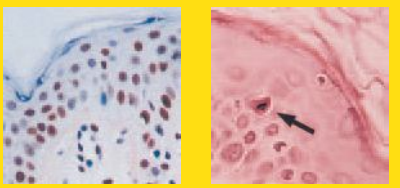
Measurement of Human Exposure to Ultraviolet Radiation

The measurement of UVR exposure is called *dosimetry* and can be done physically or biologically. Accurate physical dosimetry, in which dose rate (irradiance) is measured as W/cm^2 and exposure dose as J/cm^2 [W/cm^2 × time (seconds)], is technically demanding, and a biologic approach is more commonly used. This is based on the individual minimal erythemal dose (MED), which is the lowest dose required to produce a just perceptible erythema (sunburn) 24 hours later. In general, individuals with higher skin types have higher MEDs.[2] However, as shown in Fig. 89-1, there is considerable MED overlap between skin phototypes.

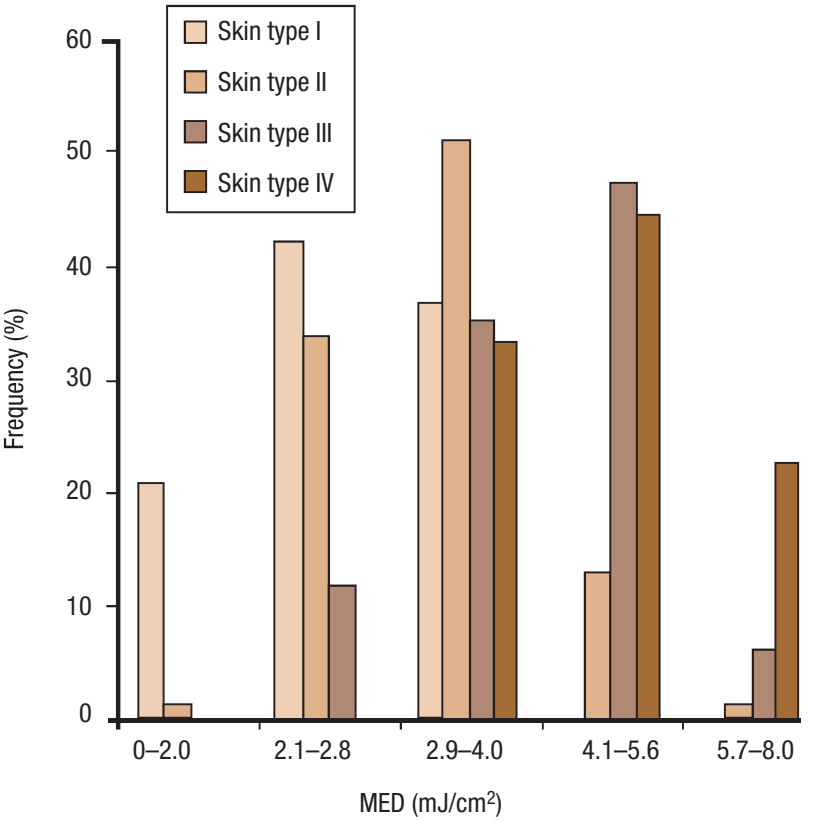
Most human UVR exposure is from sunlight, but the use of tanning devices is increasingly popular. Solar UVR exposure may be intentional or inadvertent

ACUTE AND CHRONIC EFFECTS OF ULTRAVIOLET RADIATION ON THE SKIN

AT A GLANCE



- Acute and chronic responses to ultraviolet radiation (UVR) depend on skin phototype.
- The major acute clinical effects are inflammation, tanning, and immunomodulation.
- Basal cell carcinoma, squamous cell carcinoma, malignant melanoma, and photoaging are the chronic effects of UVR.
- The majority of effects of solar UVR on the skin are the result of its small UVB content.



▲ **FIGURE 89-1** There is considerable overlap for solar simulating radiation [just perceptible minimal erythemal dose (MED) on previously unexposed buttock skin] in different white skin types. MED for skin types I, II, III, and IV are 2.9 [standard deviation (SD) ± 0.7], 3.5 (SD ± 1.0), 4.5 (SD ± 1.2), and 5.3 (SD ± 1.2) J/cm^2, respectively. (From Harrison GI, Young AR: Ultraviolet radiation-induced erythema in human skin. *Methods* **28**:14, 2002.)

and depends on specific behaviors and time spent outdoors, as well photoprotection strategies.

Action Spectroscopy

In any skin response to UVR, it is important to know which wavelengths are primarily responsible. This relationship is known as the *action spectrum* and is fundamentally based on the UVR absorbing properties of the molecule (chromophore) that initiates the effect (see Chap. 88). Major skin chromophores include DNA, urocanic acid (UCA), and aromatic amino acids (proteins) that absorb primarily in the UVC/UVB region; UVA chromophores are less well identified.[3]

Action spectroscopy enables another metric of UVR exposure known as the *standard erythema dose* (SED).[4] This is not based on individual UVR sensitivity and is equivalent to 100 J/m^2 after weighting the absolute emission spectrum of the UVR source with the standard erythema action spectrum as shown in Fig. 89-2. The SED is a useful approach in population exposure studies. For example, indoor workers in northern Europe have an annual exposure of approximately 200 SED (approximately 5 percent of ambient UVR exposure), mainly from weekend and vacation activities, whereas outdoor workers at comparable latitudes typically receive two to three times more.[5] The relationship between MED and SED for phototypes I through VI is shown in Table 89-1.

TABLE 89-1
A Classification of Skin Phototypes Based on Susceptibility to Sunburn in Sunlight, Tanning Ability, and Skin Cancer Risk

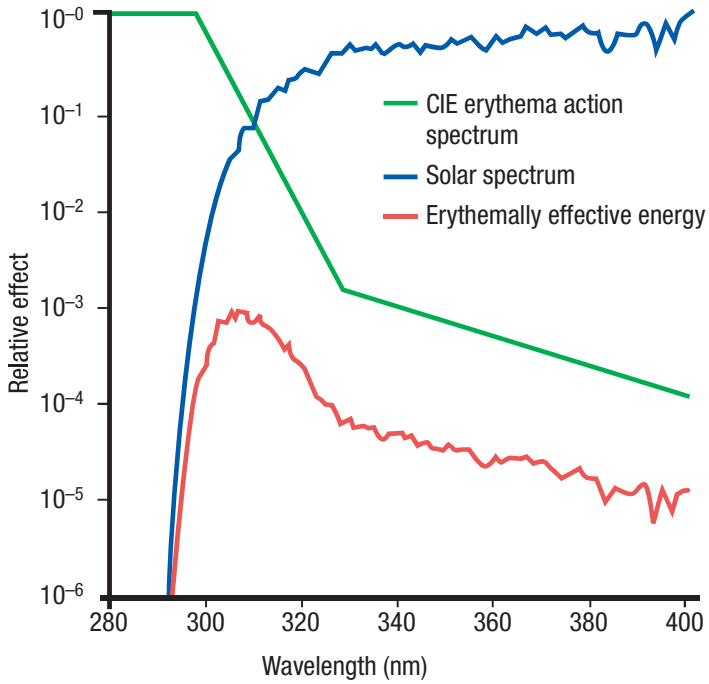
Skin Phototype	Sunburn Susceptibility	Tanning Ability	Skin Cancer Risk	No. Standard Erythema Dose[a] Required for Minimal Erythema
I	High	None	High	1–3
II	High	Poor	High	
III	Moderate	Good	Low	3–7
IV	Low	Very good	Low	
V	Very low	Excellent	Very low	7–> 12
VI	Very low	Excellent	Very low	

[a]A standard erythema dose is equivalent to an erythemally effective radiant exposure of 100 J/m^2.[62] Approximately three standard erythema doses are required to produce just perceptible or minimal erythema in unacclimatized skin of the most common Caucasian American and northern European skin types.[2]

ACUTE EFFECTS OF ULTRAVIOLET RADIATION

DNA Photodamage and Mutation (See Chaps. 109 and 112)

UVR absorption by epidermal DNA results in the formation of dipyrimidine lesions such as cyclobutane pyrimidine dimers (CPDs) and pyrimidine (6-4) py-



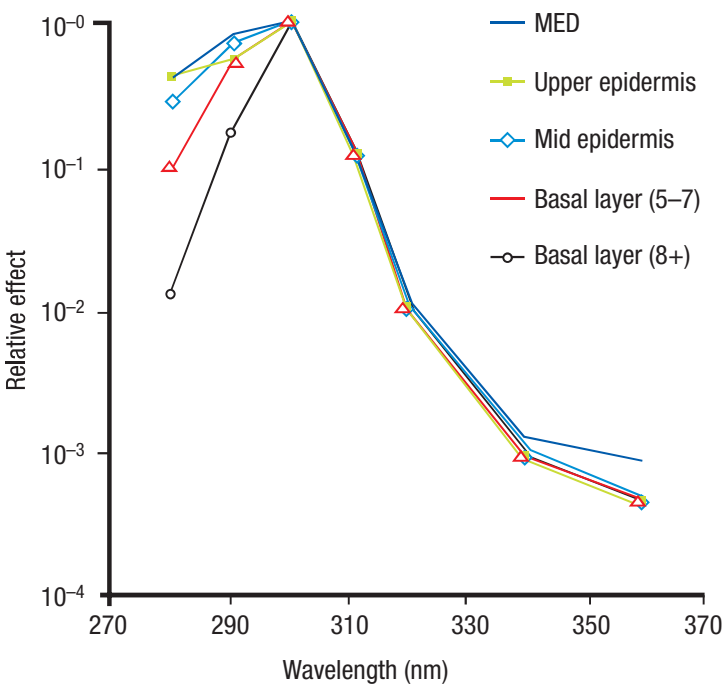
▲ **FIGURE 89-2** Standardized Commission Internationale de l'Eclairage (CIE) erythema action spectrum,[62] noontime summer spectral irradiance in London, UK (51°N 29′), and resultant erythemal effectiveness spectrum, which is the product of these two spectra. These data show that the 4.9 percent of the ultraviolet B (< 320 nm) in the solar spectrum contributes 80 percent of the erythemal effectiveness of the solar ultraviolet radiation spectrum.

rimidone photoproducts.[6] Fig. 89-3 shows an action spectrum for CPD in four different epidermal zones in skin phototypes I/II. Solar UVB causes much more damage in the basal layer than UVA per photon or unit physical dose (J/cm^2) but comparable damage is observed at comparable biologic (MED) doses. There is emerging evidence that CPDs, but not (6-4) photoproducts, can be formed by energy transfer reactions originating from UVA chromophores.[7] In vitro and in vivo studies in human skin have demonstrated UVA-induced oxidative DNA lesions such as 8-oxo-7,8-dihydro-2′-deoxyguanosine[8] and 8-hydoxy-2′-deoxyguanine.[9] The chromophores that generate the responsible reactive oxygen species after absorbing UVA are not known.

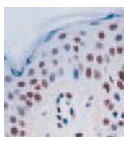
DNA REPAIR Unless repaired by nuclear excision repair (NER) dipyrimidine lesions give rise to highly characteristic so-called *UVB signature mutations*, namely C → T or CC → TT transitions.[10] NER acts in two distinct ways: (1) global genome repair (GGR) operates across the entire genome and (2) transcription coupled repair (TCR) preferentially excises lesions from actively transcribed genes. Genetic disorders provide evidence that GGR and TCR have very different biologic roles. For example, lack of GGR in xeroderma pigmentosum results in high levels of skin cancer, whereas lack of TCR in Cockayne syndrome causes acute sun sensitivity apparently without an increased skin cancer risk. Studies in transgenic mice with different GGR-TCR gene permutations confirm that these repair pathways affect different photobiological outcomes.[11]

Human studies have shown that, after a single exposure to solar simulating radiation (SSR), GGR of the (6-4) photoproduct in situ is rapid, whereas GGR of the CPD is much slower, with many lesions persisting for at least 24 hours.[6] Such slow repair means that lesions accumulate if skin is again exposed to UVR the following day, as is often the case in normal life, and this has been demonstrated with repeated sub-erythemal SSR exposure in human skin in vivo.[12] There is also limited evidence that global DNA repair in the epidermis may be inducible by repeated SSR exposure in skin types that tan well (IV) but not in skin types that tan poorly (II).[13]

SUNBURN INFLAMMATION Sunburn (erythema) shows the classic signs of inflammation (e.g., redness, warmth, pain, and swelling). Its intensity is determined by UVR exposure dose (J/cm^2) irrespective of the time over which it is delivered, at least over several hours, a relationship known as *reciprocity*. Studies with two MED SSR in skin phototypes I/II show the onset of erythema at approximately 6 hours that is maximal at 18 hours to 24 hours with persistence for at least 1 week.[6] Repeated daily sub-erythemal SSR exposures have a cumulative erythemal effect, especially in skin types I/II.



▲ **FIGURE 89-3** Comparison of action spectra for erythema and epidermal DNA photodamage (thymine dimers) in the same group of 40 skin-type I/II volunteers using same emission spectra. MED = minimal erythemal dose. (From Young AR et al: The similarity of action spectra for thymine dimers in human epidermis and erythema suggests that DNA is the chromophore for erythema. *J Invest Dermatol* **111**:982, 1998.)



The action spectra for erythema and CPD are similar. Fig. 89-3 shows an action spectrum for erythema in skin types I/II and action spectra for CPD with the same UVR spectra in the same volunteers. The similarity of these spectra provides strong evidence that DNA is a major chromophore for erythema.[14] However, there is also evidence for a UVA-absorbing chromophore that works via an oxygen-dependent mechanism.[15,16]

PHARMACOLOGIC MEDIATORS AND NEUROPEPTIDES Mast cell preformed products, such as histamine, serotonin, and tumor necrosis factor (TNF)-α, can be detected within an hour of UVR exposure and may play a role in the initial development of erythema. In general, mediators are not stored as preformed molecules but are synthesized after the activation of their respective transcription factors in the relevant cell types. An inflammatory infiltrate, consisting largely of neutrophils and T lymphocytes, is evident in the upper dermis 3 hours after UVB exposure and increases rapidly until 48 hours. At 48 hours to 72 hours, neutrophils and macrophages are also observed in the epidermis. These infiltrating cells, as well as resident keratinocytes, contribute to the inflammatory process through the release of many putative mediators including by-products of arachidonic acid metabolism, pro-inflammatory and immunosuppressive cytokines, chemokines, adhesion molecules, angiogenesis, and growth factors.[17] The pharmacology of sunburn is incompletely understood, but there is human in vivo evidence for an important role for prostaglandins, especially prostaglandin E_2, and nitric oxide.[18] The resolution of erythema is likely to be dependent on the synthesis of T helper 2 (Th2)–type anti-inflammatory cytokines such as interleukin (IL)-10, IL-4, and transforming growth factor-β1. Macrophages, which peak in skin 72 hours after exposure, play an important role in this process.[19]

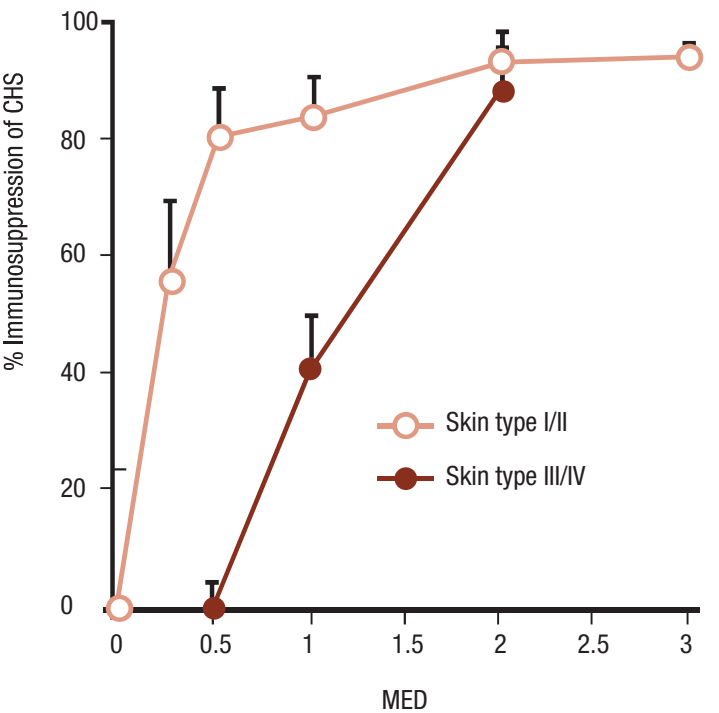
Afferent sensory nerves innervating the epidermis and dermis release a variety of neuropeptides after UVR exposure.[20] These products, such as substance P and calcitonin gene–related peptide (CGRP), may act as mediators for pain and itch as well as for inflammation and immunomodulation. In addition, a range of skin cells, including melanocytes, keratinocytes, and endothelial cells, upregulate the production of neurotrophins and hormones such as proopiomelanocortin peptides and their receptors. These mediators can then stimulate vasodilation, mast cell degranulation, and enhancement of UVR-induced cytokine production, chemokine production, and cellular adhesion molecule expression that recruit inflammatory cells into the skin. There is also evidence that the mediators, such as α melanocyte-stimulating hormone (α-MSH) and CGRP, play an important role in the resolution of UVR inflammation.

Photoimmunomodulation (See Chap. 88)

Solar UVR has immunoregulatory effects in which Th1 cytokine responses are suppressed.[21] Thus, the sensitization and elicitation arms of cutaneous cell-mediated immunity in humans, usually assessed by the contact hypersensitivity (CHS) response, are inhibited.[22] The UVR-induced depletion of epidermal Langerhans cells, the principal antigen-presenting cells, recruitment of dermal and epidermal macrophages that also act as antigen-presenting cells, and release of inflammatory mediators such as platelet-activating factor, TNF-α, IL-4, IL-10, transforming growth factor-β, α-MSH, and CGRP are important in immunomodulation. This alters the normal antigen-presentation process, leading to the generation of highly specific regulatory T cells that specifically inhibit cell-mediated immunity to newly encountered antigens.

PHOTOIMMUNOSUPPRESSION, SKIN CANCER, AND INFECTION (See Chap. 88) UVR-induced immunosuppression has a major role in mouse photocarcinogenesis, facilitating growth and emergence of tumors. Photoimmunosuppression is thought to play a role in human skin cancer as well, and the fact that organ transplant patients maintained on immunosuppressive therapy have a greatly elevated risk of all types of skin cancer is cited in support of this idea. Exposure to UVR also increases the incidence and severity of infectious diseases in animal models and suppresses the elicitation of immunity to some infectious agents in humans. To date, the best evidence for this is increased susceptibility to recurrent herpes simplex virus lesions in acutely sun-exposed skin.

Susceptibility to SSR-induced immunosuppression of the sensitization phase of CHS is skin-type dependent, which may depend on the amount of cytokine released. Individuals of skin phototypes I/II are more readily immunosuppressed than skin phototypes III/IV.[23] Fig. 89-4 shows that single sub-



▲ **FIGURE 89-4** Erythema is a poor indicator of suppression of the induction phase of the contact hypersensitivity (CHS) response. Volunteers with skin phototypes I/II are suppressed with sub-erythemal exposure to solar-simulated radiation, whereas erythemal exposures are necessary to suppress the CHS response in skin types III/IV. MED = minimal erythemal dose. (From Kelly DA et al: Sensitivity to sunburn is associated with susceptibility to ultraviolet radiation-induced suppression of cutaneous cell-mediated immunity. *J Exp Med* **191**:561, 2000.)

erythemal exposures of either 0.25 or 0.50 MED suppresses CHS responses by 50 percent and 80 percent, respectively, in normal skin phototypes I/II, whereas a full MED may only induce 40 percent suppression in skin phototypes III/IV. Such data suggest that skin phototype–dependent sensitivity to immunosuppression may be a risk factor for skin cancer. Repeated exposure of human skin to sub-erythemal SSR does not prevent photoimmunosuppression by subsequent UVR exposure.[24]

CHROMOPHORES FOR PHOTOIMMUNOMODULATION DNA is an important chromophore for photoimmunosuppression because the enhanced repair of CPD inhibits immunosuppression in animal models and the release of immunoregulatory cytokines such as TNF-α and IL-10 in vitro. IL-12 and IL-18 inhibit photoimmunosuppression by their ability to enhance NER,[25,26] and IL-12–deficient mice are more susceptible to show a higher photocarcinogenesis than wild-type mice.[27] *Trans*-UCA, a component of stratum corneum, is also an important chromophore because its photoisomerization to *cis*-UCA provokes a wide range of immunologic responses. IL-12 has also been shown to inhibit some of the immunologic effects of *cis*-UCA.[28] Such studies show a complex interaction between DNA damage, its repair, cytokines, and immunomodulation.

ADAPTIVE RESPONSES AFTER ULTRAVIOLET RADIATION EXPOSURE

Hyperplasia

Hyperplasia of the dermis, epidermis, and stratum corneum are seen after UVR exposure. This follows a period of initial growth and cellular arrest for 24 hours to 48 hours. For example, 2 weeks of daily sub-erythemal SSR results in a 20 percent to 40 percent increase in the number of cell layers in the stratum corneum in white skin phototypes.[29] A number of studies suggest that such UVR-induced hyperplasia, particularly of the stratum corneum, plays a major role in photoprotection particularly in the fair-skinned, whereas other studies suggest a much more limited effect.[30]

Tanning (See Chap. 70)

Melanin composition is a variable mixture of lighter alkali soluble, sulphur containing pheomelanin and darker insoluble eumelanin; skin types that tan well have more eumelanin. Exposure to UVA induces a rapid but transitory grayish color known as *immediate pigment darkening* (IPD) which probably results from the photo-oxidation of existing melanins and the redistribution of melanocytic melanosomes from a perinuclear position into the peripheral dendrites. IPD progresses into persistent pigment darkening (PPD), which may remain stable for up to 2 hours post exposure. The biologic functions of IPD and PPD are not known.

Delayed tanning, also known as *melanogenesis*, is primarily a UVB response that results from increased activity and numbers of melanocytes. This becomes visible 3 to 4 days after UVR exposure and is maximal from 10 days to 3 to 4 weeks depending on complexion and UVR dose. Melanocyte tyrosinase activity also increases, melanocyte dendrites elongate and branch, and melanosomes increase in number and size. UVA tanning has distinct effects that are wavelength dependent. Thus, UVAI produces an increased melanin density localized to the basal cell layer, whereas UVAII increases the synthesis and transfer of melanized melanosomes to the keratinocytes throughout the epidermis, similar to the changes seen with UVB.

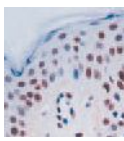
MECHANISMS OF ULTRAVIOLET RADIATION–INDUCED MELANOGENESIS (See Chap. 70) Tyrosinase, a copper-binding transmembrane glycoprotein localized to the melanosome, is the rate-limiting enzyme for melanogenesis. Its activity correlates closely with the melanin content of cultured melanocytes and increases during melanogenesis. There is evidence that DNA photodamage, and its repair, are initiators of melanogenesis. The action spectrum for human melanogenesis in vivo is similar to that for erythema,[31] which identifies DNA as the putative chromophore. Furthermore, synthetic thymidine dinucleotides (pTpT), the obligate substrate for UV-induced thymine dimers, enhance melanogenesis in vitro and in animal skin in vivo,[32] in part via p53 induction that regulates tyrosinase gene expression.[33] UVR damage also upregulates cell surface receptors for a variety of keratinocyte-derived melanogenic factors, in particular the melanocortin 1 receptor for α-MSH. In addition, there may be an increase in the production and release of factors such as basic fibroblast growth factor, nerve growth factor, endothelin-1, and proopiomelanocortin-derived products such as α-MSH, adrenocorticotrophic hormone, β-lipotropic hormone, and β-endorphin, all of which regulate the molecular and cellular aspects of melanogenesis.[34] Recent data suggest that α-MSH may enhance repair of UVR-induced DNA damage.[35] Melanogenesis may be one feature of the mammalian equivalent of the bacterial SOS response that is induced by DNA damage and reduces the impact of future exposure to DNA-damaging agents.[32] A second feature appears to be enhanced DNA repair capcity,[32,33] which may explain the strong skin cancer predisposition of phototype I/II individuals who tan poorly.

PHOTOPROTECTION AND PHOTOSENSITIZATION FROM ULTRAVIOLET RADIATION–INDUCED TANNING Several in vivo and in vitro human studies suggest that the acute photoprotection afforded by constitutive (baseline) and facultative (induced) pigmentation against DNA photodamage in keratinocytes and melanocytes and against sunburn is equivalent to a sunscreen with a sun protection factor of 2 to 4 (see Chap. 223).[36] This would result in significant reduction of biologically effective dose and such a reduction, if maintained over long periods, would theoretically be significant in terms of long-term risk of skin cancer. However, the maintenance of a facultative tan would be associated with the accumulation of epidermal DNA photodamage, negating the benefits of the protection. Furthermore, there are conflicting epidemiologic data about the role of a tan in affording protection against the development of malignant melanoma (MM).[37,38]

Although dark skin color, representing eumelanin, is clearly photoprotective, several lines of evidence suggest that pheomelanin may contribute to photosensitization and DNA damage.[39] The clinical significance of pheomelanin-mediated photodamage to skin cancer risk in blond and red-headed humans, who presumably have this pigment in their skin as well as in their hair, is not known.

Antioxidant Defenses

Various enzymatic and nonenzymatic antioxidants protect against oxidative damage in UVR-exposed skin, and are dramatically depleted after UVR exposure. Enzymes that repair oxidative injury in the skin include superoxide dismutase, catalase, and thioredoxin reductase, whereas natural antioxidants, such as vitamins A, C, and E, as well as glutathione, also act directly to prevent



oxygen radical damage. Exogenous antioxidants have also been shown to inhibit the sunburn response, immunosuppression, and photocarcinogenesis in mice.[40–42] Genetic variation at the glutathione S-transferase locus is also linked to variable susceptibility to sunburn[43] and to nonmelanoma and melanoma skin cancer risk in humans[44,45]

Photosynthesis of Vitamin D

Vitamin D_3 (cholecalciferol) is vital for bone health and its cutaneous photosynthesis is the single well-established benefit of UVR exposure. The plasma membrane–bound chromophore 7-dehydrocholesterol (also known as *provitamin* D_3) is photoconverted to previtamin D_3 that undergoes a slow thermal isomerization to vitamin D_3. Action spectra data indicate that UVB (approximately 295 to 315 nm) is responsible for vitamin D_3 production, which is also the peak region for sunburn and non-melanoma skin cancer. Vitamin D_3 is biologically inert and requires two hydroxylation steps: the first in the liver to 25-hydroxyvitamin D_3 [25-(OH)D_3] and the second in the kidney to produce the biologically active form 1,25$(OH)_2D_3$ (calcitriol). The plasma concentration of 25-(OH)D_3 is easily measured and is the conventional indicator of vitamin D_3 status. There is no standard definition of optimal vitamin D_3 status but it is generally accepted that plasma 25-(OH)D_3 below 25 n*M* constitutes deficiency as it is strongly associated with rickets and osteomalacia. It has been suggested that a level of 50 to 80 n*M* is required to optimize bone health, particularly in the elderly, however[46]; a new and controversial category of vitamin D "insufficiency" has been defined as higher vitamin D levels than those causing rickets or elevated parathyroid hormone levels but below levels that are statistically associated with other purported vitamin D benefits in population studies.[47] Cutoff values for vitamin D insufficiency vary widely in the literature, depending on the results of the reference study, and do not depend on the presence of a disease process (e.g., rickets) but only on a statistically increased risk of disease process (e.g., cancer or hypertension) in a cohort of individuals with comparable vitamin D storage levels.

WHAT IS THE BEST WAY TO ACHIEVE OPTIMUM VITAMIN D STATUS? In temperate regions above 45° latitude there is insufficient ambient UVB during October to March to synthesize vitamin D_3. Therefore, body stores, dietary intake, supplementation and UVB (but not UVA) tanning devices are the only sources during this time. Several studies have shown substantial seasonal fluctuation of 25-(OH)D_3 with significant proportions of populations being vitamin D_3–insufficient in late winter and early spring.[48] People who habitually avoid sunlight during the summer, the elderly, and populations with high constitutive pigmentation have been shown to have relatively low levels of 25-(OH)D_3 throughout the year.[49,50] It not known how much UVB exposure in combination with dietary/supplementary vitamin D_3 is needed to maintain optimal circulating 25-(OH)D_3. Sub-erythemal UVB is highly effective at increasing plasma 25-(OH)D_3, and it has been stated that a few minutes exposure of the face, arms, and hands to noonday summer sunlight two or three times a week is "sufficient" for vitamin D_3 synthesis. However, without a precise consistent definition of vitamin D sufficiency, this cannot be formally tested.

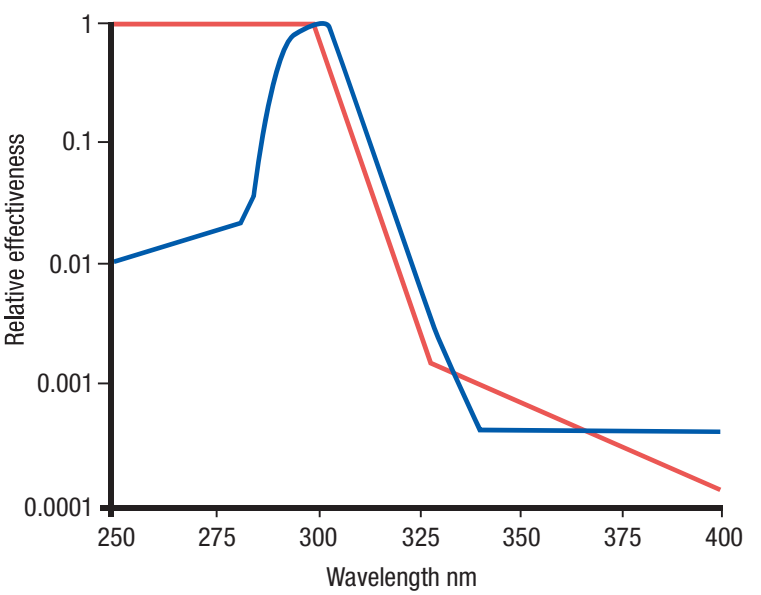
NEW ROLES FOR VITAMIN D?

CHRONIC EFFECTS OF ULTRAVIOLET RADIATION

Skin Cancer: From DNA Photodamage to Tumors (See Chap. 112)

Basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and MM are reviewed in Chaps. 114, 115, and 124, respectively. UVR, especially UVB, is a major causal factor for all types of skin cancer. Fig. 89-5 shows that the wavelength dependence for human SSC, based on animal data, is very similar to that for human erythema. Thus, the SSC effectiveness spectrum should be similar to that for erythema shown in Fig. 89-2. There are no comparable data for BCC or MM, but studies on a new transgenic mouse (HGF/SF) model for MM indicate that UVB is much more important than UVA.[53] Molecular epidemiology has also provided a direct link between non-melanoma skin cancer and dipyrimidine DNA photodamage. UVB signature mutations (C → T or CC → TT transitions) in p53 are very prevalent in SCC and in actinic keratoses, which may spontaneously regress or progress to SCC.[54] A large body of experimental data suggests that the CPD is the most important lesion. More recently, mutations compatible with UVA damage (AT → CG transversions) have been reported in p53 in actinic keratoses, BCC and SCC,[9] although mutation analysis of p53 in BCC has shown that a majority of tumors also contain UVB signature mutations.[55] BCC have also been found to harbor such mutations in the human homologue of the *Drosophila* "patched" Ptch gene,[56] shown to be critical in development of this tumor and part of the hedgehog signal transduction pathway that transmits extracellular growth and differentiation signals to the nucleus.[57]

The molecular relationship between UVR damage and MM is much less well



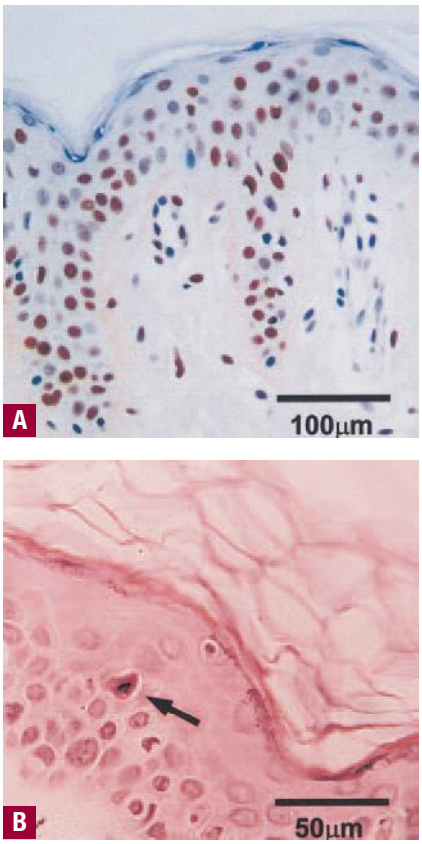
▲ **FIGURE 89-5** Commission Internationale de l'Eclairage action spectrum for human squamous cell carcinoma[63] (*blue*) in comparison with Commission Internationale de l'Eclairage erythema action spectrum[62] (*red*).

understood. Studies on familial MM have identified an important role for the CDKN2A gene that codes for two distinct tumor suppressor proteins ($p16^{INK4a}$ and $p14^{ARF}$) that affect the retinoblastoma and p53 pathways, respectively,[58] and there is emerging evidence of significant interaction between UVR and the $p16^{INK4a}$/retinoblastoma pathway, including UVR signature mutations in human MM.

Significance of Apoptosis (See Chap. 112)

The p53 protein is expressed at very low levels in normal human epidermis but is readily induced by a single dose of SSR, as shown in Fig. 89-6A. This protein monitors genomic integrity; either by responding to DNA damage (e.g., CPD) by the induction of transient cell cycle arrest at the G_1 checkpoint to facilitate DNA repair or by triggering the apoptotic death.[54] There is some evidence that UVR dose, and therefore level of DNA damage, is a factor in determining whether genomic integrity is protected by repair or apoptosis.[59] Mouse studies have confirmed that the p53 tumor suppressor gene plays an important role in apoptosis, but this can also occur via p53 independent pathways; for example, the binding of Fas ligand, TNF-α, or other cytokines to extracellular death receptors. UVB/SSR induces human epidermal apoptosis in the form of sunburn cells that are apparent within 30 minutes of exposure and maximal at 24 hours. In general, approximately two erythemal doses are required to induce sunburn cells, shown in Fig. 89-6B.

The interaction of multiple survival and apoptotic factors play a role in UVR-induced apoposis; for example, the E2F1 transcription factor that can be pro- or anti-apoptotic, depending on the circumstances.[60] Overall, keratinocyte apoptosis may have evolved to protect the skin from non-melanoma skin cancer. Much less is known about apoptosis in melanocytes, which are much more resistant to apoptotic signals in general than keratinocytes.[61] This may reflect their different roles and distribution in the skin. Numerous keratinocytes with a rapid turnover require much tighter homeostatic control than melanocytes that have a much lower density (approximately 2 percent of epidermal cells), low turnover, and are highly specialized.



▲ **FIGURE 89-6** Epidermal responses in skin phototype II at 24 hours after two minimal erythemal doses with solar-simulated radiation. **A.** Wild-type p53 (immunostained brown with DO-7 antibody) is expressed maximally. **B.** Sunburn cell counts are maximal. Note highly characteristic shrunken eosinophilic cytoplasm and condensed pyknotic nucleus after staining with hematoxylin and eosin.

Photoaging (See Chap. 108)

Photoaging is distinct from normal chronologic aging. Clinically, photoaged skin is dry, deeply wrinkled, inelastic, leathery, and telangiectatic, often with irregular pigmentation, freckling, and lentigo formation (dermatoheliosis, Fig. 89-7). Histologically, such skin shows marked quantitative and qualitative abnormalities, particularly of the dermal connective tissue, including the accumulation of abnormal elastotic material—namely, elastosis, and proteoglycans. Furthermore, the degradation and disorganization of collagen fibrils, responsible for the strength and resilience of skin, have been observed.

▲ **FIGURE 89-7** Dermatoheliosis. Severe fine and deep wrinkling. The skin appears waxy with a yellowish hue due to actinic elastosis.

CHAPTER 90

Abnormal Responses to Ultraviolet Radiation: Idiopathic, Probably Immunologic, and Photo-Exacerbated

John L. M. Hawk
James Ferguson

Abnormal responses to ultraviolet radiation (UVR) exposure can be divided into four categories (Table 90-1): acquired idiopathic, probably immunologic photodermatoses; DNA repair–defective photodermatoses; photosensitization by exogenous or endogenous drugs or chemicals, including the porphyrias; and photo-exacerbated dermatoses not directly caused by UVR. The first and last categories, and the approach to assessing the photosensitive patient, are covered in this chapter. The other categories are discussed in Chaps. 89, 91, 109, and 132 in this book.

TABLE 90-1
Abnormal Reactions to Ultraviolet Irradiation

- Acquired idiopathic, probably immunologic photodermatoses
  - Polymorphic light eruption
  - Actinic prurigo
  - Hydroa vacciniforme
  - Chronic actinic dermatitis
  - Solar urticaria
- DNA repair–defective disorders
  - Xeroderma pigmentosum
  - Cockayne syndrome
  - Trichothiodystrophy
  - Bloom syndrome
  - Rothmund-Thomson syndrome (probable)
- Chemical and drug photosensitivity
  - Exogenous
    - Systemic
    - Topical
  - Endogenous
    - The porphyrias
- Photo-exacerbated dermatoses

ACQUIRED IDIOPATHIC, PROBABLY IMMUNOLOGIC PHOTODERMATOSES

Polymorphic (Polymorphous) Light Eruption

EPIDEMIOLOGY Polymorphic light eruption (PMLE) is very common worldwide, affecting some 20 percent of southern Scandinavians,[1] 10 percent to 15 percent of North Americans[2] and southern Britons,[3] and 5 percent of southern Australians,[3] although virtually no equatorial Singaporeans.[4] Its prevalence therefore decreases steadily with decreasing latitude.

ETIOLOGY AND PATHOGENESIS A delayed-type hypersensitivity (DTH) response to sunlight-induced cutaneous photoantigen was first suggested as the cause of PMLE in 1942, based on the delay between UVR exposure and onset of the eruption as well as its lesional histologic features.[5] This has now proved almost certainly to be the case, although the considerable evidence in favor remains ultimately circumstantial.

Characterization of the inflammatory infiltrate in naturally occurring PMLE was inconclusive until biopsy specimens from lesions induced by solar-simulated irradiation eventually demonstrated the consistent appearance of a T cell–dominated perivascular infiltrate within 5 hours, peaking by 72 hours. $CD4^+$ T cells were most numerous in early lesions, whereas by 72 hours $CD8^+$ T cells predominated, perhaps abolishing the response.[6] Increased numbers of epidermal Langerhans cells and dermal macrophages were also present. These features all strongly suggested a DTH response as the basis for PMLE.

In addition, intercellular adhesion molecule-1 expression on keratinocytes overlying the perivascular infiltrate in PMLE,[7] as had been noted in DTH reactions but not irritant contact dermatitis or after the UVB irradiation of normal skin,[8,9] suggested an immunologic response. Finally, high-dose UVB and UVA irradiation of epidermal cells from a PMLE patient in one study increased their capacity to attract autologous peripheral blood monocytes,[10] again consistent with an immunologic response against a UVR-modified antigen.

More recently, the induction of allergic contact sensitization to dinitrochlorobenzene after solar-simulated irradiation of the sensitization site has been shown to occur significantly more easily in PMLE patients than in normal individuals,[11,12] which implies that patient sensitization to a putative UVR-induced cutaneous antigen may also be easier during the initial disease-inducing exposure. On the other hand, elicitation of the allergic contact response to dinitrochlorobenzene in previously sensitized PMLE patients and normal individuals was gradually and equally suppressed by irradiation,[13] which apparently also explains the frequent development of immunologic tolerance, often loosely called *hardening* or *desensitization*, in PMLE as summer progresses or during prophylactic phototherapy.

Etiologic radiation-absorbing molecules initiating PMLE have not been identified, but a variety of molecules may well be involved in the same and different patients. The altered molecule itself may hypothetically become antigenic, or else secondarily induced free radicals may interact with nearby elements to produce antigen, or both. However, any cutaneous immunologic tolerance induced by recent sunlight exposure may well inhibit the presumed DTH response.[13]

UVA radiation (315 to 400 nm) seems usually more effective than UVB (280 to 315 nm)[14,15] at initiating PMLE. In one

POLYMORPHIC LIGHT ERUPTION AT A GLANCE

- A common acquired sunlight-induced disorder, particularly at temperate latitudes, where it affects 10 percent to 20 percent of the population.
- Characterized by a pruritic, erythematous, symmetrically distributed, papulovesicular rash, on usually just some exposed areas, within hours of exposure to ultraviolet radiation (UVR), with full resolution in days to a week or two.
- Shows epidermal spongiosis with a dermal, perivascular, mainly mononuclear cell infiltrate and edema.
- Very likely a genetically determined delayed-type hypersensitivity reaction against UVR-induced cutaneous antigen(s).
- Responds to broad-spectrum sunscreen use, brief treatment with oral or topical steroids, or prophylactic low-dose immunosuppressive phototherapy in spring for frequent attacks.

wolff rev 2 lkc

study,[15] UVA irradiation successfully elicited the eruption in 56 percent of patients exposed to UVA or UVB daily for 4 to 8 days, in 17 percent of those exposed to UVB, and in 27 percent of those exposed to both. However, other reports have suggested that UVB radiation may perhaps be effective in up to 57 percent of patients.[16] Therefore, it could broadly be said that approximately 50 percent of PMLE patients seem sensitive to UVB radiation and 75 percent to UVA, including in each case approximately 25 percent who are sensitive to both, although visible light may also be responsible on very rare occasions.[17] As a result, paradoxically, patients may note that the use of sunscreens, which tend preferentially to remove UVB while transmitting UVA, may have a significant PMLE-enhancing effect.

There is very probably a genetic predisposition to PMLE,[18] but intensity of initial UVR exposure may also be important in such predisposed individuals.

CLINICAL FEATURES ***History.*** PMLE usually has onset in the first three decades of life and affects females two to three times more often than males. It occurs in all skin types and racial groups, but is more common in Caucasians. A positive family history is present in about a fifth of patients.[18]

The PMLE eruption (Fig. 90-1) typically occurs each spring or on sunny vacations after the first substantial UVR exposure after a prolonged period of no exposure. It can also occur after recreational sunbed use[19] or, very rarely, after exposure to visible radiation,[17] and often abates with continuing exposure. It is rare in winter except after exposure to UVR reflected from snow, and exposure may also occur through window glass. Individual susceptibility varies, and the period of continuing exposure needed to trigger the eruption is usually from 30 minutes to several hours, though sometimes after several days on vacations. Lesions appear in hours to days, but usually in not less than approximately 30 minutes, although itching may develop sooner. Once UVR exposure ceases, all lesions gradually resolve fully without scarring over one to several days or occasionally a week or two, rarely longer. In any given patient, PMLE outbreaks tend always to affect the same exposed sites, generally symmetrically, although perhaps gradually spreading or receding overall. Only some exposed skin is usually affected, particularly that normally covered, and large areas may be spared. An apparent extreme example of this is juvenile spring eruption,[20] which affects mainly boys in spring and is characterized by pruritic papules and vesicles of just the ear helices, although typical PMLE sometimes co-exists. Systemic symptoms in PMLE are rare, but malaise, nausea, and other sensations are possible in rare cases.

Cutaneous Lesions. PMLE has many possible morphologic forms, all probably with similar pathogenesis and prognosis. Papular, papulovesicular (Fig. 90-2), plaque (Fig. 90-3), vesiculobullous, insect bite–like, and erythema multiforme–like forms have been described, and pruritus alone may rarely occur,[21] but not, apparently, a macular variant. The papular form, characterized by large or small separate or confluent lesions that generally tend to form clusters, is most common, followed by the papulovesicular and plaque variants; the other forms are rare. An eczematous form has been claimed but almost certainly refers to mild chronic actinic dermatitis or photo-exacerbated seborrheic or atopic eczema. Differing morphologic variants may also occur at different skin sites in the same patient, with diffuse facial erythema and swelling, for example, sometimes accompanying typical papular lesions at other sites. Small papular PMLE generally sparing the face and occurring after several days of continuing exposure has been designated *benign summer light eruption* in continental Europe.[22]

▲ **FIGURE 90-3** Polymorphic light eruption. Variably sized itchy plaques on the cheek.

LABORATORY TESTS ***Histology.*** The histologic features[23] of PMLE are characteristic but not pathognomonic and vary with the clinical presentation. There is generally a moderate to dense perivascular infiltrate of the upper and mid dermis in all forms. The infiltrate consists predominantly of T cells, with neutrophils and infrequent eosinophils. Other features often seen are upper dermal and perivascular edema with endothelial cell swelling. Epidermal change, not always present, may include variable spongiosis and occasional dyskeratosis, exocytosis, and basal cell vacuolization.

Blood Tests. Assessment of the circulating anti-nuclear and extractable nuclear

▲ **FIGURE 90-2** Polymorphic light eruption. Papulovesicular lesions on the arm.

antibody titers is advisable in all patients to exclude subacute cutaneous or other form of lupus erythematosus, and, if there is any uncertainty, the red blood cell protoporphyrin concentration should be measured to exclude erythropoietic protoporphyria.

Phototesting. Cutaneous phototesting with a monochromator confirms photosensitivity in up to half of cases[24] but usually does not discriminate from other photodermatoses. However, provocation testing with a solar simulator or other broadband source, sometimes repeated over 2 or 3 successive days, may often induce the eruption, for biopsy if necessary, when the history and clinical features themselves are not diagnostic.

DIFFERENTIAL DIAGNOSIS See Box 90-1.

COMPLICATIONS A very few patients with PMLE may develop lupus, and there is a higher than normal prevalence of prior PMLE in patients with lupus.[25]

PROGNOSIS AND CLINICAL COURSE Over 7 years, 57 percent of 114 patients reported steadily diminishing sun sensitivity, including 11 percent in whom the condition totally cleared.[26]

PREVENTION PMLE may often be avoided by moderation of sun exposure, the wearing of appropriately protective clothing, and regular application of broad-spectrum high-protection-factor sunscreens, particularly those against UVA, because predominantly UVB sunscreens are often ineffective. Prophylactic phototherapy each spring or before sunny vacations also tends to prevent attacks.

TREATMENT (See eFig. 90-3.1 in on-line edition) Patients who experience PMLE only infrequently, such as on vacations, usually respond well to short courses of oral steroids prescribed to be taken with them in case an eruption develops.[27] If it does, approximately 20 to 30 mg prednis(ol)one taken at the very first sign of pruritus and then each morning until the eruption clears usually provides effective relief within several days at most, and recurrence is relatively rare during the same vacation. Rare adverse effects of nausea and depression only occasionally necessitate stopping the drug. This treatment, if well tolerated, may be safely repeated every few months if required.

More severely affected individuals experiencing repeated PMLE attacks throughout the summer may require prophylactic courses of low-dose photochemotherapy (psoralen and UVA irradiation, or PUVA) in spring. This appears to be more effective than broadband UVB irradiation, controlling symptoms in up to 90 percent compared with approximately 60 percent of cases.[28] Narrowband (312-nm) UVB phototherapy (often also called *TL-01*), effective in 70 percent to 80 percent of cases, is now probably the treatment of choice, however, because it is simpler to administer.[29] Prophylactic PUVA or UVB irradiation may sometimes trigger the eruption, particularly in severely affected patients, in which case a brief course of oral steroid therapy is indicated.

Various other therapies have also been tried but appear largely ineffective. These include the traditional hydroxychloroquine,[30] which is perhaps occasionally useful; β-carotene,[31] which is probably never effective; nicotinamide,[32] which is also ineffective; and ω-3 polyunsaturated fatty acids, which are perhaps of moderate assistance in some patients.[33]

A small proportion of patients remain who are unsuitable for, unable to tolerate, or not helped by any of these measures. For these patients, if they are severely affected, oral immunosuppressive therapy, usually intermittent, with azathioprine or cyclosporine is generally helpful, if appropriate.[34,35]

Box 90-1

Differential Diagnosis of Polymorphic Light Eruption

Usual Acute Form

- Photo-exacerbated dermatoses such as atopic or seborrheic eczema or acne
- Solar urticaria
- Erythropoietic protoporphyria
- Xeroderma pigmentosum

Rare Persistent Form

- Jessner's lymphocytic infiltrate

Actinic Prurigo

EPIDEMIOLOGY Actinic prurigo (AP) appears to occur throughout much of the world. Native Americans at all latitudes are particularly affected but also, more rarely, inhabitants of the United Kingdom, the United States, Europe, Australia, and Japan.

PATHOGENESIS AP appears to be UVR induced, in that it is more severe in spring and summer and reasonably often demonstrates abnormal skin phototest responses to the UVB or UVA wavelengths, or both.[36] In addition, sunlight exposure and solar simulating irradiation may sometimes induce a rash resembling PMLE, many patients have close relatives with PMLE,[18] and a dermal, perivascular mononuclear cell infiltrate similar to that of PMLE may be seen in early lesions.

AP may therefore be a slowly evolving, excoriated form of PMLE, and thus also a DTH reaction. In addition, human leukocyte antigen (HLA) DRB1*0401 (DR4), which is present in approximately 30 percent of normal individuals, occurs in around 80 to 90 percent of those with AP, whereas HLA DRB1*0407, found in approximately 6 percent of normal individuals and not infrequently in Native Americans, occurs in around 60 percent,[37,38] so this inherited feature may well be responsible for converting PMLE into AP. In addition, some patients with the AP tissue type demonstrate clinical PMLE but also have persistent lesions, whereas in some patients clinical AP converts to clinical PMLE and in others clinical PMLE changes to clinical AP,[38] all of which further suggests a relationship between the

ACTINIC PRURIGO AT A GLANCE

- A rare, persistent, pruritic, excoriated, papular, or nodular eruption of sun-exposed and, to a lesser extent, non-exposed skin.
- Usually begins in childhood, may remit at puberty, is generally worse in summer, and normally fades in winter.
- A persistent variant of the sometimes coexistent polymorphic light eruption (PMLE).
- Similar to hereditary or familial PMLE that predominantly affects native North, Central, or South Americans but that is usually more severe and generally persists into adulthood.
- In addition to avoidance of ultraviolet irradiation, often oral thalidomide or other immunosuppressive agent is required.
- Prophylactic immunosuppressive phototherapy and topical application of calcineurin inhibitors can perhaps reduce recurrences if the eruption is cleared first.

two disorders. The cutaneous molecular UVR absorbers responsible for initiating the eruption are not known but may well be diverse, as suggested for PMLE.

CLINICAL FEATURES ***History.*** AP is more common in females and usually begins by age 10 years.[36] A positive family history of either AP or PMLE is present in about a fifth of patients,[18] but the incidence of atopy, at around 10 percent, is not increased.[39] The eruption is often present all year round, but is generally worse in summer, although very rarely it is worse in winter or both spring and fall, with immunologic tolerance presumably developing during the summer in these instances. Exacerbations tend to begin gradually during sunny weather rather than after specific sun exposure, although PMLE-like outbreaks are also possible.

Cutaneous Lesions. Lesions are typically very pruritic, usually excoriated papules or nodules (Fig. 90-4), sometimes associated with variable eczematization, lichenification, or crusting. All exposed areas are usually affected, particularly consistently uncovered sites, with a gradual fading toward habitually covered skin. The latter areas are also often mildly affected, particularly over the sacral area and buttocks. Cheilitis, particularly of the lower lip, and conjunctivitis are also possible, particularly in Native Americans.[39] Healed facial lesions may leave small pitted or linear shallow scars.

LABORATORY TESTS ***Histology.*** Early papular lesions show changes similar to those of PMLE, namely, mild acanthosis, exocytosis, and spongiosis in the epidermis and moderate lymphohistiocytic, dermal perivascular infiltration,[23] even very rarely

suggesting lymphoma. In persistent lesions, however, excoriations, increasing acanthosis, variable lichenification, and dense mononuclear cell infiltration lead to a non-specific appearance.

Blood Tests. Assessment of the circulating anti-nuclear and extractable nuclear antibody titers should normally be undertaken to exclude subacute cutaneous or other form of lupus. The finding of HLA type DRB1*0401 (DR4) or DRB1*0407, particularly the latter, supports the diagnosis of AP.

Phototesting. Cutaneous phototesting with a monochromator confirms light sensitivity in up to half of cases[36] but as in PMLE does not discriminate from other photodermatoses. Provocation testing with a solar simulator or other broadband sources may occasionally induce a PMLE-like eruption.

DIFFERENTIAL DIAGNOSIS See Box 90-2.

COMPLICATIONS Permanent mild scarring, particularly on the face, and small, circular, atrophic, usually hypopigmented lesions elsewhere may arise from the chronic excoriations usual in the disease.

PROGNOSIS AND CLINICAL COURSE AP generally arises in childhood and often improves or resolves in adolescence, although persistence into adult life, sometimes in the form of PMLE, is possible. More rarely, the disorder arises in adulthood and persists indefinitely.[40] A closely related condition, which may affect North, Central, or South American patients of Native American or mixed race, appears indistinguishable from AP.

PREVENTION Annual prophylactic phototherapy in spring or the use of the topical calcineurin inhibitors tacrolimus and pimecrolimus sometimes prevents expression of the established disease. There is no known way to prevent its initial onset.

TREATMENT (See eFig. 90-4.1 in on-line edition) The restriction of sun exposure and use of broad-spectrum, high-protection-factor sunscreens may help in milder cases, assisted by intermittent use of topical or perhaps rarely oral steroids. Oral thalidomide, generally in low doses (50 to 100 mg at night) and preferably given intermittently, is almost always effective within weeks for more resistant disease in all age groups.[42] Adverse effects are generally mild and may include drowsiness, headache, constipation, and weight gain, whereas careful studies of nerve conduction performed every few months are important to minimize the risk of slowly progressive, probably dose-related peripheral neuropathy. Pregnancy must also be rigorously avoided because of the high risk of teratogenic effects. If thalidomide is unavailable or unsuitable, phototherapy with narrowband UVB or PUVA may occasionally help,[43] perhaps more reliably if the skin has been cleared first with oral steroids. Topical tacrolimus or pimecrolimus may also apparently help on occasion, again if the skin is cleared first, and oral immunosuppressive therapy with azathioprine or cyclosporine may also be useful if the other therapies are ineffective, unsuitable, or not tolerated. Treatment for hereditary AP is the same as for sporadic AP.

Hydroa Vacciniforme

EPIDEMIOLOGY Hydroa vacciniforme (HV) occurs in the United States, the United Kingdom, continental Europe, Japan, and very possibly elsewhere. However, its rarity and lack of universally acknowledged diagnostic criteria make precise evaluation difficult.

ETIOLOGY AND PATHOGENESIS The pathogenesis of HV is unknown. No chromophores have been identified, and although the UVB minimal erythemal dose reaction is normal in most patients, some have reduced UVA values.[44] Blood, urine, and stool porphyrin concentrations are normal, as are all other laboratory parameters. Nevertheless, the relationship of the eruption to sunlight exposure, its distribution, and its early clinical appearances are all very similar to those of PMLE, which strongly suggests a possible relationship to that disorder. On the other hand, the fully developed HV eruption is much more severe than that of PMLE, is always associated with permanent pock scarring, and is unresponsive to treatments effective for PMLE, apart

HYDROA VACCINIFORME AT A GLANCE

- A very rare, chronic, scarring photodermatosis of uncertain etiology.
- Characterized by recurrent sunlight-induced crops of papulovesicles and vesicles, most commonly on the face and dorsa of the hands.
- Usually begins in childhood and often remits at puberty.
- Could possibly be a scarring variant of polymorphic light eruption.
- Focal intraepidermal vesiculation, reticular keratinocyte degeneration, epidermal and upper dermal necrosis, and sometimes ulceration are virtually pathognomonic histologic changes.
- Avoidance of ultraviolet radiation, including the use of broad-spectrum high-protection-factor sunscreen, is the only established therapy.
- Prophylactic immunosuppressive phototherapy, administered with great care to avoid induction of lesions, may help.

perhaps from sunscreens and occasionally prophylactic phototherapy. Asian and Mexican reports of an HV-like disorder showing a regular association with Epstein-Barr virus infection probably represent a similar but not identical condition related to systemic disease.[45–47]

CLINICAL FINDINGS ***History.*** Most HV arises in early childhood and resolves spontaneously by puberty, although some patients suffer lifelong. There is a male predominance for severe forms, whereas milder disease is more common in females.[44,48] Familial incidence is exceptional. One estimate of the prevalence of HV is 0.34 cases per 100,000 with an approximately equal sex ratio; males had a later onset and longer duration of the disorder than females.[48]

The HV eruption (Fig. 90-5) typically occurs in summer,[36] with an often intense burning or stinging sensation followed by the appearance of individual or confluent papules and then vesicles within hours of sun exposure. This is

▲ **FIGURE 90-5** Hydroa vacciniforme. Vesicular, bullous, and crusted facial lesions, which are precursors of vacciniform scars.

followed by their umbilication, crusting, and progression to permanent pock scarring within weeks. The rash affects the cheeks and to a lesser extent other areas of the face, as well as usually the backs of the hands and outer aspects of the arms, generally symmetrically. It also rarely affects other sites.

Cutaneous Lesions. HV is characterized by initial erythema, sometimes with swelling, followed by symmetrically scattered, usually tender papules within 24 hours; vesiculation, occasionally confluent and hemorrhagic (Fig. 90-6); umbilication; then crusting and detachment of the lesions with permanent, depressed, hypopigmented scars within weeks. Oral ulcers and eye signs also rarely occur.[49,50]

LABORATORY TESTS ***Histology.*** Early histologic changes include intraepidermal vesicle formation with later focal epidermal keratinocyte necrosis and spongiosis in association with dermal perivascular neutrophil and lymphocyte infiltration.[23]

▲ **FIGURE 90-6** Typical hydroa vacciniforme lesions provoked by repeated ultraviolet A irradiation.

Older lesions show necrosis, ulceration, and scarring. Vasculitic features have been reported in rare cases.[44]

Blood Tests. Blood, urine, and stool porphyrin concentrations should be assessed to exclude cutaneous porphyria, as should the circulating anti-nuclear factor and extractable nuclear antibody titers to exclude the slight possibility of cutaneous lupus.

Phototesting. Phototesting may show reduced minimal erythema doses in short-wavelength UVA in some cases but is not usually able to discriminate from other photodermatoses. Simulated solar irradiation may also induce erythema at reduced irradiation doses or occasionally provoke the typical vesiculation of HV (see Fig. 90-6).

Other Tests. Viral studies to check for herpes infection or other viral disorders should be undertaken if photo-exacerbation or photo-induction of such a disorder seems at all possible.

DIFFERENTIAL DIAGNOSIS See Box 90-3.

COMPLICATIONS Pock scarring is an inevitable accompaniment of HV.

PROGNOSIS AND CLINICAL COURSE HV often resolves in adolescence but may occasionally persist into adult life.

PREVENTION Sun avoidance and sunscreen use, as well as prophylactic phototherapy annually in spring, tend to prevent HV in some patients.

TREATMENT (See eFig. 90-6.1 in on-line edition) The treatment of HV consists of restriction of sun exposure and use of high-protection-factor broad-spectrum sunscreens. Occasionally, antimalarials appear to have helped, but their true value is not established. Similar observations have been made for β-carotene, which in our hands was ineffective in three cases. As with PMLE, prophylactic phototherapy with narrowband UVB or

Box 90-3

- Subacute cutaneous lupus
- Xeroderma pigmentosum

CHRONIC ACTINIC DERMATITIS

AT A GLANCE

- A rare acquired persistent, eczematous, eruption of exposed skin, sometimes with pseudolymphomatous features.
- Affects mostly older men but sometimes young atopic patients and rarely patients with hydroa vacciniforme human immunodeficiency virus infection.
- The histologic features are eczematous, but pseudolymphomatous forms can be virtually indistinguishable from cutaneous T-cell lymphoma.
- Generally induced by small amounts of ultraviolet B irradiation, often also ultraviolet A, and sometimes visible as well; in rare cases induced by ultraviolet A or visible light alone.
- Persistent light reaction, actinic reticuloid, photosensitive eczema, and photosensitivity dermatitis are all considered clinical variants of the same condition (CAD).
- Very likely due to a delayed-type hypersensitivity reaction against endogenous photo-induced epidermal antigen(s).
- Therapy consists of strict avoidance of ultraviolet irradiation, along with topical and intermittent oral steroids use, topical calcineurin inhibitors use, or prolonged low-dose immunosuppressive phototherapy. Oral immunosuppression with cyclosporine or azathioprine is often required.

PUVA, particularly the latter, may be helpful but must be administered with care to avoid disease exacerbation.[44,48,51] If conservative measures are ineffective, however, as often occurs, topical or intermittent oral steroids, topical calcineurin inhibitors, or perhaps oral immunosuppressive medication might be tried if clinically appropriate, though they too are usually ineffective.

Chronic Actinic Dermatitis

HISTORICAL ASPECTS (Table 90-2)

EPIDEMIOLOGY Chronic actinic dermatitis (CAD) has regularly been diagnosed in the United Kingdom, continental Europe, United States, Australia, New Zealand, Japan, and India, and patients from Africa have also been seen. The disorder therefore appears to be of worldwide incidence and to affect all skin types, although it is perhaps more common in temperate regions.

TABLE 90-2
Original Criteria for Eczematous Photosensitivity Disorders

- Persistent light reaction[53]: Eczema of predominantly light-exposed skin sensitive to UVB ± UVA after acute photoallergic contact dermatitis
- Actinic reticuloid[57]: Infiltrated papules and plaques of mainly light-exposed skin with lymphoma-like histologic features and sensitivity to UVB + UVA ± visible light; negative results on photopatch tests
- Photosensitive eczema[58]: Morphologic and histologic eczema of mainly light-exposed skin with photosensitivity only to UVB; negative results on photopatch tests
- Photosensitivity dermatitis[59]: Morphologic and histologic eczema of mainly light-exposed skin with photosensitivity to UVB ± UVA; positive results on photopatch tests in a portion of cases
- Chronic actinic dermatitis[60]: Syndrome encompassing photosensitive eczema, photosensitivity dermatitis, and actinic reticuloid; persistent light reaction also later included

UVA = ultraviolet A radiation; UVB = ultraviolet B radiation.

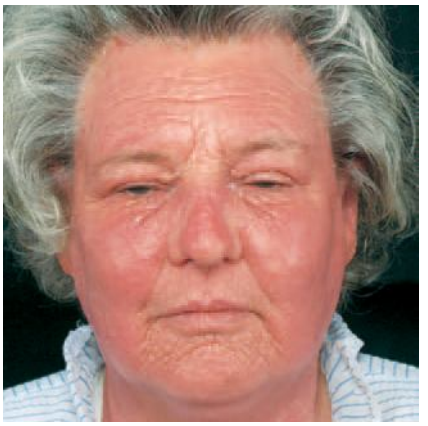
ETIOLOGY AND PATHOGENESIS The likely pathogenesis of CAD has gradually been clarified, although it is not yet fully understood. Detailed studies of its clinical, histologic, and immunohistochemical features all show it precisely to resemble the DTH reaction of allergic contact dermatitis,[62–64] even in its severe pseudolymphomatous form (formerly called *actinic reticuloid*), in which the clinical and histologic features are the same as those seen in long-standing allergic contact dermatitis.[65] It is therefore highly probable that CAD is a similar reaction; however, given that it occurs after irradiation without any contact allergen in place, the reaction is presumably in this instance against photo-induced endogenous skin antigen(s).

Assessment of the action spectrum for CAD should theoretically help identify the postulated antigen, and this has been shown to resemble in shape that for sunburn in many patients.[73] However, the eruption in CAD is eczema, although much lower exposure doses than required for erythema are often needed to evoke the response. Hence, the UVR absorber in such cases may be the same as that implicated in sunburn—namely, UVR-damaged DNA[73]—but in CAD acting as an antigen. In other cases of CAD, however, the photoallergen must be different, because some patients react only to UVA[74] and perhaps a very few others just to visible light.[75]

In summary, CAD appears to be an allergic contact dermatitis–like reaction against UVR-altered DNA or a similar or associated molecule, or more rarely other molecules, perhaps as a result of enhanced immune reactivity due to concomitant airborne contact dermatitis or else reduced immunosuppressive capacity in photodamaged skin, or both, mainly in individuals with long-standing exposure to sunlight and airborne allergens.

CLINICAL FEATURES ***History.*** CAD may arise de novo in apparently normal skin or in the skin of patients with previous endogenous eczema, photoallergic or allergic contact dermatitis, perhaps occasionally oral drug photosensitivity, or rarely PMLE.[64,77] Concurrent allergic contact sensitivity to frequently encountered, often airborne, substances such as plant allergens, fragrances, or sunscreens is also common.[68] The condition usually affects middle-aged or elderly men,[64] occurrence under 50 years of age being unusual except in patients with prior atopic eczema.[69,70] The disorder is worse in summer and often also within minutes to hours of specific sun exposure, demonstrating a pruritic confluent erythematous eruption that occasionally settles over days with scaling if exposure ceases and the condition is mild. However, severely affected patients frequently do not recognize exacerbations with sun exposure, particularly if affected all year round.

Cutaneous Lesions. The lesions in CAD may be patchy or confluent and are eczematous, whether chronic, subacute, or acute (Figs. 90-7 and 90-8). In more severe cases, lichenification is common. More rarely, scattered or widespread erythematous, shiny, infiltrated pseudolymphomatous papules or plaques are present on a background of erythematous, eczematous, or normal skin.[64] Habitually exposed areas are most often affected, commonly with sharp cutoff at lines of clothing, along with sparing particularly of the depths of skin creases, the upper eyelids, the finger webs, and the skin behind the earlobes. In severe dis-

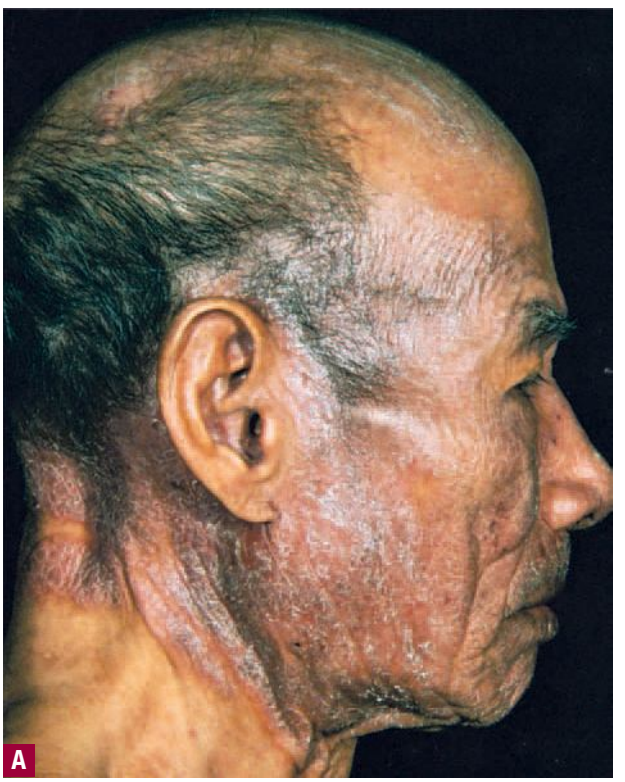


▲ **FIGURE 90-7** Chronic actinic dermatitis. Infiltrated eczematous eruption on the face.

ease, eczema of the palms and soles is also possible; eyebrow, eyelash, and scalp hair may be stubby or lost from constant rubbing and scratching, and erythroderma, usually but not always accentuated on exposed sites, may rarely supervene. Variable, sometimes geographic, sparing of exposed areas of the face or elsewhere, as well as irregular hyperpigmentation and hypopigmentation, sometimes vitiligo-like,[78] may also occasionally occur.

LABORATORY TESTS ***Histology.*** Histologic features include epidermal spongiosis, acanthosis, and sometimes hyperplasia, along with predominantly perivascular lymphocytic cellular infiltration confined to the upper dermis, with milder cases demonstrating just chronic eczema.[23] Severe CAD, however, may histologically mimic cutaneous T-cell lymphoma (CTCL), on occasion being virtually indistinguishable, with epidermal Pautrier-like microabscesses and deep, dense epidermotropic mononuclear cell infiltration, sometimes with hyperchromatic convoluted nuclei and giant cells, but no marked increase in mitoses. T-cell receptor gene rearrangement studies should be undertaken if there is any suspicion of lymphoma.

Blood Tests. Assessment of the circulating anti-nuclear and extractable nuclear antibody titers is advisable in all patients to exclude the unlikely possibility of subacute cutaneous or other form of lupus. In severe or erythrodermic CAD, there may be large numbers of circulating $CD8^+$ Sézary cells without other suggestion of malignancy.[79,80] Human immunodeficiency virus status should be checked if there is any suspicion that this infection may be a predisposing factor.[72]



▲ **FIGURE 90-8** Chronic actinic dermatitis. **A, B.** Severe light-induced eczema of the face and neck. **C, D.** Patient in full remission after low-dose psoralen plus ultraviolet A irradiation over weeks, with initial high-dose oral steroid cover to prevent initial exacerbation.

Phototesting. Phototesting is essential if available to confirm the diagnosis of CAD. Results are virtually always characterized by low erythemal thresholds and eczematous or pseudolymphomatous responses after irradiation with UVB, usually UVA, and rarely also the visible wavelengths.[64] A very small number of patients react only to UVA,[74] and fewer still to only 600-nm visible light,[75] in which case drug photosensitivity must be carefully excluded. Testing should preferably be on uninvolved skin of the back with no topical or systemic steroid therapy for at least the preceding few days to avoid false-negative results.[81] Monochromatic and broad-spectrum sources both induce abnormal responses, with the former determining the action spectrum for disease induction and the latter tending to demonstrate acute eczema.

Patch and Photopatch Testing. Patch and photopatch testing is also essential in suspected CAD, because contact sensitivity to airborne allergens such as Compositae oleoresins, phosphorus sesquisulfide, and colophony alone may closely resemble CAD or else co-exist. In addition, occasional secondary contact or photocontact sensitivity to sunscreens or other topical therapies may further complicate the clinical picture.

DIFFERENTIAL DIAGNOSIS See Box 90-4.

COMPLICATIONS Any relationship to lymphoma seems likely to be coincidental, particularly because the results of T-cell receptor, immunoglobulin gene rearrangement, and other similar studies are negative in CAD.[79,82,83] In addition, CAD gradually resolves in many patients, there is no higher incidence of malignancy in CAD patients than expected, and life expectancy of CAD patients is normal.[84] However, it has been suggested that CTCL itself may very rarely present with severe CAD-like photosensitivity, and careful investigation to exclude CTCL is necessary if that disease is suspected.[85]

Box 90-4

Differential Diagnosis of Chronic Actinic Dermatitis

- Photo-exacerbated atopic or seborrheic eczema
- Drug or chemical photosensitivity
- Cutaneous T-cell lymphoma
- Eczematized actinic prurigo

PROGNOSIS AND CLINICAL COURSE Once established, CAD usually persists for years before not infrequent, very gradual resolution.[85]

TREATMENT (See eFig. 90-8.1 in on-line edition) The treatment of CAD is often difficult and not fully effective. Rigorous avoidance of UVR and exacerbating contact allergens is essential, along with the regular application of high protection-factor broad-spectrum topical sunscreens of low irritancy and allergenic potential. Strong topical steroids such as clobetasol propionate are also often needed and frequently produce marked symptomatic relief without adverse effects, even after long-term use, if confined to affected skin; occasional oral steroid use is often helpful too for disease flares. In more resistant disease, the topical calcineurin inhibitors tacrolimus and pimecrolimus can sometimes produce good results if tolerated.[86,87] For refractory CAD, however, oral immunosuppressive therapy is almost always necessary and generally helpful if tolerated. Azathioprine 1.5 to 2.5 mg/kg/day often produces remission in months,[88] after which it may be reduced in dosage, or perhaps discontinued in the winter. Cyclosporine 3.5 to 5.0 mg/kg/day is usually rapidly effective[89] but is more likely to produce adverse effects, which sometimes necessitate withdrawal. Mycophenolate mofetil is less often useful, whereas thioguanine has been used with good effect by one of the authors. Finally, long-term low-dose phototherapy with PUVA, usually several times weekly initially followed by maintenance exposures every 3 weeks or so, may be helpful,[90] generally accompanied initially by oral and topical steroid therapy to avoid disease flares (Fig. 90-8 C,D).

PREVENTION The risk of CAD development can probably be reduced by the moderation of outdoor pursuits, particularly those associated with plant allergen exposure such as gardening, especially for individuals who already have a tendency to eczematous eruptions in exposed areas.

Solar Urticaria

EPIDEMIOLOGY Solar urticaria (SU) has been reported in Asia, Europe, and the United States, and thus probably occurs worldwide. Perhaps 3.1 per 100,000 of the population are affected.[91]

ETIOLOGY AND PATHOGENESIS Primary SU is an immediate type I hypersensitivity response against cutaneous or circulating photoallergen generated from a precursor at the time of UVR or visible light absorption. Both circulating photoallergen and reaginic antibodies have been demonstrated. Very rarely, secondary SU may occur in association with drug photosensitivity, cutaneous porphyria, or lupus. There appears to be no genetic basis for the primary condition.

Two types of primary SU have been proposed, both involving an immunoglobulin E–mediated hypersensitivity against a photoallergen. In type 1, the photoallergen is generated only in SU patients, whereas in type 2 it is generated in both SU patients and normal individuals.[92] The wide range of responsible inducing wavelengths reported is presumably attributable to their absorption by different photoallergens. Pa-

SOLAR URTICARIA AT A GLANCE

- An uncommon sunlight-induced whealing disorder, slightly more common in females.
- Very rarely, occurs secondary to phototoxic drug use or cutaneous porphyria.
- Attacks occur within 5 to 10 minutes of sun exposure and resolve in an hour or two; they may be severely disabling and, rarely, life-threatening.
- Represents an immediate type I hypersensitivity response against cutaneous or circulating photoallergen(s).
- The histologic features are those of urticaria.
- Phototesting is useful to confirm the diagnosis and determine the action spectrum.
- Sensitivity may be to ultraviolet B, ultraviolet A, visible light, or any combination, but most commonly to ultraviolet A plus visible light.
- In addition to sun avoidance, high protection-factor broad-spectrum sunscreens may help slightly.
- Phototherapy, plasmapheresis, or oral immunosuppressive drugs rarely may help.

tients with type 1 SU appear to have photoallergens of molecular mass 25 to 34 kiloDaltons (kD) and action spectra in the visible region, whereas type 2 SU has photoallergens of 25 to 1000 kD and variable action spectra.[92] The range of eliciting wavelengths can narrow or broaden over months or years.

Mast cell degranulation and histamine release are important in SU,[95] but antihistamine therapy (H_1 or H_2) is not always effective. This suggests that other mediators such as neutrophil and eosinophil chemotactic factors accompanying histamine in the blood from irradiated skin can be important. Thus, the mast cell degranulation is accompanied by neutrophil and eosinophil recruitment and eosinophil major basic protein release, which may all amplify the whealing response.

▲ **FIGURE 90-9** Solar urticaria. Pruritic wheals with a surrounding patchy flare occurring within 15 minutes of sun exposure after irradiation of the patient's back through a template.

CLINICAL FEATURES ***History.*** Primary SU is slightly more common in females and may arise at any age, with the first attack sometimes occurring after marked sunlight or, occasionally, sunbed exposure. It also seems associated with other photosensitive skin disorders more than one might expect.[96] Typically, 5 to 10 minutes or, rarely, 20 to 30 minutes of exposure leads to itching and erythema, followed by patchy or confluent urticarial whealing, with gradual resolution over a maximum of 1 to 2 hours. Very rarely, just itching occurs, or the onset of symptoms may be delayed for up to several hours,[97] or only scattered fixed sites may be affected. In patients with mild disease, or in those who quickly recognize their SU onset and avoid further exposure, whealing may not be reported, even if it is present on phototesting. With extensive whealing, patients may also describe headache, nausea, bronchospasm, and syncope, which rarely may be life-threatening. Secondary SU should be excluded by ruling out drug photosensitivity, cutaneous porphyria, and lupus erythematosus.

Cutaneous Lesions. SU usually affects all exposed skin with an initial macular erythema, generally but not always followed rapidly by whealing and a surrounding patchy erythematous flare (Fig. 90-9), often with clear demarcation at lines of clothing. Rarely, there is sparing of the face and hands as a result of UVR-induced tolerance, or only fixed sites may be affected.

LABORATORY TESTS ***Histology.*** There is dermal vasodilation, edema, and predominantly perivascular neutrophil and eosinophil infiltration at 5 minutes and at 2, but not 24, hours.[23] Endothelial cell swelling occurs early on, with mononuclear cell infiltration later at higher irradiation doses. Extensive eosinophil granule major basic protein deposition is also present in the dermis at 2 and 24 hours, which suggests eosinophil degranulation.[98]

Blood Tests. The circulating anti-nuclear factor and extractable nuclear antibody titers should be assessed to exclude cutaneous lupus, as should the blood, urine, and stool porphyrin concentrations to exclude cutaneous porphyria, both very rare causes of SU.

Phototesting. Phototesting with a monochromator, broad-spectrum source, or sunlight allows confirmation of the diagnosis of SU and identification of the inducing wavelengths. However, negative phototest results do not necessarily exclude the disorder, because the ease of SU induction, particularly in mild cases, may vary. If no monochromator is available, appropriately filtered broadband sources can be used instead, and minimal urticarial dose estimation may help in assessing treatment efficacy.

DIFFERENTIAL DIAGNOSIS See Box 90-5.

COMPLICATIONS Severe primary SU may lead to vascular collapse and is very rarely fatal. The rare secondary SU related to drug or chemical photosensitivity, cutaneous porphyria, or cutaneous lupus may be associated with the complications of the primary conditions.

COURSE AND PROGNOSIS SU often persists indefinitely, sometimes with deterioration but also sometimes with improvement, with a probability of clinical resolution at 5 and 10 years of 12 percent and 26 percent, respectively.[91]

TREATMENT (See eFig. 90-9.1 in on-line edition) Restriction of sun exposure, use of high protection-factor broad-spectrum sunscreen, and appropriate clothing cover may be helpful for UVA-sensitive but generally not visible light–induced SU. Dark-colored clothing offers better protection than light-colored. The use of non-sedating H_1 antagonists, often in higher-than-normal dosages, which are best taken an hour or so before expected exposure and probably not helped by concurrent H_2 use, are very effective in about a third of patients and partially effective in another third. Otherwise therapy is difficult, but phototherapy may be helpful for uncer-

Box 90-5

Differential Diagnosis of Solar Urticaria (SU)

- Polymorphic light eruption (may rarely co-exist)
- Subacute cutaneous lupus (may rarely co-exist and may cause secondary SU)
- Photo-exacerbated dermatoses such as atopic or seborrheic eczema
- Erythropoietic protoporphyria (very rarely may cause secondary SU)
- Hepatic porphyrias (very rarely may cause secondary SU)
- Drug or chemical photosensitivity (very rarely may cause secondary SU)

TABLE 90-3
Selection of Diseases Sometimes Exacerbated by Ultraviolet Irradiation

- Acne
- Atopic eczema
- Carcinoid syndrome
- Cutaneous T-cell lymphoma
- Dermatomyositis
- Disseminated superficial actinic porokeratosis
- Erythema multiforme
- Familial benign chronic pemphigus (Hailey-Hailey disease)
- Keratosis follicularis (Darier disease)
- Lichen planus
- Lupus erythematosus
- Pellagra
- Pemphigus foliaceus (erythematosus)
- Pityriasis rubra pilaris
- Psoriasis
- Reticulate erythematous mucinosis syndrome
- Rosacea
- Seborrheic eczema
- Transient acantholytic dermatosis (Grover disease)
- Viral infections

tain reasons in patients who develop SU tolerance as summer advances and also sometimes in those with persistent disease, although the therapy then generally needs to be continued to maintain efficacy and consequently carries a risk of long-term adverse effects. Such phototherapy should also be undertaken with extreme care early on to avoid any risk of anaphylaxis, particularly in severely affected individuals.[98] Multiple UVA exposures with increasing doses during the same day (so-called *rush hardening*) have helped some patients.[99] Others respond to plasma exchange, or plasmapheresis, particularly if found to have a circulating SU-associated serum factor, and remissions in some cases are long-lived.[100,101] Intravenous immunoglobulin has also been helpful on occasion,[102] as has oral cyclosporine.

PHOTO-EXACERBATED DERMATOSES

Several dermatoses that are not actually induced by UVR may be worsened by it (Table 90-3). Mechanisms of this photoexacerbation have only occasionally been investigated. The initial condition may be severely worsened even if it was originally only mild or sub-clinical.[103,104] These disorders are relatively common and account for a significant proportion of all photodermatoses in some countries.[5] Such conditions, particularly the eczemas, psoriasis, and acne, improve with UVR exposure in most patients, perhaps because skin immune reactivity generally is reduced, but in a small proportion of individuals, it is instead significantly aggravated.[13] If photo-exacerbation does occur, the new eruption generally develops or worsens initially at sites typical of the basic disorder (Fig. 90-10), followed sometimes by spread to many other or all exposed areas. In photo-exacerbated seborrheic eczema, however, an unpleasant sensation at the exposed sites may be the first or only feature. Treatment consists of minimization of UVR exposure, protection by suitable clothing, application of high protection-factor broad-spectrum sunscreens, and particularly very careful treatment of the basic disorder, even if it is otherwise mild or sub-clinical. This specifically includes the daily use of an anti-eczema shampoo in seborrheic eczema. Taking these steps alone frequently, if perhaps surprisingly, totally aborts the photosensitivity.[103] If these actions are inadequate, low-dose phototherapy as for PMLE can sometimes help, for example in seborrheic or atopic eczema and psoriasis, but its use is contraindicated in cutaneous lupus or dermatomyositis,[105] in which possible aggravation of systemic disease is a significant risk. Photo-exacerbated acne generally requires oral isotretinoin.[104]

APPROACH TO THE PATIENT WITH ABNORMAL SKIN PHOTOSENSITIVITY

Clinical Features

Patients with abnormal skin photosensitivity present in one of three ways: with sporadic or persistent eruptions of habitually light-exposed areas, or, infrequently, erythroderma. In sporadic cases, patients themselves usually consider the eruption to be due to sun exposure; however, in all cases careful history taking is essential, first to confirm that light exposure is probably responsible and then to clarify the likely precise diagnosis. The patient information that is usually most important in this exercise are age at disease onset, gender, family history, any previous sunlight sensitivity, occupation, leisure pursuits, and systemic or topical drug or chemical use. Important details concerning the eruption are its seasonal behavior, exposure time required for its induction, time between exposure and

▲ **FIGURE 90-10** Photo-exacerbated seborrheic dermatitis, affecting the face only at sites of predilection for the seborrheic eruption.

lesion appearance, duration of the eruption, development after exposure through window glass or clothing, any systemic symptoms, patient-assessed morphology, and distribution of lesions. For example, mostly young women develop PMLE; women or girls develop AP; children of either gender may have HV, xeroderma pigmentosum (XP), or erythropoietic protoporphyria (EPP); and elderly males or younger individuals with atopic eczema develop CAD. A family history of sunlight sensitivity may be present in patients with PMLE, AP, XP, and the porphyrias. CAD is more common in open air enthusiasts exposed both to sunlight and airborne allergens, whereas disease worsening despite sunscreen use brings to mind a possible sunscreen allergy, although such exacerbation may also occur without allergy in PMLE. A rash appearing in minutes and settling in an hour or two strongly suggests SU or occasionally photosensitivity to drugs such as previously amiodarone. Onset within 20 minutes to several hours with resolution over days suggests PMLE, HV, EPP, XP, subacute cutaneous lupus, other photo-exacerbated dermatoses, or other drug photosensitivity, such as to thiazides. Systemic malaise rarely occurs in PMLE, HV, SU, or cutaneous lupus. Development of lesions after exposure through window glass or clothing indicates a disease induction spectrum that includes UVA, although this may occur in virtually all photodermatoses except XP.

The rash appearance described by patients with PMLE is generally of small or large, elevated, itchy, red or skin-colored, and often clumped spots or blisters, sometimes confluent, that usually involve only some exposed sites. In HV, blistering with permanent scar formation occurs, and in SU elevated itchy wheals, which are often confluent. In EPP and amiodarone drug photosensitivity, a marked burning sensation without visible change is reported, whereas lengthy exposure may lead to firm, colorless or pink, diffuse swelling, rarely with scattered blisters in EPP. In most other drug photosensitivity reactions and often XP, an exaggerated sunburn-like reaction is possible, which is often maximal in XP at 2 to 3 days. In photo-exacerbated dermatoses, the rash generally resembles that of the primary disorder, although in subacute cutaneous lupus, concomitant PMLE may also occur in rare cases.

Any photosensitive eruption is normally present on some, and occasionally all, of the forehead, nose, upper cheeks, tip of the chin, rims of the pinnae, back and sides of the neck, upper chest, backs of the hands and feet, and extensor aspects of the limbs. Covered areas may also be involved to a lesser degree. On the other hand, the forehead protected by the hair fringe, upper eyelids, finger webs, skin creases, and skin under the nose, lower lip, chin, and earlobes are frequently unaffected except occasionally by associated airborne contact dermatitis. Excoriated papules suggest AP, whereas eczema, or very rarely a light-associated erythroderma, suggests CAD or photo-exacerbated atopic or seborrheic eczema, whereas skin fragility, bulla formation, and atrophic superficial scarring suggest a hepatic porphyria or pseudoporphyria, especially if there has been drug or excessive alcohol intake or regular sunbed use.

After such a clinical appraisal, the diagnosis of any causative photodermatosis is often largely clear, but for complete certainty, at least some further investigation as outlined below is needed.

TABLE 90-4
Usual Monochromatic Phototest Responses in Idiopathic, Probably Immunologic Photodermatoses

Disease	Action Spectrum	Frequency of Abnormal Findings
Polymorphic light eruption	UVA more often than UVB	Only sometimes
Actinic prurigo	UVA more often than UVB	Only sometimes
Hydroa vacciniforme	More often UVA	Only sometimes
Chronic actinic dermatitis	UVB ± UVA ± visible light	Virtually always
Solar urticaria	UVB, UVA, or visible, or combination	Usual
Xeroderma pigmentosum	UVB	Usual
Photo-exacerbated dermatoses	UVB, UVA, or combination	Rare

UVA = ultraviolet A light; UVB = ultraviolet B light.

Laboratory Studies

Unless diagnosis is certain, important investigations for all photosensitive conditions are the assessment of circulating anti-nuclear factor and extractable nuclear antibody titers, and usually also blood, urine, and stool porphyrin concentrations. Lesional histologic features are characteristic in many photodermatoses, particularly in PMLE, HV, and CAD, but except in HV are rarely diagnostic. Direct immunofluorescence may assist diagnosis in cutaneous lupus. Phototesting of normal back skin with an irradiation monochromator in CAD and SU often produces the papules or wheals of the condition itself, frequently at low irradiation doses, and defines the eruption action spectrum. It also often helps confirm XP through the delayed development of erythema over 2 to 3 days with an abnormally low dose threshold, often with eventual blistering (Table 90-4). However, this testing is only moderately reliable in the other disorders, although solar simulating or other broadband irradiation may induce the rash to aid diagnosis. In eczematous photosensitivity, patch and photopatch testing are also essential to identify any inducing or exacerbating allergens. Finally, special techniques such as the assessment of DNA excision repair or of the RNA synthesis recovery rate in cultured patient fibroblasts after UVR exposure are essential for the diagnosis of certain genophotodermatoses.

PHOTOTESTING The use of phototesting in clinical dermatology varies greatly from country to country and center to center. Although it is the investigation of choice for photodermatoses when the diagnosis is uncertain or when details of the inducing action spectrum are required, it remains primarily a research tool restricted to a small number of clinical centers.

Essentially the skin phototesting of a patient suspected to have a photodermatosis falls into two categories. Monochromatic phototesting of the skin of the upper back at a series of wavelengths and doses is performed to elicit the eruption when possible and to identify the inducing action spectrum of the disorder, and photoprovocation testing with a broad-spectrum source is performed purely to induce the eruption for clinical diagnosis and biopsy if necessary. Table 90-4 lists the disorders for which monochromatic testing is likely to be helpful.

For precise definition of the wavelength dependency of the disorder, monochromatic testing should be conducted, preferably with a xenon arc irradiation monochromator, whereas for

photoprovocation testing, the favored device is a solar simulator, usually a xenon arc–filtered source that produces a spectrum closely resembling that of terrestrial sunlight at noon on a midsummer's day in temperate regions. Several suitable protocols have also been described for using simple broad-spectrum metal halide or fluorescent light sources with filters if necessary, and in some parts of the world, sunlight with filters has also been used, although this method is generally too unpredictable for clinical use.[105,106]

Monochromatic phototesting is preferably performed on unaffected skin of the upper back lateral to the paravertebral groove (see eFigs. 90-10.1 and 90-10.2 in on-line edition), whereas lesion induction, except when relatively easy with the monochromator as in SU and CAD, is best undertaken using broadband sources with output directed over larger areas of skin known to be susceptible to the eruption. PMLE, AP, and HV are conditions in which repeated irradiation with UVA- or UVB-emitting or combined sources is often required to produce the abnormal morphology (see eFig. 90-10.3 in on-line edition).

It is important that the use of potent topical and systemic steroids be avoided when possible for at least several days before phototesting to prevent false-negative results. It is not certain if other oral immunosuppressive agents affect testing as well, but they should also preferably be stopped. False-positive results may also occur in patients with widespread disease, and the eruption should first be well controlled whenever possible, if necessary by keeping the patient in a reduced-light setting. However, it is often difficult to fulfill these requirements if the eruption is active, and in such circumstances, testing may need to be undertaken with the knowledge that the results may possibly be unreliable.

All phototesting should be undertaken at carefully standardized sequential doses (often a geometrical series) and wavelengths, and the results read at consistent times after exposure in carefully controlled conditions of light and temperature. Furthermore, because such irradiation involves UVR exposure, potentially noxious to both skin and eyes, the patient—and particularly the repeatedly exposed investigator—should be protected throughout by appropriate clothing or other shielding and goggles.

PHOTOPATCH TESTING (See Chap. 91) Photopatch testing is a well-established investigation designed to identify photoallergic contact dermatitis, although it can also be used to help define potential phototoxic agents. It is essentially a more complex version of patch testing and is used in patients with apparent exposed-site eczema, whether or not they also have another photodermatosis, to determine if photoallergy is present.

The methodology of photopatch testing has not received the attention it deserves. Historically this has been because it has fallen between the two subspecialty areas of photodermatology and contact dermatology. In an attempt to solve this problem, therefore, earlier standardization attempts[106,107] have now been formalized in Europe with the development of a consensus methodology.[108]

In this approach, the application of test materials—usually sunscreens, topical nonsteroidal and anti-inflammatory agents, and any other possible causative agents—are applied in duplicate for 24 or 48 hours. One set of test sites is then irradiated with a broad-spectrum UVA source, usually with a 5 J/cm^2 beam from fluorescent PUVA lamps, and the results read 24 and 48 hours later. A strongly positive reaction at the sites exposed to both chemical agent and light and no reaction at the dark control sites allows a diagnosis of photoallergy (see eFig. 90-10.4 in on-line edition). Occasionally, however, an exacerbation of contact irritation or allergy occurs instead or as well, and careful interpretation is always required. Furthermore, current information concerning possible photoallergens is haphazard and based on scattered, anecdotal reports, so there is a major need for careful multicenter studies. In particular, if any new chemical is suspected of photoallergenicity, phototoxicity should first be excluded by studying it in normal volunteers.

CHAPTER 91

Abnormal Responses to Ultraviolet Radiation: Photosensitivity Induced by Exogenous Agents

Henry W. Lim

Photosensitivity may be caused by exogenous or endogenous agents. It occurs when a compound, classically one with unsaturated double bonds in a six-carbon ring, absorbs radiation energy in its action spectrum, usually ultraviolet A (UVA) wavelengths. Exogenous photosensitizers can be agents administered systemically or applied topically. Well-characterized examples of photosensitivity induced by endogenous photosensitizers are the porphyrias, which are associated with enzymatic defects in heme biosynthetic pathways that result in elevated levels of porphyrins, known phototoxic agents (see Chap. 132).

Photosensitivity induced by exogenous agents can be divided into phototoxicity and photoallergy. Phototoxicity is the result of direct tissue injury caused by the phototoxic agent and radiation. It can occur in all individuals exposed to adequate doses of the agent and the activating wavelengths of radiation (Table 91-1). In contrast, photoallergy is a type IV delayed hypersensitivity response to a molecule that has been modified by absorption of light energy. It has a sensitization phase, occurs only in sensitized individuals, and requires only a minimal concentration of the photoallergen (see Table 91-1).

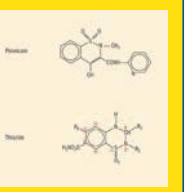
TABLE 91-2
Topical Phototoxic Agents

AGENT	EXPOSURE
Rose bengal	Used in ophthalmologic examinations
Furocoumarins	Occur naturally in plants (especially Compositae species), including fruits and vegetables (lime, lemon, celery, fig, parsley, and parsnip); used in topical photochemotherapy
Tar	Used as topical therapeutic agent; found in roofing materials

INCIDENCE

Almost 400 medications in the United States have been reported to cause photosensitivity. Only a small number of them, however, induce reactions frequently or have been well studied (Tables 91-2, 91-3, 91-4, and 91-5). In evaluations performed at photodermatology centers in New York City, Melbourne, Singapore, and Detroit, documented photosensitivity induced by a systemic drug occurred in from 5 percent to 15 percent of the referred patients.[1–4] In studies performed in the United States, United Kingdom, Europe, and Australia, the percentage of photopatch-tested patients who had clinically relevant reactions leading to a diagnosis of photoallergic contact dermatitis ranged from 1.4 percent to 12.0 percent, with the value in most series being around 10 percent.[5–10]

ABNORMAL RESPONSES TO ULTRAVIOLET RADIATION AT A GLANCE



- Photosensitivity is broadly divided into phototoxicity and photoallergy, caused by topical or systemic agents that absorb ultraviolet A (UVA) energy.
- Phototoxicity occurs in anyone exposed to sufficient drug and UV radiation and usually manifests as an exaggerated sunburn reaction.
- Photoallergy is an immune reaction to a UVA-modified chemical, commonly topical sunscreen agents in the United States and the United Kingdom and topical nonsteroidal anti-inflammatory agents in Europe. It presents as eczematous eruption on photo-exposed areas.
- History taking is an important part of the evaluation; phototesting and photopatch testing are helpful.
- Differential diagnosis includes contact allergic or contact irritant dermatitis, airborne contact dermatitis, and other photodermatoses.
- Management consists of identification and avoidance of the precipitating agent, photoprotection, and symptomatic therapy.

TABLE 91-1
Characteristics of Phototoxicity and Photoallergy

	PHOTOTOXICITY	PHOTOALLERGY
Clinical presentation	Exaggerated sunburn reaction: erythema, edema, vesicles, and bullae; burning, stinging; frequently resolves with hyperpigmentation	A "rash," usually eczematous lesions and usually pruritic
Histologic features	Necrotic keratinocytes, epidermal degeneration; sparse dermal infiltrate of lymphocytes, macrophages, and neutrophils	Spongiotic dermatitis, dermal lymphohistiocytic infiltrate
Pathophysiology	Direct tissue injury	Type IV delayed hypersensitivity response
Occurrence after first exposure	Yes	No
Onset after exposure	Minutes to hours	24 to 48 h
Dose of agent needed for reaction	Large	Small
Cross-reactivity with other agents	None	Common
Diagnosis		
Topical agent	Clinical	Photopatch tests
Systemic agent	Clinical + phototests	Clinical + phototests; possibly photopatch tests

TABLE 91-3
Systemic Phototoxic Agents

Class	Generic Name (U.S. Trade Name)[a]
Antianxiety drugs	Alprazolam (Xanax)
	Chlordiazepoxide (Librax, Librium, Limbitrol)
Anticancer drugs	Dacarbazine (DTIC-Dome)
	Fluorouracil (Adrucil)
	Methotrexate (Rheumatrex)
	Vinblastine (Velban)
Antidepressants	Tricyclics
	Amitriptyline (Elavil, Limbitrol, Triavil)
	Desipramine (Norpramin)
	Imipramine (Tofranil)
Antifungal	Griseofulvin (Fulvicin, Grifulvin V, Gris-PEG)[b]
Antimalarials	Chloroquine (Aralen)
	Quinine (Formula-Q, M-KYA, Quiphile, Q-Vel)[b]
Antimicrobials	Quinolones
	Ciprofloxacin (Cipro)
	Enoxacin (Penetrex)[b]
	Gemifloxacin (Factive)
	Lomefloxacin (Maxaquin)[b,c]
	Moxifloxacin (Avelox)
	Nalidixic acid (NegGram)[b,c]
	Norfloxacin (Chibroxin, Noroxin)
	Ofloxacin (Floxin, Ocuflox)
	Sparfloxacin (Zagam)[c]
	Sulfonamides[b]
	Tetracyclines
	Demeclocycline (Declomycin)[c]
	Doxycycline (Adoxa, Doryx, Monodox, Periostat, Vibra-Tabs, Vibramycin)[c]
	Minocycline (Arestin, Dynacin, Minocin)
	Tetracycline (Helidac, Sumycin)
	Trimethoprim (Bactrim, Polytrim, Primsol, Septra)
Antipsychotic drugs	Phenothiazines
	Chlorpromazine (Thorazine)[c]
	Perphenazine (Triavil, Trilafon)
	Prochlorperazine (Compazine)[c]
	Thioridazine (Mellaril)
	Trifluoperazine (Stelazine)
Cardiac medications	Amiodarone (Cordarone, Pacerone)[c]
	Quinidine (Quinaglute, Quinidex)[b]
Diuretics	Furosemide (Lasix)[c]
	Thiazides
	Bendroflumethiazide (Corzide)
	Chlorothiazide (Aldoclor, Diuril)[c]
	Hydrochlorothiazide (Accuretic, Aldactazide, Aldoril, Atacand, Avalide, Capozide, Diovan, Dyazide, Hyzaar, Inderide, Lopressor, Lotensin, Maxzide, Micardis, Microzide, Moduretic, Prinzide, Teveten HCT, Uniretic, Vaseretic, Zestoretic, Ziac)[c]
Dye	Fluorescein (AK-Fluor, Fluor-I-Strip, Fluorescite)
	Methylene blue (Urised)
Furocoumarins	Psoralens
	5-Methoxypsoralen[c]
	8-Methoxypsoralen (Oxsoralen-Ultra)[c]
	4,5′,8-Trimethylpsoralen[c]
Hypoglycemics	Sulfonylureas
	Acetohexamide (Dymelor)
	Chlorpropamide (Diabinese)
	Glipizide (Glucotrol, Metaglip)
	Glyburide (DiaBeta, Glucovance, Glynase PresTab, Micronase)
	Tolazamide (Tolinase)
	Tolbutamide (Orinase)[c]
Nonsteroidal anti-inflammatory drugs	Acetic acid derivative
	Diclofenac (Arthrotec, Cataflam, Voltaren)
	Alkanone derivative
	Nabumetone (Relafen)[c]
	Anthranilic acid derivative
	Mefenamic acid (Ponstel)
	Cyclooxygenase 2 inhibitor
	Celecoxib (Celebrex)
	Enolic acid derivative
	Piroxicam (Feldene)[b,c]
	Propionic acid derivatives
	Ibuprofen (Advil, Motrin, Nuprin, Vicoprofen)
	Ketoprofen (Orudis, Oruvail)
	Naproxen (Aleve, Naprelan, Naprosyn)[c]
	Oxaprozin (Daypro)
	Tiaprofenic acid
	Salicylic acid derivative
	Diflunisal (Dolobid)
Photodynamic therapy agents	Porfimer (Photofrin)[c]
	Verteporfin (Visudyne)[c]
Retinoids[d]	Acitretin (Soriatane)
	Isotretinoin (Accutane)
	Etretinate
Other	Flutamide (Eulexin)
	Hypericin (St. John's wort)
	Pyridoxine (vitamin B_6)
	Ranitidine (Zantac)

[a]Although it is the policy not to use trade names in this book, exceptions are made in cases in which we consider this information essential.—*The Editors*
[b]Also reported as a systemic photoallergen.
[c]Commonly reported.
[d]Thinning of the epidermis plays a major role.

PHOTOTOXICITY

Pathophysiology

Several pathways eventuate in the development of phototoxic tissue damage, and for many phototoxic agents, more than one pathway is responsible.

PHOTODYNAMIC PROCESSES On absorption of radiation energy by the photosensitizer (P) at its ground state, formation of an excited (usually triplet) state (^3P) molecule occurs. The excited state molecule may then participate in oxygen-dependent processes (i.e., photodynamic processes) via two major pathways, type I and type II reactions,

TABLE 91-4
Topical Photoallergens

Group	Chemical Name (USAN/Trade Name[a])
Sunscreens (see Chap. 223)	Benzophenones
	Benzophenone-3 (oxybenzone)[b]
	Benzophenone-4 (sulisobenzone)
	PABA derivatives
	Amyl dimethyl PABA (padimate A)[b]
	Ethylhexyl dimethyl PABA (padimate O)[b]
	PABA[b]
	Cinnamates
	Ethylhexyl methoxycinnamate (octinoxate)
	Cinoxate (cinoxate)
	Salicylate
	Benzyl salicylate
	Others
	Butyl methoxydibenzoylmethane (avobenzone, Parsol 1789)[b]
	Menthyl anthranilate (meradimate)
	Octocrylene (octocrylene)
	Octyl triazone
	Phenylbenzimidazole sulfonic acid (ensulizole)
Fragrances	6-Methylcoumarin[b]
	Musk ambrette[b]
	Sandalwood oil
Anti-infective agents	Surface disinfectants: halogenated salicylanilides
	Dibromosalicylanilide (dibromsalan, DBS)[b]
	Tetrochlorosalicylanilide (Irgasan BS200)[b]
	Tribromosalicylanilide (tribromsalan, TBS)[b]
	Skin cleansers
	Chlorhexidine (Hibiclens)
	Hexachlorophene (pHisoHex)
	Pesticides
	Bithionol (thiobis-dichlorophenol)[b]
	Dichlorophene (G4, Korium, Teniatol)
	Dimethylol dimethyl hydantoin
	Fenticlor (bis-hydroxy-chlorophenyl sulfide)[b]
	Personal care products
	Triclosan (Irgasan DP300, Microban, Lexol 300)
	Topical antifungals
	Buclosamide (Jadit, butylchlorosalicylamide)
	Multifungin (bromochlorosalicylanilide, BCSA)
Others	Antibiotic for cattle
	Olaquindox[b]
	Nonsteroidal anti-inflammatory agents (topical)
	Etofenamate

[b]Commonly reported to be photoallergens.

both of which result in cytotoxic injury.[11]

The type I reaction involves transfer of an electron or a hydrogen atom to the excited state photosensitizer (^3P), which results in the formation of free radicals (Eq. 1). These may then participate in an oxidation-reduction reaction that results in peroxide formation and subsequent cell damage (Eqs. 2 and 3).

$$^3P + RH \rightarrow PH\cdot + R\cdot \quad (1)$$

$$PH\cdot + PH\cdot \rightarrow P + PH_2 \quad (2)$$

$$PH_2 + O_2 \rightarrow P + H_2O_2 \quad (3)$$

Alternatively, interaction of ^3P with ground state oxygen could result in the formation of superoxide anion (O_2^-), which, in turn, can be converted into highly reactive and cytotoxic hydroxyl radicals (OH·).

The type II reaction is also known as an *energy transfer process*. Transfer of energy to ground state oxygen results in the formation of singlet oxygen ($^1O_2$), which is highly reactive and has a lifetime of 50 nsec (Eq. 4):

$$^3P + O_2 \rightarrow P + {}^1O_2 \quad (4)$$

Cytotoxic injury occurs upon singlet oxygen–induced oxidation of amino acids and unsaturated fatty acids; interaction with the latter results in the formation of hydroperoxides, which initiate lipid and protein oxidation.

triptyline, imipramine, sulfonylureas, hydrochlorothiazide, furosemide, and chlorpromazine[13] are examples of photodynamic phototoxic reactions.

GENERATION OF PHOTOPRODUCTS Exposure to radiation may result in the generation of stable photoproducts that are responsible for tissue injury. Phototoxic products have been demonstrated on irradiation of phenothiazines, chlorpromazine, tetracyclines, quinolones, and nonsteroidal anti-inflammatory agents.[14]

BINDING TO SUBSTRATE Another mechanism of phototoxicity is radiation-mediated binding of the photosensitizer to its biologic substrate. A photoaddition reaction occurs when the excited state molecule covalently binds to a ground state molecule. An example is the covalent binding of 8-methoxypsoralen to pyrimidine bases of the DNA molecules, which results in the formation of a cross-link between the DNA strands.

INFLAMMATORY MEDIATORS Mediators of inflammation and inflammatory cells participate in phototoxic tissue injury. Biologically active products of complement activation, mast cell–derived mediators, eicosanoids, proteases, and polymorphonuclear leukocytes contribute to the development of phototoxicity induced by porphyrins, demeclocycline, and chlorpromazine.[15]

APOPTOSIS Photodynamic therapy (PDT) involves the use of a photosensitizer and electromagnetic radiation to treat pre-malignant and malignant skin conditions. In addition to generating reactive oxygen species, which results in cytotoxicity, PDT also is a potent inducer of apoptosis.[16]

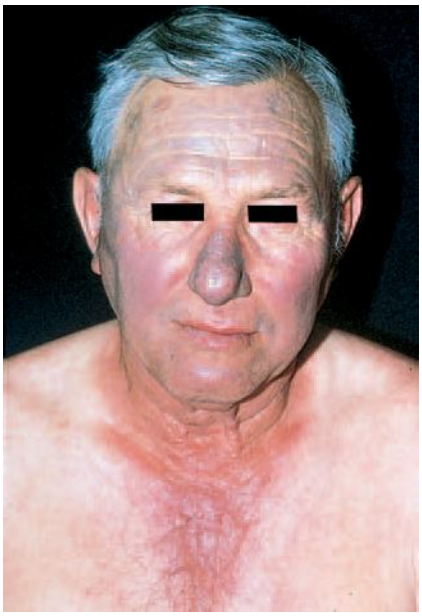
Clinical Manifestations

ACUTE PHOTOTOXICITY (See Table 91-1) Acute phototoxicity usually occurs within hours of exposure to the phototoxic agent and UV radiation. Symptoms are drug-dose and UV-dose dependent, but at sufficient doses, the patient complains of a burning and stinging sensation on exposed areas, such as forehead, nose, V area of the neck, and dorsa of the hands. Erythema and edema may appear within hours of exposure; in severe cases, vesicles and bullae may develop. Protected areas, such as nasolabial folds, postauricular and submental areas, and areas covered by clothing, are spared (Fig. 91-1). A notable exception to these kinetics is psoralen-induced phototoxicity, in which often the acute response first appears after 24 hours, and peaks at 48 to 72 hours, which is the rationale for administering psoralen plus UVA (PUVA) photochemotherapy doses 48 to 72 hours apart. The phototoxic response usually resolves with a varying degree of hyperpigmentation, which may last for months. At lower drug/UV doses, gradual tanning only, without preceding sunburn-like reaction, can be seen.

▲ **FIGURE 91-1** Phototoxicity associated with a heterocyclic antidepressant. Note erythema and edema on sun-exposed areas and sparing of sun-protected chest and shaded upper lip and neck. (Used with permission from Dr. Adrian Tanew.)

PHOTO-ONYCHOLYSIS Separation of the distal nail from the nail bed is a manifestation of acute phototoxicity, with the nail plate serving as a lens to focus UV energy on the nail bed. It has been reported with doxycycline and other tetracyclines, fluoroquinolones, psoralens, benoxaprofen, clorazepate dipotassium, and quinine (Fig. 91-2).[17]

▲ **FIGURE 91-2** Distal onycholysis in a patient receiving psoralen plus ultraviolet A therapy.



▲ **FIGURE 91-3** Amiodarone-induced phototoxicity. Note the erythema and slate-gray pigmentation (nose, forehead) on the sun-exposed area.

SLATE-GRAY PIGMENTATION Blue-gray pigmentation on sun-exposed areas has been associated with exposure to several agents.[18,19] One percent to 10 percent of patients taking amiodarone develop this side effect (Fig. 91-3). Chlorpromazine can induce a similar change. The tricyclic antidepressants imipramine and, less commonly, desipramine have also been reported to cause slate-gray pigmentation. A drug metabolite–melanin complex has been postulated to be the cause of this alteration. Chronic exposure to diltiazem, a benzothiazepine calcium channel blocker, has resulted in photodistributed, reticulated, slate-gray pigmentation (Fig. 91-4). Pigmentary incontinence and melanosome complexes are the prominent histologic and electron microscopic findings. Slate-gray pigmentation seen in argyria involves the nail lunulae, mucous membranes, and sclerae. A photochemical reaction in which silver granules are deposited in the dermis results in these pigmentary alterations.

LICHENOID ERUPTION Lichenoid eruption has been reported but is controversial.

PSEUDOPORPHYRIA The development of porphyria cutanea tarda–like cutaneous changes of skin fragility, vesicles, and sub-epidermal blisters is associated with

▲ **FIGURE 91-4** Slate-gray, reticulated patches on sun-exposed areas in a patient taking diltiazem. Note the sparing of the postauricular area and skinfolds on the neck.

several phototoxic agents (see Chaps. 132 and 151). Although histologic and immunofluorescence findings are similar to those of porphyria cutanea tarda, the porphyrin profile is normal or in the upper range of normal in these patients. Naproxen is the most commonly reported causative agent. Other drugs incriminated include amiodarone, β-lactam antibiotics, celecoxib, cyclosporine, diflunisal, etretinate, furosemide, nabumetone, nalidixic acid, oral contraceptives, oxaprozin, ketoprofen, mefenamic acid, rofecoxib (withdrawn from the U.S. market in September 2004), the tetracyclines, tiaprofenic acid, and voriconazole.[21,22]

PHOTODISTRIBUTED TELANGIECTASIA Telangiectasia on sun-exposed areas has been reported with calcium channel blockers, including nifedipine, amlodipine, felodipine, and diltiazem, and with the antibiotic cefotaxime. In some of these patients, provocation with UVA resulted in the development of telangiectasia.[23]

PERSISTENCE OF PHOTOSENSITIVITY AND EVOLUTION TO CHRONIC ACTINIC DERMATITIS Although phototoxicity usually resolves after discontinuation of the causative agent, there are reports of persistence of photosensitivity for many years after the cessation of exposure, which results in the development of chronic actinic dermatitis (see Photoallergy). This has been reported most often with dexamethahexachlorine, an ingredient previously found in some spas, but also with thiazides, quinidine, quinine, and amiodarone.[24]

CHRONIC EFFECTS Cutaneous effects of long-term, repeated phototoxic tissue injury are best exemplified by the manifestations in patients who have received long-term PUVA photochemotherapy, which is known to affect DNA. These effects include premature aging of the skin, lentigines, squamous cell and basal cell carcinomas, and melanoma. These are discussed in greater detail in Chap. 239.

Phototoxic Agents

TOPICAL AGENTS Table 91-2 lists the major topical phototoxic agents. Therapeutic or occupational exposures to these agents are the common route of contact. The action spectrum is in the UVA or visible light range.

Furocoumarins. Topical exposures to furocoumarins may occur in individuals in certain occupations (bartenders, salad chefs, gardeners) and in patients receiving topical photochemotherapy with psoralens. Such exposures were reported in the past among users of tanning preparations or perfumes containing 5-methoxypsoralen (bergapten), but these preparations have been withdrawn from the market.

Tar. Crude coal tar used in dermatologic therapy is the product of the destructive distillation of coal. It is a complex mixture of over 10,000 compounds, including many phototoxic polyaromatic hydrocarbons that produce a burning and stinging sensation on exposure to UVA ("tar smarts"). Occupational exposure to tar is associated with increased risk of non-melanoma skin cancers, in addition to phototoxicity, although the carcinogenicity of coal tar used in dermatologic therapy remains controversial.

SYSTEMIC AGENTS Table 91-3 lists the major systemic phototoxic agents.[25–53] They commonly produce an exaggerated sunburn reaction but like most phototoxins may also induce an eczematous photoallergic response in a small percentage of users, especially after topical exposure. As a rule, the action spectra are in the UVA range; exceptions include the sulfonamides and ranitidine, whose action spectra are in the UVB range, and the porphyrins, fluorescein, and other dyes, whose action spectra are in the visible light range.

Histopathology

Acute phototoxicity is characterized by individual necrotic keratinocytes and, in severe cases, epidermal necrosis (see Table 91-1). There may be epidermal spongiosis, dermal edema, and a mild infiltrate consisting of neutrophils, lymphocytes, and macrophages. Slate-gray pigmentation is associated with increased dermal melanin and dermal deposits of the drug or its metabolite.[18,19] Histologic features of lichenoid eruptions are similar to those of idiopathic lichen planus; however, there may be a greater degree of spongiosis and dermal eosinophilic and plasma cell infiltrates, and a larger number of necrotic keratinocytes and cytoid bodies. In pseudoporphyria, as in porphyria cutanea tarda, there is dermal-epidermal separation at the lamina lucida and deposits of immunoglobulins at the dermal-epidermal junction and surrounding blood vessel walls.[21,22]

Management

Identification and avoidance of the causative phototoxic agent are the most important steps in management. Beyond this, sun avoidance is essential. Because the action spectrum for most agents is in the UVA range, high sun protection factor, broad-spectrum sunscreens containing efficient UVA filters should be used (see Chap. 223). Acute phototoxicity can be managed with topical corticosteroids and compresses; systemic corticosteroids should be reserved for only the most severely affected patients. Management of patients with slate-gray pigmentation, lichenoid eruption, pseudoporphyria, and photodistributed telangiectasia is symptomatic only, and patients should be advised that it will take months after the discontinuation of the offending agent for the condition to resolve. Patients with nonsteroidal anti-inflammatory drug (NSAID)–induced pseudoporphyria who require NSAIDs should be switched to a different class of agents or to those that are less photosensitizing, such as indomethacin or sulindac.[54]

PHOTOALLERGY

Pathophysiology

Photoallergy is a type IV delayed hypersensitivity response requiring the presence of both photoallergen and the activating wavelengths of radiation, which for most agents are in the UVA range.

After the absorption of UV energy, a photoallergen may be converted to an excited state molecule, which subsequently reverts to ground state by releasing the energy. In this process, the molecule may conjugate with a carrier protein to form a complete antigen. This is thought to be the mechanism of photoallergy induced by halogenated salicylanilides, chlorpromazine, and para-aminobenzoic acid (PABA). Alternatively, a photoallergen may form a stable photoproduct on exposure to radiation, which in turn may conjugate with a carrier protein to form a complete antigen. Sulfanilamide and chlorpromazine have both been shown to participate in this reaction.

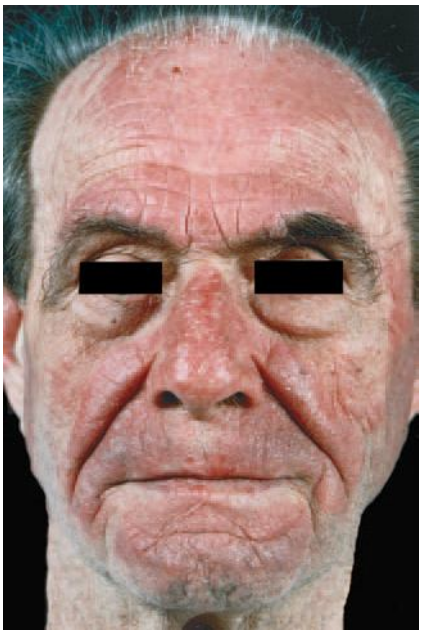
Once the complete antigen is formed, the mechanism of photoallergy is identical to that of contact allergy. The antigen is taken up and processed by Langerhans cells, which then migrate to regional lymph nodes to present the antigen to T lymphocytes. Cutaneous lesions develop when the activated T lymphocytes circulate to the exposed site to initiate an inflammatory response.

Clinical Manifestations

In sensitized individuals, exposure to the photoallergen and sunlight results in the development of a pruritic, eczematous eruption within 24 to 48 hours after exposure (see Table 91-1, Fig. 91-5). Although the morphology is clinically indistinguishable from that of allergic contact dermatitis, the distribution of the eruption in photoallergy is predominantly confined to sun-exposed areas; however, in severe cases it may spread to the covered areas, albeit at a lower intensity. Unlike the lesions in phototoxicity, those in photoallergy usually resolve without significant post-inflammatory hyperpigmentation. Lichenoid eruption has also been reported.

Currently, in the United States, United Kingdom, and France, UV filters in sunscreen products (especially benzophenone-3) are the most common cause of photoallergy, whereas NSAIDs are the leading topical photoallergens in Germany, Austria, and Switzerland.[1,8,10]

As with phototoxicity, persistence of photosensitivity and evolution to chronic actinic dermatitis (see Chap. 90) have been reported after exposure to photoallergens, including halogenated salicylanilides, musk ambrette, ketoprofen, dioxopromethazine, olaquindox, and quinidine.[55–58] The mechanism is not completely understood. One possible explanation is that UV radiation alters the carrier protein that originally binds the photoallergen; this results in the formation of a neoantigen that stimulates the immune system over the long term. This hypothesis is supported by the observation that the histidine moiety in albumin can undergo oxidation in the presence of salicylanilide, which binds to albumin.



▲ **FIGURE 91-5** Photoallergic dermatitis. This eruption is clinically indistinguishable from allergic contact dermatitis, except that it is distributed predominantly in sun-exposed areas. Note the absence of dermatitis on upper eyelids, below the nose, and in the submental and neck regions.

Photoallergens

TOPICAL AGENTS Topical exposure is the most common route of sensitization to photoallergens.[59] Table 91-4 lists the common groups of photoallergens.

SYSTEMIC AGENTS Photoallergy caused by systemic agents is much less frequent than that induced by topical agents. All but one of these photoallergenic agents (pyridoxine) are also phototoxic and have been discussed previously in this chapter (see Systemic Agents under Phototoxic Agents and Table 91-3).

Histopathology

The histologic features of photoallergy are similar to those of allergic contact dermatitis. There is epidermal spongiosis associated with infiltrate of mononuclear cells in the dermis (see Table 91-1).

Management

Management is identical to that of phototoxicity: identification and avoidance of the photoallergen, sun-protective measures, and symptomatic therapy.

EVALUATION OF PATIENTS WITH PHOTOTOXICITY AND PHOTOALLERGY

The evaluation of patients with phototoxicity and photoallergy is similar to the evaluation of patients with other photosensitivity disorders and is described in greater detail in Chap. 90. A history of exposure to known photosensitizers is most important. It is also helpful to ascertain whether window glass–filtered sunlight can induce the cutaneous eruption, because UVB and UVA2 (320 to 340 nm) are filtered out by window glass. Distribution of the cutaneous eruption is a helpful clue to the type of photosensitizer responsible. Widespread eruption suggests systemic photosensitizers, whereas topical photosensitizers produce lesions only in areas that have been exposed to both sensitizers and radiation. Vesicular and bullous eruptions are most commonly associated with phototoxicity, whereas eczematous eruptions suggest photoallergy; usually, the former is associated with a burning sensation, the latter with pruritus. Skin biopsy findings may also be helpful in differentiating these two conditions: necrotic keratinocytes are commonly seen in phototoxicity, whereas spongiotic dermatitis is associated with photoallergy (see Table 91-1).

Phototests and photopatch tests are an integral part of the evaluation of photosensitivity. Approximately 10 percent of patients who undergo photopatch testing have clinically relevant positive results, which leads to the diagnosis of photoallergic contact dermatitis.[1,5–10]

The procedures for phototesting and photopatch testing are generally as follows, although there are variations in testing methods.[62] On day 1, exposure to UVB and UVA to determine minimal erythema dose (MED) is carried out, and duplicate sets of photoallergens are applied symmetrically to another site on the back and covered by an opaque tape. On day 2, the MEDs are determined. One of the duplicate set of photoallergens is exposed to 10 J/cm^2 of UVA or 50 percent of the MED to UVA, whichever is lower. After irradiation, the exposed site is covered again with an opaque tape. On day 3, both irradiated and nonirradiated test sites are uncovered, and the reactions are

graded. On day 5 or day 8, the irradiated and nonirradiated sites are evaluated for delayed reactions. Reaction at an irradiated site only indicates photoallergy. Reaction of equal intensity at both irradiated and covered sites indicates allergic contact dermatitis. Reaction at both sites, but with higher intensity at the irradiated site, signifies both photoallergy and allergic contact dermatitis. Well-defined erythema that resolves promptly indicates an irritant dermatitis.

DIFFERENTIAL DIAGNOSIS OF PHOTOTOXICITY AND PHOTOALLERGY

Airborne allergic contact dermatitis is characterized by involvement of skinfolds on exposed areas, such as the nasolabial folds, and the eyelids that receive minimal direct sunlight. It also involves exposed areas that are relatively sun protected, such as the postauricular areas and area under the chin. Allergic contact dermatitis and irritant contact dermatitis occur in both sun-exposed and in sun-protected areas.

Other photodermatoses can be differentiated from phototoxicity and photoallergy by their characteristic time course and morphology and lack of a compatible exposure history. Polymorphous light eruption manifests itself within a few hours of sun exposure as pruritic papules, plaques, and, uncommonly, vesicles on sun-exposed sites and resolves in a few days. Chronic actinic dermatitis presents as chronically lichenified plaques on sun-exposed areas. Lesions of solar urticaria appear within minutes of sun exposure as mildly pruritic urticaria and resolve within a few hours.

OTHER EXOGENOUS AGENT–INDUCED PHOTODERMATOSES AND PHOTO-EXACERBATED DERMATOSES

Porphyria Cutanea Tarda (See Chap. 132)

Ingestion of wheat treated with hexachlorobenzene (HCB) as a preservative resulted in an outbreak of a porphyria cutanea tarda–like syndrome in Turkey in the 1950s.[63] Inhibition of the enzyme uroporphyrinogen decarboxylase by HCB was thought to be responsible for the clinical manifestations. However, a study of adults highly exposed to HCB in Catalonia, Spain, did not show any increase in prevalence of porphyria cutanea tarda or increased urinary concentrations of porphyrins.[64]

Lupus Erythematosus (See Chap. 156)

Although many medications are associated with drug-induced lupus erythematosus, the association has been best established for procainamide, hydralazine, and minocycline.[65] Arthralgia and systemic symptoms are common; photosensitivity is a rare manifestation. Most patients have antibodies to histones. Individuals whose hepatic *N*-acetyltransferase system expresses a "slow acetylator" phenotype or who are positive for human leukocyte antigen DR4 are most susceptible.

Pellagra (See Chap. 130)

Skin changes of pellagra (from the Italian *pelle agra*, "rough skin") are associated with isoniazid, 6-mercaptopurine, 5-fluorouracil, chloramphenicol, sulfapyridine, anticonvulsants, and antidepressants.[66,67] The pathogenesis of drug-induced pellagra probably is related to the inhibition of conversion of niacin to nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate.

SECTION 17

SKIN CHANGES DUE TO OTHER PHYSICAL AND CHEMICAL FACTORS

CHAPTER 92

Thermoregulation

Dean L. Kellogg, Jr.

ROLE OF SKIN IN HUMAN THERMOREGULATION: AN OVERVIEW

Human beings are homeotherms: we maintain our internal, or core, temperature of the body within a narrow range despite thermal stresses. Thermal stress can arise from variations in environmental temperature or from the human body itself, as with heat generation by skeletal muscle during dynamic exercise. When thermal stresses arise from the environment, changes in skin temperature occur before any change in core or internal temperature. When thermal stresses arise from the body itself, changes in core temperature occur before any change in skin temperature. In either case, thermal gradients are established between the skin and the body core. If skin temperature is lower than core temperature, heat will be lost from the body unless skin blood vessels constrict. If skin temperature is higher than core temperature, the body will gain heat unless skin vessels dilate and sweat glands produce perspiration. The skin is thus a crucial component of human thermoregulation.

Human thermoregulation is achieved through an integration of several physiologic processes. These integrated processes make up thermoregulatory reflexes that maintain a stable internal temperature at a "set point" of 37°C (98.6°F) despite thermal stresses. The set point is not invariant and may fluctuate as much as 0.5°C to 1.0°C (0.9°F to 1.8°F) according to circadian rhythms and during the menstrual cycle in females. The thermoregulatory reflexes designed to preserve internal temperature at the set point are coordinated by thermally sensitive neurons in the anterior hypothalamic-preoptic area and in the spinal cord that respond to changes in internal temperature and/or skin temperature. For example, when stimulated, cold-sensitive neurons in the anterior hypothalamic-preoptic area and spinal cord integrate afferent sensory inputs and activate heat-conserving mechanisms that include cutaneous vasoconstriction and increased metabolic heat production (shivering). Conversely, the stimulation of heat-sensitive neurons in the anterior hypothalamic-preoptic area and spinal cord integrate afferent sensory inputs and activate heat-dissipating mechanisms that include cutaneous vasodilation and sweat production.

HEAT TRANSFER

To maintain thermal balance, heat gained or lost by the body must equal heat dissipated from or produced by the body. This concept can be mathematically expressed as follows:

$$\Delta S = M - E \pm R \pm C \pm K - W$$

- ΔS = Change in heat storage by the body
- M = Metabolic heat production and is defined as the rate of transformation of chemical energy into heat and mechanical work.
- E = Evaporative heat loss and is defined as the rate of heat loss by evaporation of water from skin and surfaces of the respiratory tract. E is dependent on (1) the rate of sweat secretion, (2) the water vapor pressure of the environment, and (3) the area of evaporative surface.
- R = Radiant heat gain or loss and is defined as heat exchange by emission and absorption of electromagnetic (infrared) radiation. This component accounts for 50 percent to 60 percent of the heat loss in a thermally comfortable (thermoneutral) individual but can easily become a net heat

THERMO-REGULATION AT A GLANCE

- Body temperature is maintained within a narrow range.
- The skin plays a major role via the following:
  - Evaporative heat loss, modulated by sweating
  - Radiant heat loss or gain
  - Convective heat loss or gain, modulated by vasodilatation and vasoconstriction
- Papillary loops, arteriovenous anastomoses, and sweat glands are the major skin effectors.
- Cutaneous blood flow, normally approximately 5 percent of cardiac output, can vary from 0 percent to 60 percent in response to thermal stress.
- Vascular tone is subject to complex regulation by sympathetic nerves, acetylcholine, vasoactive peptides, and nitric oxide.
- Skin diseases and systemic medications may impair thermoregulation.

gain, as when the person is in direct sunlight.

C = Convective heat gain or loss and is defined as heat exchange due to forced movement of a fluid, either liquid or gas. This component is responsible for the transfer of heat to the skin through skin blood flow and transfer from the skin to the environment by air or water movement. Within the body, the cardiovascular system is the major mediator of convective heat transfer. C is dependent on (1) body surface area, (2) temperature differences, and (3) fluid (or air) movement.

K = Conductive heat gain or loss and is defined as heat transfer by flow down a temperature gradient, as between tissues and blood, between blood and skin, and between skin and the environment. This is usually combined with convective heat transfer.

W = Useful mechanical work.

The sum of R, C, and K is determined by the temperature gradient between the skin and the environment. If ΔS is zero, the body is in heat balance. This thermoneutral condition is characterized by low skin blood flow of approximately 5 percent of cardiac output. Sweating does not occur.

If ΔS is less than zero, the body is losing heat, core temperature is falling, and thermoregulatory reflexes are evoked to conserve heat. Thermal stability is maintained through reduction of skin blood flow, which can approach zero during maximal vasoconstriction. Reduction in skin blood flow increases the thermal insulation between the body and the environment by minimizing losses through conductive (K), convective (C), and radiant (R) mechanisms. If heat loss continues despite low skin blood flow, metabolic generation of heat (M) through the shivering of skeletal muscle is initiated to restore and maintain core temperature. If, despite all these mechanisms, ΔS remains negative, core temperature will fall and potentially life-threatening hypothermia can result.

If ΔS is greater than zero, the body is gaining heat and core temperature is rising. Under this condition of heat stress, thermal stability is maintained by increases in skin blood flow to facilitate heat loss through conductive (K), convective (C), and even radiant (R) losses. If heat gain continues despite these mechanisms, sweating is evoked to increase heat loss through evaporation (E) of perspiration. If ΔS remains positive, blood flow is diverted from skeletal muscle and gastrointestinal beds, which provides for dramatic increases in skin blood flow. Sweat rate will also increase until maximal levels are achieved. If, despite maximal skin blood flow and maximal stimulation of sweating, ΔS remains positive, core temperature will rise and life-threatening hyperthermia (i.e., heatstroke) will occur.

THERMOREGULATION AND THE SKIN

Anatomic Considerations

The critical role of the skin in human thermoregulation is well understood. Thermoregulation is achieved through variations in blood flow and sweat production so as to maintain thermal stability. Without these variations, thermal stability cannot be maintained, which results in risk of hypothermia or hyperthermia (see Chaps. 93 and 94). Under normothermic conditions, skin blood flow ranges from 30 to 40 mL/minute/100 g of skin in resting humans. The cutaneous vasculature is exceedingly compliant, however, so that skin blood flow can vary from nearly zero during cold stress periods with maximal vasoconstriction to 8 L/minute over the body's surface during maximal vasodilation in heat stress.[1]

Blood vessels in the skin are arranged in several plexuses in superficial and deep layers parallel to the skin surface. Most vessels are in the superficial layer and consist of high-resistance terminal arterioles, papillary loops, and postcapillary venules. Papillary loops are true capillaries. Blood flow through the loops is controlled by highly innervated arterioles. The loops are located near the dermal-epidermal junction, a region characterized by a maximal thermal gradient because of its proximity to the skin surface. Because the papillary loops also have a large surface area, blood flow through these vessels is a major determinant of heat exchange through vasodilation during heat stress and vasoconstriction during cold stress.

Although papillary loops are found in both glabrous skin (palms, soles, and lips) and non-glabrous skin (most of the body's surface, including the limbs, head, and trunk), arteriovenous anastomoses (AVAs) are found mainly in glabrous skin. They represent direct connections between arterioles and venules that bypass the high-resistance arterioles and capillaries of the papillary loops. AVAs have thick muscular walls with rich noradrenergic innervation and lie deep to papillary loops.[2] Because of their deeper location in the dermis and smaller surface area, AVAs are less efficient in heat transfer than papillary loops. Although AVAs dilate in response to heat stress and constrict during mild to moderate cold stress, their major role is to mediate local vasodilation during prolonged cold exposure. AVA vasodilation delivers warm blood to maintain tissue temperature and thus tissue viability through cold-induced vasodilation.[3]

Sweat glands also play a major role in human thermoregulation (see Chap. 81). The critical thermoregulatory role of the eccrine sweat glands that are found over most of the body surface is well known. Clearly, the main function of eccrine sweat glands is to increase heat loss through the evaporation of sweat. The density of these glands varies from 700 glands/cm^2 in palmar and plantar skin to 64 glands/cm^2 on the back.[4] These glands may hypertrophy with repeated heat exposure.[5] Each gland is made up of a secretory coil found in the dermis with a duct that extends through the dermis and epidermis to the surface of the skin. Sweat is secreted as an isotonic fluid by the coils. NaCl is reabsorbed within the ducts, so sweat that is finally delivered to the surface is hypotonic.[6] Each liter of sweat evaporated is capable of removing 580 kcal from the body. Although apocrine sweat glands have been dismissed as "atavistic scent glands," this has now been questioned.[7] Apocrine glands are usually associated with hair follicles and are most developed on the scalp, face, upper back, and chest. It has been proposed that sweat from apocrine glands acts as a surfactant at high temperatures and thus facilitates dispersion of eccrine sweat over the skin's surface. At low temperatures, sebum may function to repel water from the skin and thus reduce heat loss.

Cutaneous Thermoregulatory Mechanisms

The cutaneous circulation is a major effector of human thermoregulation. During heat stress, elevated internal temperature and skin temperature lead to cutaneous vasodilation through neural mechanisms and the local effect of

higher temperatures on the skin vessels themselves. During periods of cold stress, reduced temperatures mediate a cutaneous vasoconstriction through neural as well as local vascular effects. Under normothermic conditions, skin blood flow averages approximately 5 percent of cardiac output; however, the absolute amount of blood in the skin can vary from nearly zero during periods of maximal vasoconstriction in severe cold stress to as much as 60 percent of cardiac output in severe heat stress.[1]

Sweating

Heat dissipation through the secretion and evaporation of eccrine sweat is critical to maintaining thermal stability in hot environments or during heat stress induced by strenuous dynamic exercise. Indeed, when environmental temperature exceeds blood temperature, the evaporation of sweat is the sole mechanism for heat dispersal. Sweat secretion is controlled by sympathetic cholinergic nerves that release acetylcholine onto muscarinic receptors on the glands. Cholinergic stimulation activates the glands to produce an isotonic fluid that becomes progressively hypotonic as the Na^+ is reabsorbed in the sweat gland duct by active ion transfer (see Chap. 81).

Neural Control Mechanisms of the Cutaneous Vasculature

In glabrous skin, cutaneous arterioles are innervated by sympathetic vasoconstrictor nerves[3,8–11] that release norepinephrine and other co-transmitters.[12–15] All thermoregulatory reflex changes in blood flow in these areas are caused by changes in noradrenergic vasoconstrictor activity and the effects of local temperatures on the skin blood vessels themselves.[3,9–11]

In non-glabrous skin, changes in skin blood flow are mediated by two branches of the sympathetic nervous system: noradrenergic vasoconstrictor nerves as found in glabrous skin, and a cholinergic active vasodilator system.[3,11,16] These dual sympathetic neural control mechanisms are the major effectors of thermoregulatory responses. Vessels in non-glabrous skin also respond to the effects of local temperature changes[3,11,16] (Fig. 92-1).

In normothermia, cutaneous arterioles are under little neural tone. During cold stress, reduction of skin temperature and/or internal temperature causes a thermoregulatory reflex-mediated reduction in skin blood flow to conserve body heat. Enhanced noradrenergic vasoconstrictor tone effects an arteriolar vasoconstriction and thus decreases skin blood flow. Conversely, during heat stress, thermoregulatory reflexes that facilitate body cooling are stimulated. As internal temperature continues to rise over a threshold value of approximately 37°C (98.6°F), a cutaneous vasodilation begins. At this threshold, active vasodilator tone to the cutaneous arterioles is enhanced. At rest, sweating also begins at the same internal temperature threshold. Vasodilator tone increases as internal temperature increases. Enhanced vasodilator activity decreases smooth muscle tone, which leads to arteriolar vasodilation and thus an increase in skin blood flow, especially through the papillary loops. High skin blood flow delivers heat to the body surface, where it is dissipated into the environment in conjunction with the evaporation of sweat. Overall, the active vasodilator system is responsible for 80 percent to 95 percent of the elevation in skin blood flow that accompanies heat stress. A small but significant portion of the vasodilation is mediated by the direct vasodilator effects of local heat on the cutaneous vessels[3,17] (see Fig. 92-1).

Dual vasoconstrictor nerves and vasodilator nerves in skin were first suggested in 1931 by Lewis and Pickering[18] and confirmed by Grant and Holling.[19] They measured skin temperature as an index of blood flow in the human forearm and found that large increases in response to heat stress could be abolished by sympathectomy or nerve blockade. They noted that although sympathectomy or nerve blockade caused only a slight cutaneous vasodilation during normothermia, heat stress elicited a much greater increase in skin blood flow. In addition, nerve blockade during established heat stress abolished any cutaneous vasodilation. These results suggested that cutaneous vessels in non-glabrous skin are innervated by sympathetic active vasodilator as well as sympathetic vasoconstrictor nerves. In the 1950s, their findings were confirmed by Edholm, Fox, and MacPherson[20] and by Roddie, Shepherd, and Whelan[21] In addition, it has been shown that bretylium tosylate (a pre-junctional noradrenergic neuronal blocking agent) abolishes the cutaneous vasoconstriction induced by cold stress but does not alter the vasodilator responses induced by heat stress.[22] This confirmed that dual efferent neural systems control the cutaneous arterioles: a noradrenergic vasoconstrictor system and a non-adrenergic active vasodilator system.

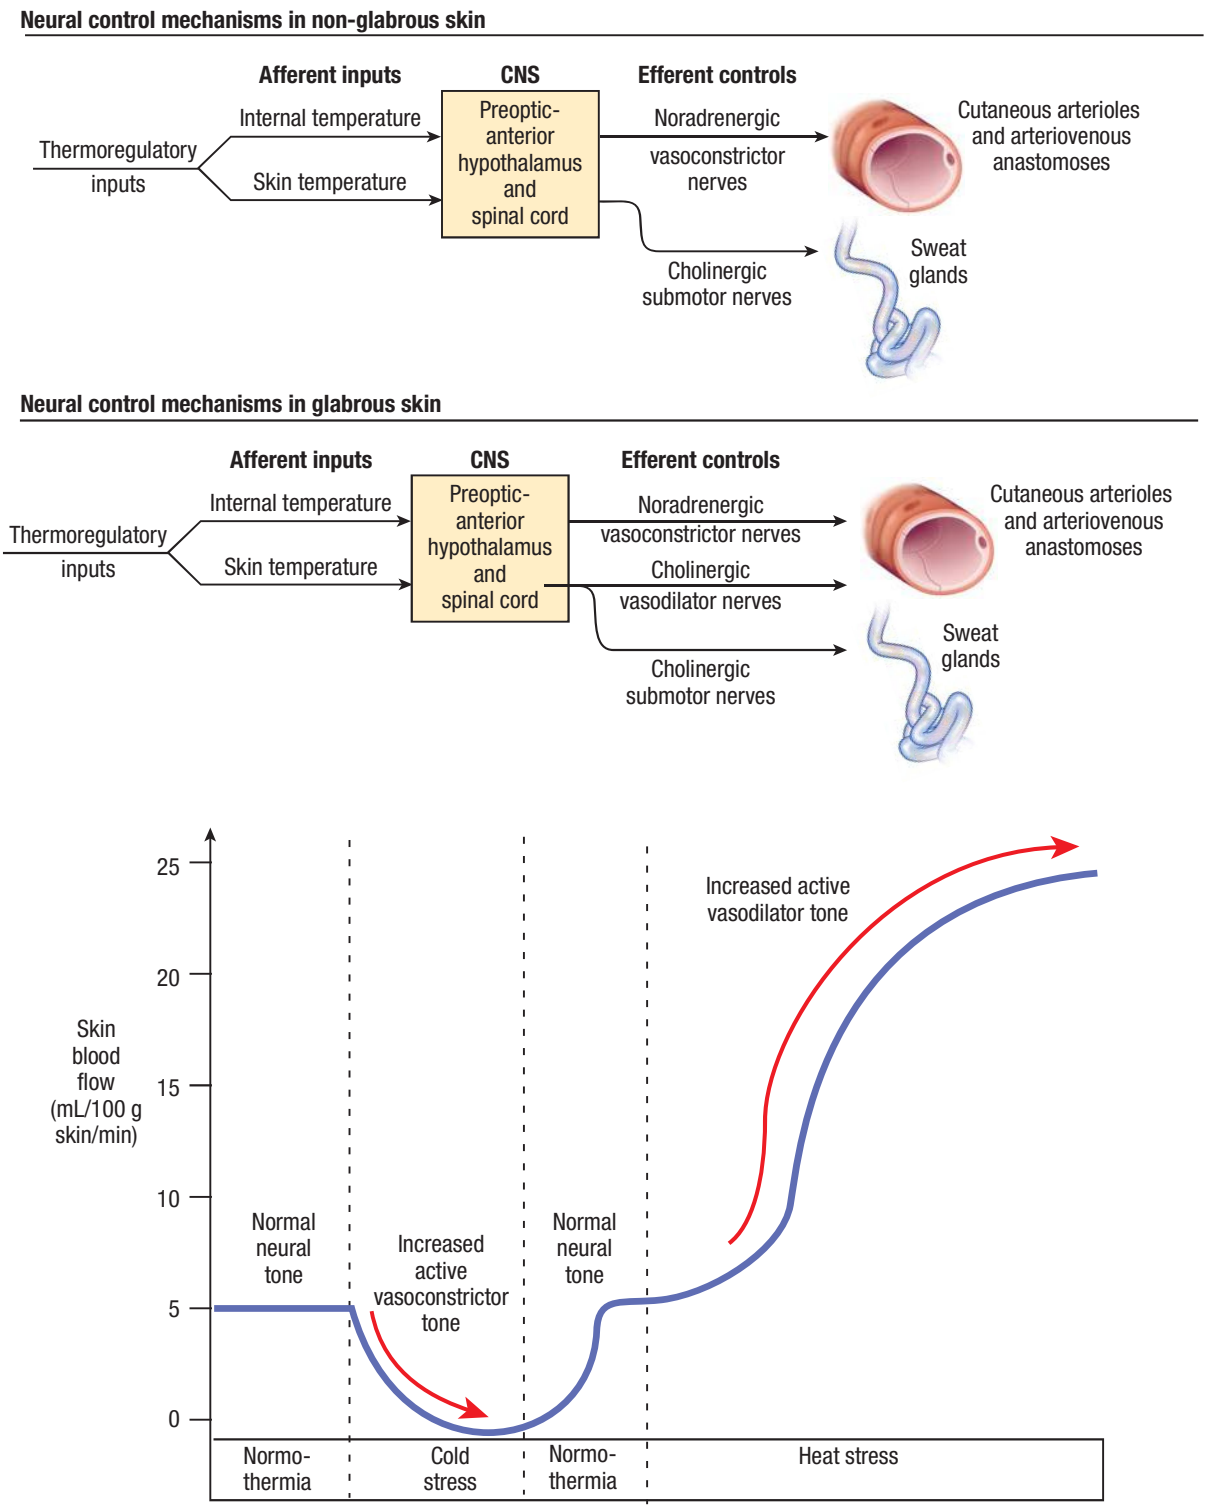
CUTANEOUS RESPONSES TO HEAT

Cutaneous Active Vasodilator Mechanisms

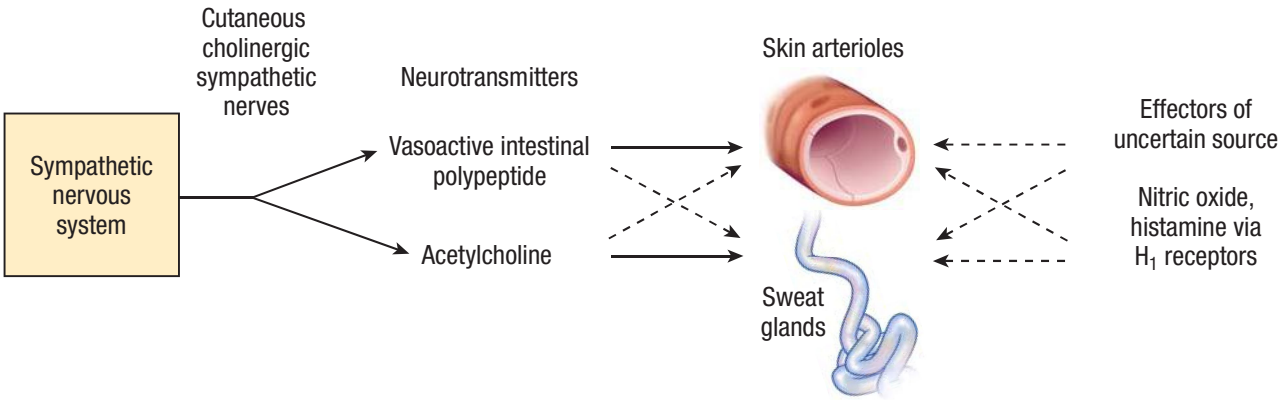
Despite the fact that the cutaneous active vasodilator system has been studied for many decades, the specific mechanisms by which this system functions are only partly understood.[18,19,23] Several hypotheses have been proposed for how active vasodilation in skin works, but none has been completely proven.

SUDOMOTOR ACTIVITY AND ACTIVE VASODILATION In the initial descriptions of cutaneous active vasodilation, it was noted that sweating and active vasodilation began at about the same time in a resting person subjected to heat stress.[19] This observation led to the hypothesis that the mechanism of cutaneous active vasodilation involved cholinergic sudomotor nerve activity.[19,24–26] Additional evidence that favored a close mechanistic relationship between active vasodilation and sweating came from observations of individuals with anhidrotic ectodermal dysplasia. Persons with this congenital anomaly lack sweat glands (see Chap. 82) and a cutaneous active vasodilator response to heat stress,[26] which makes such individuals extremely heat intolerant. Despite observations such as this, the precise relationship between sweat glands and active vasodilation remains poorly defined. Indeed, although it is clear that cholinergic sudomotor nerves control sweat glands, whether sudomotor and vasodilator nerves are one and the same or completely separate cholinergic nerves remains unknown.[27,28]

CO-TRANSMISSION AND CUTANEOUS ACTIVE VASODILATION One of the current areas of interest in thermoregulatory research is the nature of the co-transmitter (or co-transmitters) that effect active vasodilation (Fig. 92-2). Several studies support the involvement of vasoactive intestinal peptide (VIP) as a co-transmitter in active vasodilation.[30,35,36] This research tested whether active vasodilation is mediated, in part, by VIP co-released from cholinergic nerves with acetylcholine. The neuropeptide fragment VIP10-28 was administered by microdialysis to block the effects of VIP at VPAC1 and VPAC2 receptors. This agent was chosen



▲ **FIGURE 92-1** *Upper panels:* Summary of neural controls of thermoregulatory effectors in human skin. Thermoregulatory reflexes are mediated by the afferent inputs of internal and skin temperatures. These afferent inputs are integrated in the preoptic anterior hypothalamus and spinal cord areas of the central nervous system (CNS). Efferent control of blood vessels and sweat glands in glabrous skin is mediated by noradrenergic vasoconstrictor nerves and cholinergic sudomotor nerves, respectively. In non-glabrous skin regions, efferent control of blood vessels is effected through a system of dual sympathetic innervation: noradrenergic active vasoconstrictor nerves and cholinergic active vasodilator nerves. Sweat glands also receive cholinergic sympathetic innervation; however, whether cholinergic active vasodilator nerves and cholinergic sudomotor nerves are one and the same is not known. *Lower panel:* Skin blood flow responses to cold stress and heat stress in non-glabrous skin. Under normothermic conditions, skin blood flow is relatively low (approximately 5 percent of cardiac output) and skin vessels receive relatively minor neural inputs from active vasoconstrictor and vasodilator nerves. During cold stress, reductions of skin and internal temperatures lead to reflex increases in sympathetic noradrenergic vasoconstrictor nerve activity. Increased vasoconstrictor system tone reduces skin blood flow, thus increasing thermal insulation and conserving body heat. During heat stress, increasing skin and internal temperatures lead to reflex increases in sympathetic cholinergic active vasodilator nerve and cholinergic sudomotor activity. Increased activity of the vasodilator system leads to potentially dramatic increases in skin blood flow that can reach 60 percent of cardiac output. High skin blood flow delivers heat to the skin surface, where it is removed to the environment primarily through evaporation of sweat.



▲ **FIGURE 92-2** Summary of cholinergic active vasodilator co-transmitter system. Cutaneous active vasodilation is mediated by co-transmission. The classical neurotransmitter acetylcholine is released from cholinergic sympathetic nerves along with the neuropeptide co-transmitter vasoactive intestinal polypeptide and perhaps other co-transmitters. These neurotransmitters cause dilation of the cutaneous vasculature and activate sweating during periods of heat stress. The precise roles and interactions of acetylcholine and the co-transmitters in mediating thermoregulatory reflex responses to heat stress remain incompletely understood.

because it not only blocks the two major receptors for VIP, it also blocks the effects of peptide histidine methionine. These two neuropeptides share a close structural relationship, are formed from the same pre-propeptide, and are both reported to be present in human skin.[37] VIP10–28 attenuated (but did not abolish) the increase in skin blood flow during heat stress. Combining VIP10-28 with atropine did not enhance the degree of attenuation over that achieved with VIP10-28 alone. This finding showed a role for VIP in active vasodilation; however, because the effect of the combination of muscarinic receptor and VIP receptor blockade did not differ from the effect of VIP receptor blockade only, it was postulated that additional co-transmitters may well be involved in the process.[35,36]

NITRIC OXIDE AND ACTIVE VASODILATION

In the 1990s, a series of studies investigated the control of skin blood flow in the rabbit ear. Rabbits (and other lagomorphs) thermoregulate by actively dilating and constricting the blood vessels in their ears. Rabbits thus provided a possible animal model for study of the dual vasomotor controls of human nonglabrous skin. The studies in the rabbit ear showed a role for nitric oxide (NO) in thermoregulatory reflex-mediated active vasodilation.[38,39] This work provided the rationale to study and clarify roles for the NO system in cutaneous active vasodilation in humans.[40–42] Although initial work based on intra-arterial infusions of the NO synthetase (NOS) inhibitor NG-monomethyl-L-arginine (L-NMMA) was unable to establish such a role,[42] later work[40,43] used intradermal microdialysis to deliver NOS inhibitors NG-nitro-L-arginine-methyl ester (L-NAME) and L-NMMA into small areas of skin. These studies found that increases in skin blood flow caused by active vasodilation during heat stress were significantly attenuated but not abolished by NOS inhibition.[40,41,43] The results of these studies show that active vasodilation in skin requires functional NOS to achieve full expression.

The foregoing discussion of NO might lead one to believe that because "functional" NOS is required for active vasodilation, NO levels in skin must increase during heat stress to cause active cutaneous vasodilation. However, based on studies of how NO functions as a vasodilator in the rabbit ear during heat stress, a novel theory was proposed.[44] It had been noted that NOS antagonists abolished heat stress–induced active vasodilation in skin of the rabbit ear. Administration of low doses of the NO donor nitroprusside could restore ear skin vasodilation during heat stress despite NOS blockade; however, the same dose of nitroprusside infused into the ear circulation in normothermia did not raise ear blood flow at all. The implication was that active vasodilation in the rabbit ear required the presence of NO and activation of vasodilator nerves, but that these two elements were not arranged in series. This led to the idea that vasodilator nerve activity did not increase NO production, but rather that NO needed to be present to permit another neurotransmitter to effect increases in ear skin blood flow. It was thus proposed that NO played a "permissive" role in the active vasodilation rather than serving as an actual effector of the process; that is, NO had to be present for vasodilation to be effected by another neurotransmitter, but the absolute level of NO did not increase in heat stress.

An initial test of this proposal in human skin examined whether increased levels of NO breakdown products could be found in skin during hyperthermia, but no such increases were found.[45] This suggested that NO acted as a permissive factor rather than as an effector of cutaneous active vasodilation. However, the study of NO breakdown products is fraught with problems. Subsequent examinations of NO changes in heat stress were performed by measuring bioavailable NO by means of NO-selective amperometric electrodes in vivo.[46] This technique measures bioavailable NO directly from the tissue of interest. In contrast to the results of the initial study based on NO breakdown products, it was found that both skin blood flow and bioavailable NO concentrations increased during heat stress. This proved that NO does increase in skin during heat stress in humans, attendant to active vasodilation. This result suggests that NO has a role beyond that of a permissive factor in cutaneous active vasodilation. Rather, because NO increases in heat stress, it could well be an effector of cutaneous vasodilation during heat stress.[46–49]

Additional evidence in favor of NO as an active effector of cutaneous active vasodilation came from more recent work using an "NO-clamp" technique.[50] Intradermal microdialysis was used to deliver a combination of the NOS inhibitor L-NAME and the NO donor nitroprusside into skin. The effect of this combination was to "clamp" NO at a constant level—that is, NO was present but could not increase because of NOS blockade. When NO levels were clamped and not allowed to increase, active vasodilation during heat stress was attenuated. This finding showed

that NO did not act permissively, but rather was an active effector of vasodilation. It is thus clear that NO production increases during heat stress and that NO acts as an actual effector of cutaneous active vasodilation.

It should be noted that all of the foregoing work on NO in human skin was done in non-glabrous skin. This type of skin has a paucity of AVAs. In contrast, the skin of the rabbit ear is rich in AVAs. It may well be that NO plays a permissive role in AVA dilatation but not dilatation of the papillary loops of non-glabrous skin.

Another question about the role of NO in active vasodilation involves the factors that mediate increased production of NO during heat stress. One hypothesis was that acetylcholine from cholinergic nerves increased NO levels via muscarinic receptor stimulation.[51] This was investigated by examining the effects of combined muscarinic receptor blockade by atropine with NOS blockade by L-NAME on vasodilation during heat stress. These agents were given after activation of the active vasodilator system in prolonged heat stress, when skin blood flow had already risen significantly. Although atropine was found to have little effect on skin blood flow, L-NAME was found to significantly reduce skin blood flow during established active vasodilation in prolonged heat stress. This showed that although production of NO was required for active vasodilation, muscarinic receptor–mediated NO production was not needed to sustain active vasodilation during the late, established phase of heat stress.[51]

Subsequent work has examined whether muscarinic receptor activation leads to NO production *early* in heat stress.[52] Based on results of earlier studies showing that atropine delayed the onset of active vasodilation during heat stress, it was postulated that acetylcholine contributed to active vasodilation through muscarinic receptor–mediated NO production early in the process. To test this hypothesis, the effect of a combination of acetylcholinesterase inhibition with neostigmine (to magnify the agonist effects of acetylcholine) and NOS blockade with L-NAME (to abolish NO effects) on active vasodilation was examined. Neostigmine and L-NAME were delivered before initiation of body heating, when the active vasodilator system was quiescent, and continued throughout the early and late periods of heat stress. The results showed that early in body heating (when skin temperature was increased but internal temperature was not), skin blood flow increased sooner at sites treated with neostigmine (with presumably augmented acetylcholine levels). The augmenting effects of acetylcholinesterase inhibition was abolished by NOS inhibition. Late in heat stress, when active vasodilation was well established, the effect of neostigmine was lost, but skin blood flow at L-NAME–treated sites was attenuated. These results suggested that acetylcholine mediated the increase in NO production early in heat stress, but not after substantial cutaneous vasodilation had occurred.[52]

Evidence has been reported that H_1 receptors for histamine may play a role in the generation of NO during cutaneous active vasodilation in heat stress.[53] Administration of the first-generation antihistamine pyrilamine attenuated, but did not abolish, the rise of skin blood flow during heat stress. In addition, it was found that the NO generated during active vasodilation was mediated by H_1 receptor activation. Thus, there appear to be several pathways that may generate NO in the skin during heat stress.

Local Warming of the Skin and Vasodilation

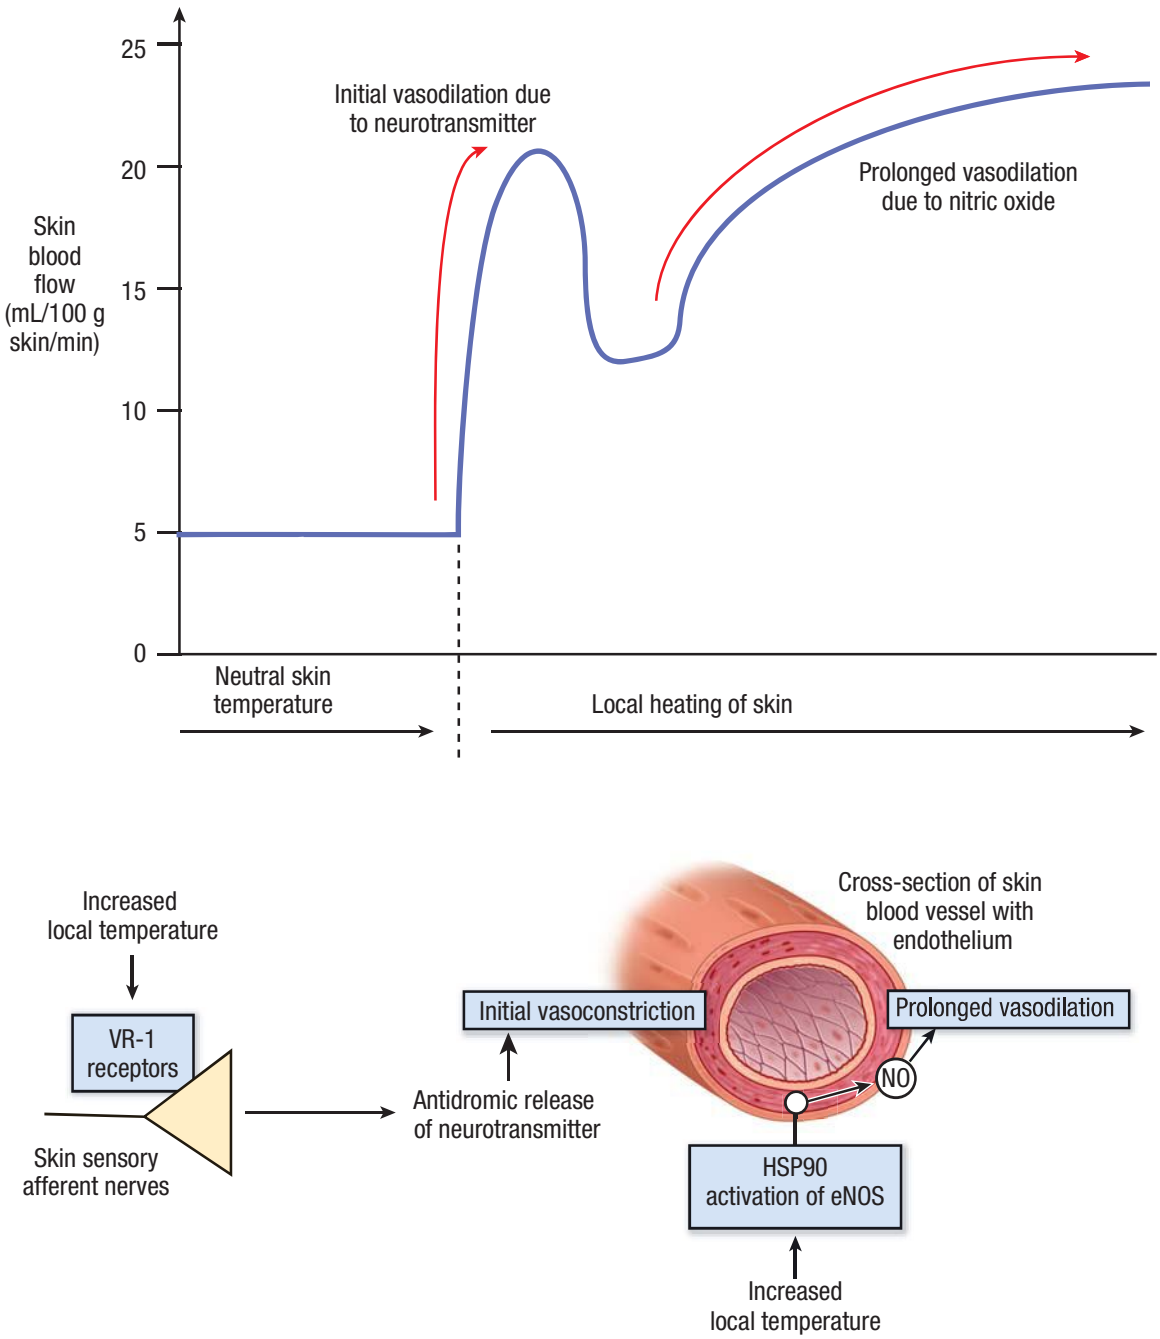
The foregoing section outlined thermoregulatory reflex responses to heat that are mediated primarily by the sympathetic nervous system. Skin vessels themselves also respond directly to changes in local temperature. For example, in response to increases in local skin temperature, cutaneous blood vessels dilate. This dilation is accomplished by purely local temperature-dependent mechanisms, the effects of which are in addition to the previously discussed neural effects.

With local warming of skin, local skin blood flow increases in direct proportion to the temperature achieved. If heating is continued at a maximally tolerable level of 42°C to 44°C (107.6°F to 111.2°F) for 35 to 55 minutes, maximal local skin blood flow can be achieved.[54] The local vasodilation is biphasic with an initial brisk vasodilation. This initial dilation rapidly reaches a peak and is followed by a slight fall in flow. With continued heat application, a second dilation occurs that can reach maximal levels in a prolonged plateau phase. For unknown reasons, the plateau phase declines after approximately 1 hour despite continued heating[55] (Fig. 92-3).

The mediators of the local, temperature-dependent cutaneous vasodilation involve both local sensory nerve axon reflex mechanisms and the local generation of NO. These two mechanisms appear to be independent of each other.[56] The previously discussed neural cutaneous active vasodilator system does not appear to be involved in this local response, because neither botulinum toxin–induced abolition of active vasodilation nor muscarinic receptor blockade with atropine alter the skin blood flow response to local skin heating.[30,57] Prostanoids do not appear to be involved either, because cyclooxygenase inhibition has no effect on the vasodilation induced by local skin heating.[57]

The initial phase of the local warming response produces a brief peak value and is mediated by local activation of afferent cutaneous sensory nerves. This initial phase of the vasodilation can be greatly attenuated by the application of a topical anesthetic directly to the heated site. Cutaneous nerve blockade at points distant from the heated site that interrupt sensory nerve function at the heated site have no effect.[56,58] This demonstrates that the initial effects of local skin heating are mediated by a neural axon reflex mechanism. The specific neurotransmitters involved in local heating responses are uncertain; however, based on studies done with topical application of the vanilloid receptor (VR-1) activator capsaicin. It has been proposed that local increases in skin temperature stimulate heat-sensitive VR-1 receptors on afferent nerves. This activates the local axon reflex to cause the antidromic release of a vasodilatory neurotransmitter (or neurotransmitters) that mediates local vasodilation.[59]

The prolonged plateau phase of vasodilation in response to local skin heating is mediated by local generation of NO. The plateau phase can be greatly attenuated by pretreatment of the locally heated area of skin with NOS inhibitors[48,56]; thus NO generation is clearly necessary for this phase. Evidence suggests that endothelial NOS (eNOS, type III NOS) is the isoform that mediates increased NO production. Heat shock protein 90 (HSP90) has been shown to bind eNOS, enhance eNOS activation, and thus increase NO generation.[60] Treatment of skin with the HSP90 inhibitor geldanamycin attenuates the plateau phase of local skin heating by approximately 20 percent. This suggests that eNOS may be the NOS isoform that mediates the prolonged plateau phase of



▲ **FIGURE 92-3** Local heating responses and vasodilator mechanisms in human skin. Increases in local temperature result in a biphasic vasodilation of skin blood vessels. The first phase consists of a prompt increase in skin blood flow that is mediated by temperature-sensitive vanilloid receptor 1 (VR-1) receptors. When heated, these VR-1 receptors cause antidromic release of neurotransmitter from afferent sensory nerves. The second phase consists of a skin blood flow plateau. This phase is observed with prolonged warming of the skin and is mediated by nitric oxide (NO). The generation of NO appears to involve heat shock protein 90 (HSP90) activation of endothelial nitric oxide synthase (eNOS). The effects of local temperature increases are independent of any changes in internal temperature. None of the responses to local heating of the skin depends on the presence of cutaneous active vasodilator nerves.

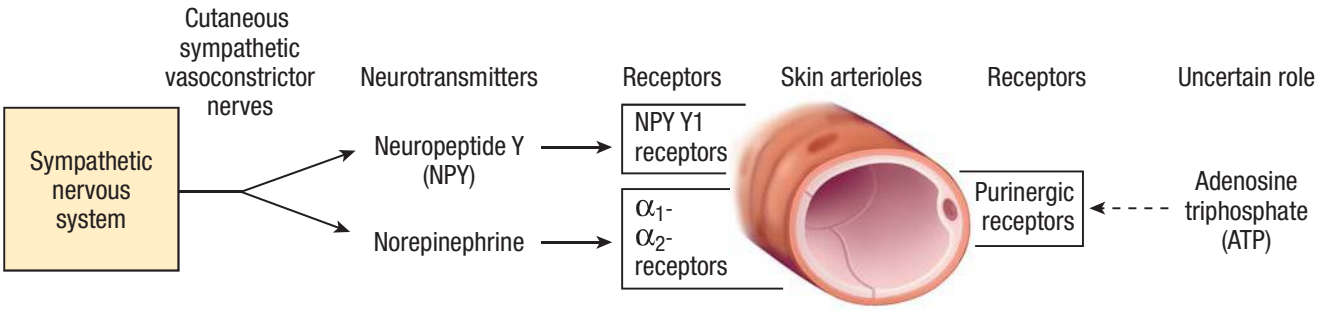
the cutaneous vascular response to local skin heating[61] (see Fig. 92-3).

CUTANEOUS RESPONSES TO COLD

Cutaneous Active Vasoconstrictor Mechanisms

Initial evidence for the control of skin blood vessels by sympathetic active vasoconstrictor nerves came from observations of the effects of peripheral sympathectomies in humans.[8,11,62] In these studies, the interruption of sympathetic nerve signaling by sympathectomy led to increases in skin blood flow when the intervention was done in a cool environment. This observation was consistent with the relaxation of cutaneous blood vessels and hence passive increases in blood flow after interruption of vasoconstrictor activity.

The sympathetic vasoconstrictor system in skin is well understood and causes vasoconstriction through noradrenergic stimulation of α_1- and α_2-adrenergic receptors.[8,11,19,20,63–67] This has been clearly demonstrated by studies using pre-junctional sympathetic nerve



▲ **FIGURE 92-4** Summary of noradrenergic active vasoconstrictor co-transmitter system. Cutaneous active vasoconstriction is mediated by co-transmission. The classical neurotransmitter norepinephrine is released from noradrenergic sympathetic nerves along with the neuropeptide co-transmitter neuropeptide Y (NPY). Norepinephrine acts on α_1- and α_2-adrenergic receptors on the vascular smooth muscle of cutaneous arterioles to cause vasoconstriction. The neuropeptide co-transmitter NPY is also involved in active vasoconstriction of skin vessels through its action on post-junctional NPY Y1 receptors.

blockade and post-junctional blockade with α-receptor antagonists.[22,64,68,69]

Sympathetic nerves in skin have now been revealed to contain several different neurotransmitters co-localized with norepinephrine, including neuropeptide Y (NPY) and adenosine triphosphate. This suggests that the sympathetic vasoconstrictor system could be a co-transmitter system. In studies that compared the effects of differing combinations of α_1- and α_2-adrenergic agents on skin vasoconstriction during cold stress it was noted that the vasoconstriction was attenuated. These results confirmed a role for post-junctional excitation of α_1- and α_2-adrenergic receptors. It was also noted that pretreatment of skin with the β-receptor antagonist propranolol led to a more profound vasoconstriction during cold stress. This suggested that a β-receptor–mediated vasodilation modulated an α-receptor–mediated vasoconstriction during whole body cooling. It is interesting to observe, however, that simultaneous and complete blockade of α_1-, α_2-, and β-receptors fails to abolish the cutaneous vasoconstriction induced by cold stress, although blockade of all neurotransmitter release from cutaneous noradrenergic nerves with bretylium tosylate does abolish the response. These studies suggest that non-noradrenergic, co-transmitter mechanisms mediate the cutaneous vasoconstriction during cold stress.[70]

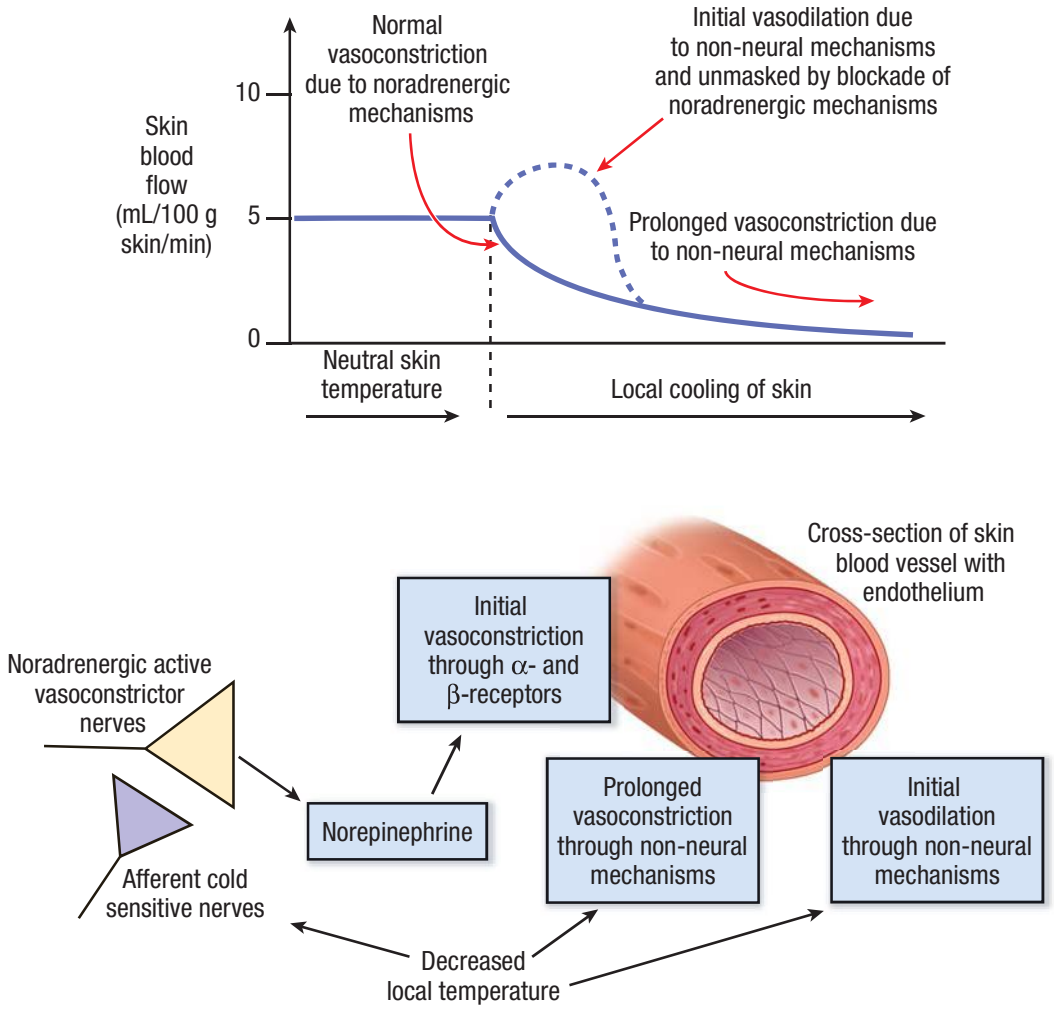
The observation that cold stress responses in skin are mediated by a co-transmitter system has led to studies designed to identify the co-transmitters of that system. It was proposed that NPY acted as a co-transmitter along with norepinephrine to mediate reductions in skin blood flow during cold stress. It was hypothesized that NPY worked through activation of NPY Y1 receptors on cutaneous arterioles. Administration of the NPY Y1 antagonist BIBP-3226 was found to significantly attenuate reductions in skin blood flow during whole body cold stress. Further, the combination of NPY Y1 receptor antagonism with complete α_1-, α_2-, and β-receptor blockade abolished reductions in skin blood flow during cold stress. These results clearly demonstrate that the cutaneous active vasoconstrictor system is a co-transmitter system that works via the release of NPY and norepinephrine. These neurotransmitters cause the post-junctional activation of NPY Y1, α_1-, α_2-, and perhaps β-receptors which in turn constricts cutaneous arterioles, reduces skin blood flow, and thus conserves body heat during cold stress[71] (Fig. 92-4).

Local Cooling of the Skin and Vasoconstriction

Decreases in skin temperature with local cooling of the skin cause a local, temperature-dependent vasoconstriction. Although the vasodilatory response to local heating of the skin is independent of the cholinergic cutaneous active vasodilator system, the vasoconstriction mediated by local skin cooling is dependent on intact noradrenergic active vasoconstrictor nerves.[58,72,73] Confirmatory studies used bretylium tosylate to block neurotransmitter release from pre-junctional noradrenergic nerve terminals in skin. When noradrenergic nerves are intact, local cooling causes a prompt and progressive reduction of skin blood flow as local temperature falls. Interruption of neurotransmitter release with bretylium changes the initial portion of the local cooling response from a prompt vasoconstriction into a prompt vasodilation. The vasodilation induced by local cooling is transient and continued local skin cooling leads to the progressive diminution of the vasodilation and eventual replacement by a progressive vasoconstriction[58,68,73] (Fig. 92-5).

Research studies have defined how the cutaneous active vasoconstrictor system participates in the vasoconstriction caused by local skin cooling and established roles for noradrenergic receptors, NPY Y1 receptors, and afferent sensory nerves.[72] It was observed that blockade of α-receptors in skin altered the local cooling vasoconstriction in the same way that bretylium did; that is, combined α- and β-receptor blockade reversed the initial phase of vasoconstriction into a vasodilation followed eventually by vasoconstriction with continued local cooling. Topical anesthesia with EMLA cream (a eutectic mixture of lidocaine and prilocaine) also reversed the initial vasoconstriction to a dilation followed again by constriction with prolonged cooling. NPY Y1 receptor blockade with BIBP-3226 had no effect on the response to local cooling. Based on this work, it is clear that local cooling of skin occurs in two phases: an initial rapid phase lasting a few minutes, and a prolonged late phase. The initial phase is caused by activation of cold-sensitive afferent neurons that mediate release of norepinephrine from sympathetic cutaneous vasoconstrictor nerves. The released norepinephrine vasoconstricts cooled skin vessels through post-junctional α-receptors. NPY Y1 receptors do not appear to be involved in either phase of the local cooling response. The mechanisms for the prolonged, late vasoconstrictor phase of cooling appear to be non-neurogenic, because no manipulations alter this portion of the response.[72]

A significant role for α_2-receptors in causing the cutaneous vasoconstriction by local skin cooling has been proposed.[74–79] For example, local skin cooling increases α_2-adrenergic receptor–mediated vasoconstriction. In contrast, local cooling does not augment constriction mediated by α_1-adrenergic receptors.[80] In mouse skin, it has been shown



▲ **FIGURE 92-5** Local cooling responses and vasoconstrictor mechanisms in human skin. Decreases in the local temperature of skin blood vessels induce a local vasoconstriction through mechanisms that require intact sympathetic noradrenergic innervation. The effects of local temperature reductions are independent of any changes in internal temperature. Reductions in local skin temperature are sensed by cold-sensitive afferent nerves. These afferent nerves mediate the release of norepinephrine from adjacent sympathetic active vasoconstrictor nerves. Norepinephrine stimulates α- and β-receptors to cause an initial vasoconstriction. Local cooling can also mediate an initial vasodilation that competes with and buffers the extent of the initial noradrenergically mediated vasoconstriction. The competing dilation is mediated through non-neural mechanisms and is only observed when release of norepinephrine or its post-junctional effects is blocked. Protracted local cooling of the skin results in a prolonged vasoconstriction that is also mediated by non-neural mechanisms. The nature of the non-neural mechanisms is unknown.

that local cooling causes augmented noradrenergic constriction through α_{2C}-adrenergic receptors.[77] Although these receptors are not directly thermosensitive themselves, they have been found to be translocated from the trans-Golgi apparatus of vascular smooth muscle cells to the plasma membrane through the cold-induced activation of RhoA and Rho kinase.[75,76] In this way, more α_{2C}-receptors appear on the surface of vascular smooth muscle. In addition, activation of these kinases enhances the calcium sensitivity of the vascular smooth muscle contractile apparatus. These factors explain how local cooling causes the response of vasoconstriction.[75]

The generation of reactive oxygen species (ROS) from mitochondria in vascular smooth muscle appears to have a role in the vasoconstriction induced by local cooling. Cooling of mouse tail skin arteries leads to increased ROS generation in vascular smooth muscle cells. Alteration of ROS levels by application of free radical scavengers abolishes the vasoconstrictor response to α_{2C}-adrenergic receptor stimulation. Manipulation of ROS levels also abolishes the activation of RhoA in cultured human vascular smooth muscle cells. Taken together, these results suggest that the vasoconstriction caused by local cooling is due to enhanced ROS generation in mitochondria of vascular smooth muscle. Increased ROS then activates RhoA/Rho kinase, which causes a consequent movement of α_{2C}-adrenergic receptors to the cell membrane. On reaching the cell surface, α_{2C}-adrenergic receptors can be activated by norepinephrine released by sympathetic neurons and cause vasoconstriction.[76]

FACTORS THAT ALTER RESPONSES TO HEAT AND COLD

Thermoregulatory responses undergo a physiologic acclimatization after repeated thermal challenges over a prolonged (2-week) period. In general, physiologic acclimatization to hot environments is much more effective than adaptations induced by cold environments in promoting thermal stability. Indeed, after repeated exposure to a hot environment, sweat glands hypertrophy to produce more sweat. Cutaneous active vasodilation begins at lower internal and skin temperatures as well. Both of these adaptations facilitate long-term

thermal stability by favoring earlier and greater heat dissipation.[81] Humans also acclimate to cold environments after repeated exposure. These adaptations include increased metabolic heat generation and habituation to cold, but they are less effective in promoting thermal stability than adaptations to heat.[82]

Acute and chronic dermatologic disorders can impair thermoregulatory stability. For example, sunburn compromises sweat production, thus impairing evaporative cooling and reducing heat tolerance. At the same time, the inflammatory vasodilation that accompanies sunburn can compete against thermoregulatory reflex vasoconstriction during cold exposure. This will compromise the ability of thermoregulatory reflexes to reduce skin blood flow and conserve body heat, and thus reduce cold tolerance.[81]

Medications are also a major factor in altering thermal tolerance, especially during heat exposure. Numerous medications used in clinical medicine, both prescription and over-the-counter drugs, have cholinergic-antagonist properties. Given that the cutaneous active vasodilator system and sweat glands are both controlled by cholinergic sympathetic nerves, it is not surprising that anticholinergic agents have deleterious thermoregulatory consequences. Examples of commonly used medications that can compromise heat stress responses include first-generation antihistamines, H_2-receptor antagonists, tricyclic antidepressants (see Chap. 230), and most agents used to treat Alzheimer disease. These systemic agents (and many others) can reduce sweat secretion, attenuate cutaneous active vasodilation, and hence impair thermoregulation, which increases the risk of heat stroke.[83]

CHAPTER 93

Cold Injuries

Gérald E. Piérard
Frédérique Henry
Claudine Piérard-Franchimont

The human capacity for physiologic adaptation to cold is minimal. This deficiency may cause problems, because seasonal changes in the outdoor environment are quite prominent, even in the temperate zones of the world. In this context, skin is important in thermoregulation, and cutaneous blood flow and the resulting skin temperature may vary widely to help preserve the core body temperature.[1,2] Physiologic, behavioral, and environmental factors modulate skin responses to cold exposure.

PHYSIOLOGIC RESPONSE TO COLD

Core body temperature is maintained within a narrow range by thermoregulatory mechanisms that rely largely on control of the cutaneous blood flow. Arteriovenous anastomoses are abundant in acral areas, and they regulate the volume of blood that passes through the skin. When the skin is cooled, there is usually an immediate acute reduction in the amount of blood that flows to the surface. These events alter skin temperature, heat loss, and color. Skin reactivity and the anatomic pattern of blood supply differ in the skin of newborns, adults, and older people. For instance, a reticulate appearance of cooled skin is a common finding in young infants (Fig. 93-1).

The parallel arrangement of large arteries and veins in the limbs allows countercurrent exchange of heat. Vasoconstriction due to cold results in shunting of blood from the superficial to the deep venous system, and heat is transferred from arteries to veins. Thus the blood going to the acral part of the limbs is precooled, and less heat is lost to the environment. With such thermoregulation, the body can maintain a constant core temperature of approximately 37°C (98.6°F) over a range of external temperatures between 15°C and 54°C (59°F and 129.2°F).

▲ **FIGURE 93-1** Reticulate appearance of cooled skin in the newborn due to the anatomic pattern of the blood supply and factors influencing flow, such as arteriolar vasoconstriction and the increased viscosity of cooled blood.

Normally, the skin is to some extent adapted to a cooler environment than the 37°C (98.6°F) of internal organs. Given the presence of many cold-adapted enzymes, the skin may even function more effectively when slightly cooled. In the case of adipose tissue, mild long-term exposure to cooling may lead to progressively better insulation. Habitually cold-exposed skin also develops a more efficient system for shunting blood away from the surface. These adaptive mechanisms are most flexible during the first years of life. Tissues in the aged are less able to develop new shunts.

The effect of swimming in cold water after extreme heating—for example, after using a sauna[3]—is somewhat comparable to accidental cold water immersion. Well-being depends substantially on the degree of subcutaneous insulation, so that overweight persons, as well as those

COLD INJURIES AT A GLANCE

- Skin is important for maintaining core body temperature within a narrow physiologic range.
- Cold weather, wind, humidity, dampness, and altitude combine to inflict skin damage.
- Nonfreezing and freezing conditions can both produce cold injuries.
- Frostbite occurs after exposure to intensely cold air, liquids, or metals. Several degrees of frostbite are recognized.
- Winter xerosis and acrocyanosis are common consequences of prolonged exposure to cold.
- Erythrocyanosis tends to occur over skin areas with thick adipose tissue, whereas chilblain is more frequently seen in lean persons.
- Cold urticaria is rare and occurs at sites of localized cooling.
- Primary erythromelalgia is a rare neuropathic disorder to which there is a genetic predisposition.

who are well clothed, can survive prolonged accidental cold water exposure.[4]

Viscosity of fluids generally increases as temperature decreases. However, blood is a non-newtonian fluid that exhibits thixotropy; that is, it becomes less viscous with increasing flow velocity, independent of temperature. This effect is strongly influenced by hematocrit and by packing of erythrocytes. Macrophages also can block capillaries when they develop pseudopods as a result of reduced flow. The combination of slow flow and leukocyte conformational changes is, in part, a physiologic process that enables these cells to migrate through the endothelial lining.[5] Other factors affecting blood viscosity include increased platelet adhesiveness, changes in concentrations of proteins, and the presence of abnormal proteins. Fibrinogen level is particularly important.

THERMOREGULATION AND HUNTING REACTION

Local and systemic thermoregulation is complex. A group of neurons in the hypothalamus responds directly to temperature. When the temperature decreases, the rate of discharges decreases. From this temperature-sensitive area, signals radiate to various other portions of the hypothalamus to control either heat production or heat loss. Stimuli that influence the autonomic nervous system, such as painful stimuli, mental stress, arousal stimuli, and deep breaths, can all produce cutaneous vasoconstriction in warm subjects but vasodilation in cold subjects.[6,7]

Cold exposure produces an initial massive cutaneous vasoconstriction, which results in a fall in skin temperature. This change serves to maintain core temperature, but at the expense of the skin. Conversely, cold-induced vasodilation represents a protective mechanism to prevent skin necrosis. This physiologic reflex, known as the *hunting reaction of Lewis*, involves transient cyclic vasodilation caused by the opening of arteriovenous anastomoses.[8,9]

COLD, WIND, HUMIDITY, AND ALTITUDE

A cold environment can be a threat to the skin, leading to a subsequent fall in core body temperature. Many physiologic, behavioral, and environmental factors predispose to the global effects of cold injuries. Marked increases in convective, conductive, or radiant heat loss are responsible for the immediate effects of cold exposure. For instance, touching cold metal objects considerably increases conductive cooling. Other predisposing factors increasing heat loss and/or decreasing heat production and insulation from clothing make people especially susceptible to cold.[10]

There is ample evidence that the effect of low temperature on skin biology is, in part, a function of environmental humidity, wind speed, and altitude. In this respect, the wind chill index is indicative of the convective heat loss. Wind chill affects the gradients of temperature and water content across the stratum corneum, which result in an imbalance in condition between outer and deeper epidermal layers.[11] High altitude, which reduces the oxygen supply to tissues, also contributes to increase the skin damage induced by cold.[12]

Environmental humidity is a key factor affecting cold injuries. This parameter indicates the mass of water vapor present in a unit volume of the atmosphere. An accurate representation of the amount of moisture in the air as a function of temperature is given by the calculation of the dew point,[13] which is defined as the temperature of the air at which the gaseous moisture begins to condense, that is, the temperature at which relative humidity reaches 100 percent.

Poor clothing insulation is a common reason for cold injuries. The insulation can be insufficient when clothing is too light, wet, tight, permeable to wind, or inadequate to cover the cold sensitive body parts. Individual factors predisposing to cold injuries are physical injuries, leanness, low physical fitness level, fatigue, dehydration, previous cold injuries, sickness, trauma, poor peripheral circulation, the wearing of tight constrictive clothing, and old age.[10] Newborns, the elderly, and individuals with impaired mental faculties remain the most vulnerable. Injury is often increased by alcohol, smoking, and psychotropic drug use.

Severe cold injuries have historically influenced the outcome of battles and wars.[14–16] Peacetime military operations also impose risks.[16,17] However, cold injuries are becoming more prevalent among the general population.[18] Many cases are associated with alcohol consumption, homelessness in urban centers, and car breakdown. Frostbite also prevails among winter sport enthusiasts, such as cross-country skiers and backpackers who get lost or trapped in a snowstorm.[2,19–22]

Adaptation to cold protects one from responding inappropriately, and a moderate degree of exposure to cooling might be health promoting by stimulating a responsive and protective vasculature. In contrast, individuals who have experienced severe cold injury may have a profoundly delayed or abolished hunting reaction in the affected limbs.[23] They are rendered more susceptible to recurrent cold injury with pain, hyperesthesia, or paresthesia.[24] Some of these individuals also have coldness of the skin, which is very persistent and probably related to a functional imbalance in the sympathetic nervous system that results from increased α-adrenergic receptor density or affinity for norepinephrine.[25] In addition, altered vascular structure may reduce vasocompliance after cold exposure. There may also be impairment of normal vascular reflexes to various stimuli, including deep inspiration, venous occlusion, neck cooling, and ipsilateral skin cooling.[25]

CLASSIFICATION OF SKIN COLD INJURIES

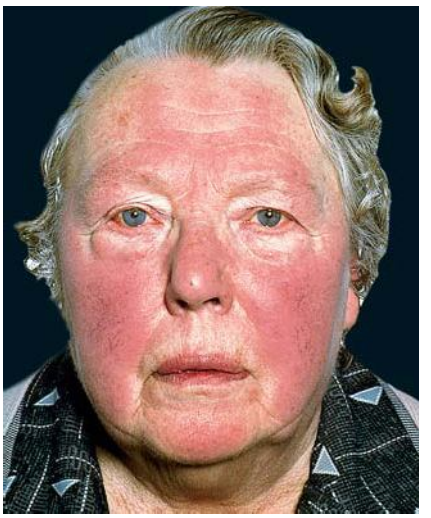
Freezing and nonfreezing injuries can be distinguished according to the severity

and duration of chilling. However, the damage caused depends on many variables other than the actual temperature. Skin conditions caused by cold temperature are not uncommon. Recognition is generally easy at a clinical level, but awareness of potential uncommon underlying disorders is important. Treatment, both physical and pharmacologic, is aimed at keeping the body warm and maintaining vasodilation.

Frostbite is the consequence of extreme and prolonged freezing conditions. In addition, the whole body may cool down so much that life-threatening hypothermia may ensue. This is an important concern for people who enjoy cold weather sports, particularly in mountains and circumpolar regions. Prompt recognition and treatment are of paramount importance, because many hypothermia victims can recover from very low body temperatures. Treatment in an adequate medical facility can make the difference between full recovery and lifelong problems. Even if the victim appears to be dead from exposure to cold, resuscitative efforts should be started and continued until the proper core body temperature is reached.[26]

Extreme and often conductive heat loss at a given body site freezes the tissues and results in localized blistering and necrosis (Fig. 93-2). Several cutaneous disorders also occur when the tissue temperature is maintained just above freezing for long periods. These conditions include chilblains, cold urticaria, cold panniculitis, erythrocyanosis, and acrocyanosis, among others. These disorders may be a consequence of impaired blood flow, reduced sensory perception, or a change in the physical properties of the tissues, such as in adipose tissue.

▲ **FIGURE 93-2** Hemorrhagic bulla and necrosis of the skin induced by freezing a wart with liquid nitrogen.



▲ **FIGURE 93-3** Facial redness in a person exposed to cold winters in a temperate climate.

Minor but long-term cold exposure combined with environmental desiccation may have profound effects on the biology of the epidermis, leading, for example, to winter xerosis.[27,28] Persistent erythema of the face and the hands is not a rare finding (Fig. 93-3).

FROSTBITE

Frostbite occurs when tissue freezes after exposure to extremely cold air, liquids, or metals. The clinical effects of accidental injury that leads to the death of tissues are similar to those caused by cryosurgery.[29] The components of tissue that may lead to damage when frozen are water, with formation of ice crystals at 0°C (32°F), and lipids such as fat globules or cell membrane constituents.

The rate of freezing determines the site of injury at the cellular level.[30] Extracellular formation of ice occurs most commonly with slow freezing, whereas fast freezing tends to produce intracellular ice. The formation of ice crystals in the extracellular space alters the osmotic properties of the tissues and disturbs the flow of water and electrolytes across the cell membranes. Thawing may be as damaging as the freezing itself, and repeated freeze and thaw cycles, as may occur in accidental injury, compound the damage, making more water available, which rapidly leads to intracellular flooding. The rewarming rate is also important. In slow rewarming, ice crystals become larger and more destructive. Cells are also exposed to a high concentration of electrolytes for a longer period than with rapid rewarming.

As the body cools, there is a reflex constriction of the arteries and veins in the extremities.[26] This results in increased venous pressure, decreased capillary perfusion, and sludging. Cooling also creates a leftward shift in the oxygen dissociation curve, and hemoglobin gives up its oxygen less readily. These two conditions result in hypoxia and damage to the capillaries and surrounding tissue. Oxygen tension is further decreased by thrombus formation in the microvasculature, which results in arteriovenous shunting. Arterial and arteriolar constriction, mediated by sympathetic outflow, initiates and probably maintains circulatory impairment. In addition, segmental vascular necrosis occurs in areas of erythrostasis, which suggests that ultimate damage may depend more on insufficient clearance of toxic substances than on initial vasoconstriction.

Cell types vary in their susceptibility to cold injury. Melanocytes are very sensitive to cold, and irreversible damage may occur at –4°C to –7°C (24.8°F to 19.4°F). This sensitivity explains the hypopigmentation that follows cryotherapy. In addition, it appears that black persons are more susceptible to frostbite than whites. Nerve axons are also easily damaged by cold, and nerve injury may occur with axonal degeneration of large myelinated fibers. Autonomic fibers are also affected, and this may account for the abnormal sweating and cold sensitivity that follow nonfreezing cold injury.[31,32] Nerve sheaths are quite resistant to cold, as are bone and cartilage.[23] Desolidification of lipids in adipose tissue and disruption of endothelial cells lining blood vessels and lymphatics, with secondary disturbances of permeability and blood flow, are other consequences of severe cold. In the overall assessment, there are marked similarities in the pathologic processes to those seen in thermal burns and in ischemia-perfusion injuries.

Three stages of cooling are recognized. The first is massive vasoconstriction, which causes a rapid fall in skin temperature. In a second step, the hunting reaction follows with a cyclic rise and fall in skin temperature. If cold exposure continues, the third stage of freezing occurs as the skin temperature falls to approach ambient temperature. The events that ensue in freezing and nonfreezing cold injuries are similar.[14,33] Consequences of cold injuries and their classification are presented in Tables 93-1 and 93-2.

Frostbite usually affects a finger, toe, ear, nose, or cheek. The clinical presentation of frostbite falls into three catego-

TABLE 93-1
Consequences of Cold Injuries

- Arterial and arteriolar vasoconstriction
- Excessive venular and capillary vasodilation
- Increased endothelial leakage
- Erythrostasis
- Arteriovenous shunting
- Segmental vascular necrosis
- Massive thrombosis

ries corresponding to mild frostbite or frostnip, superficial frostbite, and deep frostbite with tissue loss.

Frostnip involves only the skin and causes no irreversible damage. There is a sensation of severe cold progressing to numbness followed by pain. Erythema is usually present on the cheeks, ears, nose, fingers, and toes (Fig. 93-4). There is no edema or bleb formation. Frostnip is the only form of frostbite that can be treated safely in the field with first aid measures.

Superficial frostbite involves the skin and immediately subcutaneous tissues. It includes the previously described signs but with the pain subsiding to feelings of warmth. This is a sign of severe involvement. The skin has a waxy appearance, but deeper tissues remain soft and resilient. Clear blebs form, accompanied by edema and erythema within 24 to 36 hours after thawing. Lesions may become eroded (Fig. 93-5).

Deep frostbite extends to the deep subcutaneous tissue. The injured skin becomes white or bluish white with a variable degree of anesthesia. Most often the affected skin becomes deceptively pain free, and the discomfort of feeling cold vanishes. The tissue is totally numb, indurated with immobility of joints and extremities. Muscles may be paralyzed. Nerves, large blood vessels, and even bone may be damaged. Large blisters form 1 to 2 days after rewarming, and they can be classified according to depth, as in heat-induced burns (Fig. 93-6). Frostbite blister fluid contains high amounts of prostaglandins, including prostaglandin $F_{2\alpha}$ and thromboxane A_2. These mediators may contribute to increased vasoconstriction, platelet aggregation, leukocyte adhesiveness, and ultimately progressive tissue injury. The blister fluid begins to be resorbed within 5 to 10 days, which leads to the formation of hard, black gangrene. Weeks later, a line of demarcation occurs, and the tissues distal to the line undergo autoamputation (Fig. 93-7).

Prevention

Prevention is key to protecting individuals from the effects of cold weather; and frostbite, frostnip, and hypothermia always should be taken seriously. Prognostic factors[22,34–37] are listed in Table 93-3. Nonmedicated ointments are traditionally used for protection against facial frostbite, but their benefit is undocumented. The thermal insulation they provide is indeed minimal. The use of protective emollients seems to cause a false sensation of safety, which leads to an increased risk of frostbite, probably through neglect of other, more efficient protective measures.[38,39] In less extreme conditions, however, some specific topical formulations bring beneficial effects.[40]

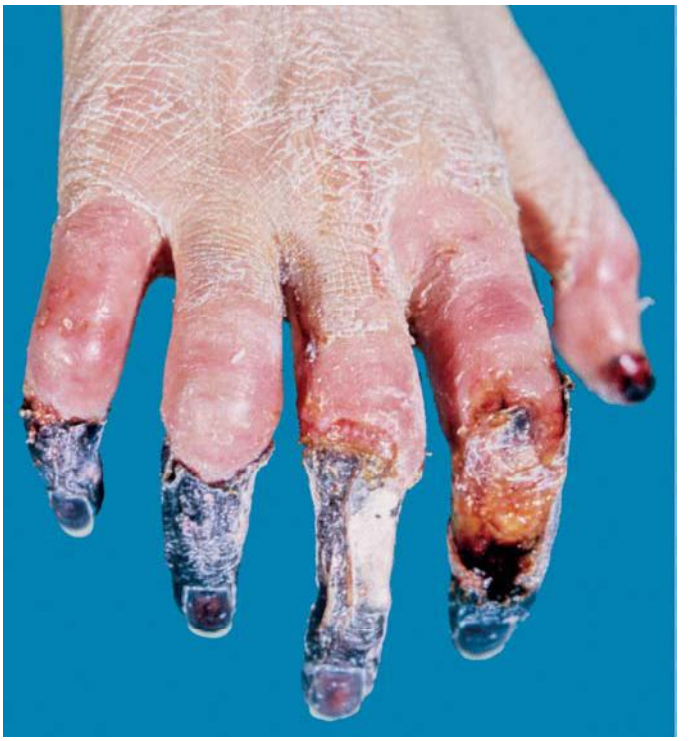
▲ **FIGURE 93-5** Superficial frostbite.

▲ **FIGURE 93-6** Deep frostbite after rewarming. Large blisters have formed. Note cyanosis of toes as a sign of developing necrosis. This cold injury occurred in a homeless person who was found on the street after heavy alcohol consumption and overnight snowfall.

Management

The first consideration in frostbite treatment is to be aware that the victim may be suffering from hypothermia.[22,26,41,42] Because of the difficulty in assessing the depth of frostbite injury, conservative waiting after the frostbite episode is often encouraged in an attempt to delineate the extent of tissue loss. Beyond this, the main principles are to avoid trauma, friction, pressure, massaging with snow, and refreezing. Slow rewarming increases tissue damage, and therefore rapid rewarming is the keystone of treatment.[17] It should be performed in a water bath no warmer than 40°C to 42°C (104°F to 107.6°F) until the most distal parts of the body are flushed. Large amounts of analgesics may be required. The damaged part should be elevated, and blisters should be left intact. Surgical debridement is often best delayed until 1 to 3 months after demarcation. However, triple-phase bone scans, magnetic resonance imaging, and magnetic resonance angiography can be used to predict ultimate tissue loss and to assess the possibility of earlier surgical intervention.[33,43,44]

There is no uniformly accepted protocol for other measures allegedly benefi-



▲ **FIGURE 93-7** Dry gangrene of all fingers in a mountain climber 5 weeks after being caught in a snowstorm.

cial in the treatment of frostbite injury.[42] Intra-arterial reserpine and sympathectomy have been used to reverse vasospasm, which may contribute to tissue loss. Their role is controversial, although some patients have benefited from this therapy. To counteract vasoconstriction caused by local release of inflammatory mediators, the use of topical aloe vera, which inhibits thromboxane synthetase, and systemic ibuprofen, which inhibits cyclooxygenase, have been advocated. Oxpentifylline has been presented as an advanced therapy.[45] In addition, several adjunctive therapies, including vasodilators, thrombolysis, and hyperbaric oxygen, are sometimes useful.[46] Tetanus toxoid should be given in the case of open wounds. Surgery and amputation remain the ultimate strategies to help the victims.[47]

TABLE 93-3
Prognostic Signs of Frostbite

Good prognostic signs	• Large, clear blebs extending to the tips of the digits • Rapid return of sensation • Rapid return of normal (warm) temperature to the injured area • Rapid capillary filling time after pressure blanching • Pink skin after rewarming
Poor prognostic signs	• Hard, white, cold, insensitive skin • Cold and cyanotic skin without blebs after rewarming • Dark hemorrhagic blebs • Early evidence of mummification • Constitutional signs of tissue necrosis, such as fever and tachycardia • Cyanotic or dark red skin persisting after pressure • Freeze-thaw-refreeze injury

Sequelae

Sequelae of frostbite include permanent hypersensitivity to cold and, less often, hyperhidrosis.[31] Squamous cell carcinoma is a rare outcome, usually occurring on the heel 20 to 30 years later.[48] Epiphyseal plate damage or premature fusion may occur in children. Premature fusion can result in shortened digits, joint deviation, and dystrophic nails. In addition, frostbite arthritis, resembling osteoarthritis, may occur weeks to years later.

NONFREEZING COLD INJURY AND DAMPNESS

Nonfreezing cold injury occurs when tissues are cooled to temperatures between approximately 15°C (59°F) and their freezing point for prolonged periods. This type of injury, which is exacerbated by dampness, has claimed numerous casualties in warfare. Nonfreezing cold injury may be followed by cold sensitivity and hyperhidrosis, which may persist for years.

During World War I, trench foot was identified as a separate entity. Wet conditions at temperatures above freezing and limb dependency due to immobility and constrictive footwear were important pathogenic factors. Three stages were described. Stage I consisted of initial erythema, edema, and tenderness. Stage II followed within 24 hours with paresthesia, marked edema, numbness, and sometimes blisters. Stage III corresponded with progression to a usually superficial gangrene. Immersion foot, similar to trench foot, was described in shipwreck survivors during World War II.

Tropical immersion foot was described during the Pacific campaign in World War II. Occurring after exposure to the warm, wet conditions of jungle warfare, this condition differed from classic trench foot and immersion foot in that it caused less tissue destruction, numbness, and anesthesia and was followed by more rapid complete recovery. The role of temperature in tropical immersion foot is unclear and may not be important.[49] As with trench foot and immersion foot, prevention is most important.

Another specific condition known as *pulling-boat hands* was described, characterized by the presence of erythematous macules and plaques on the dorsum of the hands and fingers of sailors aboard rowboats.[50] Small vesicles developed later, accompanied by itching, burning, and tenderness. These individuals were exposed to long periods of high humidity, cool air, and wind, an ideal setting for the development of nonfreezing cold injury. In addition, hours of vigorous rowing daily produced repetitive hand trauma.

WINTER XEROSIS

Many individuals present with dryness of the skin, particularly on the lower extremities, during wintertime. The hands, forearms, cheeks, lips, and trunk also may be affected. Itching, a dry appearance, chapping, and cracking of the stratum corneum are more or less prominent. The condition is markedly influenced by cold environments, especially in combination with low humidity.[27,28] Predisposing factors include atopic dermatitis, ichthyosis, and increasing age. Excessive washing exacerbates winter xerosis. In-

deed, irritant dermatitis of the hands worsens in a cold and dry environment.[51] Emollients and improvement in the environmental temperature and humidity are helpful in controlling this condition.

ACROCYANOSIS

Acrocyanosis is a bilateral dusky mottled discoloration of the hands, feet, and sometimes the face. It is persistent and accentuated by cold exposure. When the temperature is very low, the skin may be bright red. Trophic changes and pain do not occur, and pulses are present. This condition must be distinguished from Raynaud phenomenon (see Chap. 171), which is clearly episodic, often segmental, and painful, as well as from obstructive arterial disease (see Chap. 174).

Acrocyanosis is genetically determined and usually starts in adolescence. Chronic vasospasm of small cutaneous arterioles or venules with a secondary dilatation of the capillaries and subpapillary venous plexus has been postulated. Stasis in the papillary loops with aneurysmal dilatation at the tips redistributes blood flow to the subpapillary venous plexus. The blood flow may be compromised by altered erythrocyte flexibility, increased platelet adhesiveness, and other plasma viscosity factors.

Tissues are less sclerotic in acrocyanosis than in Raynaud phenomenon. They contain twisted collagen fibrils and large pericytes. In cases developing for the first time late in life, an underlying myeloproliferative disorder should be excluded. Remittent necrotizing acrocyanosis is associated with enhanced susceptibility to cooling and pain, as well as ulceration and gangrene of the fingers. Arteriolar occlusion by thrombi or intima proliferation may occur.

There is no effective treatment for acrocyanosis. Supportive measures to keep the skin warm are helpful.

ERYTHROCYANOSIS

Erythrocyanosis is a dusky cyanotic discoloration, worse in winter, that occurs over areas with a thick layer of subcutaneous fat (Fig. 93-8). The condition is seen most often on the lower legs and thighs of adolescent girls and middle-aged women. Nodular lesions similar to chilblains may occur and have been described in women with severe erythrocyanosis and paraplegia. Keratosis pilaris, angiokeratomas, and telangiectases are commonly associated. Spontaneous improvement often occurs after a few years. However, the disease may persist with long-standing edema and fibrosis.

▲ **FIGURE 93-8** Erythrocyanosis of plump upper arms of a woman.

The wearing of warm clothes and weight reduction are important to decrease the insulating effect of the subcutaneous fat, which is responsible for a chronically low skin temperature. The outcome remains unpredictable.

CHILBLAINS

Chilblains, also called *pernio* or *perniosis* (Fig. 93-9), are localized inflammatory lesions caused by continued exposure to cold above the freezing point.[52,53] Dampness and wind that increase thermal conductivity and convection play a part. Absolute temperature is less important than the cooling of nonadapted tissue. The condition shows a genetic predisposition. It has been described most often in temperate regions, where winters are occasionally cold and damp. Chilblains are seen less often in very cold climates, where well-heated houses and warm clothing are available. Both acrocyanosis and chilblains appear to be more common in children, women, and persons with low body mass index. Spontaneous remission is common when spring arrives, and relapse is frequent during the following winters. However, chilblains do not always occur at the time of maximum cold.

Chilblains develop acutely as single or multiple, burning, erythematous, or purplish swellings (see Fig. 93-9A and C). Patients may complain of itching, burning, or pain. In severe cases, blisters (see Fig. 93-9B), pustules, and ulceration may occur. Characteristic locations include the proximal fingers and toes, plantar surfaces of the toes, heels, nose, and ears, but other sites like the calves and thighs can be affected[54] (see Fig. 93-9C). Lesions usually resolve in 1 to 3 weeks but may become chronic in elderly people with venous stasis. Tight garments such as gloves, stockings, and shoes are especially to be avoided in cases in which there is also peripheral vascular disease. A papular form of chilblains resembles erythema multiforme and occurs at all times of the year, usually in crops on the sides of the fingers,[55] often superimposed on a background of acrocyanosis.

A peculiar clinical presentation may occur in young women riding horses for several hours daily during winter.[56,57] Indurated red to violet tender plaques develop on the lateral calves and thighs (see Fig. 93-9C). The condition is quite similar to the nodular perniotic lesions described in adolescent girls with erythrocyanosis. For prophylaxis, experienced riders usually wear baggy breeches that provide insulation and are not tight enough to compromise the circulation.

Perniotic lesions have been described in association with myeloproliferative disorders,[58] probably as a consequence of blood flow changes, presence of cold agglutinins, and altered inflammatory response on cooling.

Idiopathic perniosis is characterized histologically by edema of the papillary dermis and by the presence of superficial and deep perivascular lymphocytic infiltrates. Necrotic keratinocytes and lym-

▲ **FIGURE 93-9** Chilblains are common at such sites as the hands and feet when they are exposed to both cooling and tight garments. **A.** Chilblains on the toes. **B.** Chilblains on the dorsum of the foot. Children and the elderly are most commonly affected, perhaps because they take less care to protect themselves from cooling. **C.** Equestrian chilblains from horse riding on a cold morning with inadequate clothing.

phocytic vasculitis also have been reported. Thickening of blood vessel walls with intimal proliferation may lead to obliteration of the vascular lumen.[59–61]

Chilblain lupus is a distinct disease and is similar to discoid lupus erythematosus.[62,63] Lupus pernio is a variant of sarcoidosis (see Chap. 153) and is unrelated to cold injuries.

The unfamiliarity of physicians with chilblains sometimes gives rise to unnecessary hospital admissions with expensive laboratory and radiologic evaluations and, at times, hazardous therapy. The most important point in management is prophylaxis through the use of adequate, loose, insulating clothing and appropriate warm housing and workplace. Maintaining the blood circulation by avoiding immobility is also helpful. A short course of ultraviolet light therapy at the beginning of winter was a recommendation but has been challenged.[64] Once chilblains occur, treatment is symptomatic with rest, warmth, and topical antipruritics. Calcium channel–inhibiting drugs may be effective in the treatment of severe recurrent perniosis,[65] although they may cause headache and flushing that are troubling to some patients. In cases of crippling severity, thyrocalcitonin and hemodilution may be helpful.

COLD URTICARIA AND POLYMORPHOUS COLD ERUPTION

Cold urticaria (Fig. 93-10) occurs at sites of localized cooling, usually when the area is rewarmed. It may be idiopathic or associated with some serologic abnormality.[66–70] It accounts for approximately 2 percent of cases of urticaria (see Chap. 37).

Most cases fall into the group of essential cold urticaria. They can be subdivided into a rare familial type and an acquired form. Immunoglobulin E and, more rarely, immunoglobulin M have been implicated in the pathogenesis. The antigen is likely a normal metabolite produced on exposure to cold. Histamine is one of the most important mediators, but leukotrienes, platelet-activating factor, and others have been incriminated. In this disease, exposure to cold causes prolonged edematous papules and plaques, often with headache, fever, arthralgia, and leukocytosis. Swelling of the oral mucosa and esophagus may occur on ingestion of cold liquids. A rather distinctive combination of cold urticaria and dermographism or cholinergic urticaria is not uncommon. Alarming signs resembling those of histamine shock may lead to loss of consciousness. Death while swimming in cold water has been reported.

Familial cold urticaria is a rare autosomal dominant condition with onset at an early age.[71,72] A CIAS1 mutation has been identified.[72] Urticaria develops when the patient is exposed to generalized cooling, particularly chilling wind, rather than local cold application. The delayed type of familial cold urticaria is characterized by localized angioedema developing 9 to 18 hours after cold exposure.

Cold urticaria may occur in 3 percent to 4 percent of patients with cryoglobulinemia, and it also may be associated with cold agglutinins, cryofibrinogens, and cold hemolysins. Cold urticaria has been reported in cases of infectious mononucleosis in association with either cryoglobulins or cold agglutinins, but such occurrences are rare. Cold urticaria may also be a sign of the Muckle-Wells syndrome.[73] *Helicobacter pylori* has been suggested as a causative agent in some cases of acquired cold urticaria.[74]

◀ **FIGURE 93-10** Cold urticaria induced by the application of ice to the skin.

Diagnosis of cold urticaria is confirmed by placing an ice cube wrapped in a plastic bag on the skin of the forearm for periods varying from 30 seconds to 10 minutes (see Fig. 93-10). Wheals form on rewarming. Sometimes water at 7°C (44.6°F) is more effective, presumably because it causes less severe vasoconstriction. Peltier effect–based temperature challenge appears to be an improved method for diagnosis.[75]

Cold erythema seems to be a related disorder with erythema and pain but without urticaria. Familial polymorphous cold eruption is a rare autosomal dominant disease characterized by childhood onset of non-pruritic, erythematous eruptions often accompanied by influenza-like symptoms after generalized exposure to cold and leukocytosis. Results of the ice cube test are negative. The pathogenesis remains unknown. The disease frequently has been referred to as *familial cold urticaria*, although the skin lesions are not urticarial.[76]

Avoiding cold wind exposure and swimming in cold water are important preventive measures. Antihistamines reduce clinical signs and symptoms. Desensitization to cold is possible by immersing one arm into water at 15°C (59°F) for 5 minutes daily.

COLD PANNICULITIS AND RELATED ENTITIES

Cold injuries may affect the subcutaneous tissue in different ways. The freezing injury in deep frostbite results in tissue gangrene. Nonfreezing injuries also can alter the hypodermis. Among them, cold panniculitis is more common in children than in adults. It affects the cheeks and legs most commonly. Tender erythematous subcutaneous nodules appear 1 to 3 days after exposure and subside spontaneously within 2 to 3 weeks. Ice cube challenge to the child's skin for 10 minutes results in the development of an erythematous plaque 12 to 18 hours later (see Chap. 68).

A perivascular mixed infiltrate with neutrophils, lymphocytes, and histiocytes is present at the dermal-subcutaneous junction after 24 hours, followed by a well-developed panniculitis at 48 to 72 hours. Some adipocytes are necrotic and they rupture to form cystic spaces. The reaction subsides completely by 2 weeks. Infants have a higher content of saturated fatty acids in adipose tissue than do adults, and this may result in solidification at higher (less cold) temperatures.[77] Cold panniculitis should be distinguished from other related disorders, including erythrocyanosis with nodules, sclerema neonatorum, and subcutaneous fat necrosis of the newborn.

SCLEREMA NEONATORUM AND SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN (See Chaps. 68 and 106)

Sclerema neonatorum and subcutaneous fat necrosis of the newborn are distinct disorders involving the subcutaneous fat of the newborn. As noted in the prior paragraph, infant fat differs from adult fat in that it has a higher saturated-unsaturated fatty acid ratio, which results in solidification at a higher temperature. Prematurity and immaturity of enzyme systems may result in a relative inability to desaturate fatty acids, which alters the ratio further. Sepsis, dehydration, chilling, infection, and other stresses also may inhibit the enzyme system. Thus infants in general, and premature or otherwise compromised newborns in particular, are susceptible to such disorders.

Sclerema neonatorum is a rare disorder characterized by diffuse, rapidly spreading hardening of the skin and subcutaneous tissue in infants. It starts on the buttocks and trunk, usually in the first week of life. Palms, soles, and scrotum are spared. Fifty percent of affected infants are premature. They have difficulty feeding and are lethargic, and many are otherwise debilitated. Septicemia is frequent, and the prognosis is poor. Cold exposure does not seem to be important in the etiology of sclerema neonatorum; however, similar clinical findings have been seen in cases of primary cold injury.[78] Histologically, the subcutaneous layer is greatly thickened by enlarged fat cells and wide, fibrous bands. There is no fat necrosis, and many of the fat cells contain fine needle-like clefts.[79]

Treatment of sclerema neonatorum involves correcting dehydration and electrolyte imbalance and treating septicemia if present. The value of systemic glucocorticoids is controversial. Successful treatment with exchange transfusions has been reported.[80]

Subcutaneous fat necrosis of the newborn is characterized by discrete red to violaceous mobile plaques and nodules that usually appear within a few days of birth. The back, thighs, and cheeks are most commonly affected. Fat necrosis and crystallization are the hallmarks of the disease. There may be a granulomatous inflammatory response with foci of calcification. In most cases, the condition is benign and self-limited, although it has been associated with hypercalcemia and death.[81]

As in sclerema neonatorum, there is no clear etiologic relationship to cold, and the cause is likely multifactorial. It has been postulated that an underlying defect in fat composition, poor nutrition, and various physical stresses such as hypothermia may be important.

ERYTHROMELALGIA

Erythromelalgia or erythermalgia is a rare chronic cutaneous disorder characterized by erythema, burning discomfort, and warmth of the extremities.[82,83] Primary erythromelalgia is an autosomal dominant neuropathic disorder involving a mutation in a voltage-gated sodium channel subunit.[84–88] Vasoconstriction apparently precedes reactive hyperemia, similar to that seen in Raynaud phenomenon. An early-onset type and an adult-onset type have been recognized. When the extremity is lowered or heat is applied, the pain is intensified. The application of cold or elevation of the extremity has the opposite effect of decreasing the pain. Idiopathic erythromelalgia may involve increased thermoregulatory arteriovenous shunt flow. Secondary erythromelalgia is associated commonly with myeloproliferative syndrome–related thrombocythemia and is mostly evident in the adult-onset type.

Treatment for adults with erythromelalgia includes a single daily dose of acetylsalicylic acid, but children who have no associated underlying disorder obtain little to no relief from the drug. Other drugs including mexiletine[89] and venlafaxine[90] may also help. Pain may be decreased by topical amitriptyline combined with ketamine.[91] Lidocaine in patches[92] or administered intravenously in combination with oral mexiletine[93] may also alleviate pain. Sympathectomy in the upper extremities is another option for treating primary erythromelalgia.[94]

CHAPTER 94

Thermal Injuries

Robert L. Sheridan

EPIDEMIOLOGY

The very young and very old are at increased risk of domestic burns.[1] Active young adults in industrial jobs are at modest increased risk. In developed countries, about 70 percent of pediatric burns are caused by hot liquid. Flame injuries are more common in older children and young working adults. Kitchen and bathing accidents are predominant in the elderly. As much as 20 percent of burns in younger children involve abuse or neglect.

ETIOLOGY AND PATHOGENESIS

The development of an envelope of skin was a crucial component of the adaptation of aquatic sea animals to the land environment. The vapor and fluid barrier created by the epidermal layer facilitates the maintenance of fluid and electrolyte homeostasis within very narrow limits. The dermis provides strength and flexibility, and the reactive dermal vasculature facilitates control of internal body temperature. Skin appendages provide lubrication and prevent desiccation. All of these critical functions are lost when substantial areas of the skin are burned.

There is both a local and a systemic response to the burn wound.[2] The local response consists of coagulation of tissue with progressive thrombosis of surrounding vessels in the zone of stasis over the first 12 to 48 post-injury hours. An ability to truncate this secondary microvascular injury and its associated tissue loss is a major area of ongoing investigation. In larger burns, a systemic response develops that is driven initially by release of mediators from the injured tissue, with a secondary diffuse loss of capillary integrity and accelerated transeschar fluid losses. This systemic response is subsequently fueled by by-products of bacterial overgrowth within the devitalized eschar.

Burn wounds are initially clean but are rapidly colonized by endogenous and exogenous bacteria.[3] As bacteria multiply within the eschar over the days after injury, proteases result in eschar liquefaction and separation. This leaves a bed of granulation tissue or healing burn, depending on the depth of the original injury. In patients with wounds involving 40 percent or more of the body surface, the infectious challenge generally cannot be contained by the immune system, with resulting systemic infection. This explains the rare survival of patients managed in an expectant fashion with burns of this size.

The systemic response to injury is characterized clinically by fever, a hyperdynamic circulatory state, increased metabolic rate, and muscle catabolism.[4] This stereotypical response to injury has been retained by all mammalian species. It is effected by a complex cascade of mediators, including changes in hypothalamic function resulting in increases in glucagon, cortisol, and catecholamine secretions; deficient gastrointestinal barrier function with translocation of bacteria and their by-products into the systemic circulation; bacterial contamination of the burn wound with systemic release of bacteria and bacterial by-products; and some element of enhanced heat loss via transeschar evaporation. It is likely that this response overall has significant survival value, but control of some of the adverse aspects of this response, particularly muscle catabolism, is an active area of ongoing investigation.[5]

CLINICAL FINDINGS

Burns are classified by depth:

- First-degree: Red, dry, and painful and are often deeper than they appear, sloughing the next day (Fig. 94-1A).
- Second-degree: Red, wet, and very painful with enormous variability in their depth, ability to heal, and propensity to hypertrophic scar formation (see Fig. 94-1B).
- Third-degree: Leathery, dry, insensate, and waxy (see Fig. 94-1C).
- Fourth-degree: Involve underlying subcutaneous tissue, tendon, or bone (see Fig. 94-1D).

Circumferential burns require special monitoring and possible surgical decompression. If across the torso, they will interfere with ventilation. If they involve

THERMAL INJURIES AT A GLANCE

- Burns are common injuries and will be seen by many practicing dermatologists.
- Most burns are small and are managed in the outpatient setting.
- Serious burns require inpatient care, ideally in a verified burn center.
- Large burns are managed in four general phases:
  - Initial evaluation and resuscitation
  - Wound excision and biologic closure
  - Definitive wound closure
  - Rehabilitation and reconstruction
- Styles of outpatient burn care are variable, but certain general principles are important. Proper patient selection and monitored wound healing are essential.
- Long-term outcome tends to be very good, even in large burns.

▲ **FIGURE 94-1** Burn depth is classified as first, second, third, or fourth degree. **A.** First-degree burns are red, dry, and painful and are often deeper than they appear, sloughing the next day. **B.** Second-degree burns are red, wet, and very painful. There is an enormous variability in their depth, ability to heal, and propensity to hypertrophic scar formation. **C.** Third-degree burns are leathery, dry, insensate, and waxy. **D.** Fourth-degree burns involve underlying bone and/or muscle.

an extremity, limb-threatening ischemia may occur during resuscitation.

CLINICAL COURSE: PATIENT EVALUATION AND TREATMENT PLANNING

In both outpatient and inpatient settings, a careful evaluation of the patient is essential for treatment planning.

- The burn wound should be examined for size, extent, depth, and circumferential components.
- Decisions regarding outpatient care, hospitalization, or transfer will be influenced by this information (Table 94-1).
- Burn extent is best estimated using a chart based on the Lund-Browder diagram that compensates for the changes in body proportions with age. An alternative is a "Rule of Nines" for adults and children.
- In the adult Rule of Nines, the head and neck is given 9 percent, each lower extremity is given 18 percent, each upper extremity is given 9 percent, and the anterior and posterior torso are each given 18 percent.
- In the pediatric Rule of Nines, the head and neck is given 18 percent, each lower extremity is given 15 percent, each upper extremity is given 10 percent, and the anterior and posterior torso are each given 16 percent.
- For scattered or irregular burns, the entire palmar surface of the patient's hand represents approximately 1 percent of the body surface over all ages.

Patient evaluation is organized into a primary and a secondary survey, following the guidelines of the American Col-

TABLE 94-1
American Burn Association Burn Center Transfer Criteria

- Second- and third-degree burns greater than 10% TBSA in patients younger than 10 or over 50 years of age.
- Second- and third-degree burns greater than 20% TBSA in other age groups.
- Second- and third-degree burns that involve the face, hands, feet, genitalia, perineum, and major joints.
- Third-degree burns greater than 5% TBSA in any age group.
- Electrical burns, including lightning injury.
- Chemical burns.
- Inhalation injury.
- Burn injury in patients with pre-existing medical disorders that could complicate management, prolong recovery, or affect mortality.
- Any patients with burns and concomitant trauma (such as fractures, etc.) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable before being transferred to a burn center. Physician judgment will be necessary in such a situation and should be in concert with the regional medical control plan and triage protocols.
- Hospitals without qualified personnel or equipment for the care of children should transfer children with burns to a burn center with these capabilities.
- Burn injury in patients who will require special social/emotional and/or long-term rehabilitative support, including cases involving suspected child abuse, substance abuse.

TBSA = total body surface area.

lege of Surgeons Committee on Trauma, and the Advanced Burn Life Support Course of the American Burn Association.

As in trauma, the primary survey begins with an assessment, and control if necessary, of the airway. Deeper burns of the face and neck can result in progressive airway edema. Occasionally, a child will aspirate hot liquids, resulting in very severe, upper airway edema mandating urgent intubation.

A burn-specific secondary survey evaluates issues uniquely associated with burn injury (Table 94-2). This may take just a few seconds if the burn is small, but will be much more time consuming in the more seriously injured.[6] In those with small injuries, essentials include a detailed determination of the mechanism of injury, a screen for associated trauma, consideration of the possibility of abuse, and a detailed assessment of the burn wound. Delayed presentation for care, confusing stories, sharply demarcated margins, immersion patterns, and contact injuries are physical findings worrisome for abuse or neglect (Fig. 94-2).[7] All such children should be admitted for evaluation.

After the patient has been evaluated, the burn wound should be examined for size, extent, depth, and circumferential components.[8] Burn extent is best estimated using a chart based on the Lund-Browder diagram that compensates for the changes in body proportions with age (Fig. 94-3). An alternative is a modified Rule of Nines, in which, for children, the head and neck is given 18 percent (instead of the adult 9 percent), each lower extremity is given 15 percent (instead of the adult 18 percent), each upper extremity is given 10 percent (instead of the adult 9 percent), and the anterior and posterior torso are each given 16 percent (instead of the adult 18 percent). For scattered or irregular burns, the entire palmar surface of the patient's hand represents approximately 1 percent of the body surface over all ages.

Burn depth can usually be assessed accurately from clinical features (see Fig. 94-1). Near or completely circumferential burns should be identified for special monitoring, as they may need to be decompressed in the hours following injury to avoid ischemia (extremities) or failure of ventilation (torso).

The majority of burns can be successfully managed in the outpatient setting. However, poorly provided outpatient burn care can be frustrating and painful for patients and providers. The key is careful patient selection and a detailed care plan. Several issues should be considered in making this decision (Table 94-3).

TABLE 94-2
Burn-Specific Secondary Survey

- History
  - Mechanism of injury
  - Closed space exposure and extrication time
  - Delay in seeking attention
  - Fluid and pain medication given during transport
  - Prior illnesses and allergies
  - Prior child protective services involvement
- Head, eyes, ear, nose, and throat
  - Early examination of the globes for corneal burns.
  - Clinical assessment for intraocular hypertension if deep facial burns.
  - Perioral and intra-oral burns and carbonaceous material.
  - Progressive hoarseness.
  - Consider hot liquid aspiration.
  - Continuously assess endotracheal tube security.
- Neck
  - Radiographic evaluation if indicated by injury mechanism
  - Rare need for neck escharotomies
- Cardiac
  - Cardiac monitoring after significant electrical injury
- Pulmonary
  - Chest escharotomies indicated if near circumferential torso burn and difficulty with ventilation
  - Inhalation injury associated with airway obstruction and bronchospasm initially
- Vascular
  - Perfusion of burned extremities should be closely monitored.
  - Escharotomy indicated for decreasing perfusion.
  - Fasciotomy indicated after electrical or deep thermal injury when flow compromised.
  - Compartment pressures can be followed in equivocal extremities.
  - Worrisome extremities should be decompressed based on serial exam.
- Abdomen
  - Nasogastric tubes often indicated especially before air transport.
  - Inappropriate volume requirement may be a sign of an occult intra-abdominal injury.
  - Torso escharotomies may be required to facilitate ventilation.
  - Ulcer prophylaxis indicated in all with serious burns.
  - Consider abdominal compartment syndrome in very large burns or delayed resuscitation.
- Genitourinary
  - Catheterization is appropriate in all who require a fluid resuscitation.
  - Ensure that the foreskin is reduced over the bladder catheter.
- Neurologic
  - Level of consciousness often reduced during the hours after injury
  - Computed tomography scanning useful to exclude head injury if mechanism appropriate
- Extremities
  - Monitor perfusion if there are near circumferential burns or electrical injury.
  - Limbs at risk should be dressed so they can be easily reexamined.
- Wound
  - Evaluate wounds for size, depth, and circumferential components.
  - Wounds often underestimated in depth and overestimated in size initially.
- Electric
  - Monitor cardiac rhythm for high (> 1000 volt) or intermediate (> 220 volt) volt exposures.
  - Neurologic and ocular examination important.
  - Extremities should be serially evaluated for intracompartmental edema.
  - Bladder catheters useful in high voltage exposures to document clearing of pigment.
- Chemical
  - Irrigate wounds with tap water for at least 30 min.
  - Irrigate eyes with isotonic crystalloid solution.
  - Blepharospasm may require ocular anesthetic.
  - Hydrofluoric acid may be complicated by life-threatening hypocalcemia.
- Tar
  - Cool with tap water irrigation and remove later with a lipophilic solvent.
- Laboratory and radiography
  - Blood gas when inhalation injury present.
  - Normal carboxyhemoglobin does not rule out significant exposure.
  - Baseline hemoglobin and electrolytes can be helpful later.
  - Urinalysis for occult blood useful in those with deep thermal or electrical injuries.
  - Radiographic evaluation as needed for mechanism of injury.

COMPLICATIONS

In the outpatient setting, patient selection should ensure that major complica-

▲ **FIGURE 94-2** Some burn patterns are very suggestive of possible abuse. This child demonstrates flexor (popliteal fossa) sparing in an immersion injury.

tions are few (Table 94-4). The most common issues that arise are wound sepsis, excessive pain and anxiety, and underestimation of burn depth.[9] The most common wound infection in this setting is streptococcal cellulitis, which presents initially with surrounding erythema that progresses to lymphangitis and systemic toxicity (Fig. 94-4). These patients often need admission for antibiotics, observation, and, sometimes, surgery. In some situations, adequate pain and anxiety management is very difficult in the outpatient setting, especially around dressing changes. This can be addressed with judicious medication and sometimes, carefully monitored membrane dressings. Some patients will require admission. It is common for burn depth to be underestimated initially, with areas of full-thickness injury not appreciated for several days. These patients may require admission for surgery.

As burns increase in size and depth, the local injury is accompanied by an increasing degree of systemic derangement. Classically, this response has two phases. An initial "ebb" phase of reduced perfusion and metabolic rate that lasts 24 to 48 hours is followed by a "flow" phase of protein catabolism and a hyperdynamic circulation.[10] This later phase lasts until well after wound closure. Management of this physiology is an essential part of inpatient burn care. Those with large burns are susceptible to a host of other complications related to sepsis and organ failures. Careful monitoring and early intervention are essential to successful outcomes (see Table 94-4).

Burn wounds and grafts typically develop some degree of hypertrophy.[11] This involves a gradual increase in vascularity and collagen deposition in the months following healing. Some wounds will demonstrate significant contracture formation, with important functional and aesthetic consequences (Fig. 94-5). Many patients will have bothersome pruritus and sometimes temporary neuropathic pain if burns are deep. A long-term, follow-up plan, consisting of scar management strategies, rehabilitation, reconstructive surgery, and emotional support, will facilitate optimal outcomes. This care is best provided in a multi-disciplinary burn clinic, ideally part of a comprehensive burn program. With such supports in place, the long-term outcome for most patients is surprisingly good. When managed in a comprehensive follow-up program, even those who have suffered devastating burns tend to become happy and productive again.[12]

TREATMENT

Outpatient Burns

Practice patterns vary widely, but certain characteristics are universal.[13] The wound should be kept generally clean and regularly inspected for infection. Desiccated exudates and topical medications should be periodically cleansed. Burns selected for outpatient management tend to be small and superficial, with a corresponding low risk of infection, so clean rather than sterile technique is reasonable. If topical agents, rather than membrane dressings, are used, wounds may be cleansed with lukewarm tap water and a bland soap. Soaking adherent dressings before removal will decrease the pain associated with daily wound care. The wound is gently cleansed with a gauze or clean washcloth, inspected for any sign of infection, patted dry with a clean towel, and redressed. It is important to instruct each patient to return promptly if they notice erythema, swelling, increased tenderness, lymphangitis, odor, or drainage so that infectious complications can be addressed early. Most small burns are adequately managed with a daily cleansing and dressing change. In some cases, a membrane dressing is applied once it is clear that early surgery is not needed, early infection is unlikely, and wounds are superficial. Pain and anxiety are issues for many, and some will benefit from an oral narcotic given 30 to 60 minutes before a planned dressing change. If dressings are occlusive, pain between dressing changes tends to be modest.

Increasing pain and anxiety associated with dressing changes, inability to keep scheduled follow-up appointments, delayed healing, signs of infection, or a wound that appears deeper than appreciated at the time of the initial examination should prompt early return and specialty evaluation. Wounds selected for outpatient management are usually fairly superficial and heal within 2 weeks; those patients with mid- and deep dermal injuries may have a deeper component with resulting scarring that may benefit from specialty evaluation. Finally, wounds of the face, ears, hands, genitalia, and feet have a functional and cosmetic importance out of proportion to their wound size. In some cases, early specialty evaluation may be prudent, as initial care can have an impact on long-term outcome.

Inpatient Burns

A system of burn center verification has evolved to ensure that patients requiring care of more serious injuries receive coordinated efforts by experienced providers. Burn center referral criteria can be found at http://www.ameriburn.org. Care of severe burns can be divided into phases: (1) initial evaluation and resuscitation, (2) initial excision and biologic closure, (3) definitive wound closure, and (4) rehabilitation and reconstruction.[14] Important objectives of each phase are listed in Table 94-5. Critical care is an important component, especially in the first three phases. Verified burn programs are required to have embedded intensive care units.

Topical Medications and Membranes

There is an increasingly confusing array of wound medications and membranes

TABLE 94-3
Issues to Consider When Making Decision Between Outpatient and Inpatient Burn Care

- No airway compromise or need for airway monitoring.
- Wound size should generally be less than 10% (fluid resuscitation not needed).
- Patient must be able to take in adequate fluid by mouth.
- No significant burns of the face, ears, hands, genitals, or feet.
- Family must have the resources to support an outpatient care plan.
- Adult caregiver should be able to stay home with child.
- Adult able to perform wound cleansing, inspection, and dressing changes.
- Child must have transportation and access to clinic follow-up.
- Family must have transportation for clinic and emergency visits.
- No suspicion of abuse or neglect.
- No clearly full-thickness areas that will require surgery.

TABLE 94-4
Frequent and Serious Burn Complications

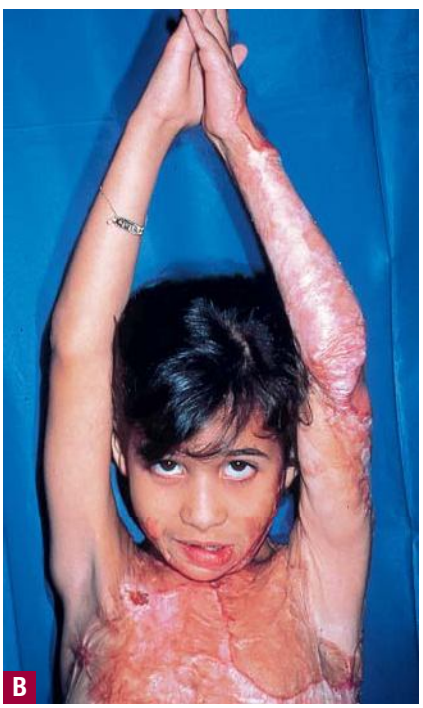
- Common outpatient burn complications
  - Wound sepsis, usually streptococcal cellulitis
  - Excessive pain and anxiety
  - Underestimation of burn depth
- Common inpatient burn complications
  - Wound sepsis, often invasive
  - Septic shock and organ failures
  - Inadequately controlled pain and anxiety
  - Compartment syndromes
  - Ocular exposure
  - Respiratory failure
  - Gut failure
  - Pancreatitis
  - Cholecystitis
  - Urosepsis
  - Donor site infection
  - Soft-tissue contractures

available for burn wounds. Wound medications and membranes provide three benefits: (1) pain control, (2) prevention of wound desiccation, and (3) reduction of wound colonization.

Topical wound medications range from aqueous solutions through antibiotic-containing ointments and débriding enzymes. Most topical agents in outpatient use have a viscous carrier that prevents wound desiccation and a more or less broad antibacterial spectrum that reduces wound colonization. A gauze wrap minimizes soiling of clothing and protects the wound from trauma. Silver sulfadiazine is in common use because it is painless on application and has a broad spectrum of antibacterial activity. Superficial burns are commonly treated with a clear, viscous antibacterial ointment containing low concentrations of various antibiotics. Wounds around the eyes can be treated with topical ophthalmic antibiotic ointments. Significant ear burns should be treated with mafenide acetate, as it is the only agent that will penetrate the relatively avascular cartilage.

Wound membranes provide temporary physiologic wound closure while the underlying wound heals.[15] Physiologic closure implies a degree of protection from mechanical trauma, vapor transmission characteristics similar to skin, and a physical barrier to bacteria. Their major benefit is that, when successful, they minimize wound manipulations and create a moist wound environment with a low bacterial density. Occlusive synthetic membranes are intended for use on selected clean superficial wounds and skin donor sites and must otherwise be used with some caution, as sub-membrane infection can occur, deepening underlying wounds and causing systemic infection and toxicity.

◀ **FIGURE 94-4** The most common wound infection seen in outpatients is streptococcal cellulitis.



▲ **FIGURE 94-5** Hypertrophic scarring and contracture formation can become difficult problems after serious burns (**A**), but are often amenable to surgical improvement (**B**).

PREVENTION

A plethora of burn prevention efforts have met with mixed success. They can be based on (1) public education, (2) legislation, or (3) engineering.[16] Examples of public education campaigns depend for their success on an educated literate community. The "stop-drop-and roll" campaign in elementary schools is an excellent example. Legislation is often more effective. Examples include safe

TABLE 94-5
Inpatient Care of Larger Burns[a]

- Initial evaluation and resuscitation (0–72 h)
  - Clearly identify all injuries.
  - Perform an accurate individualized fluid resuscitation.
  - Ensure effective decompression of extremities and torso.
- Initial excision and biologic closure (day 1–7)
  - Accurately identify all wounds requiring surgery.
  - Excise the bulk of all full-thickness wounds.
  - Effect definitive or temporary biologic closure of wounds created by excision.
- Definitive wound closure (wk 1–6)
  - Replace temporary wound membranes with permanent coverage.
  - Close physiologically small, but functionally critical areas (e.g., hands and face).
  - Separate patient from intensive care support.
- Rehabilitation and reconstruction (day 1 through 2 yr)
  - Initiate early ranging, splinting, and anti-deformity positioning.
  - Progress to active strength and endurance training.
  - Initiate scar management program.
  - Foster reintegration with family and community.

[a]Inpatient care of larger burns has three general phases. The duration and intensity of each phase will vary with wound extent and complexity. Rough time periods and major objectives of each phase are listed here.

factory set points for home water heaters and flammability standards for children's bedclothes. Engineering solutions are perhaps the most effective. Examples are common in industry and include physical isolation of high-power lines and "child-proof" cigarette lighters. Often all three are combined, a current example being the fire-safe cigarette. A self-extinguishing cigarette has been engineered and in some places its sale mandated after public education influenced the legislative process.

CHAPTER 95

Radiobiology and Radiation Effects

Frederick D. Malkinson
Renato G. Panizzon

RADIOBIOLOGY OF THE SKIN

Radiobiologic events in the skin are best interpreted from a knowledge of the general responses of cells and tissues to ionizing radiation. These responses to electromagnetic radiation (x-rays, γ rays) and to particulate radiation (electrons, neutrons, protons, α particles, etc.) may be studied in the whole organism or at the tissue, cellular, or molecular levels.

Clinical and microscopic changes in skin and its appendages were among the first reactions seen after accidental or therapeutic exposure to x-rays. In the late 1890s, Henri Becquerel and Pierre Curie both noted erythema and ulceration in their own radiation-exposed skin sites after accidental or deliberate exposure. Our current knowledge of radiation responses in skin derives from clinical observations and animal studies. The latter sources are important, because certain data for humans are only provided by accidental radiation exposure.

Mechanisms of Radiation Injury

Electromagnetic radiation with energies above 125 eV (x-rays, ^{60}Co γ rays) produce indirect ionization by ejecting orbital electrons from atoms in tissues or cells. These fast electrons ionize other atoms and break chemical bonds. The resultant free radicals (atoms or molecules carrying an unpaired electron in the outer orbital shell) have half-lives of 10^{-5} seconds, are largely formed from tissue water molecules and oxygen, and react with cell or tissue organic molecules, altering their structure and function. The activated cellular response pathways mediating cytoprotective and cytotoxic responses of cell survival or death[1] and the roles of cytokines in normal tissue radiation reactions have been reviewed.[2,3] Resulting biochemical and/or biologic changes appear within fractions of seconds, minutes, hours, days, weeks, or longer (Table 95-1).

Cellular Radiation Effects

Although functional cell loss in nonproliferating or slowly proliferating cell systems follows only large radiation doses (100 Gy*; 1 Gy = 100 rad), reproductive (mitotic) integrity is usually lost after exposure to only 3 to 4 Gy. Cell death may occur within hours but usually occurs after one to five post-radiation division cycles. Equally proliferative normal and malignant cells have similar radiation sensitivities. X-ray damage to chromosomal DNA is principally responsible for cell killing. Apoptosis, cellular necrosis, and failure to complete mitosis are the principal mechanisms of post-radiation cell death.

Loss of reproductive integrity means the loss of sustained mitotic activity of the

*Gy (gray) is the Système international d'unités unit for the absorbed dose, which replaced the former unit "rad" (radiation absorbed dose). The absorbed dose of 1 Gy is equal to the absorption of 1 J (joule) of radiation energy by 1 kg of matter. 1 Gy = 1 J/kg corresponds to 100 rad (1 rad = 100 ergs/g).

RADIOBIOLOGY AND RADIATION EFFECTS

AT A GLANCE

- Radiation reactions appear after fractions of a second, up to weeks, or longer.
- DNA is the most critical target of ionizing radiation, but the cell membranes and cytoplasm are also affected.
- Radiosensitivity varies during phases of the cell cycle.
- Among the radiation modifiers, oxygen and hyperthermia are radiation enhancers, whereas disulfides and prostaglandins are radioprotectors.
- Clinical effects of ionizing radiation include erythema, dry and moist desquamation, erosion or epilation (acute reactions), followed by fibrosis, vascular damage, ulceration hyper-/hypopigmentation, and malignancy (late reactions).

cell and consequently the possibility of the clonal growth. The loss of clonal growth is measured as the surviving fraction: The ratio of colonies in irradiated dishes to colonies in nonirradiated dishes. One also speaks of mitotic death. Mitotic death might also be provoked by spindle defects that allow aneuploid cells to develop.

Recent studies also suggest that microvascular endothelial cells may be a primary radiation target, contributing to consequent tissue or cell death.[4]

DNA and Chromosome Damage

Differences in numbers of chromosome sets (ploidy) affect radiation sensitivity.[5] Ionizing radiation impairs the synthesis of DNA, thymidine kinase, and DNA polymerase. Genetic damage from irradiation may occur in the gene at the molecular level or in the chromosome at the cellular level. Chromosome breaks may follow exposure to only 0.01 Gy (1 rad). Single-strand breaks are common and readily repaired, but infrequently erroneous repair induces mutation(s). Double-strand breaks, however, more frequently undergo error-prone repair or may be irreparable. Although more aneuploid tumors tend to be more radioresistant, there is no consistent relationship between ploidy on radiation sensitivity. When the relationship between survival and radiation-induced chromosome aberration frequency—which is a measure independent of most other modifiers of sensitivity—was determined a direct relationship between ploidy and mean lethal aberration frequency was observed. Such chromosome abnormalities may also increase genome-wide instability in future cell generations. Chromosomal translocations or inversions at sites of strand breaks may directly result in oncogene activation.

Cell Cycle Effects

Cells in the division cycle are usually more radiosensitive than non-dividing cells. In vitro and in vivo data reveal that radiosensitivity varies significantly in different phases of the cell cycle.[6] For most cell lines, G_2/M phase cells are the most radiosensitive. Late S phase and early G_1 phase cells are relatively radioresistant. Changes in DNA replication states and sulfhydryl compound content (radioprotectors) may affect cell cycle phase radiosensitivity. Overall, radiosensitivity varies by a factor of 2.5 to 3.0 among the various cell cycle phases.

Division Delay

Ionizing radiation delays cell division by 1 hour/Gy in a 2- to 10-Gy range. The delay is greatest for cells in G_2 phase.

[a]Instructions: Score the 14 subjective, objective, and management parameters with 1–4 (score = 0 if there are no toxicities); total the scores and divide by 14.

Molecular checkpoint genes arrest cells in G_2 phase to allow chromosomes to be checked for integrity and to be repaired before mitosis occurs. Cells lacking normal checkpoint genes will likely be more sensitive to radiation killing and malignant change. Shorter division delays occur in S phase cells and are least for G_1 cells.

Radiation Modifiers

There are two principal groups of radiation modifiers, radiosensitizers and radioprotectors, both of which have been widely studied in skin and hair. For these agents, toxic effects, technological limitations, and, often, a lack of differential effects on malignant versus normal cells, limit their usefulness. Only a few of these modifiers are discussed here.

RADIOSENSITIZERS ***Oxygen.*** The addition of oxygen to low prevailing pressures of 0 to 30 mm Hg in tissues increases the effectiveness of sparsely ionizing radiation (x-rays, γ-rays), up to threefold for a dose greater than 2 Gy. A further increase in oxygen tension to an atmosphere of pure oxygen has little further effect. An oxygen concentration of 0.5 percent (or 3 mm Hg) already results in a radiosensitivity that is halfway between hypoxia and that of fully oxygenated conditions. To produce this effect, mediated by free radical and H_2O_2 formation, oxygen must be present during the irradiation time. Oxygen enhancement ratios are least for densely ionizing radiations (neutrons, α particles). Hypoxic areas in tumors are best addressed by fractionation treatment schedules and use of densely ionizing radiation, where feasible. Hyperbaric oxygen therapy is markedly compromised by sharp falls in oxygen partial pressures during tissue and tumor diffusion.

Electron-Affinic Agents. Electron-affinic agents interact with radiation-damaged DNA, blocking repair of injury produced by free radicals. The agents are cytotoxic to hypoxic cells and bind to intracellular radioprotectors such as (glutathione) (see Radioprotectors), further enhancing radiosensitivity effects. Unlike oxygen, these agents diffuse over greater distances and are metabolized more slowly. The principal compounds used are nitroimidazoles, including metronidazole and misonidazole. Cytotoxic effects (neuropathies) have limited their usefulness, but newer, less-lipophilic agents have shorter tissue half-lives and display significantly enhanced sensitization potentials. Some of these agents also potentiate chemotherapeutic drug effects. A number of compounds have been evaluated in clinical trials.[8]

Hyperthermia-Induced Radiosensitization. Heating skin before, during, or after irradiation enhances cutaneous reactions in mouse or human skin. At temperatures over 41.5°C (106.7°F) structural, chromosomal, and/or repair proteins are damaged, and RNA, DNA, and protein synthesis are impaired. At least in skin, blood flow is also increased with resulting increase in oxygen tension. Above 43°C (109.4°F), cell survival curves are similar to those for ionizing radiation. Hyperthermia also induces apoptosis in some cell lines. Overall, normal and malignant cells have similar heat sensitivities. In the clinical and experimental use of hyperthermia with radiation, heat at temperatures of 43°C (109.4°F) or higher is usually administered within 4 hours before radiation. Thermal enhancement ratios range from 2 to 4 for single doses, but are lower for fractionated therapy. Combination treatment produces more partial and complete tumor responses than radiation alone, but the sole use of hyperthermia has little effect. Cooling reduces tissue oxygen tension through vasoconstriction, decreasing radiosensitivity.

RADIOPROTECTORS With sparsely ionizing radiation, dose reduction factors of 2 to 2.5 (≥ 50 percent) have been found with thiol and disulfide compounds (cysteine, glutathione) which scavenge free radicals. If a chemical or other agent acts as if to change the dose of radiation, the dose-modifying factor indicates the ratio of dose without, to dose with the agent, for the same level of effect (e.g., 50 percent survival). A dose reduction factor of 2 implies that 50 percent of the dose is required to obtain the same level of effect in presence of the modifying agent compared to irradiation alone. Similarly, dose reduction factor 6 means one-sixth (16.6 percent) of the dose in presence of the modifying agent. The most effective of these is WR-2721 (amifostine),[9] but toxicity (hypotension) may limit its effectiveness. Leukotrienes and especially prostaglandins are effective radioprotectors in microgram amounts, yielding dose reduction factors up to 6 (84 percent) for misoprostol, although the protective mechanism is not fully understood. Given before radiation, their efficacy depends on the presence of receptors for the individual agent.[10] Prostaglandins are radioprotective after local or systemic administration, greatly reducing, for example, experimental radiation-induced alopecia.[11] They also protect against chemotherapeutic agent toxicity as well, especially for doxorubicin and cyclophosphamide.[11,12] Misoprostol holds clinical promise for the protection of normal tissues (hair, mucous membranes) lying in the path of a radiation beam, although in an experimental setting it fails to protect tumors against radiation effects.[13,14]

RADIOBIOLOGY OF THE SKIN AND HAIR

Within 2 to 3 weeks after exposure of human skin to high doses of single or fractionated radiation (Fig. 95-1), acute erythema, desquamation, erosion, and hair loss occur, followed by healing. The intensity of radiation erythema depends on age, gender, anatomic site, dose, and dose rate. These early changes reflect injury, apoptosis, and reproductive failure of germinative epidermal and hair matrix cells, reduced division rates in surviving cells, and vascular damage.[15] Epidermal cell replacement occurs from the third to the fifth week after radiation. Later chronic post-radiation changes result largely from injury to dermal structures, particularly the vasculature, and fibrosis,

▲ **FIGURE 95-1** Radiation dermatitis: Acute. Localized area of erythema and edema in the radiation portal occurring at the end of radiotherapy treatment for breast cancer.

which is actually an early (within 1 week) but progressive post-radiation event that is cytokine-mediated.[15–17]

The character and magnitude of cutaneous responses to radiation depend on total dose and dose fractionation, radiation quality and ionization density, area or volume of tissue irradiated, anatomic site, and vascular supply. The responses of irradiated skin and the effects on post-radiation skin changes of radioprotectors, radiosensitizers, and hyperthermia have been investigated.[15,18] Increased radiosensitivity and carcinogenesis in genetic disorders characterized by defective cellular and DNA repair processes are well known and discussed in Chap. 109.

Post-radiation changes in the highly proliferative anagen hair matrix cells cause hair dysplasia and reduced hair length and growth rate. In humans, 3 Gy produces complete, reversible anagen alopecia; permanent alopecia begins to occur at 5 Gy. In mice, G_0 telogen matrix cells are 2.5 times more radioresistant than anagen cells, probably due to their different proliferation rates and vascular supply. Altered matrix cell uptake of isotopically labeled amino acids, incidence of hair dysplasia, measurements of reduced hair shaft diameters, and quantitative assessments of surviving hairs or later regrown hairs have all been used as biologic end points to study general cellular radiation effects, as well as radioprotective or radiosensitizing actions of numerous pharmacologic or physical agents.[15]

Radiobiologic Effects on Melanocytes and Pigment Formation

Low-dose radiation induces cutaneous hyperpigmentation after minimal inflammation. Pigmentation is directly related to dose rate and total dose, and is characterized by increased numbers of melanocytes with increased tyrosinase activity, and by enhanced melanin transfer to epidermal cells. Higher radiation doses destroy melanocytes with resultant depigmentation. Similar radiation effects occur in mid-anagen hair follicles. At higher dose rates, hair melanocytes are far more susceptible to radiation destruction than epidermal melanocytes. In mice, telogen melanocytes are much more radiosensitive than anagen melanocytes.[19] Melanocyte survival in laboratory preparations of hair follicle and depigmentation of hair in laboratory animals have both been used to quantitate combined drug-radiation effects.

Radiobiologic Effects on Langerhans Cells

Although Langerhans cells (LCs) are relatively radioresistant,[20] in one study, single doses of 20 Gy in mice reduced LC numbers by more than 80 percent within 10 days; repopulation was complete 30 days later. Whole-body irradiation to the bone marrow delayed repopulation another 3 weeks. In mice, the effects of such radiation early in life markedly accelerated skin LC loss in aged animals, perhaps reflecting dermal fibrosis and reduced blood flow or loss stem cells at the time of irradiation. Loss of LCs and their immunologic functions may contribute to reduced ability to develop contact hypersensitivity in affected sites and to increased post-radiation tumorigenesis as a result of impaired immune surveillance.

LONG-TERM RADIATION REACTIONS

Typical changes may appear in irradiated fields months to years after radiotherapy: depigmentation often associated with atrophy, telangiectasia, hyperpigmentation, depressed scars, fibrosis, and radiation keratoses. These changes are termed *chronic radiodermatitis* (Figs. 95-2, 95-3, and 95-4). The overall appearance of chronic radiodermatitis is that of poikiloderma. After high doses, tissue eventually breaks down, and a leather-like necrosis, tightly adherent to the underlying tissue, develops (Fig. 95-5A). Such lesions are extremely tender. After many years, squamous cell carcinoma can arise in such lesions (Fig. 95-5B). The required dose for chronic radiodermatitis to develop is lower than the dose usually required for the treatment of malignant tumors, with the exception of some malignant lymphomas. The Radiation Therapy Oncology Group, in collaboration with the European Organization of Research and Treatment of Cancer, has developed the LENT (late effects normal tissue) scoring system (SOMA), which can be used to document *s*ubjective, *o*bjective, *m*anagement, and *a*nalytic information (see Table 95-1).[21] In this context, "late"

The lesion is extremely painful. **B.** A large and deep ulcer in an area of atrophy, fibrosis, poikiloderma, and telangiectasia on the chest wall. This occurred 20 years after radical mastectomy, axillary lymph node dissection, and radiotherapy. The ulceration was primarily due to radionecrosis. Now the border of the ulcer is elevated and firm and so is the granulating base: This is squamous cell carcinoma arising in this radiation dermatitis.

means more than 90 days after the onset of radiation. The four SOMA criteria are defined as follows:

Subjective: Perceptions and problems reported by the patients, such as pain or pruritus

Objective: Determined by the physician through physical examination

Management: Measures necessary to treat the side effects, either medical or surgical

Analytic: Potential deficits that can only be evaluated by sophisticated methods such as computed tomographs

CHAPTER 96

Skin Problems in Amputees and Ostomates

Calum C. Lyon
Michael H. Beck

TECHNICAL BACKGROUND: LIMB PROSTHESES

In most centers, artificial limbs are constructed in a modular fashion.[1] The stump is placed in a thermoplastic socket that is then fitted into the main body of the limb. The bulk of the prosthesis comprises a metal frame with articulations and an outer casing of acrylic resin or carbon composite material. Before fitting the limb, many patients place their stump in a liner designed to reduce friction on the skin. This may be an expanded plastic cup, a silicon/mineral oil sleeve, or a cotton or nylon sock. The prosthetic limb, once fitted, is held in position by one of a range of suspension elements. In above-knee (Fig. 96-1) or proximal arm amputations, this is usually a fabric belt arrangement worn around the waist or shoulders, respectively. Below-knee amputees require a different system using either a butyl rubber sleeve or corset to hold the appliance firmly onto the thigh (Fig. 96-2). Many patients with above-knee amputations now use a suction socket device that provides sufficient suspension by holding the prosthesis in place through negative pressure without the need for additional belts (see Fig. 96-1).

DERMATOLOGIC PROBLEMS IN AMPUTEES

The skin of an amputation stump is not designed to withstand the physical insults it encounters within a prosthetic limb. For example, although some adaptation to friction or pressure occurs, some skin problems are inevitable. If these dermatoses cannot be prevented or rapidly resolved by prosthesis adjustment or medical intervention, they can incapacitate the patient, particularly those who have lower-limb prostheses. As a result, patients may suffer social isolation, emotional distress, or even financial deprivation if they are unable to work.

Skin problems may occur because of allergy or chemical irritation to materials in contact with the skin, as well as from trauma and occlusion. Examples of physical stresses on the skin include shearing and friction from elements in the socket and pressure on load-bearing areas, especially on the tibial tuberosity in below-knee amputations and the ischial tuberosity, adductor region, or groin in above-knee amputations. In all cases, the occlusion results in increased humidity from trapped perspiration, in-

SKIN PROBLEMS OF AMPUTEES AT A GLANCE

- Skin problems under limb prosthesis result from:
  - trauma
  - heat
  - pressure
  - occlusion and maceration
  - physical trauma, disturbances of tissue fluid dynamics may cause other distinctive skin changes
  - microclimate under prosthesis promotes bacterial and fungal infections
  - irritant and allergic contact dermatitis occurs due to materials applied to skin, worn, or used in construction of the prosthesis
- Koebner phenomenon may occur in skin under prosthesis.
- Management: most important are basic hygiene measures.
- Early medical intervention and collaboration with prosthetist are essential to address problems.

creasing the likelihood of irritation, allergy, and infection.

The common skin disorders in amputation stumps can be classified into diseases related to the reasons for the amputation, physical effects of a prosthesis, infection, contact dermatitis, and other cutaneous disorders.

Epidemiology

The great majority of artificial limb wearers are amputees, although a small proportion are people with congenital limb malformations. Lower-limb amputees are the most numerous and are also the group at greatest risk of skin problems. Modern limb prostheses allow many of today's amputees to lead an active life with good mobility. Nevertheless, as many as 62 percent of one cohort reported sores or skin irritation.[2] In a further group of 745 lower leg amputees, 40.7 percent had at least one skin problem. Further analysis identified four factors independently associated with dermatologic disorders, namely transtibial amputation, employment status, type of walking aid used, and peripheral vascular disease.[3] One-third of amputees experience a skin problem that interferes with the normal use of their artificial limb.[4]

▲ **FIGURE 96-2** Below-knee prosthesis. Patellar–tendon-bearing cuff suspension.

Dermatoses Related to the Reasons for Amputation

Several disorders resulting in the need for amputation can have a significant impact on skin integrity. In general, younger patients require artificial limbs because of traumatic amputations, congenital abnormalities, or malignancy, whereas in the older age group, arterial disease and vascular complications of diabetes mellitus predominate. Amputations after trauma or severe vasculitis may be associated with scarring that makes for a suboptimal prosthesis fit (Fig. 96-3). However, it is diabetes mellitus that is particularly associated with protracted skin problems as a result of impaired wound healing, susceptibility to infection, abnormal sensory nerve function, and disruption of normal tissue fluid balance.[5] Diabetic amputees as a group require more frequent clinical review to prevent complications. Treatment of the diabetic amputee not only requires good control of the blood glucose level but possibly a change of the stump environment through adjustment or redesign of the artificial limb. The diabetic amputee highlights the need for close links with a prosthetics department, which allow rapid referral of patients for assessment.

Physical Dermatoses

The physical effects of wearing a prosthesis are the most common causes of

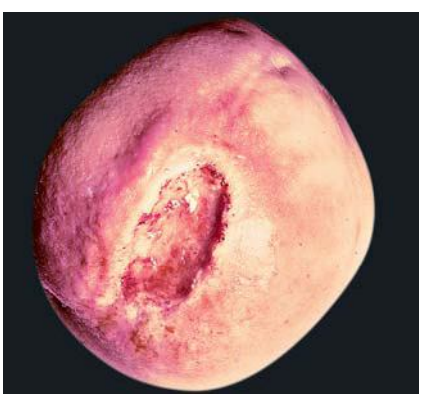
▲ **FIGURE 96-3** Scarring of the stump after amputation for severe postinfective vasculitis.

skin problems.[4,6] These can be divided into those resulting from repeated direct trauma and those secondary to disturbance of tissue fluid dynamics.

DIRECT PHYSICAL TRAUMA ***Ulceration.*** Ulceration and callus formation are seen where there is chronic pressure or repeated frictional forces on stump skin. Ulceration may also be caused by infection or poor cutaneous nutrition, particularly secondary to diabetes mellitus (Fig. 96-4). Stump ulcers should be treated early as malignancy may develop in long-standing ulceration. With repeated infection and ulceration, an amputation scar on the distal stump skin can erode further. In some cases, the skin may become completely adherent to bone and develop thick, callus-like hyperkeratosis (Fig. 96-5), which may necessitate revision of the distal bony surface. In every instance, the cause of the ulceration must be determined to resolve a chronic process that can become totally disabling.

Physical Dermatitis. In some patients, eczema may be caused by a poorly fitted or misaligned prosthesis or by edema and congestion of the terminal portion of the stump; only with alleviation of these problems does the condition clear.

Epidermoid Cysts and Follicular Keratoses. Epidermoid cysts and follicular keratoses are two ends of a spectrum of the same disorder. Repeated pressure and friction from the prosthesis appears to cause invagination of keratin around hair follicles, which then results in a foreign-body reaction. Follicular keratoses are therefore the earliest changes.[7] These are very common, often multiple, and distributed at sites of weight bearing such as the anterior tibial area, popliteal fossa, and the adductor or inguinal areas of the thigh (Fig. 96-6A). Fortunately, they cause little trouble in many cases,



▲ **FIGURE 96-4** Chronic ulcer of stump skin.

▲ **FIGURE 96-5** Chronic ulceration resulting in thick hyperkeratosis and scab formation adherent to the underlying bone.

but they can become inflamed and painful particularly if the patient picks at them to extract the keratin plug or if they become infected. Inflamed follicular keratoses can have an acneiform appearance, leading some to suggest that they represent a form of acne mechanica. When the continued pressure and friction causes the keratin to extend deeper into the dermis, larger cystic lesions, 1 cm to 3 cm in diameter, form; these are commonly termed *post-traumatic epidermoid cysts*. Deeper cysts can be very tender when compressed by the prosthesis. Some cysts have an obvious punctum and patients may express keratinous material from them. Large cysts can be so painful that the patient can no longer wear a weight-bearing prosthesis each day (see Fig. 96-6B and C). Distention of the overlying epidermis can occur, followed by spontaneous rupture. A serous, purulent, or hemorrhagic fluid is then discharged. The resulting sinus is difficult to occlude and the discharge continues as long as the prosthesis is worn. Intercommunicating sinuses can appear and spontaneous ruptures may occur. In advanced cases, a granulomatous reaction occurs around the cyst with considerable capillary dilation, vascularization, and a heavy inflammatory infiltrate progressing to abscess formation (see Fig. 96-6B).

Management of this condition can be difficult. Clearly, prevention is the ideal but is not always possible despite regular prosthetic assessments. The fit of the prosthesis is the single most important method of preventing cyst formation. The problem can sometimes be improved or successfully eliminated by proper fitting and aligning of the prosthesis and continued adjustment by the prosthetist. Rough surfaces in areas of increased contact pressure in the socket,

▲ **FIGURE 96-6** Epidermoid cysts in different stages. **A.** Early follicular keratoses in the popliteal fossa of a man with below-knee amputation. **B.** Hemorrhagic and inflamed large epidermoid abscess in a man with an above-knee prosthesis. Note the follicular hyperkeratosis. **C.** Inflamed epidermoid cysts in the groin of a man with an above-knee prosthesis.

particularly the suction socket, tend to catch the skin, increasing the shearing forces. For this reason, the lining of the socket should be kept smooth. With the idea of inserting a buffer between the skin and the socket, protective devices such as liners and stump socks are used. Various synthetic films and adhesives, such as Teflon, have been found satisfactory as liners. They allow for a smooth, gliding action of the prosthetic socket wall or brim against the skin. Applying a vapor-permeable adhesive membrane to the skin before fitting the

appliance can also help to reduce frictional trauma. Topical glucocorticoids can be used at night to reduce inflammation and provide symptomatic relief. Intralesional injection of glucocorticoids into the cysts and their channels also results in temporary improvement.

Surgical intervention is useful in cases with a few lesions that are not infected. Lesions can be surgically incised and drained. In other instances, removal of the prosthesis is sufficient to cause the lesion to involute, provided that the cyst has not become too large. However, spontaneous rupture, incision, and drainage, and even spontaneous resorption of the lesion are of only temporary benefit. When the prosthesis is worn again, these cysts can recur so that surgical excision is not always the treatment of choice, especially in continually rubbed areas.

In selected cases, systemic retinoid therapy may be appropriate to minimize hyperkeratosis. One author found oral isotretinoin to be effective in a patient described as having acne mechanica.[8]

▲ **FIGURE 96-7** Dependent edema/early verrucous hyperplasia in a man with multiple amputations after severe peripheral vasculitis and necrosis.

DISTURBANCES OF TISSUE FLUID DYNAMICS ***Edema.*** Amputation of a lower extremity greatly disturbs the normal pattern of blood and lymph channels, as well as the relationship of pressure both inside the vessels and in the surrounding tissues of the stump. An important feature of care during convalescence after amputation is the reduction of edema and stabilization of new circulatory patterns in the stump. Swelling can be partially prevented by gradual compression of the stump tissues with an elastic bandage or "shrinker" sock before fitting the prosthesis and socket.

When an amputee begins to wear a suction-socket prosthesis, the skin must adapt to an entirely new environment. The patient can expect edema, reactive hyperemia for days or weeks, a reddish-brown pigmentation resulting from capillary hemorrhage, and, occasionally, serous exudation and crusting of the skin of the distal portion of the stump. These changes are relatively innocuous, usually short-lived, and do not usually require therapy.

The extent to which edema may persist or recur in the healed stump depends on many factors.[9] Edematous portions of the skin of the distal part of the stump may become pinched and strangulated within the socket (Fig. 96-7). Such areas may ulcerate if they catch in the spring-valve opening and become gangrenous as a result of the impaired blood supply. Therapy includes eliminating all mechanical factors contributing to the edema, such as choking by the socket, poor fitting, and misalignment. Excessive negative pressure in a suction-socket prosthesis also contributes to circulatory congestion and edema. Treatment should be directed toward better support of the distal soft tissues. Occasional use of an oral diuretic sometimes allows the edema to resolve.

Verrucous Hyperplasia. *Verrucous hyperplasia* refers to a reactive hyperplastic condition, characterized morphologically by numerous, coalescent warty papules (Fig. 96-8). It occurs when the chronic pressure effects of a poor prosthetic fit disrupt vascular and lymphatic channels, resulting in chronic tissue edema. The same appearance is seen around long-standing leg ulcers where there is an element of lymphedema (see Chap. 175). Histologic examination can show evidence of pseudoepitheliomatous hyperplasia, although the condition itself is benign and potentially reversible. However, in neglected cases, malignant change can occasionally occur (see Fig. 96-8C). Bacterial infection may play a role in the development of pseudoverrucous hyperplasia, as secondary mixed flora infections are common because of the poor superficial blood flow and the convoluted surface (Fig. 96-9). External compression is the best method of treatment, in combination with topical control of bacterial infection. In below-knee amputees, the distal part of the stump is edematous; the stump dangles freely in the socket or has

▲ **FIGURE 96-8** Verrucous hyperplasia of the distal stump skin. **A.** Before compression therapy. **B.** Total resolution after compression therapy. **C.** Malignant degeneration into squamous cell carcinoma.

▲ **FIGURE 96-9** This man developed post-infectious purpura fulminans after varicella-zoster infection as a child in the 1960s and lost both legs as a consequence. He presented with infected verrucous hyperplasia having lived a reclusive life in a cabin in the woods wearing an old-fashioned unadjusted aluminum prosthesis for many years. The infection was treated with new hygiene measures, and he was fitted with a modern modular prosthesis. The skin rapidly resolved, although some of the verrucous hyperplasia changes persisted.

no distal support or partial end-bearing. When the stump end is supported in the socket by a temporary cushion or platform, compression gradually reduces and slowly clears the verrucous condition. The greater the compression on the distal stump, the more immediate and lasting is the improvement. The use of compression bandaging, shrinker socks and other pads, and partial end-bearing all have a definite place in therapy and can be skillfully applied by the prosthetist. Short courses of oral diuretics may be indicated to reduce edema of the stump. The medication can be gradually decreased when the stump and its skin return to normal.

Acroangiodermatitis. Acroangiodermatitis occurs when the chronic pressure changes result in vessel proliferation in the upper and mid-dermis. There is also extravasation of red blood cells and these features combine to give a purplish hue to the papules and plaques that appear on a background of edematous skin. The appearance may mimic Kaposi sarcoma. Some authors suggest that acroangiodermatitis occurs in above-knee amputees who use a suction socket prosthesis that exerts negative pressure.[10] However, there are reports of acroangiodermatitis in below-knee amputees,[11] and the same condition is seen in chronic venous insufficiency and in those patients with arteriovenous shunts (acroangiodermatitis of Mali). Management of this condition is the same as for stump edema and verrucous hyperplasia.

Bacterial and Fungal Infections

The bacterial flora of amputation stumps have been examined in small groups of patients,[12,13] and the most common species encountered are *Staphylococcus epidermidis*, *S. aureus*, and *Streptococcus* sp. (see Chap. 177). The moist, occluded environment under a prosthesis is ideal for fungal and bacterial growth so that minor skin infections occur fairly frequently. In one study, *S. aureus* folliculitis or *Trichophyton rubrum* infection was identified in 3 percent of the study population.[4] Infections are more common during hot weather and in those amputees who pay insufficient attention to stump hygiene, partly because in these situations the skin becomes macerated more readily and follicular infections become more likely. Although folliculitis (Fig. 96-10) and furuncles are more common, superficial infections of the skin itself may also occur (see Chap. 177). Superficial dermatophyte and candidal infection (see Chaps. 188 and 189) are also common and may be difficult to eradicate because of the ideal environment for fungal growth within a prosthesis.

The diagnosis of infection is usually obvious when the rash extends onto skin not covered by the prosthesis. Underneath the prosthesis, any superficial infection may present as a non-specific scaling erythema indistinguishable from that caused, for example, by chronic irritation. All stump rashes should be swabbed for bacterial and fungal culture.

In the management of bacterial infections, oral antibacterial therapy should be directed by bacterial culture and sensitivity. Topical antiseptics or antibacterials can be used but some antiseptic preparations can cause irritation and there is also the potential for sensitization.

Superficial fungal infections respond to appropriate topical therapy (see Chaps. 188 and 189) but can be hard to completely eradicate because of the favorable conditions for fungal growth. In this situation, systemic antifungal therapy is useful.

▲ **FIGURE 96-10** Folliculitis of stump skin showing the typical distribution in the occluded area.

Contact Dermatitis (See Chaps. 13 and 46)

The clinical presentations of irritant and allergic contact dermatitis affecting amputation stumps are indistinguishable (Fig. 96-11), ranging from dry, scaling erythema to weeping dermatitis.[4] Indeed, the morphologic features may be the same as non-specific eczematization

▲ **FIGURE 96-11** Allergic contact dermatitis to formaldehyde-releasing biocides in a lubricating "baby oil." Note the nonspecific, dry, eczematous appearance.

where no irritant, allergic, or infectious cause is found, and where there is no history of eczema or atopy. Consequently, a careful history and examination is essential if one is to identify irritant or allergic causes (Table 96-1). This includes accurate timing of the onset of dermatitis in relation to changes in the patient's appliance routine or the composition of the prosthesis. The distribution of rash typically matches the site of the contactant. To identify a primary irritant or allergen, it is particularly important for the dermatologist to observe the patient removing and refitting their limb, making note of its construction and any medicaments or other agents such as cleansers, talcs, and creams that the patient uses. These products may contain allergens such as fragrances or preservatives. Colored stump socks may contain potentially allergenic nylon dyes.

Knowledge of the materials used in prosthesis manufacture is also necessary when considering potential sensitizers and irritants. This is best achieved by liaison with the local prosthetist, as different construction techniques may be used in different areas. In general, modern modular prostheses are fabricated with sockets, liners, and casings that may contain acrylic resins, carbon composites, and thermoplastics. Epoxy and, occasionally, polyester resins are still used by some manufacturers. Acrylate-based thread sealants are commonly used in socket bolts and metalwork. Butyl or black rubber material may be used to conceal access points to the metal frame. Rubber materials can also be found in some suction socket valves (Fig. 96-12). Suspension elements often include chrome-tanned leather and sometimes have metal fastenings, rivets, or screws containing nickel. Glues containing *para*-tertiary butylphenol formaldehyde resins are often used.

Repairs or adjustments to prostheses can introduce new irritants and allergens. For example, sockets sometimes have additional leather linings cemented to points of friction or pressure.

Irritant dermatitis (see eFig. 96-12.1 in on-line edition) can be due to occluded contact with volatile solvents in glues or resins and from fragrances and detergents in topical medicaments or lubricants. Soaps and other washing materials used to clean appliances can cause irritation if they are not removed by proper washing (see Table 96-1). Burns from a malfunctioning electrode used in a myoelectric prosthesis have been reported.[14]

Contact allergy should always be considered as a cause of inflammatory and dermatitic disorders affecting the stump, especially if there is secondary spread (see Table 96-1). In addition to standard series patch testing, the authors recommend an extra series of allergens to include components of plastics, including acrylic, epoxy, and polyester resin systems, as well as an azo dyes series. It is important to test with pieces of the prostheses and all materials applied to the stump skin, including emollients, cleansers, powders, medicaments, and cosmetics. In our experience, the most common relevant allergens are nickel, acrylates, rubber, chromate (in leather), *para*-tertiary butylphenol formaldehyde resin, and components of topical applications.[4]

TABLE 96-1
Causes of Dermatitis on Amputation Stump

- Traumatic
- Irritant
  - Soaps and washing materials
  - Topical applications, including medicaments
  - Solvents in glues and resins used to make prosthesis
- Allergic
  - Active ingredients, perfume, and excipients of topically applied materials (e.g., deodorizers, cleansers, topical medicaments, and moisturizers)
  - Acrylic, epoxy, polyester, and formaldehyde resins
  - Resin hardeners
  - Other plastic additives (e.g., *para*-tertiary butylphenol catechol)
  - Nickel
  - Rubber accelerators and antioxidants
  - Chromate (leather)
  - Nylon dyes

Other Cutaneous Disorders

Common skin diseases, for example, eczema (see eFig. 96-12.2 in on-line edition) and psoriasis (see eFig. 96-12.3 in on-line edition), may affect amputation stumps. Those diseases that exhibit the Koebner phenomenon, especially psoriasis or lichen planus, have been reported on amputation stumps with little involvement of other areas of skin. Treatment should always consider the caveat for occluded environment of a prothesis.

Benign keratoses, warts, nevi, and a variety of cutaneous papillomas may occur on stump skin and occasionally cause discomfort when a prosthesis is worn. Malignancies have also been described and squamous cell carcinoma may develop in non-healing chronic stump ulcers or verrucous hyperplasia (see Fig. 96-8C). Patients who have amputations for lymphangiomas may develop the Stewart-Treves syndrome and metastatic lymphangiosarcoma (see Chap. 128).

Treatment of these benign and malignant tumors is the same as when they occur elsewhere on the skin. Healing after tumor excision may take weeks, during which time the artificial limb may not be worn.

▲ **FIGURE 96-12** Allergic contact dermatitis to rubber materials in a suction socket from an arm prosthesis. **A.** The prosthesis fitted. **B.** The dermatitis is worst around the areas where the pressure is released on removing the limb.

General Management Considerations

Many of the more common skin problems can be prevented or controlled by adherence to an appropriate hygiene and skin-care regimen in conjunction with regular prosthetics reviews, which ensure that the prosthesis remains appropriate and correctly adjusted. To this end, it is important that good communication exists between the dermatologist and prosthetist, which permits rapid referral of patients before skin disorders become established.

As a general routine, the stump skin should be washed at night rather than in the morning, because newly washed skin is hydrated and swollen, thereby increasing the likelihood of friction and shearing trauma. Nonperfumed soap should be used to minimize contact with potential sensitizers and fully removed with tepid water and gentle rubbing with a nonabrasive towel.

Antibacterial soaps and washes can reduce the possibility of infection in addition to their cleansing action. However, these antiseptic preparations can cause irritation or allergy in a small number of cases and patients should be warned about this. If a stump sock is worn, it should be changed daily and washed and rinsed fully as soon as it is taken off, before perspiration is allowed to dry within it. Silicone liners should be washed every day.

SKIN PROBLEMS IN PATIENTS WITH ABDOMINAL STOMAS (OSTOMATES)

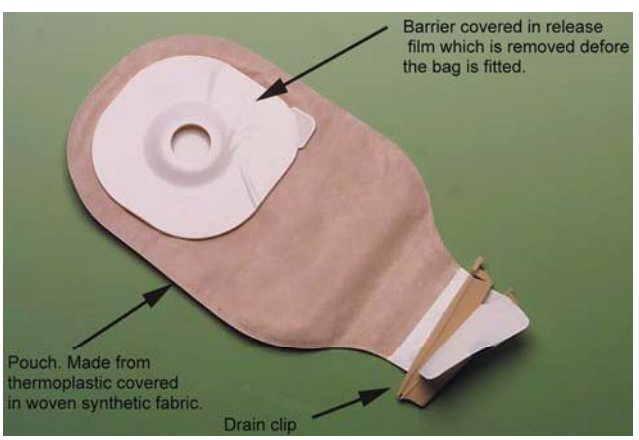
A stoma is a surgically created opening onto the skin of part of the gastrointestinal or urinary tract to drain the effluent from that viscus. The most frequently performed stomas are ileostomies, colostomies, and ileal conduits (urostomies). The most common indications for stoma surgery are inflammatory bowel disease, malignancy, and neurologic problems. A patient with a stoma is usually termed an *ostomist* or *ostomate*.

Epidemiology

There are estimated to be more than 1 million ostomates in the United States and 100,000 in the United Kingdom. Some stomas are temporary with surgical anastomosis delayed pending resolution of the acute disorder. Many stomas formed for malignant indications can be seen as palliative procedures.

A stoma appliance is essentially a device for collecting stoma effluent with a high degree of comfort and security until it can be disposed of. Essentially, the device is a pouch or bag held in place over the stoma by an adhesive skin barrier made solely or partly from hydrocolloid (Fig. 96-13). Many ileostomists and urostomists use two-piece appliances where the barrier remains on the skin for 2 to 4 days and is detachable; disposable bags are changed as necessary. Appliances with convexity on the surface next to the skin are available for patients with short or buried stomas.

At least two-thirds of ostomates experience skin problems that interfere with the normal use of their stoma appliance[15] and such dermatoses are the most common reasons for a visit to outpatient stoma services.[16] The majority of these problems are irritant reactions, usually dermatitis secondary to leaks from the stoma; however, there are also a number of other well-defined irritant reactions. Common coincidental dermatoses, particularly psoriasis and constitutional eczema, account for approximately 15 percent of the diseases seen.[15,17]



◀ **FIGURE 96-13** A typical drainable stoma bag.

STOMA PATIENTS AT A GLANCE

- Peristomal skin is chronically occluded and subject to:
  - pressure
  - shearing forces
  - fecal/urine soiling
- Two-thirds of ostomates develop skin problems.
- Most common: irritant reactions, common skin diseases, and infections.
- Occlusion under stoma appliance can result in unusual clinical appearances of common dermatoses.
- Swab all rashes to exclude primary or secondary infection.
- Uncommon: allergic contact dermatitis but advise patients to minimize exposure to potential allergens (fragrances and preservatives).
- Psoriasis and pyoderma gangrenosum more common around stomas than expected.

Irritant Reactions

DERMATITIS Dermatitis most frequently results from the chronic leakage of effluent onto the skin because the patient is using an inappropriately shaped appliance or one with too large a hole for their stoma. The most common cause is the remodeling of the stoma and abdominal wall that occurs in the months after surgery, whereby a stoma usually becomes a little shorter and thinner, resulting in leaks unless a correctly fitting appliance is selected (Fig. 96-14, see eFigs. 96-14.1, and 96-14.2 in on-line edition). Leaks also occur when patients gain a lot of weight after surgery and the effective length of their stoma diminishes because it becomes buried by subcutaneous fat. Irregular scarring after surgery or retraction of the stoma may also be associated with chronic leakage. Chronically irritated skin can become markedly hyperkeratotic and acanthotic (see eFig. 96-14.3 in on-line edition). These problems can be prevented and resolved by careful postsurgical follow-up by the enterostomal therapist

▲ **FIGURE 96-14** Irritant contact dermatitis circumferentially around an ileostomy because the bag aperture was cut too big, thereby allowing soiling of the skin around this short stoma.

(stoma nurse specialist) to ensure that the correct appliance is being used. Severe, acute irritant dermatitis can be effectively treated with a short course of topical corticosteroid while longer-term appliance modifications are being undertaken (Table 96-2).

Anxieties about possible leaks and odors can lead to excessively frequent bag changing, which may cause an irritant dermatitis by stripping the skin. Patients may, for the same reasons, wear waist belts too tightly thereby causing pressure damage, even ulcers (see eFig. 96-14.4 in on-line edition) and occasionally necrosis. Whatever the cause of skin inflammation, a vicious cycle can develop when the damaged skin prevents proper bag adhesion, necessitating more frequent bag changes.[20] Careful counseling is usually necessary to reassure the patient regarding leaks.

Approximately 15 percent of ostomates with skin problems suffer from a chronic or recurrent dermatitis for which no irritant, allergic, or infective cause can be found, and in whom primary skin disease is ruled out.[15] In the absence of a primary treatable cause, the use of topical corticosteroid lotions is appropriate. Most patients require only occasional short courses for a maximum of 4 weeks' duration. A small number of patients require intermittent applications longer term. Provided that the frequency of application is no more than once every 10 days, steroid atrophy of the skin appears to be unusual.

In ileostomy patients with short bowel, the output may be very high and corrosive due to the enzyme content. In this situation, some leaks are inevitable despite the use of proprietary barrier preparations or soothing lotions. Where the irritation has resulted in an eroded dermatitis, sucralfate powder applied at every stoma bag change can be very effective. In addition to forming a sticky barrier, the preparation is thought to promote healing.[21] Surgical scars and even large striae (see eFig. 96-14.5 in on-line edition) can lead to ulcerations and bag failures that may respond to topical carmellose sodium or sucralfate powders. Wound dehiscence can cause severe difficulties for bag adhesion (see eFig. 96-14.6 in on-line edition) and presents particular challenges for nursing management, in which case the dermatologist may be called on for advice as part of the multidisciplinary team.[22]

TABLE 96-2
Topical Corticosteroid Treatment of Inflammatory Peristomal Conditions

- Good adhesion between the appliance and the skin is essential. Ointments, creams, and greasy lotions cause a bag to lift so that most patients do not use them.
- One approach tolerated by some patients is to use dressings, such as thin hydrocolloid or vapor-permeable membranes, placed over the cream preparation and before applying a stoma bag.
- Another approach is to apply a cream preparation for 1 to 3 h/day before wiping off and applying a stoma bag. While the cream is in place, a nonadhesive bag can be worn, held in place with a waist belt, provided that the patient is sedentary during this time.
- A number of alternative vehicles for delivering topical corticosteroid are available, although none is ideal or designed for stoma use.
  - Adhesive tapes impregnated with fludroxycortide, 4 μg/cm^2
  - Scalp lotions (oil-free; 40 percent isopropyl alcohol): betamethasone valerate 0.1 percent, clobetasol propionate 0.05 percent. These sting on broken skin and can be applied to the bag adhesive and allowed to dry before applying to the stoma.[18]
  - Scalp gels: Fluocinolone acetonide 0.025 percent. This preparation contains propylene glycol that may impair bag adhesion a little.
  - Steroid asthma inhalers: beclomethasone dipropionate, 250 μg/metered dose. Several activations are used to the affected area.
  - Carmellose sodium oral pastes are especially useful in ulcerative conditions such as mild pyoderma gangrenosum (e.g., triamcinolone acetonide 0.1 percent in carmellose sodium paste).
- Alternative nongreasy steroid sprays are available in some regions.[19]
- With each of these preparations, the steroid is under occlusion and therefore effectively more potent. Skin atrophy and absorption, particularly in children, must be considered. The authors limit initial courses to a maximum of 4 wk and thereafter one to two times/wk if needed.

CHRONIC PAPILLOMATOUS DERMATITIS

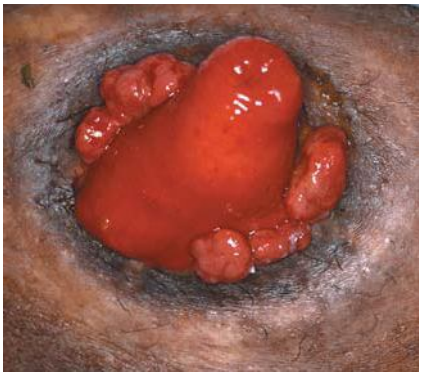
Chronic papillomatous dermatitis (CPD) refers to clinical appearance of warty excrescences around urostomies resulting from leaks and pooling of urine on the peristomal skin (Fig. 96-15). Recurrent

▲ **FIGURE 96-15** Chronic papillomatous dermatitis affecting a urostomy in a patient who is using a bag with too large an aperture. The red area is the stoma and is becoming stenosed by the warty papules. The brown pigmentation is a typical finding in long-standing urostomies in all races. (Used with permission from Anita Eriksson, Karolinska Institute, Stockholm, Sweden.)

urinary tract infections appear to increase the likelihood of CPD, probably due to the presence of ammonia from urea-splitting bacteria. Histologically, there is massive hyperkeratosis and acanthosis. Pseudoepitheliomatous hyperplasia may also be a feature but is not universal. The histology is therefore not specific and is comparable to that of other irritant reactions. Verrucous lesions with similar appearances are occasionally seen affecting ileostomies (see eFig. 96-14.3 in on-line edition).[23] In severe cases, the lesions can encroach on the stoma and cause stenosis (see Fig. 96-15). When the leaking of urine is caused by a receding stoma, CPD resolves rapidly if a convex-backed appliance is used to increase the effective length of the urostomy and thereby stop leaks. Acetic acid soaks (10 percent domestic vinegar in water[24]) at each bag change are effective in some cases. Larger excrescences may be shaved off under local anesthetic to allow a bag with a smaller aperture to be used. In severe cases, surgical revision of the stoma may be required.

GRANULOMAS The term *granuloma* is commonly used for a range of papular lesions, which are almost all secondary to irritation. The authors have only seen the condition affecting ileostomies or colostomies and not urostomies. They may affect the stoma itself (inflammatory colonic or ileal polyps) or the mucocutaneous junction, or may be found more widely, extending onto the peristomal skin (Fig. 96-16). The latter is more frequent in patients with colostomies, and in this situation the papules may become very extensive. This occurs when the patient enlarges the stoma bag aperture to accommodate a papule, thereby exposing normal skin to fecal irritation which precipitates further lesions and prompts the patient to enlarge the aperture still further. Histologically, the lesions contain a chronic inflammatory infiltrate, granulation tissue, and sometimes metaplastic bowel mucosa where the metaplasia is probably a response to fecal irritation. Comparable lesions occur around ileostomies but are generally flatter and may even present as sheets of cherry-red granulation tissue. These lesions are sometimes caused by seeding mucosa at the time of surgery.[25]

Asymptomatic, solitary lesions can be left. When they are painful[26] or bleed easily, leading to poor stoma bag adhesion, they can be destroyed by cautery (thermal or silver nitrate) or by cryotherapy, using a liquid nitrogen spray. Larger and proliferating lesions, especially around colostomies, are best removed by shave and cautery under local anesthetic and an appliance with a correctly sized aperture fitted to prevent massive proliferation. Laser ablation is increasingly regarded as a first-line treatment being less painful and possibly more effective.[27]



▲ **FIGURE 96-16** "Granulomas" around a colostomy. The patient has cut the bag aperture larger to accommodate the original lesion, and the area thus exposed is seen as a ring of post-inflammatory hyperpigmentation in which new lesions developed.

PSORIASIS (See Chap. 18) Psoriasis is a common cause of peristomal skin disease because it may appear in irritated or traumatized skin (Koebner phenomenon), and because it is associated with inflammatory bowel disease. Peristomal psoriasis presents as a glazed erythema similar to flexural psoriasis (see eFig. 96-16.1 in on-line edition) and can be treated in the same way with topical corticosteroids, although, at the peristomal site, a non-greasy base should be selected.

Superficial x-ray (grenz ray) therapy has been used in recalcitrant cases.

INFECTIONS The most frequent peristomal skin infection is staphylococcal folliculitis, usually, but not exclusively, in those individuals with hairy abdomens who shave regularly to help the bags to stick (see eFig. 96-16.2 in on-line edition). It responds to oral antibiotics and to a reduction in shaving frequency to no more than once per week. Although antiseptic washes can be a useful additional therapeutic measure, they can cause irritant reactions if the skin is not correctly rinsed before being occluded by the stoma bag. Localized skin infections, usually staphylococcal or streptococcal, can produce a rash indistinguishable from irritant dermatitis or primary skin disease such as psoriasis or eczema. Furthermore, pre-existing psoriasis or eczema can become secondarily infected under occlusion.

PYODERMA GANGRENOSUM Pyoderma gangrenosum (PG) is a rare, inflammatory, ulcerative neutrophilic dermatosis (see Chap. 32) and is more common in peristomal skin than in the general population.[30,31] This is partly due to its strong association with inflammatory bowel disease. There is some evidence, however, that the increased use of convex-backed appliances may contribute to the incidence via the pathergic effect of increased pressure on the skin. Although some cases of PG are associated with active inflammatory bowel disease, the association is not universal; indeed, peristomal PG occurs in ostomates who have no history of inflammatory bowel disease.[32] Peristomal PG presents as a painful papule or pustule, often hemorrhagic, which then ulcerates and is usually very painful (see eFig. 96-16.3 in on-line edition). The pain and the ulceration can have profound effects on the patient's ability to wear a bag and therefore on their quality of life. The ulcers heal with cribriform scarring that can itself impair bag adhesion: rapid, effective treatment of PG is essential (see Chap. 32).

The authors' approach to the management of PG is found in the electronic version of this text.

Contact Allergy

Modern stoma bags are made largely from food-grade materials and those with a low potential for sensitization. Nonetheless, there are case reports of sensitivities to individual ingredients, including GANTREZ (GAF Corporation, Wayne, NJ) resins and acrylate adhesive systems. Furthermore, there is a potential for contact allergy from deodorizers and topically applied preparations. These case reports of peristomal allergic contact dermatitis have recently been the subject of a literature review.[39] Despite the fact that contact allergy is a relatively uncommon cause of peristomal dermatitis, most patients and many health professionals regard contact hypersensitivity to their appliance as the likely cause of a peristomal rash. Patch testing is indicated in patients with persisting problems where infection, irritation, and constitutional skin disease has been ruled out.[40] The authors have patch tested well over 100 such patients and relevant positive allergic reactions were found in only three cases of topically applied materials, including fragrance in a deodorizer and biocides in wet wipes.

Other Conditions

In theory, almost any of the multitude of skin disorders might affect a stoma. In clinical practice, the common disorders (e.g., psoriasis) predominate, and others are more common than expected (e.g., PG). Some less common peristomal dermatoses are worthy of note either because they present practical difficulties, such as pemphigoid[41] and nicorandil ulceration (see eFig. 96-16.4 in on-line edition), or, in the case of lichen sclerosus, because they have an unusual predilection for this site.[42]

CHAPTER 97

Corns and Calluses

Thomas M. DeLauro
Nicole M. DeLauro

EPIDEMIOLOGY

Every human being, with the exception of the non–weight-bearing infant, is vulnerable to the development of corns and calluses, because the skin is subjected to regular mechanical stress. The prevalence of corns and calluses can be readily appreciated by the number of nonprescription products aimed at reducing or preventing them—a billion-dollar market annually.

The earliest known discussion of these lesions can be found in the writings of Cleopatra, who authored a textbook on cosmetics.[1] Corns and calluses have plagued humankind since antiquity, affecting those at all socioeconomic levels.

Certain foot types and regions are prone to mechanically induced skin thickening, regardless of race, gender, or age.

ETIOLOGY AND PATHOGENESIS

Corns and calluses result from the prolonged application of excessive mechanical shear or friction forces to the skin. In theory, these forces induce hyperkeratinization, which leads to a thickening of the stratum corneum, although the precise mechanism by which this occurs remains unknown. If the abnormal forces are distributed over a broad area (i.e., more than 1 cm^2), a callus develops. In contrast, a corn will form if the same forces are applied to a focused location, with the lamellae of the stratum corneum becoming impacted to form a hard central core known as the *radix* or *nucleus* (Fig. 97-1).

Mechanical keratoses are not determined genetically. Heredity does play a role, however, in configuring the individual's skeletal architecture. A family history of bony abnormality or ligamentous laxity predisposes the person to the presence of sites of increased cutaneous friction or shear. The prevalence of these lesions has also proven to be significantly higher in females, certain ethnic groups, and mentally ill patients.[2,3]

CLINICAL FINDINGS

History

Corns and calluses produce painful symptoms often described as burning, especially when the affected area is weight bearing and/or shoes are worn. This discomfort is thought to result from microtearing of the thickened, inflexible skin.

Cutaneous Lesions

Corns [clavi or helomata (singular: clavus or heloma)] and calluses [tylomata (singular: tyloma)] are, respectively, keratotic papules and plaques that occur in areas that are subject to sustained excessive mechanical shear or friction forces.

Related Physical Findings

The lesions occur in predictable pedal locations, corresponding to a structural deformity or biomechanical fault. Crookedness of the lesser toes leads to prominence of the proximal and/or distal interphalangeal joints. Keratoses can therefore form either dorsal to those joints, between the toes, at the distal end of the toe, or on the lateral aspect of the fifth toe and/or toenail (lateral toenail corn, also known as *Durlacher's corn*; see eFig. 97-1.1 in on-line edition). Interdigital corns can be hard when they are adjacent to the interphalangeal joint(s) (see eFig. 97-1.2 in on-line edition) or soft when deep within the fourth interdigital space. The softness of latter last corn results from trapped perspiration, which leads to maceration of the keratotic tissue (Fig. 97-2).

In patients with bunions (hallux valgus), a callus usually forms at the medioplantar aspect of the hallux. During gait, the individual rolls off that portion of the great toe because of its incorrect position. The skin is subsequently

CORNS AND CALLUSES AT A GLANCE

- Corns and calluses result from prolonged application of forces to the skin and produce painful symptoms.
- Every weight-bearing human being is vulnerable.
- Lesions occur in predictable pedal locations.
- Corns and calluses show changes within the epidermis, dermis, and adipose layer.
- There are no associated systemic abnormalities.
- Treatments are available and vary in aggressiveness.

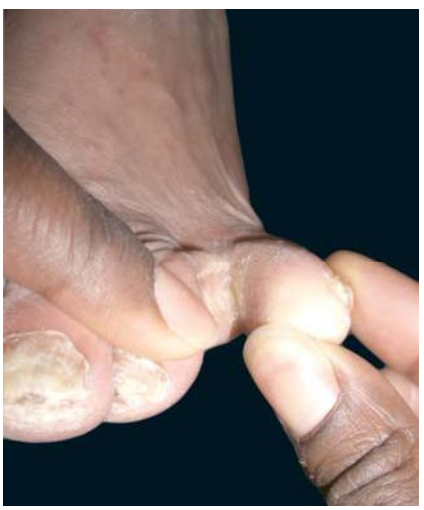
▲ **FIGURE 97-1** A simple corn beneath the third metatarsal head. Note the white central radix or nucleus. This radix must be pared to provide comfort.

pinched to form a "pinch callus" (see eFig. 97-2.1 in on-line edition). In addition, the first metatarsal often does not bear its fair share of the weight-bearing load. Weight is therefore transferred laterally to the second metatarsal head, which usually leads to the development of an additional corn or callus beneath that bone.

Other favored locations for lesser metatarsal head keratosis include the following:

- Beneath the first and fifth metatarsal heads in cavus foot types
- Beneath the fifth metatarsal head alone in persons with tailor's bunions (bunionette)
- Beneath the second through fourth metatarsal heads when multiple hammertoes or an equinus deformity co-exists
- Erratic locations (e.g., beneath the third and fifth metatarsal heads, isolated third or fourth metatarsal head, second and fourth metatarsal heads) in individuals with structural abnormalities such as brachymetatarsia or dislocated metatarsophalangeal joints, as in rheumatoid arthritis or neuroarthropathy (Fig. 97-3)

Another variant of corn is that referred to as *heloma miliare*, or seed corn. This title is derived from the clinical appearance of these corns: multiple guttate keratoses that are easily pared. When seamed nylon hosiery was fashionable, this garment was considered the causative factor. However, patients still present with seed corns even though they have never worn seamed stockings.



▲ **FIGURE 97-2** A soft corn (also known as a *heloma molle*) located deep within the fourth interdigital space.

HISTOPATHOLOGY

In contrast to nonmechanically induced keratoses, corns and calluses exhibit changes within the epidermis, dermis, and adipose layer. Corns demonstrate a parakeratotic plug within the stratum corneum, with a pressure-related loss of the stratum granulosum as well as atrophy of the stratum malpighii. The dermis displays significant fibrosis, dilated eccrine ducts and blood vessels, hypertrophied nerves, and scar tissue replacement of subcutaneous fat. Overall, the histologic changes in calluses are less pronounced, and include a thickened stratum corneum but intact stratum granulosum.[4]

Because corns and calluses are the result of mechanical friction and shear alone, there are no associated hematologic, chemical, serologic, or immunohistochemical abnormalities.

▲ **FIGURE 97-3** A large callus beneath the fifth metatarsal head in a post-poliomyelitis patient whose foot is now in rigid adductovarus.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS (Box 97-1)

PROGNOSIS AND CLINICAL COURSE

If left untreated, corns and calluses result in painful ambulation and also in

Box 97-1

Differential Diagnosis of Corns and Calluses

Most Likely (Secondary to Structural Deformity)

Deformity	Corn or Callus Location
Pronation	Medioplantar heel
Pes planus foot type	Medioplantar heel
Charcot neuroarthropathy	Midsole
Cavus foot type	Submetatarsal heads 1 and 5
Tailor's bunion	Submetatarsal head 5
Hallux valgus	Submetatarsal head 2 Medioplantar hallux
Brachymetatarsia	Submetatarsal heads 3, 5
Dislocations as in rheumatoid arthritis and other structural abnormalities	Submetatarsal heads 3, 4 Submetatarsal heads 2, 4
Transmetatarsal amputation without tendo-Achilles lengthening	Stump of amputation

Consider

- Multiple guttate keratoses
  - Heloma miliare
- Painful corns
  - Intractable plantar keratoses
  - Neurofibrous or neurovascular corn
  - Porokeratosis plantaris discreta

Always Rule Out

- Lesions not associated with bony prominences
  - Verruca
  - Genokeratoses
  - Cutaneous neoplasms
  - Neuroborreliosis

subhelomal bursitis and blistering that can rupture to the surface. Because of the close proximity of some corns to joints and bone, septic arthritis and/or osteomyelitis can ensue. The mechanical forces that cause corns and calluses can also rupture portions of the subcutaneous vascular plexus, which leads to hemorrhage into keratotic tissue. In healthy patients, such findings are of minor significance, but in other cases (e.g., in diabetic patients and patients with connective tissue disease), they may herald extensive skin ulceration or vasculitis.

The need for lower-extremity amputation is a dominant fear in most diabetic patients. Such amputations are most often preceded by a history of foot ulceration (see Chap. 152). Although a number of co-morbidities contribute to the development of ulceration (e.g., peripheral vascular disease, neuropathy, and limited joint mobility), minor trauma via repetitive pressure is the pivotal precipitating event. As markers of repetitive friction and shear, corns and calluses in the diabetic foot are of special significance. Simple débridement of these hyperkeratotic lesions decreases peak plantar pressures by as much as 26 percent.[5] In a retrospective review of more than 200 diabetic foot ulcerations, patients who had their corns and calluses pared frequently experienced a statistically significant decrease in the incidence of foot ulceration, hospitalization, and surgical intervention.[6] Hemorrhage within a corn or callus is an especially ominous sign, indicating subcutaneous breakdown with a strong potential for ulceration. Therefore, ulcer care should include paring of calluses. The use of proper footwear by the diabetic as well as the non-diabetic patient may also play a role in not only preventing but also reducing the development of callosities. Shoes should be correctly sized to accommodate the width and length of the patient's foot, and the heel should be elevated minimally if at all to prevent pathology and pain.[7,8]

Box 97-2

Treatment

	PHYSICAL		TOPICAL		SURGICAL
First line	Paring Padding	Central radix of corn requires débridement	Keratolytics[a]	40% salicylic acid or 40% urea cream used as directed	
Second line	Injections[b]	4% alcohol mixed with local anesthetic	Lipid extract with garlic[c]		Osseous and/or soft-tissue procedures[d]

[a]Keratolytics are to be used with caution. Their use is contraindicated in patients with co-morbid peripheral neuropathy or arterial disease.
[b]Injections are useful for soft corns and intractable plantar keratoses. Typically up to seven injections may be required, with darkening and thrombosis of the lesion heralding a cure.[9,10]
[c]Newer modality under research. Side effects include blistering, redness, burning, and hyperpigmentation.[11]
[d]Osseous procedures are designed to redistribute weight-bearing pressures, whereas soft-tissue procedures (i.e., adipofasciocutaneous flaps[12]) are used to eliminate cicatrix (fifth digit) secondary to the use of medicated padding.

TREATMENT (Box 97-2)

PREVENTION

Corns and calluses can be prevented only by reducing or eliminating the mechanical forces that created them. Usually, this is a daunting, if not impossible, task. Repetitive occupational motions are often unavoidable, patients are commonly reluctant to alter shoe styles, and osseous architecture is predetermined through heredity.

CHAPTER 98

Sports Dermatology

Dirk M. Elston

EPIDEMIOLOGY

Skin problems are common among athletes. During an 8-week survey of university athletes, 40 percent reported skin problems.[1] In a study of mountain biking injuries, skin lesions accounted for 75 percent of all injuries.[2] Skin lesions account for 35 percent of all in-line skating injuries.[3] Skin infections are more prevalent in athletes than in the general population.[4] Skin-related complaints are especially common in warm, humid climates. During the 1993 Central American and Caribbean Games, held in Puerto Rico, 1 out of every 100 athletes had a skin-related complaint severe enough to require medical care.[5] Similarly, sports that involve repeated immersion in water are associated with an increased incidence of skin injury and infection.[6]

Table 98-1 lists some unique sports-associated skin conditions that are worthy of mention but are not discussed further in this chapter (Figs. 98-1 and 98-2).

PYOGENIC SKIN INFECTIONS

Epidemiology

Cutaneous community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has emerged as the most important pathogen among athletes. Athletes at risk include weightlifters, wrestlers, and members of competitive sports teams.[7–9] During an outbreak of CA-MRSA in a college football

SPORTS DERMATOLOGY AT A GLANCE

- Forty percent of all athletes develop skin problems.
- Infections are highly prevalent.
- Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has emerged as the most important pathogen among athletes.
- CA-MRSA typically presents as an abscess or folliculitis.
- The most important intervention for a CA-MRSA abscess is drainage.
- Control of CA-MRSA outbreaks requires treatment of fomites and skin colonization.
- Infections with *Pseudomonas*, *Vibrio*, and atypical mycobacteria are frequently associated with water sports.
- Heat and cold injury remain important problems in athletes.

team, linemen had the highest attack rate (18 percent). Having pre-existing cuts or abrasions and sharing bars of soap were important risk factors associated with infection. Nasal carriage was associated with sharing towels, living on campus, and having a locker near a teammate.[10] Cosmetic body shaving has also been identified as a risk factor for CA-MRSA infection.[11] Data from an outbreak of CA-MRSA abscesses among members of a professional football team indicate that most infections developed at turf abrasion sites. Infection was significantly associated with playing the lineman or linebacker position as well as with having a higher body mass index. MRSA was cultured from whirlpools and taping gel as well as from 35 of the 84 nasal swabs taken from players and staff.[12] In competitive male athletes, abscesses generally occur at sites of minor abrasions. In weightlifters, abscesses favor the axillae. Abscesses among female athletes favor the thighs and buttocks. Folliculitis and abscesses noted during an outbreak of CA-MRSA infection in a saturation diving facility involved the nose, external ear canal, neck, back, extremities, and buttocks.[13]

TABLE 98-1
Sports-Associated Skin Conditions

- Bikini bottom: bacterial folliculitis on the buttocks of swimmers
- Jazz ballet bottom: buttock cleft abscess
- Jogger's nipples: painful, swollen, eroded or hyperkeratotic nipples
- Karate cicatrices: linear scars on the dorsal aspects of the hands
- Mogul skier's palm: traumatic hypothenar ecchymosis
- Painful piezogenic pedal papules: transdermal fat herniations
- Ping-pong patches: traumatic ecchymotic patches
- Pool palms: smooth, shiny, tender palms secondary to rough pool surfaces
- Pulling-boat hands: pernio-like condition produced by friction and damp cold
- Rower's rump: lichenification
- Runner's nail: multiple Beau's lines or periodic shedding of the nail plate (see Fig. 98-1)
- Runner's rump: ecchymoses of the superior gluteal cleft
- Stingray hickey: bite ecchymosis
- Stretcher's scrotum: scrotal hematoma
- Swimmer's shine: facial oiliness seen in swimmers
- Swimmer's shoulder: abrasion of the shoulder by the beard during crawl stroke
- Talon noir (black heel): intradermal hemorrhage
- Tennis toe: subungual hematoma with or without subungual hyperkeratosis or nail dystrophy (jogger's toe, hiker's toe, skier's toe are similar) (see Fig. 98-2)
- Turf toe: metatarsophalangeal joint sprain

Etiology and Pathogenesis

CA-MRSA isolates usually contain the type IV staphylococcal chromosomal cassette (SCC)mec coding for methicillin resistance, as well as the Panton-Valentine leukocidin virulence factor.[14] There is a high risk of colonization in close contacts of individuals with CA-MRSA infection, and those who are colonized commonly progress to clinical infection.[15,16]

Clinical Findings

CA-MRSA infection in athletes typically presents as folliculitis or spontaneous abscess (see Chap. 177). Abscesses may begin as furuncles but rapidly evolve to fluctuance with surrounding cellulitis.

▲ **FIGURE 98-1** Runner's nail. In this case there are multiple Beau's lines with onychoschizia.

Treatment

Like other abscesses, CA-MRSA abscesses respond to drainage. Surveillance data from Baltimore, Atlanta, and Minnesota including 1647 cases of CA-MRSA infection show that therapy to which the strain was resistant was not associated with adverse patient-reported outcomes if the abscess was incised and drained.[17] Other data also suggest that many CA-MRSA abscesses respond to drainage alone.[18,19] Failure to drain CA-MRSA abscesses may have catastrophic results, even if effective antibiotic therapy is prescribed. In one report, bilateral blindness resulted.[20]

Although the SCCmec type IV gene cassette present in most CA-MRSA strains codes only for methicillin resistance, an isolate from a Japanese athlete also contained a transmissible plasmid coding for multiple-drug resistance.[21]

▲ **FIGURE 98-2** Tennis toe. Subungual hemorrhage seen in runners and basketball and tennis players that produces anxiety because of fear of melanoma. It can be easily differentiated from melanoma by dermoscopy.

Other CA-MRSA isolates have emerged that are resistant to multiple antibiotics. Some CA-MRSA isolates from Taipei carry a distinct SCCmec cassette (type VT) that codes for resistance to multiple antibiotics.[22] Although drainage will cure many CA-MRSA abscesses, some athletes require antibiotic therapy. Of the inexpensive oral agents available to treat CA-MRSA infections, sulfa drugs consistently show the best mean inhibitory concentrations. Tetracyclines are good alternative agents, although only approximately 80 percent of CA-MRSA organisms will be sensitive in many locations. Lincosamide resistance is increasing.[23–25] Inducible resistance related to the erm gene results in strains that test clindamycin susceptible in vitro but may be resistant in vivo. A D-test can be used to determine the presence of inducible resistance. In the D-test, clindamycin and erythromycin disks are placed close together on a culture plate. If inducible lincosamide resistance is present, the zone of inhibition around the clindamycin disk will be flattened on the side toward the erythromycin disk, resembling a capital letter D. Rates of inducible lincosamide resistance vary from 8 percent in Houston to 94 percent in Chicago.[26–30] In some areas in the United States, CA-MRSA strains were less likely than methicillin-sensitive strains to demonstrate inducible resistance.[31] In contrast, some locations in Asia report that 100 percent of tested CA-MRSA strains demonstrate the ermB gene.[32]

Some serious CA-MRSA infections require the use of linezolid, vancomycin, fluoroquinolones, daptomycin, quinupristin/dalfopristin, or newer-generation carbapenems. Fluoroquinolones and linezolid have the advantage of oral administration. In some groups of severely ill patients, linezolid has proved superior to vancomycin.[33–35] Daptomycin has been used effectively to treat serious MRSA infections, but resistance has been reported, and disk diffusion testing may not predict clinical outcome.[36,37] A new cephalosporin, ceftobiprole medocaril, appears to offer a good balance of efficacy and tolerability.[38]

Prevention

Because of the risk of contagion through physical contact and shared equipment, topical antiseptics such as chlorhexidine, povidone iodine, quaternary ammonium compounds, triclosan, and Dakin's solution play an important role in management. Chlorhexidine gluconate is widely used and generally has good activity against staphylococci. Some MRSA isolates are less sensitive to chlorhexidine than are methicillin-susceptible *S. aureus* (MSSA) isolates.[39,40] Some chlorhexidine-resistant isolates also exhibit resistance to quaternary ammonium compounds. Resistance can be overcome by using disinfectants containing both alcohol and chlorhexidine.[41] Seventy percent ethanol alone is an effective agent for fomite sterilization if contact can be maintained for 3 minutes.[42] Povidone iodine has shown good activity against both MRSA and MSSA isolates.[39] Triclosan-based products are readily available as "no-wash" hand sterilizers. Some triclosan resistance has been documented, and some MRSA isolates are less sensitive than MSSA isolates.[43,44] Mupirocin is commonly used to treat staphylococcal nasal carriage, but resistant strains have emerged.[45] In one double-blind, placebo-controlled trial, successful nasal eradication occurred in only 44 percent of cases.[46]

Other Pyogenic Skin Infections Among Athletes

Group A streptococcal infections may also spread rapidly among athletes.[47] Pyoderma with a nephritogenic *Streptococcus* can cause epidermic glomerulonephritis. Streptococci also produce erysipelas and lymphangitis (see Chaps. 177 and 179).

Pseudomonas infections are commonly associated with water.[48] *Pseudomonas* folliculitis, green nails, and *Pseudomonas* webspace infection are the most common (see Chap. 180 and on-line version).

VIRAL SKIN INFECTIONS

Herpes simplex virus (see Chap. 193) can be transmitted by skin-to-skin contact during any contact sport. Herpes gladiatorum is recognized as a major problem among wrestlers. Attack rates as high as 34 percent have been reported.[59] Ocular involvement is a serious complication. Wrestlers with active infections are barred from participation. The use of abrasive shirts may contribute to the spread of herpes simplex virus infection among wrestlers.[60] They should be avoided. Oral antiviral drugs such as acyclovir, valacyclovir, and famciclovir can be used to shorten the course of an outbreak. It is likely that all three of these drugs can prevent outbreaks of herpes gladiatorum when given as long-term or periodic prophylaxis.

FUNGAL INFECTIONS (See Chap. 188)

Tinea infection is particularly common among wrestlers.[61] Tinea pedis may be spread by floors around swimming pools.[62] Prevalence among runners increases with age, and asymptomatic carriers are common.[63] Periodic prophylactic treatment of carriers with topical agents to prevent clinical disease may be possible.

TRANSMISSION OF BLOOD-BORNE PATHOGENS

There is growing concern about possible transmission of blood-borne pathogens during contact sports. Minor cuts and abrasions are both a source of contamination and a portal of entry for human immunodeficiency virus and hepatitis viruses. Lacerations can be covered with self-adherent biosynthetic dressings to prevent blood transmission from minor wounds during contact sports.

HEAT AND COLD INJURY

Heat injury is a common cause of morbidity during sports participation. The skin serves as the major organ of thermal regulation. Regular exercise modifies the responsiveness of cutaneous vessels, increasing cutaneous perfusion during periods of activity.[64] The duration of exercise can be safely increased in hot environments if a volume of fluid at least equal to that lost in sweat is ingested within 60 minutes before and during exercise.[65] Uniforms promote heat retention, and adequate skin surface must be exposed during exercise to reduce the risk of heat stress injury. Evaporative cooling from forearm skin is more efficient than that from the upper trunk; therefore, the use of short-sleeved uniforms is helpful in hot climates.[66] Clothing should be lightweight and have high water permeability to facilitate evaporative cooling. At high humidity levels, evaporative cooling from skin is inefficient, and the risk of heat stress increases. Spraying water on the skin during exercise can reduce skin temperature but results in vasoconstriction and does not reduce core body temperature.[67] The use of cooling vests can improve athletic performance in hot weather.[68,69] Harlequin syndrome is a disorder of the sympathetic nervous system characterized by diminished sweating and flushing in response to exercise.[70]

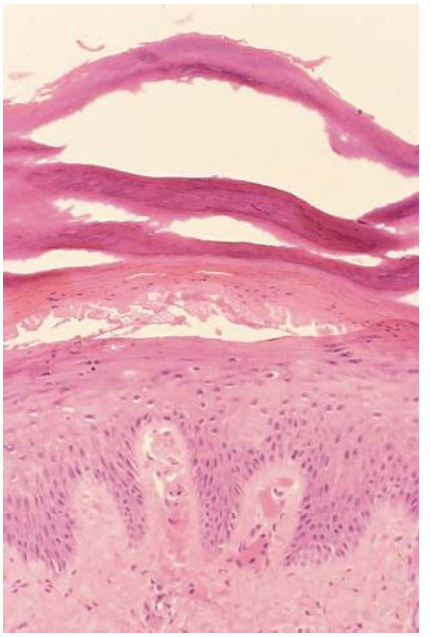
Younger athletes have a greater skin surface area, which places them at greater risk for hypothermia in cold environments. Skin injuries such as frostbite and perniosis are seen in sports enthusiasts who engage in cold weather sports. Frostbite is a common problem among joggers and may involve the face, hands, feet, and penis. The decreased oxygen tension at high altitudes contributes to peripheral vasoconstriction, which decreases peripheral blood flow and increases the risk of frostbite.[71] Clothing must remain dry to retain its insulating properties. Frequent changes of socks and periodic breaks in a warm environment are important safeguards. If frostbite occurs, rapid re-warming should be accomplished as soon as the individual is in a safe environment with no risk of refreezing.

SKIN INJURIES

Skin and soft tissue injuries are common among athletes. New treatments, including hydroactive wound dressings, have advanced the treatment of superficial wounds. Application of a hydroactive dressing can provide a protective barrier that can allow an athlete to return to training. Cold gel application has been shown to provide effective symptomatic relief for sports-related soft tissue injuries.[72]

Friction Blisters

Friction blisters occur as a result of midepidermal necrosis (Fig. 98-3). Proper fitting of footwear and the use of gloves and chalk can reduce the incidence of blistering. Heat, sweating, and maceration increase the risk of blistering. Antiperspirants have been used in an attempt to reduce the incidence of blistering, but results have been mixed and they may cause irritant dermatitis. Attempts to reduce the incidence of irritant dermatitis through the addition of emollients reduces the efficacy of the antiperspirant.[73] In a study of cross-country hikers, use of a 20 percent solution of aluminum chloride hexahydrate in anhydrous alcohol reduced the rate of blister formation from 48 percent to 21 percent, but the incidence of irritant dermatitis was high and non-compliance with the treatment regimen was common.[74] The use of closed-cell neoprene insoles, acrylic socks, or thin polyester socks combined with thick wool or polypropylene socks that maintain their bulk can reduce the incidence of blisters.[75] The use of mesh-top footwear can decrease the risk of blistering by providing a cooler, dryer environment without the use of antiperspirants.



▲ **FIGURE 98-3** Friction blisters are a manifestation of intraepidermal necrosis.

Lime Burns

The use of calcium oxide (quicklime) or calcium hydroxide (slaked lime) instead of calcium carbonate (chalk) to line sports fields may result in chemical burns, especially in wet weather. Second- and third-degree burns may occur. Lime use may also result in severe inhalation and ocular injury.

ATHLETE'S NODULES

Collagenous "surfer's nodules" are a well-described complication of surf boarding. Boxers, marbles players, and football players are also prone to collagenous nodules. Surgical excision may be required.

ACTINIC DAMAGE (See Chaps. 89 and 112)

Actinic irradiation can cause burns and a risk of skin cancer in later life. Even relatively short periods of exposure during sports are associated with an increase risk of basal cell carcinoma.[76] Sweating alters hydration of the stratum corneum and lowers the minimal erythema dose of ultraviolet B light by as much as 40.9 percent after just 15 minutes of jogging.[77] Participation in water sports is an independent risk factor for melanoma.[78]

ALLERGIC CONTACT DERMATITIS (See Chap. 13)

Rubber allergens are the most common cause of sports-associated allergic contact dermatitis (Fig. 98-4). Rubber adhesives and rubber chemicals in the box toe and cushioning materials can cause dermatitis from footwear. Contact dermatitis can also result from equipment, swimming pool chemicals, athletic tape, and topical creams and sprays.

BITES AND STINGS

Unexpected bites and stings are frequent while playing sports (see Chap. 210).

SKIN PROBLEMS RELATED TO WATER SPORTS

Skin eruptions account for almost half of all illnesses related to recreational water.[79] Monitoring of water for fecal coliforms has been practiced for years and has proved to be a better predictor of the risk of skin disease than of the risk of gastrointestinal disease.[80] Contamination by storm runoff results in a predominance of organisms linked to skin infections.

Exposure to the rough surfaces of diving boards can result in a chronic plantar dermatosis. The fingers can also be affected. Some individuals with this disorder have a history of atopic dermatitis, psoriasis, or juvenile plantar dermatosis. The rough interior of swimming pools can result in "pool palms." The skin appears taught, shiny, and erythematous with loss of dermatoglyphics (Fig. 98-5). Green hair is related to the presence of copper in pool water. Copper pipes or algicides may be the source of the high copper levels. Acidic pH, fluoridation of water, and swimming pool chlorination all contribute to the release of copper into pool water. Green hair has been

▲ **FIGURE 98-4** Athletic shoe allergic contact dermatitis.

▲ **FIGURE 98-5** Finger dermatitis in this diver paralleled the intensity of her training. It resolved during breaks from training.

treated with penicillamine shampoo, hot vegetable oil, hydrogen peroxide, edetic acid, and 1-hydroxyethyl diphosphonic acid.

Swimming pool water may be treated with chlorine, bromine, or ozone ionization. All three methods are acceptable, although the use of bromine with ozone may be associated with a slightly lower risk of cutaneous reactions.

Swimmer's Itch (See Chap. 209)

Swimmer's itch is related to avian schistosome cercariae. Newly created bodies of water, such as recently abandoned quarries, are associated with a lower incidence of swimmer's itch. Administration of praziquantel to ducks inhabiting a lake can reduce the incidence of swimmer's itch.[81] Chemical control or mechanical removal of snails can also be effective. The rash heals spontaneously in 2 to 3 weeks. Topical steroids and antihistamines may be beneficial. Topical antipenetrants have been evaluated, but an ointment based on IR3535 (ethyl butylacetylaminopropionate) failed to prevent an outbreak of cercarial dermatitis during swimming races across Lake Annecy in France.[82]

Sea Bather's Eruption (See Chap. 209 and on-line version)

Other Skin Problems Related to Ocean Sports (See also Chap. 209)

Jellyfish stings result in immediate pain and may produce delayed immune-mediated reactions. *Cyanea* and *Chrysaora* sea nettles are the most common causes of jellyfish dermatitis. *Chrysaora* jellies are especially common off Atlantic beaches. *Physalia physalis*, the Portuguese man-of-war, is common in the southeastern United States and the Gulf of Mexico. *P. utriculus,* the blue bottle jellyfish, is native to the Pacific. Stings of *Chironex fleckeri*, the Pacific box jellyfish or sea wasp, may result in shock or death. Victims of any marine envenomation should immediately be removed from the water. Administration of antivenin can prevent cardiovascular collapse. Verapamil shows little effect in experimental animals and may negate some of the beneficial effect of antivenin. Unlike verapamil, $MgSO_4$ has been shown to prevent cardiovascular collapse in test animals.[84] First aid includes mechanical removal of tentacles by seawater and sand. Most northern sea nettle nematocysts are inactivated in alkaline conditions, and most man-of-war nematocysts are inactivated in acidic conditions; however, the use of either acid or alkaline solutions can be complicated by the release of venom in some species. Application of ice can provide analgesia. Most marine venoms are inactivated by heat, and hot water immersion [40°C to 41°C (104°F to 105.8°F)] generally results in better pain relief.[85] Jellyfish sting inhibitors can be added to sunscreen lotions.[86] *Haloclava producta*, the "ghost anemone," is responsible for summer outbreaks of dermatitis off the coast of Long Island, New York.[87]

Stingray injury usually occurs when a swimmer accidentally steps on a ray. Roughly 750 stingray stings are reported each year off the U.S. coast.[88] Stings are associated with severe pain, hyperhidrosis, hypotension, muscle cramps, and dysrhythmia. Tissue necrosis can be extensive, and surgical exploration is commonly required.[89,90] Hot water immersion is effective in the control of acute pain but may not prevent skin necrosis.[91] Lion fish are most common in the sub-tropical waters of the Pacific but are increasingly being reported off the coast of the United States. Stings cause pain, swelling, redness, bleeding, and mild systemic symptoms. Hot water immersion generally produces pain relief. Surgical exploration may be prudent for injuries involving the hands.

Corals, especially fire coral, can produce contact dermatitis in divers. Their stinging cells produce a powerful irritant that can produce severe local reactions, including reactions that resemble full-thickness burns. Contact with seaweed has been implicated in vesiculo-bullous reactions. Algal organisms in seaweed can cause "stinging seaweed dermatitis" and pustular folliculitis.

Mycobacterium marinum can cause epidemics of swimming pool granuloma (see Chap. 184). Mycobacterial infections are also commonly acquired in brackish coastal waters. Marine *Vibrio* infections (see Chap. 180) also occur with exposure to brackish coastal waters. Necrotizing fasciitis and sepsis may occur. Culture of specimens from wounds contaminated with seawater have a greater yield if thiosulfate-citrate-bile-sucrose agar is used, and the cultures are incubated both at room temperature and at 30°C (86°F).[92]

Decompression injury may affect the skin of divers. Livedo reticularis is commonly noted. In a porcine model of decompression injury, vascular congestion and vasculitis were common findings in skin biopsy specimens.[93]

HISTAMINE-MEDIATED REACTIONS

Exercise-associated urticarial reactions include cholinergic urticaria, solar urticaria, symptomatic dermatographism, pressure-induced urticaria, cold urticaria, aquagenic urticaria, latex-induced contact urticaria, and exercise-induced anaphylaxis. These entities are discussed in Chap. 37.

ACNEIFORM LESIONS

Acne mechanica is common among athletes, occurring under chin straps, helmets, and shoulder pads. The lesions may respond better to keratolytics than to antibacterial agents.[94] Severe acne may be a sign of anabolic steroid use. The use of these drugs is widespread among athletes of all ages.[95] Although the standard in drug testing is immunoassay screening followed by gas chromatography–mass spectrometry of urine samples to provide confirmation, newer technology may allow reliable detection of anabolic steroids in hair.[96]

DERMATOLOGIC PROBLEMS OF SPECIAL ATHLETES

Athletes with atopic eczema may experience bouts of pruritus with exercise. However, there is evidence that the sweating and vascular response improve with athletic training and that athletics may not interfere with treatment of atopic dermatitis.[97,98] Application of an emollient after showering and short periods of rest can inhibit sweat-induced itching in atopic athletes, and regular moderate exercise does not cause deterioration in the condition of their skin.[99]

The athlete treated with oral retinoids also faces special problems. Arthralgia, staphylococcal colonization, photosensitization, and fatigue may result in lost training time or lost seasons. Retinoids cause disruption of epidermal integrity and skin fragility. Greater trochanter enthesopathy (pain at the site of tendon insertion) may be a complication of short-term oral retinoid therapy in athletes.[100] When possible, retinoid treatment should be planned between seasons.

CHAPTER 99

Decubitus (Pressure) Ulcers

Tania J. Phillips
Lilian M. Odo

Estimates are that between 1.5 and 3 million people in the United States have pressure ulcers and that these chronic wounds cost approximately $5 billion annually to treat. The incidence of pressure ulcers varies with the clinical setting. In acute care the incidence ranges from 0.4 to 38 percent, in long-term care from 2.2 percent to 23.9 percent, and in home care from 0 percent to 17 percent. Most pressure ulcers develop during the first few weeks of hospitalization. The prevalence of pressure ulcers in acute care settings is approximately 15 percent, in long-term care settings from 2.3 percent to 28 percent, and in home care from 0 percent to 29 percent.[1–4]

Pressure ulcers are more common in the elderly, especially those over the age of 70; in patients who have had surgery for hip fracture; and in patients with spinal cord injury.

The majority of pressure ulcers occur on the lower part of the body, 65 percent in the pelvic area and 30 percent on the lower limbs.[1–4]

ETIOLOGY AND PATHOGENESIS

The main etiologic factors contributing to pressure ulcer development include pressure, friction, shearing forces, and moisture.

Pressure or force per unit area is considered to be the most important factor in pressure ulcer formation. Normal tissue pressure is between 12 and 32 mm Hg. Pressures higher than this upper limit can compromise tissue circulation and oxygenation. When a patient lies immobile on a hospital bed, pressures as high as 150 mm Hg can be generated, especially over bony prominences. The duration as well as degree of pressure is important. If pressure is relieved regularly, tissue recovery can occur, whereas constant pressure can lead to tissue death (Fig. 99-1). Often, damage occurs deep at the bone-muscle interface, which may not be apparent at the skin surface (Fig. 99-2). Patients who are immobile should therefore be turned regularly to prevent pressure ulceration. The pathophysiology of pressure ulcer formation is summarized in Fig. 99-3, and common sites of pressure ulcers are shown in Fig. 99-4.

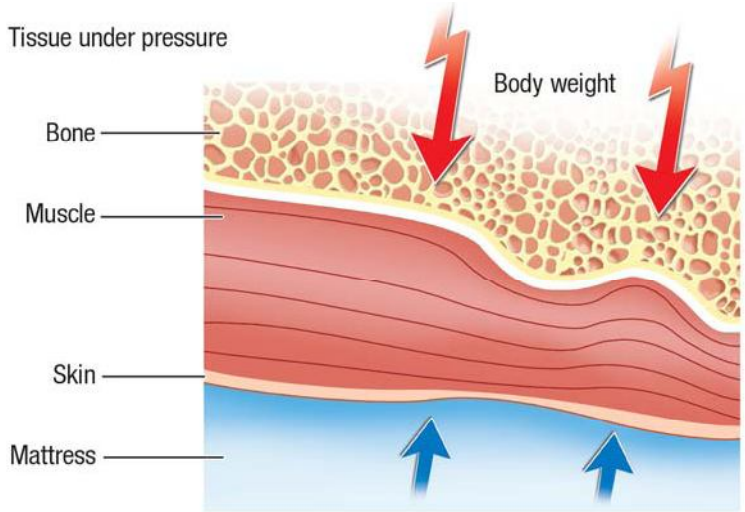
Shear force results from the motion of bone and subcutaneous tissues relative to the skin when the skin is fixed (e.g., when the upper body of a supine patient is raised to an angle above 30 degrees and the skin remains in contact with the bed). Shearing forces are parallel to the tissue surface, and the subsequent sliding pressure is transmitted to deeper tissues, which can become angulated and occlude the blood vessels (Fig. 99-5A).

Friction is the force that resists the relative motion between two surfaces that are in contact. This causes damage to the superficial layers of the skin (e.g., when a patient is dragged across the bedsheets) (Fig. 99-5B).

PRESSURE ULCERS[1,2] AT A GLANCE

- Commonly known as *decubitus ulcers*, *pressure sores*, and *bedsores*.
- Affect approximately 0.5 percent to 2.2 percent of the population.
- Tend to occur over bony prominences, more common from the waist down.
- Etiologic factors include pressure, shearing, frictional forces, and moisture.
- Related risk factors are prolonged immobilization, sensory deficit, impaired consciousness, circulatory disturbance, poor nutrition, and chronic diseases.
- Staged according to the degree of tissue damage observed (I to IV); pathologic findings depend on the stage of evolution.
- No specific laboratory findings. The diagnosis is made clinically.

▲ **FIGURE 99-1** Pressure ulcer, stage IV. (From Falanga V et al: *Text Atlas of Wound Management*. London, Martin Dunitz, 2000.)



▲ **FIGURE 99-2** Tissue under pressure. (From *Preventing Pressure Ulcers: Clinical Practice Guideline.* Washington, DC, US Department of Health and Human Services, AHCPR publication 92-0047 May 1992.)

A moist environment from urinary incontinence, perspiration, or excessive wound drainage can cause maceration of the skin, which increases the risk of pressure ulcer formation fivefold. Other risk factors for pressure ulcer development include prolonged immobilization, sensory deficit, circulatory disturbances, poor nutrition, acute illness, advanced age, and a previous history of pressure ulcers as well as fecal and urinary incontinence, hip fractures, smoking, and dry skin. Concomitant use of medications such as corticosteroids, which can impair healing; sedatives and analgesics, which can impair consciousness; and drugs that can cause alterations in cutaneous blood flow, such as anti-hypertensives, can also increase pressure ulcer risk, and such drugs should be used with care (Table 99-1).

CLINICAL FINDINGS (Fig. 99-6)

History

History taking and physical examination for pressure ulcer patients should incorporate a risk assessment scale. A number of risk assessment tools have been devised in an attempt to identify persons at risk for pressure ulcers. The Braden, Waterlow, and Norton scales have been extensively tested for reliability and validity and have been recommended by the Agency for Healthcare Research and Quality for predicting the risk of developing pressure sores. Components of these scales assess the following risk factors: mobility, activity level, nutritional status, mental status, incontinence/moisture conditions, general physical condition, skin appearance, medication use, friction and shear, weight, age, predisposing diseases, and prolonged pressure (Table 99-2).

Physical Examination

All pressure ulcer patients should undergo a full physical examination to identify systemic disease contributing to wound development, such as anemia, chronic cardiac or respiratory disease, and neurologic disorders.

Ulcer Evaluation

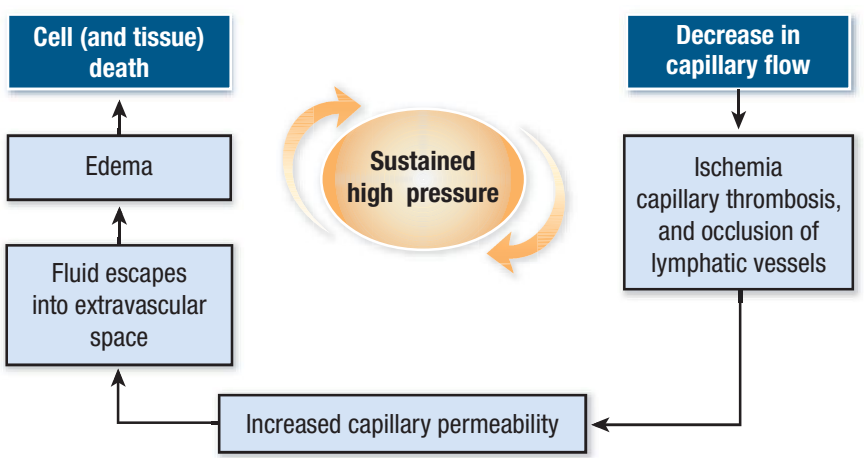
Staging is an assessment system that classifies pressure ulcers based on anatomic depth of soft-tissue damage. Pressure ulcers often progress from lower to higher stages, and any small pressure ulcer should be considered as the possible "tip of an iceberg." Table 99-3 shows the clinical appearance of pressure lesions and ulcers and their histopathologic correlates as defined by the National Pressure Ulcer Advisory Panel. Palpation is important to assist visual evaluation, and débridement is often necessary to determine the extent of the ulceration. Ulcers that initially appear superficial can end up being classified as stage III or IV after débridement reveals their true depth. The epidermis may be hypertrophic at the ulcer margin with varying degrees of pigmentation.[5]

There are several staging systems for classifying pressure ulcers. Three of them, the National Pressure Ulcer Advisory Panel, Shea, and Yarkony and Kirk systems, are the most commonly used. Table 99-4 compares these three classification systems.[2,5–7]

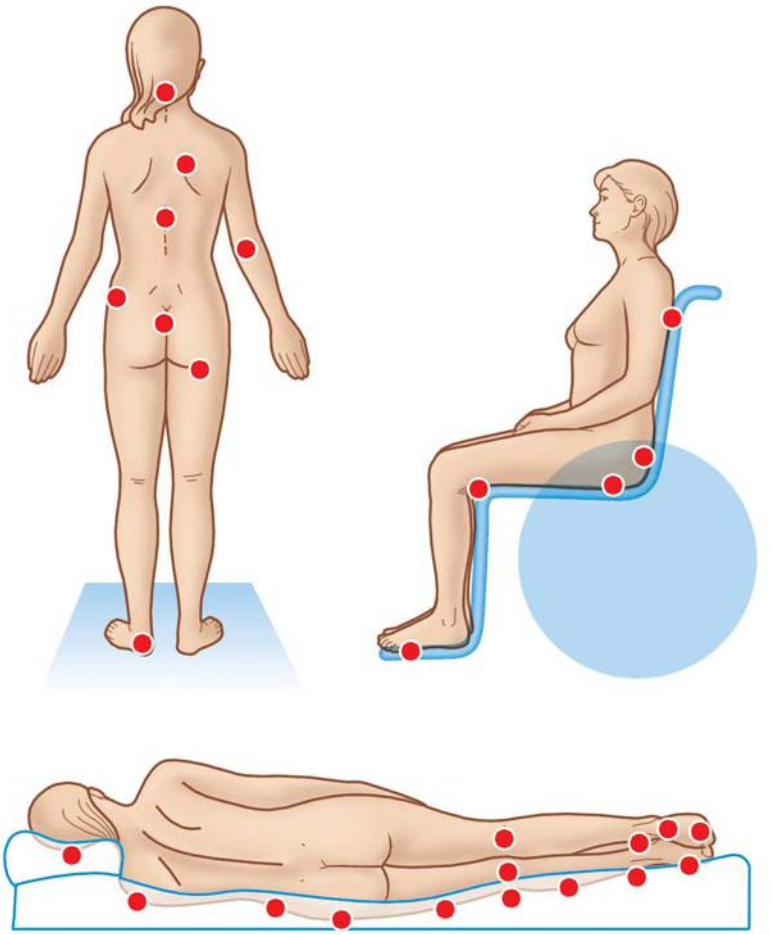
Related Physical Findings

Tenderness, erythema, edema and warmth of surrounding skin, exudate, and foul odor are symptoms and signs of infection. Fever and declining mental or physical status should raise suspicion of bacteremia or osteomyelitis.

Spasticity secondary to inflammation and infection may trigger muscle contractures and joint deformity that can limit motion, which complicates positioning. Weakness and signs of anemia and dehydration can be found secondary to profound loss of fluid and protein from these open, draining wounds.



▲ **FIGURE 99-3** Pathophysiology of pressure ulceration. (From Grey JE, Harding KG, Enoch S: Pressure ulcers. *BMJ* **332**:472, 2006, with permission of Blackwell Publishing.)



▲ **FIGURE 99-4** Common sites of pressure ulcer development. (From *Preventing Pressure Ulcers: A Patient's Guide*. Washington, DC, US Department of Health and Human Services, USGPO 617-025/68298, 1992.)

LABORATORY TESTS

The diagnosis is made clinically. However, anemia, leukocytosis, hypoproteinemia, or reduced serum iron levels may be present. It is important to exclude other diseases that can cause skin ulcers, including calciphylaxis, vasculitis, and connective tissue diseases.

Biopsy

Histologic analysis may be helpful to diagnose the pressure ulcer stage when clinical findings are insufficient to determine depth and to exclude other diseases that can present with skin ulcers. In long-standing pressure ulcers, squamous cell carcinoma can develop (Marjolin's ulcer). Histologic findings in pressure ulcers are described in Table 99-3.

Imaging Studies

Radiology is most useful to identify complications, particularly of deep pressure sores. Plain radiographs can identify ectopic bone, air in the ulcer cavity, and sclerotic or destructive changes in the underlying bony prominence. Ectopic bone can cause a pressure sore by altering the patient's posture and locally increasing pressure over soft tissue.[8] When there is clinical uncertainty about the size or extent of a pressure ulcer, sinography can be performed. Direct magnification radiography of sacral areas is useful when plain radiographs leave doubt about the condition of the bony cortex adjacent to a pressure sore. If the cortex is intact, osteomyelitis is unlikely.

Computed tomographic scanning is useful to determine the extent of a pressure ulcer and its anatomic relation to surrounding structures. It is helpful in assessing large, complicated lesions with associated sinus tracts or extensive undermined margins. Computed tomography is the only radiographic modality that can define the external margin of the lesion.

Magnetic resonance imaging (MRI) is helpful in determining the depth and extent of soft-tissue involvement underlying decubitus ulcers. It can also be a useful tool for identifying osteomyelitis, fluid collections, abscesses, and sinus tracts.[9,10] The gold standard for the diagnosis of osteomyelitis is histologic/microbiologic analysis of surgical biopsy specimens, but MRI is accurate in the diagnosis of osteomyelitis (sensitivity, 98 percent; specificity 89 percent) and associated soft-tissue abnormalities. It also can delineate the extent of infection to assist in guiding limited surgical resection and preserving viable tissue.[8]

COMPLICATIONS (Table 99-5)

Local Infection/Bacteremia

It is important to distinguish between bacterial colonization (the harmless presence of bacteria on the wound) and infection (bacterial invasion into tissue). Most chronic wounds are colonized by bacteria.[2] Common bacterial strains isolated from chronic wounds include *S. aureus* (the most prevalent), *Pseudomonas aeruginosa*, *Escherichia coli*, *Proteus mirabilis*, *Enterobacter cloacae*, *Serratia marcescens*, *Streptococcus* group G, *Staphylococcus epidermidis*, β-hemolytic *Streptococcus* group A, *Enterococcus* and *Acinetobacter* sp., and other organisms.[9] Anaerobic bacteria may also be present.

Results of superficial swab culture generally reflect colonization rather than infection, and ideally tissue samples should be obtained by needle aspiration, biopsy, or curettage.[2]

Wounds with fewer than 10^6 bacteria per gram of tissue may improve without systemic antibiotic therapy, whereas clinical signs and symptoms such as erythema, warmth, local pain or tenderness, purulent discharge, and the presence of a foul odor may indicate infection into soft tissue with more than 10^6 bacteria per gram of tissue. In patients with associated co-morbidities and advanced age, however, systemic signs of infection such as fever and leukocytosis may not be obvious, and delayed wound healing may be the only sign of infection.[9]

Pressure ulcers can cause bacteremia and may be complicated by osteomyelitis, endocarditis, sepsis, and death. Bacteremia is caused predominantly by hospital-associated organisms and occurs mainly in diabetic, malnourished, or immunosuppressed patients. This complication is associated with a mortality rate of 50 percent to 70 percent.

Osteomyelitis

Long-standing, deep decubitus ulcers (i.e., stage III or IV) are often complicated by osteomyelitis. This can occur through direct extension or blood dissemination. If bone is visible in a long-standing deep pressure ulcer, osteomyelitis is highly likely. Common organisms causing osteomyelitis include *S. aureus, Bacteroides fragilis*, *P. mirabilis*, *E. coli*, *Klebsiella* sp., *Pseudomonas* sp., streptococci, and enterococci.[10] Osteomyelitis should be considered whenever a pressure sore does not heal.

Fistulas/Sinus Tracts

Sinus tracts are drainage pathways from a deep focus of acute infection through tissue and/or bone to an opening on the skin surface. A sinogram is useful in determining the extent of the sinus tract or fistula. These can extend deep enough to reach the joint space or even deep viscera and cause osteomyelitis. Large sinus tracts can be demonstrated by MRI.

Malignancies (Marjolin's Ulcers)

The term *Marjolin's ulcer* is often used to describe neoplastic transformation in chronic ulcers. Squamous cell carcinoma has an estimated incidence of 0.5 percent of pressure ulcers[2] and usually behaves aggressively, with a metastatic rate of 61 percent. This makes early diagnosis and treatment imperative.[11] The possibility of malignant transformation should be considered in pressure ulcers that are unresponsive to treatment or that show morphologic changes indicative of malignancy.

Metabolic Alterations

Patients with pressure sores can demonstrate typical features seen in patients with chronic inflammatory disorders, including normocytic, normochromic anemia with reduced serum iron levels and reduced transferrin levels and transferrin saturation, but elevated ferritin levels. Hypoproteinemia with hypoalbuminemia, inverse albumin-globulin ratio, increased level of globulins, high erythrocyte sedimentation rate, and high C-reactive protein level and white cell counts may also be seen. These abnormalities return slowly to normal levels after healing of pressure sores. Bone reabsorption can lead to hypercalcemia, hypercalciuria, ectopic calcification, renal calculi, and bladder stasis.

Necrotizing Fasciitis/Myonecrosis

Necrotizing fasciitis is an aggressive soft-tissue infection that requires rapid diagnosis, early surgical intervention, frequent operative débridements, and soft-tissue reconstruction. It is rare but has a very aggressive course (see Chap. 179).

Myonecrosis and rhabdomyolysis have been described after prolonged surgery. Initially the disorder presents with an area of buttock skin breakdown, diagnosed as a simple decubitus ulcer, but it then develops into extensive myonecrosis leading to renal failure the necessitates dialysis.

Other Complications

Among elderly bedridden patients who have surgery for pressure ulcers, the mortality rate is high (68 percent in one series).[12] Other postsurgical complications include hematoma, seroma, wound dehiscence, abscess formation, sepsis, and death. Death has been reported to occur during acute hospitalization in 67 percent of patients who develop a pressure ulcer compared with 15 percent of at-risk patients without pressure ulcers. The risk does not appear to correlate with the severity of the pressure ulcer.

Other less commonly reported complications of pressure ulcers include amyloidosis, endocarditis, meningitis,

septic arthritis, myiasis, pseudoaneurysm formation, and gangrene.

PROGNOSIS

The prognosis of pressure ulcers depends on the cause. In paraplegic patients 50 percent to 70 percent of pressure ulcers heal with non-surgical intervention. However, in the long-term care setting in which patients may have multiple medical problems, the prognosis is worse, and complications such as sepsis, osteomyelitis, amyloidosis, anemia, and malignancy can develop.[13]

The age-adjusted mortality rate for pressure ulcers has been calculated as 3.79 deaths per 100,000 population. The majority of pressure ulcer–associated

TABLE 99-3
Comparison of Clinical and Histologic Findings by Ulcer Stage

Classification/Stage NPUAP (1989)	Clinical Findings	Histopathologic Description
Stage I 	Non-blanchable erythema of intact skin	Epidermis appears normal. Striking red blood cell engorgement of capillaries and venules, mainly in papillary dermis with platelet thrombi and hemorrhage. Degeneration of sweat glands and subcutaneous fat is often seen.
Stage II 	Partial-thickness skin loss involving epidermis, dermis, or both.	Epidermis is lost. Dermal papillae are often identifiable. Acute inflammation of papillary and reticular dermis is found. In addition to a perivascular lymphocytic infiltrate, neutrophils are seen. Necrotic changes in the appendages and fat are more pronounced.
Stage III 	Full-thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia.	Hemorrhagic crust containing acute inflammatory cells or a thin zone of coagulation necrosis on the surface. Diffusely fibrotic dermis. Loss of appendageal structures.
Stage IV 	Full-thickness skin loss with extensive necrosis of or damage to muscle, bone, or supporting structures.	Full-thickness destruction of skin. The tissue appears basophilic with obliteration of cellular detail, although the general dermal architecture is preserved. Inflammatory infiltrate is often not seen.

NPUAP (1989) = National Pressure Ulcer Advisory Panel biennial conference since 1989 (http://www.npuap.org).

deaths occur in people at least 75 years of age. Septicemia was present in 40 percent of patients whose deaths were associated with pressure ulcers. Incapacitating chronic and neurodegenerative conditions were common co-morbidities, and mortality rates in blacks were higher than those in other racial or ethnic groups.

Interestingly, although stage II pressure sores were found to be more likely to heal than pressure ulcers of stage III or IV, the depth of the pressure ulcer did not correlate with mortality. Patients with a stage II pressure ulcer on admission to care were as likely to die as patients with a stage III or IV ulcer.[14]

TREATMENT

Therapy should be individualized for each patient and involves more than simple wound management. Pressure ulcers are frequently a clinical sign of underlying medical conditions that should be treated to facilitate healing. Few controlled trials have evaluated specific treatment modalities for pressure ulcers. The general principles of therapy for pressure ulcers are the following.

Relief of Pressure, Shear, and Frictional Forces

POSITIONING Positioning techniques are critical in the management of tissue loads.

While in bed, patients should be positioned to avoid pressure over existing ulcers or over bony prominences, specially the trochanter. Pillows or foam wedges can be used to raise a pressure ulcer off its support surface or to prevent direct contact between bony prominences, such as knees or ankles. It is important to limit the amount of time the head of the bed is elevated and to maintain the head of the bed at the lowest possible level of elevation tolerable to reduce shearing forces at sacral tissues. Immobilized patients are usually placed in a 30° oblique position to the left or right, which should be alternated every 2 hours at a minimum.

The patient and caregivers must learn appropriate transfer or mobilization techniques to avoid friction. The patient should be lifted rather than dragged across the bedsheets, using lifting devices such as a trapeze or bed linen. Repositioning should be done as frequently as warranted by the patient's condition.

Moisture from urinary or fecal incontinence, perspiration, or wound drainage should be minimized, and the skin should be kept clean. Absorbant underpads or briefs, diapers, and occasionally urinary catheters or rectal tubes may be required to help manage incontinence. Skin barrier creams can help protect the skin from maceration.

Patients who are sitting may select a pressure-relieving cushion based on specific needs. Donut-type devices should

TABLE 99-4
Staging Systems for Classifying Pressure Ulcers

Classification	Shea (1975)[5]	NPUAP (1989)	Yarkony and Kirk (1990)[7]
Stage I	Limited to epidermis, exposing dermis	Non-blanchable erythema of intact skin	Red area A. Present > 30 min but < 24 h B. Present longer than 24 h
Stage II	Full thickness of dermis to junction of subcutaneous fat	Partial-thickness skin loss involving epidermis, dermis, or both	Epidermis and/or dermis ulcerated with no subcutaneous fat observed
Stage III	Fat obliterated, limited by deep fascia undermining of skin	Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend to, but not through, underlying fascia	Subcutaneous fat observed, no muscles observed
Stage IV	Bone at the base of ulceration	Full-thickness skin loss with extensive necrosis of or damage to muscle, bone, or supporting structures	Muscles observed, but no bone observed
Stage V	Close large cavity through a small sinus (closed pressure ulcer)	—	Bone observed but no involvement of joint space
Stage VI	—	—	Involvement of joint spaces

NPUAP (1989) = National Pressure Ulcer Advisory Panel biennial conference since 1989 (http://wwwnpuap.org).

be avoided because they result in venous congestion and may worsen ulcers. Patients should be encouraged to reposition themselves frequently.

SUPPORT SURFACES Support surfaces can be used on top of or instead of standard mattresses. They distribute pressure over a large surface area, and the type of support surface used will depend on the patient's needs and abilities.

Static support surfaces are recommended for patients who can assume several positions without bearing weight on an ulcer. These include foams, fluid- or air-filled mattresses, and overlays.

- Foam is probably the most commonly used material for pressure reduction, because it is easy to use, lightweight, and inexpensive. An investigative study showed that the combination of turning every 4 hours and the use of a viscoelastic polyurethane foam mattress decreased the incidence of pressure ulcers (grade II to IV) in at-risk patients from 14.3 percent to 3.0 percent. [15]
- Fluid-filled products consist of small or large chambers filled with air, water, or other viscous fluid materials (silicon or polyvinyl). Most of them permit a high degree of immersion, allowing the body to sink into the surface as it conforms to the bony prominences. This increases the surface pressure distribution area and lowers the interface pressure by transferring the pressure to adjacent areas.

Patients who cannot tolerate frequent turning due to pain or severe illness, immobile patients, those with large or multiple ulcers, and patients with unresponsive ulcers may require dynamic support surfaces. These provide cyclical, alternating pressure relief, and include air-fluidized, low-air-loss, and or alternating-air beds.

- Air-fluidized beds contain microspheric silicon-coated beads encased in an air-permeable fabric (polyester or Gore-Tex). The beads are suspended by pressurized streams of warmed air, which allows patients to "float" and decreases pressure through the principle of immersion while simultaneously reducing shear. Feces and body fluids flow freely through the sheet; thus the skin is kept dry.
- Low-air-loss systems use a series of connected, air-filled cushions that are inflated to specific pressures. Some have alternating and pulsating pressure features. A prospective, randomized trial demonstrated that the use of low-air-loss beds resulted in threefold faster wound contraction than use of a foam mattress.[16] Unlike with air-fluidized beds, urine and feces do not pass through the fabric of low-air-loss beds.
- Alternating-pressure systems distribute pressure by shifting the body weight to different surface contact areas. The air is pumped into the chambers at periodic intervals to inflate and deflate them in opposite phases, which thereby changes the location of contact pressure.

Wound Management

CLEANSING Cleansing should be performed gently to minimize mechanical and chemical trauma to healing tissues. Normal saline is preferred because it is most physiologic in relation to the wound. Safe and effective irrigation pressures for ulcers range from 4 to 15 psi; higher pressures than this may cause trauma and drive bacteria into the wound tissue. Certain skin cleansers and antiseptics such as povidone iodine, sodium hypochlorite solution, hydrogen peroxide, acetic acid, and liquid detergents should be avoided, because these agents are cytotoxic and may retard epithelialization.

DÉBRIDEMENT Ulcers with devitalized, necrotic tissue should be débrided, because necrotic tissue supports the growth of pathogenic organisms. Mechanical débridement techniques include application of moistened saline or wet-to-moist dressings, hydrotherapy (whirlpool), wound irrigation, and application of dextranomers. Wet-to-dry dressings changed every 4 to 6 hours are painful and are non-selective for necrotic tissue. Whirlpool devices can be considered for pressure ulcers with thick exudate, slough, or necrotic tissue. For wound irrigation, a large 35-mL syringe and 19-gauge angiocatheter can be used to provide adequate pressure.[1]

Sharp débridement involves the use of a scalpel, scissors, or other sharp instrument to remove devitalized tissue and is generally indicated in cases in which there is eschar. For smaller ulcers, local anesthesia can be used, whereas larger stage III or IV ulcers may require extensive surgical débridement under general anesthesia. Enzymatic débridement can be used in patients who cannot tolerate surgery. Topical agents such as sutilains, collagenase, papain, fibrinolysin, and deoxyribonuclease can be used. Dressings should be changed once to several times daily. Contact dermatitis can sometimes occur, and these agents should not be used if tendon is exposed.[2]

Autolytic débridement involves the use of synthetic dressings to cover the wound, which allows digestion of necrotic tissue by enzymes normally present in wound fluids.

In addition to traditional débridement methods, the use of sterile fly larvae (maggots) to clean necrotic tissue is gaining popularity and appears to be safe and effective.

DRESSING PRODUCTS Dressings can help protect the wound from the environment, reduce or prevent wound infection, stimulate autolytic débridement, reduce wound pain, and stimulate the development of granulation tissue. It has been demonstrated experimentally that wounds maintained in a moist environment heal 40 percent faster than air-exposed wounds. Control of moisture and drainage from the wound helps provide an optimum wound environment for healing. There are several types of dressings, each one of which has specific properties, advantages, and disadvantages. e Creams or gels containing metronidazole, balsam of Peru, trypsin, recombinant human platelet-derived growth factor, and papain-urea are also available. A variety of specialized dressings may be helpful for pressure ulcer management, including a bilayer matrix wound dressing, pig-derived acellular small intestine submucosa, and natural latex biomembrane.

Intact skin surrounding the ulcer should always be assessed for signs of inflammation and infection. Periwound skin must be adequately moisturized but neither macerated nor eroded.[15] Irritation of surrounding skin can be the result of epidermal skin stripping during dressing changes or maceration secondary to contact with feces, urine, or wound drainage.

Bacterial Colonization and Infection Management

Ulcer cleansing and débridement are important to control microbial burden in pressure sores. Systemic antibiotic therapy is not recommended for contamination or minor localized infections but is indicated when bacteremia, cellulitis, or osteomyelitis is present.

Topical antibiotics are used to prevent or treat wound infection, reduce bacterial load, or reduce odor and signs of inflammation. Topical antibiotics such as neomycin and bacitracin are common allergens and can cause contact dermatitis and, rarely, anaphylaxis. Topical formulations of antibiotics that are used systemically (e.g., gentamicin) should be avoided because bacterial resistance may develop. However, the Agency for Healthcare Research and Quality guideline recommends a short 2-week course of topical antibiotics for a clean ulcer that is not healing or that is producing a moderate amount of exudate despite appropriate care.[18]

Pain Management

Pain management requires a combination of conservative measures, medications, and appropriate wound care. Muscle relaxants and physical and occupational therapy may be helpful to decrease muscle spasm in the area of ulceration. Transcutaneous electrical nerve stimulation may help relieve acute and chronic pain. The use of topical anesthetics such as lidocaine-prilocaine cream on wounds 30 minutes before débridement significantly reduces pain associated with wound care procedures.

Nonopioid analgesics (aspirin, other nonsteroidal anti-inflammatory drugs) are first-line systemic therapy, followed by stronger medications such as opioids. Adjuvant medications such as tricyclic antidepressants can be used to enhance analgesia.[19] They can also improve depression in some chronic pain states and have sedative, sleep-enhancing qualities.

Nutritional Management

Screening for nutritional deficiencies is an important part of assessment and management of pressure ulcers. Adequate patient dietary intake of protein is important in healing pressure ulcers.[20] A reasonable protein amount is between 1.2 and 1.5 g/kg/day, and caloric intake should be between 30 and 35 kcal/kg/day. Vitamin C or zinc deficiency can have negative effects on wound healing, but supplementation is useful only when deficiency is confirmed or suspected. If dietary intake continues to be inadequate, oral or parenteral nutritional supplementation may be required. Markers of nutritional deficiency include a serum albumin level of less than 3.5 mg/dL and unintentional weight loss of more than 15 percent of baseline. Patients should be kept adequately hydrated.

Surgery

The long-term efficacy of surgical repair of pressure ulcers, especially in older patients, has been questioned because of high recurrence rates and mortality. The decision to undertake surgical repair should be made with full knowledge of the risks and benefits, surgical and nonsurgical alternatives, and complications associated with each procedure. Surgical techniques include skin grafting; creation of cutaneous, muscle, and fasciocutaneous flaps or pedicled flaps; microvascular free tissue transfer reconstruction; and simple direct suture, depending on the site, number, and grade of lesions, and the patient's clinical condition. In general, surgery is often required for stage IV ulcers, whereas more superficial ulcers may heal with conservative therapy.

Adjunctive Therapies

Adjunctive therapies have been used in case studies, but more data are needed to determine the effectiveness of these therapies.[21] These therapies are outlined in the electronic version of this book. e

Whenever possible, others factors that impair healing such as smoking; hypovolemia; cold; chronic diseases in-

TABLE 99-6
Preventive Measures

- Maintain personal hygiene.
- Try to assure adequate nutrition and hydration.
- Evaluate and manage urinary and fecal incontinence.
- Position to alleviate pressure over bony prominences and shearing forces over heels and elbows, base of head, and ears.
- Try to reposition every 2 h when in bed and every hour when in a chair; if alert and capable, the patient should be taught to shift his or her weight every 15 min while in a chair.
- Use appropriate positioning devices and foam padding; do not use donut-shaped devices.
- Try to avoid placing the patient on his or her trochanters or directly on the wound.
- Maintain the lowest head elevation possible.
- Use lifting devices such as draw sheets or a trapeze.
- Try to prevent contractures.
- Do not massage reddened areas over bony prominences.

cluding diabetes mellitus, systemic arterial hypertension, anemia, and vascular alterations; and the use of medications such as corticosteroids should be limited or controlled.

PREVENTION

Preventive actions can decrease the patient's risk of developing pressure ulcers. These steps can also keep pressure ulcers from getting worse. Preventive measures are listed in Table 99-6.

CHAPTER 100

Body Art

Anne Laumann

Body art is art made on, with, or consisting of the human body. The most common forms of body art are tattoos, body piercings, and body painting, but other types include scarification, branding, tongue splitting, and extraocular implants. *Tattooing* is the practice of producing an indelible mark or figure on the human body by inserting a pigment under the skin using needles or other sharp instruments.[1] *Body piercing* refers to the cosmetic piercing of body parts for the implantation of objects such as rings, studs, or pins.[2] *Body painting* is the application of paint onto the skin. It includes face painting, the application of mehndi, and temporary tattoos. *Scarification* is a means of permanently marking the skin by cutting alone, without the use of pigments. This includes the deliberate formation of keloids. When purposeful third-degree burns are used to induce a scar, the procedure is called *branding*.[3] *Tongue splitting* is the bisection of the tongue from the tip toward the back for about 3 to 5 cm, leading to an appearance similar to the tongue of a lizard.[4] *Extraocular implantation* is the placing of sterile non-pyrogenic platinum jewelry inside the interpalpebral conjunctiva of the eye.[5]

TATTOOING

Background

Epidemiology

Twenty-four percent of 18- to 50-year-olds in the United States have tatoos, including as many as 36 percent of those under the age of 30.[7–9] They are equally common among men and women and are seen in all ethnic groups. They are still found more commonly in those with a military association and in those of low educational and socioeconomic backgrounds. They are associated with the abuse of alcohol, the taking of illicit drugs, and having spent significant time in prison. They are inversely associated with having a religious affiliation and having never drunk alcohol.[9] Most tattoos are done in a dedicated studio, but approximately a one-fourth of people with tattoos have at least one tattoo done elsewhere.

BODY ART AT A GLANCE

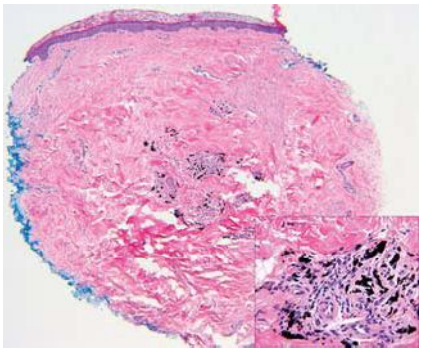
- Tattoos are becoming more common: 24 percent of the U.S. 18- to 50-year-olds in 2004; equal numbers of men and women.
- Tattooing medical complications are rare: Mainly related to pigment ingredients, but include viral, bacterial, fungal, and, in particular, transfusion transmitted diseases.
- Tattoo social associations and complications are significant.
- Piercing: Soft earlobes 37 percent, and body piercing excluding the soft earlobe 14 percent of the U.S. 18- to 50-year-olds in 2004, mainly women. Body-piercing fashion started in the late 1980s.
- Piercing medical complications are common: Metal-induced contact allergic dermatitis, broken teeth, anesthetic risks, and infections of all types.
- The relationship to hepatitis is unclear.

▲ **FIGURE 100-1** Tattooing with a hand-held electric tattoo machine.

Process

A hand-held device, powered by low-voltage direct current, holds solid needles placed singly or in groups of up to 14 on an oscillating bar (Fig. 100-1). The needles are dipped into colored inks and then moved across the skin in the desired pattern, penetrating vertically 0.5 to 2.0 mm into the skin at between 50 and 3000 vibrations per minute, depositing the pigment into the dermis. A thin layer of petroleum jelly is applied to the skin before and during the procedure to minimize blood loss and prevent spatter. After the tattoo is finished, the area is cleaned with a mixture of alcohol and water, and more ointment is applied. Sometimes, the ink is spread over an area of skin, and the needles penetrate through it to carry the particles into the skin. Amateur tattooers often do it this way using hand-held needles wound round with thread to prevent too deep penetration. Other instruments used may be pencils, pens, and straight pins. Much of the pigment is extruded through the epidermis during the first 10 days (Fig.100-2). The final location of the

▲ **FIGURE 100-2** Five days after application of this tattoo. One can see extrusion of much of the inserted pigment.



▲ **FIGURE 100-3** Tattoo pigment is seen in the reticular dermis. The particles are within fibroblasts, macrophages, and occasional mast cells around blood vessels.

pigment is in the mid to lower dermis (Fig. 100-3), but the pigment in amateur tattoos tends to be more superficially and more variably placed. The particles are membrane bound (in secondary lysosomes) within fibroblasts, macrophages, and, occasionally, mast cells around blood vessels. They may also be seen around hair follicles and sebaceous glands. Many of the pigment conglomerations are too large to traverse the vessel walls and leave the area of original deposition, but over time this may happen, leading to blurring of the visible design (Fig. 100-4) as well as the deposition of pigment in the draining lymph nodes.[10,11]

Pigments

The composition of tattoo ink as obtained from the manufacturer, and possibly further mixed by the artist, is complex, usually non-sterile, unregulated, variable, and evolving. In recent times, industrial organic pigments, including azo and polycyclic compounds, sandalwood, and brazilwood, as well as aluminum, cadmium, calcium, copper, iron, phosphorus, silica, and sulfur, have been identified.[12] In addition, titanium dioxide and barium sulfate are often used to lighten the color. The 1976 Food, Drug and Cosmetic Act limited the content of lead and mercury in cosmetics for application to the skin so that now these two elements are rarely found.[13,14] The pigment in amateur tattoos is usually black and carbon-based, often deriving from India ink, charcoal, soot, or mascara (Table 100-1).

▲ **FIGURE 100-4** This tattooed eyeliner has dispersed so that only a blur remains.

Complications

Medical complications are unusual in developed countries. Clearly, there is a real risk of contracting a contagious disease, but most recent reports are anecdotal[15–17] or from the developing world (Table 100-2).[18,19] There have been outbreaks of hepatitis B traced to tattoo parlors in the past, but currently there is a controversy as to how often hepatitis C in the United States is transmitted during the act of tattooing. During the same time that the prevalence of tattoos has increased, the absolute numbers of reported acute hepatitis B and C cases have fallen to an all-time low of 1.8/100,000 in 2005 from a high of 11.5/100,000 in 1985 for hepatitis B; and 0.2/100,000 in 2005 from a high of 2.4/100,000 in 1992 for hepatitis C.[20] Most

• Endocarditis (rare)	

hepatitis C infection is asymptomatic. The sources of approximately 65 percent of the cases of hepatitis C are unidentified. Cross-sectional data from a number of population groups (e.g., veterans,[21] attendees in an orthopedic practice,[22] and hospital outpatients[23]) have been inconsistent in identifying tattoos as an independent risk factor for the presence of hepatitis C. Variables such as getting the procedure in a dedicated studio or in a penitentiary[24] may be relevant, and the confusion may relate to the fact that, in some people, tattoos are a marker for other unconventional or socially disapproved behaviors.[25,26] The American Blood Bank Association recommends that blood for donation not be taken from anyone within a year of a tattoo or a body piercing unless it was done in a state-regulated facility.[27]

Many, but not all, of the pigment-based reactions are in the red areas of tattoos (Fig. 100-5). Now that cinnabar, vermillion, or other pigments containing mercuric sulfide are rarely used, other culprits have been identified. These include cadmium selenide and quinacridone.[28] Reactions may be photosensitive, and histologic evaluation of biopsied tattoo skin may show pseudolymphomatous, lichenoid,[29] or granulomatous reactions. The latter may manifest histologically as a foreign body type reaction with numerous giant cells containing pigment, or a hypersensitivity type with dense aggregates of epithelioid cells, a thin peripheral ring of lymphocytes, and few giant cells. Hypersensitivity reactions may be localized or generalized,[30] but standard epicutaneous patch testing is not often helpful, presumably related to the dermal placement of the tattoo antigen. The social implications of tattooing are protean and may alert the onlooker to other risk-taking behaviors.

▲ **FIGURE 100-5** Red tattoo reaction.

Tattoo Removal

Most people are proud of their tattoos, but approximately 17 percent desire their removal. In addition, 5 percent opt for and 8 percent are considering further tattooing to cover a disliked or faded image. Often, these people have obtained their tattoos at a young age and want them removed or changed to enhance self-esteem, or for social, domestic, and family reasons.[31,32] Many tattoo removal methods have been documented (Table 100-3), but most are only partially effective and leave scarring and pigmentary changes. In general, proximally placed and old tattoos are easier to remove than distally placed and more recent ones. With the advent of the theory of thermal relaxation, lasers with very short (nanosecond), high-energy pulses have been designed, which are less likely to heat the surrounding tissue and leave scars (Table 100-4). On the horizon are lasers (titanium:sapphire) with picosecond pulse durations, which may be even more effective. The laser energy photoacoustically explodes the pigment particles. Some of these may be allergenic or carcinogenic (Fig. 100-6). Macrophages engulf the fragments so that they are removed via the draining lymphatics, and some may be extruded through the epidermis. Lightening may take several weeks following a single treatment session, and maximum lightening may take many (often 8 to 10) sessions.

Removal of tattoos in dark-skinned individuals is difficult. A long wave-

TABLE 100-3
Methods of Tattoo Removal

Excision with primary closure or grafting	For grafting, to avoid donor site scars, techniques may be used that enzymatically separate the excised epidermis from the underlying excised pigment containing dermis and grafting this epidermis to the original tattoo site.[43]
Mechanical dermabrasion	May use a handheld mechanical unit or sterile sandpaper to abrade the skin to the reticular dermis. Rotating (up to 33,000 revolutions per minute) wire brushes, diamond fraises, or serrated wheels attached to compact electric machines are available.
Salabrasion	First described by Aetius, a Greek physician in 543 A.D., tap water dipped in salt is rubbed vigorously to abrade the skin overlying the tattoo.
Chemical extraction using a remover paste	The remover paste, made with deionized water, zinc oxide, magnesium oxide, calcium oxide, triethanolamine, isopropanol, and benzoic acid is applied.[44] A superficial microtattoo process is used to puncture the skin over the tattoo, and the paste is reapplied. Inflammation ensues and the pigment is extruded.[45]
Cryosurgery	Salt/ice –20°C (–4°F) or dimethyl ether/propane –50°C (–58°F) mixtures, solid carbon dioxide –79°C (–110°F), nitrous oxide –70°C (–94°F) or liquid nitrogen –196°C (–321°F) may be used.
Application of caustic chemicals	Phenol, trichloroacetic acid, tannic acid, or oxalic acid with silver nitrate. Nitric acid application described in Scientific American in 1891 [Todd TW, *Scientific American* **LXIV**(18):273 (May 2, 1891)]
Argon and carbon dioxide lasers	Early tattoo removal lasers but currently mainly used for the removal of tattoo granulomas, as healing times are prolonged. Significant thermal damage and hypertrophic scarring often ensue.
Q-switched lasers	Nanosecond pulses similar to the Tr of the target pigment. Each pulse has a very high peak power. Surface cooling may be used to prevent epidermal damage.

Tr = thermal relaxation time, the time it takes for the target chromophore to lose 50 percent of its incident heat without conducting heat to the surrounding tissue.

TABLE 100-4
Q-Switched Lasers for Tattoo Removal

Q-Switched Laser	Wavelength in Nanometers	Pulse Duration in Nanoseconds	Fluence Joules/cm^2	Used for This Color
Nd:YAG	1064	10	6–12	Black, blue
Frequency doubled Nd:YAG	532	10	2–12	Red, orange, purple
Ruby	694	~25	8–10	Black, blue, green
Alexandrite	755	50–100	4.5–8	Black, blue, green

Nd:YAG = neodymium yttrium:aluminum-garnet.

length laser (Q-switched Nd:YAG) may be used together with skin freezing to cause lightening of the epidermis so that the laser light not only penetrates deeply enough but also bypasses the melanin in the epidermis to avoid a permanent pigment change. Red, white, and flesh-tone tattoos, which often contain ferric and/or titanium oxides, may darken with laser treatment related to the reduction of the chemicals by the laser beam (see Chap. 240).

Temporary Tattoos

Traditional henna tattooing, practiced throughout Africa, the Middle East, and India (mehndi) for thousands of years, very rarely causes hypersensitivity reactions. Henna is made from the leaves of the plant *Lawsonia inermis*, a member of the loosestrife family, and is a reddish-brown color. Recently, the application of temporary tattoos has become popular in the developed world. Some of these are made with "black henna" found to contain up to 16 percent para-phenylenediamine, which is used as a darkening agent. Concentrations of para-phenylenediamine as high as this commonly cause sensitization and lead to contact allergic dermatitis (see Chap. 13).

▲ **FIGURE 100-6** This leg became increasingly painful after each of three attempts at laser tattoo removal.

BODY PIERCING

Background

Epidemiology

A U.S. cross-sectional study of 18- to 50-year-olds in 2004 found that 19 percent of men and 49 percent of women had soft earlobe piercings; and 8 percent of men and 21 percent of women have body piercings in other parts of the body. Thirty-six percent of the 18- to 29-year-olds have body piercings.[9] In another study of youth aged 12 to 22 years, 27 percent had had a body piercing other than the soft earlobe.[34] Women are more likely to have body piercings than men, and over 50 percent of those with body piercings have more than one. Most piercings are done in tattoo or dedicated shops, but soft earlobe piercings are often done in department or specialty stores. Important behavioral and social associations include some cultural normative attributes (e.g., being of Hispanic or South Asian heritage), but they also include the participation in a number of risk-taking behaviors such as being a drinker, having used illicit drugs, having spent time in jail, having a limited religious affiliation, and having early and multiple sex partners. It may also be a marker for depression.[35]

Process

A hollow 12- to 16-gauge needle is passed through the body part, and body jewelry is inserted in the hole. A piercing gun (Fig. 100-7) is often used for soft earlobe piercings, but these are difficult to sterilize, may lead to crush injuries, and, if used in a cartilaginous area, to loosening of the perichondrium. Swelling occurs immediately so that the jewelry inserted has to be long and fine enough to allow for this. It should be made of titanium, niobium, ≥ 14 karat yellow gold, or stainless steel to avoid the induction of nickel and/or cobalt delayed-type hypersensitivity. Postoperative healing times,

▲ **FIGURE 100-7** A plastic piercing gun with polyamide studs. The gun is hard to sterilize, but in this machine, the "carrier" and the piercing stud are disposable.

from 2 weeks for clitoris to 9 months for navel, vary with the site. There are two types of bead closures. The captive bead ring is held closed by pressure. The bead screw is similar to any other screw mechanism and is often part of hoops, barbells, and circular barbells.

Complications

Complications vary with the site on the body of the piercing, as well as with the place the procedure was done (e.g., at home or in a commercial studio). Bleeding may occur during or immediately following the procedure, and bacterial, fungal, or viral diseases may be transmitted, especially if non-sterile instruments are used (Table 100-5).[36] However, most infection comes from the subject's own flora, often related to poor hygienic practices during the healing period leading to localized infection (erythema, edema, purulent drainage). Rates of infection as high as 35 percent after ear cartilage piercings have been reported, sometimes leading to loss of ear cartilage and, rarely, endocarditis.[37] Other high-risk areas include the navel, with its propensity for movement, and any intraoral site. The treatment may not necessarily include removal of the jewelry, as this may lead to sac formation, but rather to leave it in place to facilitate drainage, as well as improving the local hygienic measures, using compresses, a topical and, if necessary, an oral antibiotic. If pseudomonas is suspected, a fluoroquinolone, which will also cover staphylococcus, is a good choice. The important viral infection that may be transmitted through the piercing needle is hepatitis, in particular hepatitis C but also hepatitis B and D, although it is not clear that this happens

TABLE 100-5
Bacterial Complications of Piercing

Complication	Reported Organisms
Loss of ear cartilage	*Staphylococcus aureus* *Pseudomonas aeruginosa*
Endocarditis: Usually superimposed on a known underlying cardiac abnormality, but occasional reports without prior cardiac abnormality	Skin piercing *S. aureus* Group A β-hemolytic streptococcus *S. epidermidis* Mucosal piercing *Streptococcus viridans* *Neisseria mucosa* *Haemophilus aphrophilus* *H. parainfluenzae*
Septic arthritis	Group A β-hemolytic streptococcus
Osteomyelitis	*S. aureus*
Toxic shock syndrome	*S. aureus*
Lymphadenitis	Lactobacillus
Cephalic tetanus	*Clostridium tetani*
Acute glomerulonephritis (may lead to acute renal failure)	Group A β-hemolytic streptococcus
Ludwig angina	Oral piercing *S. viridans* *N. mucosa* *H. aphrophilus* *H. parainfluenzae*
Fournier gangrene	Male genital piercing Group A streptococcus and mixed Gram-negative bacilli and anaerobic organisms
Brain abscess	Tongue piercing resulting in a mixed infection *S. viridans* *Peptostreptococcus micros* Actinomyces species *Eikenella corrodens*
Lupus vulgaris	*Mycobacterium tuberculosis* inoculation at time of nose piercing (India)

very often in the United States of today,[38] where disposable or sterilized piercing equipment is generally used. Transmission of human immunodeficiency virus is another potential risk that has not been proved to occur. Many non-infectious complications may also be seen (Table 100-6). In view of the high and increasing prevalence of nickel allergy,[39] some countries have restricted the amount of nickel released from the metal used in jewelry to < 0.5 μg/cm^2/week. Institution of this rule in Denmark in 1992 has lowered the incidence of new sensitization.[40]

Piercing tracts are not necessarily permanent, as they may close if the jewelry is removed. This is common with tongue piercings as the epithelium in the depths of the tract is thin and possibly missing.[41] Replacement of tongue jewelry before anesthesia can be done with a fine flexible inert catheter.

▲ **FIGURE 100-8** Magnetic jewelry avoids a piercing but still can be inhaled accidentally or become embedded in the tissue.

TABLE 100-6
Miscellaneous Complications of Piercing

- Bleeding: Usually at time of or immediately after procedure. This may lead to significant blood loss.
- Avulsion injuries
  - Earlobe tear, urethral rupture, splitting of urinary stream, rejection of jewelry near the eyebrow, navel, or nipple
- Scarring
  - May lead to phimosis or strictures
  - Keloid formation
  - Cyst related to tract closure
- Neurologic damage
  - Loss of taste, increased salivary flow, clitoral numbness
- Anesthetic risks
  - Interference with free access to the airway,[a] postoperative laryngospasm, pressure on area during surgery, electrosurgical burns, problems with catheterization
- Intra-oral
  - Aspiration of jewelry ball
  - Broken teeth and gingival recession
  - Speech impairment
  - Loss of taste
  - Increased salivary flow
  - Embedding of jewelry in tongue
- Nipples
- Galactorrhea related to hyperprolactinemia due to nipple stimulation
- Penis
  - Priapism related to entrapment of penis in a scrotal piercing hole
  - Paraphimosis related to inability to replace the prepuce over jewelry in the glans
  - Glanular hypospadias
  - Split urinary stream
- Jewelry-induced contact allergy
  - Nickel and cobalt are the most likely allergens (type IV delayed hypersensitivity)
    In the United States:
    - 12% jewelry allergy in those without piercings
    - 31% in those with piercings: 48% in those with three piercings
  - Gold and palladium rarely cause delayed reactions, which may be of granulomatous (sarcoidal) type.[45]

[a]To avoid problems, remove tongue, chin, or cheek jewelry before anesthesia and insert a nonreactive thread to preserve tract patency.

Magnetic Jewelry

This is occasionally used to avoid piercing (Fig. 100-8). Aspiration of the magnetic back of the jewelry or tissue embedment are possible complications.

SECTION 18

NEUROCUTANEOUS AND PSYCHOCUTANEOUS SKIN DISEASE

CHAPTER 101

Neurobiology of the Skin

Martin Steinhoff
Thomas A. Luger

CENTRAL NERVOUS SYSTEM AND SKIN

The nervous system is ultimately involved in cutaneous biology and disease. The central nervous system (CNS) proper is connected to skin function either directly via efferent nerves or CNS-derived mediators or indirectly via the adrenal glands or immune cells.[1] Cutaneous nerves also respond to internal stimuli from the circulation (e.g., pH changes, osmotic changes, bradykinin, cytokines) or the skin itself and to emotions (internal trigger factors).[2] Under normal circumstances, the sensory and the autonomic nervous systems modulate important biologic functions such as body temperature, blood flow, and cell growth. Mechanically induced nerve impulses transmit information such as pressure to the CNS. Chemical- or heat-responsive afferent nerve fibers are involved in recognizing dangerous signals potentially compromising body integrity. Thus, normally the innervated skin is a crucial barrier protecting the body from danger from the external environment. This is also supported by the finding that not only the dermis but also the epidermis is highly innervated up to the stratum corneum.[3]

Sensory as well as autonomic (predominantly cholinergic sympathetic) nerves influence a variety of physiologic and pathophysiologic functions of the skin such as embryogenesis, vasoconstriction, vasodilation, body temperature, barrier function, secretion, growth, differentiation, cell nutrition, nerve growth, and hair growth, and inflammation, immune defense, apoptosis, proliferation, and wound healing, respectively.

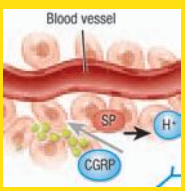
In unstimulated nerves, neuromediators are barely detectable within the skin. On direct stimulation by physical stimuli [thermal, ultraviolet (UV) light, mechanical, electrical], chemical stimuli, or chemical/biologic stimuli such as allergens, haptens, microbiologic agents, trauma, or inflammation, a significant increase of regulatory neuropeptides, neurotrophins, neurotransmitters, or oxygen products (e.g., nitric oxide) can be detected in vitro and in vivo. Thus, mediators derived from sensory or autonomic nerves may play an important regulatory role in the skin under many physiologic and pathophysiologic conditions. In addition to neuromodulation in the periphery, however, a subtle and complex communication network also exists between the spinal cord, the CNS, and the immuno-endocrine system that also modulates skin function.

The autonomic nerves exert their effects mainly by releasing classical neurotransmitters or—to a lesser extent—neuropeptides. In contrast, primary afferent (sensory) nerves release different classes of molecules such as neuropeptides, prostanoids, and nitric oxide.[1]

The skin expresses a variety of receptors for these mediators, most of them G protein–coupled receptors. This neuromediator-receptor interaction is controlled by endopeptidases [neutral endopeptidase (NEP), angiotensin-converting enzyme (ACE), endothelin-converting enzyme (ECE)], which terminate neuropeptide-induced inflammatory or immune responses.[1,2,4] A close multidirectional interaction between neuromediators, high-affinity receptors, and regulatory proteases is critically involved in maintaining tissue

◀ "Neurotic" excoriations: chin. Multiple erythematous and pigmented macules and a few crusted erosions on the chin of a 45-year-old woman with mild facial acne. No primary lesions are seen. The patient, who is moderately depressed, has mild acneiform lesions, which she compulsively picks with her fingernail.

NEUROBIOLOGY OF SKIN AT A GLANCE



- In an interactive network, cutaneous nerves communicate with various skin cells, the endocrine system, and the immune system.
- Neurocutaneous interactions influence a variety of physiologic and pathophysiologic functions such as cell growth, inflammation, host defense, pruritus, and wound healing.
- Primary afferent as well as autonomic nerves release neuromediators and activate specific receptors on many target skin cells.
- Cutaneous cells express a variety of specific receptors tightly controlled by upregulatory or downregulatory signals.
- Many mediators (peptides, proteases, cytokines, kinins, neurotrophins, etc.) are critically involved in physiologic and pathophysiologic conditions in the skin.
- New pathways are being defined for the treatment of various skin diseases in which the neuro-immuno-endocrine axis is implicated.

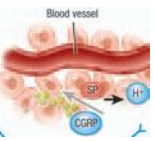
integrity and regulating pathophysiologic conditions in the skin. From this background, it is clear that a better understanding of the complex skin nervous system opens an avenue for future therapeutic approaches to a number of skin diseases.

Taken as a whole, present information clearly indicates a crucial role for the neuronal skin network in influencing a variety of physiologic and pathophysiologic functions such as host defense, inflammation, pruritus, pain, burning, wound healing, and probably cancer (e.g., by modulating angiogenesis).

ANATOMY OF THE SKIN NERVOUS SYSTEM



Sensory Nerves

Most nerve fibers are found in the middermis and the papillary dermis. Region-specific differences can be observed with respect to the mucocutaneous border, glabrous skin, and hairy skin.[5] In the epidermis, sensory nerves are linked to keratinocytes, melanocytes, Langerhans cells, and Merkel cells. Cutaneous nerve fibers are principally sensory, with an additional complement of autonomic nerve fibers.[6,7] In contrast to sensory nerves, autonomic nerves never innervate the epidermis in mammals. Sensory nerves innervate the epidermis and dermis as well as the subcutaneous fatty tissue[8–10] (see Fig. 102-1 in Chap. 102).

Sensory nerves are categorized into two groups: the epidermal and the dermal skin nerve organs. The epidermal skin nerve organs consist of free nerve endings or nerve organs (e.g., Merkel cells). In the dermis are found free sensory nerve endings, the hair nervous network (Pinkus discs), and the encapsulated endings [Ruffini's, Meissner's, Krause's, and Vater-Pacini (vibration) corpuscles, and mucocutaneous end organ]. These can be subdivided into four groups: A-α fibers (12 to 22 mm) are highly myelinated, show a fast conduction velocity (70 to 120 m/second), and are associated with muscular spindles and tendon organs. A-β fibers are moderately myelinated (6 to 12 μm) and innervate touch receptors. A-δ fibers have a thin myelin sheath (1 to 5 μm), show an intermediate conduction velocity (4 to 30 m/second), and are generally polymodal. The slow-conducting C fibers (0.5 to 2.0 m/second) are unmyelinated and small (0.2 to 1.5 μm). A-δ fibers constitute approximately 80 percent of primary sensory nerves sprouting from dorsal root ganglia, whereas C fibers make up approximately 20 percent of the primary afferents.[11,12]

Among human peripheral nerves, 45 percent of the cutaneous afferent nerves were found to belong to a sub-type of sensory nerves that are both mechano- and heat-responsive C fibers (C-m^+h^+).[13] However, 13 percent of these nerves were found to be only mechano-sensitive (C-m^+), 6 percent were heat sensitive (C-h^+), 24 percent were neither heat nor mechano-responsive (C-m^-h^-), and approximately 12 percent were of sympathetic origin. Fifty-eight percent of C-m^+h^+ responded to mustard oil, whereas 30 percent of C-m^+ or (C-m^-h^-) did so.[13]

A specific receptor distribution appears to be important for the various functions of the different sensory nerve sub-types. For example, mechanoreceptors exclusively express the T-type calcium channel Ca(v)3.2 in the dorsal root ganglion of D-hair receptors. Only small-diameter primary afferents express the transient receptor potential vanilloid 1 receptor.[14]

UV light, immune responses, inflammation, and trauma are able to stimulate the activation and/or sensitization of sensory nerves.[15,16]

Autonomic Nerves

Compared to sensory nerves, autonomic nerves represent only a minority of cutaneous nerve fibers. In human skin, autonomic nerve fibers derive almost completely from sympathetic (cholinergic) and rarely from parasympathetic (also cholinergic) neurons.[17] The distribution of autonomic nerves is restricted to the dermis, where they innervate blood vessels, arteriovenous anastomoses, lymphatic vessels, erector pili muscles, eccrine glands, apocrine glands, and hair follicles.[18]

Postganglionic autonomic nerves in the skin predominantly generate acetylcholine, although observations have revealed an additional role for neuropeptides in the skin autonomic nervous system. For example, neuropeptide Y (NPY) and atrial natriuretic peptide[19] are expressed solely by autonomic nerve fibers.[20]

The cutaneous autonomic nervous system adjusts sweat gland function, thereby regulating body temperature, and modulates water and electrolyte balance in various organs. Under pathophysiologic conditions, autonomic nerves are involved in hyperhidrosis or hypohidrosis, congenital sensory neuropathy type IV, progressive segmental hypohidrosis, diabetic neuropathy, syringomyelia, lepra, and dysfunction after sympathectomy.[21–24]

Autonomic nerve fibers are crucially involved in the regulation of vascular effects in the skin. Sympathetic nerve fibers release noradrenalin and/or NPY to innervate arterioles, arteriovenous anastomoses, and venous sinusoids, which results in vasoconstriction, whereas parasympathetic nerves mediate vasodilation through activation of venous sinusoids by the release of acetylcholine and vasoactive intestinal peptide (VIP)/peptide histidine methionine[25–28] (Tables 101-1 and 101-2).

TABLE 101-1
Role of Nerves in Pruritus and Pain

Pruritogenic Stimuli (in Alphabetic Order)	Receptors	Sources, Receptors by Which Expressed	Comments
Acetylcholine (ACh)	Nicotinergic (nAChR) and muscarinergic (mAChR) ACh receptors	Autonomic cholinergic nerves, keratinocytes, lymphocytes, melanocytes, dermal fibroblasts, endothelial cells	Mediates itch in atopic dermatitis; mAChR3 is probably involved in itch.
Calcitonin gene–related peptide (CGRP)	CGRP receptors	Sensory nerve fibers	Expressed on central terminals; sensitizes receptive endings. Associated with increased pain transmission, prolongation of itch latency after substance P injection (inhibitory effect on itching). Involved in itchy skin diseases.
Corticotropin-releasing hormone (CRH) and pro-opiomelanocortin (POMC)	CRH receptors (CRH-R1, CRH-R2)	CRH-R1: keratinocytes, mast cells CRH-R2: bone marrow mast cells	Induces release of histamine, cytokines, TNF-α, VEGF from mast cells. CRH-like immunoreactivity seen on sensory nerves (rat).

(continued)

TABLE 101-1
Role of Nerves in Pruritus and Pain (Continued)

Pruritogenic Stimuli (in Alphabetic Order)	Receptors	Sources, Receptors by Which Expressed	Comments
Cytokines	Cytokine receptors (e.g., IL-2, IL-31)	Leukocytes, keratinocytes, endothelial cells, nerves	T cells release IL-31 during inflammation and activate monocytes and keratinocytes via the IL-31 receptor (IL-31R). IL-31R is upregulated in atopic dermatitis and prurigo.
Endocannabinoids	Cannabinoid receptors (CB1, CB2)	Nerves, immune cells, keratinocytes, hair follicles	Antipruritic in the periphery.
Endothelins (ETs)	Endothelin receptors (ET_A, ET_B)	Endothelium, mast cells	Induces burning itch. Degraded by chymase via ET_A-receptor activation.
Endovanilloids (heat, acidosis, eicosanoids, histamine, bradykinin, extracellular ATP, prostaglandins, various neurotrophins)	Activation of transient receptor potential vanilloid 1 (TRPV1) Sensitization of TRPV1 via activation of specific receptors (see in this table)	TRPV1 is expressed on sensory neurons, mast cells, epidermal and hair follicle keratinocytes, Langerhans cells, smooth muscle, and sebocytes	Short-term TRPV1 activation: Induces pain and itch, depletes neuropeptides from sensory neurons. Long-term antipruritic effect of TRPV1 agonists (e.g., capsaicin): Suspend interplay between sensory neurons and mast cells. Affects epidermal and hair follicle proliferation, differentiation, apoptosis, and cytokine release. Increased expression in epidermal keratinocytes of prurigo nodularis patients.
Histamine	Histamine receptors (H_1R to H_4R)	Sensory fibers	In humans, histamine induces itch by stimulating specific sensory fibers, whereas H_1 (and to a lesser extent H_2) antagonists reduce itch in numerous clinical trials. In mice, H_3 antagonists induce scratching behavior, whereas H_1 and H_4 antagonists effectively suppress pruritus.
Kallikreins, proteases	Partly proteinase-activated receptors (PARs), tryptic enzymes	Keratinocytes, endothelial cells, mast cells, platelets	Massive itch behavior in mice overexpressing epidermal kallikrein-7. Potential role of other kallikreins. Chymase degrades pruritic and antipruritic peptides. Tryptase induces inflammation and itch by a neurogenic mechanism via PAR-2. Microbial proteases may induce itch and inflammation via PAR-2.
Kinins	Bradykinin receptors (B1R, B2R)	Endothelial cells, immunocytes	Bradykinin induces pain rather than pruritus. B2R antagonists reduce itch.
Leukotriene B_4	Leukotriene receptors	Sensory nerves fibers, keratinocytes	Leukotriene B_4 induces itch and is also involved in the substance P– and nociceptin-mediated induction of itch.
Neurokinin A (NKA) and substance P (SP)	Tachykinin (neurokinin) receptors (NKRs)	Sensory nerve fibers	NKA: Upregulates keratinocyte nerve growth factor expression. SP: At low (physiologically relevant) concentrations, primes mast cells. Mediates release of TNF-α, histamine, leukotriene B_4, and prostaglandins from mast cells (agents involved in pruritus and burning).
Nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophins (NT-3, NT-4)	Specific receptors TrkA: NGF TrkB: NT-4, BDNF TrkC: NT-3	Keratinocytes, mast cells, fibroblasts, eosinophils.	NGF levels enhanced in atopic dermatitis. Induces tryptase release from mast cells. Inducible by histamine. TrkA: Enhanced in keratinocytes during inflammation. NT-4: Enhanced in atopic dermatitis and induces sprouting of sensory nerves. BDNF: Increases eosinophil chemotaxis levels in atopic dermatitis and inhibits apoptosis. Neurotrophins sensitize receptive nerve endings and upregulate neuronal neuropeptides and TRPV1.
Opioids	μ, κ, δ opioid receptors (partly receptor-independent cell activation)	Nerves, keratinocytes	Antipruritic effect of μ-opioid antagonists (central effect) and κ-opioid agonists (spinal cord level). Opioid agonists do not provoke itch on injection or intradermal application. μ-Opioid receptor upregulated in atopic dermatitis
Pituitary adenylate cyclase–activating polypeptide (PACAP) and vasoactive intestinal peptide (VIP)	VPAC receptors	Autonomic and sensory nerve fibers, lymphocytes, dermal endothelial cells, Merkel cells	PACAP: Involved in flush, vasodilation, pain, neurodegeneration, pruritus(?). Induces release of histamine from mast cells. VIP: Histamine release from mast cells, allodynia (no allodynia in atopic dermatitis) intensifies ACh-induced itch in atopic dermatitis patients (together with ACh).
Prostaglandins	Prostanoid (P) receptors	Sensory nerve fibers, keratinocytes	Prostaglandin E_2 induces itch in humans but not in mice. Prostaglandin D_2 reduces immunoglobulin E–mediated scratching in mice.

ATP = adenosine triphosphate; IL = interleukin; TNF-α = tumor necrosis factor-alpha; VEGF = vascular endothelial growth factor.

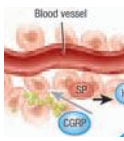


TABLE 101-2
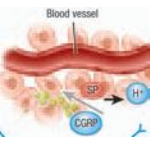
Role of Nerves in Inflammation

Neuromediator	Receptor	Source	Target Cells/Function
Acetylcholine	Nicotinergic and muscarinergic acetylcholine receptors	Autonomic cholinergic nerves, keratinocytes, lymphocytes, melanocytes	Innervation of sweat glands and arteriovenous anastomoses; keratinocyte and lymphocyte differentiation, proliferation, adhesion, migration. α_7-Nicotinergic receptor modulates keratinocyte function, modulates skin microcirculation.
Catecholamine, noradrenaline	Adrenergic receptors	Autonomic adrenergic nerves, keratinocytes, melanocytes	Innervation of blood vessels, erector pili muscles; pain transmission; regulation of activity in natural killer cells and monocytes; induction of apoptosis in lymphocytes. β-Adrenergic–induced inhibition of keratinocyte migration
Substance P	Tachykinin (neurokinin) receptor	Sensory nerve fibers	Mediation of skin erythema, edema, pruritus; upregulation of cell adhesion molecule expression on keratinocytes and endothelial cells; induction of release of IL-8, TNF-α, histamine, leukotriene B_4, prostaglandin D_2; regulation of sebaceous glands. Released by proteinase-activated receptor 2 (PAR-2) agonists.
Neurokinin A	Tachykinin (neurokinin) receptor	Sensory nerve fibers	Upregulation of keratinocyte nerve growth factor expression.
Vasoactive intestinal peptide	VPAC receptors	Sensory nerve fibers, Merkel cells	Sweat secretion, vasodilation; proliferation, migration of keratinocytes; histamine release from mast cells. Downregulation of VPAC2 receptor in mast cells in atopic dermatitis.
Pituitary adenylate cyclase–activating polypeptide	VPAC receptors	Autonomic and sensory nerve fibers, lymphocytes, dermal endothelial cells	Vasodilatation, immunomodulation; effect on T cells and macrophages; modulation of mast cell function; inhibition of antigen-induced apoptosis of mature T lymphocytes; downregulation of pro-inflammatory cytokines and chemokines in T cells; upregulation of cytokines and cell adhesion molecules in dermal microvascular endothelial cells; nociception.
Calcitonin gene–related peptide (CGRP)	CGRP receptors	Sensory nerve fibers	Keratinocyte and endothelial cell proliferation; stimulation of cytokine production. Increased CGRP nerves in atopic dermatitis and nummular eczema; released by PAR-2 stimulation.
Pro-opiomelanocortin (POMC)	Melanocortin receptors	Melanocytes, keratinocytes, endothelial cells, Langerhans cells, mast cells, fibroblasts, monocytes, macrophages	Antagonism of effects of pro-inflammatory cytokines (IL-1α, IL-1β, IL-6, TNF-α, endotoxins); upregulation of IL-10; induction of release of histamine from mast cells; inhibition of nuclear factor κ B. Thioredoxin regulates POMC genes. MSH-induced exocytosis from melanosomes. Melanocortin 1 receptor expressed on human keratinocytes. α-MSH reduces oxidative stress.

IL = interleukin; MSH = melanocyte-stimulating hormone; TNF-α = tumor necrosis factor-α.



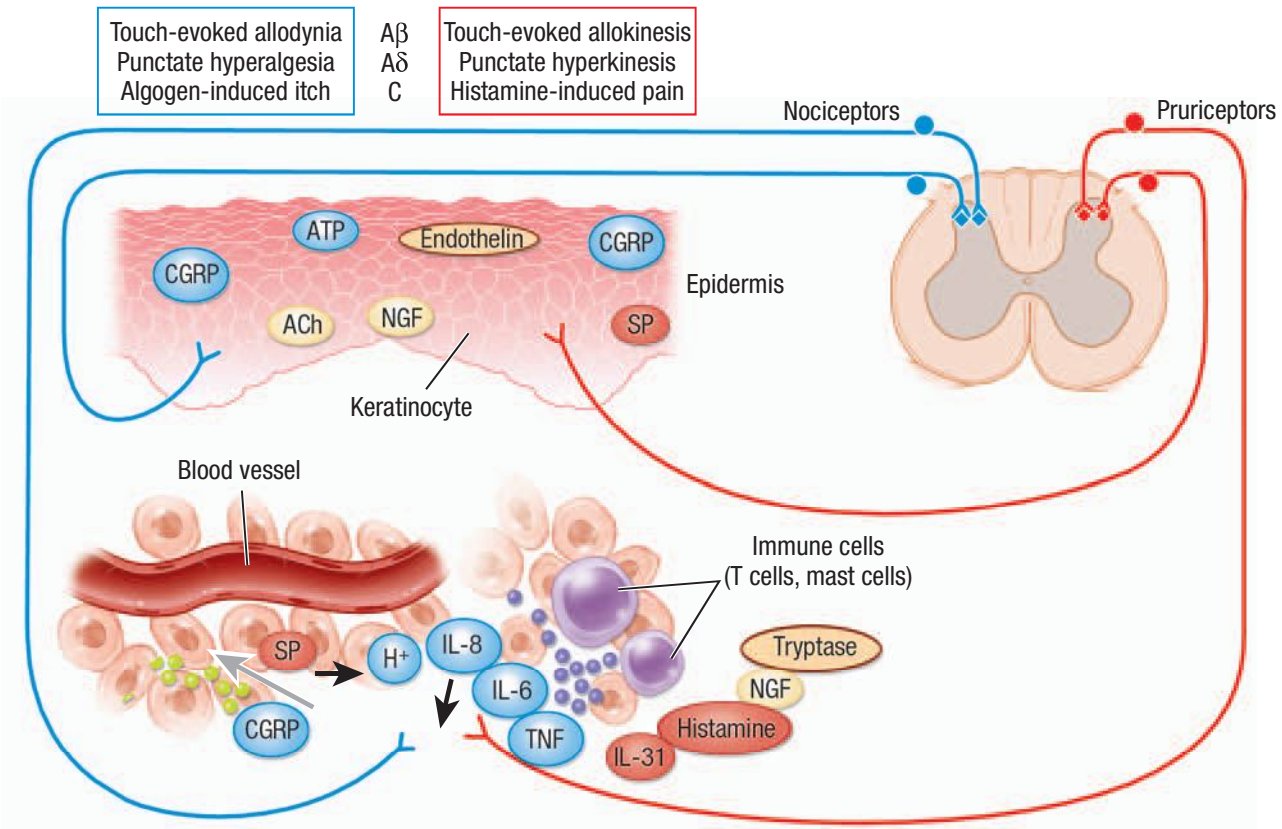
Small arteries and arterioles as well as the arteriovenous anastomoses are richly supplied with noradrenergic nerves.[29] Previous studies suggested that this system is cholinergic and involves a co-transmitter, possibly VIP.[30] Cholinergic sympathic nerves are also known to stimulate eccrine sweat glands via muscarinic receptors,[17] whereas higher concentrations of acetylcholine induce an axon-reflex flare mediated via nicotinic receptors. In the vasoconstrictor system, the transmitter appears to be norepinephrine along with one or more co-transmitters. The best-characterized sympathic co-transmitters that participate in the regulation of blood flow include adenosine triphosphate[31] and NPY.[32]

Interestingly, even without intact sensory or autonomic function the skin reveals a vasodilator response, which is replaced by non-neurogenic vasoconstriction. The mechanisms for the non-neurogenic vasodilator and vasoconstrictor components of the response to direct cooling are unknown but perhaps involve nitric oxide and sensory nerves.

BIOCHEMISTRY OF THE CUTANEOUS NERVOUS SYSTEM

Skin Neuropeptides and Neuropeptide Receptors

Classically, small peptides ranging from as few as 4 to more than 40 amino acids that are released by nerve endings and modulate various biologic functions were characterized and defined as neuropeptides. Later, these molecules were found to be generated by non-neuronal cells as well (e.g., epithelial cells and immune cells). Therefore, the designation *regulatory peptide* may be more applicable.[33] These peptides mainly activate members of the G protein–coupled receptor superfamily with seven transmembrane domains. To date more than 20 neuropeptides, including substance P (SP), neurokinin A (NKA), neurotensin, calcitonin-gene–related protein (CGRP), VIP, pituitary adenylate cyclase–activating polypeptide (PACAP), peptide histidine-isoleucinamide, NPY, somatostatin (SST), β-endorphin, enkephalin, galanin, dynorphin, cannabinoids, secretoneurin, melanocyte-stimulating hormone (MSH), and corticotropin-releasing hormone (CRH), have been detected in the skin.[1,2,34] Tables 101-1 and 101-2 list the neuropeptides and other molecules involved in pruritus, pain, and inflamma-



▲ **FIGURE 101-1** Mediators and the sensitization pattern of nociceptive and pruriceptive neurons. Sensitizing and activating mediators in the skin are shown for primary afferent fibers involved in itch and pain processing. Predominantly pruritic mediators are shown in *red*, algogenic mediators are shown in *blue*, and mediators equally involved in pain and itch are shown in *yellow*. Note that different classes of fibers subserve pain (mechano-sensitive polymodal nociceptors and mechano-insensitive "sleeping" nociceptors) and itch (histamine-sensitive mechano-insensitive pruriceptors,[3] and probably mechano-sensitive pruriceptors). In the spinal cord, noxious input can induce central sensitization for pain, and pruriceptive input can provoke central sensitization for itch. Of note is the corresponding pattern of central sensitization to touch by amyloid-β (A-β) fibers (allodynia vs. allokinesis), by A-δ fibers (punctate hyperalgesia vs. punctate hyperkinesis), and by C fibers (histamine-induced pain vs. algogen-induced itch). ACh = acetylcholine; ATP = adenosine triphosphate; CGRP = calcitonin gene–related protein; H^+ = hydrogen ion; IL = interleukin; NGF = nerve growth factor; SP = substance P; TNF = tumor necrosis factor.

tion, and Figs. 101-1 and 101-2 depict the basic concepts and knowledge concerning these neuropeptides. The on-line edition discusses detailed structural and physiologic functions.

Various neuropeptides are produced and released by a sub-population of unmyelinated afferent neurons (C fibers) known as *C-polymodal nociceptors*. In addition, it has been shown that cutaneous cells themselves, such as keratinocytes, microvascular endothelial cells, Merkel cells, fibroblasts, and leukocytes, are capable of releasing regulatory peptides under physiologic or pathophysiologic circumstances.

In the skin, nerves are closely linked to the vascular system. Dermal blood vessels are not only tightly associated with sensory and autonomic nerve fibers, they also synthesize certain neuropeptides after activation and express receptors for neuropeptides, which suggests that a complex autocrine and paracrine neuroendocrine system may exist in the skin. Arterial sections of arteriovenous anastomoses, precapillary sphincters of metarterioles, arteries, and capillaries appear to be the most intensely innervated regions. Although sensory nerves are important for vasodilation, neuropeptides from sympathetic neurons such as NPY mediate vasoconstriction, which supports an important role for neuropeptides in vascular regulation. Both endothelial cells and smooth muscle cells respond to neuronal modulation in inflammatory diseases such as atopic dermatitis and rosacea and during host defense, neovascularization, and wound healing.

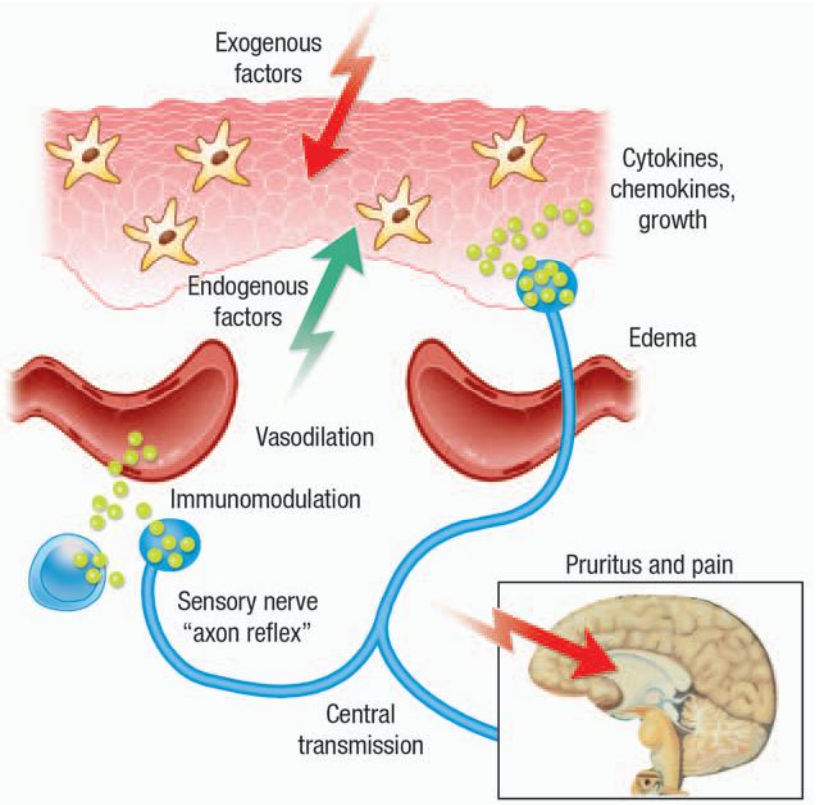
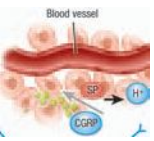
Neuropeptide-Degrading Enzymes[1]

Cytokines and Chemokines from a Neuronal Perspective[1]

Cytokines are capable of inducing pruritus, and, conversely, cytokine inhibitors have been demonstrated to reduce neurogenic inflammation, pain, and pruritus. Thus, cytokines and chemokines may communicate with sensory nerves via high-affinity receptors[194–199] (see Fig. 101-1, Table 101-1).

"Neurophilic" cytokines include interleukin 1 (IL-1), IL-6, IL-8, and IL-31 (re-





▲ FIGURE 101-2 Cutaneous neurogenic inflammation. Exogenous trigger factors (heat, scratching, irritants, allergens, ultraviolet light, microbiologic agents) or endogenous trigger factors (pH changes, cytokines, kinins, histamine, proteases, neurotransmitters, hormones, stress) may directly or indirectly stimulate nerve endings from primary afferent neurons. Signals are transmitted to the central nervous system and thereby affect regions involved in pruritus, pain, somato-sensory reactions (scratching), and probably emotional responses. In addition, peripheral nerve endings stimulate neighboring afferent nerve fibers in the dermis and epidermis in a process known as *axon reflex*. Stimulated release of neuropeptides results in vascular responses (triple response of Lewis, erythema by vasodilation, and edema by plasma extravasation), modulation of immunocyte function (e.g., mediator release from mast cells), and regulation of mediator release (cytokines, chemokines, growth factors) from keratinocytes and Langerhans cells.

viewed in refs. 33, 36). Of note, transgenic mice overexpressing IL-31 released by T cells and macrophages developed a chronic inflammatory skin disease characterized by a T-cell infiltrate and pruritus, similar to atopic dermatitis in humans. IL-31 activates the IL-31 receptor (IL-31R), a heterodimeric receptor composed of the IL-31R A subunit and the oncostatin M receptor subunit. Whether IL-31 exerts its pruritic effects via direct activation of IL-31R on sensory nerves or indirectly (e.g., via keratinocytes) is currently unknown. The finding that keratinocytes express IL-31R suggests that IL-31 may induce pruritus through the induction of a yet unknown keratinocyte-derived mediator that subsequently activates unmyelinated C fibers in the skin. Therefore, one may speculate that IL-31 is upregulated in pruritic forms of cutaneous inflammation.[200,201] These findings were confirmed in mice: The expression of cutaneous IL-31 messenger RNA was significantly higher in NC/Nga mice with scratching behavior than in NC/Nga mice without scratching behavior. Therefore, IL-31 may participate in causing an itch sensation and promoting scratching behavior.[202,203] Thus, IL-31 may serve as a link between the immune and neural systems by regulating inflammation as well as itch. For this reason, IL-31 and the IL-31R are promising targets for the treatment of inflammatory and itchy dermatoses such as atopic dermatitis.

ROLE OF THE NERVOUS SYSTEM IN SKIN PATHOPHYSIOLOGY

A number of human clinical diseases appear to have a significant neurogenic component, including atopic dermatitis, prurigo, pruritus, psoriasis, rosacea, urticaria, herpes zoster, and inflammatory arthritis[1] (see Tables 101-1, 101-2). The peripheral nervous system also modulates inflammatory responses in other organs, such as during eye inflammation, asthma, and inflammatory bowel syndrome. Moreover, neuronal mediators play a role during wound healing by regulating growth, proliferation, and angiogenesis.

The ability of neuropeptides to activate human mast cells and induce urticaria has been appreciated for a number of years.[204] For example, chronic idiopathic urticaria and, to a lesser extent, pressure urticaria showed enhanced SP- and CGRP-induced wheal-and-flare reactions (see Fig. 101-2). Certain transient receptor potential ion channels are expressed by sensory nerves as well as by mast cells.

A neurogenic component in the pathophysiology of psoriasis is suggested based on clinical observation (e.g., stress induction) and is supported by experimental studies.[205–208] Data suggest a role for nerve growth factor (NGF) as a mediator of inflammatory responses in psoriasis.[209]

In acute as well as lichenified lesions of atopic dermatitis, increased staining of cutaneous nerves or concentrations of neuropeptides has been observed.[62,116,210–216] Also, characteristics of the triple response (erythema, wheal, flare) of neurogenic inflammation as well as pruritus have been observed after injection of neuropeptides into human skin.[217,218] Furthermore, the lesions of patients with atopic dermatitis show enhanced concentrations of mast cell tryptase, a ligand for the proteinase-activated receptor 2, which is upregulated in atopic dermatitis and mediates pruritus, inflammation, and upregulation of intercellular cell adhesion molecule 1 or nuclear factor κB.[219–222] A role for pro-opiomelanocortin peptides in the pathogenesis of atopic dermatitis is supported by the in vitro observation that α-MSH modulates immunoglobulin E production and the finding of increased levels of pro-opiomelanocortin peptides in the skin of patients with atopic dermatitis.[223,224] Some studies also suggest that neurotrophins may participate in the pathophysiology of atopic dermatitis.[225]

Neuropeptides are obviously involved in the regulation of epidermal antigen presentation.[226,227] Also, pre-treatment of the skin with capsaicin enhances contact hypersensitivity (CHS) at the site of treatment. It has been suggested that capsaicin-sensitive neurons modulate this reaction via the release of neuropeptides.[93,228] Studies also indicate that SP agonists can prevent impaired CHS and tolerance after UVB irradiation.[180] CGRP significantly inhibited antigen presentation to antigen-specific T cells.[93,229] The effect of CGRP on murine Langerhans cells is probably mediated by a specific

CGRP receptor, which leads to intracellular increase in cyclic adenosine monophosphate.[230] Accordingly, IL-10 can be upregulated by CGRP.[231]

α-MSH is one of the most powerful neurohormones in terms of its ability to modify CHS reactions.[232–234] PACAP is also able to inhibit CHS reactions.[235]

The skin nervous system also plays a crucial role during wound healing and impaired wound healing processes. Released neuropeptides participate in inflammation, cell proliferation, cytokine and growth factor production, and neovascularization.[236,237] Of note, delayed wound healing occurred in animal models after surgical resection of cutaneous nerves.[238–242] For instance, decreased concentrations of SP, SST, and CGRP were observed in wounds in rats[243]; elevated levels can be observed in other wound models.[240,243] CGRP promotes proliferation and migration of human keratinocytes[244–246] and stimulates proliferation of human dermal endothelial cells.[247] VIP has both inhibitory and stimulatory effects on the proliferation of keratinocytes.[244,245,248] Angiotensin II appears to influence tissue repair via activation of the angiotensin I receptor in fibroblasts, which leads to collagen remodeling, collagen gel contraction, and upregulation of collagen-binding integrins in vitro.[249] NGF induces human skin and lung fibroblast migration but not proliferation.[250] In a mouse model, it could be observed that NGF accelerated the rate of wound healing.[251] These findings have encouraged successful treatment of leg ulcers in humans with topical NGF.[252,253] Parathyroid hormone–related protein expression is temporarily upregulated in migratory keratinocytes, myofibroblasts, and infiltrating macrophages in guinea pig skin, although topical application of a parathyroid hormone–related protein agonist did not change the healing rate or morphology in these wounds.[254,255]

NEP expression appears to be both increased and redistributed in the wound environment during wound healing, which indicates a role for neuropeptide-degrading enzymes in this process.[256] In normal skin, NEP immunoreactivity was restricted to the basal layer, whereas during wound healing, NEP was also detected in the suprabasal layer of human skin. Future studies using transgenic and knockout animals in which certain components of the neurologic system are overexpressed or deleted by homologous recombination may make it possible to examine the role of the cutaneous nervous system in normal and delayed wound healing.[257]

Pruritus is one of the most frequent symptoms of skin diseases and derives from stimulation of sensory nerve endings, spinal cord modulation, or dysfunction of certain areas in the CNS[33,258–260] (see Table 101-1). Polymodal C fibers stimulated by chemicals or heat transmit signals to the spinal cord and CNS, which results in itching. Accordingly, both the peripheral cutaneous system and the CNS coordinate the sensation of itch, which leads to the autonomic reflex of scratching. Histamine is the best-studied, albeit definitely not the only, mediator of pruritus. New histamine receptors (e.g., histamine receptor-3, histamine receptor-4) have now been cloned; their role in human itch is unknown. Another important mediator of pruritus in patients with atopic dermatitis may be IL-31[200,203,261,262] (see Table 101-1, Fig. 101-1). In notalgia paresthetica, a neuropathy characterized by pruritus, pain, and hyperalgesia, immunostaining for several neuropeptides revealed that affected areas had a significant increase in intradermal nerve fibers as well as epidermal dendritic cells, which suggests that sensory nerve fibers are involved in the pathogenesis of this disease. Agents such as capsaicin that deplete neuropeptides from sensory neurons have been shown to have a therapeutic effect in diseases associated with pruritus and pain. Other neuromediators such as opioids seem to be involved in the pathophysiology of cholestatic pruritus.[263,264] Cholestatic pruritus can be significantly reduced by application of an antagonist to 5-hydroxytryptamine.[265] Like opioids, endogenous cannabinoids appear to be implicated in itching.[33,169,260,266] Under inflammatory conditions,[267] cannabinoids are capable of activating and sensitizing the transient receptor potential vanilloid 1 receptor.[268,269] Cannabinoid receptors also induce release of analgesic β-endorphin from murine keratinocytes.[126]

SUMMARY AND PERSPECTIVES

In many ways, the nervous system modulates (and eventually "manipulates") the function of the skin, which leads to either control of skin homeostasis or disease. The interaction of the skin with the peripheral nervous system as well as the CNS plays a crucial role in skin homeostasis and disease states. Recent discoveries have increased knowledge about molecular mechanisms of neuropeptide and neuropeptide receptor functions and along with the development of modern techniques offer exciting insights into the complex network of the skin, the nerves, and the immune system during inflammation. With the use of novel technical approaches, it will be possible to define new ways to treat inflammatory skin diseases in which the neuro-immuno-endocrine axis is involved.

CHAPTER 102

Pathophysiology and Clinical Aspects of Pruritus

Gil Yosipovitch
Aerlyn G. Dawn
Malcolm W. Greaves

INTRODUCTION

Pruritus (itching) is the predominant symptom of skin disease and can best be defined as a sensation that leads to a desire to scratch. All human beings experience this sensation in the course of their lifetime; therefore, it is important to make a distinction between acute itch, which is of limited period of time ranging from seconds to a week such as the itch related to acute insect bite reaction, and chronic itch, which lasts for months and is the focus of this chapter. Chronic itch consists of multidimensional phenomena including sensory, emotional, and cognitive components. In most cases, chronic itch results from interaction of the brain-skin axis. Although itch and pain are separate and distinct sensations, itch has many similarities to pain.[1] Both itch and pain are unpleasant sensory experiences, follow similar neural pathways, and can severely impair patients' quality of life. However, the behavioral response patterns differ—pain elicits a reflex withdrawal, whereas itch leads to a scratch reflex.

The limited understanding of itch results from the subjective nature of itching, the absence of specific and sensitive investigational methods to study the neuropathophysiology and molecular basis of itch in humans, and from the lack of convincing animal models and incomplete knowledge of pharmacologic mediators of pruritus. Significant progress has been made in the past 10 years, partly as a result of microneurography that enables recordings to be made from individual afferent neurons after stimulation in man in vivo. The concept that itch is transmitted to the central nervous system (CNS) and processed in the brain should lead to new approaches to antipruritus therapy.[2]

TABLE 102-1
Prevalence of Itch Caused by Skin Disorders and Infectious Skin Diseases

CAUSE	ESTIMATED PREVALENCE OF PRURITUS
Skin disease	
Atopic dermatitis	17% of population
Contact dermatitis	Unknown
Poison ivy	70% of U.S. population will acquire if exposed to plant
Elderly idiopathic xerosis	30%–60% of adult population
Urticaria	15%–23% in United States
Psoriasis	80% of 40,350 psoriatics
Pityriasis rosea	Unknown
Seborrheic dermatitis	Unknown
Neurodermatitis: lichen simplex chronicus, prurigo nodularis, lichen amyloidosis	Unknown
Pityriasis rubra pilaris	Unknown
Dermatitis herpetiformis	110–588/million/yr
Linear immunoglobulin A disease	Unknown
Bullous pemphigoid	Unknown
Collagen disease	
Dermatomyositis	38%
Sjögren syndrome	Unknown
Infection	
Varicella	4 million cases of varicella occur in United States each year (equivalent to annual birth rate in United States)
HIV disease	HIV-associated folliculitis in 25%–50% of HIV patients; non-specific pruritic eruption in 11%–46% of HIV patients
Onchocerciasis	6 million have severe itching
Scabies	Unknown
Superficial fungal infections	Unknown

HIV = human immunodeficiency virus.

PRURITUS AT A GLANCE

- Pruritus is the predominant symptom of skin disease.
- May originate in the skin or nervous system.
- Clinical classification of itch includes:
  - itch caused by skin disorders
  - itch caused by systemic disorders
  - neuropathic itch
  - psychogenic itch
- Chronic itch consists of multidimensional phenomena including sensory, emotional, and cognitive components.
- Central and peripheral mediators include opiates, neuroadrenaline, substance P, histamine, proteinases, nerve growth factor, interleukins, and prostaglandins.
- Treatment should address the multifactorial nature of pruritus including central pathway and peripheral mediators.

EPIDEMIOLOGY

Itch is a symptom rather than a specific disease entity; therefore, epidemiologic data for itch are limited. Nevertheless, itch has been found to be the dominant skin complaint among all age groups.[3] Dalgard et al. found the prevalence of pruritus to be approximately 8 percent among Norwegian adults.[3] Itch is a primary symptom in a diverse range of skin diseases as well as in systemic diseases. The prevalence of pruritus in different dermatologic and systemic diseases is outlined in Tables 102-1 and 102-2.

ETIOLOGY AND PATHOGENESIS

Pruritus may originate in the skin or in the CNS. There is no single, definitive classification of pruritus. For the purpose of this chapter, we use the following clinical classification of itch based on Bernhard[4] and Twycross et al.[5]

TABLE 102-2
Prevalence of Pruritus in Systemic Disease

Disease	Estimated Prevalence of Pruritus
• Chronic renal failure, end stage	25%–85%
• Hepatic	
• Cholestatic jaundice	20%–25%
• Primary biliary cirrhosis	100%
• Hepatitis C	4%
• Cholestasis of pregnancy	Unknown
• Hematopoietic	
• Polycythemia vera	48%
• Iron deficiency anemia	Unknown
• Multiple myeloma	Unknown
• Mastocytosis	Unknown
• Hodgkin lymphoma	30%
• Non-Hodgkin lymphoma	Unknown
• Endocrine	
• Hyperthyroidism	60%
• Hypothyroidism	Unknown
• Carcinoid syndrome	Unknown
• Anorexia nervosa	58%

- Itch caused by skin disorders originates in the skin due to inflammation, dryness, or other skin damage and is transmitted by C nerve fibers. Examples include itch due to atopic dermatitis, scabies, urticaria, and insect bite reactions. Whether a result of specific chemical mediators or physical stimuli, such as mechanical stimulation from wool fibers, pruritus generated in the skin derives from non-specialized receptor units located within the epidermis and in the vicinity of the dermal-epidermal junction.
- Itch caused by systemic disorders may result from an imbalance in the μ- and κ-opioid systems or from changes in levels of interleukins (ILs) and neuropeptides. Examples include itch related to chronic liver disease or chronic renal failure.
- Neuropathic itch arises because of disease located at any point along the afferent pathway.[6] Post–herpes zoster neuropathy, notalgia paresthetica, and the itch occasionally associated with multiple sclerosis and brain tumors are in this category.
- Psychogenic itch is seen in the delusional state of parasitophobia, obsessive compulsive disorder, and depression.

Of course, two or more types of itch can co-exist—for example, itch of prurigo nodularis probably results from both itch of skin inflammation and neuropathic itch as well as psychogenic causes. In many cases, the etiology of itch remains elusive, particularly when it occurs in clinically normal skin.

Itch-Scratch Cycle

Itch and scratching are interwoven together in both acute and chronic itch conditions. Phylogenetically, itch is probably a mechanism for animals to remove parasites residing in the hairy skin. Scratching is also a behavioral response and studies suggest that repetitive scratching activates areas in the prefrontal cortex and orbitofrontal cortex that may involve reward systems and decision making. This may explain the hedonic and compulsive components of scratching. Furthermore, the hedonic experience may be associated with release of endogenous opioids. Repetitive scratching in chronic conditions such as atopic dermatitis and psoriasis further damages the skin and causes secretion of neuropeptides and opiates that may further augment the vicious itch-scratch cycle (Fig. 102-1).

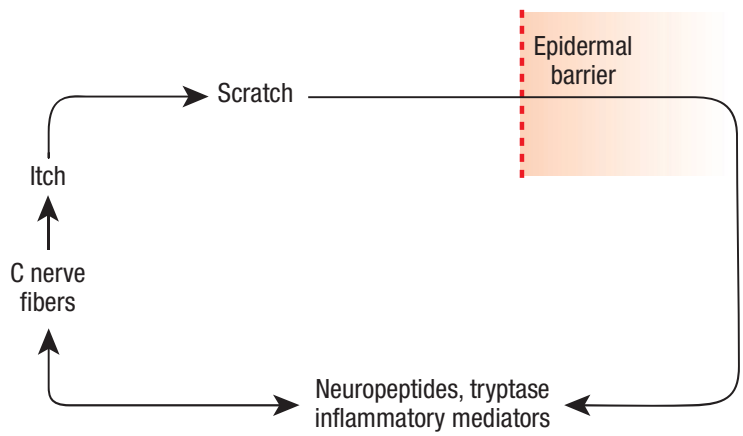
Alloknesis: "Itchy Skin"

Alloknesis is a phenomenon in which a normally innocuous stimulus induces itch. For example, application of a fine brush to an itchy site induces itch. Alloknesis is analogous to the better known allodynia (injury to skin results in well-localized, short-lived, intense pricking pain and a surrounding diffuse area of hyperalgesia). This type of itch is mediated by mechanical mechanoreceptor units as well as an ongoing activity of afferent C nerve fibers and is considered a central neural sensitization response. Alloknesis is common in chronic atopic dermatitis; sweating or slight mechanical stimulation associated with wearing wool exacerbates itch. The exact role of central sensitization in pruritus associated with specific diseases is unknown.

Itch Transmission in the Skin

The only peripheral tissues from which itch can be evoked are skin, mucous membranes, and cornea. Interestingly the nerves in the deeper layer of the reticular dermis and subcutaneous fat do not transmit itch and inflammatory skin diseases, such as panniculitis, cause pain but not itch. Removal of the epidermis abolishes perception of pruritus, suggesting that pruritus receptor units are located predominantly within this layer.[7] We suspect that the epidermis acts as a receptor for itch, but a specific receptor has not yet been identified. Light microscope and ultrastructural studies of human skin have shown the existence of intraepidermal nerve fibers with "free" non-specialized nerve endings extending to the stratum granulosum.[8] It has not been possible to prove that these include free nerve endings that transmit pruritus; however, many of these fibers stain positively for neuropeptides.

Keratinocytes express a variety of neural mediators and receptors, all of which appear to be involved in the itch sensation.[9] These include opioids, proteases, substance P (SP), nerve growth factor (NGF), neurotrophin 4, and their respective receptors, including μ- and κ-opioid receptors, proteinase activated receptor-2 (PAR-2), vanilloid receptors, tropomyosin-related kinase A (TRKA), transient receptor potential vanilloid (TRPV) ion channels, and cannabinoid receptors 1 and 2. Keratinocytes also have voltage-gated adenosine triphosphate channels and adenosine receptors



▲ **FIGURE 102-1** Basic etiologies of the itch-scratch cycle.

similar to C nerve fibers. Because these channels have a role in pain,[10] these findings suggest that keratinocytes may act as itch receptors.

Dedicated Itch-Transmitting C Nerve Fibers

Significant advances in our understanding of itch neurophysiology have been achieved in the past ten years. Microneurography has helped to disprove the historic concept that pruritus and pain are simply responses of the same neurons to mild versus intense stimuli, respectively. Studies using electric field stimulation coupled with microneurography have identified individual histamine-sensitive C nerve fibers that transmit itch.[11] The C nerve fibers have exceptionally slow conduction velocity, unusually wide innervation territories, and represent no more than 5 percent of total C fibers. These neurons are sensitive to pruritogenic and thermal stimuli, but not mechanical stimuli. The co-responsiveness of this subset of C neurons to temperature change as well as pruritic stimuli is of interest because raising the temperature of skin lowers the threshold of receptors to pruritic stimuli[12] and most pruritic patients complain of aggravation of pruritus in a warm environment. In chronic itch, spontaneous activity in these C fibers occurs.[13] In contrast, the vast majority of C fibers are sensitive to mechanical and heat stimuli and are entirely insensitive to histamine.[14]

The existence of a subset of dedicated itch-transmitting C neurons receives further support from studies of spinal cord pathways. Itch-transmitting primary afferent C neurons synapse with secondary transmission neurons that cross over to the contralateral spinothalamic tract and ascend to the thalamus. In the cat, microneurography identified lamina 1 neurons in the lateral spinothalamic tract that selectively responded to histamine, suggesting a central dedicated nerve pathway for itch.[15]

Other C nerve fibers transmit itch as well. Mechanically induced itch is commonly observed clinically; for example, itch associated with contact with wool cannot be explained by histamine-sensitive nerve fibers. Moreover, in patients with chronic pruritus, electrical or painful stimuli can also induce itch.[16,17] Oral antihistamines are ineffective in the treatment of most types of itch, suggesting that nonhistamine-mediated fibers also play an important role. In addition, the perceived sensation of pruritus can vary greatly in quality. Patients may experience sensations of burning, pricking, insects crawling on the skin, or tickle, but the neurophysiologic and psychologic correlates of these differences have not yet been elucidated. Information obtained from itch questionnaires based on previously developed pain questionnaires has enabled us to better understand the different characteristics of itch.[18–21]

Mediators of Pruritus

Both central and peripheral mediators are important in pruritus. Pro-inflammatory pharmacologic mediators cause pruritus in inflammatory skin diseases, such as urticaria. Most of such mediators also cause other signs of inflammation (pain, erythema due to vasodilation, increased vascular permeability). Several mediators cause pruritus indirectly by evoking release of histamine and other mediators from mast cells (e.g., SP and several opioid peptides) or by potentiating the actions of other mediators [e.g., prostaglandin E_1 (PGE_1)]. Potentially important peripheral mediators of pruritus include histamine, proteinases, SP, NGF, ILs, and PGs. Central mediators include opiates and neuroadrenaline.[22]

HISTAMINE Histamine is the archetypal mediator of signs and symptoms of inflammation including pruritus. Histamine is synthesized in the mast cells of the skin and stored in mast cell granules. It is released by these cells in response to a variety of injurious stimuli. Histologically, dermal mast cells and unmyelinated neurons are closely juxtaposed, raising the possibility of a pseudosynaptic relationship and implying a close functional relationship between the immune and nervous systems. Histamine acts to produce itch by way of the H_1 receptor and not via H_2 receptors.[23] Histamine also rapidly causes tachyphylaxis in human skin[24]; therefore, it is unlikely to be responsible for sustained pruritus. Nevertheless, it is an important mediator in short-lived urticarial wheal-and-flare reactions and causes pruritus after a single intradermal injection. Histamine's pruritic action can be potentiated by PGE_1. Firm evidence for histamine as the main mediator of pruritus is limited to skin diseases including acute and chronic urticaria, mastocytosis (urticaria pigmentosa), insect bite reactions, and allergic drug reactions. H_1 antihistamines are usually effective in these disorders. The role of histamine in most types of chronic itch is minimal, and antihistamines do not alleviate itch. In atopic dermatitis, histamine has no significant role, and low-sedation H_1 antihistamines are ineffective. Other histamine receptors such as H_4-receptors may also play a role in itch as demonstrated in mouse models.[25]

PROTEINASES Proteinases and their respective receptors appear to play an important role in regulation of cutaneous inflammatory and immune responses. Human dermal mast cells produce two proteases: tryptase and chymase. The proximity of dermal mast cells to afferent C neuron terminals in skin allows a functional relationship by which tryptase induces itch.[26] The activated mast cell releases tryptase (along with other mediators, including histamine), which in turn activates the PAR-2 receptor, a recently identified G protein–coupled receptor subfamily localized on C fiber terminals. The activated C fibers transmit this information to the CNS, where it may cause the sensation of itch. Additionally, activation leads to local release of neuropeptides including SP. This forms an additional pathway for itch, and represents another example of interaction between the immune and nervous systems.

PARs may play a significant role in regulation of cutaneous neurogenic inflammation. In the skin, PAR-2 expressed on sensory neurons is self-activated by peptide ligands exposed after extracellular cleavage by trypsin or mast cell tryptase. PAR-2 agonists have been demonstrated to induce release of calcitonin gene-related peptide and SP, which induce neurogenic inflammation.[27] Studies using dermal microdialysis have shown that levels of tryptase and its receptor (PAR-2) are elevated four-fold in atopic dermatitis.[28] PAR-2 is also highly expressed in the epidermis of atopic dermatitis patients. It is noteworthy that proteinase activity can also be found in common allergens[29] and staphylococcal skin infections, both of which are known to aggravate atopic dermatitis and itch.

SUBSTANCE P SP is a neuropeptide widely distributed in the periphery and CNS and is thought to intensify itch perception. SP is synthesized in the cell bodies of C neurons and causes vasodilation and increased vascular permeability. Intradermal injection of SP provokes itch as well as characteristics of neurogenic inflammation such as erythema, wheal, and flare.[30–32] SP is elevated in atopic dermatitis patients compared to con-

trols and significantly correlates with disease activity.[33]

SP is co-localized with other neurotransmitters, such as serotonin, dopamine, or calcitonin gene-related peptide, and acts as a neuromodulator. Although endogenously released SP does not degranulate mast cells in healthy human skin[34] or cause any sensation at physiological concentrations,[35] direct communication between nerve fibers and mast cells through SP has been verified.[36] High concentrations of SP are required to cause immediate mast cell degranulation; however, low concentrations can specifically activate Neurokinin 1 receptors on mast cells, leading to sensitization of these cells and increased production of tumor necrosis factor (TNF-α).[37] In turn, TNF-α sensitizes nociceptive nerve endings, which provide further evidence of the extensive cross-talk between nerve and mast cells.

OPIOIDS Opioid peptides are potent neurotransmitters and have both a central and a peripheral itch-producing action. Opioids appear to induce itch via two possible mechanisms. First, by degranulation of cutaneous mast cells[38] and second, via a direct central and peripheral pruritogenic effect by activating μ-opioid receptors.[38–41] Morphine and other endogenous and exogenous μ-opioid receptor agonists are known to cause generalized pruritus.[42–45] The concept of central sensitization in chronic pruritus and possible involvement of pruritic mediators located in the CNS is becoming increasingly recognized as important in both cutaneous and systemic diseases. The perception of pruritus is modified by endogenous opiates via central opioid receptors. Generalized pruritus may result from an imbalance between the μ- and κ-opioid systems.[43,44,46,47] Activation of μ-opioid receptors stimulates itch perception, whereas κ-opioid–receptor stimulation inhibits μ-receptor effects both centrally and peripherally.[43,44,47]

NEUROTROPHINS NGF is the prototypical neurotrophin—a factor that regulates the growth and function of nerve cells. Other members of this family include neurotrophins 3, 4, and 5 and brain-derived neurotrophic factor.[48] Increased levels of epidermal NGF correlate with the proliferation of terminal cutaneous nerves and upregulation of neuropeptides. NGF is known to induce sprouting of nerve fibers, sensitization of nerve endings, axonal transport in spinal ganglia (dorsal root ganglion cells), and increased expression of neuropeptides. NGF is required not only for survival and regeneration of sensory neurons but also controls the responsiveness of such neurons to external stimuli.[49,50] There is a significant correlation between plasma levels of NGF with disease activity in atopic dermatitis.[33] Increased cutaneous gene expression of NGF in mast cells, keratinocytes, and fibroblasts of atopic dermatitis patients was highly associated with plasma levels of NGF, thus providing further data that NGF may contribute significantly to itch in atopic dermatitis.[51] Other neurotrophins, such as neurotrophin 4, are upregulated in keratinocytes of atopic dermatitis patients.[52]

PROSTANOIDS PGs enhance histamine-induced itch in the skin.[53,54] PGs are not themselves pruritogenic when injected into skin; however, intradermal injection of PGE_1 enhances pruritus due to histamine subsequently injected into the same site.[55] Only pruritic neurons that display lasting activation after histamine are excited by PGE_2, and mechanosensitive fibers are unresponsive to both histamine and PGE_2.[14] Evidence suggests that cyclooxygenase 2 is induced in the spinal cord in response to cutaneous inflammation, and that spinal cord tissue levels of PGE_1 and PGE_2 correlate with central pruritus. PGE_2 has a direct, low-level pruritogenic effect without inducing protein extravasation in healthy and atopic dermatitis patients, suggesting that prostanoids' peripheral action is not solely via histamine and that they may potentiate pruritus via a nonspecific effect on nerve fibers. Oral administration of aspirin, a cyclooxygenase inhibitor, does not ameliorate pruritus except in polycythemia vera[56]; however, topical salicylates and topical aspirin often significantly reduces pruritus in patients with chronic localized itch.[57]

INTERLEUKINS The role and effect of ILs in inducing itch has not been thoroughly investigated. In atopic dermatitis, several cytokines induce itch, including IL-2 and IL-6. IL-2, the prototype pruritogenic cytokine, induces itch in atopic dermatitis as well as in cancer patients receiving recombinant IL-2. Inhibition of IL-2 production forms the basis for treatment of atopic dermatitis with cyclosporine and immunomodulators such as tacrolimus and pimecrolimus. IL-2 and IL-6 have receptors in nerve cells. The recent discovery of IL-31 itch induction in mice, as well as elevated IL-31 levels in atopic dermatitis and prurigo nodularis, suggests a specific role for this cytokine in pruritus.[58]

CLINICAL FINDINGS

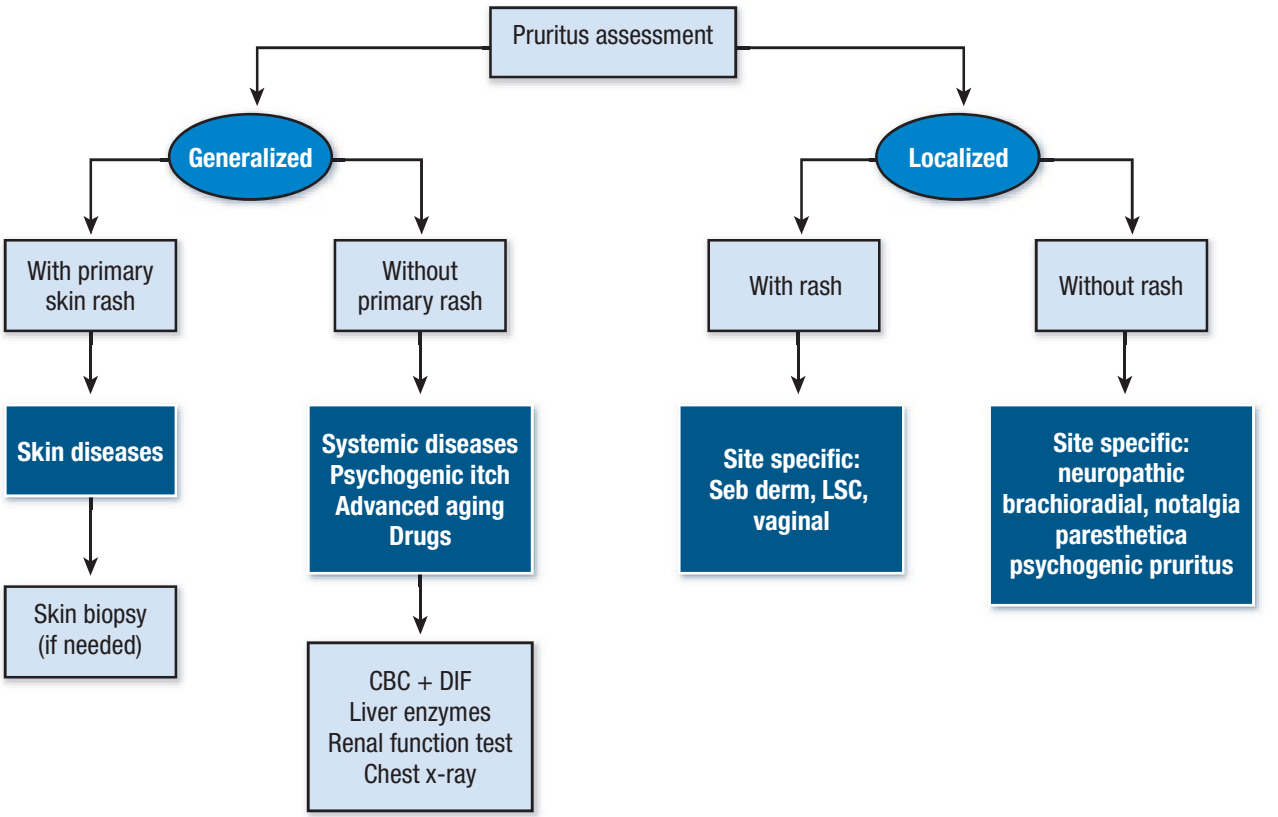
History

It is of prime importance to determine whether the cause is related to a primary skin disease or systemic disease. Diseases such as skin dryness or scabies may exhibit few primary skin lesions; therefore, careful history and laboratory evaluation can be particularly important. It is important to differentiate between generalized pruritus and localized itch, which usually is not associated with a systemic cause. Careful history, including a full drug history, and physical examination including lymph nodes, are the starting points. The history should take into account the multidimensional nature of itching and should include details of quality, distribution, and timing. Any patient referred with generalized pruritus in the setting of other family members with pruritus should be assumed to have scabies until proved otherwise—skin signs may be clinically inapparent, perhaps confined to a few small nodules on the genitalia.

Fig. 102-2 is an algorithm showing the approach to a patient with pruritus.

Cutaneous Lesions

Secondary skin lesions characteristic of pruritus include excoriations, lichenification, and hyper- or hypopigmentation. Lichenification results from continuous rubbing or scratching and consists of well-developed, thickened plaques with marked accentuation of skin creases (see Chap. 14). Post-inflammatory hyperpigmentation or hypopigmentation is common in patients with skin phototypes skin type 4 through 6 (see Chap. 89). Lichenified plaques are most commonly distributed in areas the patient can easily scratch or rub (i.e., nape of neck, below the elbow, ankle, buttock, and genitalia). The butterfly sign consists of normal-appearing skin in the middle of the back outlined by a butterfly pattern of contrasting hyperpigmentation in areas subjected to persistent scratching, resulting from the patient's inability to reach the middle of the back. Shiny fingernails may result from prolonged rubbing. Prurigo nodules are excoriated papules that form nodules in patients with chronic pruritus (see Chap. 15). In many cases,



▲ **FIGURE 102-2** Approach to a patient with pruritus. CBC = complete blood cell count; DIF = differential; LSC = lichen simplex chronicus; Seb derm = seborrheic dermatitis.

this type of itch is accompanied by a painful, burning sensation suggestive of a neuropathic component. Prurigo nodules are frequently associated with emotional stress and obsessive compulsive disorder; however, they can be also be a manifestation of itch in patients with atopic dermatitis or chronic renal failure. Such nodules are usually distributed over extensor aspects of the limbs.

Some pruritic states have specific clinical patterns. Despite severe pruritus, chronic urticaria usually does not show secondary skin lesions associated with scratching. Neuropathic itch in disease entities, such as postherpetic neuralgia, brachioradial pruritus, and notalgia paresthetica, is typically associated with pain and burning sensation. Atopic dermatitis may also be associated with burning sensation after scratching.

Laboratory Tests and Special Tests

Laboratory tests to be considered in the evaluation of generalized pruritus are outlined in Table 102-3. Secondary laboratory considerations may include stool examination for ova and parasites, screening for hepatitis B or C, plasma protein electrophoresis, and immunoelectrophoresis. A computed tomography scan of the chest and abdomen may be justifiable to help rule out lymphoma. A skin biopsy is useful to exclude clinically inapparent cutaneous mastocytosis or bullous pemphigoid.

DIFFERENTIAL DIAGNOSIS (Box 102-1)

COMPLICATIONS

Pruritus can significantly impair patients' quality of life. Patients with chronic pruritus often have difficulty sleeping, difficulty concentrating, decreased sexual desire and sexual function, agitation, and depression.[18,59] In addition, eczematous lesions resulting from scratching can become secondarily infected, particularly in patients with atopic dermatitis.

TABLE 102-3
Recommended Laboratory Tests for Investigation of Patients with Generalized Pruritus

- Recommended
  - Complete blood cell count with differential
  - Chemistry profile: urea, creatinine, liver enzymes
  - Thyroid function tests
  - Chest radiograph
- Optional
  - Stool examination for parasites
  - Human immunodeficiency virus testing with other associated symptoms and signs

PROGNOSIS AND CLINICAL COURSE

Generalized pruritus can wax and wane. Changes in the clinical presentation may be associated with seasonal changes, such as exacerbation of atopic dermatitis in the winter, or changes between dry and humid environments. Pruritus associated with underlying internal disease is often multifactorial, involving both systemic and external factors, including ambient temperature and humidity. Chronic itch associated with skin disease may also include central neural sensitization.

Itch Caused by Skin Disorders

PRURITUS IN ATOPIC DERMATITIS (See Chap. 14) Pruritus in atopic dermatitis remains a controversial area and the molecular

Box 102-1

Differential Diagnosis of Generalized Pruritus without Primary Skin Disease

- Chronic renal disease
- Cholestasis

  - Hodgkin disease
  - Polycythemia vera
  - Myeloid and lymphatic leukemia
  - Myelodysplasia
  - Mastocytosis
- Solid malignant tumors (paraneoplastic manifestation)
- Human immunodeficiency virus–associated pruritus
- Itching in senescence
- Aquagenic pruritus
- Itching as a manifestation of psychiatric disease
  - Delusions of parasitosis
  - Itch associated with obsessive compulsive disorder
  - Pruritus of anorexia nervosa
- Neuropathic itch
  - Post-cerebrovascular accident pruritus
  - Multiple sclerosis–associated pruritus
  - Pruritus of Creutzfeldt-Jakob disease ("prion pruritus")
- Drug-induced pruritus
  - Opiate-associated pruritus
  - Hydroxyethyl starch–induced pruritus

basis of pruritus in atopic dermatitis remains largely unexplained. Whether itch precedes skin lesions or vice versa is also an unresolved issue. What is certain is that a vicious itch-scratch cycle (see Fig. 102-1) exists in atopic patients, in which scratch damage enhances pruritus. Itching is particularly acute in response to punctate stimuli such as wool fibers; rubbing or scratching elicits surround inhibition. Alloknesis (see Alloknesis: "Itchy Skin") is a prominent feature of the itch of atopic dermatitis and explains the bouts of intense itching associated with sweating, sudden changes in temperature, dressing, undressing, and direct contact with wool. That there is a central (neurogenic) component to the itch of atopic dermatitis is suggested by the poor response to low sedation H_1 antihistamines.[60] The intensity of itch in atopic dermatitis has been related to mental factors,[61–63] and itch may be induced by cognitive stress, such as anxiety, as well as depression. Opioid peptides may serve as central mediators because opioid antagonists are effective in some patients. Nocturnal scratching is a major problem in atopic dermatitis, occurs during superficial sleep, and occupies 10 percent to 20 percent of the total sleeping time, leading to tiredness and irritability.

PSORIASIS Itch in psoriasis is a significant but under-recognized problem in dermatology. Several studies have demonstrated that itch is a principal symptom of psoriasis.[64–68] Among psoriasis patients, 77 percent experience pruritus on a daily basis.[59] Dermatologists emphasize observable criteria of psoriasis, such as visible lesions; however, itching frequently occurs in areas of the body where no psoriasis plaques are visible. Scalp itching, in particular, is specific to psoriasis and may require different therapies than pruritus in other areas of the body.[66]

Neuropathic Itch

POSTHERPETIC NEURALGIA Postherpetic neuralgia commonly has neuropathic pain; and often, associated neuropathic itch as well. Pruritus commonly accompanies both acute zoster and postherpetic neuralgia, particularly lesions affecting the head, face, and neck.[69]

NOTALGIA PARESTHETICA Notalgia paresthetica is a chronic localized itch, affecting mainly the interscapular area especially the T2–T6 dermatomes, but occasionally with a more widespread distribution, involving the shoulders, back, and upper chest. The sensation perceived by the patient is part itch, part paraesthesia. There are no specific cutaneous signs, apart from those attributed to scratching and rubbing. Amyloid deposition in skin biopsies is a secondary event. The current view on etiology is that it is a neuropathic itch due to entrapment of spinal nerves as they emerge through the axial muscles of the back.[70]

BRACHIORADIAL PRURITUS Brachioradial pruritus, a localized pruritus, is becoming increasingly common. Patients, usually fair skinned, affluent, and middle aged, habitually indulge in golf, tennis, sailing, or other leisure outdoor activities in sunny climates.[71,72] They develop persistent pruritus of the outer surface of the upper arm, elbow, and forearm, associated with clinical evidence of chronic sun damage and xerosis in the pruritic skin. The itch may gradually become more widespread. Results of phototesting are negative and the problem seems consequent on straightforward chronic ultraviolet (UV) overexposure (see Chap. 89).

Systemic Itch

PRURITUS OF CHRONIC RENAL DISEASE (See Chap. 151) Pruritus is one of the most distressing symptoms of chronic renal failure. It affects 50 percent of patients with chronic renal disease, especially those on dialysis, although it is becoming less prevalent, probably due to more efficient dialysis techniques.[73] Scratching is common and patients may be heavily excoriated or the skin may appear lichenified or present with prurigo nodules. The back is invariably affected, and the arm bearing the arteriovenous fistula is also a common site in dialysis patients. Patients with uremic pruritus often have dry skin, but correction of this by emollients usually provides minimal relief. Etiologic factors may include elevated calcium levels, release of pruritogenic cytokines during hemodialysis, damage to C nerve fibers, proliferation of sensory nerve endings in skin, increased numbers of dermal mast cells, elevated plasma histamine levels, secondary hyperparathyroidism and abnormal levels of divalent cations.[74,75] Secondary hyperparathyroidism, though common in patients with renal failure, is a rare cause of renal pruritus. The proliferation of nerve endings in skin is most likely a response to incessant scratching and rubbing, rather than the primary cause of pruritus. Elevation of histamine levels, with or without increased population density of dermal mast cells, is also unlikely to be important because antihistamines are rarely effective. Evidence based on response of patients to a selective κ-opioid agonist raises the possibility that opioid peptides may be involved, although this finding needs further verification.[76]

PRURITUS OF CHOLESTASIS (See Chap. 151) Pruritus of cholestasis is a highly distressing and persistent pruritus of biliary obstruction that often begins with an acral distribution, but later becomes more generalized. Both peripheral and central mechanisms are important. Cholestatic pruritus is associated with high plasma levels of bile salts; however, there is little or no evidence of a correlation between skin or serum concentrations of bile salts and itching,[77] although administration of cholestyramine, which lowers bile salt levels, does provide some relief. Patients also have elevated plasma opioid levels,[78] and pruritus has been shown to improve with treatment with opioid antagonists

including naloxone, naltrexone, and butorphanol.[79–81] In addition, animal models of cholestasis are associated with elevated levels of opioid peptides and scratching, relieved by naloxone.[82,83] Thus, combination of both bile salt–lowering and opioid antagonist strategies appear reasonable in the management of pruritus of cholestasis.

PRURITUS OF ENDOCRINE DISEASE (See Chap. 152) Generalized intractable itching is a recognized feature of thyrotoxicosis and may be a presenting symptom.[84] This may be due to increased blood flow, which raises the skin temperature, which, in turn, reduces the threshold to itching.[12] Hypothyroidism is less frequently associated with itch. Generalized itching is not a feature of diabetes mellitus.[85] However, anogenital itching is a common presenting feature, and is due to mucocutaneous candidiasis. Localized itching of the scalp and lower extremities in the form of lichen simplex chronicus can also be a manifestation of diabetic neuropathy,[86] which may respond to topical capsaicin treatment.[87]

PRURITUS IN HEMATOLOGIC DISEASE AND LYMPHORETICULAR MALIGNANCY (See Chaps. 145 and 146) Itch is common in hematologic disorders. In widespread cutaneous T-cell lymphoma, and erythrodermic forms of cutaneous T-cell lymphoma including Sézary syndrome (T-cell leukemia), intractable itch is difficult to manage. In polycythemia vera, it occurs in approximately 50 percent of patients, is often precipitated by contact with water ("bath itch"), and is associated with raised blood histamine levels.[88,89] In other lymphoproliferative diseases, itch can also be precipitated by contact with water. In Hodgkin disease, it may be a presenting symptom.[90] In cutaneous mastocytosis (see Chap. 150), itching occurs locally following rubbing the skin, although it can be widespread in severely affected patients, when it is usually associated with systemic symptoms. Itching may occur in patients with myeloid and lymphatic leukemia and myelodysplasia.

PRURITUS AS A MANIFESTATION OF SOLID MALIGNANT TUMORS (See Chap. 154) Traditionally, the onset of pruritus in a middle-aged or elderly patient with an otherwise normal-looking skin prompts a thorough investigation for underlying systemic causes, including internal neoplasia, although the latter is an uncommon cause. Although pruritus may occasionally be present years before the tumor becomes clinically detectable, even if resources are available, full investigation for a causative solid tumor is probably not worthwhile.[91,92]

PRURITUS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION (See Chap. 189) Itch is an early symptom of human immunodeficiency virus (HIV) disease and may be associated with skin disease or a result of systemic disease (e.g., hepatic, renal, adverse drug reactions, lymphoma, and systemic and skin infections including *Staphylococcus aureus* and *Pityrosporum*). However, it may occur as a primary symptom of HIV.[93] The most common example is eosinophilic folliculitis. Other common types of itch in HIV are insect bite hypersensitivity reaction, pruritic papules other than eosinophilic folliculitis, and itch associated with skin xerosis and lichenoid dermatitis, as well as exacerbation of seborrheic dermatitis and psoriasis.

Psychogenic Itch (See Chap. 103)

Delusions of parasitosis is one of the more challenging types of itch that dermatologists encounter. The patient holds a false belief that they are infested with parasites, although careful inspection reveals no supporting clinical findings. The patient often brings "evidence" in the form of collected fragments, although on examination the material proves to be non-specific debris. The patients often refuse to see a psychiatrist. Delusions of parasitosis is classically treated with typical antipsychotic agents; pimozide is most commonly used by dermatologists. Olanzapine (5 mg/day) is another new option to treat this severe type of psychogenic itch. Localized pruritus in the form of prurigo nodularis or anogenital pruritus could be a manifestation of obsessive compulsive disorders and anxiety. Patients with depression, fibromyalgia, and other somatoform disorders can suffer from severe itch that responds well to selective serotonin reuptake inhibitors (SSRIs).

Miscellaneous Types of Itch

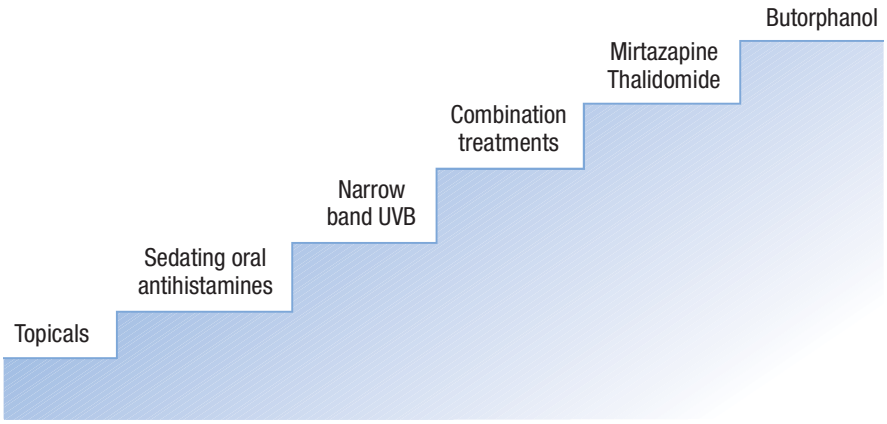
SENESCENT SKIN AND ITCH Itch is the most common dermatologic symptom among people over 65 years of age.[96,97] At least 50 percent of persons aged 70 years or older suffer from prolonged bouts of troublesome pruritus. Idiopathic itch in the elderly, sometimes referred to inappropriately as *senile pruritus*, is common and presents a diagnostic and therapeutic challenge. Itch in senescent skin can result from a variety of causes including dry skin, inflammatory skin diseases such as low-grade eczema and scabies, as well as underlying systemic disease, especially cholestasis and renal failure. Several drugs can induce pruritus without a rash including opioids and angiotensin converting enzyme inhibitors. However, in many instances, no cause is found. Although dry skin is probably the most common associated factor, it may not be the cause of pruritus; many elderly patients have senescent skin without xerosis. Other factors may play important roles, such as age-related changes in nerve fibers and loss of input from pain fibers leading to central disinhibition of itch. Additional skin changes in elderly patients that may contribute to itch include decreased skin surface lipids, decreased clearance of transepidermally absorbed materials from the dermis, decreased sweat and sebum production, and diminished barrier repair.[98]

ITCH ASSOCIATED WITH BURNS AND SCARS (See Chaps. 64 and 94) Burn scars are common in both children and adults and are associated with significant pruritus. Fifteen percent of patients experience persistent pruritus and 44 percent occasional pruritus.[99] Compared to healthy skin, burn-graft skin displays significantly elevated SP nerve fibers as well as significantly elevated thresholds for pinprick, warming, touch, and vibration.[100] Keloids are frequently associated with itch at the periphery of the keloid lesion and less frequently pain in the center of the keloid.[101] These findings probably result from damage to small nerve fibers from traction neuropathy.

AQUAGENIC PRURITUS Originally described by Shelley[102] and subsequently characterized by Greaves et al.,[103] aquagenic pruritus is a rare, intractable pruritus of unknown etiology found mainly in the middle-aged and elderly.[104] Characteristically, local itching without visible skin signs is provoked by contact with water. Notably, aquagenic pruritus can be associated with lymphoproliferative disorders such as polycythemia vera.[89,105]

TREATMENT OF PRURITUS

Unfortunately, there are no general-purpose antipruritic drugs. Treatment of pruritus depends on identifying and removing the cause, whether systemic or



▲ **FIGURE 102-3** Therapeutic ladder for antipruritic therapies. UVB = ultraviolet B.

cutaneous. False hopes of highly effective treatment for those patients in whom no cause can be found should not be raised; there are no systemic or topical antipruritic agents that are both effective and selective with acceptable tolerability.

It is important to elicit a detailed history, including the precise quality, timing, and distribution of the itch, so that more focused therapy can be instituted. The sensation of itching is heightened if the skin is warm,[12,106] therefore measures should be taken to cool the skin down, including tepid showering, light clothes, and air conditioning where appropriate. Cooling lotions, such as calamine lotion or menthol 1%, may help. A general therapeutic ladder for generalized pruritus is presented in Fig. 102-3.

Topical Antipruritic Treatments

There is a lack of controlled studies for most topical antipruritic treatments. Many topical agents are claimed to be effective for pruritus; however, few claims are supported by more than anecdotal evidence. Although capable of relieving pruritus due to inflammatory skin disease, corticosteroids are not intrinsically antipruritic. Antihistamines are only antipruritic if the pruritus is caused by histamine, as in urticaria. However, a number of pharmacologic mechanisms offer promising avenues for treatment of itch. A summary of topical antipruritic treatments is given in Table 102-4.

BARRIER CREAMS AND COMBINATION THERAPIES Emollients and barrier repair creams often reduce pruritus through improved barrier function. They help the stratum corneum to retain water and provide an exogenous barrier to prevent transepidermal water loss. Such barrier creams are often effective treatments for itch associated with dry skin and atopic dermatitis; however, the mechanism of their antipruritic effects are not fully understood. Restoration of the barrier minimizes fissuring and reduces exposure of C nerve fibers. Atopic dermatitis patients treated with ceramide-dominant emollients demonstrate improved transepidermal water loss and overall severity of skin disease. Lipids, occlusives, and humectants also reduce damage to skin by decreasing contact between skin proteins, lipids, and surfactants. Acidifying the stratum corneum may also reduce itch. High pH solutions increase the swelling of the stratum corneum, change lipid rigidity, and increase secretion of serine proteases, suggesting that neutral or acidic pH solutions are less damaging.

TOPICAL SALICYLATES Clinical trials have shown that applying a topical salicylic acid solution to the skin relieves itch. Topical salicylic acid is a common keratolytic agent and may also increase hydration and soften the stratum corneum by decreasing its pH (see Chap. 222). Topical aspirin significantly reduced pruritus in patients with lichen simplex chronicus—a form of localized itch[57]; however, oral salicylates do not relieve pruritus except in polycythemia vera.

TOPICAL IMMUNOMODULATORS (See Chap. 221) Although topical immunomodulators, such as tacrolimus and pimecrolimus, are used primarily for atopic dermatitis, these medications are promising antipruritic treatments in other dermatologic diseases as well. Tacrolimus and pimecrolimus have both been shown to directly affect C nerve fibers.[107]

COOLANTS AND COUNTER-IRRITANTS A distinct subset of sensory neurons may directly sense changes in thermal energy via cutaneous nerve endings via receptors

TABLE 102-4
Topical Antipruritic Treatments

MEDICATION	DOSE	INDICATION	NOTES
Barrier repair creams	N/A	Atopic dermatitis, dry skin	—
Salicylic acid	2%–6%	Lichen simplex chronicus	Stinging
Tacrolimus	0.1% ointment	Atopic eczema, contact dermatitis	Stinging, burning sensation
Pimecrolimus	1% cream	Atopic eczema, contact dermatitis	Stinging, burning sensation
Menthol	1% cream	Patients who respond well to cold showers	Skin irritation
Capsaicin	0.75%–1.0% cream	Neuropathic itch (notalgia paresthetica, postherpetic itch), uremic itch, psoriasis, atopic dermatitis	Poor compliance due to transient burning sensation
Pramoxine	1.0%–2.5%	Facial eczema, atopic eczema	Particularly effective for pruritus of face
Polidocanol	5% urea + 3% polidocanol (laurylmacrogol)	Atopic dermatitis, contact dermatitis, psoriasis, uremic pruritus	—
Doxepin	5% cream	Atopic dermatitis	Drowsiness in 25% of patients; allergic contact dermatitis
Cannabinoids		Atopic dermatitis, uremic pruritus	Combine with a barrier cream

of TRP ion channels. These include vanilloid receptors, such as TRPV1, which respond to warmth and capsaicin. These receptors act synergistically with other receptors involved in itch, such as PAR-2 and SP receptor (Neurokinin 1). These receptors are targets for treatment of itch. Other receptors from the same family include cold receptors, such as TRPM8. Menthol has been used as a symptomatic topical treatment for pruritus for centuries and relieves itch in some patients by activating nerve fibers that transmit a cool sensation. Menthol may reduce itch via TRPM8 receptors in keratinocytes and nerve fibers. Menthol 1 percent cream is popular with patients who have pruritic skin; however, higher concentrations can induce skin irritation.[108] Those patients who report that cold showers and ice relieve their itch tend to respond extremely well to treatment with menthol.

CAPSAICIN Topical capsaicin, the active compound in the chili pepper, causes release of neuropeptides, including SP, from C nerve fibers. The exact mechanism is not fully understood; however, prolonged application of capsaicin to the skin depletes stores of SP, desensitizes neurons, and abolishes pruritus at the site of application. Capsaicin activates the vanilloid receptor TRPV1, which is abundant in the epidermal layer of the skin.[10] Several reports have supported capsaicin's value for localized, chronic pruritic disorders, particularly those of neuropathic origin, including notalgia paresthetica, postherpetic itch, and uremic itch. It has also been proposed for the treatment of pruritus of atopic dermatitis.[109] Unfortunately, compliance is poor because initial application causes an intense, transient burning sensation at application sites; however, this usually resolves after using the medication for a few days or with application of a topical anesthetic.

TOPICAL ANESTHETICS ***Pramoxine.*** Pramoxine is a topical anesthetic that reduces itch, especially when applied to facial areas, by blocking the transmission of nerve impulses. A double-blind study has shown that pramoxine inhibits histamine-induced itch in humans.[110]

Polidocanol. Polidocanol is a non-ionic surfactant with both local anesthetic properties and moisturizing effects. In an open-label study, a combination of 5 percent urea and 3 percent polidocanol (Larylmacrogol) was found to significantly reduce pruritus in patients with atopic dermatitis, contact dermatitis, and psoriasis.[111]

TOPICAL ANTIHISTAMINES Doxepin is a tricyclic antidepressant with potent H_1- and H_2-antihistamine properties and significant atropine-like (anticholinergic) side effects. Doxepin 5 percent cream has been shown to relieve pruritus in patients with atopic dermatitis in a large placebo-controlled, double-blind study.[112] However, percutaneous absorption of doxepin, causing drowsiness, occurs in approximately 25 percent of patients, limiting its usefulness. Allergic contact dermatitis is also a recognized adverse effect.

TOPICAL CANNABINOIDS Uncontrolled trials have shown that topical cannabinoids combined with a barrier cream have an antipruritic effect in patients with atopic dermatitis and uremic pruritus.[113]

FUTURE TOPICAL THERAPIES Although none is currently available, topical drugs that inhibit serine proteases may be an additional mechanism for future antipruritic therapies. Drugs that inhibit NGF and neurotrophin 4 may also have a potential therapeutic role in itch.

Systemic Antipruritic Treatments

ANTIHISTAMINES (See Chap. 230) Pruritus due to histamine is mediated exclusively via H_1 receptors; H_2 antihistamines are ineffective in relieving pruritus. First-generation (classic) H_1 antihistamines have marked sedative and atropine-like (anticholinergic) actions. Second generation (minimal- or low-sedation) H_1 antihistamines have lower lipophilicity and consequently are associated with less drowsiness and other unwanted side effects. Sedative (first-generation) antihistamines are useful in severe chronic urticaria with or without angioedema because they suppress pruritus and alleviate associated anxiety. Hydroxyzine is especially valuable in this context along with doxepin. Second-generation H_1 antihistamines are suitable in the daytime for relief of pruritus due to urticaria; however, the role of these non-sedating antihistamines is limited in other pruritic disorders. A summary of systemic antipruritic treatments is given in Table 102-5.

OPIATE ANTAGONISTS AND AGONIST-ANTAGONISTS As mentioned in Opioids, μ-opioid receptor agonists can cause generalized pruritus.[42,43,45,47] μ-Opioid antagonists, such as naloxone and naltrexone, have been used for the treatment of pruritus associated with cholestasis, uremia, and dermatologic diseases. The efficacy of such opioid antagonists is supported by data from controlled clinical trials.[41,79,81,114–116] Naltrexone was effective in the treatment of some cases of severe, intractable pruritus.[117] However, such μ-antagonists are associated with significant side effects including hepatotoxicity, nausea and vomiting, difficulty sleeping, and reversal of analgesia, among others. κ-Receptor agonists also inhibit μ-receptor effects. In animal models, κ-opioid receptor agonists inhibit pruritus and scratching induced by SP or histamine.[43,44] The novel κ agonist, nalfurafine (TRK-820), has been shown to be effective in treatment of severe uremic pruritus.[46,76] Thus, κ agonists are a promising treatment for severe itch;[46] however, nalfurafine is not commercially available.

Butorphanol is a commercially available opioid agonist-antagonist analgesic with both κ-agonist activity and μ-antagonist activity. Previous studies have found that epidural butorphanol was effective in relieving pruritus associated with epidural morphine.[118,119] Intranasal butorphanol is an effective treatment for many patients with chronic, severe, and intractable pruritus due to systemic diseases and inflammatory skin diseases.[120]

MIRTAZAPINE The oral antidepressant mirtazapine has been shown to relieve itch in some patients.[121,122] Unlike other SSRIs, mirtazapine is a central presynaptic α_2 noradrenergic inhibitor and specific serotonergic antidepressant. Mirtazapine is a safe medication without serious side effects and may be an effective alternative for the treatment of nocturnal pruritus.[122] It has been shown to be effective when used to treat systemic pruritus as well as pruritus of skin inflammations and in particular nocturnal itch using a low dose of 15 mg at night. A randomized, controlled study has shown that paroxetine also significantly reduces itch.[123] Other SSRIs do not appear to reduce itch.

THALIDOMIDE (See Chap. 236) Thalidomide has shown antipruritic efficacy in treatment of inflammatory skin diseases, such as prurigo nodularis, actinic prurigo, eczema, and idiopathic elderly pruritus. Thalidomide has been used for years as an immunomodulatory agent whose spectrum of activity is not fully characterized. The antipruritic activity could be related to several mechanisms, including inhibition of TNF-α synthesis. Although TNF-α does not have any di-

TABLE 102-5
Non-Classical Systemic Antipruritic Treatments

Medication	Dose	Indication	Notes
Doxepin	25–100 mg PO qd	Chronic urticaria	Drowsiness, dry mouth; abrupt withdrawal may cause confusion; should not be co-administered with other antidepressants
Naloxone	0.002 μg/kg/min increased gradually up to 0.2 μg/kg/min over 24 h	Cholestatic pruritus, uremic pruritus	Hepatotoxicity, nausea and vomiting, difficulty sleeping, reversal of analgesia
Naltrexone	12.5–250 mg PO qd	Cholestatic pruritus, uremic pruritus	Hepatotoxicity, nausea and vomiting, difficulty sleeping, reversal of analgesia; contraindicated in patients with liver dysfunction
Butorphanol (intranasal)	1–4 mg inhaled qhs	Intractable pruritus due to systemic and some inflammatory skin disease	Drowsiness, dizziness, nausea and vomiting
Mirtazapine	15 mg PO qhs	Systemic and inflammatory skin disease	Drowsiness, increased weight and appetite, dry mouth
Paroxetine	20 mg PO qd	Generalized pruritus	Insomnia, sexual dysfunction
Thalidomide	100 mg PO qd	Prurigo nodularis, actinic prurigo, postherpetic neuralgia, uremic pruritus, atopic dermatitis, idiopathic elderly pruritus	Teratogenic, peripheral neuropathy, drowsiness
Gabapentin	300–2400 mg PO qd	Neuropathic itch	Drowsiness, constipation

rect pruritogenic effect, it is elevated in many pruritic dermatoses. Thalidomide may also act directly as a peripheral and central nerve depressant. The major adverse effects of thalidomide are peripheral neuropathy and teratogenicity.

GABAPENTIN Gabapentin is a structural analog of the neurotransmitter γ-aminobutyric acid has been used as an anticonvulsant; however, its mechanism of action in the CNS is poorly understood. Studies have shown that gabapentin is effective for treatment of brachioradial pruritus, multiple sclerosis–induced itch, other types of neuropathic itch as well as uremic itch. Gabapentin appears to alter sensation and pruritus associated with itch related to nerve damage in dermatologic and systemic disease. Gabapentin may inhibit central itch pathways, as it does in pain. Pregablin is a new neuropathic pain medication that has a similar structure and function to gabapentin with fewer side effects and can reduce neuropathic itch or alter the sensation of itch in systemic diseases.

Nonpharmacologic Treatments for Itch

PHOTOTHERAPY (See Chap. 238) Phototherapy has been used for more than a decade to treat different types of itch. Recent reports have suggested that narrow band UVB may be as effective for treatment of pruritus as broad-band UVB or psoralen and UVA light. Phototherapy decreases the population density of mast cells by inducing apoptosis, causes peripheral nerve dysfunction, and reduces divalent cations in the skin. Phototherapy is an effective treatment for itch associated with atopic dermatitis, psoriasis, and chronic renal failure. Remissions may last for as long as 18 months.

CUTANEOUS FIELD STIMULATION Cutaneous field stimulation (CFS) is a new technique that electrically stimulates afferent fibers, including nociceptive C fibers. CFS has similarities to transcutaneous electrical nerve stimulation, which activates large myelinated nerve fibers; however, CFS more specifically targets unmyelinated C nerve fibers. CFS may act through endogenous central inhibitory mechanisms that are normally activated by scratching.[124] Long-term CFS appears to be an effective alternative treatment for severe localized pruritus. In patients with localized itching, CFS significantly reduces patient-reported itch and causes degeneration of epidermal nerve fibers.[125] However, CFS is only practical for localized disease.

BEHAVIORAL THERAPY TARGETING THE CENTRAL NERVOUS SYSTEM Stress and other psychogenic factors are important in itch.[126] Several studies have shown that behavioral modification therapy reduces itch intensity and perception. Other possible behavioral interventions include stress reduction and biofeedback.[126]

CHAPTER 103

Psychocutaneous Diseases

Andrea Sandoz
Thomas Koenig
Daniel Kusnir
Francisco A. Tausk

Scientific advances are shedding new light on the understanding and treatment of long-recognized conditions located at the interface of dermatology and psychiatry. Both arising from ectoderm, the skin and the nervous system are connected by more than just their common origins. The skin is one of the major avenues by which we perceive the world, and, in turn, are perceived by it. When these perceptions go awry, great distress may result to the patient, as is the case in delusional parasitosis. When the skin itself is markedly affected by a primary dermatologic condition, psychological sequelae often follow, greatly impacting the patient's self-esteem, confidence, and overall quality of life.

The central nervous system (CNS) can influence the health (both actual and perceived) of other organ systems, including the skin. Psychophysiologic mechanisms for this interaction range from the stress responses mediated by neuroadrenal connections and associated changes in immunologic function, to the systemic and local action of various neuropeptides and neurohormones.[1,2]

CLASSIFICATION OF PSYCHOCUTANEOUS DISEASES

Following the original description of Koblenzer,[3] psychocutaneous diseases can be classified based on their primary etiology as:

- Primary psychiatric disorders, which can present with a variety of symptoms and behaviors, that can lead to perceived or actual dermatologic conditions, or
- Primary dermatologic disorders that can be either triggered or amplified by contextual causes (for example, life circumstances or interpersonal relationships) that may lead to demoralization, anxiety, depression, and distress through their impact on the patient's physical appearance and well-being.

The classification can guide in implementing an effective treatment approach including dermatologic, psychiatric, and contextual aspects of the disease aimed to interrupt the circular reinforcement of pathology.

Role of the Dermatologist

Between 20 percent and 40 percent of patients seeking treatment for skin complaints have some type of psychiatric or psychological problem causing or complicating the presenting symptoms.[4,5] A large number of these patients lack insight into the possible psychogenic origin of their symptoms and are often reluctant to accept any kind of psychiatric referral. Therefore, in the absence of a psychiatry liaison clinic in the dermatologic setting,[6] the dermatologist must be familiar with the most common of these diagnoses, their clinical manifestations (both psychological and dermatologic), and the basic principles of treatment.

When approaching these issues, it is important to explore psychiatric and particularly psychotic symptoms as well as compliance with medications. Collateral informants such as family members can be quite helpful if the patient grants permission. Last but not least, the consequences that the symptoms of the patient have on his or her familial and social life, or both, can be of much assistance in understanding the issues to be to addressed by the dermatologist. Nonpharmacologic therapies can be very useful in the management of these patients (Table 103-1).

PRIMARY PSYCHIATRIC DISORDERS (Table 103-2)

Delusion of Parasitosis

Dermatologic patients occasionally show evidence of monosymptomatic hypochondriacal psychosis,[7] characterized by the presence of delusions and, occasionally, hallucinations. Delusions are fixed, false beliefs that patients hold with unshakable conviction, not endorsed by the larger cultural, ethnic, or religious community. Hallucinations are sensory perceptions that occur without any external stimulus and can occur in any of the five sensory modalities. The most frequent form of this condition seen by dermatologists is delusion of parasitosis (DP),[8] a condition in which patients manifest the circumscribed false belief of being infested with parasites. Because this is frequently the only overt manifestation of the subject's psychosis, these patients most often present to dermatologists and entomologists rather than to psychiatrists.

TABLE 103-1
Nonpharmacologic Treatments

Cognitive-behavioral therapy
Insight-oriented psychotherapy
Hypnosis
Mindfulness-based cognitive therapy
Biofeedback
Family therapy
Behavioral therapy

EPIDEMIOLOGY DP predominates in middle-aged to elderly females with premorbid social isolation. In approximately 12 percent of patients the delusion of infestation is shared or at least endorsed by a family member (*folie à deux*).[9,10]

CLINICAL FINDINGS Patients with DP frequently present to the clinician in an anx-

PSYCHOCUTANEOUS DISEASES AT A GLANCE

- Primarily psychiatric
  - Body dysmorphic disorder, atypical pain/burning, trichotillomania, delusional, or factitious disorders.
  - Affecting approximately 5 percent of dermatology patients.
  - Variable degree of insight, mostly poor.
  - Mostly self-induced lesions.
  - Poor prognosis if untreated.
- Primarily dermatologic
  - Secondary emotional component (stress, depression, and other co-morbidities).
  - Affects approximately 30 percent of dermatologic patients.
  - Good insight.
  - Stress exacerbates pre-existing diseases (such as psoriasis and eczema).
  - Distress produced by pre-existing skin disease leads to psychiatric manifestations such as anxiety and depression.

TABLE 103-2
Psychocutaneous Diseases

	Disease Entity	Patient Insight (0 to ++++)	Treatment of Choice
Primary psychiatric diseases	Delusion of parasitosis	0	AAP.
	Dysesthesias/formication (illusion of parasitosis) (nondelusional dysesthesias)	++	Antidepressants, anxiolytics + NPT, eventually add AAP/G.
	Body dysmorphic disorder	0 to +	High-dose antidepressants.
	Self-induced disorders		Antidepressants + NPT.
	Dermatitis artefacta	0 to +	May need the addition of low-dose atypical antipsychotics. Doxepin and mirtazapine are useful if severe pruritus present.
	Trichotillomania	Variable: 0 to ++	
	Neurotic excoriations	+++ to ++++	
	Atypical pain/burn	++++	NPT + antidepressants.
Primary dermatologic diseases	Eczema, psoriasis, urticaria, vitiligo, seborrheic dermatitis, etc.	++++	Antidepressants, NPT, anxiolytics.

AAP/G = atypical anti-psychotics and/or gabapentin; NPT = nonpharmacologic treatment; 0 to ++++ = none to complete awareness.

ious, ruminative, overwhelmed state, with a history of visits to multiple physicians without satisfaction. In addition to proffering a long and detailed history that includes visual or tactile hallucinations of the organisms, the patient also frequently provides "evidence" of the parasitic infection in the form of clothing lint, skin crusts, or other debris that are delusionally misinterpreted as entire organisms, body parts, larvae, or ova. Skin manifestations can be quite variable, if present. Oftentimes they reflect unsuccessful attempts at treating the infestation, resulting in lesions ranging between mild excoriations to large ulcers,[11] including the damage from "topical" treatments undertaken by the patient in an attempt to free themselves of the perceived infestation.[3] Because this is a monosymptomatic delusional disorder, some patients have a well-organized train of thought and typical outward appearance, resulting in the conviction by those surrounding them that the subject has a true infestation. The delusion becomes apparent to the physician when the subject is approached.

DIFFERENTIAL DIAGNOSIS Actual infestation must be ruled out (see Section 33). Subsequently, the differential diagnosis of psychosis must be parsed through, distinguishing between the primary psychiatric conditions that manifest with delusions of infestation. True monosymptomatic hypochondriasis represents a form of delusional disorder characterized by a rather discrete, circumscribed delusional belief with possible associated hallucinations without clear syndromic changes in affect or personality.[12] On the contrary, patients with uni- or bipolar depressive psychosis describe predominantly classic changes in mood, motivations, sleep, and appetite, along with feelings of hopelessness, helplessness, and worthlessness. Schizophrenic patients may have a history of previous psychotic episodes and often show a deterioration in global functioning, impaired social relatedness, thought disorder, paranoid traits, and more bizarre delusions and hallucinations extended often to other areas of their perception beyond the skin symptoms. In arriving at the diagnosis of DP it is critical that the clinician differentiate true DP from formication, a disorder which involves the cutaneous sensation of crawling, biting, and stinging, lacking the fixed unshakable conception that the skin sensations are induced by parasites. These patients, on occasion, attribute their sensory misinterpretations to infestations, and may be considered as having illusions of parasitosis.

PROGNOSIS AND CLINICAL COURSE Although often regarded as chronic, unremitting, and difficult to treat, these patients have an improved recovery rate after appropriate pharmacologic therapy.

TREATMENT The critical tenet of treatment is to keep the patient engaged. Empathetic listening, expressing concern about how the problem is affecting his or her life and examining the material that the patient brings in helps to establish a trustful relationship.[13] Because these patients frequently reject psychiatric referrals,[14] various authors have suggested means by which patients can be retained in treatment paving the road leading to the psychiatric referral.[14,15] Targeted therapy is undertaken with antipsychotic medications. Pimozide has been used historically as the drug of choice,[11] although it is now replaced by atypical antipsychotics such as olanzapine, aripiprazole, and risperidone, which are associated with a more favorable neurologic side-effect profile.[16–19] However, the clinician needs to be aware of the need for monitoring for metabolic syndrome characterized by abdominal obesity, insulin resistance and impaired glucose tolerance, disturbance in lipid metabolism, hypertension, and very significant weight gain.[7,20]

Body Dysmorphic Disorder

Body dysmorphic disorder (BDD) is a condition characterized by an excessive preoccupation or concern with a presumed defect in physical appearance despite normal or only minimally objective anomalous findings.[21] Also known as *dysmorphophobia*,[22,23] this is a psychological experience that also results in functional impairment in various arenas of the patient's life.[12] BDD's chronicity is particularly problematic because these individuals have unusually poor functional quality of life and treatment response.

The nosologic classification of BDD revolves around the intensity with which patients hold on to their abnormal beliefs. Those with unshakable convictions are currently diagnosed as having a delusional disorder.[12] However, there appears to be a continuum of intensity and insight from preoccupations, through overvalued ideas, to clear delusions.[8,24–26] The evidence linking BDD to the obsessive-compulsive spectrum of disorders has significant potential treatment implications.[27,28] BDD patients have obsessive thoughts about their "flaws" and engage in compulsive behaviors related to how they perceive their appearance, similar to behavior seen in obsessive-compulsive disorder (OCD). BDD often causes great distress and disability and is commonly accompanied by depression and suicidality. Seventy percent of patients report a his-

tory of suicidal ideation attributed primarily to BDD, and 22 percent to 24 percent have attempted suicide.

EPIDEMIOLOGY The prevalence of BDD is estimated to be from 1 percent in the general population to 12 percent in dermatology clinic patients,[29,30] often in association with mood disorders such as major depressive disorder (37 percent), phobia (33 percent), and OCD (26 percent).[31,32] Improvement of major depressive disorder and BDD seems to be closely related, with the improvement of each disorder significantly predicting the remission of the other. Improvement of OCD significantly predicts remission of BDD, but not vice versa.

CLINICAL FINDINGS Patients present with intensely articulated distress about various body parts. Most patients also develop ideas of reference in which they think or are convinced that others notice and comment upon the presumed defect.[31,33,34] Frequently compulsive behaviors often accompany the worrisome thoughts, consuming hours each day, including repeated examination in mirrors, covering up the defect and asking others for reassurance. Consultations with other physicians are common and a history of past operations on the perceived defect is seen in a significant proportion of patients.[35] Marked restriction in social and occupational functioning is seen in up to 98 percent of individuals and 30 percent of patients were described as housebound.[31,36] Thoughts and attempts of suicide, occasionally successful, are frequent. Current or past suicidal ideation should thus be routinely assessed by the practitioner. Particular monitoring may be needed with younger patients as antidepressant action increases impulsivity and likelihood of suicidal attempts.[24,31,37–39]

TREATMENT As noted before, many patients with BDD seek dermatologic, surgical, or other nonpsychiatric treatment over the course of their illness. Evidence suggests that if patients receive such treatment they do not improve, are usually disappointed with the results,[35] and may even experience an exacerbation of their symptoms.[36] Thus, it is strongly recommended that these lines of treatment be avoided. BDD is a severe and complex disorder that often requires multimodal treatment using cognitive behavioral therapy, exposure response prevention, and medication.

Pharmacologic trials show a good response to selective serotonin reuptake inhibitors (SSRIs), decreasing distress, compulsions, and frequency and intensity of obsessions about perceived defects; they also improve insight. Interestingly, SSRIs appear equally effective for delusional as well as nondelusional patients. Relatively high dosages are usually necessary for 12 to 16 weeks for a therapeutic effect, with close monitoring of side effects. Issues of compliance require close monitoring, because they are a frequent cause of treatment failure. A significant proportion of patients who fail one adequate SSRI trial respond favorably to a trial with another one, suggesting that serial trials of similarly acting agents should be administered in initially refractory cases. Lack of clear success has been noted with other agents, such as antipsychotics (including pimozide), tricyclic antidepressants (other than clomipramine), benzodiazepines, and anticonvulsants.[24,27,28,31,34,36,40–45]

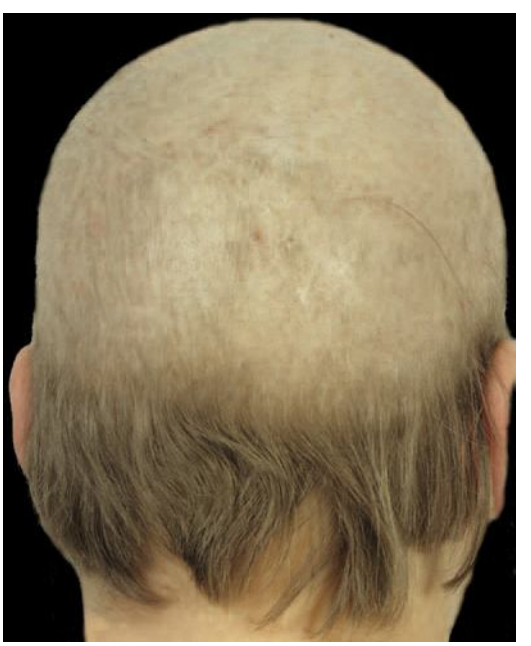
PROGNOSIS AND CLINICAL COURSE BDD is a chronic illness without clear evidence for spontaneous remission without treatment. As seen in Treatment, pharmacotherapy with appropriate medications may lead to improvement in a considerable number of patients. However, we want to reiterate that effective high doses of SSRIs required are usually beyond than those approved by the U.S. Food and Drug Administration; the data also suggest that recurrence rates are extremely high with discontinuation of treatment,[31,40] and thus patients may require long-term treatment, which should also include insight-oriented psychotherapy.

Self-Inflicted Dermatoses

TRICHOTILLOMANIA Trichotillomania is currently classified as an impulse control disorder[12] characterized by repetitive pulling of hair, resulting in alopecia. Strict criteria also include a buildup of tension before hair pulling or when resisting an urge to do so, pleasure or relief after pulling out the hair, and significant functional impairment and distress in the patient.

Epidemiology. Prevalence rates are estimated to be between 0.5 percent and 3.5 percent, with a mean age of onset between 10 and 13 years of age. Despite its current classification, there are marked similarities with OCD, which may have important treatment implications. Co-morbid psychiatric disorders are depression, anxiety, and OCD.[46–51]

Clinical Findings. (Fig. 103-1) Trichotillomania presents clinically with nonscarring alopecia, most commonly with hairs broken at different lengths; occasionally, repeated trauma may ultimately result in some scarring. Body areas involved typically include the scalp, eyelashes, eyebrows, and pubic hair, with a majority of patients pulling hair from more than one site.[46,52] Rarely, this is followed by the ingestion of the hair,[46] leading to the potentially dangerous complication of trichobezoar.[53] Awareness of the behavior is partial to complete in a vast majority of patients,[52] and frequently occurs while patients are engaged in isolated, sedentary activities.[46,54] Attempts to resist the behavior and to disguise its cosmetic sequelae are common.[46,51] Typical histo-



◀ **FIGURE 103-1** Trichotillomania. Hairs broken off at different lengths.

pathologic findings that may be helpful in confirming the diagnosis in questionable cases include catagen hairs, pigment casts, and traumatized hair bulbs without significant inflammation or scarring.[55,56]

Treatment. Because of trichotillomania's similarities to OCD, the use of SSRIs and clomipramine has received much attention. Successful monotherapy with paroxetine, sertraline, fluoxetine, citalopram, escitalopram, venlafaxine, olanzapine, and clomipramine have been reported, as well as the augmentation of SSRIs with the addition of olanzapine, risperidone, or pimozide. Low-dose atypical antipsychotic agents in combination with SSRIs appear to have promising results.[52,57–68] Nonpharmacologic treatment of trichotillomania relies heavily on behavioral therapies, especially habit reversal,[69,70] which entails engaging the patient in a behavior incompatible with hair pulling when the urge appears. The addition of cognitive-behavioral[71] or insight-oriented psychotherapy have good results; hypnotherapy may also be very useful, particularly in children.[72]

Prognosis and Clinical Course. Trichotillomania is a chronic disorder, and data on long-term success of pharmacologic and psychotherapeutic interventions are inconclusive. Although short-term success occurs, sustained improvement has yet to be shown convincingly.[73]

DERMATITIS ARTEFACTA Dermatitis artefacta is a form of factitious disorder in which patients intentionally feign symptoms and produce signs of disease in an attempt to assume the patient role. Unlike patients with malingering who engage in similar behavior for external or "secondary gain" (such as monetary reward or relief from occupational or other social responsibilities), the factitious patient seeks the "primary gain" of the emotional and psychological benefits that accrue to those who are "ill." Patients with borderline personality disorder also frequently exhibit self-mutilation behavior. Occasionally, a psychologically disturbed adult induces skin lesions in their children,[74,75] a form of Münchausen syndrome by proxy.

Epidemiology. Predominating in females, the age of onset varies significantly from adolescence through adulthood.[76] Comorbid depressive and personality disorders may also be seen.

Clinical Findings. (Fig. 103-2) Although it has long been observed that patients with dermatitis artefacta may present with lesions in virtually all areas of the body that can mimic most dermatoses,[77] some common elements may hint at this diagnosis. Lesions are often in areas readily accessible to the patient,[78] and may have geometric patterns or angulated borders surrounded by completely healthy skin. Morphology is often bizarre and does not conform to typical presentations of known dermatoses (Fig. 103-3). Patients are often unable to provide a clear history of the initial appearance or evolution of the process, and typically deny any role in the production of the lesions. Characteristically, the histopathology is unrevealing.

◀ **FIGURE 103-2** Dermatitis artefacta. Linear, sharply bordered ulcer.

Differential Diagnosis. As in all cases of factitious disease, the clinician must rule out possible disease entities that are consistent with the history and clinical findings. Unusual presentations of common illnesses and rare conditions must be entertained. However, exhaustive searches for primary skin pathology without supporting clinical evidence may compound the problem and actually perpetuate the patient's factitious behavior. Occlusive dressings (e.g., Unna's boot) or other means of preventing manipulation by the patient lead to healing of the lesions and are often helpful strategies in clarifying the diagnosis.

Treatment. A supportive, nonconfrontational, empathic approach to the patient is indicated initially. Immediate confrontation regarding the suspicion that the patient's lesions are self-induced can be counterproductive in that the patient often flees from treatment at that point. Frequent visits and symptomatic topical treatments are useful in the beginning.[79] However, the clinician must be careful not to collude in the patient's abnormal illness behavior and, ultimately, the recognition of the patient's role in the production of the lesions must be broached. The goal is to establish a trusting and supportive enough relationship with the patient that he or she accepts a psychiatric referral to explore the complex personality and behavioral derangements that often underlie this condition. Antidepressants and low-dose atypical anti-

◀ **FIGURE 103-3** Dermatitis artefacta. Solitary ulcer on dorsum of hand; tendons are visible at the base.

psychotics have also been reported to be useful adjunctive therapies.[80,81] In the case of Münchausen syndrome by proxy, in which the lesions are induced in children by parents or other caregivers, child protective services or equivalent agencies must be alerted immediately to safeguard the welfare of the child.

Course and Prognosis. Course and prognosis are fundamentally determined by the underlying psychopathology. In those patients with severely disturbed personalities, the recurrent self-defeating and destructive behaviors are likely to continue.[82]

NEUROTIC EXCORIATIONS Neurotic excoriation is also a condition in which patients induce skin lesions through repetitive, compulsive excoriation of their skin. However, unlike patients with dermatitis artefacta, these patients admit their role in the production of the lesions. This condition seems to be associated with underlying obsessive-compulsive personality traits and depressive disorders.[83,84]

Epidemiology. Neurotic excoriations have been reported in up to 2 percent of dermatology clinic patients,[85] with a predominance in middle-aged females, and is frequently associated with obsessive-compulsive personality and mood disorders.[86]

Clinical Findings. Patients with neurotic excoriation often describe significant itch leading to persistent scratching, which is frequently antedated by considerable psychological stressors. The development of this disorder has also been noted to be associated with the marked limitation in activity seen in illness or senescence.[87] The repeated excoriation can lead to the development of an "itch-scratch cycle," perpetuating the behavior. Patients present with multiple excoriations in various stages of evolution and healing, with postinflammatory hyperpigmentation, and frequent scarring (Fig. 103-4). The distribution of the lesions reflects their self-inflicted nature with most being on the extensor surfaces of the extremities, upper back, and face, sparing unreachable areas. Frequently, patients develop neurotic excoriations overlying pre-existing dermatosis, such as folliculitis and acne (acne excoriée). Prurigo nodularis[88] can be considered an extreme variant of this entity, characterized by severely pruritic nodules that may vary from a few millimeters to 1 to 2 cm in diameter, preferentially located on the lower extremities. Up to 58 percent of these patients have been found to have significant depressive disorder, and 45 percent co-morbid OCD.

▲ **FIGURE 103-4** Neurotic excoriations. Lesions present in all stages of evolution.

Differential Diagnosis. The clinician must evaluate the patient for causes of pruritus (see Chap. 102) and rule out possible internal diseases including neoplasms, in particular, lymphomas. The differential for the underlying psychiatric disorder, if present, must include depressive and anxiety disorders and, more rarely, excoriations secondary to DP.

Treatment. Workup for pruritus should be instituted in those patients with significant itch. In the absence of organic cause, these patients may improve with phototherapy. Additional treatment should be directed at underlying psychopathology when identifiable. Antidepressants, helpful in both depressive and anxiety disorders, including OCD, are very useful.[89] Subsequent addition of low-dose atypical antipsychotics, such as olanzapine, have been found effective. Supportive psychotherapeutic approaches are usually helpful and well tolerated,[83] and behavioral interventions similar to those used to treat self-injurious behaviors in Tourette syndrome may be useful.[90]

Course and Prognosis. Neurotic excoriation can be a chronic condition whose prognosis[83] depends on the underlying psychiatric illness. With appropriate therapy, patients with affective and anxiety disorders may have excellent outcomes, with a symptom-free, normally functioning state.

ATYPICAL CHRONIC PAIN/BURN SYNDROME Occasionally, patients present to dermatologists with complaints of burning, pain, or dysesthesias in the skin or mucus membranes for which no identifiable pathology can be found. This can be a frustrating situation for patient and clinician alike. A psychiatric approach to these patients may offer a means of understanding the complex factors underlying this syndrome, such as co-morbid affective disorders, personality vulnerabilities, behavioral problems, and life circumstances that may perpetuate the pain cycle and maintain the patient in an illness role.

There is a significantly increased rate of depression in patients with chronic pain syndromes[91] and a clear relationship between lifetime depression and the development of medically unexplained symptoms, including pain.[92] Depression not only worsens the experience of pain by psychologically magnifying negative perceptions, but may also interfere with the function of descending monoaminergic neurons that dampen nociceptive transmission.[93,94] This could explain the role for tricyclic antidepressants in analgesia. Other complicating factors include anxiety, which is also commonly seen in patients with chronic pain.[92,95] Personality disorders influence all aspects of patients' lives and may make the burden of a chronic condition more challenging to bear. At times, family or social environments may unwittingly play a role in undermining the chronic pain patient's rehabilitation by rewarding illness behaviors with well-meaning, yet oversolicitous, attention. Pain states can further be complicated if the patient develops an inappropriate pattern of using prescribed analgesics. For all of these reasons, the best course of action for patients presenting with poorly explained chronic pain is to refer them to a multidisciplinary pain center where thorough evaluation and treatment can be under-

TABLE 103-3
Antipsychotics: Typical and Atypical[a]

Drug	Dose (mg/day)	Most Common/Serious Side Effects					
		EPS	NMS	Metabolic Syndrome	Seizures (at High Doses)	Cardiac	Other[b]
Clozapine (Clozaril)[c]	25–900	±[d]	±	++	+	Myocarditis, hypotension	Severe agranulocytosis[e]
Olanzapine (Zyprexa)[c]	2.5–10.0	±[d]	±	++++	+	Hypotension	Dizziness
Risperidone (Risperdal)[c]	0.25–8.00	±[d]	±	+++	+	Hypotension	Hyperprolactinemia Dizziness
Quetiapine (Seroquel)[c]	25–400	±[d]	±	+++	+	Hypotension	Cataracts
Ziprasidone (Geodon)[c]	20–80	±[d]	±	++	+	Arrhythmia, prolonged QT, hypotension	
Aripiprazole (Abilify)[c]	2.5–30.0	±[d]	±	++	+	Hypotension	Headache
Pimozide (Orap) (typical antipsychotic)	1–10	+++	+++	–	++	++ Arrhythmia prolonged QT, ++ hypotension	

EPS = extrapyramidal symptoms (including dystonia, akathisia, rigidity, tardive dyskinesia); NMS = neuroleptic malignant syndrome; ± = very rare occurrence; – = not seen; + to ++++ = rare to very likely to occur.
[a]Important: The antipsychotics have to be titrated slowly, starting at the lowest possible dose.
[b]All antipsychotics have been associated with early death in the elderly (thromboembolism).
[c]Atypical antipsychotics.
[d]Although rare with atypical antipsychotics, can be seen in the young and elderly (particularly with risperidone).
[e]The possibility of life-threatening agranulocytosis requires close monitoring.

taken. The presence of burn syndrome may occasionally respond to the administration of gabapentin. Awaiting U.S. Food and Drug Administration approval, milnacipran is considered a serotonin/norepinephrine reuptake inhibitor (SNRI) of choice for chronic pain/burn/dysesthesia syndrome. Extreme forms of chronic dysesthesia can resolve with the administration of antipsychotic medication, suggesting that it represents a form of delusion.

PSYCHOGENIC PRURITUS Psychogenic pruritus and itch in general are discussed in Chap. 102.

PSYCHOTROPIC MEDICATIONS USED IN DERMATOLOGY

Dermatologists who elect to treat psychocutaneous disorders routinely use a number of different classes of psychotropic medications. Knowledge of the drugs and their actions, indications, side effects, therapeutic doses, and potential drug interactions is, therefore, critical.[96–102]

These drugs are classified according to their clinical utility (e.g., antidepressants or antipsychotics) and further identified by their chemical structure and/or mechanism of action. All of the drugs discussed in this section exert their clinical effects through modulation of neurotransmitter function in the CNS by altering presynaptic reuptake of the transmitters, blocking their pre- and/or postsynaptic receptor binding, stimulating those receptors, or some combination thereof. The most appropriately used in each of the following three major classes are discussed: antipsychotics, antidepressants, and anxiolytics.

Antipsychotics (Table 103-3)

Antipsychotics have a wide variety of uses in psychiatry, but their primary indication in psychocutaneous medicine is in the symptomatic treatment of disorders characterized by delusions and/or hallucinations. The most common indications in dermatology are DP and, less frequently, for the treatment of self-induced dermatoses.[80] The drugs are believed to exert their beneficial effects by the blockade of postsynaptic dopamine receptors in the CNS. Dopaminergic tracts in the mesolimbic and mesocortical systems are felt to be the most important with regard to the production of symptoms of psychotic illness. However, dopamine is found widely throughout the brain and its blockade in the nigrostriatal and tuberoinfundibular pathways can lead to significant side effects.

Antipsychotics are now classified as typical (or conventional) and atypical. The older, typical antipsychotics are potent, nonspecific blockers of postsynaptic D_2 dopamine receptors and have varying degrees of inherent anticholinergic activity. The newer atypical antipsychotics have different affinities for dopamine receptors subtypes and serotonergic blocking properties at the serotonin-2 (5-HT2) receptor. This combination allows a continued potent antipsychotic effect but with a much more preferable neurologic side-effect profile because of decreased interference with dopamine transmission in the basal ganglia. The advantages of these over typical antipsychotics include reduced risk of extrapyramidal symptoms, enhanced efficacy in treatment of cognitive and executive dysfunctions, and mood stabilizing/elevating effects. The disadvantages include significant cost and the development of metabolic syndrome.

COMPLICATIONS The most dramatic complications of the typical antipsychotics, including pimozide, are neurologic. They are divided into acute and delayed. The acute neurologic side effects (also known as *extrapyramidal symptoms*) are a result of dopaminergic blockade in the striatum causing (1) dystonias (acute increases in tone and abnormal posturing, typically involving muscles of the face, neck, tongue, and pharynx), (2) parkinsonism (with tremor, gait disturbance, stiffness, cogwheeling rigidity, marked facies, and general bradykinesia), and (3) akathisia (an experience of marked restlessness in the muscles that should be distinguished from psychic anxiety or agitation). These acute neurologic side effects are best managed by co-administration of an anticholinergic medication such as benztropine (Cogentin), 0.5 to 2.0 mg twice

daily, or diphenhydramine, 75 to 100 mg orally. In severe acute dystonia, which is most likely to occur within the first week of treatment, patients may develop muscular rigidity and cramping in the neck, tongue, face, and back, occasionally with dysphagia. Muscular cramps can cause joint dislocation and, most dangerously, laryngeal dystonia with compromise of the airway. Benztropine, 2 mg intramuscularly (IM) or intravenously (IV), or diphenhydramine, 50 mg IM or IV, often provides relief. If there is no effect, the dose can be repeated in 20 minutes. If the dystonia is still unresponsive, lorazepam, 1 mg IM/IV, may be of benefit. In laryngeal dystonia, doses may need to be IV and repeated in 10 minutes.

The most worrisome delayed side effect of antipsychotic treatment is tardive dyskinesia (TD), characterized by repetitive purposeless movements that usually involve the lips, tongue, face, and upper extremities. It is rare in patients with fewer than 6 months of treatment. Risk factors for the development of TD may include older age, female gender, and the presence of affective disorder.[83] Treatment of TD includes decrease or discontinuation of the antipsychotic if the underlying psychiatric illness allows and stopping anticholinergic medications; administration of benzodiazepines is also helpful. Quetiapine has been reported to decrease and sometimes reverse TD.

Nonneurologic side effects of antipsychotics include sedation, galactorrhea, and effects on cardiac conduction. Because of pimozide's, ziprasidone's, and aripiprazole's effect on the repolarization phase, prolongation of the QT interval is possible, which is a potential risk factor for the development of fatal ventricular tachyarrhythmias. Therefore, electrocardiograms should be obtained for all patients at baseline and after dose changes. In those patients with existing QTc prolongation or in those patients who develop it during treatment, the drug should be discontinued.

Finally, neuroleptic malignant syndrome, characterized by fever, autonomic instability, diffuse increase in muscle tone, mental status changes, rhabdomyolysis, and renal failure, is fortunately rare but potentially fatal complication of antipsychotic treatment (Table 103-4). This can occur at any time during treatment, but is more common during the first few weeks or months, or during rapid dose increases. Patients presenting with such features should be referred for emergent evaluation.

TABLE 103-4
Neuroleptic Malignant Syndrome

- Incidence of 0.2%
- Rare with atypical antipsychotics
- More frequent with high doses or rapid titration of neuroleptics
- Diagnostic criteria
  - Hyperthermia [body temperature > 38°C (100.4°F)]
  - Muscle rigidity
  - Change in mental status
  - Elevated creatine phosphokinase
  - Diaphoresis
  - Tachycardia
- Requires emergent evaluation

The more modern atypical antipsychotics have more acceptable side-effect profiles and are associated with a much smaller risk of extrapyramidal symptoms. All the drugs in this group may induce a metabolic syndrome characterized principally by abdominal obesity and insulin resistance or glucose intolerance. A thorough discussion of these risks should take place with the patient before initiating treatment. Baseline and follow-up laboratory tests should include complete blood cell count with platelet count, urinalysis, liver function tests, fasting glucose, and a lipid panel, in addition to regular measurements of weight. Incidences of cardiac, neurologic, and other side effects are summarized in Table 103-5. Finally, the following precautions should be considered in the use of antipsychotic medications:

History: Personal and family history of obesity, cardiovascular disease (particularly conduction hypertension), diabetes, and dyslipidemia.

Baseline and subsequent follow up: Weight, body mass index, waist circumference (umbilical level), blood pressure, fasting plasma glucose, lipid profile, and prolactin levels. Initially monthly and subsequently quarterly.

Consider additional interventions, referral, or change in treatment if: Significant changes in weight (>5 percent), body mass index (>25), hypertension, diabetes, lipid profile, or prolactin problems occur.

Antidepressants (See Table 103-5)

A wide array of antidepressant options currently exists, including tricyclic antidepressants, SSRIs, SNRIs (duloxetine,

TABLE 103-5
Antidepressants

Mechanism of Action/ Chemical Structure	Drug	Dose[a] (mg/day)	Side Effects
Serotonin reuptake inhibitors	Citalopram (Celexa) Escitalopram (Lexapro) Fluoxetine (Prozac) Fluvoxamine (Luvox) Paroxetine (Paxil) Sertraline (Zoloft)	10–40 10–30 10–80 100–300 20–60 50–200	Anxiety, irritability, increased suicide rates, akathisia, sexual dysfunction, hypomania/ mania, agitation, weight gain.
Norepinephrine-serotonin reuptake inhibitors	Venlafaxine (Effexor) Duloxetine (Cymbalta) Milnacipran[b]	37.5–225.0 20–60 25–100	Hypertension, tachycardia, anxiety, nausea, sexual dysfunction.
Norepinephrine-dopamine reuptake inhibitors	Bupropion (Wellbutrin)	100–450	Seizures. Avoid in patients with convulsive history, eating disorders, or alcohol withdrawal.
Blockage of presynaptic reuptake of monoamines: tricyclics	Amitriptyline (Elavil) Nortriptyline (Aventyl) Clomipramine (Anafranil) Doxepin (Sinequan)	25–150 50–150 75–250 50–300	Arrhythmias, hypertension, orthostatic hypotension, dry mouth, constipation, sexual dysfunction, sedation; avoid in glaucoma.
Presynaptic α-2, 5-HT2c/5-HT3 antagonist	Mirtazapine (Remeron)	15–45	Agranulocytosis, weight gain, dizziness.

5-HT = serotonin.
[a]These doses include minimal to maximal dose. Some of the latter may be higher than recommended by the U.S. Food and Drug Administration (FDA), but may be required for effectiveness.
[b]Milnacipran, still awaiting FDA approval, appears particularly indicated for patients with atypical pain syndrome and fibromyalgia. **All antidepressants have increased risk of suicide.**

venlafaxine, milnacipran), norepinephrine/dopamine reuptake inhibitor (bupropion), monoamine oxidase inhibitors (phenelzine, tranylcypromine, isocarboxazid, and, more recently, a safer transdermal version of selegiline), and others (presynaptic α2 blockade, 5-HT2A, 5-HT2C, and 5-HT3 antagonist: mirtazapine). In dermatology, these drugs are used to treat affective disorders such as major depression, anxiety disorders, and obsessive-compulsive spectrum disorders such as trichotillomania and BDD. This section discusses the classes most frequently used by dermatologists: tricyclics and SSRIs.

TRYCYCLIC ANTIDEPRESSANTS The tricyclic antidepressants are agents that block the presynaptic reuptake of monoamines from the synapse in the CNS. Thus, norepinephrinergic and serotonergic transmission is potentiated. Most agents in this class block this reuptake rather nonspecifically, although the drug clomipramine acts most prominently on 5-HT reuptake, which underlies its special utility in the treatment of some OCDs.

The tricyclic doxepin has found frequent use in dermatology (perhaps even more than psychiatry currently) because of its potent antihistaminergic properties in addition to its antidepressant effects. In those patients with anxious depressions in whom pruritus is a significant co-morbid dermatologic symptom, this may be the antidepressant of choice.

Dosing. In general, low initial dosing with gradual titration to therapeutic levels is advised. As most are sedating, bedtime dosing is recommended. An advantage of this class of antidepressants is that serum levels are readily obtainable and can aid in the choice of appropriate daily doses. Because individual metabolism of these compounds varies radically, objective evidence of actual blood levels is quite helpful. These levels can inform the clinician about toxicity, patient compliance, and subtherapeutic dosing, major factors that must be considered when the treatment regimen is unsuccessful.

Complications. The tricyclic antidepressants not only affect monoaminergic transmission in the CNS, but also have varying degrees of anticholinergic, antihistaminergic, and peripheral anti–α_1-adrenergic properties that can lead to significant side effects, including constipation, dry mouth, urinary retention, precipitation of an attack of narrow-angle glaucoma, sedation, and orthostatic hypotension. Orthostatic pulse and blood pressure measurements should be documented in the record for all patients receiving tricyclic antidepressants. These drugs can also lead to significant alteration in the repolarization phase of cardiac conduction, increasing the risk for ventricular tachyarrhythmias. A baseline electrocardiogram should be obtained in all patients. Tricyclics should not be used in those patients with significant prolongation of the QTc interval, left bundle-branch block, or bifascicular block. They also cause tachycardia as a result of a reflex increase secondary to orthostatic hypotension and a general decrease in vagal tone to the heart. They may also induce seizures.

Like all antidepressants, the tricyclics have the potential to precipitate an episode of mania or hypomania if used in patients with bipolar affective disorder. These patients should be screened for such a history before initiating therapy and referred to a psychiatrist who can follow the patient closely for signs of an emerging manic episode. Tricyclics are also potentially fatal in overdose; therefore, patients who express suicidal ideations are best treated by a psychiatrist.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS As their name implies, SSRIs selectively block the reuptake of 5-HT into the presynpatic nerve terminal. Effective antidepressants, they are also very valuable agents in the treatment of anxiety and OCDs.

Dosing. Table 103-5 lists the usual dose ranges for SSRIs. For obsessive-compulsive spectrum disorders, higher doses of these agents may be required for clinical effect.

Complications. These are generally well-tolerated medications, even in the geriatric population. Unlike tricyclics, most of these drugs are somewhat stimulating and morning dosing is the rule. Decreased appetite, insomnia, akathisia, nausea, and diarrhea (due to 5-HT's action on gut motility) are fairly common. These are typically seen on initiation of therapy or after dose changes, and often disappear with continued treatment. Approximately 30 percent of patients experience sexual dysfunction, with decreased libido and orgasmic delay or anorgasmia being seen in both sexes. Similar to the tricyclics, SSRIs can lead to manic episodes in bipolar patients. They may actually be more likely to cause rapid cycling in which the patient experiences several depressive and manic swings in a relatively short period of time. The SSRIs are relatively safe in overdose. Because of their lack of effect on the myocardium and minimal, if any, impact on seizure threshold, they do not have the same risks as tricyclics. However, because they can be somewhat activating, patients with suicidal ideation treated with SSRIs should be followed extremely closely as energy may return before the dysphoria and suicidal wishes disappear. One rare, however life-threatening, side effect while on SSRIs includes the serotonin syndrome. This is a hypermetabolic state resulting from serotonergic excess with symptoms consisting of: disorientation, confusion, agitation, tremor, myoclonus, hyperreflexia, twitching, shivering, ataxia, hyperactivity, and hyperthermia.

These drugs also inhibit subtypes of the cytochrome P_{450} system; therefore, other drugs metabolized by this pathway are subject to significant alterations in serum levels. Dose adjustment and careful monitoring are important when coadministering such medications. When discontinuing SSRIs after prolonged use, it is important to gradually taper them to avoid withdrawal symptoms (somatic symptoms: dizziness, lethargy, nausea, vomiting, diarrhea, headache, fever, sweating, chills, malaise, incoordination, insomnia, and vivid dreams; neurologic symptoms: myalgia, paresthesia, and dyskinesias; psychological symptoms: anxiety, agitation, crying, irritability, confusion, impulsivity, disorientation, hypomania, and depersonalization).

SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS SNRIs now comprise three medications: venlafaxine, duloxetine, and, more recently, milnacipran. They block the reuptake of both 5-HT and norepinephrine with differing selectivity. Whereas milnacipran blocks 5-HT and norepinephrine reuptake with equal affinity, duloxetine has a 10-fold selectivity for 5-HT, and venlafaxine has a 30-fold selectivity for 5-HT. All three SNRIs are efficacious in treating a variety of anxiety disorders, and all three seem to be helpful in relieving chronic pain associated with or independent of depression, whereas SSRIs are generally less effective. Tolerability of an SNRI at therapeutic doses varies within the class; venlafaxine seems to be the least well tolerated, combining serotonergic adverse effects (nausea, sexual dysfunction, withdrawal problems) with a dose-dependent hypertension. Duloxetine and milnacipran appear better tolerated and essen-

tially devoid of cardiovascular toxicity. The indication of milnacipran appears to be directed to the treatment of fibromyalgia and will probably prove effective for atypical pain syndrome.

Anxiolytics (Table 103-6)

Although antidepressants are effective drugs used to treat anxiety disorders, the symptomatic treatment of anxiety occasionally involves the use of other anxiolytics. Benzodiazepines are currently the most widely used class of anxiolytics, supplanting previous use of barbiturates. Buspirone, a nonbenzodiazepine anxiolytic, has also found utility in certain patients.

Benzodiazepines are CNS depressants, exerting their influence through action at the γ-aminobutyric acid (GABA) receptor. GABA is the major inhibitory neurotransmitter in the CNS. Thus, in addition to treating anxiety, other effects include sedation, loss of muscle coordination, and possible amnesia or blackouts. Buspirone is a partial 5-HT1A receptor agonist without the same liability for dependence and subsequent withdrawal phenomena common to all GABA active agents. Because of the potential for physical and psychological dependence, benzodiazepines should be used with great caution. All benzodiazepines can induce dependency, but is seen more frequently with potent, short-acting agents such as alprazolam and lorazepam. In general, the short-term symptomatic treatment of anxiety symptoms while other more definitive pharmacologic and psychotherapeutic measures are being undertaken remains the main indication for the use of these medications by the nonpsychiatrist.

Buspirone is an anxiolytic approved for the treatment of generalized anxiety disorder. It is thought to mediate its effects through serotonergic mechanisms. Unlike benzodiazepines, buspirone must be taken chronically for anxiolytic effects to be seen.

Lorazepam (between 0.5 and 2.0 mg), clonazepam (0.25 to 5.00 mg), and buspirone (between 5 and 10 mg) can be administered between one and three times a day. It is prudent to start on lower doses to evaluate tolerance.

TABLE 103-6
Anxiolytics

Drug	Dose (mg/day)	Side Effects
Lorazepam[a] (Ativan)	0.5–2.0	Fatigue, drowsiness; habit forming[b]
Clonazepam[a] (Klonopin)	0.25–4.00	Fatigue, dizziness, salivation; habit forming[b]
Buspirone (BuSpar)	5–60	Headache, dizziness, hypomania in elderly

[a]Benzodiazepines.
[b]Withdrawal syndrome with risk of seizures and delirium.

NONPHARMACOLOGIC TREATMENTS FOR PSYCHOCUTANEOUS DISORDERS (See Table 103-1)

The dermatologist should request a consultation with a psychiatrist or a liaison clinic during the treatment of patients with psychocutaneous disorders as soon as it is amenable to the patient. Although dermatologists are becoming more comfortable with the use of certain psychotropic medications, they generally do not have the time or the training to use effectively other treatment modalities such as psychotherapy and hypnosis. It is therefore sufficient that the practicing dermatologist be aware that a variety of psychotherapeutic approaches are available, including insight-oriented, cognitive-behavioral, supportive, and, to a lesser extent in current practice, psychodynamic therapy.[103] Certain types of therapies may be more effective for a given condition which underscores a fundamental point: diagnosis should drive choice of therapy and patients should not be formulated based on rigid therapeutic or theoretic biases.

PRIMARY DERMATOLOGIC DISORDERS

Role of Stress in Skin Diseases

The presence of a force that threatens to disrupt the organism's homeostatic balance is perceived as a stressor, and the ensuing reaction reflects the typical response aimed at the preservation of life.[104] Mammalian organisms respond to external (i.e., physical, environmental) or internal provocations (infections, anxiety, or anticipatory stress) by triggering a cascade of events that ultimately activate the hypothalamic-pituitary-adrenal axis,[105] allowing the organism to cope with noxious stimuli and mount a successful "fight-flight" reaction. This adaptation to challenges ("stress response"[19]) is critical for survival after an acute provocation; however, its persistence chronically can lead to exhaustion, distress, and, eventually, disease.[106,107] Whereas short-lived (acute) stressors are known to enhance immunity, chronic stress has an adverse effect on health and life expectancy, alters immunity, and favors the progression of infections as well as an increase in the development of experimentally induced neoplasms.[2] A number of studies provide clear evidence that psychosocial factors, including stress and other emotional states (such as depression), have a deleterious effect on the outcome of numerous human diseases, including those of the skin.[2,108]

Although suspected for many years, retrospective and prospective studies have provided the clinical basis to support the notion that stressful events can correlate with the onset or exacerbation of skin diseases. Additional evidence was gleaned from the results of therapeutic trials using psychotherapeutic approaches and stress-reducing interventions[21] in the treatment of dermatologic ailments such as atopic eczema, psoriasis, urticaria, herpes simplex virus (HSV) infection, alopecia areata,[109] and warts,[110] among others.

ATOPIC DERMATITIS (See Chap. 14) More than most other skin diseases, atopic eczema exemplifies the delicate balance between inherited factors, environmental influences, and psychosocial issues in the maintenance of health.[15] Up to 70 percent of atopic subjects reported preceding emotional stressors before the first episode of dermatitis,[22] whereas numerous patients with eczema suffer exacerbations of their skin symptoms after episodes of psychological stress.[113] These subjects have increased anxiety, altered coping mechanisms, and a close connection between severity of symptoms and stressful life events.[114,115] Psychodynamic approaches have emphasized the role played by an abnormal family structure[116] and altered mother-child relationships in this disease,[1] an issue that is highlighted by the improvement in the symptoms of children with atopic eczema when their mothers receive psychological treatment.[114,117,118] Other psychosocial interventions found to be effective as sole or adjuvant therapies for pediatric and adult patients[21] include behavioral therapies and biofeedback, stress reduction regimens, psychoanalysis, hypnosis, and relaxation techniques.[119–121]

PSORIASIS (See Chap. 18) Psychosocial issues appear to be closely linked to the

well-being of patients with psoriasis. Stressors often precede the initial onset of the disease or subsequent flares.[122–132] Individual or group psychotherapy, behavioral approaches, and biofeedback, among other techniques, have resulted in improvement of the psoriatic plaques, as well as enhancement of overall well-being.[133,134] A randomized controlled trial showed that highly suggestible patients treated with hypnosis significantly improved when compared to the control group,[135] and patients who used meditation tapes at the time of phototherapy cleared in half the time when compared to those who did not use them.[136]

HERPES SIMPLEX (See Chap. 193) There is strong evidence to support the role of stress in the evolution of HSV infections. Experimental restraint stress correlates with the reactivation of latent HSV infection in the dorsal root ganglion neuron of rats.[137] Human studies show that persistent, but not single, stressful events are associated with the frequency of recurrences,[138,139] which is in accordance with findings that chronic but not acute stress correlates with the development of experimental viral infections in normal volunteers.[140] Furthermore, psychosocial interventions decrease the frequency of recurrences of herpes simplex infections.[141]

URTICARIA (See Chap. 37) The relationship between stress and some forms of urticaria is supported by numerous anecdotal observations. Patients suffering from adrenergic urticaria report that their symptoms invariably follow acute stressful events.[142] Others with hereditary angioedema are known to have symptoms frequently triggered by emotional stress.[143,144] The finding that stress mediates the degranulation of mast cells via corticotropin-releasing factor[145] and neuropeptides[146] supports its putative role in the pathogenesis of urticaria.

Almost all inflammatory skin diseases have been anecdotally reported at one time or another to be associated to stressors. Up to 50 percent of females with acne suffer flares after stress,[147] and patients with seborrheic dermatitis,[148,149] lichen planus,[149,150] alopecia areata,[151] and even pemphigus vulgaris[152,153] have been reported to have symptoms triggered or exacerbated by emotional stress.

Skin Diseases and Psychosocial Distress

The physical or perceived disfigurement can become a source of significant distress, with a considerable impact on an individual's psychological, social, and physical well-being. Dermatologic conditions are responsible for a significant source of social stigmatization in many human societies and cultures, contributing to the development of co-morbid diseases such as depression and anxiety. Psoriasis, for example, impairs the social life of 40 percent of patients and 64 percent feel that their disease significantly impacts their socioeconomic functioning.[154] The presence of the frequent co-morbid associations such as depression and anxiety can be identified using available validated instruments such as the Depression Anxiety Stress Scales. The clinician should be aware of the incidence of depression and anxiety in patients with cutaneous diseases, which can be treated with the pharmacologic and nonpharmacologic approaches delineated above.

The Dermatology Life Quality Index[155] and the Skindex-16[156] are simple and practical validated instruments that can be used both in the office setting and for research purposes to quickly evaluate quality of life. Specific instruments are also available for patients with psoriasis,[155] eczema,[157] acne,[158] and urticaria[159] among others. These tests are helpful tools that can assess improvement in both the physical and the psychosocial aspects of a patient's disease. The sum of observations, studies, and therapeutic interventions suggests that stress plays a significant role in the biology and clinical expression of skin diseases, and supports the notion that therapies that address this issue may have a positive impact on the well-being of patients with dermatologic diseases. Adjuvant psychosocial interventions could also mediate an increased adherence to medical treatments, provide social support, decrease stress or alter the response to stress, ameliorate anxiety, aid patients to develop better coping mechanisms, improve depression, and help with self-image or distorted body perception.

CHAPTER 104

Cutaneous Manifestations of Drug Abuse

Miguel R. Sanchez

Drug abuse can be suspected or diagnosed on the basis of skin findings. The parenteral administration of drugs causes skin lesions and eruptions predominantly through local or systemic, toxic, or hypersensitivity-induced effects of the drug itself, adulterants, or infectious agents. Intravenous administration can produce a number of recognizable stigmata, which may identify an individual abusing drugs to anyone aware of illicit drug use practices.

Behavior associated with drug abuse continues to be an important factor in the spread of human immunodeficiency virus (HIV) infection. Approximately 4 of 10 acquired immunodeficiency syndrome deaths are related to drug abuse.[1] Parenteral drug users also have high risks for contracting hepatitis B and C and other blood-borne infections. About 60 percent of all new hepatitis C infections in the United States are attributed to syringe and needle sharing with an infected individual.[1] In some user populations, hepatitis C is transmitted so rapidly that within 6 months of injecting drug, one-third of users become infected, and within 2 years, 90 percent have contracted the infection.[2] Drug addicts also

CUTANEOUS MANIFESTATIONS OF DRUG ABUSE

AT A GLANCE

- The pattern and appearance of skin lesions can identify persons with former and current drug dependency.
- The most specific signs of injectable drug abuse are skin tracks, punctures, ecchymoses, or crusted papules along veins, phlebitis, scars of undetermined etiology, woody dermal induration, and cutaneous ulcerations in unusual body areas.
- Drug addicts have higher prevalences of sexually transmitted diseases, and those who inject chemicals are at higher risk of contracting blood-borne infections including human immunodeficiency virus; syphilis; hepatitis B, C, and D; and human T-lymphotropic virus 1 and 2.
- Drug-addiction-related bacterial infections predominantly involve the skin and soft-tissue. Culture-guided antibiotic therapy is essential because infection with unusual organisms, antibiotic-resistant strains, and polymicrobes is more common.

have higher incidences of sexually transmitted diseases, depression, accidental injuries, and trauma due to criminal violence or domestic abuse. Numerous sociologic problems, such as loss of work productivity and increases in crime, prison occupancy, and property damage, result from drug abuse and dependence. The Office of National Drug Control Policy reported the annual economic cost to society from drug abuse in 1998 as $143.4 billion and projected an increase to $204 billion in 2007, with health care costs accounting for 9 percent of these figures.

DEFINITIONS

COMMONLY ABUSED DRUGS

Cannabis (marijuana, Mary Jane, pot, herb, ganja, weed, boom) is a mixture of dried shredded leaves and flowers of *Cannabis sativa* that contains the chemical delta-9-tetrahydrocannabinol. Diacetylmorphine (heroin, junk, smack, horse, scag), the fastest-acting and most potent opiate, accounts for 90 percent of the opiate abuse in the United States. A "rush" develops within 7 to 8 seconds if the opiate is injected intravenously or within 10 to 15 minutes if it is snorted or smoked. Persons addicted to opiates may alternate injections of heroin and cocaine (crisscrossing) or inject highly addictive "speedballs" of the two drugs together. Cocaine (coke, blow, toot, flake, and snow) is an alkaloid stimulant and topical anesthetic that is extracted from the leaves of the coca shrub. Crack (base, rock, hubba, gravel, girl), or crystallized, freebase cocaine, is far more addictive than heroin. Crystallized methamphetamine (ice, crystal, glass, meth, tina) is usually inhaled or injected intravenously to produce a stronger rush. The typical portrait of a "speed freak" with pale, sagging sweaty complexion, body odor, cachectic appearance, discolored teeth, skin ulcers, and scars has been popularized in the media. Because withdrawal symptoms are so intense, methamphetamine addiction is more difficult than any other addiction to treat. 3,4-Methylenedioxymethamphetamine, often abbreviated as MDMA (speed, ecstasy, Adam, XTC, hug, beans, love drug) is a synthetic psychoactive drug with stimulant and mildly hallucinogenic properties. Sedatives, which are frequently misused by polydrug addicts, enhance the euphoric effects of heroin. Flunitrezepam is 10 times more potent than diazepam. Lysergic acid diethylamide (acid) continues to be a popular hallucinogen.

STATISTICS

Between 3 and 5 percent of the global population abuse drugs, and approximately 13 million of them inject them. The National Survey on Drug Use and Health estimated that 19.5 million people 12 years of age or older (8.2 percent of the population) used an illicit drug in the prior month. Injection is one of the most harmful routes of administration.

PATHOGENESIS OF DRUG ABUSE

CLINICAL MANIFESTATIONS

Most cutaneous manifestations of drug abuse are lesions that occur also in other conditions, but it is their pattern, appearance, and distribution that identify persons with drug dependency (Box 104-1).

Box 104-1

Differential Diagnosis of Cutaneous Manifestations of Drug Abuse

Most Likely

- External trauma scars (skin tracks)
- Self-induced scars (skin or pop tracks)
- Livedoid vasculitis (pop scars)
- Sporotrichosis (linear plaques)
- Atypical mycobacterial infection (nodules and ulcers)
- Ecthyma (necrotic ulcers)

Consider

- Panniculitis (woody induration)
- Mondor disease (phlebitis)
- Polyarteritis nodosa (ulcers)
- Leishmaniasis (ulcers)
- Ulcerative sarcoid (ulcers)
- Tularemia (ulcers)
- Anthrax (necrotic ulcers)
- Actinomycosis (abscess)
- Wegener granulomatosis (ulcers and nodules)
- Exposure to chromium solutions (nasal perforation)
- Nasal septum trauma from surgery, intubation, nasogastric tube (nasal perforation)
- Nasal malignancies (nasal perforation)
- Syphilis or yaws (nasal perforation)
- Rhinosporidiosis (nasal perforation)

Scars

The most specific sign of drug abuse by injection is the presence of skin tracks (Fig. 104-1). Initially, punctures, ecchymoses, and crusted lesions trail along the length of the vein (Fig. 104-2). With repeated injections of irritating drugs and adulterants, the veins become inflamed and scarred.[1] Due to their easy access, the veins of the arms and hands are injected initially by most novice addicts. However, to avoid the presence of incriminating tracks, some addicts prefer injections on the legs and feet. When these areas become scarred, drugs are injected into the vessels of the neck, abdomen, axillae, groin, sublingual area, genitals, hemorrhoids, and any visible or palpable vein or artery. When intact veins cannot be found, the skin may be cut superficially with razor blades or knifes and powdered drugs rubbed into the lacerations. Some young addicts actually prefer this technique. Subcutaneous and intradermal injections cause irregular, round, leukodermic, atrophic depressions known as *skin popping scars* (Fig. 104-3). In some

▲ **FIGURE 104-1** Skin tracks along the veins of the dorsal hand.

▲ **FIGURE 104-2** Purpuric puncture marks on several veins, suggesting intravenous drug use.

cases, indurated, linear, hypertrophic, or keloidal scars form.

Cocaine is a vasoconstrictor and can produce tissue ischemia, especially when extravasated. It does not regularly form tracks, but cutaneous fibrotic scars on the extremities resulting from intracutaneous injection have been reported.[7] Pentazocine injection can cause brawny, fibrotic skin.[8]

Ulcerations

Intradermal injections or accidental extravasation of certain drugs and adulterants can cause tissue injury. Heroin and other powder drugs are frequently "cut" with fillers such as lactose, mannitol, dextrose, baking soda, and flour.[9] Injection of sclerosing adulterants and drugs can produce tender and inflammatory plaques or nodules that ulcerate (Fig. 104-4) and heal with epidermal pigmentary changes, woody induration of the dermis and subcutaneous tissue, and retracted cicatrices. These are known as *shooter's patches*.

Even inhalation of cocaine can cause skin and muscle infarction.[10] Extensive necrosis of the nose and upper lip accompanied by a necrotizing infection of the subcutaneous soft tissue of the cheeks, forehead, and temporal regions has been caused by forced intranasal impaction of crack cocaine.[11] Injection into soft tissue of barbiturates, which are highly alkaline, results in tender, erythematous, indurated plaques that break down into deep ulcers and frequently become infected. Tripelennamine (pyribenzamine), an antihistamine usually injected in combination with pentazocine or another opioid, also induces tissue necrosis and ulceration.[12] After pentazocine injection, the skin often breaks down, resulting in irregularly shaped, deeply penetrating ulcers that extend to fat and even muscle.[8] Drug addicts have been known to sabotage medical wound healing efforts to maintain the granulation tissue for heroin injections.[13]

Granulomas

Pulmonary foreign body granulomas have been found in 30 percent of addicts on whom autopsies have been performed. Although cutaneous granulomas are not common, they can develop months and up to 50 years after the last intravenous or subcutaneous injection because granuloma formation requires conversion of silica to its colloidal form.[14] Most granulomas are caused by the injection of hydrous magnesium silicate (talc) and, less often, starch into the subcutaneous tissue, deep dermis, and walls of veins. The lesions are firm, movable cutaneous nodules. Talc granulomas also may develop in the liver, lymph nodes, spleen, and bone marrow. In addition to being a popular adulterant for powder drugs, talc is the main ingredient in some narcotic tablets that are crushed, diluted in liquid, and injected.[14]

Burns

Burns from lit matches, cigarettes, paraphernalia, and contact with fire during cooking are common during the altered state of consciousness produced by drug intoxication. Cigarette burns, most commonly on the digits and sternum, occur from lit cigarettes that addicts were smoking before falling asleep. The necklace sign is produced by cigarette ashes that fall on the neck when the smoking addict dozes off.[1] Singeing of the eyelashes and eyebrows, resulting in madarosis, may be caused by rising hot vapors during smoking of crack cocaine. Individuals who use crack also may develop linear, circular, or oval blackened, hyperkeratotic lesions caused by the heat of the glass pipe.[15] The areas affected are the thenar eminences of the thumbs (crack thumbs) and the palm (crack hands) of the dominant hand. More severe thermal burns may be incurred on the hands while lighting a crack-cocaine pipe with a butane lighter directed downward onto the pipe.

Solvent inhalation is especially popular among adolescents. Minor, superficial burns occur as a result of flash fires caused by the ignition of lighter fluid, composed of butane and isobutane, in enclosed spaces while the fumes are being inhaled. Extensive explosion burns can occur involving the face, neck, arms, and hands, as well as the trunk and/or

◀ **FIGURE 104-3** Depressed, circular scars ("pop scars") due to subcutaneous heroin injection.

▲ **FIGURE 104-4** Foreign body response and cellulitis from subcutaneous and intravenous injection of adulterated heroin.

lower extremities.[16] Severe burns also occur when other solvents, such as paint thinner or petrol, become ignited by a cigarette that the sniffer is simultaneously smoking.

Pigmentary Changes

Post-inflammatory pigmentary changes are more common in persons with darkly pigmented skin. Circumferential pigmented bands due to pressure from tourniquets are common in dark-skin intravenous drug users. Soot tattoos are black macules produced by inadvertent injection of residual carbon that remains on the needle after flaming. Persons who abuse methamphetamine develop grayish, dry, leathery skin with a strange odor.

Vascular Lesions

The most common vascular lesions in addicts are ecchymosis and hematomas from extravasated blood along injected vessels.[17] Petechiae may form distal to tourniquets. Addicts who inject drugs intra-arterially are at risk of developing vascular compromise of the hands, with discoloration, edema, and cold temperature.[17] Arterial constriction or emboli can lead to gangrene and loss of digits or a limb.[17] Repeated vascular injury and infection of the digits may cause irreversible contractures (camptodactylia) that resemble Dupuytren disease.[18] It is important to evaluate any patient with contractures, inflammation, or edema of the hand for soft tissue infection, as well as for underlying musculoskeletal complications, such as fibrous myopathy, joint restriction, muscle contractures, inflexible ankylosis, and suppurative tenosynovitis. Distal thrombosis with extensive infarctive skin lesions and associated hepatitis and glomerulonephritis may follow intravenous injection of cocaine into an arm vein.[19] Painful discoloration with resulting ulceration of the palm also can result from injection of cocaine into the radial artery.

Quinine, which is popular because of its bitter taste similar to heroin and its enhancement of the narcotic euphoria, is destructive to lymphatics, and repeated injections can lead to chronic, non-pitting hand or limb edema.[1] Injected propoxyphene produces thrombophlebitis and skin necrosis.[20]

Cocaine may produce superficial or deep venous thrombosis.[21] Mycotic aneurysms occur in 15 percent to 25 percent of patients with infective endocarditis, most frequently in the femoral artery, and require immediate surgery. Pseudoaneurysms result from infected injury to arteries during intra-arterial injection of drugs ("hitting the pinkie") and are most common in the extremities and groin.[17] The typical lesion is a tender, diffusely indurated, pulsatile mass with an associated bruit (50 percent to 60 percent of cases) and decreased peripheral pulses (25 percent). Local suppuration, petechiae, and purpura are often present.

An erythematous, tender cord is the hallmark sign of superficial septic thrombophlebitis. However, patients with deep vein thrombophlebitis present with a tender, swollen extremity, with or without erythema, that resembles cellulitis or an abscess. Indeed, infection may be simultaneously present, further complicating the diagnosis.

Cases of Henoch-Schönlein purpura, polyarteritis nodosa, and necrotizing angiitis with renal and pulmonary disease have been reported in intravenous drug abusers.

Vasculitis

Necrotizing vasculitis from injected drugs usually develops on the neck or extremity as a warm, firm, tender mass that may be misdiagnosed as an abscess. Pseudovasculitis with aggressive nasal destruction, as well as oropharyngeal and cutaneous ulcers may be misdiagnosed as Wegener granulomatosis in cocaine addicts, especially because perinuclear antineutrophil cytoplasmic antibody results may be false-negative.[22]

Vesiculobullous Lesions

Traumatic vesicles or bullae at the site of injection are observed occasionally. Comatose patients who have overdosed with barbiturates or other sedative drugs often develop pressure erythema, bullae, and ulcers.[9] Unlike bedridden patients, who typically develop pressure-induced lesions on the sacral or ischial areas, elbows, or heels, addicts may present with bullae in unusual body areas and varying configurations, depending on the body position in which they lost consciousness.

Acne and Pilosebaceous Effects

Anabolic steroid abuse can cause acne, cysts, oily hair and skin, male and female pattern alopecia, increased hair growth in women, gynecomastia in men, coarse skin, edema, testicular atrophy, and clitoral enlargement. There have been reports in habitual users of MDMA of a papulopustular, facial, acneiform eruption that may indicate a higher risk of systemic adverse effects, such as hepatic damage.[23] Hyperhidrosis is a common adverse effect of amphetamines.[23] Piloerection, paresthesias, and percutaneous flushings are manifestations of the somatic but not the perceptual phase of lysergic acid diethylamide intoxication. Together with constricted pupils and runny nose, gooseflesh skin is a sign of opiate intoxication.

Pruritus

Chronic cocaine use coupled with marijuana inhalation may cause pruritus. Prolonged use of cocaine may lead to the development of formication, tactile hallucinations during which the individual senses that insects are crawling on or under the skin (coke bugs). Foraging behavior, involving compulsive searching for pieces of crack cocaine in locations where it was once used, has been reported by some long-term users. Repetitive, stereotypical skin picking leading to excoriations and skin ulcers on the face and extremities has been observed in individuals who abuse methamphetamine. The feeling of euphoria provided by heroin may be accompa-

▲ **FIGURE 104-5** Cocaine-induced granuloma of the nasal septum.

nied by skin flushing and itching, as well as dry mouth, watery eyes, and runny nose. Heroin addicts often have dry skin that becomes easily irritated and pruritic.

Generalized or focal, especially genital, itching after drug administration has been named *"high" pruritus*. Hypoesthesia is a manifestation of low-dose exposure to phencyclidine.

Mucous Membrane Lesions

The abuse of drugs via an intranasal route is an increasingly prevalent pattern of behavior. Snorting cocaine causes erythema and erosion of the nasal turbinates, nasopharynx, and soft palate. With continued use, the erosions progress to necrosis, atrophy, and eventual perforation of the nasal septum and even the palate (Fig. 104-5).[24] The pathogenesis is vasoconstriction with resulting ischemia and occasionally infection. Chronic rhinitis, epistaxis, osteolytic sinusitis, gingival retraction, and bruxism are other complications. Halitosis and frequent lip smacking are signs of cocaine abuse. Cuts from chipped glass pipes and thermal burns may be present on the lips of some crack users. Sniffing heroin less often causes these changes. However, invasive fungal rhinosinusitis appears to be a complication unique to intranasal narcotic abuse.[24] A case of pemphigus vegetans, Neumann type, restricted to the intranasal tissue was reported to have been induced by inhalation of heroin.[25]

Xerotic cheilitis is observed commonly in methamphetamine and heroin addicts.[9] Methamphetamine users also have red, dry noses. Transient eyelid edema has been described with opiate abuse. The typical red or "bloodshot" eye frequently occurs with marijuana and sometimes with cocaine or phencyclidine use. Scleral hemorrhages in drug addicts are usually traumatic but may be caused by septic emboli due to endocarditis. There are reports of men applying cocaine powder to their glans penis to postpone ejaculation and of women rubbing cocaine on their genitals to enhance pleasure. These practices can lead to priapism, irritant dermatitis, and even ulcerations. Priapism can follow crack inhalation.[26] Penile ulcers have developed after injection of heroin into the shaft veins.

Marked dental decay and gingival disease are common in hard-core users of opiates as a result of the effects of opiates and poor hygiene. Hallucinogen-induced xerostomia also predisposes to caries. Persons addicted to methamphetamine, especially snorters, have higher tooth wear caused by teeth clenching. Habitual chewing of betel palm seeds, which contain a narcotic stimulant—a practice in some areas of Southeast Asia—stains the teeth.

Bacterial Infection

Skin and soft-tissue infections are the most common disorders for which drug addicts seek health care or are hospitalized.[27,28] In a study of 127 hospitalized intravenous drug users, the diagnoses were cellulitis (40.9 percent), abscess with cellulitis (32.3 percent), abscess alone (16.5 percent), infected skin ulcers (10.2 percent), necrotizing fasciitis (7.1 percent), and septic phlebitis with cellulitis (5.5 percent).[29] Cellulitis (see Chap. 179) is the most common (see Fig. 104-4) and lymphangitis may accompany skin infection. In any addict with soft-tissue infection, the possible presence of osteomyelitis or pyogenic arthritis should be considered. Because upper extremity vessels are used preferentially, cellulitis of the hand, arm, and forearm is very common and should be treated aggressively. Gangrene has been reported in 7 percent of drug abusers with upper extremity cellulitis.[18] About 10 percent of hand infections may require amputation of digits or of the hand, even after appropriate antibiotic and surgical treatment.[18]

In parenteral drug users, *Staphylococcus aureus* is the most frequently cultured bacterium from soft issue infections, followed by streptococcal species.[29] An attempt to obtain a culture is prudent because skin infection by Gram-negative bacteria, anaerobes, and unusual organisms is also common.[30] Notably, the flora spectrum of street heroin has no relationship to the bacteria causing infections in intravenous drug users.[18] However, tripelennamine and pentazocine may allow for the selective survival of *Pseudomonas aeruginosa*. The use of quinine to adulterate heroin appears to predispose to *Clostridium* infection. Wound botulism due to *C. botulinum* type A occurs almost exclusively in drug addicts.[31] Several cases have been reported from California and other western states during the past decade.[32] It is associated with parenteral injection, especially skin popping of black tar heroin, a form that derives its color from impurities during its manufacture and from adulterants. This form of heroin is highly hygroscopic and has a high water content that supports the growth of organisms. The spores of *C. botulinum* are not destroyed by heating the contaminated heroin and are inoculated into the subcutaneous tissue, where they germinate and produce toxin. There is pain, tenderness, and swelling, but in the early stages a cellulitis or abscess may not be prominent. In cocaine snorters, the intranasal septum or paranasal sinuses may become infected.[30] Necrotizing cellulitis of the scrotum and penis has been reported in addicts who accidentally injected drugs into the femoral artery instead of the vein.[33]

Due to the popularity of skin popping, the incidence of abscesses has been increasing. Abscesses from such subcutaneous drug injection are often multi-lobulated and deep and have extensive necrosis that requires exploration and débridement.[12] Superficial abscesses may rupture spontaneously, leaving punched-out ulcers. Abscesses may develop in any skin area of the body in which the addict injected drugs. Abscesses may be contiguous with bone when osteomyelitis of the long bones is present. Cervical abscesses usually occur in the anterior cervical triangle and may cause life-threatening complications such as mediastinitis, pneumomediastinum, airway obstruction, internal jugular vein thrombosis, and extension into the carotid sheath. Abscesses in the groin may present with only tenderness and edema. These abscesses can be deep and extensive, especially if they originate in the femoral triangle. The degree of pain usually exceeds that suspected from clinical findings. Computed tomographic scanning is needed to determine the extent of involvement of deep abscesses and abscesses in regions such as the neck and groin.

In more than one-half of the abscesses, only one pathogen is cultured, but in 33 percent to 45 percent of abscesses, more than one organism is present.[29] Fever and leukocytosis are not absolutely reliable

measures of severity and are absent in about one-half of cases. Any bacteria may be recovered from an abscess, but the more commonly cultured ones are *S. aureus* (20 percent to 60 percent), *Streptococcus* sp. (25 percent), and Gram-negative rods (up to 25 percent). Anaerobic bacteria are also common, especially in polymicrobial infections. In one study, anaerobic bacteria were recovered from two-thirds of abscesses, and in one-third of these, they were the only cultured organism.[34] *Eikenella corrodens*, an oral flora bacterium, is cultured from some abscesses caused by injections of methylphenidate. Curiously, some abscesses develop months after a patient has ceased to use drugs.

Necrotizing fasciitis with or without myositis (see Chap. 179) requires extensive subfascial débridement. In some cases, only swelling or inconspicuous cellulitis is apparent. However, severe pain, disproportionate to the clinical signs, is present in 94 percent of cases.[35,36] If the clinician disregards the patient's complaint merely as a request for narcotics, the outcome may be devastating.[35] For this reason, surgical exploration is mandatory in any addict with cellulitis and unexplainable severe pain. Multiple organisms are cultured in 59 percent to 85 percent of cases. Anaerobes are present in 12 percent of cases. The presence of gas is not pathognomic for *Clostridium* infection. The infection will progress in 75 percent of patients treated with parenteral antibiotics without débridement.[36] A decrease in the mortality rate from 27 percent to 7 percent was reported with a protocol consisting of early diagnosis, intravenous wide-coverage antimicrobial therapy, supportive care, early subfascial débridement, and repeated wound débridement every 8 to 12 hours until no necrotic tissue is formed. Between two and four débridements are needed.[35]

Sporadic cases of toxic shock syndrome related to intravenous heroin abuse have been reported. Nephrotic syndrome from amyloidosis has been reported in skin poppers and intravenous drug users with chronically draining skin lesions.[37]

Infectious endocarditis is the most common systemic bacterial infection in intravenous drug users and accounts for 5 percent to 8 percent of hospitalizations (see Chap. 181). Although in some reports, one-third of hospitalized addicts with skin and soft-tissue infection have positive blood cultures, bacteremia from skin infection is not common.[20] Intravenous drug users with advanced HIV immunosuppression are more predisposed to developing infectious endocarditis.[38]

Fungal Infection

Even in the absence of HIV infection, the incidence of dermatophytosis, including onychomycosis, tinea pedis, tinea cruris, and tinea corporis (see Chap. 188), is higher among intravenous drug addicts.[39] Injections of brown heroin have caused disseminated candidiasis due to yeast overgrowth in the lemon juice used to dissolve the heroin. For clinical signs and symptoms, see Chap. 189. Complications include ocular disease (uveitis, endophthalmitis), monarthritis, osteochondritis, and pleuritis.[40] Unlike HIV infection, intravenous drug use is a predisposing factor to zygomycosis (see Chap. 190). The characteristic cutaneous lesion is a cellulitic plaque or abscess that becomes necrotic.

DRUG-INDUCED REACTIONS

As expected, hypersensitivity reactions to drugs, especially exanthematous eruptions, urticaria, fixed drug reactions, leukocytoclastic vasculitis, erythema multiforme, and toxic epidermal necrolysis, occur more frequently in users of illicit drugs than in the general population. Dermatographism is common. Pigmented patches on the skin and mucous membranes may be extensive in addicts with fixed drug eruptions.

Narcotic abuse is a common cause of falsely reactive nontreponemal tests for syphilis (VDRL, rapid plasma reagin tests). In these cases, treponemal tests (microhemagglutinin-treponema pallidum, fluorescent treponemal antibody absorption tests) will be nonreactive. However, in addicts who have had syphilis, not only will both tests be positive but the titers of the treponemal test also may not decrease after treatment.

ASSOCIATED NON-INFECTIOUS SKIN DISEASES

Seborrheic dermatitis may be more frequent in chronic cocaine users. Eczemas, especially contact dermatitis, have been reported to occur more frequently. Drug abuse may indirectly cause skin lesions through congenital malformations in the offspring, domestic violence, or systemic disease. Pseudoacanthosis nigricans has been observed in heroin addicts.

TREATMENT

A detailed discussion of the treatment of drug abuse and dependence is beyond the scope of this chapter, but it is essential to recognize that these are chronic illnesses that require long-term strategies.[41] Potential therapies for opiate dependence include drug detoxification (office-based, inpatient, or ultrarapid under anesthesia), agonist maintenance (methadone, levomethadyl, or buprenorphine), antagonist maintenance (naltrexone), pharmacologic treatment of withdrawal symptoms (clonidine, lofexidine, or guanfacine), psychotherapy, acupuncture, counseling, and 12-step programs, which, if effective, exert benefit through peer support. Although relapses are common, successful outcomes are accomplishable, indicating the importance of candid, supportive, nonjudgmental, care-facilitating discussions in patients whose drug use has been revealed through skin examination.

CHAPTER 105

Skin Signs of Physical Abuse

Howard Pride

CHILD ABUSE

Child abuse is an uncomfortable topic for most practitioners and is a source of anxiety, anger, and confusion among those who care for children. True incidence statistics are difficult to determine, but each year in the United States, of the approximately three million children referred to child protective services, approximately one million are determined to be the victims of abuse and neglect and approximately 1500 die from abuse or neglect. Clearly, those whose practices involve the dermatologic care of children encounter real or suspected child abuse. Practitioners must have some basic knowledge of abuse and its evaluation to appropriately manage these cases.

Because many forms of physical abuse have external manifestations, the skin examination may serve as the first clue that abuse is taking place. Conversely, a broad knowledge of skin diseases provides a unique insight into those diagnoses that may suggest various forms of child abuse (Tables 105-1 and 105-2). The literature is rich in examples in which an astute clinician averted the disastrous results of a false claim of abuse by correctly diagnosing a dermatologic condition.

True abuse must be reported and a thorough evaluation conducted. It is essential that practitioners develop a relationship with the institution or individual in their area who is best able to manage these difficult cases. Ideally there should be an abuse team consisting of a dermatologist, pediatrician, social worker, medical photographer, and, when needed, pediatric subspecialists such as orthopedists, hematologists, psychologists, and gynecologists. It is most helpful if one's relationship is forged with the abuse team before an abuse incident and a set protocol for dealing with alleged or suspected abuse is established in the practitioner's office. Local emergency phone numbers for reporting abuse can be obtained from the Child Welfare Information Gateway or Childhelp National Headquarters (Table 105-3).

Child abuse spans all ages, races and socioeconomic classes, but typical children who suffer abuse are between the ages of 5 and 15 years, have emotional or behavioral problems, have special medical needs, have several siblings, live in single-parent households, or live at or below the poverty level. Abuse is approximately two times more common in Pacific Islanders, American Indians, Native Alaskans, and African American children compared to the average American population. Perpetrators tend to have emotional or psychological problems, have frequently been victims of abuse themselves, abuse drugs or alcohol, are perpetrators of spousal abuse or have a history of marital discord, have marginal parental skills or knowledge, and have poor self-esteem. Although these profiles are helpful, it is important to remember that any child may be the victim of abuse.

ABUSE AT A GLANCE

- Child abuse, elder abuse, and domestic violence are common.
- Abuse is a problem of all socioeconomic classes and races.
- Bruising on soft padded areas of the body and patterned bruising that are multiple and in different stages of healing are suspicious of abuse.
- Burns that are bilateral and uniform are suspicious of abuse.
- Law mandates the reporting of all suspected cases of child abuse and, in some states, elder abuse.

The Battered Child

Bruising is the result of blunt trauma, delivered either accidentally or intentionally. Active children, particularly toddlers, are prone to multiple bruises, and the identification of abusive injury is fraught with difficulty. The size, shape, color, and feel of a bruise varies based on anatomic site, the degree of force used, the firmness of the object delivering the force, and the underlying health of the injured individual. Great care and attention to detail must be exercised when evaluating these children who likely have been brought to the office for some other complaint. The history should include as much detail as

TABLE 105-1
Conditions Mistaken for Abusive Bruising

- True petechiae and purpura
  - Disorders of coagulation
  - Ehlers-Danlos syndrome
  - Infections
    - Rocky Mountain spotted fever
    - Meningococcal infections
    - Group A streptococcal infections
  - Palpable purpura of vasculitis
  - Valsalva petechiae
  - Lichen sclerosus
  - Folk remedies
    - Cao gio: rubbing vigorously with a hard object such as a coin
    - Cupping: suction mark left by the cooling of a warm metal cup
- Nodular lesions mimicking deep bruises
  - Neuroblastoma
  - Vascular malformations
  - Dermatomyositis-associated nodules
- Discolorations that look like bruises
  - Phytophotodermatitis
  - Maculae caeruleae from lice infestation
  - Mongolian spots
  - Dye from blue jeans
- Inflammatory conditions that mimic bruising
  - Urticaria/angioedema/urticarial vasculitis
  - Pernio
- Conditions that mimic whip marks
  - Incontinentia pigmenti
  - Striae
  - Phytophotodermatitis

TABLE 105-2
Conditions Mistaken for Nonaccidental Burns

- Phytophotodermatitis
- Folk remedies (Maquas, or moxibustion): burns delivered near diseased organs or therapeutic sites as in acupuncture
- Impetigo
- Epidermolysis bullosa
- Immunobullous diseases
- Sunburn/xeroderma pigmentosum
- Burns from objects heated by sun
- Electric burn from an enuresis blanket
- Chemical burn from use of undiluted acetic acid
- Chemical burn from Icy Hot balm
- Chemical burn from calcium chloride
- Diaper dermatitis
- Pernio
- Fixed drug eruption

possible and inconsistencies in the parent's story clearly documented in the medical record. It is essential to perform a total body skin and mucous membrane examination. It is also important to note the child's behavior and parent-child interactions.

The color of all bruises should be noted and clearly documented. This may aid in determining the age of a bruise and may point out inconsistencies in the caretaker's history. Multiple bruises of differing colors may indicate ongoing trauma rather than one isolated incident.

▲ **FIGURE 105-1** Purpura and erosions on the soft, padded areas of the buttock and thighs, representing very obvious abuse. (Used with permission from Paul Bellino, MD.)

Caution must be exercised in dogmatically stating the time of injury based on bruise characteristics because color depends on the intensity, depth, and location of the injury. There is good evidence that a bruise with any yellow color must be older than 18 hours, but a bruise may be red, blue, or purple/black throughout its life span, from beginning to resolution. Bruises of identical age and cause on the same person may not appear as the same color and may not change at the same rate. It is most prudent to document color without alluding to a specific age of a bruise in the medical record.

Although there are no absolute differentiating features, certain aspects of an intentionally inflicted bruise may suggest abuse. Because young children tend to explore in a forward direction, accidents are more frequent on the distal arms and legs, knees, elbows, and forehead. Soft, padded, posterior, and protected areas of the body are far less likely to be accidentally injured. Bruises on the abdomen, buttocks (Fig. 105-1), thighs, genitalia, ear lobes, and cheeks are uncommon so marks in these areas should raise concern.

Inflicted bruises often leave patterned imprints of a hand, whip, or hard object.

▲ **FIGURE 105-2** Linear purpura representing the interdigital spaces from a hand slap. Note the inferior triangular shape that corresponds to the finger web space. (Used with permission from Paul Bellino, MD.)

▲ **FIGURE 105-3** Linear, circumferential hyperpigmentation at the site of previous ligature. (Used with permission from Paul Bellino, MD.)

Linear purpura with a small triangle at the base (Fig. 105-2), representing the interdigital and finger web spaces, occur after a slap injury. Grab or pinch marks can be recognized by their location on soft padded areas and their unusual patterning. Circumferential purpura or hemosiderin pigmentation (Fig. 105-3) suggest a ligature injury, which would be difficult to explain as accidental. Bite marks (Fig. 105-4) are always inflicted, although they are sometimes from siblings or other children. The shape and size of the marks can identify an adult mouth versus a bite from a child. It is helpful to include a ruled measuring scale in any photographs to help forensic identification at a later date.

The head is the most common target of physical abuse (see eFig. 105-4.1 in online edition). Black eyes are common accidental injuries but are more suspicious if they are bilateral or are unaccompanied by evidence of trauma to the nose or superior orbital ridge. Subconjunctival hemorrhages can be seen in 0.5 percent to 13.0 percent of typical newborns, but a large subconjunctival hemorrhage beyond 1 and 2 weeks of life is suspicious of abuse. Petechiae in the periorbital region have been seen in children with abuse related retinal hemorrhages. Acci-

▲ **FIGURE 105-4** Human bite marks. (Used with permission from Paul Bellino, MD.)

dental bruising or other injuries to the oral mucous membranes are unusual and should be considered as suspect (see eFig. 105-4.2 in on-line edition).

Any bruises in a young infant who is not yet pulling to a stand should raise concerns of abuse or of an unsafe environment (see eFig. 105-4.3 in on-line edition). A shaken infant may have bruising on the hands because he or she is liable to be flailing during the shaking incident (see eFig. 105-4.4 in on-line edition). Concern should be raised whenever the history of an accident is inconsistent with the developmental level of the child.

Inflicted Burns

The most common agent involved in childhood burns, both accidental and inflicted, is hot liquid. Accidents such as inadvertently stepping into a hot tub or pulling a hot liquid off a table counter or stove leave irregular or geographic burn patterns that lack symmetry. By contrast, inflicted scalds tend to be symmetric, with sharply demarcated edges and an absence or paucity of splash marks. In one study, all the children whose bathtub burns were inflicted had associated features of abuse, including bruises, fractures, or evidence of neglect. Stocking and glove burns result when the feet or hands are forcibly held under hot water. The uniformity of the burn indicates that the child was not able to reflexively withdraw from the scalding water as would happen with accidental immersion. A common pattern of inflicted immersion burn involves the buttocks, low back, and thighs. The child is flexed at the waist and dipped into the hot water, frequently as a punishment for a toilet training accident. Inflicted splash burns are much more difficult to differentiate from accidents. A careful history is needed to detect inconsistencies between the proposed injury and the physical examination. When doubt exists, it is mandatory that child protective services be contacted.

An inflicted contact burn can be recognized by the pattern that duplicates the object creating the injury (see eFig. 105-4.5 in on-line edition). Accidental contact burns tend to be smaller, less severe, less patterned, and of irregular depth. When a child is held against a hot object, the depth is more uniform, the pattern is more clearly defined, and the burn is more severe. Irons, curling irons, hot plates, and cigarettes are objects commonly used to inflict burns. Some burns may, in fact, be accidental but represent inadequate supervision and neglect. This situation is also harmful to children and needs to be reported to the appropriate agencies.

Sexual Abuse

It is estimated that more than 300,000 children suffer from sexual abuse each year in the United States. The lifetime risk of sexual abuse is approximately 25 percent to 40 percent for girls and approximately 10 percent for males. *Sexual abuse* is defined by the American Academy of Pediatrics as the engaging of a child in sexual activities that the child cannot comprehend, for which the child is developmentally unprepared, and cannot give informed consent and violate the social taboos of society. This broad definition includes inappropriate touching, genital penetration, fondling, and sexual kissing, but also includes non-contact activities such as exhibitionism, voyeurism, and the involvement of a child in verbal sexual propositions or the making of pornography. Clearly, many forms of sexual abuse leave no physical examination findings.

Girls are more likely than boys to suffer sexual abuse and the risk rises in preadolescence (Fig. 105-5). Most abuse is at the hands of someone known to the child and only 18 percent is carried out by strangers. Victims and perpetrators span all racial, religious, and socio-economic spectrums but risk factors for sexual abuse include the presence of a stepfather, single-parent families, children whose mothers are extensively out of the home, a history of parental violence, parents who have suffered abuse themselves, parental substance abuse, and low household income level.

Most victims of sexual abuse have no physical findings. Pregnancy, positive cultures for sexually transmitted diseases, presence of sperm or acid phosphatase, acute genital or anal injuries without plausible explanation, and marked hymeneal opening enlargement with associated hymeneal disruption are very definitive signs of abuse. It is very seldom that such signs are present. The American Academy of Pediatrics Committee on Child Abuse and Neglect recommends that certain findings are consistent with, but not diagnostic of, abuse. These include chafing, abrasions or bruising of the inner thighs and genitalia, scarring, tears or distortion of the hymen, a decreased amount or absent hymeneal tissue, scarring of the fossa navicularis, injury to or scarring of the posterior fourchette, scarring or tears of the labia minora, and enlargement of the hymeneal opening, even without disruption of the hymen.

▲ **FIGURE 105-5** Sexual abuse. Perianal wound in a 3-year-old girl after anal penetration. (Used with permission from Dr. Francesca Navratil, Zurich, Switzerland.)

The child's spoken word is the most valuable piece of evidence in establishing sexual abuse. All historical information must be very well documented and preserved with the same care as any piece of forensic evidence. It is immensely important to enlist the help of an experienced abuse team in obtaining the history and completing an appropriately thorough physical examination with the aid of colposcopic observations.

The skin examination's greatest contribution may be in correctly diagnosing those dermatoses that may look similar to sexual abuse but are not. Irritant dermatitis, atopic dermatitis, psoriasis, seborrheic dermatitis, pinworms, candidiasis, scabies, and other common dermatoses tend to cluster in the diaper region and should be easily diagnosed with a critical eye. Other conditions that have been reported as mimickers of sexual abuse are listed in Table 105-4.

TABLE 105-4
Conditions Mistaken for Sexual Abuse

- Lichen sclerosus
- Crohn disease
- Localized vulvar pemphigoid
- Langerhans cell histiocytosis
- Perianal streptococcal dermatitis
- Hemangiomas
- Urethral prolapse
- Entities that look like condylomata acuminata
  - Focal epithelial hyperplasia
  - Darier disease
  - Lymphangioma circumscriptum
  - Pigmented vulvar hamartomas
  - Pseudoverrucous papules
- Entities that look like herpes simplex
  - Localized varicella/zoster
  - Allergic contact dermatitis

Genital warts pose a particularly difficult problem for practitioners. They certainly can be sexually transmitted to children, and the possibility of sexual abuse needs to be discussed with parents. However, there is much evidence that genital warts can be acquired perinatally from an infected mother, through autoinoculation from warts on other parts of the body or through nonsexual contact with caretakers. Children younger than 3 years of age at the onset of warts are least likely to have acquired their warts from sexual contact, whereas children with onset at older than 5 years of age have a much greater risk of having suffered sexual abuse. The ages in between represent a gray zone. Other signs of abuse will seldom be present to aid in the diagnosis, and human papillomavirus typing is not helpful. History provides the most valuable insight into the correct diagnosis; again, it is imperative that an abuse team be involved. At the author's institution, all children with perianal or genital warts are referred, in a nonaccusatory and nonjudgmental fashion, to the hospital's abuse social worker and pediatrician as routine protocol.

ELDER ABUSE

Elder abuse is one of the fastest growing forms of abuse. Although statistics vary, the National Center on Elder Abuse in Washington, DC, estimates that 1 to 2 million Americans 65 years of age or older are victims of various forms of abuse each year. Abuse may affect a range of 2 percent to 10 percent of the elderly population. Those older than age 80 years are two to three times more likely to suffer abuse, and the American population in this age range continues to increase each year. For every case of reported elder abuse, at least another five cases go undetected. All segments of society are affected. Although there is inherent inaccuracy in these statistics, it is readily apparent that elder abuse is common enough for a busy dermatologist to encounter a few abused patients every week.

The U.S. National Academy of Sciences has defined *elder abuse* as: "(a) intentional actions that cause harm or create a serious risk of harm (whether or not harm is intended) to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder, or (b) failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm." Acts of commission and omission are thus included in the definition. Types of abuse and their respective incidence rates are listed in Table 105-5. More than one type of abuse can occur simultaneously.

TABLE 105-5
Types of Elder Abuse

- Neglect: 55%
- Physical abuse: 15%
- Financial and material abuse: 12%
- Emotional or psychological abuse: 8%
- Sexual abuse: 1%
- Unspecified forms of abuse: 9%

Abuse most often occurs at the hands of caregivers or family members who have frequent close contact with patients and often may live with them. Historically, adult children of the abused patient have been the most common perpetrators, but most recent data show that spouses now account for the majority of abuse cases. Men are more likely to abuse than women. The abuser is often financially dependent on the victim, and they are usually in a shared living situation. Financial abuse, however, is more common among those who live alone. Risk factors for abuse are listed in Table 105-6. Note that the risk factors have far more to do with the caretaker than the abused patient. In particular, the level of debility or health status of the patient does not predict abuse.

Physical abuse is defined as the intentional application of any force that causes bodily injury, pain, or impairment to an elderly individual. It may include acts such as hitting, beating, shaking, kicking, slapping, pushing, pinching, burning, overly aggressive force-feeding, and the improper use of physical or chemical restraints. The signs discussed in Child Abuse apply to elder abuse as well and include multiple bruises or fractures in different stages of healing, bruises in normally well-protected areas such as the inner thighs, odd-shaped injuries such as from pinching or slapping, belt marks or patterned bruising (see eFig. 105-5.1 in on-line edition), unusual welts or puncture wounds, cigarette burns, rope marks that might indicate restraints, bed sores, strangely patterned alopecia, attempts to hide part of the body, and signs of malnutrition or dehydration. Because many of these signs, particularly multiple bruises, can occur normally in elderly individuals, detection of abuse can be very challenging. Unexplained repetitive injuries or explanations by caretakers that do not match the pattern of injury are concerning. Caretakers who act withdrawn, infantilize the patient, or insist on providing the medical history should alert the clinician.

TABLE 105-6
Risk Factors for Elder Abuse

- Older age
- Lack of access to resources
- Low income
- Social isolation
- Minority status
- Low level of education
- Functional impairment
- Substance abuse by elder or caregiver
- Previous history of family violence
- History of psychological problems
- Caregiver stress
- Cognitive impairment

It is important to interview by directing questions to the patient rather than the caregiver, and it is prudent to try to arrange a time to confer with and examine the patient alone. Repetitive follow-up visits help develop a rapport with the patient and allow serial observation of past and ongoing injuries. The assurance of confidentiality facilitates garnering sensitive information.

Once abuse is suspected, most states mandate that physicians contact the appropriate authorities. Information on a particular state's laws can be obtained from the National Center on Elder Abuse (see Table 105-3). The nearest medical center's social service department is well equipped to offer guidance, but the agencies listed in Table 105-3 are also helpful resources. Treatment, support, and counseling may be needed for the perpetrator as well.

DOMESTIC VIOLENCE

Domestic violence is a pattern of coercive behaviors that may include repeated battering, psychological abuse, sexual abuse, social isolation, deprivation, and intimidation perpetrated by someone who is or was involved in an intimate relationship with the victim. Conservative estimates say that approximately 1 million people suffer domestic violence each year, but the actual number likely approaches 4 million. Women comprise approximately 90 percent to 95 percent of all victims, and men 95 percent of all perpetrators. Forty percent to sixty percent of men who abuse their partner or spouse are also abusing their children. In the United States, approximately one in three women suffers a least one physical assault during her life,

and 1500 women are murdered by their husbands or boyfriends each year. Domestic violence is a devastatingly common problem.

The profiles of domestic abuse are similar to child and elder abuse. Women ages 19 to 29 years are the most common victims, with other risk factors being low income, mental health issues, alcohol or substance abuse by the victim or the perpetrator, pregnancy, large age difference between partners, separated or divorced status, and a family history or personal past history of abuse and violence. Women with educational or occupational levels above that of their partners may be at higher risk. Abusers are typically underachievers with occupational status below their educational level.

Whenever possible, the patient should be interviewed alone, without the partner's presence. A thorough examination should be done with a nurse chaperone, but not the partner, in the room. Repeat visits may be used to document new or progressing skin findings and to build trust with the patient. Statements such as "Because domestic violence is such a prevalent problem, we have begun to ask about it routinely" may open the door to more discussion regarding difficulties at home. Literature and posters in the clinic setting with information and hotline numbers for abuse victims indicate the reality of abuse and may facilitate disclosures.

For various reasons, a victim may not want to reveal abuse. Implausible explanations for an injury or a delay in seeking medical attention may be clues of abuse. Signs of depression, excessive use of sedatives, chronic pain disorders, or vague stress-related symptoms may be subtle signs of abuse.

Physical examination findings are the same as outlined for child and elder abuse. The distribution of injuries tends to be central, and the perpetrator may choose to injure hidden areas, such as the breast or genitals, to deter detection. Unlike infants or debilitated adults, blows to a young adult may be to areas suggesting a defensive posture and might include purpura, sprains, dislocations, and fractures to the wrist or forearms, palms, and soles.

The social service department at the local medical center is a good resource for information and help on domestic violence. The National Domestic Violence hotline (800-799-7233) is a 24-hour resource for women who need to find a local shelter. Other helpful organizations can be contacted (see Table 105-3).

SECTION 19

FROM BIRTH TO OLD AGE

CHAPTER 106

Neonatal, Pediatric, and Adolescent Dermatology

Mary Wu Chang
Seth J. Orlow

Many, if not all, dermatologic diseases exhibit different manifestations in infants and children. As it is impossible to discuss all of pediatric dermatology in one chapter, we focus instead on certain methods, diseases, and issues pertinent to the practice of pediatric dermatology. Within this chapter, three age divisions are used: neonates and infants, children, and adolescents. Topics of special importance to pediatric dermatology, such as pediatric medication use and biopsy pitfalls, are discussed, and a selected drug formulary is provided.

NEONATES AND INFANTS

The neonatal period is defined as the first 30 days of life. Neonatal skin diseases evolve much more rapidly than adult skin diseases, and some conditions that initially appear to be serious turn out to be trivial, whereas in others, the opposite is true. Infancy is defined as beginning after the first 30 days of life.

Neonatal Skin

After birth, the neonate's skin undergoes a series of changes in adaptation to the extrauterine environment. In utero, the skin of the fetus is protected by the vernix caseosa and is surrounded by amniotic fluid. After birth, the vernix is wiped off, and the skin is exposed and adapts to the dry ambient air. For example, desquamation of the upper layers of the stratum corneum occurs normally in all infants and is believed to be a normal adaptive process.

Research regarding the maturation of the neonatal stratum corneum in neonates has produced varying results, and the question of when full barrier function is achieved is not fully answered. Barrier stabilization appears to be a dynamic process, one dependent upon a balance between different biologic and environmental parameters. Postnatal life is believed to accelerate stratum corneum maturation in premature and term infants. Parameters such as skin thickness, skin pH, and stratum corneum hydration indicate that neonatal skin is continuously adjusting to the extrauterine environment, in contrast to the adult skin, which remains in a steady state.[1]

Although the term infant seems to possess stratum corneum function with adult barrier properties, the term infant has an increased risk for systemic toxicity from topically applied substances. This is due in large part to the great surface area–body mass ratio in the infant. In addition, the infant's metabolism, excretion, distribution, and protein binding of substances can be significantly different from those of an adult and add to increased risk of toxicity.[2]

The postmature infant (> 40 weeks' gestation) usually has dry and cracked or peeling skin noted soon after birth (Fig. 106-1). Shedding of the dry peeling skin of postdates infants occurs spontaneously in the first month of life, leaving normal, healthy skin. Topical care should include moisturizers and avoidance of overbathing.

NEONATAL, PEDIATRIC, AND ADOLESCENT DERMATOLOGY AT A GLANCE

- Many dermatologic diseases exhibit different manifestations in newborns, infants, children, and adolescents.
- Some dermatoses are encountered only in neonates and infants and therefore require special attention.
- Obtaining a history and methods of clinical examination in infants and children differ from the approaches chosen for adults. In adolescents, different interviewing skills are required to enhance compliance.
- The infant has increased risk for systemic toxicity from topically applied substances, and this is even more so in premature infants.
- Drug labeling for pediatric patients is different from that in adults, causing anxiety. Also, dosimetry has to take growth and increase of body weight into account. A selective pediatric dermatology formulary is presented.

Premature infants, particularly those born before 34 weeks of gestation, have markedly decreased epidermal barrier function and an even greater surface area–body mass ratio than term infants.

▲ **FIGURE 106-1** The feet of a postdates newborn. The dry, hyperlinear, and scaly skin is typical of a postdates baby. There are also pustules of transient neonatal pustular melanosis.

In addition, the immature organs of the premature infant may affect the metabolism, excretion, distribution, and protein binding of chemical agents. Local or systemic toxicity can occur in the premature infant not only from topical medications, but also soaps, lotions, or other cleansing solutions.[2,3]

Increased skin fragility is a hallmark of prematurity. Epidermal and dermal injury may lead to significant cutaneous pain accentuated by routine handling and nursing care. The premature infant is at risk for infection and sepsis from skin-associated organisms entering through breaks in the thin and fragile skin and via iatrogenic portals of entry. Sweating in the premature infant is functionally reduced and contributes to poor thermal regulation. Heat regulation is dysfunctional due to a thin subcutaneous fat layer for insulation, poor autonomic control of cutaneous vessels, and a large surface–body ratio. In the nursery, the premature infant is usually placed in a temperature and humidity-controlled isolette until the infant matures and temperature and fluid regulation stabilizes.

The application of preservative-free, petrolatum-based ointments decreases trans-epidermal water loss of neonatal skin.[4] However, a threefold increase in the incidence of systemic candidiasis was reported after emollient therapy was implemented in extremely low birthweight (≤ 1000 g) premature infants in a neonatal intensive care unit.[5] Another outbreak of systemic candidiasis occurred in very low birthweight neonates (≤ 1500 g) in a different neonatal intensive care unit.[6] Until prospective, controlled trials are performed, neonates receiving petrolatum-based emollient therapy should be carefully monitored for systemic candidiasis, particularly those infants with birth weights less than 1500 g.

Once at home, bathing once or twice a week in plain water is sufficient for most infants; if bathing is more frequent, moisturization with unscented, simple emollients is recommended. The face, hands, and diaper area may be cleansed daily using a small amount of a mild, unscented, pH-neutral cleanser. Well-meaning parents often bathe their infants too frequently and use a multitude of products on their infant's skin. In addition to irritation and asteatosis, these practices may increase the risk of allergic contact dermatitis in infants. It has been estimated that the average newborn is exposed to approximately 10 skin care products in the first month of life, leading to exposure to more than 50 different chemicals ranging from mildly toxic to toxic.[7] Parents should be taught that "less is best."[8]

Examination Techniques

A complete history includes gestational and birth history as well as family history. Exposures during pregnancy, including medications, illicit drugs, and infectious diseases such as varicella and sexually transmitted diseases, should be reviewed. Obstetric data, including placental appearance and cultures, can be invaluable. The most important element in the examination of an infant is thoroughness. Whether the infant is examined in the lap of the parent or on the examination table, all surfaces, including the creases and valleys of body folds and the diaper region (including the genitalia), deserve close examination. A vascular stain, vasoconstricted macule, or erosion can be the presenting sign of a hemangioma.[9] A stray hair may later strangulate an appendage and should be removed. Infants with digital tourniquet (pseudoainhum) and clitoral tourniquet have been described.[10,11] Congenital lesions of all classifications (e.g., pigmented, vascular, aplasias) warrant closer inspection to rule out associated findings. Midline lesions on the face, scalp, or spine may have central nervous system (CNS) connections and should not be biopsied without proper evaluation. The diaper area has its own unique set of problems and deserves examination at every visit.

The infant is vulnerable and completely dependent on the caretakers. The social support system and family structure must be considered when implementing a medical plan.

Medical and surgical decision making for the infant is based primarily on function rather than cosmesis. For example, extraction of a natal tooth is indicated if breast-feeding is impaired; whether or not the tooth is a component of a genetic syndrome is a separate issue. There are times when the parents' desire for treatment may not be in the best interest of the patient.

Diseases of Neonates and Infants

TRANSIENT DERMATOSES OF THE NEONATE

Skin conditions encountered in newborns that tend to resolve by 30 days of age are considered to be transient. They are very common, and many are expected in newborns.

Caput Succedaneum and Cephalohematoma. Caput succedaneum is subcutaneous edema over the presenting part of the head and is a common occurrence in newborns. Cephalohematoma is a subperiosteal collection of blood and is less common. Both lesions are due to shearing forces on the scalp skin and skull during labor.

Caput succedaneum is soft to palpation, and borders are ill defined. Cephalohematoma is bounded by the suture lines of the skull and often feels fluctuant. If purpura is extensive, it can lead to hyperbilirubinemia. Congenital lymphedema or lymphatic malformations (such as in Turner syndrome) can mimic caput succedaneum. Both caput succedaneum and cephalohematoma resolve spontaneously; however, caput usually fades in 7 to 10 days, whereas cephalohematoma slowly resolves over several weeks.

Milia. Milia are multiple pinpoint- to 1-mm papules representing benign, superficial keratin cysts. They are seen most commonly on the nose of infants and may be present in the oral cavity as well, where they are called *Epstein's pearls*. They are expected findings in the newborn and resolve spontaneously within a few weeks of life.

Sebaceous Gland Hyperplasia. At least 50 percent of normal newborns have sebaceous gland hyperplasia (Fig. 106-2). Tiny (< 1-mm) yellow macules or papules are seen at the opening of each pilosebaceous follicle over the nose and cheeks of term newborns. It is a benign condition that clears spontaneously by 4 to 6 months of age.

▲ **FIGURE 106-2** Sebaceous hyperplasia on the nose of a 1-day-old infant.

Erythema Toxicum Neonatorum. Erythema toxicum neonatorum (ETN) is an idiopathic, common condition seen in up to 75 percent of term newborns. It is rarely seen in premature infants. Blotchy erythematous macules 1 to 3 cm in diameter with a 1- to 4-mm central vesicle or pustule are seen in ETN (Fig. 106-3). They usually begin at 24 to 48 hours of age, but delayed eruption as late as 10 days of age has been documented.[12] These follicular-based lesions can be located anywhere but tend to spare the palms and soles. A smear of the central vesicle or pustule contents will reveal numerous eosinophils on Wright-stained preparations. A peripheral blood eosinophilia of up to 20 percent may be associated, particularly in infants, with numerous lesions. Transient neonatal pustular melanosis (TNPM) mimics ETN, except that neutrophils rather than eosinophils are found within the pinpoint vesicles, and individual lesions heal with residual pigmentation, which is not seen in ETN. Bacterial infections, *Pityrosporum* folliculitis, and congenital candidiasis also may mimic ETN. Bacterial and fungal culture of lesions and Gram staining will help differentiate among these entities. ETN is benign and clears spontaneously by 2 to 3 weeks of age without residua.

Transient Neonatal Pustular Melanosis. TNPM is an idiopathic pustular eruption of the newborn that heals with tiny brown pigmented macules (Fig. 106-4). It is less common than ETN and is more prevalent among newborns with darkly pigmented skin. Lesions are present at birth or shortly thereafter as superficial vesicles and pustules, with ruptured lesions evident as collarettes of scale. Pigmented macules are also often present at birth or develop at the sites of resolving pustules or vesicles within hours or

▲ **FIGURE 106-3** Erythema toxicum neonatorum. Erythematous macules, some with a tiny central papulopustule, on the arm of a 1-day-old newborn.

during the first day of life. Lesions can occur anywhere but are common on the forehead and mandibular area. The palms and soles may be involved. Smear of the vesicle or pustule contents will reveal a predominance of neutrophils with occasional eosinophils on Wright-stained preparations.[13]

Miliaria rubra is frequently confused with ETN and TNPM. The erythema around miliaria rubra is small in area (1 to 2 mm vs. 20 to 30 mm in ETN). The central pustule of TNPM may mimic congenital candidiasis, *Pityrosporum* folliculitis, or bacterial folliculitis lesions. Herpes simplex should be considered if lesions are vesicular. A Gram-stained slide of the pustules of ETN or TNPM will not show organisms. A Wright-stained slide usually will show a predominance of neutrophils.

TNPM is a harmless condition that requires no treatment. The pustules usually disappear by 5 days of age, leaving residual pigmented macules that resolve over 3 weeks to 3 months.

Mottling. Mottling is a blotchy or lace-like pattern of dusky erythema over the extremities and trunk of neonates that occurs with exposure to cold air. Virtually all babies demonstrate mottling at some time during the newborn period due to immaturity of the autonomic control of the skin vascular plexus. This physiologic mottling disappears on re-warming, differentiating it from cutis marmorata telangiectatica congenita and livedo reticularis. Normal mottling resolves spontaneously by 6 months of age.

Harlequin Color Change. Harlequin color change is a rare vascular phenomenon occurring in low-birth-weight infants. When the infant is placed on one side, an erythematous flush with a sharp demarcation at the midline develops on the dependent side, and the upper half of the body becomes pale. The color change usually subsides within a few seconds of placing the baby in the supine position but may persist for as long as 20 minutes. The exact mechanism of this unusual phenomenon is not known, but it may be due to immaturity of autonomic vasomotor control. Harlequin color change is seldom seen after 10 days of age.

▲ **FIGURE 106-4** Transient neonatal pustular melanosis. **A.** A newborn with congenital, thin-walled pustules that rupture easily. **B.** Hyperpigmented macules appeared by 10 hours of age.

Sucking Blisters. Sucking blisters are uncommonly apparent at birth as the result of intrauterine sucking. Sucking blisters, however, are more commonly seen during the first weeks of life. Sucking blisters are usually solitary, intact oval or linear blisters, erosions, or drying crusts, arising on noninflamed skin of the dorsal aspect of forearms, wrists, or fingers or on the upper lip. They resolve within a few days. If the affected extremity is brought up to the infant's mouth, the infant will often commence sucking at the site, confirming the diagnosis. Herpesvirus infection is often considered when sucking blisters are encountered, but lesions of herpes simplex are grouped vesicles occurring on an erythematous base or punched out, hemorrhagic erosions.

Neonatal Acne. Neonatal acneiform facial lesions usually develop within the first 30 days of life and are estimated to occur in 50 percent of newborns (Fig. 106-5). This benign eruption appears to be hormonally mediated (see Chap. 78). Neonatal acne may be hard to distinguish from benign neonatal cephalic pustulosis, which has been attributed to overgrowth of *Malassezia* sp.[14] Most cases resolve spontaneously, but severe cases can be treated topically with ketoconazole, benzoyl peroxide, or erythromycin.

HAIR LOSS IN THE INFANT[15] ***Telogen Effluvium.*** Telogen effluvium occurs frequently in newborns and is often overlooked. The hair loss may be gradual or sudden, and may occur as soon as the first few days of life, with the telogen hairs shed by 3 to 4 months of age. No treatment is indicated as spontaneous resolution is the rule.

A transient circumscribed patch of non-scarring alopecia develops at the occiput in many infants. This is believed to be due to a combination of physiologic telogen effluvium and possibly localized pressure from laying in the supine position. This spontaneously resolves.

Triangular Temporal Alopecia. Triangular temporal alopecia is a form of non-scarring hair loss noted at 2 to 5 years of age as a triangular-, oval-, or lancet-shaped area of alopecia at the frontotemporal scalp. Often, a thin row of hair separates the affected area from the forehead. The terminal hairs are replaced by vellus hair. The condition is often mistaken for alopecia areata; however, distinguishing features include the typical location and shape, the presence of vellus hairs, and the absence of exclamation point hairs and the histologic findings of alopecia areata. There is no known treatment, and the condition persists unchanged. However, triangular temporal alopecia is benign and will not expand.

◀ **FIGURE 106-5** Neonatal acne. Tiny papulopustules on the cheeks of a 3-week-old infant.

Alopecia Areata. Alopecia areata occurs in all ages (see Chap. 86). All forms of alopecia areata occur in infants and children (patchy, universalis, etc.), with the same disease presentation and treatment challenges as in adults. Onset at younger than 2 years of age is estimated to occur in 1 percent to 2 percent of alopecia areata patients; however, it may be more common than this due to under-recognition. Several cases of congenital alopecia areata have been documented. Early onset is considered to be a marker of severe disease. Total alopecia during the first year of life after having hair at birth should be distinguished from genetic disorders, such as congenital atrichia and the alopecia associated with vitamin D–resistant rickets.

Tinea Capitis. Tinea capitis can occur at any age, including infancy (see Chap. 188). Hair loss associated with scaling, broken hairs, pustules, or black dots should prompt a potassium hydroxide scraping and fungal culture to confirm the diagnosis. Just as in older children, *Trichophyton tonsurans* is the most common dermatophyte, and oral griseofulvin is the treatment of choice. Tinea capitis and fungal infections are discussed in Chap. 188.

BIRTHMARKS Birthmarks represent an excess of one or more of the normal components of skin per unit area: blood vessels, lymph vessels, pigment cells, hair follicles, sebaceous glands, epidermis, smooth muscle, collagen, or elastin. Although most birthmarks are of little medical or psychosocial consequence, the social and cultural impact of a disfiguring birthmark should not be underestimated, from both the patient's and the parents' perspectives.[16] The age-old theory of maternal imprinting is still widely accepted in many countries, including the United States, and the mother may be subtly or actively blamed for congenital conditions in the newborn. With selective photothermolysis offered by lasers and advances in surgical and topical therapies, therapeutic options are increasing.

The two most common birthmarks are the salmon patch (see Chap. 173) and Mongolian spots (see Chap. 122). Salmon patches occur most commonly on the glabella and nuchal area and are observed with high frequency in all races, occurring in 70 percent of white infants and 59 percent of black infants. Mongolian spots, which represent collections of dermal melanocytes, are seen in 80 percent to 90 percent of infants of color but in only 5 percent of white infants.[17,18] Solitary café-au-lait macules are extremely common and benign, however the appearance of multiple café-au-lait macules raises the possibility of neurofibromatosis type 1 (see Chap. 142). Other common birthmarks are listed in Table 106-1.

TABLE 106-1
Common Birthmarks in the Newborn

- Mongolian spots
- Salmon patch ("stork bite," "angel's kiss") (see Chap. 173)
- Port-wine stain (nevus flammeus) (see Chap. 173)
- Hemangioma (see Chap. 126)
- Epidermal nevus, including nevus sebaceus (see Chap. 118)
- Congenital nevocellular nevi (see Chap. 122)
- Congenital melanocytic nevi (see Chap. 122)
- Nevus depigmentosus (see Chap. 73)
- Café-au-lait spots (see Chap. 73)

HEMANGIOMAS Infantile hemangiomas are the most common tumors of infancy. They must be differentiated from vascular malformations and other vascular anomalies. Hemangiomas are discussed in detail in Chap. 126.

LYMPHANGIOMAS Both types of lymphatic malformations, microcystic (lymphangiomas) and macrocystic (cystic hygromas), are discussed in Chap. 173.

UNCOMMON DERMATOSES OF THE NEONATE Selected dermatoses of the neonate are discussed in the following sections. Box 106-1 lists differential diagnoses for selected cutaneous conditions encountered in neonates and infants.

Cutis Marmorata Telangiectatica Congenita. Cutis marmorata telangiectatica congenita is characterized by persistent cutis marmorata, telangiectasia, and sometimes associated underlying cutaneous atrophy (Fig. 106-6). Its incidence is sporadic, and its etiology is obscure. Theories of vascular malformation are currently favored. Diagnosis is usually evident on clinical examination. Usually a lower extremity is involved, but location on the trunk or upper extremity is not uncommon. A multitude of associated anomalies can occur, including limb asymmetry, hemangiomas, and other vascular birthmarks, pigmented nevi, and aplasia cutis congenita (ACC). However, the majority of patients have a good prognosis, with half demonstrating improvement of the mottled appearance over the first two years.[19]

Subcutaneous Fat Necrosis of the Newborn. Subcutaneous fat necrosis of the newborn is characterized by firm, circumscribed, reddish or purple subcutaneous nodules or plaques that appear over the back, cheeks, buttocks, arms, and thighs (Fig. 106-7; see Chap. 68). The lesions usually begin within the first 2 weeks of life and resolve spontaneously over several weeks.[20]

Sclerema Neonatorum. Sclerema is diffuse hardening of the skin in a sick premature newborn and is becoming rare as neonatal care improves worldwide. The onset is characteristically after 24 hours of age. The skin feels hard and immobile and looks yellow and shiny. The trunk is always involved. Severely ill premature newborns that have suffered sepsis, hypoglycemia, metabolic acidosis, or other severe metabolic abnormalities are at risk. Histologically, edema of fibrous septa surrounding fat lobules is found. There is no necrosis of fat, differentiating it from subcutaneous fat necrosis of the newborn. The etiology of this rare condition is unclear, and infant mortality is high.

Box 106-1

Selected Differential Diagnosis of Neonates and Infants

- Pustules in the neonate
  - Erythema toxicum neonatorum
  - Transient neonatal pustular melanosis
  - Congenital candidiasis
  - Letterer-Siwe disease (pustular psoriasis, Langerhans cell histiocytosis) (see Chap. 148)
  - Neonatal cephalic pustulosis
  - Bacterial sepsis
  - Herpes simplex infection (see Chap. 193)
- Blistering in the neonate
  - Sucking blisters
  - Herpes simplex virus (see Chap. 193)
  - Aplasia cutis congenita
  - Cutaneous mastocytosis (see Chap. 150)
  - Epidermolysis bullosa
  - Neonatal pemphigus
  - Varicella (see Chap. 194)
  - Impetigo
  - Incontinentia pigmenti
  - Epidermolytic hyperkeratosis (see Chap. 47)
- The red scaly baby
  - Physiologic scaling and redness (postdates) infant
  - Psoriasis
  - Atopic dermatitis
  - Scabies
  - Seborrheic dermatitis
  - Immunodeficiency (see Chap. 144)
  - Hypohidrotic ectodermal dysplasia (see Chap. 143)
  - Netherton syndrome (see Chap. 47)
  - Acrodermatitis enteropathica (see Chap. 130)
- The collodion baby (see Chap. 47)
  - Lamellar ichthyosis (see Chap. 47)
  - Congenital ichthyosiform erythroderma
  - Gaucher syndrome
  - X-linked ichthyosis (see Chap. 47)
  - Epidermolytic hyperkeratosis (see Chap. 47)
- The "blueberry muffin" baby
  - TORCH infections
  - Congenital leukemia
  - Congenital self-healing reticulohistiocytosis (see Chap. 149)
  - Blue rubber bleb nevus syndrome
  - Twin-twin transfusion

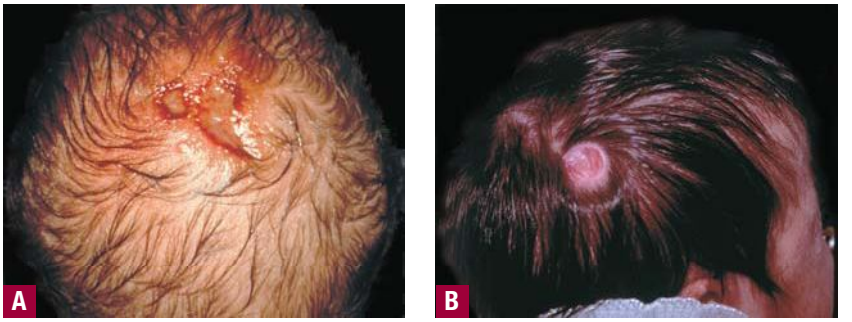
TORCH = *t*oxoplasmosis, *o*ther agents, especially syphilis, but also hepatitis B, coxsackie virus, Epstein-Barr virus, varicella-zoster virus, and human parvovirus, *r*ubella, *c*ytomegalovirus, *h*erpes simplex virus.

▲ **FIGURE 106-6** Cutis marmorata telangiectatica congenita. Note the atrophic, dusky, stellate patches with overlying telangiectasias.

Aplasia Cutis Congenita. ACC represents a developmental failure of the skin usually occurring on the scalp, but any location on the body surface can be affected (Fig. 106-8). It is often an isolated finding, but a multitude of associated conditions have been described.

ACC has no single underlying cause.[21] Some cases may represent a forme fruste of a neural tube defect.[22] In the most common form of ACC, oval, sharply marginated atrophic macules are seen on the midline of the posterior scalp. They are usually solitary, but may be multiple. Aplasia cutis is always hairless, and may appear vesicular, ulcerated, or covered by a thin epithelial

▲ **FIGURE 106-7** Subcutaneous fat necrosis of the newborn. This infant developed an erythematous firm mass on the back by 2 weeks of age. She later developed hypercalcemia.



▲ **FIGURE 106-8** Two infants with aplasia cutis congenita. **A.** Scalp erosions grouped at the vertex scalp. Scraping or biopsy is contraindicated. **B.** An atrophic, well-circumscribed round patch with visible capillaries on the scalp of an infant. (**A** used with permission from 1991 Yale Resident Photograph Collection.)

membrane. When healed, lesions are usually atrophic, but sometimes develop a keloidal scar. Epidermis, dermis, and fat all may be missing, or single layers may be absent. Lesions may range from a few millimeters to many centimeters in diameter. Epidermolysis bullosa (see Chap. 60) may present as ACC, especially on one or both legs.

Scalp ulcers at birth of aplasia cutis may be mistaken for obstetric trauma. Other forms of congenital circumscribed hair loss should be considered. Midline blisters or erosions should not be biopsied, scraped for herpes cultures, or otherwise traumatized. After a careful examination to rule out associated malformations, ACC is treated conservatively to allow healing. Surgical revision of the scar later in childhood or adolescence can be done electively to improve cosmesis.

Hair Collar Sign. The "hair collar sign" is a ring of darker and/or coarser terminal hairs on the scalp, typically surrounding ACC, dermoid cyst, encephalocele, meningocele, or heterotopic brain tissue.[22] The hair collar sign itself is a marker of cranial dysraphism and its presence, like aplasia cutis, mandates careful examination of the infant, particularly of midline structures and fusion planes.

Anetoderma of Prematurity. A specific form of anetoderma has been described in premature infants. Most were extremely premature infants (born at 24 to 29 weeks' gestation); however, one was born at 32 weeks' gestation. The development of localized anetoderma appears to be triggered by the placement of monitoring leads on the skin of low-birthweight, growth-restricted infants; the majority were very ill premature infants.[23] However, anetoderma of prematurity is not well understood, and it remains a rare dermatosis despite the widespread use of monitoring leads in the neonatal intensive care unit. Anetoderma is discussed in Chap. 65.

Infections of the Neonate

Infants younger than the age of 2 months are less able to localize infection due to immature immunologic function, and life-threatening sepsis can develop insidiously. Subtle clues such as a decrease in body temperature, poor feeding, or other non-specific signs are taken seriously by the pediatrician, and a "rule out sepsis" admission is implemented when suspicions are high. At a minimum, blood, cerebrospinal fluid, and urine cultures are obtained, and intravenous antibiotic therapy begun pending cultures.

CONGENITAL VIRAL INFECTION Petechiae, purpura, jaundice, hepatomegaly, splenomegaly, microcephaly, encephalopathy, ocular abnormalities, anemia, thrombocytopenia, conjugated hyperbilirubinemia, or elevated serum hepatic transaminases should prompt the consideration of congenital viral infection, particularly if these signs arise in combination. Cutaneous infections of the neonate are listed in Table 106-2. Bacterial infections, such as staphylococcal scalded skin syndrome, and viral infections, such as varicella, are discussed in Chaps. 177, 178, and 194, respectively.

NEONATAL HERPES SIMPLEX VIRUS INFECTION (See Chap. 193) It is estimated that untreated neonatal herpes simplex virus (HSV) has a 50 percent mortality rate, with three-fourths of survivors suffering neurologic sequelae.[20] The greatest risk of neonatal herpes occurs when the delivery is vaginal and the mother has primary genital herpes (as opposed to recurrent herpes, in which the mother has antibodies protective to the neonate), the herpes infection involves the cervix, and the infant is premature and delivered with instrumentation (e.g., scalp electrodes).

The vast majority of cases are due to HSV type 2 (see Chap. 193). The typical lesions of herpes are present in the skin, eye, or mouth in a large majority of infected neonates, but some patients with CNS or disseminated disease never have skin lesions[24,25] (Fig. 106-9). Vesicles present during the first 24 hours of life suggest in utero acquisition of HSV, but onset during the first week to 10 days of life is more common, representing infection during birth.[25]

A high index of suspicion should be maintained even in the absence of maternal infection or history of genital herpes. Specimens for Tzanck smear, direct fluorescent antibody assays, and/or viral cultures for HSV should be obtained. Cultures require 12 to 120 hours to grow, and in all infected or suspected neonates, cultures of skin lesions, urine, nasopharynx, eyes, and cerebrospinal fluid are indicated. If available, a polymerase chain reaction test can be helpful in rapid diagnosis. Intravenous acyclovir should be instituted as soon as possible after specimens are collected to minimize the chance of replication of virus in the CNS and systemic dissemination of HSV. Prompt recognition and early therapeutic intervention lead to an improved outcome in the HSV-infected infant.[25]

TABLE 106-2
Selected Cutaneous Infections in the Neonate

- Staphylococcal infections (see Chap. 177)
- Impetigo
- Staphylococcal scalded-skin syndrome (see Chap. 178)
- Omphalitis
- Breast abscess (usually due to *Staphylococcus aureus* and Gram-negative organisms)
- Viral infections (see Chap. 192)
- Varicella (see Chap. 194)
- Herpes simplex virus (see Chap. 193)
- Fungal/candidal infections (see Chaps. 188, 189)
- Scabies (see Chap. 208)

Congenital Malformations of the Skin

MINOR ANOMALIES Congenital malformations are developmental defects and are frequently observed in newborns. Single minor anomalies occur in approximately 15 percent of all newborns and are, by definition, of no functional sig-

◀ **FIGURE 106-9** Herpes simplex infection. Grouped vesicles on an erythematous base. Pustules and erosions are also present. (Used with permission from Alvin H. Jacobs, MD.)

nificance. The supernumerary nipple and the accessory tragus are common examples of minor malformations. The occurrence of two is less common, however, and the presence of three or more is unusual; a complete thorough physical examination is indicated to rule out other congenital abnormalities.[26,27]

CUTANEOUS MARKERS OF DYSRAPHISM

The skin and the nervous system are both derived from the ectoderm. The neural ectoderm separates from the epithelial ectoderm during the third to fifth week of gestation, occurring simultaneously with the formation and closure of the neural tube. Hence, errors in neural tube development [i.e., dysraphism (incomplete fusion)] can be associated with cutaneous lesions. Midline facial lesions, such as dermoid cysts, nasal gliomas, and ACC, can be markers of cranial dysraphism, whereas cutaneous lesions seen on the lumbosacral midline can signify underlying spinal dysraphism. Imaging studies should be considered for midline nasal lesions before biopsy to rule out intracranial connections.[28]

A retrospective review of 54 cases of congenital lumbosacral skin lesions (including deviated gluteal cleft)[29] demonstrated that the highest risk of occult spinal dysraphism occurs with the presence of two or more congenital midline lumbosacral skin lesions, or if spinal cord dysfunction exists in the presence of one lumbar skin lesion. In addition, lumbosacral lipoma, human tail, or dermal sinus (as isolated findings) were highly associated with occult spinal dysraphism. Lumbosacral magnetic resonance imaging is indicated when these high-risk congenital lesions are present. An intermediate risk of occult spinal dysraphism was associated with atypical sacral dimple (≥ 5-mm diameter, or location ≥ 2.5 cm away from the anus), ACC, overlying hamartoma, or deviated gluteal cleft. In the presence of any of these lesions, ultrasound can be used to screen for occult spinal dysraphism if the infant is less than 4 months of age. If the infant is older, magnetic resonance imaging is needed to rule out dysraphism. Low-risk lesions that do not require imaging include isolated lumbosacral hemangioma, port-wine stain, hypertrichosis, pigmented nevus, Mongolian spot, or simple sacral dimple (≤ 5-mm diameter and location 2.5 cm or closer to the anus).[29] These findings are summarized in Table 106-3.

TABLE 106-3
Congenital Lumbosacral Midline Skin Lesions and Risk of Occult Spinal Dysraphism

Risk of Occult Spinal Dysraphism	Congenital Lumbosacral Midline Lesion
High	Group 1: MRI indicated • Two or more lesions of any kind • One lesion + spinal cord dysfunction • Lipoma • Tail • Dermal sinus
Intermediate	Group 2: Ultrasound if younger than age 4 mo (then MRI if ultrasound is abnormal), MRI indicated for age > 4 mo • Atypical sacral dimple (deep, farther than 2.5 cm from the anus, size ≥ 5 mm) • Unclassified hamartoma • Aplasia cutis congenita • Deviation of gluteal crease
Low	Group 3: No imaging needed • Hemangioma • Port-wine stain • Hypertrichosis • Pigmented nevus • Simple sacral dimple (< 5-mm diameter, 2.5 cm or closer to the anus) • Mongolian spot

MRI = magnetic resonance imaging.

INFANCY AND CHILDHOOD

Evaluation Techniques

When entering the room, prolonged or intense eye contact with the young child should be avoided because this can be threatening to the child. Observing the play of a child allows for a quick assessment of his or her neurologic development.

If a language barrier exists between the parents and physician, one should resist the urge to have the bilingual patient serve as interpreter for the parents. This practice places an inappropriate burden of responsibility on the child and may increase fear and anxiety in the child. In addition, inaccurate transmission of information may occur.

Examination of young children may be performed with the child on the parent's lap or while playing with toys on the examination table. Examination of the perineum and genitalia is best accomplished with the child in the knee-chest position on the examination table (Fig. 106-10) or the parent's lap. Alternatively, the child may sit on the parent's lap with legs held apart by the parent. Fig. 106-11 illustrates anatomic terminology of the young female genitalia for accurate documentation. Caution must be used in interpreting the genital exam-

▲ **FIGURE 106-10** The knee-chest position allows visualization of the perineum and genitalia. (From Finkel MA, DeJong AR: Medical findings in child abuse, in *Child Abuse: Medical Diagnosis and Management*, edited by Reece EM. Philadelphia, Lea & Febiger, 1994, p 185, with permission.)

ination in the young female so as not to underdiagnose or overdiagnose disease or abuse. For example, the presence of labia minora adhesions is not diagnostic of trauma or abuse because they occur in as many as one-third of girls who are not abused.[30] The diastasis ani is a normal structure that can be mistaken for perianal scarring.[31] The infantile perianal pyramidal protrusion may be mistaken for condyloma acuminata but is a harmless normal finding (discussed later in this chapter in Infantile Perineal Protrusion).[32,33] Child abuse is discussed in Chap. 105.

Performing Procedures on the Young Child

Historically, there has been a widespread reluctance to biopsy skin lesions in children. In addition, children may be fearful of procedures because of their experience with immunizations and an age-appropriate fear of bodily mutilation. However, with proper preparation of the parent and child, skin biopsies and other outpatient procedures are easily performed. There are certain situations in which a biopsy can be detrimental; examples of these "biopsy pitfalls" are outlined in Table 106-4.

Eutectic mixtures of lidocaine and prilocaine (EMLA cream) or lidocaine alone (LMX cream) are useful in minimizing the pain of intralesional injections or local anesthetic injections for biopsies. As EMLA use has become widespread, reports of toxicity in children have appeared, including methemoglobinemia and seizures. The maximum dose, body surface area exposed to drug, and application time should not be exceeded; these parameters are age dependent and are listed in Chap. 243. The application of ice or anesthetic cryospray is another option to numb the skin before injections.

Before and during procedures, young infants can be soothed with a pacifier dipped in a sucrose solution. A randomized, controlled, double-blinded study of 201 newborns found that orally administered glucose solution was superior to topical EMLA cream in reducing pain with venipuncture.[34] Infants may be swaddled with a blanket for comfort and immobilization. The young child can be effectively immobilized and comforted with a restraining "hug," by a parent or assistant. Distraction techniques are invaluable as well. For example, instructing the child to blow a colorful toy windmill, blow soap bubbles, or "wiggle" his or her toes during an injection or procedure helps to decrease pain. Older children may be effectively soothed by listening to music with headphones or by watching a movie during procedures.

Alkalinizing local anesthetics to a pH of 7.0 (0.1 mEq/mL sodium bicarbonate or a 1:10 bicarbonate–anesthetic ratio by volume) minimizes the pain of cutaneous infiltration without limiting anesthetic effects.[35] Alkalinization decreases the solution's shelf life to approximately 1 week[36] due to more rapid oxidation of epinephrine. Warming lidocaine also lessens the pain of injection.[35]

Instruments and materials should be laid out ahead of time to ensure rapid performance of the procedure. Needles, instruments, and blood-stained gauze should be kept out of view and out of reach of the patient.

The use of general anesthesia for dermatologic procedures in pediatric patients is very safe when properly performed. Fears of general anesthesia should not be a barrier to delivering necessary surgical or laser procedures to healthy children.[37]

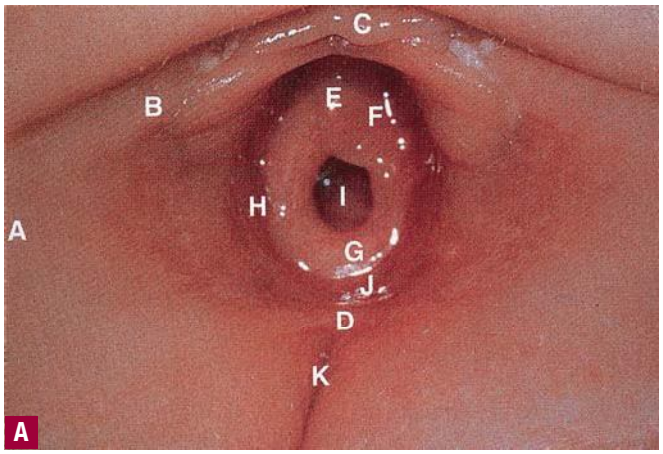
Diseases of Infancy and Childhood

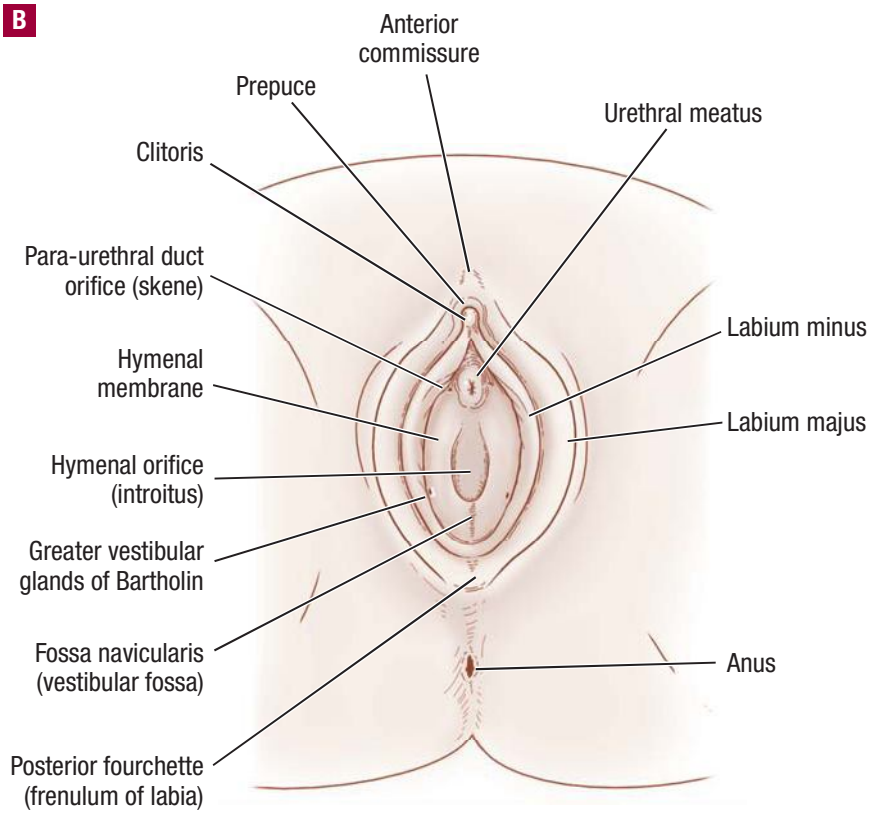
INFANTILE PERINEAL PROTRUSION Also known as *infantile pyramidal protrusion*, infantile perineal protrusion (IPP) is a benign condition that occurs almost exclusively in female prepubertal girls. It appears as a pyramidal, soft-tissue, "tongue-like," smooth, or velvety pink protrusion. It is usually located in the midline just anterior to the anus. IPP is usually asymptomatic, but painful defecation has been reported. It occurs in three settings: constitutional, functional (after constipation, diarrhea, or other irritant exposure), or associated with lichen sclerosus et atrophicus. Often, IPP is misdiagnosed as condyloma acuminatum, hemorrhoids, or as a sign of trauma. Conservative management is indicated. Spontaneous resolution as well as resolution following high-fiber diet to relieve constipation has been noted.[32,33]

DIAPER DERMATITIS Diaper dermatitis, like hand dermatitis, denotes a group of region-specific dermatoses. Diaper dermatitis is one of the most common dermatologic conditions in infants and children, noted in approximately 1 million pediatric outpatient visits each year.[38] With the advent of superabsorbent disposable diapers in the last decade, severe forms of diaper dermatitis have diminished in incidence. Irritant and candidal diaper dermatitis comprise the vast majority of diaper dermatitides in diaper-wearing individuals of all ages.

The etiology of diaper dermatitis is multifactorial. The initiating factor is prolonged and increased wetness to the skin. This leads to increased frictional damage, decreased barrier function, and increased reactivity to irritants. Other interrelated etiologic factors include contact with urine and feces, fecal proteolytic and lipolytic digestive enzymes, increased skin pH, and superinfection with *Candida* and, less commonly, bacteria.[39]

Irritant Diaper Dermatitis. By far the most common type of diaper dermatitis is irritant diaper dermatitis or generic diaper





▲ **FIGURE 106-11** **A.** Magnified view of a normal female child's genital anatomy. The following structures are labeled: A, labia majora; B, labia minora; C, clitoris; D, posterior fourchette; E, urethra; F, periurethral tissue; G, hymen; H, perihymenal sulcus; I, vagina; J, posterior navicular fossa (fossa navicularis); K, perineum. (From Siegfried EC, Frasier LD: The spectrum of anogenital diseases in children. *Curr Probl Dermatol* **9**:33, 1997, with permission.) **B.** Genital anatomy of an older female child. (From Finkel MA, DeJong AR: Medical findings in child abuse, in *Child Abuse: Medical Diagnosis and Management*, edited by Reece EM. Philadelphia, Lea & Febiger, 1994, p 185, with permission.)

dermatitis. This dermatitis occurs in any person who wears diapers, regardless of age. Irritant diaper dermatitis appears as erythematous, moist, and sometimes scaly patches on the convexities of the genitalia and buttocks, beginning in areas in closest contact with the diaper. Shallow erosions are sometimes present on the convex surfaces. It can be asymptomatic or tender. Irritant dermatitis of the buttocks is often seen in toddlers who transition to pull-up diapers at night, which are poorly absorbant.

Candida *Diaper Dermatitis.* (See Chap. 189) *Candida* diaper dermatitis is the second most common type of diaper dermatitis and presents with bright red erythematous, moist papules, patches, and plaques that tend to involve body folds as well as convex surfaces. Satellite lesions are very characteristic. Oral thrush can be associated. *Candida* from intestinal flora frequently contaminates any type of diaper dermatitis present for greater than 3 days, and *Candida* levels increase with the clinical severity of the dermatitis.[40]

Miliaria Rubra ("Heat Rash"). (See Chap. 82) Miliaria rubra tends to occur at sites where plastic components of the diaper cause occlusion of eccrine ducts of the skin. It is also seen in the folds of the neck and upper torso, and is particularly common when there is a rapid shift to warm weather, and the child is overdressed.

Pseudoverrucous Papules and Nodules. Pseudoverrucous papules and nodules occur in the diaper and perianal areas in patients of any age with a predisposition to prolonged wetness. Children who wear diapers due to chronic urinary incontinence are prone to this type of dermatitis.

Infantile Granular Parakeratosis. Infantile granular parakeratosis represents an idiopathic form of retention keratosis in diaper-wearing infants. There are two clinical patterns: bilateral linear plaques in the inguinal folds and erythematous geometric plaques underlying pressure points from the diaper. A thick, flake-like scale is present in both forms and is characteristic. Therapeutic responsiveness to topical agents is ambiguous; however, spontaneous clearance after months to 1 year appears to be the rule.[41]

Jacquet Erosive Dermatitis. Jacquet erosive dermatitis is an uncommon, severe diaper dermatitis that can occur at any age. It is characterized by well-demarcated, punched-out ulcers or erosions with elevated borders. Prolonged contact with urine and feces under occlusion leads to this condition.[42] It is seen less commonly since the advent of superabsorbent diapers.

Granuloma Gluteale Infantum. Granuloma gluteale infantum is an uncommon condition characterized by reddish purplish nodules of different sizes (0.5 to 3.0 cm) occurring on the convexities of the diaper area in 2- to 9-month-old infants. It arises within pre-existing diaper dermatitis. Biopsy shows dense dermal infiltrates of lymphocytes, plasma cells, neutrophils, and eosinophils, but no true granulomas. It appears to be an unusual reaction to the usual irritant factors, candidal infection, and, in some cases, topical steroid use in the diaper region.[42] Treatment consists of

TABLE 106-4
Biopsy Pitfalls in Pediatric Dermatology

Age Group	Lesion and Site	Diagnosis	Danger	Proper Management
Newborn	Erosion or vesicle on the scalp	Aplasia cutis congenita Differential diagnosis: herpes, fetal scalp electrode trauma	Possible intracranial connection, risk of meningitis with biopsy or scraping	Protect site; do not scrape lesion or biopsy, consider ultrasound or MRI of head
Infant	"Hair collar" sign surrounding lesion on scalp or midline lesion	Encephalocele, spina bifida occulta, meningomyelocele	Possible intracranial connection; risk of meningitis	Preoperative imaging; consider neurosurgical consultation
Infant	Tuft of hair over midline spine	Spina bifida occulta, meningomyelocele	Possible intracranial connection; risk of meningitis	Preoperative imaging; consider neurosurgical consultation
Infant	Preauricular "tag"	Accessory tragus	Risk of chondritis if removed by shave or snip excision or if ligated with suture[58]	Appropriate closure when excised, if cartilaginous component present[57]
Infant or child	Mass along midline scalp, glabella, side of forehead, or other embryonic fusion plane	Dermoid cyst	Intracranial connection in up to 25 percent for midline dermoids; risk is higher if sinus present[59]; dermoids near the lateral eyebrows rarely have intracranial connections[60]	Consider MRI and neurosurgical consultation
Infant, young child	Nasal midline mass	Nasal glioma, encephalocele, or other dysraphic state Differential diagnosis: "hypertelorism," hemangioma	Intracranial connection in 100 percent of encephaloceles; gliomas may extend into oropharynx or have intranasal connections[59]	Consider MRI and neurosurgical consultation
Infant, young child	Vascular mass with greatly increased warmth, often with pulsation or bruit	Arteriovenous malformation Differential diagnosis: hemangioma	Uncontrolled bleeding, problematic bony or soft tissue hypertrophy	Consider Doppler studies, MRI, and surgical consultation

MRI = magnetic resonance imaging.

avoidance of irritants, use of barrier pastes, and avoidance of topical steroids. Resolution occurs over several months.

Dermatoses Not Etiologically Related to Diaper Wearing. Seborrheic dermatitis, atopic dermatitis, psoriasis (Fig. 106-12), bullous impetigo, acrodermatitis enteropathica, scabies, hand-foot-and-mouth disease, herpes simplex infections, and Langerhans cell histiocytosis (Letterer-Siwe disease) are conditions that occur in the diaper region but are not primarily due to the wearing of diapers and should be considered in the differential diagnosis. Skin biopsy is indicated to rule out Langerhans cell histiocytosis (see Chap. 148) if non-healing erosions or petechiae are seen in the diaper area (Fig. 106-13).

Treatment of Diaper Dermatitis. The treatment of diaper dermatitis is outlined in Box 106-2.[43] Irritant diaper dermatitis and *Candida* diaper dermatitis (or a combination of both) comprise the vast majority of diaper rashes. *Candida* is more likely to complicate diaper rash if present for more than 3 days. Although many antifungal creams are effective in this region, a new and convenient (though more costly) combination prescription cream containing both miconazole and zinc oxide is now approved for diaper dermatitis.

Education of parents and primary care physicians should include instructions regarding the use of topical steroids in the diaper area. Because of greatly increased percutaneous absorption of steroids from moisture and occlusion from diapers, topical steroid use in this anatomic region should be limited to a short course (3 to 7 days) of hydrocortisone (1 percent or 2.5 percent) ointment. This is effective in nearly all cases

▲ **FIGURE 106-12** Infantile psoriasis with involvement in the diaper region.

▲ **FIGURE 106-13** **A, B.** Langerhans cell histiocytosis. Note hepatosplenomegaly, and petechiae and erosions of the skin.

Box 106-2

ABCs in the Treatment of Diaper Dermatitis

A = Air. The diaper should be left open as much as possible when the infant sleeps to allow drying of the skin.

B = Barrier ointments. Zinc oxide pastes, petrolatum, and other bland, unmedicated barrier preparations are mainstays of therapy. A continuous layer of barrier paste or ointment should be maintained, reapplying with every diaper change, if necessary. Baby powder on the diaper area offers no antimicrobial benefit to the infant and adds a risk of aspiration.

C = Cleansing and anti-candidal treatment. Gentle cleansing with plain water, mineral oil, or unscented gentle cleanser is recommended. Avoidance of friction or rubbing is important. A topical anti-candidal agent should be added for any signs of candidiasis. Oral nystatin is indicated if oral thrush is present.

D = Diapers. Diapers should be changed as frequently and as soon after soiling as possible, especially if cloth diapers are used.

E = Education of parents and caregivers.

Modified from Boiko S: Making rash decisions in the diaper area. *Pediatr Ann* **29**:50, 2000.

when a topical steroid is needed. Similarly, use of the combination products containing halogenated steroids, such as nystatin and triamcinolone and clotrimazole and betamethasone dipropionate, should be avoided due to increased risks of steroid atrophy and hypothalamic-pituitary axis suppression when these middle- and high-potency topical steroids are used in the diaper area.

Last, parents will be reassured by the fact that even the most problematic diaper dermatitis will resolve when toilet training is achieved, and diapers are not worn.

TINEA CAPITIS (See Chap. 188) Scrapings for potassium hydroxide examination and fungal culture should be obtained before administration of systemic antifungal therapy. In children, collection of specimens for tinea capitis may be accomplished by the use of a toothbrush, ring curette, moistened cotton swab, a scalpel, or by collection of infected hairs. Alternatively, a media plate with nonslanted agar may be applied directly to the infected areas of the scalp to collect material.

ADOLESCENT DERMATOLOGY

Dermatologic diagnoses of adolescents overlap with those of general adult dermatology; however, caring effectively for the adolescent patient requires different interviewing skills and strategies to enhance compliance.

Evaluation Techniques

Greeting the adolescent first and the parents second, and interviewing the adolescent patient alone at the beginning of the visit help to earn the patient's trust.[44] The confidentiality laws of each state should be considered and the patient's right to privacy respected. Many states protect the adolescent's right to confidential medical care for problems such as drug abuse, sexually transmitted diseases, contraception, pregnancy, and abortion.

The open-ended questioning style used for adults frequently fails with adolescents. Phrasings using the third person and giving choices when asking questions are more effective techniques to obtain information. For example, "Many women on oral contraceptives forget to take their pill once in a while. How often do you forget to take your birth control pills: often, sometimes, or almost never?" will yield a more accurate reply than, "Do you take your birth control pills every day?"

Adolescents lack a well-developed sense of future time, and long-term consequences are less valued than immediate outcomes. Goals should be concrete, short term, and relevant to the present. Rather than using goals related to more distant benefits, such as the reduction of potentially serious disease complications (e.g., smoking causes increased risk of lung cancer), emphasis should be placed on immediate and concrete effects (e.g., smoking causes your clothes, hair, and breath to smell bad and your teeth to turn yellow). Body image is a more powerful motivator (e.g., tanning salons cause premature wrinkles and ugly skin) than future health concerns (e.g., tanning salons increase your risk of skin cancer). Any treatment that is disfiguring or has visible side effects will meet with resistance.[44]

Physical and psychosocial development may not be congruent. An adolescent should not be expected to shoulder all medical responsibilities for himself or herself or for younger siblings. The physician's role is not to befriend, nor is it to parent the adolescent patient, but rather it is to be a trusted, valuable authority.

Acne and the Adolescent (See Chap. 78)

Acne vulgaris is an extremely common and variable disorder that can have far-reaching detrimental effects on self-image and self-esteem. Increased unemployment has been documented among patients with a history of severe acne.[45] For adolescents, a single- or two-drug regimen will optimize compliance and cost-effectiveness.

The U.S. Food and Drug Administration (FDA) has received some reports of depression and suicide in patients using isotretinoin. The question of isotretinoin-induced depression is complicated by the high baseline incidence of depression and suicide in the adolescent population and by the depression and stress associated with severe acne.[46,47] A cohort study of 132 teenage patients with moderate to severe acne demonstrated that isotretinoin therapy did not increase symptoms of depression. On the contrary, treatment of acne with either conservative therapy or with isotretinoin was associated with a decrease in depressive symptoms.[48] Though causation is still unproven, the black box warning must be discussed with patients.

SPECIAL TOPICS IN PEDIATRIC DERMATOLOGY

Drug Labeling for Pediatric Patients

The lack of FDA approval for pediatric use does not imply that a drug is contraindicated or disapproved; it simply means that insufficient data are available to grant approval status. Although attempts have been made to equate off-label prescribing with recklessness in the medical malpractice arena, the American Academy of Pediatrics has stated that failure to prescribe medications for off-label uses when the medication is appropriate under standard of care may constitute malpractice.

The thalidomide tragedy (see Chap. 236) led to more stringent regulation of drugs in the early 1960s, and manufacturers began omitting drug studies in infants and children. In the 1970s, pediatric dosage information in package inserts tended to exclude children from therapeutic benefit. Performing research in healthy children is problematic because of ethical and logistic questions, medicolegal risk, and cost. According to the American Academy of Pediatrics, only a small fraction of all drugs marketed in the United States today have had clinical trials performed in pediatric patients, and a majority of marketed drugs are not labeled or are insufficiently labeled for use in pediatric patients.[49] Safety and effectiveness information for drug use in children under 2

years of age is particularly lacking. The absence of pediatric testing and labeling poses significant safety risks for children. Additionally, children may be denied the benefits from therapeutic advances because physicians choose to prescribe existing, less effective medications in the face of insufficient pediatric information about a new medication. In 1997, as part of the FDA Modernization Act, Congress enacted a new law known as the *Pediatric Exclusivity Provision* that provides marketing incentives (i.e., extension of patent protection) to manufacturers who conduct studies of drugs in children. This law has been effective in generating pediatric studies on many drugs. Hopefully, in the near future, physicians caring for children will no longer need to prescribe drugs "off label," and children will no longer be "therapeutic orphans."

Topical Medications

Children are at increased risk for toxicity from topically applied agents because of increased surface area–body mass ratio and alterations in metabolism of drugs. Patients with disorders of cornification (e.g., lamellar ichthyosis, Netherton syndrome) and infants, are at much higher risk of toxicity. Examples of cases of percutaneous poisoning from topical agents are listed in Table 106-5.

TABLE 106-5
Topical Medications Reported to Cause Systemic Toxicity in Children

Topical Medication	Complication	Reference
Benzocaine, 3% (Lanacane)	Methemoglobinemia in a 2-yr-old child	61
Iodoquinol, clioquinol (Vioform)	Neurotoxicity when used as treatment for diaper dermatitis	62, 63
Lindane	Neurologic toxicity in children with disrupted epidermal barrier and/or excessive topical application or ingestion	64, 65
N, N–diethyl-*m*-toluamide (DEET)	Slurred speech, tremors, seizures, and death in children after repeated and extensive application of high concentrations of DEET	66
Povidone-iodine (Betadine)	Hypothyroidism in infants with spina bifida	67
Povidone-iodine (Betadine)	Decreased free thyroxine and elevated iodine levels in infants treated with diluted povidone-iodine during *Staphylococcus aureus* epidemic	68
Salicylic acid	In a 7-yr-old boy treated for ichthyosis vulgaris, life-threatening salicylism occurred with neurologic sequelae lasting 6 mo	69
Saline, sodium chloride	Fatalities in infants and children following ancient Turkish custom of "salting"	70
Viscous lidocaine, 2%	Lidocaine overdose following frequent application to oral lesions	71

Systemic Medications

DRUG DOSAGES Pediatric doses of systemic medications are calculated according to body weight (mg/kg) or body surface area to account for size variations between patients of the same age and to account for weight gain due to growth. Prescriptions for syrups or suspensions must indicate concentration (e.g., milligrams per teaspoon) to avoid serious error. A selected pediatric dermatology formulary of systemic drugs is presented in Table 106-6. The reader is also directed to references including *Red Book*[50] and *The Harriet Lane Handbook*.[51]

SYSTEMIC GLUCOCORTICOIDS Hypothalamic-pituitary axis suppression, osteonecrosis, and other adverse effects of systemic glucocorticoid therapy affect patients of all ages and are reviewed in Chap. 225. The potential risk of growth suppression is unique to childhood. Exogenous glucocorticoids disrupt the secretion of growth hormone (GH), causing abnormal spontaneous GH secretion with reduced pulse amplitude of GH release and reduced response to provocative stimuli.[52,53] There is also decreased local production of insulin-like growth factor 1. These and other effects of glucocorticoids act to cause delayed growth at the bony epiphyses, with the most noticeable reduction in growth velocity occurring during early childhood and adolescent growth spurts. There is a linear relation between the daily dose and growth suppression. Alternate-day dosing, with single morning doses, decreases the risk of glucocorticoid growth suppression. Most children will have adequate catch-up growth eventually with reduction of doses, alternate-day therapy, or cessation of therapy.[54] For the pediatric patient on long-term systemic steroid therapy, charting height and weight on a standardized growth curve is the best method to screen for decreasing growth velocity.

Children taking immunosuppressive doses of systemic glucocorticoids should not be vaccinated with live-virus vaccines (e.g., measles, oral polio, varicella). A dosage equivalent to 2 mg/kg/day or greater of prednisone or a total of 20 mg/day or greater for children weighing more than 10 kg, when given for more than 14 days, is sufficient to warrant withholding immunization with live-virus vaccines.[55] Systemic steroids should not be given to a healthy child if he or she has had recent varicella exposure and is not varicella-immune because varicella infection can be fatal in this situation. In addition, children with ocular herpes simplex and untreated tuberculosis should not be given systemic steroids, and patients with underlying diabetes, hypertension, peptic ulcer disease, renal insufficiency, or psychosis should be treated with great caution or with an alternative agent.[50]

ANTIMICROBIALS Use of tetracycline family medications is contraindicated in children younger than 8 years of age because it causes brown discoloration of developing teeth and decreased bone growth.[50] Ciprofloxacin and quinolone use in children younger than 18 years of age is restricted because the fluoroquinolones have been shown to cause cartilage damage in every juvenile animal model tested at therapeutic doses.[50] The mechanism is unknown. To date, ciprofloxacin is the fluoroquinolone that has been used most extensively in children. It appears to be well tolerated, does not appear to cause arthropathy, and is an effective oral agent for a number of diseases that otherwise would require parenteral therapy. It is recommended that its use be restricted to relatively serious infections for which no other oral agent is available or intravenous antibiotics would be impractical

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Antiviral Agents			
Acyclovir (Zovirax)	Caps: 200 mg Tabs: 400, 800 mg Susp: 200 mg/5 mL	Note: Max. dose of oral acyclovir in children: 80 mg/kg/day. Immunocompetent patient with mucocutaneous HSV: • Initial infection: 1200 mg/day in three divided doses PO × 7–10 days. • Recurrence: 1200 mg/day in three divided doses PO × 5 days, or 1600 mg/day in two divided doses × 5 days. • Chronic suppressive therapy: 800–1000 mg/day in two to three divided doses PO for up to 1 yr; then reassess. Zoster: 4000 mg/day ÷ 5 times/day PO × 5–7 days for patients ≥ 12 yr. Varicella: 80 mg/kg per day in four divided doses × 5 days. Max. dose: 3200 mg/day.	Start therapy within the first 24–48 h of signs/symptoms. Oral absorption unpredictable. Use ideal body weight for calculating dosage for obese patients. Dose alteration necessary in patients with impaired renal function. Infrequent repots of headache, vertigo, insomnia, GI irritation, urticaria, fever. See *Red Book*[72] for neonatal, immunocompromised, and parenteral indications and dosing.[73] Resistant strains of HSV and varicella-zoster virus reported in immunocompromised patients (e.g., advanced human immunodeficiency virus infection). See Chap. 232 for treatment of viral infections.
Famciclovir (Famvir)	Tabs: 125, 250, 500 mg	Adolescents: Genital HSV: • Initial outbreak: 250 PO tid × 5 days. • Recurrences: 125 mg PO bid × 5 days. • Suppressive therapy: 125–250 mg PO bid × 1 yr; then reassess. Adults: • Herpes zoster: 500 mg q8h PO × 7 days. • Recurrent herpes labialis (cold sores): 1500 mg PO × 1 dose. • Genital herpes simplex: 125 mg PO q12h × 5 days. • Single day dosing for recurrent genital herpes: 1000 mg at first sign of onset, then 1000 mg 12 hours later. • Suppression of recurrent genital herpes: 250 mg PO bid for up to 1 yr; then reassess.	Not FDA approved for use in children. Start therapy within the first 24–48 h of signs/symptoms. Drug is converted to active form (penciclovir). Better absorption than PO acyclovir. May cause headache, diarrhea, nausea, and abdominal pain. Concomitant use of probenecid and other drugs eliminated by active tubular secretion may result in decreased penciclovir clearance. Adjust dose in renal failure. See Chap. 232 for treatment of viral infections.
Valacyclovir (Valtrex)	Tabs: 500, 1000 mg	For immunocompetent adolescents/adults.[70] Genital HSV: • Initial outbreak: 1 g PO bid × 10 days. • Recurrences: 500 mg PO bid × 3–5 days. • Suppressive therapy: 500–1000 mg PO per day × 1 yr; then reassess. For immunocompetent adults: • Zoster: 1 g PO tid × 7 days within 48–72 h of onset of rash. • Recurrent herpes labialis (cold sores): 2 g PO q12 h × 1 day.	Not FDA approved for use in children. Drug is converted to acyclovir. Better oral absorption than acyclovir, cannot be substituted for acyclovir on a 1:1 basis. Start therapy within the first 24–48 h of signs/symptoms. Adjust dose in renal failure. Use with caution in hepatic and renal insufficiency.
Antibiotics			
Amoxicillin (Amoxil, Trimox, and others)	Drops: 50 mg/mL Susp: 125, 200, 250, 400 mg/5 mL Caps: 250, 500 mg Chewable tabs: 125, 200, 250, 400 mg	Infants ≤ 3 mo: 20–30 mg/kg/day ÷ bid. Children: • Standard dose: 25–50 mg/kg/day PO ÷ bid–tid. • High dose: 80–90 mg/kg/day PO ÷ bid. Adults: 250–500 mg/dose PO tid. Max. dose: 2–3 g/day.	Rash and diarrhea may occur. Renal elimination. Serum levels about twice those achieved with equal dose of ampicillin. Chewable tabs contain phenylalanine.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Amoxicillin-clavulanate (Augmentin)	Tabs: • For tid dosing: 250, 500 mg amoxicillin (with 125 mg clavulanate) • For bid dosing: 875 mg amoxicillin (with 125 mg clavulanate); Augmentin XR 1 g amoxicillin (with 62.5 mg clavulanate) Chewable tabs: • For tid dosing: 125, 250 mg amoxicillin (31.25 and 62.5 mg clavulanate, respectively) • For bid dosing: 200, 400 mg amoxicillin (28.5 and 57 mg clavulanate) • Susp: For tid dosing, 125, 250 mg amoxicillin/5 mL (31.25 and 62.5 mg clavulanate/5 mL) For bid dosing: 200, 400 mg amoxicillin/5 mL (28.5 and 57 mg clavulanate/5 mL) Augmentin ES-600: 600 mg amoxicillin/5 mL (42.9 mg clavulanate/5 mL)	Dosage based on amoxicillin component. Children < 3 mo: 30 mg/kg/day PO ÷ bid (recommended dosage form is 125 mg/5 mL suspension). Children ≥ 3 mo: • For tid dosing: 20–40 mg/kg/day PO ÷ tid. • For bid dosing: 25–45 mg/kg/day PO ÷ bid. Augmentin ES-600: ≥ 3 mo and < 40 kg: 90 mg/kg/day ÷ bid PO × 10 days. Adults: 250–500 mg/dose tid PO or 875 mg/dose bid PO for more severe and respiratory infections. Augmentin XR: > 16 yr and adults: 2 g bid PO × 10 days for acute bacterial sinusitis or × 7–10 days for community-acquired pneumonia. Max. dose: 2 g/day	Clavulanate extends coverage of amoxicillin to include β-lactamase-producing strains of *Haemophilus influenzae*, *Moraxella catarrhalis*, *Neisseria gonorrhoeae*, and some *Staphylococcus aureus*. The bid dosing schedule is associated with less diarrhea. For bid dosing, the 875-mg tab, the 200- and 400-mg chewable tab, or the 200 and 400 mg/5 mL susp should be used. Phenylketonurics should not use the bid dosage forms because they contain phenylalanine. Adjust dose in renal failure. The 250 mg or 500 mg tab cannot be substituted for Augmentin XR.
Azithromycin (Zithromax)	Tabs: 250, 500, 600 mg Susp: 100 mg/5 mL, 200 mg/5 mL Oral powder (sachet): 1 g	Children ≥ 6 mo: Otitis media or community-acquired pneumonia: 10 mg/kg PO on day 1 (not to exceed 500 mg), followed by 5 mg/kg/day PO every day (not to exceed 250 mg/day) for days 2–5 Pharyngitis/tonsillitis (≥ 2 yr old):12 mg/kg/day PO every day × 5 days (not to exceed 500 mg/day). Adolescents/adults: • Respiratory tract, skin, and soft tissue infection: 500 mg PO day 1, then 250 mg/day PO on days 2–5.	Dosages vary depending on patient's age and indication; see *Red Book*[72] and *Harriet Lane Handbook*[51] for more details. Contraindicated in patients allergic to erythromycin. Aluminum- and magnesium-containing antacids decrease absorption. Can cause cholestatic jaundice, GI discomfort. Less risk for drug interactions compared with other macrolides. central nervous system penetration poor.
Cefadroxil (Duricef and others)	Susp: 125, 250, 500 mg/5 cc Tabs: 1 g Caps: 500 mg	Infants and children: 30 mg/kg/day PO ÷ bid. Adults: 500 mg PO bid. Max. dose: 2 g/day.	First-generation cephalosporin. See Cephalexin.
Cephalexin (Keflex and others)	Susp: 125 mg/5 cc, 250 mg/5 cc Drops: 100 mg/mL Tabs: 250, 500 mg Caps: 250, 500 mg	Children: 25–100 mg/kg/day PO ÷ qid. Adults: 1 g/day PO ÷ qid. Max dose: 4 g/day.	Use with caution in renal insufficiency. Some cross-reactivity with penicillin. For uncomplicated infections, less frequent dosing (bid or tid) can be used. Give on empty stomach. Adjust dose in renal failure.
Cephradine (Velosef and others)	Susp: 125, 250 mg/5 cc Caps: 250, 500 mg	Infants ≥ 9 mo and children: 25–50 mg/kg/day PO ÷ qid or bid. Adults: 1–4 g/day PO ÷ qid or bid. Max. dose: 4 g/day.	First-generation cephalosporin. See Cephalexin.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Clarithromycin (Biaxin)	Film tabs: 250, 500 mg Extended release tabs: 500 mg Granules for suspension: 125, 250 mg/5 mL	Children: Acute otitis media, pharyngitis, tonsillitis, pneumonia, uncomplicated skin infections: 15 mg/kg/day PO ÷ bid. Max. dose: 1 g/day. Adults: Pharyngitis, tonsillitis, bronchitis, pneumonia, uncomplicated skin infections: 250–500 mg/dose PO bid. Extended release: 1000 mg PO qd.	Contraindicated in patients allergic to erythromycin. Cardiac arrhythymias can occur in patients receiving terfenadine, astemizole, and cisapride. Side effects include diarrhea, nausea, abnormal taste, dyspepsia, abdominal discomfort (less than with erythromycin but more common than with azithromycin), and headache. May increase carbamazepine, theophylline, cyclosporine, and tacrolimus levels. Inhibits CYP450 3A4. Adjust dose in renal failure. All dosage forms may be administered with food.
Clindamycin	Caps: 75, 150, 300 mg Oral solution: 75 mg/5 mL	Children: 10–30 mg/kg/day ÷ PO q6–8h. Adults: 150–450 mg/dose q6–8 h. Max. dose: 1.8 g/day.	Pseudomembranous colitis may occur up to several weeks after completion of therapy. May cause diarrhea, granulocytopenia, thrombocytopenia, Stevens-Johnson syndrome.
Co-trimoxazole (trimethoprim, sulfamethoxazole, TMP-SMX, Bactrim, Septra, and others)	Tabs: 80 mg TMP/400 mg SMX Tabs (double strength): 160 mg TMP/800 mg SMX Susp: 40 mg TMP/200 mg SMX per 5 mL	Doses based on TMP component: Children: 8–10 mg/kg/day ÷ bid. Adults (> 40 kg): 160 mg/dose bid.	Not recommended for use in infants < 2 mo. Contraindicated in patients with megaloblastic anemia due to folate deficiency. May cause kernicterus in newborns; may cause blood dyscrasias, glossitis, renal or hepatic injury, GI irritation, Stevens-Johnson syndrome, hemolysis in patients with G6PD deficiency. Do not use at term pregnancy. Use with caution in renal and hepatic impairment.
Dicloxacillin (Dynapen and others)	Caps: 250, 500 mg Oral susp: 62.5 mg/5 mL	Children (< 40 kg): • Mild/moderate infections: 12.5–25 mg/kg/day PO ÷ qid. • Severe infections: 50–100 mg/kg/day PO ÷ qid. Adults (≥ 40 kg): 125–500 mg/dose PO ÷ q6h. Max. dose: 4 g/day.	Same side effects as other penicillins. Give on empty stomach. Use of oral suspension may be limited due to its taste and because dose can be a large volume due to 62.5 mg/5 mL concentration.
Doxycycline (Vibramycin and others)	Caps and tabs: 20 (Periostat), 50, 75, 100 mg Syrup: 50 mg/5 cc Susp: 25 mg/5 cc	Initial (≤ 45 kg): 5 mg/kg per day ÷ bid PO × 1 day to max. dose of 200 mg/day (> 45 kg): 100 mg bid PO × 1 day. Maintenance (≤ 45 kg): 2.5–5 mg/kg/day PO ÷ qd–bid; (> 45 kg): 100–200 mg/day PO ÷ qd–bid. Max. adult dose: 300 mg/day.	For treatment of acne, see Chap. 78. Use under age 8 yr may cause discoloration of teeth and dental enamel hypoplasia. Use with caution in hepatic or renal disease. May cause increased intracranial pressure. GI symptoms. and photosensitivity. See also Tetracycline. For periodontitis, adult dose is 20 mg bid PO for ≤ 9 mo.
Erythromycin preparations (Erythrocin, Pediamycin, E-Mycin, Ery-Ped, and others)	Erythromycin base Tabs: 250, 333, 500 mg Delayed-release tabs: 250, 333, 500 mg Delayed-release caps: 250 mg Erythromycin ethyl succinate Susp: 200, 400 mg/5 cc Oral drops: 100 mg/2.5 mL Chewable tabs: 200 mg Tabs: 400 mg Erythromycin estolate Susp: 125, 250 mg/5 cc	Children: 30–50 mg/kg/day ÷ tid. Max. dose: 2 g/day. Adults: 1–4 g/day ÷ qid. Max. dose: 4 g/day.	GI side effects common. Give doses after meals. Use with caution in liver disease. Adjust dose in renal failure. May produce elevated digoxin, theophylline, carbamazepine, cyclosporine, and methylprednisolone levels. Inhibits CYP450 1A2 and 3A3/4 isoenzymes. Contraindicated with concomitant use of cisapride, astemizole, and terfenadine. Because of different absorption characteristics, higher oral doses of erythromycin ethyl succinate are needed to achieve therapeutic effects.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Erythromycin preparations *(continued)*	Tabs: 500 mg Caps: 125, 250 mg Oral drops: 100 mg/mL Chewable tabs: 125, 250 mg Erythromycin stearate Tabs: 250, 500 mg		
Minocycline (Minocin and others)	Tabs and caps: 50, 75, 100 mg Pellet-filled caps: 50, 100 mg Oral susp: 50 mg/5 mL	Children (8–12 yr): 4 mg/kg per dose × 1 PO; then 2 mg/kg per dose bid PO. Max. dose: 200 mg/day. Adolescents and adults: 200 mg/dose × 1 PO; then 100 mg bid PO.	High incidence of vestibular dysfunction. Nausea, vomiting, allergy, photophobia, injury to developing teeth, and hyperpigmentation may occur. Do not take with milk or dairy products. Hepatitis and liver failure rarely reported. See Chap. 78 for treatment of acne.
Penicillin V potassium (Pen-Vee K, V-Cillin K, and others)	Tabs: 250, 500 mg Oral solution: 125 mg/5 mL, 250 mg/5 mL	Children: 25–50 mg/kg/day PO ÷ tid–qid. Max. dose: 3 g/day. Adults: 250–500 mg/dose PO tid–qid.	Give 1 h before or 2 h after meals. Adjust dose in renal failure.
Tetracycline (Sumycin and others)	Susp: 125 mg/5 cc Caps: 250, 500 mg	Children (8 yr and older): 25–50 mg/kg/day PO ÷ qid. Max. dose: 2 g/day. Adults: 1–2 g/day ÷ qid–bid PO. Max. dose: 2 g/day.	Discoloration of teeth in children less than 8 yr of age. May cause photosensitivity, GI upset, and hepatotoxicity. Do not give with dairy products or with divalent cations (Fe^{2+}, Ca^{2+}, Mg^{2+}). Give 1 h before or 2 h after meals. Do not use outdated tetracyclines. For treatment of acne, see Chap. 78.
Antifungal/Anti-Yeast Agents[a]			
Clotrimazole troche (Lotrimin, Mycelex, and others)	Oral troche: 10 mg	Children 3 yr and older and adults: For oral thrush: Dissolve slowly (15–30 min) 1 troche in mouth 5 × per day for 14 days.	Liver enzyme elevation may occur, GI symptoms.
Fluconazole (Diflucan)	Tabs: 50, 100, 150, 200 mg Susp: 10, 40 mg/mL	Oropharyngeal and esophageal candidiasis: • Children (3–13 yr): Loading dose: 6–12 mg/kg PO; then maintenance (begin 24 h after loading dose): 3–6 mg/kg/day PO qd. • Adults: Loading dose of 200 mg PO followed by 100 mg qd 24 h after; doses up to max. dose of 400 mg/day may be used for esophageal candidiasis. Vaginal candidiasis: 150 mg PO × 1.	Not FDA approved for tinea capitis in children. Superiority to griseofulvin in the treatment of tinea capitis has not been demonstrated. May cause nausea, headache, rash, vomiting, abdominal pain, hepatitis, cholestasis, and diarrhea. Periodic monitoring of liver function tests recommended. Decrease dose in renal failure. Inhibits CYP450 2C9/10 and 3A3/4. May increase effects or levels of cyclosporine, phenytoin, theophylline, warfarin, oral hypoglycemics, and zidovudine. Rifampin increases fluconazole metabolism. Cardiac arrhythmias may occur when used with cisapride, terfenadine, and astemizole. Concomitant administration of fluconazole with any of these drugs is contraindicated. See references for other drug interactions.[73]
Griseofulvin (Grifulvin V, Grisactin, Fulvicin)	Microsize: Susp: 125 mg/5 mL Tabs: 250, 500 mg Ultramicrosize: Tabs: 125, 165, 250, 330 mg (250-mg ultramicrosize is about equivalent to 500-mg microsize)	Microsize: • Children (> 2 yr): 20–30 mg/kg/day PO ÷ qd–bid. • Adults: 500–1000 mg/day PO ÷ qd–bid. Max. dose: 1 g/24 h. Ultramicrosize: • Children (> 2 yr): 10–15 mg/kg/day PO qd. • Adults: 330–750 mg/day PO ÷ qd. Max. dose: 750 mg/day.	Give with milk or fatty food to enhance absorption. For tinea capitis, 6- to 8-week course recommended. Contraindicated in porphyria, hepatic disease. Penicillin allergy is not a contraindication. Not recommended in pregnancy due to possible teratogenicity. Reversible elevation of liver enzymes. Photosensitivity may occur. May reduce effectiveness or decrease level of oral contraceptives, warfarin, and cyclosporine. Phenobarbital may enhance clearance of griseofulvin. Not effective against *Candida* or other yeasts. See Chap. 233 for treatment of fungal infections.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Itraconazole (Sporanox)	Caps: 100 mg Solution: 10 mg/mL	All dosages given in capsules. Experimental dosages for tinea capitis in children (limited data)[73–75]: 3–5 mg/kg/day × 4–6 wk. or 10–20 kg: 100 mg every other day; 20–30 kg: 100 mg/day; 30–50 kg: alternate 100 mg/day with 200 mg/day. Pulse dosing is promising, but current data are limited.	Not FDA approved for use in pediatric patients. Periodic monitoring of liver function tests recommended. Solution is approved for treatment of oral pharyngeal and esophageal candidiasis in adults. Solution should not be used interchangeably with capsules; solution has greater bioavailability, and cyclodextrin vehicle produced pancreatic adenocarcinoma in rats at normal human doses. Reversible elevation of liver enzymes, GI symptoms, headache, and dizziness may occur. Do not use with terfenadine or other non-sedating antihistamines. See Chap. 233 for treatment of fungal infections. See references for other drug interactions.[74]
Ketoconazole (Nizoral)	Tabs: 200 mg	Children (≥ 2 yr): 3.3–6.6 mg/kg/day PO qd. There are very limited data for the use of this agent in the treatment of tinea capitis in children.[73–75] Adults: 200–400 mg/day PO. Max. dose: 800 mg/day.	Give with acidic meal or drink to enhance absorption. Drugs that decrease gastric acidity will decrease absorption. Monitor liver function in long-term use. May cause nausea, vomiting, rash, headache, pruritus, and fever. Cardiac arrhythmias may occur when used with cisapride, terfenadine, or astemizole. Concomitant administration of ketoconazole with any of these drugs is contraindicated. Inhibits CYP450 3A4 isoenzyme. See references for other drug interactions.[74] Not FDA approved for the treatment of tinea capitis in children; periodic monitoring of liver function tests recommended if used for tinea capitis. See Chap. 233 for treatment of fungal infections.
Nystatin (Mycostatin, Nilstat, and others)	Susp: 100,000 U/mL Tabs: 500,000 U Troches/pastilles: 200,000 U	Infants: 1 mL (100,000 U) to each side of mouth qid. Children/adults: Susp: 4–6 mL (400,000–600,000 U) swish and swallow qid. Troche: 200,000–400,000 U 4–5 × per day.	May produce diarrhea and GI side effects. Treat until 48–72 h after resolution of symptoms. Drug poorly absorbed through the GI tract. Do not swallow troches whole. Allow troche to dissolve as slowly as possible, and oral suspension should be retained in mouth as long as possible before swallowing.
Terbinafine (Lamisil)	Tabs: 250 mg	Experimental dosage for tinea capitis in children (limited data): 3.125–6.25 mg/kg/day × 4 wk. or < 20 kg: give 62.5 mg PO every day; 20–40 kg: give 125 mg PO every day; > 40 kg: give 250 mg PO every day.[73]	Less effective for *Microsporum canis* than *Trichophyton tonsurans* infection. Inhibitor of CYP450 2D6. Rifampin increases clearance of drug. Cimetidine decreases clearance of drug. See references for other drug interactions.[74] Side effects include diarrhea, dyspepsia, abdominal pain, nausea, flatulence, and taste disturbance. Periodic monitoring of liver function tests recommended.
Corticosteroids, Nonsteroidal Anti-Inflammatory Drugs, and Analgesics			
Acetaminophen (Tylenol, Tempra, Panadol, and others)	Tabs: 325, 500, 650 mg Chewable tabs: 80, 160 mg Infant drops/solution/susp: 80 mg/0.8 mL Child solution/susp: 160 mg/5 mL Elixir: 80, 120, 130, 160, 325 mg/5 mL Caplets: 160, 325, 500 mg	10–15 mg/kg per dose PO/PR q4–6h. Or dosing by age: • 0–3 mo: 40 mg/dose. • 4–11 mo: 80 mg/dose. • 1–2 yr: 120 mg/dose. • 2–3 yr: 160 mg/dose. • 4–5 yr: 240 mg/dose. • 6–8 yr: 320 mg/dose. • 9–10 yr: 400 mg/dose.	Metabolized in the liver. Adjust dose in renal failure. Some preparations contain alcohol (7%–10%) and/or phenylalanine. Contraindicated in patients with known G6PD deficiency. Shake suspensions before use. Antipyretic, analgesic, but not anti-inflammatory.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Acetaminophen *(continued)*	Suppository: 80, 120, 125, 325, 650 mg Sprinkle capsule: 80, 160 mg	11–12 yr: 480 mg/dose. Adults: 325–650 mg/dose. Max. dose: 4 g/day, 5 doses/day.	
Ibuprofen (Motrin, Advil, Nuprin, and others)	Susp: 100 mg/5 cc Oral drops: 40 mg/mL Chewable tabs: 50, 100 mg Caplets: 100 mg Tabs: 200, 300, 400, 600, 800 mg	Children: • Analgesic/antipyretic: 5–10 mg/kg dose q6–8h PO. Max. dose: 40 mg/kg/day PO. Adolescents/adults: • Pain/fever/dysmenorrhea: 200–400 mg per dose PO q4–6h. • Inflammatory disease: 400–800 mg per dose PO q6–8h. Max. dose: 3.2 g/day.	GI distress (lessened with milk), ocular problems, granulocytopenia, anemia may occur. Inhibits platelet aggregation. Use caution with aspirin hypersensitivity, hepatic or renal insufficiency, or dehydration. Contraindicated with ulcer disease.
Prednisone (many brand names)	Tabs: 1, 2.5, 5, 10, 20, 50 mg Syrup/solution: 1 mg/mL (5% alcohol) Concentrated solution: 5 mg/mL (30% alcohol)	Anti-inflammatory, immunosuppressive: 0.5–2 mg/kg/day PO ÷ qd–qid.	Alternate daily dosing or single morning dosing lessens side effects. See Chap. 225 for relative steroid potencies, side effects, and monitoring.
Prednisolone (Prelone, Orapred, Pediapred, and others)	Tabs: 5 mg Syrup: 5 mg/mL (Pediapred) or 15 mg/5 mL (Prelone)	See Prednisone.	Syrup more palatable than prednisone syrup. See Prednisone.
Antihistamines/Sedatives			
Cetirizine (Zyrtec)	Tabs and chewable tabs: 5, 10 mg Syrup: 5 mg/5 mL	6 mo to < 2 yr: 2.5 mg PO qd; dose may be increased for child 12–23 mo to a max. dose of 2.5 mg PO q12h. 2–5 yr: 2.5–5 mg PO qd. ≥ 6 yr/adult: 5–10 mg PO qd.	Mild, dose-related sedation may occur. Dry mouth and other side effects common to antihistamines may occur. Decrease dose in patients with renal or hepatic insufficiency.
Chloral hydrate (Aquachloral and others)	Caps: 500 mg Syrup: 250, 500 mg/5 mL Suppositories: 324, 500, 648 mg	Children: • Sedative: 25–50 mg/kg/day PO/PR ÷ q6–8h. Max. dose: 500 mg/dose. • Sedation for procedures: 25–100 mg/kg per dose PO/PR. Max dose: 1 g (infant); 2 g (child). Adults: • Sedative: 250 mg per dose tid PO/PR. • Hypnotic: 500–1000 mg per dose PO/PR. Max. dose: 2 g/day.	Not analgesic. Peak effects occur in 30–60 min. Do not exceed 2 wk of chronic use. Sudden withdrawal may cause delirium tremens. May cause GI irritation, paradoxical excitement, hypotension, and myocardial/respiratory depression. Requires appropriate monitoring. Contraindicated in patients with hepatic or renal disease.
Chlorpheniramine maleate (Chlor-Trimeton and others)	Tabs: 4 mg Sustained release caps and tabs: 8, 12 mg Chewable tabs: 2 mg Syrup: 2 mg/5 mL Combined immediate and sustained-release tabs (Efidac 24): 16 mg (4 mg immediate and 12 mg sustained)	Children: 0.35 mg/kg/day ÷ q4–6h PO. or 2–6 yr: 1 mg per dose PO q4–6h. Max dose: 6 mg/day. 6–11 yr: 2 mg per dose PO q4–6h. Max. dose: 12 mg/day. Sustained release (6–12 yr): 8 mg per dose PO bid. ≥ 12 yr/adults: 4 mg per dose q4–6h PO. Max. dose: 24 mg/day. Sustained release: 8–12 mg PO bid. Efidac 24: 16 mg PO qd. Max. dose: 16 mg/day.	May cause sedation, dry mouth, urinary retention, polyuria, disturbed coordination. Young children may be paradoxically excited. Sustained-release forms not recommended in children less than 6 yr old; and should not be crushed, chewed, or dissolved. Give with food.
Cyproheptadine (Periactin)	Tabs: 4 mg Syrup: 2 mg/5 mL (5% alcohol)	Children: 0.25–0.5 mg/kg/day PO ÷ bid–tid. Or dosing by age: • 2–6 yr: 2 mg q8–12h PO. Max. dose: 12 mg/day. • 7–14 yr; 4 mg q8–12h PO. Max. dose: 16 mg/day. • Adults: 12–32 mg/day PO ÷ tid. Max. dose: 0.5 mg/kg/day.	Contraindicated in neonates, patients on monoamine oxidase inhibitors, patients with glaucoma, asthma, or GI/genitourinary obstruction. May produce anticholinergic side effects, including appetite stimulation. Consider reduced dose with hepatic insufficiency.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Diphenhydramine (Benadryl and others)	Elixir (may contain alcohol): 12.5 mg/5 mL Liquid, syrup: 12.5 mg/5 mL Caps/tabs: 25, 50 mg Chewable tabs: 12.5 mg	Children: 5 mg/kg/day PO ÷ qid. Max. dose: 300 mg/day. Adults: 10–50 mg per dose PO tid–qid. Max. dose: 400 mg/day.	Dry mouth, sedation, and other side effects common to antihistamines. Central nervous system side effects more common than GI disturbances. May cause paradoxical excitement. Contraindicated in neonates or with concurrent monoamine oxidase inhibitor use. Adjust dose in renal failure.
Fexofenadine (Allegra)	Tabs: 30, 60, 180 mg Caps: 60 mg	6–11 yr: 30 mg bid PO. 12 yr–adult: 60 mg bid PO; 180 mg may be used in seasonal rhinitis.	Do not administer antacids within 2 h of dose. May cause drowsiness, fatigue, dyspepsia, nausea, and dysmenorrhea. Reduce dose if renal function impaired.
Hydroxyzine (Atarax, Vistaril)	Tabs: 10, 25, 50, 100 mg Caps: 25, 50, 100 mg Syrup: 10 mg/5 mL Suspension: 25 mg/5 mL	Children: 2 mg/kg/day ÷ tid–qid. May use up to 5 mg/kg/day in mast cell diseases. Adults: 25–100 mg per dose ÷ tid–qid. Max. adult dose: 600 mg/day.	May potentiate barbiturates, meperidine, and other depressants. Dry mouth, drowsiness, tremor, convulsions, blurred vision, hypotension, and paradoxical excitement may occur.
Loratadine (Claritin)	Tabs: 10 mg Rapidly disintegrating tabs: 10 mg Syrup: 1 mg/mL	2–5 yr: 5 mg PO every day. ≥ 6 yr/adults: 10 mg PO every day.	Reduce dose in hepatic or renal insufficiency. Low incidence of drowsiness. May cause dry mouth, dizziness, and other side effects common to antihistamines.
Miscellaneous			
Isotretinoin (Accutane, Claravis, Sotret, Amnesteem)	Caps: 10, 20, 30, 40 mg	Cystic acne: 0.5 mg/kg/day PO bid × 20 wk.	Known teratogen, contraindicated in pregnancy. Conjunctivitis, xerosis, pruritus, epistaxis, anemia, hyperlipidemia, pseudotumor cerebri, bone pain, muscle aches, skeletal changes, and other toxicities. Vitamin A or tetracyclines should not be given concomitantly. Monitor complete blood cell count, liver function tests, triglycerides, and monthly pregnancy tests. Severe forms (acne fulminans) may require higher doses and longer treatment course. See Chap. 78 for treatment of acne.
Ivermectin (Stromectol)	Tabs: 3, 6 mg	Scabies: 0.2 mg/kg per dose PO × 1 per day. Cutaneous larva migrans or strongyloidiasis: 0.2 mg/kg PO per day × 1–2 days. Or dosing by body weight: Weight (kg) single oral dose: 15–24: 3 mg 25–35: 6 mg 36–50: 9 mg 51–65: 12 mg 66–79: 15 mg ≥ 80: 0.2 mg/kg	Adverse reactions in strongyloidiasis include diarrhea, nausea, vomiting, pruritus, rash, dizziness, and drowsiness. See Chap. 207 for more information on parasitic infections.
Mebendazole (Vermox)	Chewable tabs: 100 mg	Children/adults: • Pinworms: 100 mg PO × 1; repeat in 2 wk if not cured.	May be swallowed whole or chewed. Experience in children < 2 yr old is limited. Family may need to be treated concurrently. Therapeutic effect may be decreased if receiving carbamazepine or phenytoin. Give with food. See Chap. 207 for more information on parasitic infections.
Thiabendazole (Mintezol)	Suspension: 500 mg/5 mL Chewable tabs: 500 mg	Cutaneous larva migrans: Children and adults: 50 mg/kg/day ÷ bid × 2–5 days. Max. dose: 3 g/day. Suspension may be applied topically and may preclude need for oral therapy.	Use with caution in renal or hepatic impairment. Nausea, vomiting, and vertigo are frequent side effects. May increase levels of theophylline. Limited data in children < 30 lb. See Chap. 207 for more information on parasitic infections.

(continued)

TABLE 106-6
Pediatric Dermatology Formulary of Selected Systemic Drugs (Continued)

Generic Name (Trade Name)	Dosage Forms	Dose	Comment
Iron preparations (Fergon, Fer-In-Sol, Feosol, and others)	Ferrous sulfate (20% elemental Fe) • Drops (Fer-In-Sol): 75 mg (15 mg Fe)/0.6 mL, 125 mg (25 mg Fe)/1 mL • Syrup (Fer-In-Sol): 90 mg (18 mg Fe)/5 mL (5% alcohol) • Elixir (Feosol): 220 mg (44 mg Fe)/5 mL • Caps: 250 mg (50 mg Fe) • Tabs: 195 mg (39 mg Fe), 300 mg (60 mg Fe), 324 mg (65 mg Fe) Ferrous gluconate: (12% elemental Fe) • Tabs: 240 mg (27 mg Fe), 300 mg (34 mg Fe), 320 mg (37 mg Fe), 325 mg (38 mg Fe) Many other preparations available.	Iron deficiency anemia: • Children: 3–6 mg elemental Fe/kg/day ÷ PO qd–tid. • Adults: 60 mg elemental Fe PO bid–qid. Prophylaxis: • Children: 1–2 mg elemental Fe/kg/day ÷ qd–tid. Max dose 15 mg elemental Fe per day. • Adults: 60 mg elemental Fe per day PO ÷ qd–bid.	Iron preparations are variably absorbed. Less GI irritation when given with meals. Vitamin C, 200 mg per 30 mg Fe, may enhance absorption. Liquid iron preparations may stain teeth. Give with dropper or drink with straw. Side effects include constipation, dark stools, nausea, and epigastric pain. False-positive stool guaiac test is controversial. Iron and tetracycline inhibit each other's absorption. Antacids may decrease iron absorption.
Zinc salts	Tabs as sulfate, 23% elemental zinc: 66, 110, 200 mg. Caps as sulfate, 23% elemental zinc: 220 mg. Tabs as gluconate, 14.3% elemental zinc: 10, 15, 50 mg. Liquid as acetate: 5, 10 mg elemental zinc/mL (requires compounding by pharmacist.)	Zinc deficiency: • Infants and children: 0.5–1 mg elemental zinc/kg/day PO ÷ qd–tid. • Adults: 25–50 mg elemental zinc per dose PO tid.	Approximately 20%–30% of oral dose is absorbed. May give with food if GI upset occurs. Shake liquid before administering. Nausea, vomiting, GI disturbances, leukopenia, and diaphoresis may occur. Patients with excessive losses (burns) or impaired absorption may require higher doses.

Caps = capsules; FDA = U.S. Food and Drug Administration; Fe = iron; G6PD = glucose-6-phosphate dehydrogenase; GI = gastrointestinal; HSV = herpes simplex virus; max. = maximum; Susp = suspension; Tabs = tablets.
[a]Griseofulvin is currently the only FDA-approved drug for the treatment of tinea capitis in children. The use of fluconazole, terbinafine, and itraconazole for tinea capitis in children, while promising, is still experimental, and the reader should consult the primary literature before use.
Note: 5 mL = 1 teaspoon.
The drug information and doses listed herein are given as guidelines only and are not intended to be comprehensive. Drug selection and dosage should be chosen according to the individual situation. Drug information may have changed since publication of this textbook. Parenteral and neonatal indications and dosages are not listed.

and for certain pathogenic infections or situations such as multidrug resistance.[50]

Griseofulvin doses of 20 mg/kg/day of the liquid and 15 mg/kg/day of the ultramicrosized tablets for 6 to 8 weeks remain first-line therapy for tinea capitis. This drug remains the only FDA-approved drug for tinea capitis in children at this time. Although further studies are needed, itraconazole and terbinafine appear to be effective with a good safety profile. These drugs remain second-line agents for pediatric tinea capitis, and monitoring should be considered during this off-label indication. Fluconazole was not very effective in pediatric tinea capitis in a large multicenter, double-blinded randomized trial of 880 children.[56]

Child Abuse

In the United States in 2003, 906,000 children were determined to be victims of child abuse and neglect by child protective agencies, and an estimated 1500 children died of child abuse. Ninety percent of all abused children are said to have suggestive or confirmative dermatologic findings.[57] Child abuse is discussed in Chap. 105.

CHAPTER 107

Skin Changes and Diseases in Pregnancy

Julie K. Karen
Miriam Keltz Pomeranz

CUTANEOUS CHANGES COMMONLY ASSOCIATED WITH PREGNANCY

Pregnancy is characterized by altered endocrine, metabolic, and immunologic milieus. These dramatic alterations result in multiple cutaneous changes, both physiologic and pathologic. A comprehensive list of physiologic alterations within the skin and appendages is provided in Table 107-1.[1–3]

Pigmentary disturbances are the most common of these physiologic changes (see Table 107-1). Hyperpigmentation of the areola, axillae, and genitalia is well documented in pregnancy. *Linea nigra* refers to the typically reversible darkening of the linea alba, a hypopigmented linear patch extending from the pubis symphysis to the xiphoid process of the sternum (Fig. 107-1). Melasma or chloasma is a related finding comprising irregular, blotchy, facial hyperpigmentation that occurs in up to 70 percent of pregnant women (Fig. 107-2). This tendency is aggravated by sun exposure and by oral contraceptive intake by nonpregnant women. Melasma may regress postpartum, but oftentimes persists, posing a therapeutic challenge.[1]

Changes in melanocytic nevi were historically deemed "normal" during pregnancy. However, few studies have objectively studied whether and how nevi evolve during pregnancy. Pennoyer et al.[4] photographically monitored 129 melanocytic nevi throughout the pregnancies of 22 healthy Caucasian women. Only eight nevi (6.2 percent) changed in diameter from the first to third trimester, with a mean change in size of zero. The authors concluded that significant change in nevus size (excluding nevi on the pregnant abdomen) does not appear to be a feature of most pregnancies.[4] Until further controlled studies are performed, any pigmented lesion in a pregnant woman that undergoes change in morphology (size, color, or shape) or symptomatology (begins to itch, bleed, or scale) should be considered for histopathologic review.

The most common structural change during pregnancy is striae distensae, also known as *striae gravidarum* or *stretch marks* (Fig.107-3). Sites of predilection for striae include those areas most prone to stretch, including the abdomen, hips, buttocks, and breasts. Genetic factors as family history, personal history, and race are the strongest predictors of an individual's risk of developing striae distensae, surpassing pregnancy weight gain or changes in body mass index.[5] These findings strongly support a genetic predisposition to this condition.

Pruritus, a common complaint during pregnancy, may be physiologic, but may herald a flare of a pre-existing dermatosis or onset of a specific dermatosis of pregnancy. The majority of patients with pruritic skin disease during pregnancy have conditions unrelated to pregnancy (i.e., atopic dermatitis).[6] The remainder of this chapter outlines the relatively rare conditions that may be specific to pregnancy. An overview of these conditions is provided in Table 107-2.

DERMATOSES ASSOCIATED WITH FETAL RISK IN PREGNANCY

Pemphigoid (Herpes) Gestationis

Pemphigoid (herpes) gestationis (PG; see Chap. 57) is an intensely pruritic, vesiculobullous eruption of mid to late pregnancy and the immediate postpartum period. PG classically begins during the second or third trimester, and is manifest by the abrupt appearance of severely pruritic urticarial lesions on a background of normal or erythematous skin. PG is associated with an increased incidence of small-for-gestational age

CUTANEOUS CHANGES COMMONLY ASSOCIATED WITH PREGNANCY AT A GLANCE

- Cutaneous changes result from the altered endocrine, metabolic, and immunologic milieus that characterize pregnancy.
- Pigmentary disturbances, including hyperpigmentation, darkening of the linea alba, and melasma are the changes most commonly observed.
- Significant change in nevi size is not a feature of most pregnancies.
- Structural changes known to occur during pregnancy include, most commonly, striae distensae.
- Pruritus is a common complaint during pregnancy and may be related to flare of a pre-existing dermatosis or onset of a specific dermatosis of pregnancy.

TABLE 107-1
Physiologic Skin Changes during Pregnancy

Pigmentary
- Diffuse hyperpigmentation
- Selective hyperpigmentation (genitalia, axillae, recent scars)
- Secondary areolae
- Linea nigra
- Melasma (chloasma, mask of pregnancy)
- Darkening of ephelides and melanocytic nevi

Hair
- Hirsutism
- Thickening of scalp hair
- Postpartum telogen effluvium
- Postpartum androgenetic alopecia

Nail
- Subungual hyperkeratosis
- Distal onycholysis
- Transverse grooving
- Brittleness
- Accelerated growth

Glandular
- Increased eccrine function (except palms) (miliaria, dyshidrotic eczema, hyperhidrosis)
- Elevated thyroid activity with resultant relative iodine deficiency
- Increased sebaceous function (growth in Montgomery's tubercles) (see eFig. 107-0.1 in on-line edition)
- Decreased apocrine function

Structural changes
- Striae distensae (striae gravidarum)
- Molluscum fibrosum gravidarum (acrochorons)

Vascular
- Spider angiomas (spider nevi, nevi aranei)
- Palmar erythema (see eFig. 107-0.2 in on-line edition)
- Carpal tunnel syndrome
- Non-pitting edema (hands, ankles, feet, face)
- Varicosities
- Cutis marmorata
- Vasomotor instability
- Dermographism/pruritus
- Purpura
- Gingival hyperemia or hyperplasia
- Pyogenic granuloma (granuloma gravidarum, pregnancy epulis)
- Hemorrhoids
- Hemangiomas, hemangioendotheliomas, glomangiomas
- Unilateral nevoid telangiectasia (unilateral dermatomal superficial telangiectasia)

Mucosa
- Gingivitis (marginal gingivitis, papillomatous hypertrophy of the gums)
- Jacquemier-Chadwick sign (bluish discoloration of vagina and cervix)
- Goodell's sign (cervical softening)

Adapted from Elling SV, Powell FC: Physiological changes in the skin during pregnancy. *Clin Dermatol* **15**:35, 1997; Kroumpouzos G, Cohen LM: Dermatoses of pregnancy. *J Am Acad Dermatol* **45**:1, 2001; and Muzaffar F, Hussain I, Haroon TS: Physiologic skin changes during pregnancy: A study of 140 cases. *Int J Dermatol* **77**:429, 1998.

births and premature delivery. PG is immunologically mediated.[7]

Cholestasis of Pregnancy

NOMENCLATURE AND EPIDEMIOLOGY The terms *obstetric cholestasis*, *intrahepatic cholestasis of pregnancy*, *recurrent jaundice of pregnancy*, *cholestatic jaundice of pregnancy*, *idiopathic jaundice of pregnancy*, *prurigo gravidarum*, and *icterus gravidarum* all refer to the same clinical entity, cholestasis of pregnancy (CP), characterized by a reversible form of cholestasis in late pregnancy. Svanborg and Ohlsson first recognized CP as a distinct entity, separate from other causes of jaundice during pregnancy in 1939.[8] Jaundice develops in approximately 1 in 1500 pregnant women. With an estimated incidence of 70 cases per 10,000 pregnancies in the United States, CP ranks second only to viral hepatitis in terms of etiology of jaundice in pregnant women.[9] Mild cases of CP, in which pruritus is not accompanied by jaundice, were previously referred to as *prurigo gravidarum*.

CP is most common in Scandinavia and South America. The highest reported incidence rates are in Chile (14 percent to 16 percent), whereas much lower rates are seen among pregnant women in the United States (less than 0.1 percent to 0.7 percent), Canada (0.1 percent), Australia (0.2 percent to 1.5 percent), and Europe (0.1 percent to 1.5 percent).

Etiology

Although the precise pathogenesis remains unclear, the interplay of hormonal, genetic, environmental, and alimentary factors is thought to induce a

DERMATOSES ASSOCIATED WITH FETAL RISK IN PREGNANCY AT A GLANCE

- Pemphigoid gestationis is an immunologically mediated, intensely pruritic, vesiculobullous eruption of mid to late pregnancy that is associated with fetal risk.
- Cholestasis of pregnancy represents a reversible form of cholestasis in late pregnancy associated with biochemical abnormalities and a risk of fetal complications, but invariably lacking primary cutaneous lesions. Symptoms remit within 2 to 4 weeks of delivery, but recurrences in subsequent pregnancies are common.
- Pustular psoriasis of pregnancy is a rare, acute, pustular eruption often accompanied by fever, leukocytosis, and an elevated erythrocyte sedimentation rate. This is generally regarded as a variant of psoriasis.

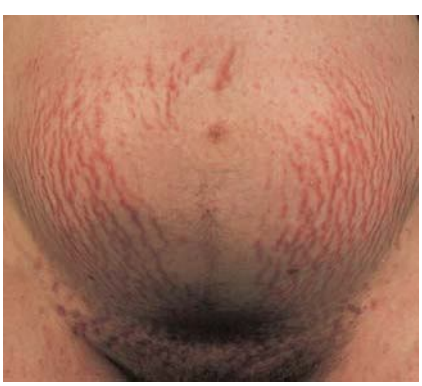
▲ **FIGURE 107-1** Linea nigra. A hyperpigmented line extends from the pubis symphysis to the xiphoid process of the sternum. Hyperpigmentation is often more pronounced inferior to the umbilicus.

biochemical cholestasis in susceptible individuals. A prominent role for hormonal alterations is suggested by the following observations: (1) CP is a disease of late pregnancy (corresponding to the period of highest placental hormone levels); (2) CP spontaneously remits at delivery when hormone concentrations normalize; (3) twin and triplet pregnancies, characterized by greater rises in hormone concentrations, have been linked to CP; and, (4) CP recurs during subsequent pregnancies in an estimated 45 percent to 70 percent of patients.[9,10]

Geographic variation and familial clustering indicate a genetic predisposition. CP appears to be a polygenetic condition. Candidate genes include those mutated in a variety of other forms of inherited cholestasis: ABCB4 (multidrug resistance gene3), ABCB11 (Bsep), and ATP8B1 (FIC1). A recent decline in prevalence rates in Chile, reports of higher incidence rates during the winter months, and reports of relative reductions of selenium levels in CP patients all point towards etiologic roles for environmental and alimentary factors.[9,11] At least one study confirmed a higher risk of hepatitis C virus infection among women with CP.[12]

▲ **FIGURE 107-2** Melasma. Blotchy, mottled hyperpigmentation is evident on the malar cheek and upper cutaneous lip.

CLINICAL FEATURES Patients classically present during the third trimester with moderate to severe pruritus, which may be either localized to the palms and soles or generalized. Pruritus begins during the first and second trimester in 10 percent and 25 percent of cases, respectively. Intense pruritus is oftentimes associated with secondary excoriations, although primary cutaneous lesions are invariably absent. Initially, patients may complain of nocturnal pruritus only, and symptoms generally are more severe at night throughout the course of illness. CP is sometimes preceded by a urinary tract infection. Constitutional symptoms such as fatigue, nausea, vomiting, or anorexia may accompany the pruritus. Progression to clinical jaundice, dark urine, or lightly colored stools occurs in approximately one in five patients. Pruritus generally precedes the onset of these symptoms by 1 to 4 weeks.[9]



▲ **FIGURE 107-3** Striae distensae.

COURSE A hallmark of CP is that symptoms and associated biochemical abnormalities typically resolve within 2 to 4 weeks of delivery. Recurrences during subsequent pregnancies occur in an estimated 45 percent to 70 percent of patients. Some women experience recurrent CP after exposure to oral contraceptives or to contraceptive aids, such as synthetic estrogens and progestational agents.

Maternal outcomes are generally favorable, although women with severe cases are predisposed to postpartum hemorrhage secondary to vitamin K depletion. Additionally, affected women have a tendency towards the later development of cholelithiasis or gallbladder disease. Fetal risks in CP include increased rates of prematurity, intrapartal fetal distress, and fetal death. These complications are thought attributable to acute placental anoxia and an increased incidence of meconium-stained amniotic fluid. Such fetal complications may be reduced with treatment and induction of labor after fetal pulmonary maturation has been documented.[9]

LABORATORY STUDIES Elevation in serum bile acids is the single most sensitive indicator of CP. In healthy pregnant women, total bile acids (TBAs) are slightly elevated above baseline and levels as high as 11.0 μ*M* are accepted as normal in late pregnancy. Clearly defined biochemical indices of CP have not yet been established. However, Brites et al.[13] identified the following common features of CP: (1) serum TBA concentrations greater than 11.0 μ*M* (normal range, 4.6 to 8.7 μ*M*); (2) cholic acid–chenodeoxycholic acid ratio greater than 1.5 (normal range, 0.7 to 1.5) or cholic acid proportion of TBAs greater

TABLE 107-2
Summary of Dermatoses of Pregnancy

	Morphology	Distribution	Usual Onset	Fetal Risk	Synonym(s)
Pemphigoid (herpes) gestationis	Urticarial papules and plaques progress to vesicles and bullae	Begins on trunk, then progresses to generalized eruption Spares face, mucus membranes, palms, soles	Second or third trimester, or immediately postpartum	Small-for-gestational-age births Preterm delivery Neonatal pemphigoid gestationis	Herpes gestationis
Cholestasis of pregnancy	Excoriations and excoriated papules ± jaundice	Localized to palms and soles or generalized	Third trimester	Preterm delivery Fetal distress Fetal death	Intrahepatic cholestasis of pregnancy Obstetric cholestasis Recurrent jaundice of pregnancy Cholestatic jaundice of pregnancy Idiopathic jaundice of pregnancy Prurigo gravidarum Icterus gravidarum
Pustular psoriasis of pregnancy	Erythematous patches with subcorneal pustules at their margins	Begins in flexures Generalizes demonstrating centrifugal spread	Third trimester	Placental insufficiency may lead to stillbirth or neonatal death	Impetigo herpetiformis
Pruritic urticarial papules and plaques of pregnancy	"Polymorphous" including urticarial papules and plaques ± vesicles	Begins within abdominal striae Spreads to remainder of trunk and then extremities Spares umbilicus	Third trimester or immediately postpartum	None	Polymorphic eruption of pregnancy Bourne's toxemic rash of pregnancy Nurse's late onset prurigo of pregnancy Toxemic erythema of pregnancy (Holmes)
Prurigo of pregnancy	Excoriated or crusted papules	Extremities, occasionally trunk	Second or third trimester	None	Besnier's prurigo gestationis Nurse's early onset prurigo of pregnancy Papular dermatitis of Spangler Atopic eruption of pregnancy[a]
Pruritic folliculitis of pregnancy	Follicular papules and pustules	Trunk, sometimes generalized	Second or third trimester	None	NA Atopic eruption of pregnancy[a]

NA = not applicable.
[a]A newly proposed classification by Ambros-Rudolph et al.[34] combines the previously distinct entities prurigo of pregnancy and pruritic folliculitis of pregnancy into a single entity, atopic eruption of pregnancy. Atopic eruption of pregnancy also includes eczema in pregnancy, which is characterized by a pruritic eruption with a flexural predilection occurring in patients with a personal and/or family history of atopy. Atopic eruption of pregnancy may be eczematous or prurigo-like in morphology, equally affects the trunk and extremities, generally begins before the third trimester, and is not associated with any fetal risk.

than 42 percent; (3) glycine conjugates–taurine conjugates of bile acids ratio less than 1.0 (normal range, 0.9 to 2.0) or glycocholic acid concentration greater than 2.0 μ*M* (normal range, 0.6 to 1.5 μ*M*).[13] Degree of pruritus and disease severity generally correlate with bile acid concentrations.

Mild perturbations in liver function tests, including elevated transaminases, alkaline phosphatase, 5′-nucleotidase, cholesterol, triglycerides, phospholipids, and lipoprotein X are commonly found. Among these parameters, alanine transaminase is particularly sensitive, as an elevation in this enzyme is not a feature of healthy pregnancies, but is commonly seen in CP. γ-Glutamyl transferase, which is generally low in late gestation, is typically normal or slightly elevated in CP. Direct (or conjugated) fractions of bilirubin are most commonly elevated in CP. Albumin may be slightly reduced, whereas α_2-globulins and β-globulins are appreciably elevated. Routine liver tests alone, however, are not a sufficient basis for the diagnosis of CP.[13]

Cutaneous biopsy does not aid in the diagnosis of CP. Although generally unnecessary, hepatic biopsy reveals intrahepatic cholestasis with dilated, plugged bile canaliculi and deposits of bile pigment in centrilobular hepatocytes.[9]

DIFFERENTIAL DIAGNOSIS Distinction from prurigo of pregnancy (PP) can be challenging and the two conditions may be etiologically linked. The presence of erythematous, excoriated papules points away from a diagnosis of CP, which lacks primary lesions. Other causes of liver derangement and jaundice, such as viral and nonviral hepatitis, medications, hepatobiliary obstruction, and other intrahepatic diseases (i.e., primary biliary cirrhosis) must be ruled out. Finally, it must be remembered that hyperthyroidism, allergic

reactions, polycythemia vera, lymphoma, pediculosis, and scabies may each manifest as generalized pruritus in pregnant as in nonpregnant women.

TREATMENT Given the increased risk for adverse fetal outcomes, intense fetal surveillance is essential to the management of CP. Although obstetric management varies, the need for weekly fetal monitoring beginning in the thirty-fourth week of gestation is widely accepted. Additionally, most authors recommend early induction of labor, commonly at 37 to 38 weeks' gestation, but as soon as there is evidence of fetal pulmonary maturity in severe cases.[9]

In mild cases, adequate relief of symptoms can be achieved with bland emollients and topical antipruritic agents. Patients rarely respond to antihistamines. Ultraviolet B phototherapy has been variably effective. Dexamethasone suppression of fetoplacental estrogen was reported effective in an uncontrolled trial of 10 pregnant women with CP.[7,9,14] However, the literature contains one report of CP worsening after dexamethasone administration.[15]

Cholestyramine and other anion exchange resins bind bile acids, thereby decreasing their enterohepatic circulation. Several uncontrolled trials have suggested cholestyramine may effectively reduce symptoms in up to 70 percent of patients with mild CP. However, the lack of randomized, placebo-controlled cholestyramine trials precludes definite conclusions about the efficacy of this agent. Furthermore, cholestyramine must be administered for several days before taking effect, its efficacy in treating severe cases has been disappointing, and, importantly, it may precipitate vitamin K and thereby trigger a coagulopathy.[16,17]

Ursodeoxycholic acid (UDCA), a naturally occurring hydrophilic bile acid, exerts a hepatoprotective effect through augmentation of the excretion of hydrophobic bile acids, sulfated progesterone metabolites, and other hepatotoxic compounds. UDCA decreases bile acid levels in colostrum, cord blood, and amniotic fluid. The results of several small, randomized, placebo-controlled UDCA trials demonstrate that when administered at doses between 450 mg and 1200 mg daily, UDCA is well tolerated and highly effective in controlling the clinical and liver function abnormalities that define CP.[17] The effect of UDCA is more rapid and lasts longer than that of cholestyramine. Enhanced efficacy may be achieved by co-administration with *S*-adenosylmethionine.[18] UDCA is a safe and well-tolerated treatment and may decrease fetal mortality associated with CP. Randomized, controlled trials comparing UDCA head-to-head with either dexamethasone[19] or cholestyramine[20] demonstrated UDCA's superior efficacy.

Successful treatment of a case of severe and refractory CP has been reported using plasmapheresis beginning at 32 weeks' gestation. The treatment was well tolerated and led to marked and instantaneous relief of symptoms. However, the treatment did not reverse the associated biochemical abnormalities.[21]

▲ **FIGURE 107-4** Pustular psoriasis of pregnancy. Erythematous patches are studded with subcorneal pustules.

Pustular Psoriasis of Pregnancy (Impetigo Herpetiformis)

NOMENCLATURE Von Hebra first used the designation *impetigo herpetiformis* in 1872 to describe an acute pustular eruption with usual onset during the third trimester of pregnancy. It is now generally regarded as a variant of pustular psoriasis attributable to hormonal alterations during pregnancy; however, some authors maintain that it is a distinct clinical entity.[22]

CLINICAL FEATURES Pustular psoriasis of pregnancy is characterized by an acute eruption occurring as early as the first, but generally during the third, trimester of an otherwise uneventful pregnancy. The condition manifests as erythematous patches whose margins are studded with subcorneal pustules (Fig. 107-4). The eruption typically originates in flexural areas but spreads centrifugally and sometimes generalizes. Subungual lesions may result in onycholysis. Rarely, mucous membrane involvement may lead to painful erosions. The face, palms, and soles are commonly spared. The rash may be pruritic or painful. Onset of the eruption is accompanied by such constitutional symptoms as fever, chills, malaise, diarrhea, nausea, and arthralgias. Rarely, tetany, delirium, and convulsions occur if hypocalcemia is severe.[1]

Although generally regarded as a form of pustular psoriasis (see Chap. 18), absence of a positive family history, abrupt resolution of symptoms at delivery, and a tendency to only recur during subsequent pregnancies distinguish this entity from generalized pustular psoriasis. Moreover, factors known to trigger pustular psoriatic flares, such as infection, exposure to culprit drugs, or abrupt discontinuation of systemic corticosteroids are lacking in virtually all patients with pustular psoriasis of pregnancy.[1,23]

LABORATORY STUDIES Histopathologic examination reveals classic features of pustular psoriasis (see Chap. 18).

The most common laboratory derangements include leukocytosis, neutrophilia, an elevated erythrocyte sedimentation rate, hypoferric anemia, and hypoalbuminemia. Less commonly, calcium, phosphate, and vitamin D levels are decreased. Serum parathormone levels are rarely decreased. Cultures of pustule contents and peripheral blood are negative unless secondarily infected.[1]

COURSE Pustular psoriasis of pregnancy classically presents during the last trimester, but there are reports of cases occurring as early as the first trimester, during the puerperium, in nonpregnant women taking oral contraceptives, and in postmenopausal women. Symptoms are invariably progressive throughout pregnancy. A cardinal feature of this disorder is the rapid resolution of symptoms after delivery. Recurrences in subsequent pregnancies are common and characteristically are more severe with onset earlier in

gestation.[1] Several reports of subsequent menstrual exacerbation occurring either during or immediately preceding menses exist in the literature.[24]

More widespread disease generally portends a worse prognosis. Life-threatening maternal complications are infrequent today, but may result from profound hypocalcemia and bacterial sepsis. The most feared complications are placental insufficiency and consequent stillbirth or neonatal death. For these reasons, early induction of labor is often contemplated.[22]

DIFFERENTIAL DIAGNOSIS Box 107-1 outlines the differential diagnosis of pustular psoriasis of pregnancy.

TREATMENT Resolution after delivery is the norm. However, given its consistently progressive course, treatment is indicated to reduce the risk of fetal and maternal complications during pregnancy. Topical treatments include wet dressings and topical corticosteroids, but are rarely effective as monotherapy. Systemic corticosteroids (60 to 80 mg/day) are the mainstay of therapy during pregnancy. Cyclosporine, which is categorized as pregnancy category "C," has been successfully used at doses between 5 and 10 mg/kg daily to treat cases refractory to high-dose systemic corticosteroids.[13,25]

Fluid status and electrolytes should be monitored with rapid correction of imbalances. Fetal monitoring is essential as decelerations in fetal heart rate may be the earliest sign of fetal hypoxemia. Maternal cardiac and renal functions may be compromised with disease progression and therefore should be monitored as well. Induction of labor is an option when symptoms do not remit despite supportive and pharmacologic therapy. The therapeutic armamentarium available after pregnancy termination or after delivery in a non-nursing mother is much broader, and includes: phototherapy with or without oral retinoids, clofazimine, methotrexate, and sulfapyridine and sulfones.[13,26]

DERMATOSES NOT ASSOCIATED WITH FETAL RISK IN PREGNANCY

Pruritic Urticarial Papules and Plaques of Pregnancy (Polymorphic Eruption of Pregnancy)

NOMENCLATURE AND EPIDEMIOLOGY Pruritic urticarial papules and plaques of pregnancy (PUPPP) is a common benign intensely pruritic dermatosis that occurs almost exclusively in primigravidas during late pregnancy. The term *PUPPP*, introduced by Lawley et al. in 1979,[27] is synonymous with Bourne's toxemic rash of pregnancy, Nurse's late onset PP, toxic erythema of pregnancy, and polymorphic eruption of pregnancy.[28] *Polymorphic eruption of pregnancy*, a more recent term, best describes the clinical spectrum of this entity, and is favored throughout Europe.[29] The incidence of PUPPP ranges between 1 in 300 pregnancies and 1 in 130 pregnancies.[6]

ETIOLOGY The pathogenesis remains unknown. An association between PUPPP and multiple gestations is suggested by the higher than expected rates of twin and triplet pregnancies in most published series.[6,15,30] Reports linking PUPPP to increased maternal–fetal weight gain[6,31] are contested. Some postulate that increased abdominal cutaneous distension leads to altered collagen and/or elastic tissue, thereby triggering maternal immune-reactivity to previously non-antigenic stimuli.[6] Additionally, fetal DNA has been detected in involved maternal skin and is hypothesized to be etiologically linked to this condition.[32]

CLINICAL FEATURES PUPPP typically occurs in primigravidas during the last trimester of pregnancy (mean onset, 35 weeks); however, cases of otherwise classic PUPPP have occurred earlier in pregnancy and in the immediate postpartum period. Polymorphous in nature, lesions may be urticarial (most commonly), vesicular, purpuric, polycyclic, or targetoid in appearance (Fig. 107-5). Within an individual patient, lesions are generally morphologically uniform.[1]

Typical lesions are 1- to 2-mm erythematous urticarial papules surrounded by a narrow pale halo. The eruption begins on the abdomen, classically within the striae gravidarum, and demonstrates periumbilical sparing. Pruritus generally parallels with the eruption and is localized to the involved skin. Rapid spread to the thighs, buttocks, breasts, and arms is the norm. Involvement of the palms, soles, or skin above the breast is exceptional.[1] Severe pruritus contributes to disturbed sleep in many; however, no other systemic symptoms are reported by patients.

LABORATORY STUDIES Laboratory investigations reveal no abnormalities. Histopathologic findings, although nonspecific, generally include parakeratosis, spongiosis, and occasional exocytosis of eosinophils (eosinophilic spongiosis). The adjacent dermis may be edematous and contains a perivascular infiltrate of lymphocytes admixed with variable numbers of eosinophils and neutrophils. Direct immunofluorescence (DIF) studies reveal no

DERMATOSES NOT ASSOCIATED WITH FETAL RISK IN PREGNANCY AT A GLANCE

- Pruritic urticarial papules and plaques of pregnancy is a common, self-limited, intensely pruritic dermatosis that occurs almost exclusively in primigravidas during late pregnancy. The term *polymorphic eruption of pregnancy* appropriately encompasses the wide spectrum of clinical presentations.
- Pruritic folliculitis of pregnancy is a benign, pruritic, follicular papular, and/or sterile pustular eruption with classic onset between the fourth and ninth months of pregnancy.
- Prurigo of pregnancy (PP) manifests with discrete pruritic excoriated papules commonly on extensor surfaces. PP is not associated with any specific laboratory or histopathologic abnormalities; maternal and fetal outcomes are unaltered.
- Atopic eruption of pregnancy represents a newly introduced complex comprising pruritic folliculitis of pregnancy, PP, and eczema flares occurring during pregnancy.

▲ **FIGURE 107-5** Pruritic urticarial papules and plaques of pregnancy. **A.** The earliest lesions are 1- to 2-mm, erythematous, urticarial papules localized within and around the striae distensae and sparing the umbilicus. **B.** The papules coalesce to form erythematous plaques that spread to involve the buttocks and thighs.

specific immunoreactants and indirect immunofluorescence studies are negative.[1]

COURSE PUPPP mostly affects primigravidas in the last trimester, although it may occur as early as the first trimester. There are several reports of cases occurring in the immediate postpartum period as well. Duration of symptoms is typically brief, averaging 6 weeks. Severe symptoms, however, rarely persist for more than 1 week. Spontaneous remission within days of delivery is the rule. Recurrences in subsequent pregnancies or with exposure to oral contraceptives are the exception. Fetal and maternal prognoses are unaltered.[1] A single report of involvement of a newborn exists in the literature.[33] In one series, an unusually high sex ratio (male-female of 29:14) has been reported.[6]

DIFFERENTIAL DIAGNOSIS Box 107-2 outlines the differential diagnosis of PUPPP.

TREATMENT Although harmless to the mother and fetus, pruritus is often intense and unremitting. Symptomatic relief of pruritus can usually be achieved with topical antipruritics, antihistamines, and topical corticosteroids. A brief course of oral corticosteroids is rarely required, but effectively controls symptoms in most cases refractory to topical treatment. Early induction of labor has been rarely considered in instances in which severe pruritus is unrelenting, but is generally considered unnecessary.[1,34] Patient reassurance regarding the self-limited nature of PUPPP can help to assuage unnecessary anxiety.

Prurigo of Pregnancy (Prurigo Gestationis)

NOMENCLATURE AND EPIDEMIOLOGY *Prurigo of pregnancy* refers to an ill-defined group of disorders comprising Besnier's prurigo gestationis, Nurse's early onset PP, and papular dermatitis of Spangler. This relatively common pruritic dermatosis of pregnancy is thought to occur in approximately 1 in 450 pregnancies.[7] In 2006, Ambros-Rudolph et al. proposed reclassifying PP as part of a newly defined disease complex, atopic eruption of pregnancy (AEP; see Atopic Eruption of Pregnancy).[35]

CLINICAL FEATURES PP presents with discrete, pruritic, excoriated papules with classic onset during the second trimester. Lesions measure 5 to 10 mm and have a predilection for extensor surfaces (Fig. 107-6). Pustules may be evident, but vesicles are never seen. Occasionally, lesions appear crusted or eczematous.[1] Some posit an etiologic role for atopy, as this condition appears to be more common among women with an atopic background, and elevated serum immunoglobulin E has been detected in several individuals.[6] Other studies, however, did not demonstrate an association between PP and an atopic diathesis.[7]

▲ **FIGURE 107-6** Prurigo of pregnancy. Multiple discrete, excoriated papules demonstrate a predilection for extensor surfaces.

LABORATORY STUDIES Serologic tests reveal no abnormalities. Histopathologic features are non-specific, revealing a superficial chronic inflammatory cell infiltrate with occasional epidermal involvement. Direct and indirect immunofluorescence studies are negative.[1]

COURSE Onset is typically during the second or third trimester, with a peak incidence during the second trimester. Lesions commonly resolve with delivery, but may persist for up to 3 months postpartum. Recurrence with subsequent pregnancies is variable. Maternal and fetal prognoses are excellent.[1]

DIFFERENTIAL DIAGNOSIS PP may resemble atopic dermatitis, and distinguishing between the two conditions can be difficult. CP, pruritic folliculitis of pregnancy (PFP), microbial folliculitis occurring in a pregnant woman, and, rarely, PUPPP may also be considered in the differential diagnosis.

TREATMENT Treatment seeks to ameliorate pruritus and includes mid-potency topical corticosteroids and antihistamines.[1]

Pruritic Folliculitis of Pregnancy

EPIDEMIOLOGY The incidence of PFP has been estimated to be 1 in 3000 pregnancies.[37] However, underreporting due to misdiagnosis as acne or microbial folliculitis is likely common, and thus the true incidence is probably higher.

CLINICAL FEATURES PFP is characterized by a pruritic, follicular, monomorphous, papular eruption with onset during the second or third trimester. Individual lesions are small, erythematous papules and pustules with a predilection for the trunk, although the eruption can be generalized.[1]

LABORATORY FINDINGS Histopathologic examination reveals a sterile folliculitis with intraluminal pustule formation containing neutrophils, lymphocytes, macrophages, and variable eosinophils. Focal perifollicular granulomatous inflammation is sometimes seen. Mild superficial dermal edema associated with a perivascular infiltrate of lymphohistiocytes and occasional eosinophils is commonly seen in the adjacent dermis. Special stains for organisms (i.e., Gram, periodic acid-Schiff, and Fite) are invariably negative. DIF studies are negative for deposition of immunoglobulins and complement.[38]

COURSE Classically, onset is during the second or third trimester, and spontaneous resolution occurs within 2 to 3 weeks postpartum. Recurrences in subsequent pregnancies are uncommon.[1] Maternal and fetal prognoses are unaltered by the condition. However, one prospective study of 14 patients indicated a predominance of male fetuses (2:1) and decreased fetal birth weight among women with PFP.[6]

DIFFERENTIAL DIAGNOSIS Other papulopustular eruptions, such as acne, microbial folliculitis, and pruritic dermatoses of pregnancy (i.e., PUPPP, PP, and PG), must be entertained in the differential diagnosis. The absence of comedones, lack of facial involvement, and the presence of pruritus can be helpful in distinguishing PFP from acne. Infectious folliculitis can be ruled out with special stains and culture. Unlike PUPPP, PFP has neither a predilection for the striae nor an urticarial component. Routine histology can further help distinguish these two conditions but is rarely necessary. Lesions of PP are non-follicular and favor the extremities. Finally, the absence of bullous lesions, together with histologic and DIF findings, are helpful in excluding PG.

TREATMENT Symptomatic relief can often be achieved with topical agents containing 10 percent benzoyl peroxide, low-potency topical steroids, or both.[1,39] Topical antifungals, as well as topical and systemic antibiotics have not proven beneficial.[38] One case of successful treatment of PFP with narrow band ultraviolet B phototherapy after 20 treatments has been reported.[40]

Atopic Eruption of Pregnancy

Ambros-Rudolph et al.[35] have proposed the term *atopic eruption of pregnancy* to denote a new disease complex comprising the previously distinct entities PP and PFP, as well as *eczema in pregnancy* (EP), which has not previously been considered a specific dermatosis of pregnancy.[35] The authors retrospectively reviewed data from 505 pregnant women who presented with a generalized, pruritic skin condition that first developed during pregnancy. Among these patients, EP was the most frequently observed skin disorder, occurring in 49.7 percent of patients. Distinguishing features of EP included onset early in pregnancy, a predilection for flexural skin, and a personal and/or family history of atopy. Total serum immunoglobulin E levels were elevated in 71 percent of EP patients whose serum was tested. Considerable clinical and histopathologic overlap was noted among patients with EP and those with PP and PFP. The authors therefore introduced the term *AEP* to encompass all patients formerly diagnosed with PP, PFP, and EP.[35]

Relative to other specific dermatoses of pregnancy, symptoms of AEP occurred significantly earlier during gestation and there was equal involvement of the trunk and extremities. No specific association with parity or gestation was observed. Whereas 20 percent of AEP patients presented with a flare of pre-existing atopic dermatitis, the remaining patients were without prior atopic dermatitis and manifested with either eczematous features (E-type AEP) or prurigo-type lesions (P-type AEP). The authors posited that shifts in cytokine profile expression leading to preferential expression of T helper 2 cytokines may favor the exacerbation of atopic dermatitis during pregnancy. Insofar as eczema is so common in pregnant as in nonpregnant women, it is unclear whether AEP warrants consideration as a distinct dermatosis of pregnancy. Eczematous eruptions, however, are the most common reason for a pregnant woman to present with a generalized pruritic skin condition, and must always be considered in the clinical differential.[35]

CHAPTER 108

Aging of Skin

Mina Yaar
Barbara A. Gilchrest

EFFECTS OF AGING

In both developed and developing nations, the number and proportion of older people are increasing. Thirty-one percent of the U.S. population is expected to be 55 years of age or older by the year 2030.[1] This demographic shift compels health care providers and government officials to confront the pathophysiology of aging and associated health issues.

Aging is a process of progressive decreases in the maximal functioning and reserve capacity of all organs in the body, including the skin. This naturally occurring functional decline in the skin is often compounded and accelerated by chronic environmental insults, such as ultraviolet (UV) irradiation.

Aging occurs at the cellular level and reflects both a genetic program and cumulative environmentally imposed damage. Mammalian cells can undergo only a limited number of cell divisions and then arrest irreversibly[2–4] in a state known as *replicative senescence*, after which they are refractory to mitogenic stimuli. This fact has led to the perception that aging evolved in multicellular organisms as a cancer prevention mechanism[5] because it prevents the unlimited and possibly unregulated growth of cells whose DNA has been progressively damaged over their life span. Of note, in general the more proficient the DNA repair mechanisms of the organism, the longer its life span.[6] Furthermore, there is an inverse correlation between the organism's life span and metabolic rate[7] consistent with the understood role of cumulative oxidative DNA damage, due to aerobic metabolism, in the aging process.[6]

AGING MECHANISMS

Telomeres and Aging[8]

Telomeres, the terminal portions of eukaryotic chromosomes, consist of up to many hundreds of tandem short sequence repeats (TTAGGG in all mammals). During mitosis of somatic cells, DNA polymerase cannot replicate the final base pairs of each chromosome, resulting in progressive shortening with each round of cell division. A special reverse transcriptase, telomerase, can replicate these chromosomal ends, but, with the exception of stem cells and germline cells, the enzyme is normally expressed at extremely low levels, insufficient to maintain telomere length. Human telomeres shorten more than 30 percent during adulthood even in relatively quiescent skin fibroblasts, and telomeres of patients with premature aging syndromes, such as Werner syndrome,[9] progeria,[10] and dyskeratosis congenita,[11] are shorter than those of age-matched controls. Critically short telomeres signal for proliferative senescence or apoptosis, depending on cell type, and appear to compromise DNA stability and transcription of subtelomeric genes,[12] presumably contributing to the aged phenotype. Thus, telomeres appear to serve as a biologic clock that determines proliferative life span of the cell.

SKIN AGING AT A GLANCE

- Intrinsic (chronologic) aging occurs throughout the skin and causes primarily functional losses.
  - Caused by oxidative damage, cell senescence, amino acid racemization, nonenzymatic glycosylation of proteins.
  - Displays flattening of the dermal epidermal junction, decreased cellularity, decreased dermal thickness, loss of vascular and lymphatic beds.
- Photoaging is the superposition of chronic ultraviolet-induced damage on intrinsic aging and accounts for most age-associated changes in skin appearance.
  - Triggered by receptor signaling, mitochondrial damage, protein oxidation.
  - Displays variable epidermal thickness, dermal elastosis, decreased/fragmented collagen, increased matrix degrading metalloproteinases, inflammatory infiltrate, vessel ectasia.
- Dermatologic problems with increased incidence in the elderly include skin cancer, xerosis, pruritus, varicella-zoster infection, ulcers, bullous pemphigoid and drug eruptions.

DNA Damage and Aging[13]

In humans, the only genes implicated in the rate of aging are those in which mutations are responsible for premature aging syndromes. For example, Cockayne syndrome patients display mutations in DNA helicases, enzymes that participate in the repair of DNA damage[14]; ataxia telangiectasia is caused by a mutation in the *ATM* gene,[15] encoding a kinase that senses DNA damage; and Werner syndrome is caused by mutation in a protein with DNA helicase and exonuclease domains.[16] Progeria, a disease that leads to death from atherosclerotic heart disease often in the first decade of life, is caused by mutations in lamin A, a protein important in maintaining chromatin organization in the nucleus for transcriptional control and for DNA damage repair.[17,18] These human premature aging diseases suggest that decreased DNA repair capacity is associated with accelerated aging and that cumulative DNA damage plays a major role in the aging process. Still, the role of these genes in normal aging is not established, as patients with so-called *premature aging syndromes* display some manifestations of aging at an accelerated rate but lack other features of normal aging and have characteristic findings that differ greatly from those of normal aging.

Aging and the Immune System[19]

The immune system has two major roles: defense against external insults and internal immunologic surveillance. The function of antigen-presenting cells, antigen-specific B and T cells, and lymphocyte cytokine secretion declines with age.[20] Conversely, the level of proinflammatory cytokines increases with age. These changes have been attributed to oxidative stress and contribute to the increased incidence of infections and malignancies in the elderly.

SKIN AGING

Cutaneous aging includes two distinct phenomena: Intrinsic aging is a universal, presumably inevitable change attributable to the passage of time alone; photoaging is the superposition on intrinsic aging of changes attributable to chronic sun exposure, which are neither universal nor inevitable. The former is

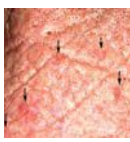

TABLE 108-1
Histologic Features of Aging Human Skin

EPIDERMIS	DERMIS	APPENDAGES
Flattened dermal-epidermal junction	Atrophy (loss of dermal volume)	Depigmented hair
Variable/decreased thickness	Fewer fibroblasts	Loss of hair
Variable cell size and shape	Fewer mast cells	Conversion of terminal to vellus hair
Occasional nuclear atypia	Fewer blood vessels	Abnormal nail plates
Fewer melanocytes	Shortened capillary loops	Fewer glands
Fewer Langerhans cells	Abnormal nerve endings	

manifested primarily by physiologic alterations with subtle but undoubtedly important consequences for both healthy and diseased skin. The latter has major morphologic as well as physiologic manifestations and corresponds more closely to the popular notion of old skin.

Intrinsic Skin Aging

The skin changes that occur with aging (Table 108-1) lead to a gradual physiologic decline (Table 108-2).[21] Major age-related changes in the skin's appearance include dryness (roughness), wrinkling, laxity, and a variety of benign neoplasms. Aged skin is inelastic and recovers more slowly after injury.

MECHANISMS OF INTRINSIC SKIN AGING A major aging theory[22] suggests that cumulative damage to biomolecules, including DNA as a result of continuous generation of free radicals, results in increased cellular vulnerability and eventually terminates in senescence or apoptosis. The skin, like other bodily systems, is continuously exposed to reactive oxygen species (ROS) generated during aerobic metabolism (Fig. 108-1A). Although the skin contains a network of antioxidant enzymes (superoxide dismutases, catalase and glutathione peroxidase) and nonenzymatic anti-oxidant molecules (vitamin E, coenzyme Q10, ascorbate, and carotenoids), this system is less than completely effective and tends to deteriorate with aging.[23]

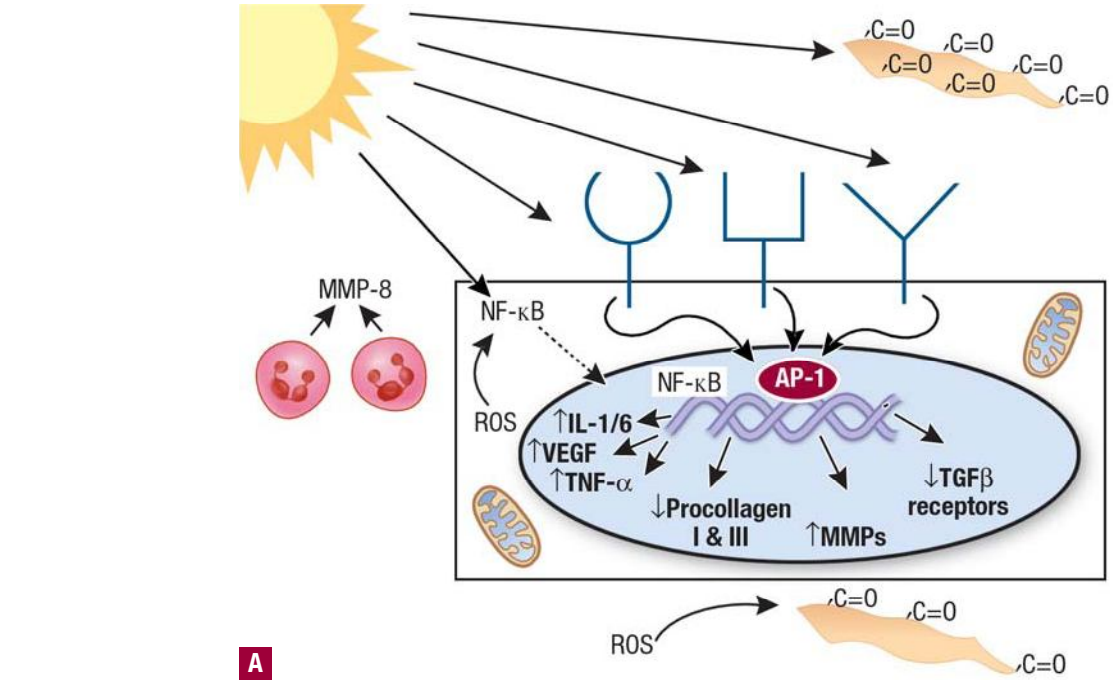
Oxidative stress upregulates the level of stress regulatory proteins, one of which is nuclear factor κB, a transcription factor that induces the expression of pro-inflammatory cytokines like interleukin (IL)-1 and IL-6, vascular endothelial growth factor (VEGF), and tumor necrosis factor (TNF)-α. These proteins are involved in immunoregulation and cell survival,[24] stimulate the expression of matrix-degrading metalloproteins,[25] and are believed to play a central role in the aging process.

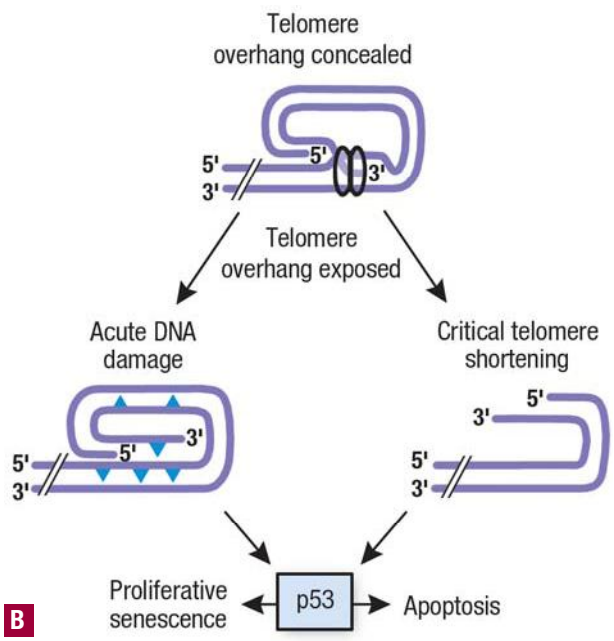
Oxidative damage also affects telomeres. A recent hypothesis suggests a common cellular signaling pathway[26,27] activated by DNA damage and involving the terminal portion of the telomeres. The terminal portion of the 3′ telomeric strand extends beyond the complementary 5′ strand (Fig. 108-1B), leaving a single stranded G-rich overhang. It is suggested that during both telomere shortening and repair of telomere damage, such as that encountered by oxidative stress, the normal loop structure at the end of telomeres is disrupted, exposing the 3′ overhang that under baseline conditions is "buried" in the loop structure.[26,27] Exposure of the TTAGGG tandem repeat sequence then appears to activate p53[28] and to stimulate[29] p53-dependent responses known to include proliferative senescence and apoptosis.[29] Thus, the intrinsic component of skin aging involves progressive oxidative stress and telomere signaling as telomeres shorten during serial cell division and in response to oxidative DNA damage[26] (see also Chap. 109).

EPIDERMIS The most striking and consistent histologic change is flattening of the dermal-epidermal junction with effacement of both the dermal papillae and epidermal rete pegs.[35] This results in a considerably smaller surface between the epidermis and dermis and presumably less communication and nutrient transfer. Dermal-epidermal separation has been demonstrated to occur more readily in old skin, undoubtedly explaining the propensity of the elderly to torn skin and superficial abrasions after minor trauma.

There is an age-associated epidermal thinning of 10 percent to 50 percent between the ages of 30 and 80 years.[36] Variability in epidermal thickness and individual keratinocyte size increases, including those of the basal layer. Evidence suggests that epidermal keratinocytes senesce, and senescent cells are more resistant to apoptosis. Such keratinocytes are therefore more likely to accumulate mutations, increasing their risk for malignant transformation. Studies also show loss of epidermal stem cell population in aged skin as determined by the loss of cells expressing CD71 (transferrin receptor) and α_6 integrin, accepted markers for keratinocyte stem cells.[37] At the electron microscopic level, sun-protected old skin is characterized by some widening of inter-keratinocyte spaces, by reduplication of the lamina densa and anchoring fibril complex in the basement membrane zone, and by loss of the numerous microvillous projections of basal cell cytoplasm into the dermis.[36]

Average thickness and degree of compaction of the stratum corneum appear constant with increasing age, although individual corneocytes become larger. The skin surface pattern, a patchwork of fine lines possibly determined by papillary dermal architecture, reveals slight age-associated loss of regularity. Age effects on percutaneous absorption depend in part on drug structure, with hydrophilic substances such as hydrocortisone and benzoic acid being less well absorbed through the skin of old versus young individuals but with hydrophobic substances such as testosterone and estradiol being equally well absorbed.[38] Of perhaps greater clinical importance, aging markedly delays the recovery of barrier function in damaged stratum corneum, apparently because of slow replacement of neutral lipids, leading to decreased amount of lipids in the newly formed lamellar bodies.[39] Lipid synthesis and activities of enzymes required to generate stratum corneum lipids decrease with age possibly because





▲ **FIGURE 108-1** Mechanisms of skin aging. **A.** Reactive oxygen species (ROS) generated during aerobic metabolism activate the transcription factor nuclear factor κB (NF-κB) that induces the expression of the pro-inflammatory cytokines, vascular endothelial growth factor (VEGF), and tumor necrosis factor (TNF)-α. ROS also lead to the formation of carbonyl groups (C=O) in proteins, leading to the accumulation of damaged proteins. Ultraviolet (UV) irradiation directly activates cell surface receptors (indicated by symbols on the cell membrane), initiating intracellular signaling that eventually activates the nuclear transcription complex AP-1. AP-1 increases transcription of matrix metalloproteinases (MMPs) and decreases expression of the procollagen I and III genes and transforming growth factor (TGF)-β receptors, with a final consequence of reduced dermal matrix formation. UV also activates the NF-κB transcription factor that induces the expression of multiple proteins and aggravates the degradation of dermal matrix by increasing MMP levels. Matrix degradation is further exacerbated by MMP-8 (collagenase) of neutrophil origin, following neutrophil infiltration into UV-irradiated skin. Mitochondria display large DNA deletions and compromised function. Damaged proteins containing carbonyl groups accumulate in the upper portions of the dermis. [From Halachmi S, Yaar M, Gilchrest BA: Advances in skin aging/photoaging: Theoretic and practical implications (Part I). *Ann Dermatol Venereol* **132**:362, 2005, with permission.] **B.** Telomeres normally exist in a loop configuration, held in place by the final 150 to 200 bases (TTAGGG repeats) on the 3′ strand that forms a single-stranded overhang. When the loop is disrupted when telomeres become critically short (e.g., after repeated cell divisions or when telomeres are damaged as a result of UV irradiation or oxidative damage), the overhang becomes exposed, activating the tumor suppressor protein p53 to induce proliferative senescence or apoptosis, depending on the cell type. IL = interleukin. (From Yaar M: Clinical and histological features of intrinsic versus extrinsic skin aging, in *Skin Aging*, Springer, 2006, p 9, with permission.)

of aberrations in elements that regulate enzyme transcription, or abnormal autocrine/paracrine signaling.[40]

In the elderly, the skin often appears dry and flaky, especially over the lower extremities, an area in which a remarkable age-associated decrease in the content of epidermal filaggrin has been reported.[41] Filaggrin, required for binding of keratin filaments into macrofibrils, is also decreased in the skin of patients with ichthyosis vulgaris, and its lack has been postulated to cause the increased scaliness in both conditions.[41] Barrier function also may be affected by this structural change.

Epidermal turnover rate and thymidine-labeling index decrease approximately 30 percent to 50 percent between the third and eighth decades, with a corresponding prolongation in stratum corneum replacement rate. Linear growth rates also decrease for hair and nails. Epidermal repair rate after wounding likewise declines with age.

A decrease in the number of enzymatically active melanocytes per unit surface area of the skin, approximately 10 percent to 20 percent of the remaining cell population each decade, has

been documented repeatedly, presumably reducing the body's protective barrier against UV radiation. The number of melanocytic nevi also decreases progressively with age, from a peak of 15 to 40 in the third and fourth decades to an average of four per person after age 50 years; such nevi are rarely observed in persons beyond age 80.

Between early and late adulthood there is a 20 percent to 50 percent reduction in the number of morphologically identifiable epidermal Langerhans cells, the skin's immune effector cells responsible for antigen presentation. The remaining cells display morphologic abnormalities, including less and shorter dendrites, and they display reduced antigen-presenting capacity.[42] These changes, compounded by decreases in cytokine production by keratinocytes and lymphocytes and failure of migration through the lymphatic system, presumably contribute to the observed age-associated decrease in cutaneous immune responsiveness.

An endocrine function of human epidermis that declines with age is vitamin D production.[43] Vitamin D, by binding its nuclear receptor, induces the transcription of numerous genes.[44] Vitamin D deficiency leads to osteoporosis and recently has been implicated also in diabetes, hypertension, and prevalent tumors.[45] Elderly individuals frequently have reduced serum levels of vitamin D, leading to osteomalacia,[46] the decreased mineralization of bone classically associated with vitamin D deficiency. Although avoidance of dairy products (the principal dietary source of vitamin D), insufficient sun exposure, and sunscreen use undoubtedly contribute to vitamin D deficiency in the elderly, the level of epidermal 7-dehydrocholesterol per unit skin surface area also appears to decrease linearly by approximately 75 percent between early and late adulthood,[43] suggesting that lack of its immediate biosynthetic precursor also may limit vitamin D production. Together these observations argue for use of vitamin D dietary supplements in the elderly.[47]

With regard to susceptibility to oxidative damage, there is progressive accumulation of damaged cellular proteins and lipids with aging.[36,48] Furthermore, antioxidant defense systems decline with age, and, in addition, there is a decrease in DNA damage repair capacity.[36] These changes in combination increase cellular mutability or their tendency to become senescent, or both.

DERMIS Loss of dermal thickness approaches 20 percent in elderly individuals, although in sun-protected sites significant thinning occurs only after the eighth decade.[49] Old skin is relatively acellular and avascular, and there is age-related loss of normal elastic fibers and dermal collagen.[50,51]

Decreased inflammatory responses in the elderly are the result of decreased synthesis and secretion of keratinocyte-derived cytokines and inflammatory mediators in addition to decreased endothelial response. The dermal microvasculature in middle-aged or elderly subjects also may show mild vascular wall thickening, especially in the lower legs as a result of gravitational forces[52]; vascular wall thinning to less than one-half the normal young adult measurement, associated with absent or reduced perivascular veil cells, has been reported in skin of very elderly subjects and probably contributes to vascular fragility. Loss of elastin contributes to vascular rigidity. Electron microscopic studies show focal degeneration of the elastic component of dermal arterioles. The striking age-associated loss of vascular bed, especially of the vertical capillary loops that occupy the dermal papillae in young skin, and increased distance from the epidermis of existing loops, is thought to underlie many of the physiologic alterations in old skin, including pallor, decreased skin temperature, and the approximately 60 percent reductions in basal and peak induced cutaneous blood flow.[53]

VEGF of epidermal origin appears to play a major role in maintaining dermal vasculature, inducing the expression of anti-apoptotic proteins in endothelial cells,[52] and decreased VEGF level in aged skin probably contributes to endothelial cells apoptosis. Also, recent evidence suggests that there is an age-associated decline of both angiogenic and anti-angiogenic factors, disrupting cutaneous angiogenic homeostasis.[54] Decreased endothelial cell permeability response and decreased capacity to induce white cell adhesion[55] contribute to the compromised immune response. When exposed to intense heat or cold, aging vessels demonstrate reduced ability to constrict, dilate, or shunt.[52] Compromised thermoregulation, which predisposes the elderly to sometimes fatal heat stroke or hypothermia, may be due in part to reduced vasoactivity of dermal arterioles and, in the latter instance, to loss of subcutaneous fat as well. Reduction in the vascular network surrounding hair bulbs and eccrine, apocrine, and sebaceous glands may contribute to their gradual atrophy and fibrosis with age.

Age-associated decreases in wheal resorption and dermal clearance of transepidermally absorbed materials have been reported,[56] probably due to alterations in both the vascular bed and the extracellular matrix. Conversely, the time required for development of a tense blister after topical ammonium hydroxide application is nearly twice as long in older individuals, suggesting a decreased transudation rate with age in injured skin. Impaired transfer of cells as well as solutes between the extravascular and intravascular dermal compartments is suggested by several studies; multiple factors undoubtedly contribute.

With aging there is a decrease in the density and lumen size of lymphatic vessels accompanied by increased rigidity and decrements in lymphatic drainage, affected no doubt by decreased surrounding elastic fibers.[52] Biochemical changes in collagen, elastin, and dermal ground substance lead to increased skin rigidity primarily due to modifications in collagen. Collagen content per unit area of skin surface decreases approximately 1 percent per year throughout adult life,[57] and the remaining collagen fibrils appear disorganized, more compact, and granular, and they display increased collagen cross-links.[58–60] The latter is the result of decreased collagen I and III synthesis; decrements in enzymatic processing of collagen as well as nonenzymatic glycosylation, a process that leads to molecular damage of proteins with a long half-life such as collagen[36]; and increased collagenase levels. Such changes almost certainly contribute to impaired wound healing in the elderly.[59]

Beginning in early adulthood, elastic fibers decrease in number and diameter; by old age, they often appear fragmented, with small cysts and lacunae, especially in the dermal-epidermal junction[61] most likely due to enzymatic degradation of elastin. Elastic fibers also show progressive cross-linkage and calcification with age. At the biochemical level, there is an age-associated decrease in numerous elastic fiber components, including elastin, fibrillin, and fibulin-2. With aging, the level of fibulin-5, an extracellular matrix protein that functions as a scaffold for elastic fibers, appears to decrease before other changes are observed, suggesting that loss of fibulin-5 is a marker for skin aging.[62]

The ground substance mucopolysaccharides, glycosaminoglycans (GAGs), and proteoglycans are decreased relative

to dry weight or collagen content of the skin, especially hyaluronic acid,[63] possibly due to decreased hyaluronan secretion or due to decreased hyaluronic acid extractability.[64] Aging also affects GAG composition and binding to elastin, impeding the drainage of molecules into lymphatic vessels.[52] These changes may adversely influence skin turgor because proteoglycans bind 1000 times their own weight in water and also impact collagen fiber deposition, orientation, and size.[65]

Changes with age in the mechanical properties of the skin during adulthood include progressive loss of elastic recovery, consistent with gradual destruction of the dermal elastic network, and marked prolongation of the time required for excised skin to return to its original thickness. In vivo ultrasound studies also show age-associated differences in water distribution in the dermis,[66] no doubt affecting dermal pliability, resilience, and elasticity. Overall, a picture emerges of aging dermis as an increasingly rigid, inelastic, and unresponsive tissue that is less capable of undergoing modifications in response to injury or stress.

SUBCUTANEOUS TISSUE, MUSCLES, AND BONE Like other striated muscles, facial muscles show accumulation of the "age pigment" lipofuscin, a marker of cellular damage. Compounded by diminished neuromuscular control, this deterioration contributes to wrinkle formation.[67] In addition, subcutaneous fat is depleted from distinct facial regions, including the forehead, preorbital, buccal, temporal, and perioral regions. In contrast, there is a prominent increase in fatty tissue in other areas, including the submental regions, the jowls, the nasolabial folds, and the lateral malar areas. In contrast to the young face in which fat is diffusely dispersed, fat in the aged face, subject to the force of gravity, contributes to sagging and drooping of the skin.[68]

Finally, like other parts of the skeleton, facial bones display reduced mass with age. Bone resorption affects particularly the mandible, maxilla, and frontal bones. Bone loss in these areas enhances facial skin droopiness and contributes to the obliteration of the demarcation between the contour of the jaw and the neck that is so distinct in young adults.[69]

HAIR By the end of the fifth decade, approximately one-half the population has at least 50 percent gray (white) scalp hair, and virtually everyone has some degree of graying due to progressive and eventually total loss of melanocytes from the hair bulb.[70] Loss of melanocytes is believed to occur more rapidly in hair than in skin because the cells proliferate and manufacture melanin at maximal rates during the anagen phase of the hair cycle, whereas epidermal melanocytes are comparatively inactive throughout their life span. More specifically, hair graying reflects loss of the melanocyte stem cell population in hair follicle bulge due, at least in part, to compromised interaction between two transcription factors, microphthalmia-associated transcription factor (Mitf) and Pax3[71] (see Chap. 70).

Scalp hair may gray more rapidly than other body hair because its anagen to telogen ratio (see Chap. 84) is considerably greater than that of other body hair. Advancing age is also accompanied by a modest decrease in number of hair follicles, due in part to atrophy and fibrosis. In addition, with aging there is an increase in the proportion of telogen hair follicles. Remaining hairs may be smaller in diameter and grow more slowly. One hypothesis suggests that melanocyte loss and lack of melanosomal transfer may increase oxidative stress level in highly metabolic hair follicle keratinocytes, affecting their function and viability.[72]

The process termed *balding* results primarily from the androgen-dependent conversion of the relatively dark, thick, terminal scalp hairs to lightly pigmented short, fine, villous hairs similar to those on the ventral forearm. Women are affected less often and far less severely than men. However, in post-menopausal women, hair loss is also the result of decreased estrogen levels and estrogen-androgen ratio.[73,74] Besides hair loss, almost 50 percent of women older than age 60 years display mild facial hirsutism, presumably attributable to the same hormonal changes as scalp hair loss. In susceptible women, testosterone and/or progestin derivatives that are present in some hormone replacement regimens may exacerbate these changes.

CUTANEOUS GLANDS AND NERVES Eccrine glands decrease by approximately 15 percent in average number during adulthood in most body sites. Spontaneous sweating is further reduced by more than 70 percent in healthy older subjects as compared with younger controls, attributable primarily to a decreased output per gland, predisposing the elderly to heat stroke. Apocrine gland size and function also decrease with aging. Sebaceous gland size and number appear not to change with age, but there is an exponential decrease in sebum production in both men and women most likely due to a decrease in production of gonadal or adrenal androgens.[75]

Pacinian and Meissner's corpuscles, the cutaneous end organs responsible for pressure perception and light touch, progressively decrease to approximately one-third their initial average density between the second and ninth decades of life and display greater size variation and structural irregularities.

Decreased sensory perception in old skin encompasses optimal stimulus for light touch, vibratory sensation, and corneal sensation; ability to discriminate two points; and spatial acuity.[76,77] Cutaneous pain threshold increases up to 20 percent with advancing adult age, and compromised arteriolar constriction on changing position from supine to standing is reflective of decreased responsiveness of the sympathetic nervous system.

EFFECTS OF MENOPAUSE Estrogens play a critical role in female development and reproduction and also influence skin and hair. Not surprisingly, their influence decreases dramatically after menopause. Menopause typically occurs in a woman's early 50s, so that, with life expectancy in the developed world approaching 80 years,[78] women are post-menopausal for approximately one-third of their lives. In pre-menopausal women, the predominant estrogen is estradiol, which is produced by the ovaries,[79] and after menopause levels decrease by more than 90 percent,[80] with estron, a less active estrogen, becoming the predominant form.[81] Progestin and androgen levels also fall markedly after menopause.[81] The reduced levels of estrogen underlie many physiologic effects, including hot flashes, atrophy of reproductive tissue, and changes in non-reproductive tissues that are estrogen sensitive.[81] Age-associated decrements in keratinocyte barrier function, immune-regulation, and wound healing appear to be compounded by decreased estrogen levels and/or decreased responsiveness of cells to existing estrogens. Because both estrogen and androgen receptors are expressed by skin-derived cells, both hormones are likely to play a role in skin structure and function.

Structural and Functional Changes in Post-Menopausal Skin. Decreased circulatory levels of estrogens are associated with reduced dermal collagen content,[82–84] increased cutaneous extensibility,[85,86] and

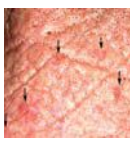


TABLE 108-3
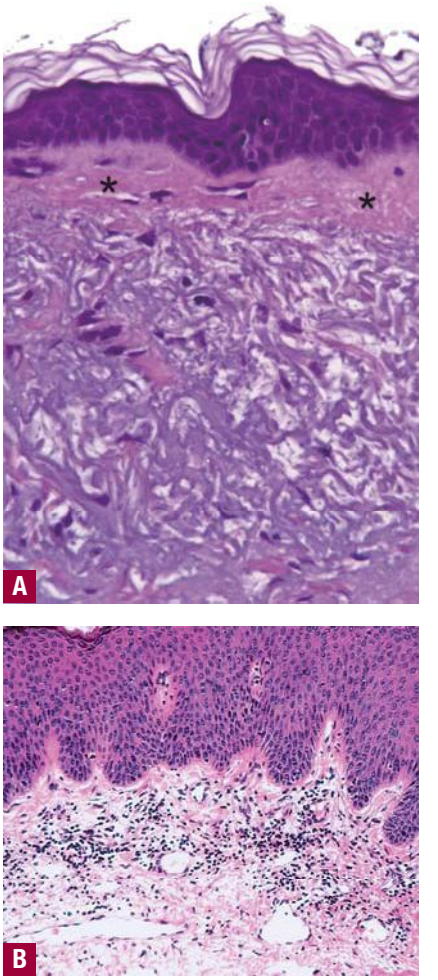
Features of Photoaged Skin[a]

CLINICAL	HISTOLOGIC
Dryness (roughness)	Increased compaction of stratum corneum, increased thickness of granular cell layer, reduced epidermal thickness, reduced epidermal mucin content
Actinic keratoses (see Chap. 113)	Nuclear atypia, loss of orderly, progressive keratinocyte maturation; irregular epidermal hyperplasia and/or hypoplasia; occasional dermal inflammation
Irregular pigmentation	
Freckling	Reduced or increased number of hypertrophic, strongly DOPA-positive melanocytes
Lentigines (see eFig. 108-4.1 in on-line edition)	Elongation of epidermal rete ridges; increases in number and melanization of melanocytes
Guttate hypomelanosis	Reduced number of atypical melanocytes
Diffuse irreversible hyperpigmentation (bronzing) (see eFig. 108-4.2 in on-line edition)	Increased number of DOPA-positive melanocytes and increased melanin content per unit area and increased number of dermal melanophages
Wrinkling	
Fine surface lines	None detected
Deep furrows (see Figs. 108-2 and 108-4)	Contraction of septae in the subcutaneous fat
Stellate pseudoscars (see eFig. 108-4.3 in on-line edition)	Absence of epidermal pigmentation, altered fragmented dermal collagen
Elastosis (fine nodularity and/or coarseness) (see Fig. 108-4)	Nodular aggregations of fibrous to amorphous material in the papillary dermis
Inelasticity	Elastotic dermis
Telangiectasia	Ectatic vessels often with atrophic walls
Venous lakes	Ectatic vessels often with atrophic walls
Purpura (easy bruising)	Extravasated erythrocytes and increased perivascular inflammation
Comedones (maladie de Favre et Racouchot) (see eFig. 108-4.4 in on-line edition)	Ectasia of the pilosebaceous follicular orifice
Sebaceous hyperplasia	Concentric hyperplasia of sebaceous glands

[a]Basal cell carcinoma and squamous cell carcinoma also occur in photoaged skin but, unlike the table entries, affect only a minority of individuals.



▲ **FIGURE 108-3** Photodamaged facial skin. **A.** Large masses of deranged elastic fibers characterize solar elastosis. A thin sub-epidermal Grenz zone (*asterisks*) is present, and the epidermis is acanthotic. (Used with permission from Jag Bhawan.) **B.** Marked dermal inflammatory infiltrate associated with the heliodermatitis (dermatoheliosis) that is characteristic of ongoing and chronic actinic exposure. (Used with permission from Lorraine H. Kligman.)

decreased elasticity.[87] Also, decreased water-holding capacity, increased dryness, and increased fine wrinkling are reported after menopause,[88] as are decreased sebum levels.[89] These changes are related more to menopause than to chronologic age alone,[90] and wrinkling is reported to be more pronounced in postmenopausal women who are not taking hormone replacement therapy than in treated women.[91]

After menopause, the decreased rate of wound healing is associated with reduced levels of collagen I.[92] Estrogen and progesterone are also reported to modulate cutaneous inflammation, enhance keratinocyte proliferation and collagen synthesis, decrease the activity of matrix metalloproteinases (MMPs), and increase the synthesis of dermal mucopolysaccharides and hyaluronic acid.[74,93]

Photoaging

Clinical and histologic features of actinically damaged skin are listed in Table 108-3. A prominent feature of photoaged skin is elastosis, a process characterized clinically by yellow discoloration and pebbly surface (Fig. 108-2) and histologically by tangled masses of degraded elastic fibers that further deteriorate to form an amorphous mass composed of disorganized tropoelastin and fibrillin (Fig. 108-3A). Although fibrillin is abundant in the elastotic material deeper in the dermis, in the upper portions of the dermis at the dermal-epidermal junction, fibrillin is reduced.[94] In addition, the amount of ground substance, largely composed of GAGs and proteoglycans, increases in photodamaged skin, whereas the amount of collagen decreases, in part because of increased metalloproteinase activity. In contrast with aged sun-protected skin that demonstrates hypocellularity, photodamaged skin frequently displays an increased number of hyperplastic fibroblasts as well as increased inflammatory

▲ **FIGURE 108-2** Photoaged versus intrinsically aged skin of an elderly man. Habitually sun-exposed skin above the collar line is prominently wrinkled and lax, in contrast with the equally chronologically aged but sun-protected skin of the lower neck and shoulder. Despite the striking difference in appearance, both areas manifest age-associated functional decrements.

▲ **FIGURE 108-4** Photoaging: heliodermatitis. Pronounced furrowing, yellow discoloration, and pebbly surface (solar elastosis) with plugged follicles on the neck. *Arrows* denote small actinic keratoses.

cells (Fig. 108-3B), including mast cells, histiocytes, and other mononuclear cells, giving rise to the term *heliodermatitis* (literally, "cutaneous inflammation due to sun"; Fig. 108-4). Immunohistologic studies show increased $CD4^+$ T cells in the dermis. Dermal vasculature in mildly photodamaged skin displays venule wall thickening; in severely photodamaged skin, thin vessel walls with compromised perivascular veil cells display dilations (telangiectases).

In contrast with chronologically aged skin, photodamaged epidermis is frequently acanthotic, although severe atrophy also can be seen in addition to loss of polarity and cellular atypia. Also, there is a more profound decrease in the number and function of Langerhans cells. Additional changes are described in Table 108-3.

The relative severity of sun-induced cutaneous changes varies considerably among individuals, undoubtedly reflecting inherent differences in vulnerability and repair capacity for the solar insult. Photoaging occurs not only in fair-skinned individuals (skin phototypes I and II) but also in individuals with darker skin phototypes III and IV with a history of ample past sun exposure. It usually involves the face, neck, or extensor surfaces of the upper extremities most severely. Interestingly, the gross appearance of photodamaged skin of individuals with skin phototypes I and II differs from that of individuals with darker skin types. The former generally show atrophic and dysplastic skin changes with actinic keratoses and epidermal malignancies, whereas the latter manifest hypertrophic responses such as furrowing, lentigines, and coarseness (Fig. 108-5). One study noted that patients presenting with basal cell carcinoma (BCC) are less wrinkled than peers of similar complexion and degree of photodamage,[95] suggesting that certain phenotypes of photoaging correlate with a predisposition to mutation and carcinogenesis.

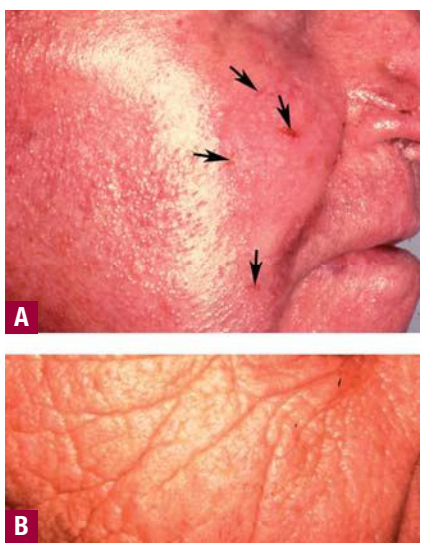
Photoaging occurs not only in whites but also in Asians, Hispanics, and Africans. The differences in clinical appearance of photoaged skin between whites and other ethnic groups is primarily due to differences in their UV defense systems. In the latter three groups, melanin is a major form of protection, whereas in whites, melanin plays a lesser role, and stratum corneum thickening is relatively more important.[96] One study reported a sun protection factor for black epidermis of 13.4, compared to 3.4 for white epidermis.[97] Black epidermis transmitted approximately 6 percent of UVB to the dermis, compared to almost 30 percent transmission through white epidermis.[97] Similarly, only ~18 percent of UVA was transmitted into black dermis, compared to more than 55 percent to white dermis.[97]

Major clinical features of photoaging in Asian skin are solar lentigines and mottled pigmentation.[98] Also, melasma is common in Asians and is considered a clinical sign of photodamage in this ethnic group. Moderate to severe wrinkling occurs in Asians but only in the sixth decade and only in individuals who regularly spent ample time in the sun.[99]

There are no specific studies addressing photoaging in Hispanics, and studies on photoaging of black skin have been published only in African Americans. As expected, fairer-skinned Hispanics and Africans display clinical photoaging signs earlier and more prominently than those with very dark skin.[98] Changes include fine wrinkling and mottled pigmentation.[94,98]

MECHANISMS OF PHOTOAGING Mechanisms involved in intrinsic aging also play a role in photoaging.[100] Additional mechanisms are discussed below.

Membrane and Nuclear Signaling. UV irradiation, in part through ROS generation that inhibit phosphatases whose function is to maintain receptors in their inactive state,[101] activates (phosphorylates) cell surface receptors, including receptors for epidermal growth factor, IL-1, and TNF-α, to induce intracellular sig-



▲ **FIGURE 108-5** Photoaging. **A.** An individual with skin type I displaying atrophic skin photodamage response with relatively few wrinkles but with several actinic keratoses (*arrows*) and a site of previous basal cell carcinoma over the lateral aspect of the nose. **B.** An individual with skin phototype IV displaying hypertrophic skin photodamage response with deep wrinkles and leather-like coarse skin. (From Yaar M: The chronic effects of ultraviolet radiation on the skin: Photoaging, in *Principles and Practice of Photodermatology*, edited by Lim H. New York, Taylor & Francis LLC, 2007, p 91–106, with permission.)

naling culminating in activation of the nuclear transcription complex AP-1, composed of the proteins c-Jun and c-Fos.[102] In intact human skin, even suberythemogenic doses of UVB [~0.1 minimal erythema dose (MED)] transcriptionally upregulate and activate AP-1.[103] Increased AP-1 activity interferes with synthesis of the major dermal collagens I and III by blocking the effect of transforming growth factor (TGF)-β , a cytokine that enhances collagen gene transcription.[102,103] AP-1 also decreases the level of TGF-β receptors, further inhibiting collagen transcription,[104] and also antagonizes intrinsic retinoid effects in skin, leading to a functional retinoid deficiency and reducing collagen synthesis normally promoted by retinoic acid bound to its nuclear receptors. Additionally, UV induces the synthesis and secretion of a cysteine-rich growth regulatory factor (CYR61) that reduces type I procollagen synthesis, increases MMP-1 levels, decreases TGF-β receptor level, and induces AP-1 activation.[105] Hence, in habitually UV-irradiated photodamaged skin there is an overall reduction in collagen synthesis.[106] Increased AP-1 activity also increases the levels and activity of several enzymes that degrade extracellular matrix components, notably the MMP-1 (collagenase), MMP-3 (stromelysin-1), and MMP-9 (92-kd gelatinase).[102,57] UV also activates the nuclear factor κB transcription factor that induces the expression of multiple proteins as discussed in the section Mechanisms of Intrinsic Skin Aging (reviewed in ref. 24) and aggravates the degradation of dermal matrix by increasing the levels of MMP-1 and MMP-9.[103] Matrix degradation is further exacerbated by MMP-8 (collagenase) of neutrophil origin after neutrophil infiltration into UV-irradiated skin.[107] Although there is also a concomitant upregulation of tissue inhibitors of metalloproteinases (TIMPs) that limit matrix degradation, TIMPs presumably are not completely effective in blocking cumulative damage to dermal collagen.[108]

UV-induced collagen degradation is generally incomplete, leading to accumulation of partially degraded collagen fragments in the dermis, thus reducing the structural integrity of the skin.[102] In addition, the large collagen degradation products inhibit new collagen synthesis,[109] and, thus, collagen degradation itself negatively regulates new collagen synthesis. Interestingly, increased stress-associated AP-1 activity, increased CYR61 and MMP levels, and reduced collagen production have been documented in intrinsically aged skin,[105,110] suggesting that similar mechanisms may contribute to chronologic aging, perhaps again through the generation of ROS, as discussed in the section Mechanisms of Intrinsic Skin Aging.

Mitochondrial Damage. Mitochondria are cellular organelles that produce energy (adenosine triphosphate) by consuming oxygen. Although equipped with antioxidant defense systems, continuous generation of ROS damages mitochondrial DNA (mtDNA). To date, machinery to remove bulky DNA lesions has not been identified in mitochondria, although they display capacity for base excision repair relevant to repair of oxidative damage. Still, mtDNA mutation frequency is approximately 50-fold higher than that of nuclear DNA, and photodamaged skin has higher mtDNA mutation frequency than sun-protected skin, displaying large DNA deletions[111–114] and resulting in decreased mitochondrial function, leading to further accumulation of ROS and compromising the cell's ability to generate energy. Also, a correlation was noted between decreased mitochondrial function and increased MMP-1 levels without concomitant increase of MMP-1–specific TIMP,[111] exacerbating collagen degradation[111–114] and aggravating skin photoaging.

Protein Oxidation. Proteins are affected by oxidative damage, and photodamaged skin shows accumulation of oxidized, damaged proteins in the upper portions of the dermis.[115] In vitro studies suggest that UVA is a major contributor and the accumulation of such proteins further inhibits proteasomal function and the ability of the cell to successfully degrade additional damaged proteins.[116]

ACTION SPECTRUM The action spectrum for human photoaging has not been determined, but many studies have explored the relative contribution of the various spectral bands within sunlight, using animal models. In rodent skin, an elastosis-like condition can be produced by prolonged intense irradiation with either a predominantly UVB or UVA source.[117,118] UVB photons are on average 1000 times more energetic than UVA photons and are overwhelmingly responsible for sunburn, suntanning, and photocarcinogenesis after sun exposure.[119] UVB is the major cause of direct DNA damage and induces inflammation and immunosuppression, as well as synthesis and release of prostaglandins (PGs), particularly PGE_2, through induction of the enzyme cyclooxygenase-2. UVB also induces ornithine decarboxylase, the rate-limiting enzyme in the biosynthesis of polyamines that stimulates cellular proliferation (contributing to cancer formation[120]) and contributes to cutaneous angiogenesis by decreasing the expression of the angiogenic inhibitor thrombospondin-1 and inducing the expression of VEGF and platelet-derived endothelial cell growth factor, two angiogenic factors.[121,122] UVB also triggers the penetration of elastase-producing leukocytes into the skin, aggravating elastin degradation.

Despite the well-documented affects of UVB, UVA is suspected of playing a proportionately larger role in photoaging because of its minimally 10-fold greater abundance in terrestrial sunlight, far greater year-round and day-long average irradiance, and greater average depth of penetration into the dermis compared to UVB. Moreover, human skin exposed daily for only 1 month to sub-erythemogenic doses of UVA alone demonstrates epidermal hyperplasia, stratum corneum thickening, Langerhans cell depletion, and dermal inflammatory infiltrates with deposition of lysozyme on the elastic fibers.[123] UVA also induces the synthesis and release of cytokines and MMPs, particularly collagenase (MMP-1) and elastase, and triggers mtDNA mutations.[124–127] Both UVA and UVB lead to the generation of ROS that damage cellular lipids, proteins, and DNA.[128,129] Studies using laser-capture microdissection of human skin show that p53-mutant keratinocytes of the basal layer, in addition to UVB signature mutations, have more mutations associated with UVA (and primarily 8-OXO-dG photolesions), suggesting that UVA is an important etiologic factor in the generation of BCC.[30] UVA is more effective than UVB in inducing oxidative damage. Indeed, the degree of solar elastosis and cutaneous photoaging appear to correlate with the level of accumulated dermal protein oxidation[115] but not epidermal oxidation, suggesting a superior antioxidant network and/or better repair capacity in the epidermis.

Sun light also transmits infrared irradiation (IR) (760 nm to 1 mm).[130] Wavelengths of 760 to 1400 nm can penetrate the skin to reach the subcutaneous tissue without inducing a significant increase in

skin temperature. In contrast, wavelengths of 1400 nm to 1 mm are primarily absorbed in the epidermis and considerably increase skin temperature.[131] IR is particularly important in regions of high insulation and aggravates UVA-induced dermal changes, producing severe elastosis. Even when delivered without UV, IR affects dermal elastic fibers and increases the amount of dermal ground substance.[131] In the hairless mouse model, IR contributes to UV-induced thickening of the epidermis and dermis and alone induces the expression of MMP-3 and the mouse equivalent of MMP-1.[130] Furthermore, in human skin, the expression of tropoelastin, a major component of elastic fiber that associates with microfibrils, is increased as a result of IR, and IR induces the expression of fibrillin-1, a component of the microfibrils.[132] In addition, the level of MMP-12, the enzyme that degrades elastin, is increased.[132] Thus, IR appears to contribute to UV-induced photoaging.

Many of the age-associated physiologic decrements, such as slowed wound healing and loss of immunoresponsiveness, also appear to be accelerated in sun-exposed skin. Furthermore, cells cultured from chronically sun-exposed skin sites differ from cells cultured from sun-protected sites of the same donors in having shortened culture life spans, slower growth rates, lower saturation densities, and altered responsiveness to retinoic acid,[133] all changes also observed as a function of advanced chronologic donor age. Several of the mechanisms known to be involved in UV-mediated cellular damage are also postulated to underlie chronologic aging,[134,135] although the changes only appear after the seventh decade.[110] These include DNA injury and/or decreased DNA repair, oxidative damage, lysosomal disruption, elevated MMPs, reduced collagen production, and connective tissue damage.

Smoking and Skin Aging

Cigarette smoking exacerbates photoaging, particularly in women, with a direct correlation between the number of pack-years smoked and the severity of wrinkling and grayish discoloration.[136,137] Histologic analysis of "smoker's skin" reveals elastic fiber thickening and fragmentation, similar to that found in sun-damaged skin.[138] However, whereas solar elastosis is restricted in the papillary dermis, elastic fiber changes in smoker's skin also occur in the reticular dermis. This dermal elastosis has been suggested to result from increased elastase activity in neutrophils,[139] chronic dermal ischemia, and the pro-oxidant effects of cigarette smoke compounded by decreased levels of vitamin A, which reduce the capacity to quench free oxygen radicals and increase DNA damage.[136,137] Smoking also has been associated with decreased stratum corneum water content[136,137] and accelerated hydroxylation of estradiol, leading to decreased estrogens in the skin that may in turn contribute to dryness and atrophy.[136] Smokers display poor wound healing capacity[140] and increased incidence of skin cancers as well as increased severity of photoaging-like changes compared with nonsmokers with otherwise similar risk factors,[141] consistent with the possibility that mutagens present in cigarette smoke directly affect cells in the dermis and epidermis.

Relevance to Skin Disease in the Elderly

Closely associated with aging is increased vulnerability to disease and injury. Disorders of the skin are known to be common and bothersome in the elderly, and some occur predominantly in this age group.[1] Such disorders often appear to be the consequence of age-associated intrinsic losses of cutaneous cellular function. However, many dermatoses observed more commonly in the elderly reflect the higher prevalence of systemic diseases, such as diabetes, vascular insufficiency, and various neurologic syndromes, that compound physiologic changes in the skin itself. The increased prevalence of some disorders also may reflect reduced local skin care due to immobility or neurologic impairment rather than changes in the skin itself. As well, subtle age-associated changes in immune status may contribute, in analogy to the increased prevalence and severity of skin disease in patients with acquired immunodeficiency syndrome.

Reduced tolerance to systemically administered drugs is well documented in the elderly[142] due to decrements in lean body mass and metabolism and renal excretion of the active ingredients. Comparable data for topically applied medications do not exist, but it is tempting to postulate that retarded dermal clearance of absorbed material, reduced dermal mass and cellularity, and, possibly, altered metabolic capacity may render old skin more susceptible to both beneficial and adverse effects of topical medications or may at least alter the optimal therapeutic schedule. In the case of glucocorticoid preparations, relative vascular unresponsiveness may render blanching of erythema an unreliable indicator of other effects in old skin.

Selected common cutaneous disorders in the elderly are discussed briefly in the following sections, with special emphasis on their pathogenesis and clinical presentation in this population (Table 108-4). Most of these entities are covered more comprehensively in other chapters.

TUMORS

Skin Cancer (See Chaps. 113 to 115)

The age-specific incidence of skin cancer, including melanoma, increases exponentially with age,[148] presumably due in part to cumulative exposure to carcinogens over a lifetime interspersed with cell division, with the attendant risk of mutation. There are also well-documented age-associated decreases in DNA repair capacity[48,149] and immunosurveillance,[150] as well as subtle loss of proliferative homeostasis.

The major etiologic factor for skin cancer is UV irradiation. Habitual sun exposure of fair-skinned individuals induces squamous cell carcinoma as well as actinic keratoses, a premalignant lesion that may evolve into squamous cell carcinoma in a direct dose-response relationship.[151] In contrast, the risk of BCCs and particularly malignant melanoma is related not only to total sun exposure but also to intense intermittent sun exposure.[152] The mechanism underlying these different epidemiologic patterns is unknown, although inducible protective responses and relative resistance of the responsible cell types to apoptosis may contribute.[153]

The elderly, particularly men, present with melanomas (see Chap. 124) that are thicker than those of young adults, presumably in part because of failure to properly examine their skin, poor vision, and other medical problems; and their melanomas arise on a background of multiple benign cutaneous lesions. Presumably because of delayed diagnosis, men older than age 50 years have an increased mortality risk from melanoma compared with women or younger men. Although all types of melanoma have increased age-specific incidences,[148] lentigo maligna melanoma overwhelmingly develops in the 60s or later in habitually sun-exposed skin.[154]

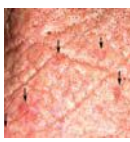


TABLE 108-4
Presumptive Pathophysiology of Common Cutaneous Disorders in the Elderly

DISORDER	PATHOPHYSIOLOGY
Benign neoplasia	
Seborrheic keratosis	Focal epidermal homeostatic loss leading to increased endothelin-1
Malignant neoplasia	
Squamous cell carcinoma and actinic keratosis	Ultraviolet-induced DNA damage
Basal cell carcinoma	Decreased DNA damage repair capacity
Malignant melanoma	Cumulative age-associated DNA damage
Merkel cell carcinoma	Decreased DNA damage repair capacity
Angiosarcoma	
Papulosquamous disorders	
Psoriasis	Changes in patient's environment leading to Koebnerization Systemic medications
Xerosis/asteatotic dermatitis	Disturbance of epidermal maturation (decreased filaggrin production and/or altered lipid profile) Decreased water content in outer layers of stratum corneum Slower corneocyte transit
Pruritus	Penetration of irritants through damaged stratum corneum (?) Altered sensory threshold (neuropathy) (?) Metabolic disorder Endocrine disorder Malignant neoplasm Adverse drug reaction Parasitic infestation
Infections	Compromised local cutaneous health predisposing to growth of infective organism Age-associated decreased immune function Underlying systemic disorder associated with decreased immune function
Ulcers	Impaired wound healing capacity (decreased levels of growth factors, decreased cellular proliferative capacity, increased perivascular fibrin deposition) Decreased mobility Underlying systemic disorder Compromised local cutaneous health (venous stasis, arteriosclerosis, hypertension)
Bullous pemphigoid	Flattening of the dermal-epidermal junction Increased circulating autoantibodies
Photosensitivity reactions	Medications with unsaturated ring structures

Merkel cell carcinoma (trabecular carcinoma) (see Chap. 120) is a rare cutaneous tumor thought to arise from a pluripotential cell that displays neuroendocrine differentiation.[155,156] It is seen most often in sun-exposed areas of the head, neck, or extremities and presents as a rapidly growing nodule. More than 90 percent of patients diagnosed with this tumor are older than age 50, with the mean age of onset being 68 years.

The most common form of angiosarcoma (see Chap. 128) occurs overwhelmingly on the head and neck of the elderly. Its rapid growth, associated with early metastasis, usually results in death within 2 years of diagnosis.[157]

PAPULOSQUAMOUS DISORDERS

Psoriasis[158] (See Chap. 18)

Xerosis and Asteatotic Dermatitis

Xerosis is a dry, rough quality of skin that is almost universal in the elderly and may be attributed to a subtle disturbance of epidermal maturation, such as inadequate filaggrin production[41] or altered lipid profile.[39,160] Histologic studies reveal little alteration of either the viable epidermis or the stratum corneum with age. Available data fail to demonstrate an overall decrease in stratum corneum lipids[39,40] or altered amino acid composition as etiologic factors.[161] Water content of the viable epidermis is normal, but there is some reduction in the outermost layers of the stratum corneum.[40] The surface irregularity may be attributed simply to slower transit of corneocytes through the stratum corneum, allowing accumulation of damage in situ. There is no explanation for the pruritus that often accompanies xerosis.[162] Speculations include frequent penetration of irritants through an abnormal stratum corneum and an altered sensory threshold due to subtle neuropathy.

Asteatotic eczema, a condition frequently found in the elderly during the wintertime, is a dermatitis superimposed on xerosis. It is often caused by low humidity in a heated environment. It manifests by dry, fissured skin with fine scale and is usually located to the pretibial region. This condition, which may be extremely pruritic, responds to application of medium-potency topical steroid ointments and/or liberal application of emollients.

Pruritus[162] (See Chap. 102)

Pruritus is perhaps the most common skin-related complaint of the elderly. In a majority of cases, pruritus is attributable only to xerosis, often exacerbated by low humidity, frequent bathing, or application of irritants to the skin. However, in up to 10 percent to 50 percent of patients in some series, pruritus may have other etiologies. These include metabolic or endocrine disorders, such as diabetes mellitus, renal failure, thyroid disease, or hepatic disease, in particular the obstructive type. Pruritus can be a manifestation of a malignant neoplasm, in particular lymphoma or leukemia, or the result of a hematologic disease such as polycythemia vera. Adverse drug reactions can manifest predominantly or exclusively as pruritus and always should be considered in this segment of the population. Finally, infestations such as scabies lead to intense pruritus, and associated primary skin lesions may be overlooked.

INFECTIOUS PROCESSES

Bacterial[163]

Impetigo and folliculitis in the elderly are caused by staphylococci, in contrast to

impetigo in the pediatric population, which usually is caused by streptococci (see Chap. 177). Hence, in the older age group, impetigo should be treated with penicillinase-resistant semisynthetic penicillin or erythromycin until culture confirms the identity of the organism.

Distinct forms of cellulitis (see Chap. 179) preferentially affect older individuals. These include orbital cellulitis that is caused by *Streptococcus viridans* alone or in combination with gram-negative bacteria. Another form of cellulitis that is relatively rare in the younger population is *Pseudomonas* cellulitis of the ear, an infectious process that affects elderly diabetic individuals. Erysipelas, a β-hemolytic streptococcal infection of the skin, is more common in the elderly and tends to spread more readily in this age group, creating a life-threatening situation.

Necrotizing fasciitis (see Chap. 179), caused by a strain of *Streptococcus*, is a rare cutaneous infection, but it is more frequent in the elderly and is associated with increased morbidity and mortality in this age group.

Methicillin-resistant *Staphylococcus aureus* (MRSA) has become an increasingly important pathogen in hospital and community acquired infections, and age > 80 years is significantly associated with MRSA carriage.[164] Because community-associated MRSA infection most often presents as skin and soft tissue infections, dermatologists should be aware of this possibility when managing infections in the elderly.

Parasitic[165] (See Chap. 208)

Scabies can occur in any age group, but nursing homes provide a fertile ground for rapid spread of the infestation. In the elderly, in part because of their decreased immunity, lesions may be atypical and display less inflammation and pruritus. In addition, frequently the elderly have xerosis, and their pruritus at times may be attributed to this etiology.

Dermatophytes and Yeasts[166] (See Chaps. 188 and 189)

Onychomycosis is present in approximately 40 percent of patients after age 60 years, and tinea pedis is present in approximately 80 percent of this patient population. Although usually present for decades, tinea pedis may exacerbate with age. Indeed, in elderly diabetic patients, interdigital tinea pedis may ulcerate and predispose to bacterial cellulitis, a presentation that is relatively rare in the young adult immunocompetent patient.

Cutaneous infections due to *Candida albicans* are common in the elderly. When recurrent or difficult to control, candidiasis may be a sign of poorly controlled diabetes, an endocrinopathy, malnutrition, or malignancy.

Viral (Varicella-Zoster Virus)[163] (See Chap. 194)

The incidence of herpes zoster peaks at approximately 1500 cases per 100,000 persons annually at age 75 years. Postherpetic neuralgia, uncommon in patients younger than 40 years old, occurs in more than 40 percent of patients aged 60 to 69 years and 50 percent of patients 70 years of age or older.[78] A number of patients older than 60 years also experience paresthesias and muscle weakness. Decreased cellular immunity and impaired wound healing in the elderly may account for slower resolution of the acute eruption, but the pathogenesis of their postherpetic neuralgia is unclear.

Ulcers[167]

Chronic ulcers of all etiologies are more common in the elderly than in younger individuals, presumably due to a combination of impaired wound healing and higher prevalence of underlying diseases. The most common are leg ulcers, usually in the setting of chronic venous insufficiency leading to venous hypertension (see Chap. 175). Exudation of macromolecules such as fibrinogen into the dermis may block the passage of oxygen and nutrients and sequester cytokines and growth factors required for tissue homeostasis, maintenance, and repair. The sclerotic indurated quality of affected skin, termed *lipodermatosclerosis*, is postulated to further impair healing. In addition, diseases such as diabetes mellitus and atherosclerotic peripheral vascular disease may contribute to ulcer evolution.

Decubitus ulcers (see Chap. 99) are proportionately far more common in elderly hospitalized patients than in younger patients, as the former tend to be less mobile, needing help turning in bed, and have additional aggravating disorders such as dry skin over bony prominences, incontinence, and/or poor nutritional state.[168]

Bullous Pemphigoid (See Chap. 54)

Bullous pemphigoid is far more common after age 60 years than in younger persons, a predilection that may be explained in part by the age-associated increases in circulating autoantibodies and ease of dermal-epidermal separation,[169] although many other autoimmune and blistering dermatoses are not more common in old age. Possibly, age-associated changes in the basement membrane itself render it specifically vulnerable to this disease process. Bullous pemphigoid is a self-limited condition that frequently resolves within 6 to 12 months, but elderly patients may experience increased morbidity and mortality because of debilitated general health or as a side effect of treatment.

DRUG ERUPTIONS

Adverse drug reactions of all kinds increase with age, in part because the elderly consume more medications than younger age groups and in part because of medical conditions, including impaired renal, cardiac, or hepatic function, that compromise drug metabolism or excretion. The most frequently observed adverse cutaneous drug reactions are pruritus, exanthems, and urticaria, but drug-induced autoimmune reactions, including pemphigus, bullous pemphigoid, and lupus erythematosus, also occur in the elderly. A careful history to elicit all prescription medications as well as over-the-counter preparations is critical to diagnosis and optimal patient care.

SECTION 20

CARCINOGENESIS

CHAPTER 109

Genome Instability, DNA Repair, and Cancer

Kenneth H. Kraemer
Thomas M. Rünger

INTRODUCTION

The integrity of the genome of all living organisms is constantly threatened by exogenous and endogenous DNA-damaging agents. Exogenous DNA-damaging agents include physical agents, such as ultraviolet (UV) or ionizing radiation, and a wide variety of chemical agents, such as components of cigarette smoke. Endogenous DNA damage arises from regular metabolic processes within the cell, mediated, for example, by reactive oxygen species. Maintaining the stability of the genome is of utmost importance to all living organisms. Therefore, since early evolution, all organisms ranging from prokaryotes to eukaryotes have been equipped with mechanisms that react to and repair DNA damage and thereby maintain genomic stability. The types of damage produced include alterations in the structure of nucleotides, DNA strand breaks, DNA cross-links, and DNA adducts. Different types of DNA-damaging agents induce different types of DNA damage (Table 109-1), which in turn require different responses and repair pathways for processing (Table 109-2).[1]

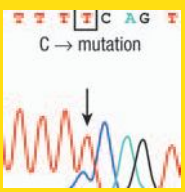
If DNA damage is not repaired adequately, it may lead to altered cell function, cell death, or the formation of mutations (alterations of the DNA sequence) in the damaged cells. These DNA damage–induced mutations will persist as long as the affected cell survives. At a cellular level, mutations in vital genes can lead to alterations of cell functions or malignant transformation. Accumulation of mutations may lead to organ dysfunction, aging, and cancer. Although most DNA damage is adequately repaired, none of the cellular responses is 100 percent effective in repairing all DNA damage under all circumstances.

A hereditary or acquired impairment in the way cells respond to DNA damage may result in genome instability with an increased rate of mutation formation. Numerous hereditary disorders are characterized by such genome instability (reviewed in Chap. 140). Many, but not all, of those are associated with an increased cancer risk and/or accelerated aging.

Exposure of the skin to UV light has multiple cellular and clinical effects, including an increase in skin cancer risk. The photocarcinogenesis cascade of events (Fig. 109-1) exemplifies the link between genome instability, DNA repair, and cancer. UV light produces a type of DNA damage involving the generation of photoproducts, which are alterations in the structure of nucleotides. The major DNA photoproducts are cyclobutane pyrimidine dimers (CPDs; Fig. 109-2) and 6,4-pyrimidine–pyrimidone dimers. Unrepaired CPDs or 6,4-pyrimidine–pyrimidone dimers may result in characteristic mutations: C to T single base and CC to TT tandem base substitution mutations.[2–4] Such mutations are typical for UV light exposures and only rarely are induced by other mutagens. They have therefore been termed *UV-signature mutations* (see Fig. 109-2).

◀ Lentigo maligna melanoma. A large lentigo maligna on the left cheek with the typical variegation in color. The lesion is flat and macular and represents in situ melanoma. In the center of the irregular lesion there is a pitch-black nodule that indicates a switch from the radial to the vertical growth phase and thus invasiveness: The lesion is now called lentigo maligna melanoma.

GENOME INSTABILITY, DNA REPAIR, AND CANCER AT A GLANCE



- DNA can be damaged by physical agents (ultraviolet or ionizing radiation) or chemical agents in the environment.
- DNA damage may lead to mutations (changes in DNA sequence).
- The ability of cells to repair DNA damage and to maintain genome stability is of utmost importance to prevent malignant transformation.
- Different agents induce different types of DNA damage, which in turn require different responses and repair pathways.
- A number of hereditary disorders are characterized by genome instability due to defects in genes involved in DNA repair or DNA damage signaling.
- Many different laboratory tests can be used to diagnose genome instability and/or DNA repair defects.
- Inherited or acquired genome instability is associated with an increased cancer risk.

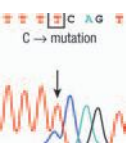
TABLE 109-1
Cellular Damage Induced by Physical and Chemical Agents

AGENT	DAMAGE
Ultraviolet radiation	Dipyrimidine cyclobutane dimers (TT, TC, CT, or CC), pyrimidine-pyrimidone (6-4) photoproducts (mostly TC), DNA-protein cross-links
X-irradiation	DNA single- and double-strand breaks, oxidative base damage (see below)
Psoralens plus ultraviolet A	DNA-psoralen monoadducts, DNA interstrand cross-links (binds to T at TA sequences)
Mitomycin C	DNA interstrand cross-links
Benzo-[a]-pyrene	Bulky adducts
Reactive oxygen species	Oxidative base damage (8-oxo-deoxyguanine, thymine glycol), cyclopurines (A or G) making bulky lesions

TABLE 109-2
Types of DNA Damage and Associated DNA Repair Pathways

TYPE OF DNA DAMAGE	DNA REPAIR PATHWAY
DNA photoproducts (CPDs, 6,4-PP)	Nucleotide excision repair
Oxidative base modifications (e.g., 8-oxoG)	Base excision repair
Incorrect DNA base pairing	Mismatch repair
DNA double-strand breaks	Non-homologous end joining, homologous recombination (i.e., recombination repair)
DNA adducts	Nucleotide excision repair
DNA cross-links (interstrand and intrastrand)	Recombination repair
Persistent DNA lesions	Translesion (bypass) DNA synthesis

CPDs = cyclobutane pyrimidine dimers; 6,4-PP = 6,4-pyrimidine–pyrimidone photoproducts; 8-oxoG = 8-oxo-deoxyguanine.

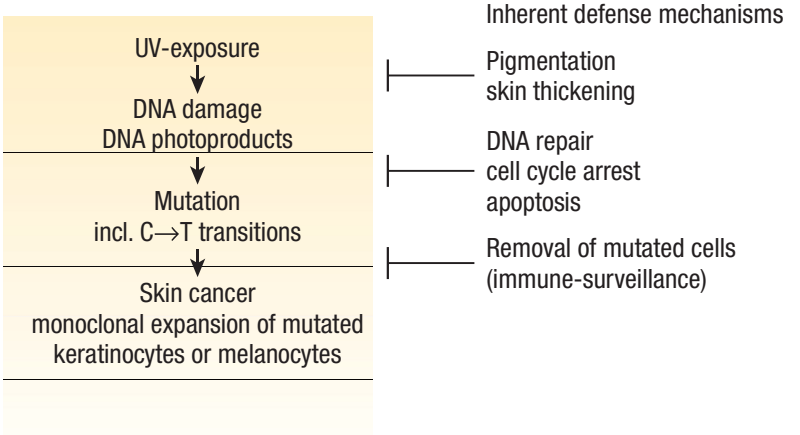


DNA repair is an important cellular defense mechanism that prevents mutation formation at sites of DNA damage after UV exposure. However, it is not the only defense mechanism (see Fig. 109-1). Most mutations are generated during replication of damaged DNA. Therefore, a damage-induced arrest in cell cycling, which allows more time for repair, is another important cellular damage response that prevents mutation formation.[5,6] Furthermore, programmed cell death (apoptosis) prevents the survival of cells with overwhelming DNA damage, and through that mechanism the frequency of cells with UV-induced mutations is also reduced.[7] Other inherent defense mechanisms against the ultimately carcinogenic properties of UV light include increased melanogenesis and thickening of the epidermis and stratum corneum, which protect from future DNA damage, as well as removal of mutated cells through host immune responses (see Fig. 109-1).

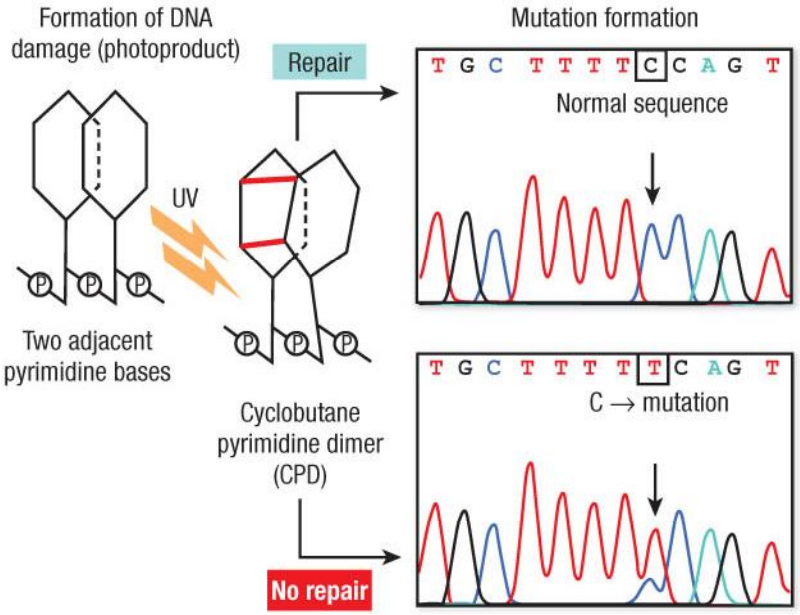
DNA DAMAGE AND REPAIR

More than 100 DNA repair genes have been identified (http://www.cgal.icnet.uk/DNA_Repair_Genes.html#NER). The nucleotide excision repair (NER) pathway acts on DNA damaged by UV radiation, repairing CPDs and other photoproducts, as well as on DNA damaged by certain carcinogens (such as benzo-[a]-pyrene) (see Table 109-2). In NER, the damaged nucleotide is removed and replaced with undamaged DNA. Multiple proteins act in concert to repair UV-induced DNA damage (Fig. 109-3). Defects in these repair genes can cause human diseases (Table 109-3), including xeroderma pigmentosum (XP), Cockayne syndrome, and trichothiodystrophy (for details on these disorders, see Chap. 140). For instance, XP can be caused by a defect in any one of several genes involved in NER. Based on cell fusion experiments, cells/patients with defects in the same gene are considered to be in the same complementation group, and in different complementation groups if different genes are affected. If DNA repair in the fused cell is normalized, with the wild-type gene from each cell giving rise to a functional protein that is absent in the other cell, the cells "complement" each other and are in different complementation groups. Seven such complementation groups have been identified (XPA to XPG), which implies that mutations in any of seven distinct genes can cause XP.

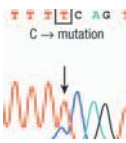
Transcribed genes are repaired faster than the rest of the genome. In the NER pathway, the first steps involving DNA damage recognition are different in non-transcribed and transcribed genes (global genome NER and transcription-coupled NER). In non-transcribed genes and noncoding areas, which represent most of the genome, the *XPE* and *XPC* gene products bind to UV-damaged DNA, marking it for further processing. In contrast, DNA damage in transcribed genes is probably sensed by a stalled

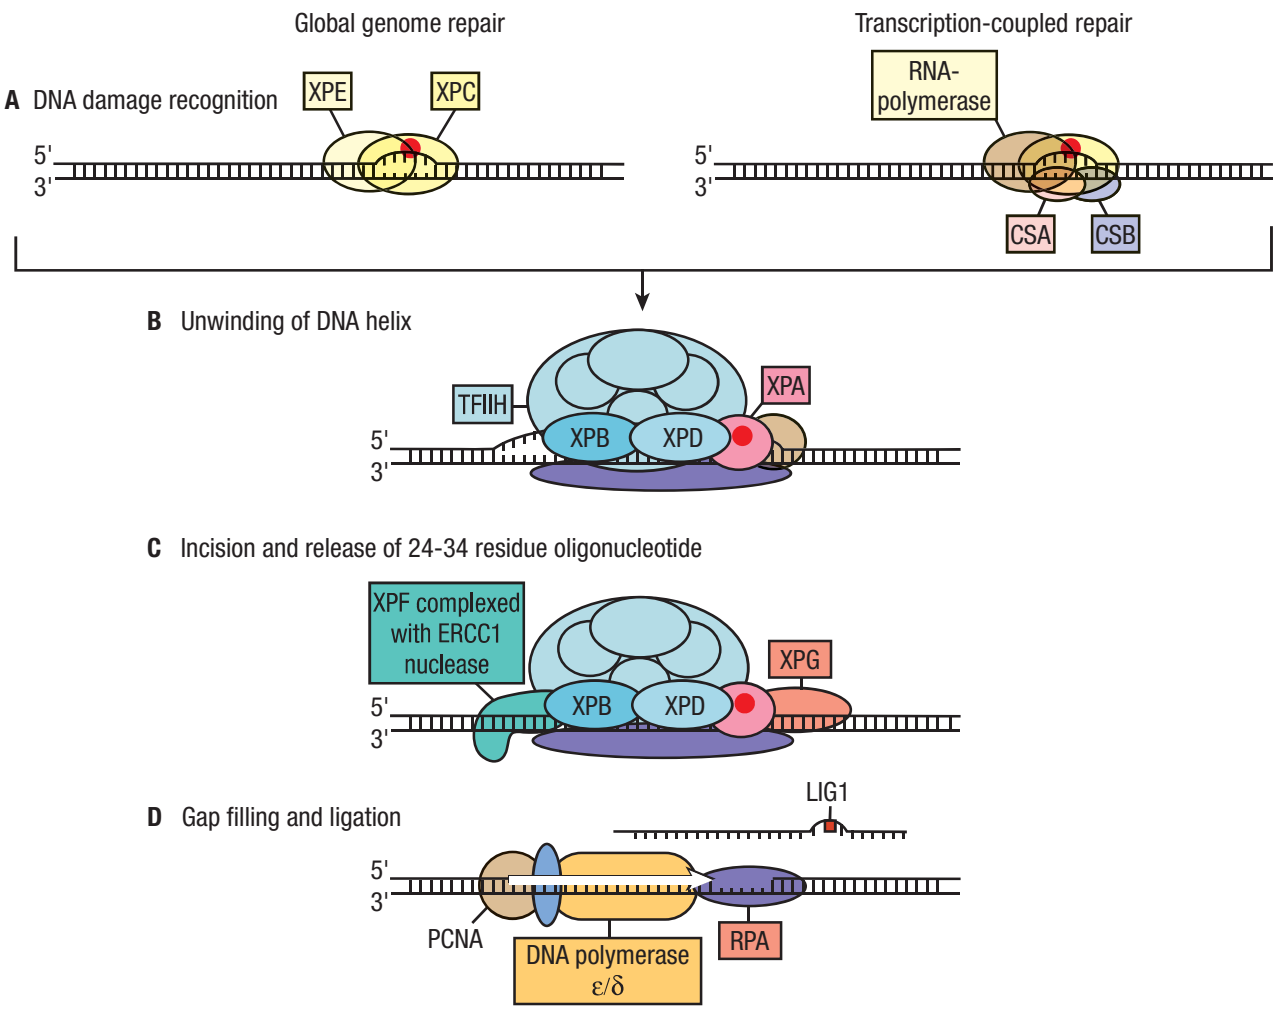


▲ **FIGURE 109-1** Photocarcinogenesis cascade of events. Exposure to ultraviolet (UV) light induces typical types of DNA damage, namely, cyclobutane pyrimidine and 6,4-pyrimidine–pyrimidone photoproducts. These often generate single and tandem base substitution mutations (C→T and CC→TT) that are typical for UV light exposure and are therefore termed *UV-signature mutations*. With sufficient numbers of inactivating mutations in crucial genes (tumor suppressor genes), individual cells may undergo malignant transformation, clonally expand, and form skin cancers. Several inherent defense mechanisms counteract this chain of events (see text).



◀ **FIGURE 109-2** Example of ultraviolet (UV) light–induced generation of DNA damage and a subsequent mutation. On direct excitation of the DNA molecule by UV light, adjacent pyrimidine bases (cytosine or thymine) may form covalent bonds between them, which leads to creation of pyrimidine dimers. The illustration shows an example in which two covalent bindings generate a tri-cyclic cyclobutane ring between two pyrimidines. Hence, this type of UV light–induced DNA damage is called a *cyclobutane pyrimidine dimer*, a common type of DNA photoproduct. The nucleotide excision repair DNA repair system functions to remove this damage, which results in the normal DNA sequence (*upper box*). If the damage is not repaired, this type of DNA photoproduct can lead to formation of a typical C⟶T single base substitution mutation (*lower box*). This is most likely to occur on replication of damaged DNA and misincorporation of adenine opposite the cytosine-containing photoproduct. An example of such a UV-signature mutation is shown on the right.[4] Note that the mutation is located within a run of seven pyrimidines, a common location for UV-signature mutations.



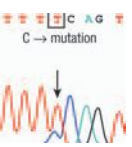


▲ **FIGURE 109-3** DNA nucleotide excision repair scheme. **A.** *Right:* Damaged DNA in actively transcribed genes results in stalling of the RNA polymerase in a process that involves the CSA and CSB proteins. This serves as a signal to initiate transcription-coupled DNA repair. *Left:* Damaged DNA in the remainder of the genome is bound by the XPE and XPC gene products. This serves as a signal to initiate global genome repair. **B.** A portion of the DNA, including the damage, is unwound by a complex of proteins including the XPB and XPD gene products. These proteins are also part of the 10-subunit basal transcription factor IIH (TFIIH). The XPA protein may stabilize the unwound DNA. **C.** The XPF and XPG nucleases make single-strand cuts on either side of the damage, releasing a 24- to 34-residue segment of DNA. **D.** The resulting gap is filled by DNA polymerase in a process that includes the proteins proliferating cell nuclear antigen (PCNA) and replication protein A (RPA). CSA, CSB = Cockayne syndrome complementation groups A and B; ERCC1 = excision repair cross-complementing gene 1; LIG1 = ligase 1; XPA, XPC, etc. = xeroderma pigmentosum complementation groups A, C, etc.

TABLE 109-3
DNA Repair Genes Associated with Human Diseases

Gene[a]	Chromosome Location	Repair Pathway	Function
XPA	9q22.3	NER	Binding of damaged DNA
XPB (ERCC3)	2q21	NER	DNA helicase, part of TFIIH
XPC	3p25	NER	Binding of damaged DNA, global genome repair
XPD (ERCC2)	19q13.3	NER	DNA helicase, part of TFIIH
XPE (DDB2)	11p12-p11	NER	Binding of damaged DNA, global genome repair
XPF (ERCC4)	16p13.3-p13.11	NER	DNA endonuclease
XPG (ERCC5)	13q22	NER	DNA endonuclease
TTDA (GTF2H5)	6p25.3	NER	Part of TFIIH
CSA (ERCC8)	5q12	NER	Transcription-coupled repair
CSB (ERCC6)	10q11	NER	Transcription-coupled repair
XPV (polymerase eta)	6p21.1-p12	Bypass	DNA damage bypass polymerase
MSH2	2p22-p21	MMR	Mismatch repair (Muir-Torre syndrome, HNPCC)
MLH1	3p21.3	MMR	Mismatch repair (Muir-Torre syndrome, HNPCC)
PMS1	2q31-q33	MMR	Mismatch repair (HNPCC)
PMS2	7p22	MMR	Mismatch repair (HNPCC)
MSH6	2p16	MMR	Mismatch repair (HNPCC)
TFGBR	23p22	MMR	Mismatch repair (HNPCC)
MLH3	14q24.3	MMR	Mismatch repair (HNPCC)

ERCC = human excision repair cross-complementing genes that correct defects in cultured hamster cells; HNPCC = hereditary non-polyposis colon cancer; NER = nucleotide excision repair; MMR = mismatch repair; TFIIH = transcription factor IIH.
[a]The genes designated XP are defective in the corresponding xeroderma pigmentosum complementation group, and those designated CS are defective in the corresponding Cockayne syndrome complementation group.



RNA polymerase acting in conjunction with the CSA and CSB (Cockayne syndrome complementation groups A and B) gene products. After the DNA damage recognition steps, global genome NER and transcription-coupled NER follow the same pathway. The *XPA* gene product probably functions in conjunction with replication protein A, the transcription factor IIH (TFIIH), XPF, and excision repair cross-complementing gene 1 (ERCC1). The following steps occur in both non-transcribed and transcribed gene repair:

- The *XPB* and *XPD* gene products partially unwind the DNA in the region of the damage, thereby exposing the lesion for further processing. These proteins are part of the TFIIH basal transcription factor (see Fig. 109-3B).
- The *XPF* gene product, in a complex with ERCC1, makes a single-strand nick at the 5′ side of the lesion, whereas the *XPG* gene product makes a similar nick on the 3′ side, which results in the release of a region of approximately 30 nucleotides containing the damage (see Fig. 109-3C).
- The resulting gap is filled by DNA polymerase using the other (undamaged) strand as a template in a process involving proliferating cell nuclear antigen. DNA ligase 1 seals the region, restoring the original undamaged sequence (see Fig. 109-3D).

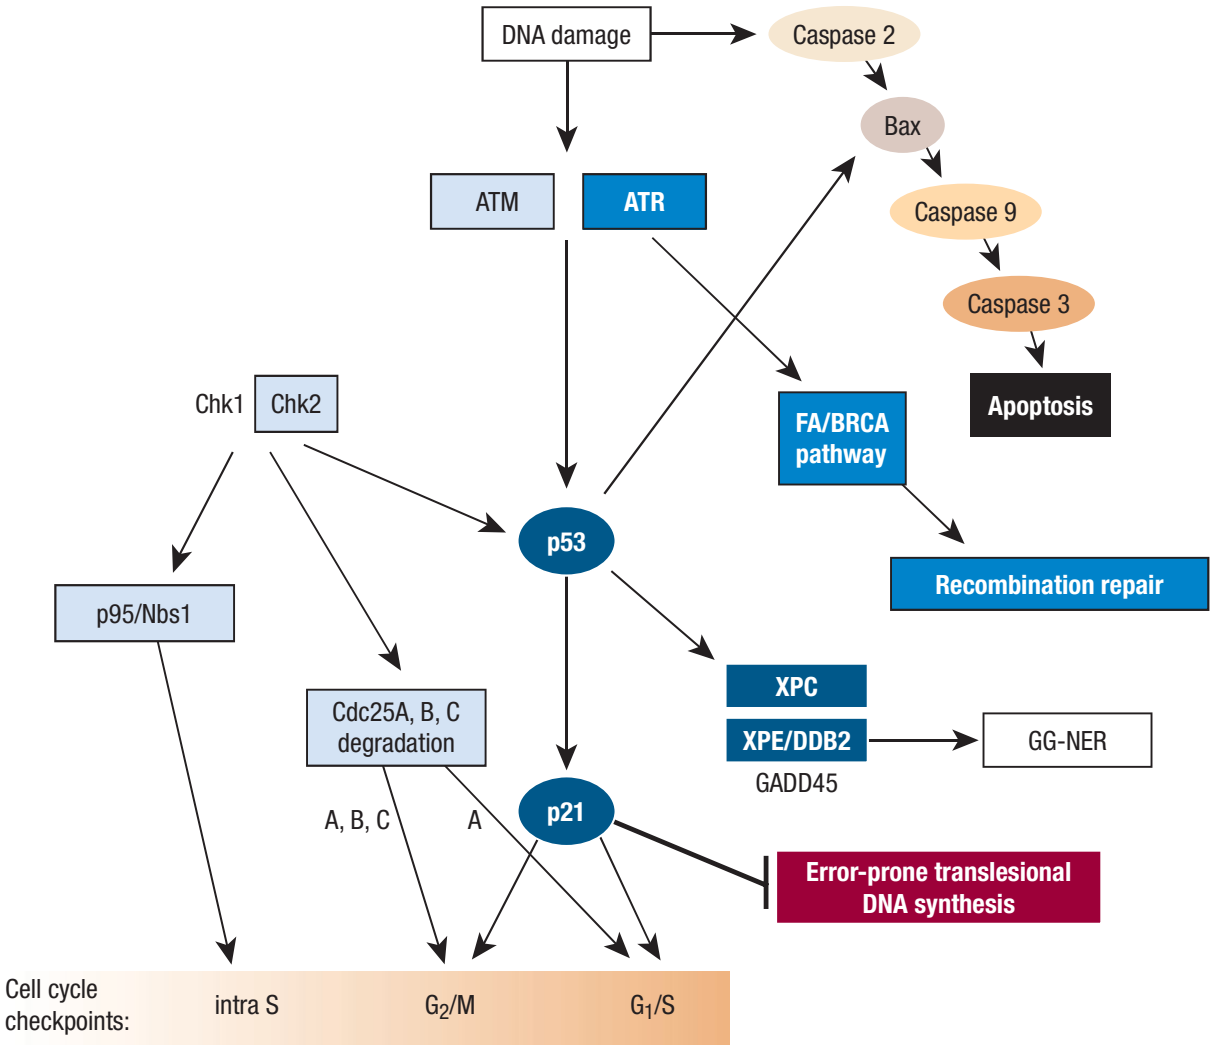
Other DNA repair pathways include base excision repair, recombination repair, and mismatch repair. Defects in mismatch repair are also associated with human diseases—Muir-Torre syndrome and human non-polyposis colon cancer. More extensive descriptions of these pathways may be found in refs. 1, 8, 9, and 10.

REGULATION OF CELLULAR RESPONSES TO DNA DAMAGE

As outlined in the introduction, several cellular responses to DNA damage contribute to the maintenance of genome integrity. These include cell cycle arrest, apoptosis (programmed cell death), and DNA repair.[5,11–18] Because these responses need to be carefully orchestrated, there are many proteins involved in the signaling of DNA damage and the regulation of DNA damage responses (Fig. 109-4). Different types of DNA-damaging agents and different types of DNA damage require different DNA damage responses. Fig. 109-4 presents some of the major players in signaling DNA damage and regulating DNA damage responses. As with defects in DNA repair genes (see Table 109-3), defects in many of these DNA damage–signaling genes (boxed in Fig. 109-4) are also implicated in hereditary disorders of genome instability (Table 109-4; for further details see Chap. 140).

The tumor suppressor gene p53, termed the *guardian of the genome*,[19] plays a pivotal role in regulating and orchestrating these responses and is mutated in many cancers, including cutaneous squamous cell carcinomas. Upstream regulators of p53 in the cellular DNA damage response pathway are ATM (ataxia telangiectasia mutated) and ATR (ataxia telangiectasia- and Rad3-related) genes. One of p53's several functions is the regulation of the cell cycle in response to DNA damage. After cell division (mitosis), cells have 23 pairs of chromosomes and are in the G_1 phase of the cell cycle. The chromosomes then replicate during DNA synthesis, or S phase, and as a result have twice the number of chromosomes (G_2 phase) just before mitosis (M phase). The cell stops cycling (arrests) in specific cell cycle phases called *cell cycle checkpoints*. An important downstream effector in preventing cells from entering S phase (G_1/S checkpoint) is p21.[5,11] p53 also induces NER by transcriptionally inducing XPC, XPE/p48, and GADD45.[20,21]

If cells enter S phase with unrepaired DNA damage, or if cells are UV exposed during S phase, regular DNA polymerases stall at DNA photoproducts and fall off the DNA strand. For these instances, cells are equipped with several specialized DNA polymerases for translesional DNA synthesis.[22] DNA polymerase eta is one of these; it is specialized to bypass DNA photoproducts but may introduce mutations while doing so.[23] It is mutated in XP variant, which is clinically indistinguishable from XP (see Table 109-3, Chap. 140).[24,25] This demonstrates the importance of this second line of defense against the mutagenic and carcinogenic consequences of DNA photoproducts. It was reported that p53 and



▲ FIGURE 109-4 Signaling cascades that regulate apoptosis, DNA repair, translesional DNA synthesis, and activation of cell cycle checkpoints in response to DNA damage. This is a highly simplified diagram that depicts only the most important players in the intricate and interwoven DNA damage–signaling networks. The traditional thinking was that ATM (ataxia telangiectasia mutated gene) is activated (phosphorylated) in response to ionizing radiation (IR) and ATR (ataxia telangiectasia- and Rad3-related gene) is activated in response to ultraviolet (UV) radiation, but newer data indicate that both are activated by IR and UV. ATM/ATR can activate (i.e., phosphorylate) p53 either directly or indirectly through activation (phosphorylation) of Chk2 (an ATM target) or Chk1 (an ATR target). Through transcriptional activation of p21 and subsequent inhibition of cyclin-dependent kinases, which usually drive cells from the G_1 into the S phase of the cell cycle, activated p53 activates the G_1/S checkpoint (i.e., arrests cells in G_1). The G_1/S checkpoint is also activated by Chk1/Chk2-induced phosphorylation and then degradation of Cdc25A and subsequent failure to activate cyclin-dependent kinases. Phosphorylation and subsequent degradation of Cdc25A, Cdc25B, and Cdc25C also mediate the G_2/M arrest, as does p21. Intra–S phase arrest is mediated through activation (phosphorylation) of p95/Nbs1. p53 also induces global genome nucleotide excision repair (GG-NER) through transcriptional activation of XPC, XPE/p48, and GADD45. Translesional DNA synthesis has been shown to be downregulated by p53 via p21. Recombination repair is mediated through the Fanconi anemia (FA)/BRCA pathway, which in turn is dependent on ATR activation. The mitochondrial pathway of apoptosis is activated through activation of Bax by caspase 2 and p53, the initiator caspase 9, and the effector caspases 3, 6, and 7 (for references, see text). Gene products that are defective in hereditary human diseases are boxed. DDB2 = DNA damage binding protein 2; XPC, XPE = xeroderma pigmentosum complementation groups C and E.

p21 also downregulate the activity of this translesional DNA synthesis to maintain a low mutagenic activity at the price of reduced damage bypass.[26]

If this translesional DNA synthesis fails, cells can use recombination repair to resolve stalled replication forks.[27] When invoked in response to damage from UV light, this third line of defense is mediated by activation of the Fanconi anemia/BRCA DNA damage response pathway.[28] The exact mechanisms that initiate these DNA damage response signaling cascades is under investigation. Telomeres, which are repeats of TTAGGG that cap the ends of chromosomes and whose ends form a loop structure, are suggested to be important players in sensing DNA damage, for example, through opening of the telomere loop.[29] Other sensors may be stalled DNA or RNA polymerases, or proteins that detect bending of the DNA helix at sites of DNA damage.

Apoptosis is a regulated physiologic process leading to cell death characterized by cell shrinkage, membrane blebbing, and DNA fragmentation. A group of cysteine proteases called *caspases* are central regulators of apoptosis. Triggers may be extrinsic or intrinsic to the cell (e.g., DNA damage) and involve separate initiator caspases (e.g., caspase 2 in response to

DNA damage) but share the same downstream effector caspases.[7]

APPROACHES TO DIAGNOSIS OF GENOME INSTABILITY AND/OR DNA REPAIR DEFECTS

When a disorder of genome instability is suspected, the clinician is challenged with choosing the appropriate laboratory tests to secure a diagnosis and to provide guidance for affected patients and families. Table 109-5 lists some hallmark clinical features that may indicate the presence of such disorders and should prompt clinicians to initiate testing. Various laboratory tests for genome stability, DNA repair, and response to physical and chemical agents are listed in Table 109-6.

Use of Cultured Cells

Cells obtained directly from patients and grown in culture medium are termed *primary cultures*. Dermal fibroblasts generally grow easily in culture and can generally be established from a 2- to 4-mm sterile skin punch biopsy specimen. The inner surface of the upper arm has proven to be a suitable biopsy site because this area heals easily, the resulting scar is not readily visible, the site is shielded from UV radiation, and attempts to establish cultures from specimens are generally successful. The tissue is placed in sterile culture medium (or sterile saline) with antibiotics and transported to a cell culture laboratory at room temperature.

Human cell cultures are made available for research by the National Institutes of Health–funded Human Genetic Mutant Cell Repository (401 Haddon Ave, Camden, NJ 08103; telephone: 856-966-7377; http://ccr.coriell.org/Sections/Collections/NIGMS/SsId=8).

Diagnostic Tests of Genome Instability and DNA Repair

Tests to assess genome instability and/or DNA repair capacity may be divided into tests of intact cellular function and tests of chromosome integrity and breakage in response to DNA-damaging agents. Other tests measure the mechanism of impairment of a cell function such as DNA repair or characterize or determine the expression of defective genes (see Table 109-6).

TESTS OF INTACT CELL FUNCTION Tests of cellular function measure the capacity of the intact cell to recover from DNA damage. These tests do not provide information regarding the specific type of damage resulting in cellular injury or the mechanism of cellular recovery, but they do form

TABLE 109-5
Hallmark Clinical Features That May Indicate a Disorder of Genome Instability or DNA Repair and Prompt Clinicians to Initiate Testing[a]

DISORDER	CLINICAL FEATURES
Xeroderma pigmentosum	Congenital photosensitivity, childhood freckling, early or multiple skin cancers
Cockayne syndrome	Congenital photosensitivity, postnatal growth failure, sensorineuronal deafness
Trichothiodystrophy	Brittle hair, photosensitivity, ichthyosis
Ataxia telangiectasia	Telangiectasias, ataxia, leukemias, and lymphomas
Bloom syndrome	Photosensitivity, malar erythema, growth retardation
Fanconi anemia	Aplastic anemia, growth retardation, café-au-lait spots, thumb abnormalities
Muir-Torre syndrome	Sebaceous tumors, keratoacanthomas, personal or family history of colon cancer

[a]Refer to Chap. 140 and Table 140-1 for more information.

TABLE 109-6
Diagnostic Tests of Genome Stability, DNA Repair, and Response to Physical or Chemical Agents[a]

- Intact cell function (proliferation or cell death)
  - Cell counts (growth in mass culture)
  - Thymidine incorporation
  - Colony-forming ability
- Chromosome integrity and breakage
  - Giemsa-stained metaphase karyotype analysis
  - G_2 chromosome breakage
  - Sister chromatid exchanges
  - Fluorescent in situ hybridization
  - Microsatellite instability testing
- DNA repair
  - Unscheduled DNA synthesis
  - RNA synthesis inhibition
  - Host cell reactivation
  - Comet assay
  - Immunological analysis of DNA damage and removal (enzyme-linked immunosorbent assay, slot blot)
  - Microsatellite instability testing
- Characterization and expression of defective genes
  - Real-time polymerase chain reaction
  - Western blotting
  - DNA sequencing

[a]Agents are listed in Table 109-1.

TABLE 109-7
Suggested Sequence of Diagnostic Testing for Diseases of Genome Instability or DNA Repair[a]

Disease	Step 1	Step 2	Step 3	Step 4	Testing Available[b]
Xeroderma pigmentosum	Post-UV hypersensitivity	Post-UV DNA repair	DNA sequencing	—	CLIA/R
Xeroderma pigmentosum variant	Post-UV hypersensitivity (with caffeine)	Post-UV DNA repair (normal)	DNA sequencing	—	R
Cockayne syndrome	Post-UV hypersensitivity	Post-UV inhibition of RNA synthesis	DNA sequencing	—	CLIA
Trichothiodystrophy[c]	Post-UV hypersensitivity	Post-UV DNA repair	DNA sequencing	—	CLIA/R
Ataxia telangiectasia	Chromosome breakage	X-ray hypersensitivity	Western blotting for level of protein	DNA sequencing	CLIA/R
Bloom syndrome	Chromosome breakage	Sister chromatid exchange	DNA sequencing	—	CLIA
Fanconi anemia	Chromosome breakage	Hypersensitivity to DNA cross-linking agents	Western blotting for FANCD2	DNA sequencing	CLIA/R
Muir-Torre syndrome	Microsatellite instability	Western blotting for level of protein	DNA sequencing	—	CLIA

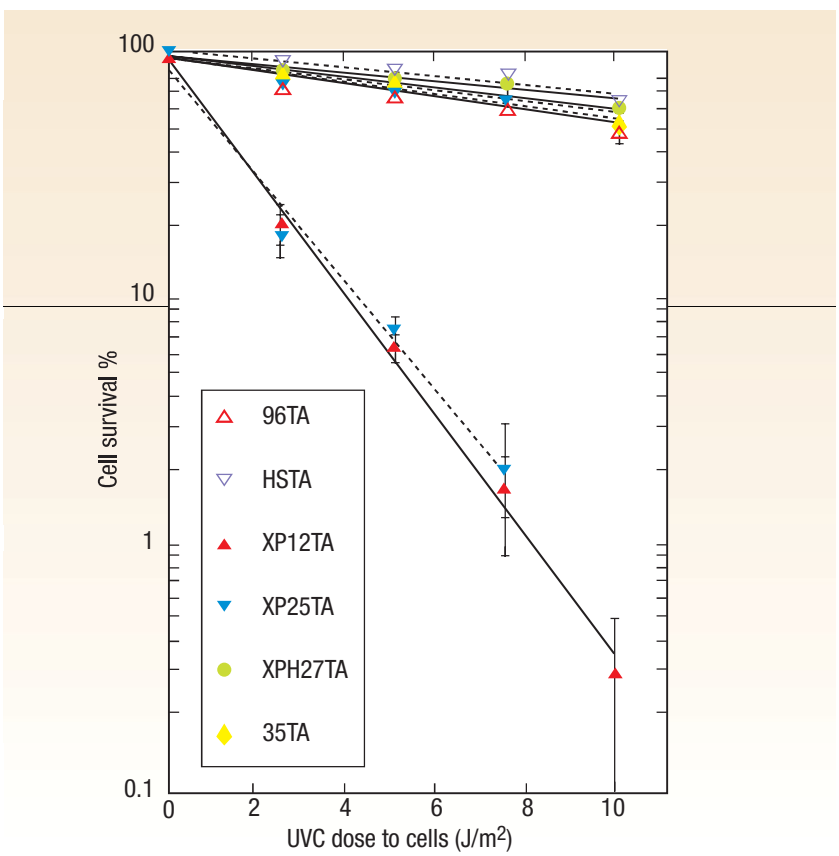
CLIA = testing available by laboratories certified under the Clinical Laboratory Improvement Act; R = research testing available; UV = ultraviolet radiation.
[a]These are suggestions only and may change based on availability of different assays or new scientific information.
[b]Testing laboratories are listed on the National Institutes of Health–funded website http://genetests.org.
[c]Screen by polarizing microscopic examination of hair followed by measurement of sulfur-containing amino acids in the hair (see Chap. 140).

the basis for identifying cells as hypersensitive to DNA-damaging agents and are often used as simple screening tests.

Cell Counts or Thymidine Incorporation. One of simplest tests after exposure to UV radiation or x-rays is the assessment of the growth rate in mass culture by using a microscope or an automated cell counter to count the number of cells or by measuring incorporation of radioactive thymidine into newly synthesized DNA (see Tables 109-6 and 109-7).

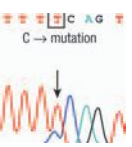
Colony-Forming Ability. A test of colony-forming ability assesses the capacity of a single cell to proliferate enough to form a visible colony (Fig. 109-5).

TESTS OF CHROMOSOME INTEGRITY AND BREAKAGE ***Chromosome Breakage.*** Chromosome breakage is usually assessed in primary cultures of mitogen-stimulated peripheral blood leukocytes or in long-



◀ **FIGURE 109-5** Colony-forming ability assay of cell sensitivity. Xeroderma pigmentosum (XP) fibroblasts from two affected siblings (XP12TA and XP25TA), their father (XPH27TA), and an unaffected brother (35TA) as well as normal fibroblasts (96TA and HSTA) were treated with 254-nm ultraviolet C (UVC) radiation and colony-forming ability was determined. The XPC (XP complementation group C) fibroblast strains from the affected siblings were much more sensitive than the normal strains and showed similar post-UVC hypersensitivity. Cells from the unaffected brother and the clinically normal father, a heterozygous carrier of the XPC defect, had normal post-UVC survival. (Modified from Slor H et al: Clinical, cellular, and molecular features of an Israeli xeroderma pigmentosum family with a frameshift mutation in the XPC Gene: Sun protection prolongs life. *J Invest Dermatol* **115**:974, 2000.)

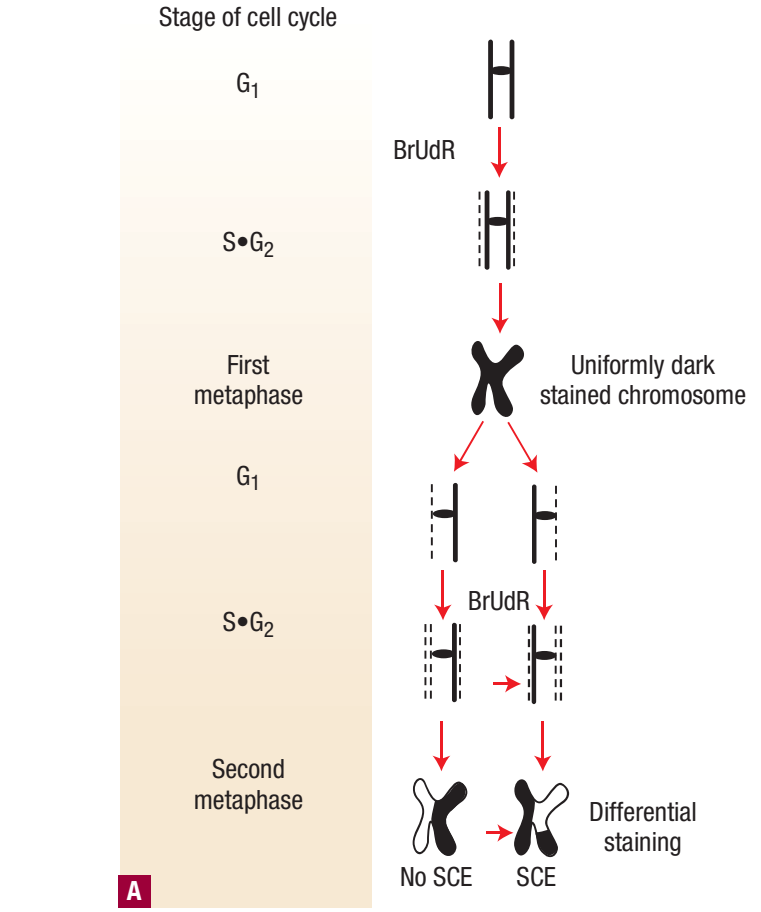
term cultures of fibroblasts or lymphoblastoid cell lines. Cell cycle progression is stopped at metaphase by treatment of the cells with an inhibitor of mitosis such as colchicine. In this procedure, the 23 pairs of metaphase chromosomes from a single cell are spread over a discrete area of the slide and stained (usually with Giemsa stain). Preparations may be analyzed for the number of chromosomes per metaphase, the morphology of the individual chromosomes, and the attachments or rearrangements of chromosomes in relation to each other.



Sister Chromatid Exchange. During DNA replication, chromatids occasionally exchange positions along the arms of a chromosome. This sister chromatid exchange may be detected by permitting the cells to grow through two cycles of replication in medium containing the nucleic acid analog bromodeoxyuridine (Fig.109-6). Sister chromatid exchanges are thought to be related to DNA recombination repair, although their precise significance is not understood.

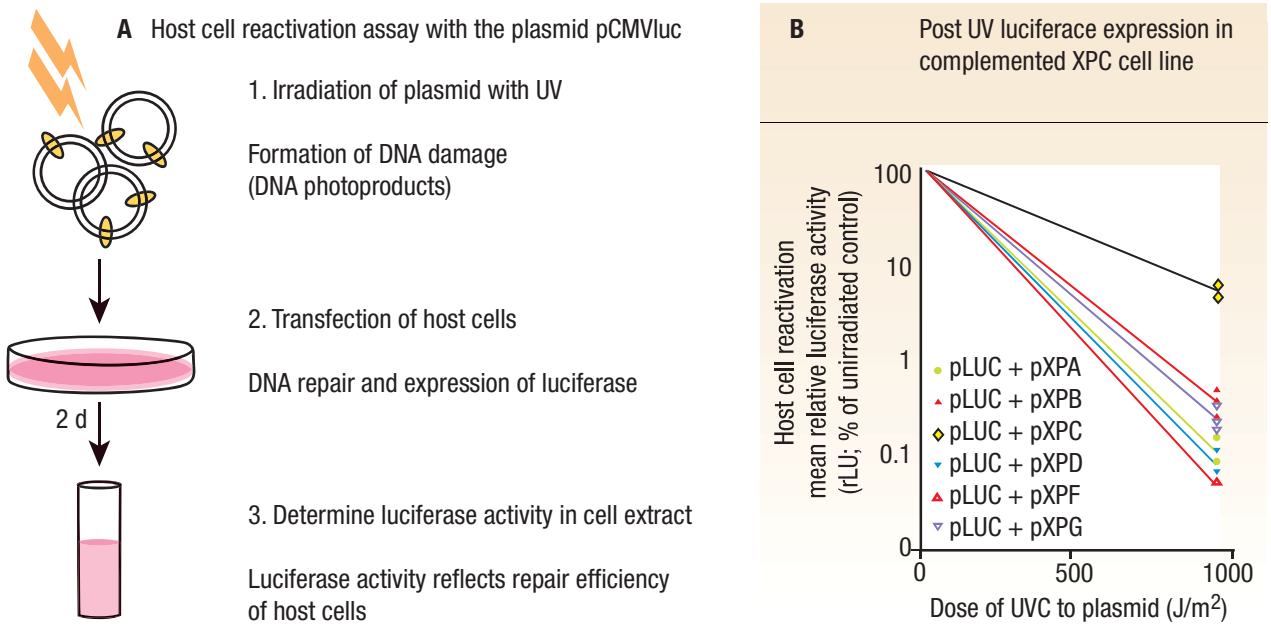
TESTS OF DNA REPAIR ***Unscheduled DNA Synthesis.*** One of the most commonly used tests of NER is unscheduled DNA synthesis. This test has been used to measure DNA repair in intact human skin, in cultured epidermal or dermal cells, and in blood cells, and for prenatal diagnosis using amniotic fluid cells. Unscheduled DNA synthesis testing measures the repair-associated DNA synthesis in G_1 or G_2 cells (which usually do not synthesize DNA). Cells are treated with UV radiation or another DNA-damaging agent and then incubated in medium containing radioactive thymidine. During the process of NER, the damage is removed and the radioactive thymidine is incorporated into the repaired region. The cells are treated with fixative, coated with autoradiographic (photographic) emulsion, and kept in the dark for an appropriate interval, and then the emulsion is developed. UV radiation of normal fibroblasts results in a large increase in the number of grains seen over all the nuclei. In marked contrast, irradiation of the XP fibroblasts that cannot repair DNA damage results in very few grains over the nuclei.

RNA Synthesis Inhibition. After exposure to UV radiation, normal cells temporarily reduce RNA synthesis from active genes. Synthesis resumes when the damage is repaired. This resumption of RNA synthesis is delayed in cells from patients with Cockayne syndrome and some forms of XP.



▲ **FIGURE 109-6** **A.** Sister chromatid exchange (SCE) assay of chromosome integrity. After the first cycle of replication, the DNA of the newly synthesized strand is labeled with bromodeoxyuridine (BrUdR), whereas the older strand is unlabeled. Such chromosomes appear uniformly dark with Giemsa stain. After a second cycle of replication in BrUdR-containing medium, one arm of a chromosome will contain two labeled chromatids, whereas the other will contain one labeled and one unlabeled chromatid. The doubly substituted arm will stain lightly, whereas the singly substituted arm will stain darkly. If an SCE occurred during replication, a portion of each chromosome arm will be doubly substituted and the remainder singly substituted with BrUdR. **B.** Undamaged normal cultured peripheral blood lymphocytes have approximately 10 SCEs per metaphase. **C.** Cultured peripheral blood lymphocytes from a patient with Bloom syndrome have a manifold increase in SCEs. (From Chaganti RS, Schonberg S, German J: A manyfold increase in sister chromatid exchanges in Bloom's syndrome lymphocytes. *Proc Natl Acad Sci U S A* **71**:4508, 1974, with permission.)

Host Cell Reactivation. The host cell reactivation assay relies on the fact that plasmids do not have the ability to repair



▲ FIGURE 109-7 Plasmid host cell reactivation assay with assignment to xeroderma pigmentosum (XP) complementation group. **A.** The plasmid is damaged by ultraviolet (UV) radiation and introduced into cultured human cells by a transfection technique. The cells' DNA repair enzymes repair the damage in a manner similar to the repair of cellular DNA. Repaired DNA will then function to transcribe the plasmid-encoded luciferase gene in the human cell. The amount of luciferase activity within the host cells therefore reflects the efficiency of the cellular DNA repair system. This assay can also be used to determine the complementation group by co-transfecting UV-treated plasmid plus plasmids expressing wild-type XP complementary DNA (cDNA). **B.** The results of plasmid host cell reactivation experiments and complementation group assignment with DNA excision repair–deficient XP46DC cells. UV-treated plasmid showed low expression in the XP65BE cells that was increased only by co-transfection with a plasmid expressing the wild-type XPC cDNA. This result indicates that XP65BE cells are in XP complementation group C (XPC). rLU = relative light units; pCMVluc and pLUC = plasmids containing gene for luciferase; pXPA–pXPG = plasmids expressing xeroderma pigmentosum complementation groups A–G.

damage to their DNA but depend on cellular repair systems. Thus, damaged plasmids would be expected to be expressed at a higher level in cells with normal repair capacity. A non-replicating plasmid that contains the gene for the firefly enzyme luciferase, constructed to permit expression in human cells,[30] is widely used; generation of light provides a quantitative endpoint for its repair (Fig. 109-7).

Comet Assay. The comet assay is a single cell–based technique that allows detection and quantitation of DNA damage. Damaged nuclei are embedded in agarose, lysed, and exposed to an electric field. The DNA migrates out of the nucleus forming a "comet" when stained. The length of the comet is proportional to the fragmentation of the DNA. This assay can be modified for detection of single-strand or double-strand DNA breaks, UV damage, or oxidative DNA damage. Cells from patients with XP have defective repair in the post-UV comet assay.

Microsatellite Instability. Normal DNA has tens of thousands of regions with repeats of the dinucleotide CA or other short motifs up to five nucleotides long. In normal individuals each of these microsatellites (also called *simple sequence repeats* or *short tandem repeats*) has a uniform size. However, these sizes are highly variable among different individuals and are often used for DNA "fingerprinting." The appearance of abnormally longer or shorter simple sequence repeats in different tissues or tumors from a patient is called *microsatellite instability*. This can be associated with a defect in mismatch repair genes.

CHARACTERIZATION AND EXPRESSION OF DEFECTIVE GENES ***Real-Time Polymerase Chain Reaction.*** In some genome instability genes, mutations create premature stop codons for protein synthesis. These mutations result in low levels of messenger RNA (mRNA) for the gene product through a process called *nonsense-mediated message decay*. The mRNA levels can be accurately measured by use of quantitative reverse transcriptase real-time polymerase chain reaction. For example, low XPC mRNA levels have been found in cells from most XP patients with defects in this gene.[31]

Western Blotting. Some mutations result in reduced levels or size of encoded proteins, often through creation of premature stop codons.[31] Reduced protein levels are most commonly detected by Western blotting. Cells are lysed and the proteins are extracted and separated by gel electrophoresis. The separated proteins are transferred to a membrane and probed with an antibody that is specific for the protein of interest. The intensity of the antibody staining reflects the amount of protein in the cells, and its location on the membrane is an indication of the size of the protein molecules.

DNA Sequencing. Direct sequencing of defective genes is the gold standard for determination of the presence of a mutation. The final step in confirmation of a diagnosis may be DNA sequencing to determine the disease-causing mutation. By definition, disease-causing mutations alter the function of genes. Of note, however, not every alteration in the sequence of a gene alters the function of the encoded protein. In the human genome there are millions of single nucleotide polymorphisms, or changes in one nucleotide, that are not associated with disease and may not even change the amino acid composition of

the encoded protein. In recessive disorders, each clinically unaffected parent has one normal allele and one potentially disease-causing mutation in the other allele. The affected child receives an allele with a disease-causing mutation from each parent. The two mutations must be in the same gene, although they need not necessarily be identical to each other.

Considerations in Diagnostic Testing

Diagnosis of disorders of genome instability or DNA repair is often a multistep process. A suggested sequence of steps is listed in Table 109-7. As new tests are developed and new information is obtained about these disorders, testing procedures may change accordingly. In addition, decisions regarding the extent of testing performed may be made with consideration of how much the tests cost and whether additional information would alter treatment. For example, DNA sequencing is rarely required for establishment of a diagnosis of XP in a child with classical clinical features and cells that are hypersensitive to killing by UV and have defective DNA repair. But if a family has one child affected with XP and is considering having additional children, DNA sequencing might offer them the possibility of prenatal diagnosis through DNA sequencing of a trophoblast biopsy specimen.

Genetic counseling is an important component of patient management for these genetic diseases. This function may be performed by the treating physician or by a trained genetic counselor.

In the United States, only laboratories certified in accordance with the Clinical Laboratory Improvement Act (CLIA) are allowed to perform these specialized tests in the context of patient care. Tests performed in research laboratories generally have limited use in clinical practice. However, a research laboratory may identify a disease mutation in cells from a patient that could then be confirmed in a CLIA-certified laboratory and used in clinical practice. A listing of laboratory testing facilities for these diseases may be found at the website http://genetests.org, funded by the National Institutes of Health.

CHAPTER 110

Carcinogenesis: Chemical

Andrzej A. Dlugosz
Stuart H. Yuspa

CUTANEOUS CANCER AND PUBLIC HEALTH

Cutaneous cancers account for more than one-half of all malignancies diagnosed in the United States, totaling more than 1 million non-melanoma skin cancers (NMSCs) [800,000 to 900,000 basal cell carcinomas (BCCs) and 200,000 to 300,000 squamous cell carcinomas (SCCs)] and over 62,000 melanomas, according to estimates for 2006 by the American Cancer Society. The precise number of NMSCs is unknown, because unlike other malignancies, they are not routinely reported to registries. Although only a small fraction of patients with NMSC will die from their disease, which is nearly always SCC, the frequency of these cancers nonetheless results in an estimated death rate between 1000 and 2000 per year. In contrast, although much less common than NMSC, melanoma has a death rate estimated at nearly 8000 per year,[1] and a staggering 1 in 59 individuals born today is predicted to develop melanoma during his or her lifetime, based on 2001–2003 data compiled by the National Cancer Institute's Surveillance Epidemiology and End Results program (http://www.seer.cancer.gov). Because they are so common, cutaneous cancers have a major impact on health care costs: in addition to the mortality burden, treatment is associated with considerable morbidity and cosmetic defects. For these reasons, understanding the etiology and pathogenesis of these malignancies is a significant public health goal, and development of rational, non-deforming therapies to reduce morbidity and mortality is urgently needed. The high prevalence of skin cancer, the external location of the tumors, and well-defined pre-neoplastic lesions all provide an excellent opportunity for studying the factors regulating cutaneous cancer induction in humans. Those qualities that facilitate the study of cutaneous neoplasms in human populations have also been useful in establishing relevant animal models. Advances in molecular genetics, keratinocyte cell culture, and development of genetically altered mice and reconstructed human skin models have greatly facilitated the analysis of basic mechanisms of cutaneous carcinogenesis. The main focus of this chapter is on NMSC: the reader is referred to Chap. 124 for further discussion of melanoma.

CHEMICALS ASSOCIATED WITH SKIN CANCER INDUCTION IN HUMANS

The ultraviolet radiation (UVR) in sunlight is the primary etiologic agent for all skin cancers, and, thus, UVR is the major carcinogen in the human environment. The powerful carcinogenic activity of UVR is attributable to its ability to damage DNA and cause mutations, its capacity to clonally expand incipient neoplastic cells whose altered signaling pathways provide a survival advantage in the face of ultraviolet-induced cytotoxicity, its ability to induce reactive oxygen species, and its activity as an immune suppressant (see Chap. 112). The association of UVR with skin cancer is so strongly supported by clinical, epidemio-

CHEMICAL CARCINOGENESIS AT A GLANCE

- More than 200 chemicals have been linked to human cancer development.
- Chemicals implicated in human skin cancer development include polycyclic aromatic hydrocarbons and arsenic.
- Chemical carcinogenesis studies in mouse skin have defined operational stages of epithelial carcinogenesis, which include initiation, promotion, and malignant progression. Based on their activity in this assay, chemicals linked to human cancer can be classified as tumor initiators, promoters, or "complete" carcinogens.
- Tumor initiation is irreversible, because it is associated with gene mutations that permanently alter the biologic responsiveness of the initiated cell; tumor promotion is a non-mutagenic process that provides a selective growth advantage to initiated cells and is reversible at early stages; agents that facilitate malignant progression are generally genotoxic.
- Most carcinogens must undergo metabolic activation that involves several enzymes involved in xenobiotic metabolism, including cytochrome p450 enzymes and glutathione S-transferase.
- An individual's likelihood of developing chemically induced skin cancer is a function of exposure history, presence of additional risk factors, and genetic background, including gene polymorphisms that influence susceptibility to chemical carcinogens.

logic, and experimental data that it represents the most clear-cut etiologic factor in human malignancy. Also implicated in the development of human skin cancer are various chemicals as a result of environmental, occupational, or medicinal exposures (Table 110-1). In 1775, Sir Percivall Pott[2] attributed the increased incidence of scrotal cancer in chimney sweeps to repeated exposure to soot. This report provided the first link between occupational exposure and the development of cancer as well as the first example of chemical carcinogenesis. According to the National Toxicology Program's 11th Report on Carcinogens, published in 2005, (http://ntp.niehs.nih.gov/ntp/roc/toc11.html), 246 agents are listed as known or likely human carcinogens, and the great majority of these are chemicals. In the last 35 years, the mechanisms by which chemicals cause cancer have been unraveled and reveal striking similarities to the properties responsible for UVR carcinogenicity, namely DNA damage, selective cytotoxicity, and immune suppression. The carcinogenic potential of coal and petroleum derivatives is now firmly established as a result of experimental animal studies and epidemiologic reports. Petroleum products and grease, as well as insecticides, herbicides, and fungicides, are particularly pathogenic for SCC, while fiberglass and dry-cleaning agents increase the incidence of BCC.[3] Cigarette and pipe smokers have an overall twofold increased risk for cutaneous SCC, and the risk increases with the intensity of the tobacco use.[4]

Arsenic exposure is associated with the development of pre-malignant keratoses, Bowen disease, SCC, and BCC, as well as a number of internal malignancies.[5] Although Fowler's solution (1 percent potassium arsenite) is no longer used in medical practice, certain herbal medicines are still a source of arsenic exposure. Occupational exposures to arsenic as a component of agricultural pesticides, sheep and cattle dip, mining and smelting, glass manufacturing, and other industries are well documented. A more insidious source of environmental arsenic exposure is contaminated drinking water or shellfish, and analysis of affected populations shows a dose-dependent increase in skin cancer.[6] Mouse models have provided evidence for an interaction of ingested arsenic acting as a co-carcinogen with solar radiation to increase the frequency and size of cutaneous carcinomas and reduce the latency period.[7,8]

A variety of medications have been associated with the development of skin cancer. Systemic treatment with immunosuppressive agents results in an increased incidence of both benign and malignant skin lesions,[9] which is generally attributed to reduced immune surveillance of nascent tumor cells. However, a more specific mechanism predisposing to skin cancer has been proposed for azathioprine, which may sensitize DNA to ultraviolet A radiation via its metabolite, 6-thioguanine, leading to the production of mutagenic reactive oxygen species.[10] Topical nitrogen mustard also increases the risk of developing skin cancer. Despite the clear-cut association between occupational exposure to tars and skin cancer, the use of crude coal tar in the treatment of psoriasis appears to pose a relatively low risk for the development of skin tumors. In contrast, the use of ionizing radiation to treat a variety of skin diseases increases the risk of BCC in all treated patients and SCC in individuals with sun-sensitive skin.[11]

Systemic administration of psoralen and ultraviolet A light (PUVA) is associ-

TABLE 110-1
Environmental Agents Associated with the Development of Human Skin Cancer

AGENT	INDIVIDUAL AT RISK	ROUTE OF EXPOSURE	TUMOR TYPES
Ultraviolet radiation	General population	T	BCC, BD, SCC, M
Cigarette smoke	Smokers	T or S	SCC
Soot	Chimney sweep	T	SCC
Coal tar, pitch	Coker of coal, steelworker	T	SCC
Petroleum oils	Machinist, textile worker	T and S	SCC
Arsenic	Agriculture worker, etc.	S and/or T	BD, SCC, BCC
4,4′-Bipridyl	Pesticide manufacturer	T	SCC, BD
Polychlorinated biphenyl	Petrochemical worker	T or S	M
Dry-cleaning reagents	Dry cleaners	T or S	BCC
Fiberglass	Insulators	T	BCC
Psoralen (PUVA)	Psoriasis patient	T and S	SCC, BCC, M
Nitrogen mustard	Cutaneous T-cell lymphoma patient	T	SCC
Immunosuppressants	Transplant recipients, etc.	S	SCC, BCC
Ionizing radiation	Various skin disorders	T	BCC, SCC

BD = Bowen disease; BCC = basal cell carcinoma; M = melanoma; PUVA = psoralen and ultraviolet A; S = systemic; SCC = squamous cell carcinoma; T = topical.

ated with a dose-dependent increase in the risk of developing cutaneous SCC that persists after discontinuation of therapy.[12]

THE NATURE OF CHEMICAL CARCINOGENS: CHEMISTRY AND METABOLISM

How can such a diverse group of chemical and physical agents contribute to cutaneous cancer when the great majority of environmental agents to which humans are exposed are not carcinogenic? We now know that carcinogens can be genotoxic, non-genotoxic, or both.[16] Genotoxic carcinogens have high chemical reactivity (such as alkylating agents like nitrogen mustard) or can be metabolized to reactive intermediates by the host (such as petroleum products). They form covalent adducts with macromolecules and target DNA in the nucleus and mitochondria.[17] Because there is a good correlation between the ability to form covalent DNA adducts and the potency to induce tumors in laboratory animals, DNA is considered the ultimate target for most genotoxic carcinogens. The interaction with DNA is not random, and each class of agents reacts selectively with purine and pyrimidine targets.[17] Furthermore, targeting of carcinogens to particular sites in DNA is determined by nucleotide sequence, by host cell, and by selective DNA repair processes making some genetic material at risk over others. As expected from this chemistry, genotoxic carcinogens are potent mutagens, particularly adept at causing base mispairing or small deletions, leading to missense or nonsense mutations. Others may cause macrogenetic damage such as chromosome breaks and large deletions. In all cases, mutations detected in tumors represent a combination of the effect of the mutagenic change on the function of the protein product and the effect of the functional alteration on the behavior of the specific host cell type.

A number of chemicals that cause cancers in laboratory rodents and contribute to human skin cancer incidence are not demonstrably genotoxic.[18] Synthetic pesticides and herbicides, dry-cleaning reagents, and arsenic may fall within this group. The mechanism of action by non-genotoxic carcinogens is controversial and may be related in some cases to toxic cell death and regenerative hyperplasia. Induction of endogenous mutagenic mechanisms such as DNA oxyradical damage,[19] depurination of DNA, and deamination of 5-methylcytosine may contribute to carcinogenicity of these agents. Non-genotoxic carcinogens may interfere with host protective mechanisms as has been suggested for the action of arsenic in suppressing DNA repair or inhibiting the activity of tumor suppressor genes.[7] Thus, non-genotoxic carcinogens may serve as modifiers in concert with genotoxic agents such as UVR.

A number of metabolic pathways activate or detoxify carcinogens and procarcinogens (chemicals that can be transformed into active carcinogens).[20] These pathways are complex and interactive,[21] and genetic polymorphisms both in animal models and humans contribute to cancer susceptibility.[22] In general, metabolic activation of carcinogens involves oxidation at carbon–carbon double bonds or saturated carbon atoms, or oxidation or reduction at nitrogen moieties, yielding reactive intermediates that bind to DNA. Conjugations are also frequent intermediates of metabolism of many carcinogens and can be both activating and detoxifying pathways.[21] Metabolic activation of carcinogens and the polymorphic nature of metabolic activity among individuals provide an approach to estimate individual risk profiles for particular exposures. Furthermore, a number of metabolic pathways are inducible and modified by diet, hormones, and additional exposures, adding further complexity to the process of carcinogenesis.

HEREDITARY CANCER SYNDROMES

If DNA is the target for carcinogens, and mutagenesis is the underlying mechanism of cancer pathogenesis, how do we determine the genetic targets that contribute to the phenotype of cutaneous neoplasms? Considerable insight into the genetic basis of sporadic skin cancers has come from the elucidation of specific genes or genetic loci that define hereditary skin tumor syndromes (Table 110-2).[23] In particular, the importance of DNA as a target for carcinogenesis was strongly supported by the discovery of defects in DNA repair genes that comprise the complementation groups of skin-cancer-prone xeroderma pigmentosum (XP) families.[24,25] (see Chaps. 109 and 140). At least six independent genes on distinct chromosomal loci define proteins involved in nucleotide excision repair, a process critical for the protection of DNA against both UVR and chemical carcinogen-induced damage.[26] Among these are proteins that recognize and bind to sites of DNA damage (XPA, XPC, XPE), helicases (XPB, XPD), and endonuclease components (XPG, XPF), defects in any of which give a skin-cancer-prone phenotype. Potential polymorphisms with functional consequences in these and other DNA repair genes may contribute to susceptibility states in the general population as well.[27–29] Examination of SCCs and BCCs from XP patients has also revealed potential target genes for cancer induction because signature mutations in patched homolog 1 (*PTCH1*), *RAS*, *p53*, and *INK4a-ARF* (alternative reading frame) have been found with high frequency.[30] Chromosomal mapping studies in the basal cell nevus syndrome (see Chap. 116), coupled with genetic and functional studies in *Drosophila* and mice, implicated mutations in the *PTCH1* gene and other defects in the Hedgehog (Hh) signaling pathway in the development of hereditary and sporadic BCCs,[31] and a variety of internal malignancies.[32] All of these tumors are characterized by heightened levels of Hh signaling activity. The *INK4a-ARF* locus, specifically mutations in the *INK4A* gene, was identified in the etiology of melanoma[33] through mapping of the inheritance pattern of familial melanoma. Detection of specific mutations in Cowden syndrome [phosphatase and tensin homolog (*PTEN*)],[34,35] Muir-Torre syndrome [mutS homolog 2 (*MSH2*), mutL homolog 1 (*MLH1*)],[35,36] multiple cylindroma [cylindromatosis (*CYLD1*)],[37] multiple trichoepithelioma [cylindromatosis (*CYLD1*)],[38] Birt-Hogg-Dubé syndrome [folliculin (*FLCN*)],[39] sporadic pilomatricomas [β-catenin (*CTNNB*)],[40] and sebaceous tumors [lymphoid enhancer-binding factor 1 (*LEF1*)][41] have illuminated genetic defects associated with the development of adnexal tumors. The delineation of the specific genes mutated in other syndromes where locus mapping is confirmed (see Table 110-2) should provide even more insight into the molecular pathogenesis of a broader spectrum of skin neoplasms.

ANIMAL MODELS VERIFY THE GENETIC BASIS FOR CUTANEOUS NEOPLASMS

Using human hereditary cancer syndromes as a guide, genetically based animal models have been developed that validate the contribution of individual genes to human cancer susceptibility by prospective experimental analysis.[42] These models have also contributed to the un-

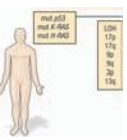

TABLE 110-2
Gene Targets for Mutations in Hereditary and Sporadic Cutaneous Cancers

GENE	FUNCTION	LOCUS	TUMOR TYPE	SYNDROME	SPONTANEOUS
P53	DNA repair, apoptosis, cell cycle regulation	17p13.1	BCC, SCC	Li-Fraumeni (but no increase in skin cancers)	Yes
XPA, XPB	DNA repair	9q22.3, 2q21	BCC, SCC, melanoma	Xeroderma pigmentosum	Possible
XPC, XPD	DNA repair	3p25, 19q13.2-q13.33	BCC, SCC, melanoma	Xeroderma pigmentosum	Possible
XPF, XPG	DNA repair	16p13.3-p13.13, 13q33	BCC, SCC, melanoma	Xeroderma pigmentosum	Possible
PTCH1	Hedgehog receptor	9q22.3	BCC, trichoepithelioma	Nevoid basal cell carcinoma	Yes
SMO	Hedgehog effector	7q31-q32	BCC	?	Yes
$p^{16INK4A}$	Cyclin-dependent kinase inhibitor	9p21	Melanoma, SCC	Familial melanoma	Yes
CTNNB (*β-catenin*)	Cell–cell adhesion, transcription factor	3p22-p21.3	Pilomatricoma	?	Yes
LEF1	Transcription factor	4q23-q25	Sebaceous tumors	?	Yes
CYLD1	Nuclear factor kappa B inhibitor	16q12-q13	Cylindroma	Multiple cylindroma, multiple trichoepithelioma	Yes
PTEN	Phosphatase	10q23.3	Trichilemmoma	Cowden	Unknown
MSH2	Mismatch repair	2p22-p21	Sebaceous gland carcinoma	Muir-Torre	Unknown
MLH1	Mismatch repair	3p21.3	Sebaceous gland carcinoma	Muir-Torre	Unknown
FLCN (*folliculin*)	?	17p11.2	Fibrofolliculoma	Birt-Hogg-Dubé	Unknown
?	?	9p21	Trichoepithelioma	Multiple trichoepithelioma	Unknown
?	?	Xq24-q27	BCC	Bazex	Unknown
?	?	9q31	Keratoacanthoma	Ferguson-Smith	Unknown

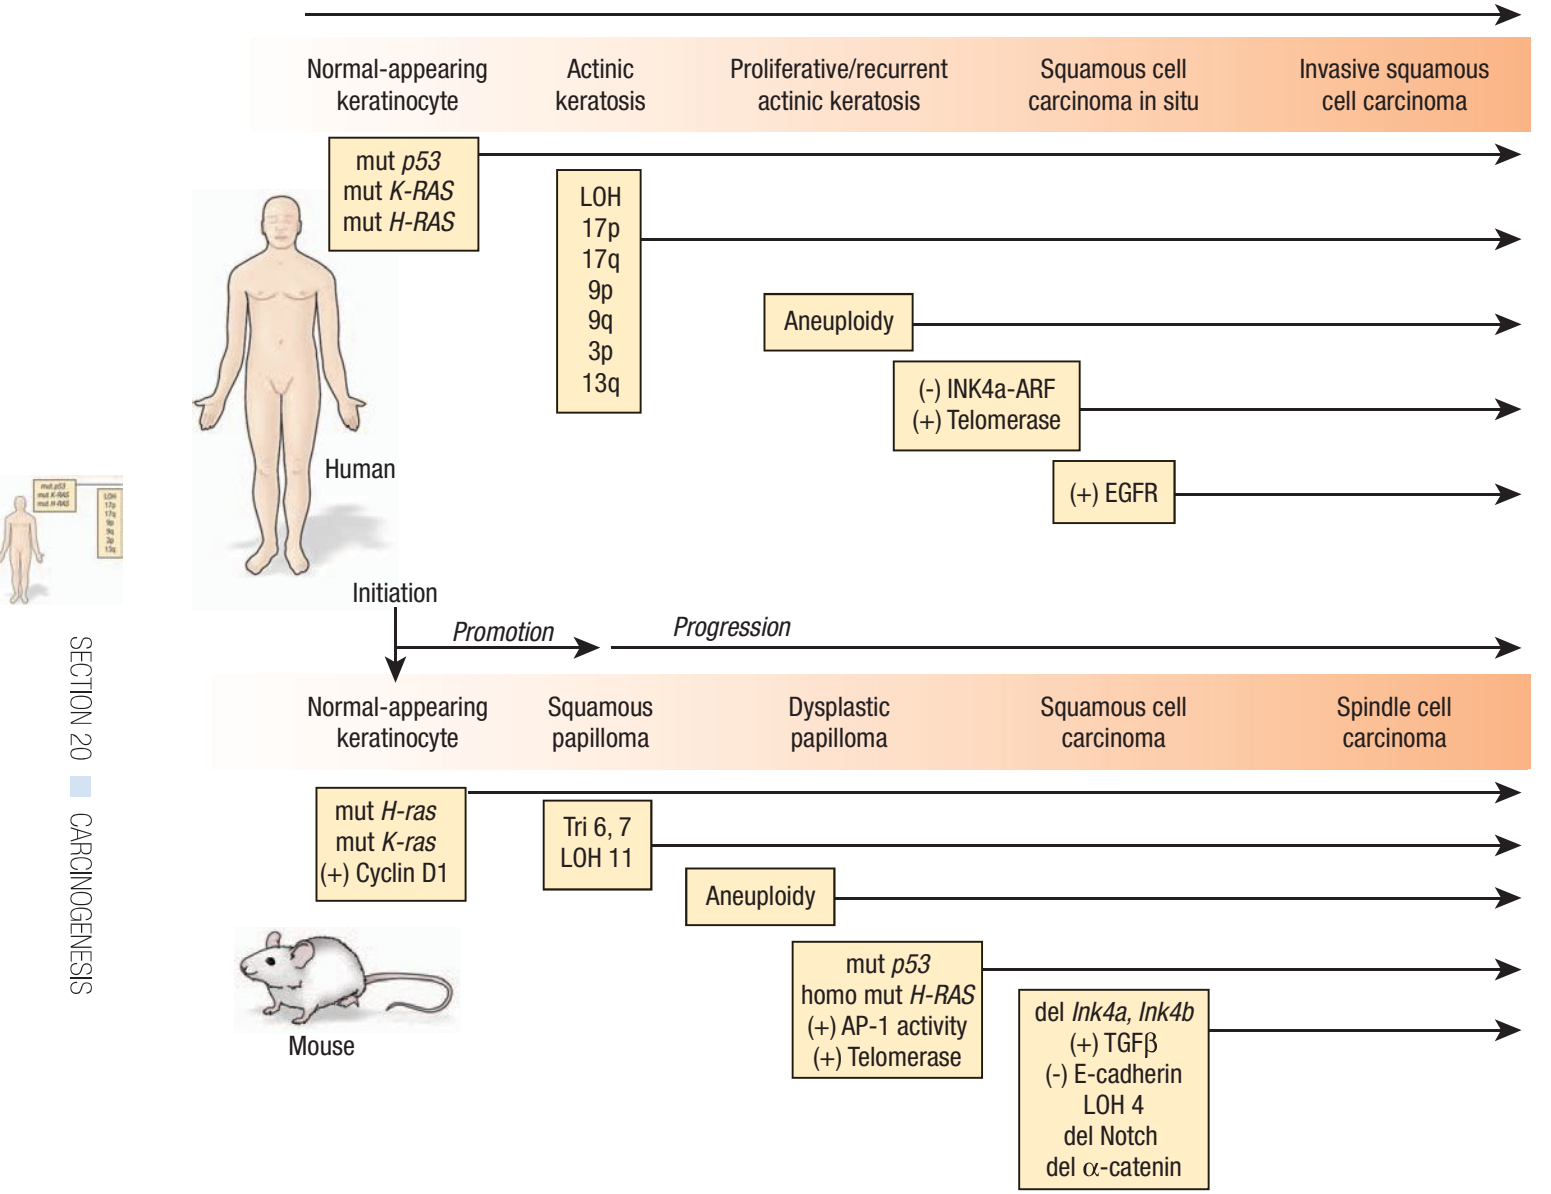
derstanding of gene–environment interactions by testing the influence of chemical and physical carcinogens on tumor development in the setting of an altered genetic makeup. The discovery of inactivating *PTCH1* mutations and activating smoothened homolog (*SMO*) mutations in BCCs led to the development of several mouse models exploring the role of deregulated Hh signaling in BCC tumorigenesis.[31] Keratinocyte-targeted overexpression of sonic hedgehog (SHH)[43,44] or an activated form of the Hh pathway signaling molecule SMO (M2SMO)[45,46] resulted in the development of basal cell–like proliferations or follicular hamartomas in mouse skin. Overexpression of SHH in human keratinocytes grafted onto severe combined immunodeficiency mice also resulted in BCC-like lesions.[47] Mice with heterozygous disruption of the *PTCH1* gene have features in common with basal cell nevus syndrome patients,[48,49] including microscopic hair follicle–derived tumors and various macroscopic skin tumors, including BCCs, after treatment with UVR or ionizing radiation.[50,51] When GLI1 or Gli2 transcription factors, which are nuclear effectors of Hh signaling, are targeted to mouse keratinocytes, multiple skin tumors develop. GLI1 mice display a variety of follicle-derived tumors with relatively few BCCs,[52] whereas Gli2 mice develop BCCs exclusively.[53] Interestingly, when Gli2 expression was extinguished in gene-switch mice, BCCs regressed but left behind a subset of residual tumor cells, at least some of which may be able to form growing tumors when the Hh pathway is re-activated.[54] Collectively, these findings provide strong evidence supporting the notion that constitutive Hh signaling plays a key role in, and may be sufficient for, BCC development.

The multistage induction of cutaneous SCC (Fig. 110-1)[55] and the absence of a hereditary syndrome that specifically imparts uniquely high susceptibility to this lesion have made the delineation of specific genetic loci involved in SCC induction more complex. Nevertheless, the analysis of genetic defects in human SCCs has focused attention on specific targets such as DNA repair genes, *RAS*, *p53*, *p16*(*INK4A*), and the epidermal growth factor receptor (EGFR) pathway. Significant progress has been made in defining pathways capable of driving NMSC development using reconstructed human skin, comprising genetically altered primary human keratinocytes on architecturally intact dermis, grafted onto immunedeficient mice.[56] Using this powerful system for modeling human skin cancer in mice, it has been shown that co-



▲ **FIGURE 110-1** Genetic changes associated with development of cutaneous squamous cell carcinomas (SCCs) in humans and mice. The multistage evolution of invasive SCC in humans is depicted schematically with frequently associated genetic changes. Single base mutations in early lesions frequently are characteristic of ultraviolet light–induced damage, whereas later changes are associated with genomic instability. Increased activity of telomerase (deletion of inhibitor) or epidermal growth factor receptor (EGFR) tyrosine kinase (gene amplification) may also result from epigenetic changes. In chemically induced mouse cutaneous SCC, the multistage evolution to spindle cell tumors in this model is highly ordered both temporally and genetically. Operationally defined stages include initiation, promotion, and progression. *Ras* mutations are characteristic of chemical mutagens used to initiate tumor formation. Early upregulation of cyclin D1 and later upregulation of transforming growth factor-β1 (TGF-β1) occur through epigenetic mechanisms and appear to be important components of carcinogenesis. Note that though *p53* alterations are seen at early stages of human SCC development and ultraviolet radiation–induced mouse SCC development (not shown), *p53* mutations occur at later stages during mouse chemical carcinogenesis. AP-1 = activator protein 1; LOH = loss of heterozygosity; mut = mutant. (Modified from Dlugosz A, Merlino G, Yuspa SH: Progress in cutaneous cancer research. *J Investig Dermatol Symp Proc* **7**:17, 2002, with permission of Nature Publishing Group, London, U.K.)

expression of oncogenic Ras and either cyclin-dependent kinase 4 (Cdk4) or the nuclear factor κB inhibitor, I-κB, in human keratinocytes rapidly leads to invasive SCC development in reconstructed skin grafts.[57,58]

Mouse models for XPA, XPC, and XPE deficiency have been constructed, and all show sensitivity to UVR and enhanced development of SCC after either UVR or chemical carcinogen exposure.[25] A number of other DNA repair–deficient mutant mice are also being tested for cancer susceptibility and may reveal the mechanistic basis for new clinical syndromes by reverse genetics.[59] Mouse mutants targeting the *Ras* gene have revealed important information concerning the contribution of the Ras pathway to particular stages of SCC development. Heterozygous activating *Ras* gene mutations are sufficient to induce a benign squamous papilloma, the precursor to SCC, and the yield of chemically induced tumors in mice genetically deleted in the *H-ras* allele is markedly reduced.[60] Homozygosity of a mutant *ras*

gene is associated with progression to SCC,[61] suggesting that high penetrance of the Ras pathway can recruit additional changes required for progression. Transgenic targeting of oncogenic *Ras* to suprabasal epidermis produces terminally benign tumors while mosaic targeting to basal cells or hair follicle outer root sheath cells encourages progression to SCC,[62] indicating the target cell for early mutations may also determine the tumor phenotype.[63] Although heterozygous p53 inactivation is detected early in human SCC, p53 deletion in mice enhances malignant progression but does not increase benign tumor formation.[64] This may be analogous to the common loss of heterozygosity seen at the *p53* locus later in human SCC development.[65] Of particular interest for human tumor development is the frequent observation that double heterozygotes for p53 deletion and other cancer prone phenotypes (such as DNA repair deficiency) further sensitize mouse skin to tumor induction by UVR or chemical carcinogens. Mice with genetically defined defects in the $p^{16Ink4a}$ locus or its downstream target Cdk4 are sensitive to both squamous tumor and melanoma induction after treatment with carcinogenic chemicals, consistent with defects in this pathway detected in both melanoma and non-melanoma human skin cancers.[66,67]

TABLE 110-3
Examples of Agents Capable of Inducing Skin Cancer in Rodents

Initiating Agents	Promoting Agents
Polycyclic aromatic hydrocarbons	Phorbol esters
• Benzo(a)pyrene[a]	• 12-*O*-Tetradecanoylphorbol 13-acetate
• 7,12-Dimethylbenz(a)anthracene	• Croton oil[a]
• 3-Methylcholanthrene	Aromatics
• Tobacco tar[a]	• Phenol[a]
• Dibenz(a,h)anthracene[a]	• Anthralin[a]
Aromatic amines	• 7-Bromomethylbenz[a]anthracene
• 2-Acetylaminofluorene	Other
Alkylating agents	• Dihydroteliocidin (fungal product)[a]
• β-Propriolactone[a]	• Wounding[a]
• 4-Nitroquinoline-*N*-oxide	• Abrasion[a]
• Bis(chloromethyl)ether[a]	• Cigarette smoke condensate[a]
• Nitrogen mustard[a]	• Benzoyl peroxide[a]
• Cisplatin[a]	• 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin[a]
Nitrosamines and nitrosamides	• Diacylglycerols
• *N,N′*-Dimethylnitrosourea[a]	• Ultraviolet radiation[a]
• *N*-Methyl-*N′*-nitro-*N*-nitrosoguanidine[a]	• Dodecane
Other	• Retinoic acid[a]
• Urethane[a]	
• Dinitropyrene[a]	
• Ionizing radiation[a]	
• Ultraviolet radiation[a]	

[a]Known human exposure.
Documented activity of these agents in rodent carcinogenesis models does not necessarily indicate that they also contribute to skin cancer development in humans.

TUMOR BIOLOGY AND BIOCHEMISTRY

General Principles

Malignant tumors exhibit fundamental alterations in behavior that distinguish them from the normal tissues in which they arise. These differences include a reduced requirement for growth stimuli, impaired response to growth inhibitory/differentiation signals, alterations in apoptosis, delayed or blocked senescence, prolonged angiogenesis, and the capacity for invasion and metastasis.[68] Although one or more of these abnormalities can be detected at different stages of tumor progression and may thus be seen in pre-malignant lesions, all are present in advanced cancers. The driving force behind many of these changes is genomic instability, which facilitates the accumulation of mutations in both oncogenes and tumor suppressor genes that contribute to the observed aberrations in cell function.[69] Although some of these changes are cell-autonomous and can be studied in purified populations of tumor cells, others depend on various additional cell types recruited to participate in the development and progression of cancer in intact organisms. Both the intrinsic alterations in neoplastic keratinocytes and the influence of collaborating cell types in skin tumor biology are being elucidated through the use of powerful experimental models.

From analyses of both human SCC pathogenesis and experimental skin tumor induction by chemical carcinogens, specific pre-malignant and malignant stages have been identified that have typical phenotypic, genetic, and biochemical characteristics (see Fig. 110-1).[70,71] Note that in contrast to SCCs and most other cancers, BCCs do not appear to have precursor lesions or give rise to more aggressive cancers. This is likely related to the observation that the genomic instability that fuels neoplastic progression in other tumor types is largely missing in BCCs, even though a substantial proportion of these tumors harbor p53 mutations that would be expected to facilitate the accumulation of additional genetic defects. SCC starts as a single or small number of specific mutations in a cell that has the capacity to cycle, a change understood as the "initiation" of carcinogenesis. On clonal expansion, initiated cells form a pre-malignant lesion, such as a squamous papilloma in the mouse and an actinic keratosis in the human. Agents that enhance clonal expansion of initiated cells are called *tumor promoters*. Tumor promotion may occur as a consequence of exogenous exposures such as UVR, topical chemicals, medications, infections, or wound healing. Promotion may be an endogenous process influenced by diet, smoking, or immune suppression. The acquisition of additional mutations that provide a growth advantage to the incipient cancer cell may also serve as an autonomous promoting stimulus. Pre-malignant lesions undergo further phenotypic changes, often in a predictable sequence and commonly multifocal within a single lesion.[72] Some foci or lesions progress at a faster rate than others, and these are at highest risk for malignant conversion.[73] Pre-malignant progression encompasses the majority of the tumor latency period before malignant conversion, when the lesion shows invasive properties.

Initiation is usually a low-frequency genetic event and is directly dependent on carcinogen dose. A large variety of carcinogen classes can initiate skin tumors in rodents (Table 110-3). The phenotype of initiated epidermal cells as defined from in vitro analysis includes a defect in maturation, escape from senescence, and an enhanced growth poten-

tial, but initiated cells are still responsive to negative regulation, for example by transforming growth factor-β (TGF-β). At the molecular level, initiation involves an alteration in signal transduction pathways that regulate cellular responses to extracellular signals, and these are internally regulated by proto-oncogenes and tumor suppressor genes.[68,74] Tumor promotion is generally a non-genotoxic stimulus that results in a disturbance of tissue homeostasis.[72] Multiple classes of agents have promoting properties in experimental skin carcinogenesis (see Table 110-3). The mechanisms of tumor promotion include activation of cell surface receptors, activation or inhibition of cytosolic enzymes and nuclear transcription factors, stimulation of proliferation, inhibition of apoptotic cell death, and direct cytotoxicity. Genotoxic carcinogens also can have promoting properties, and repeated exposures to low concentrations of genotoxic carcinogens can induce tumors more effectively than fewer exposures to the same total dose in experimental carcinogenesis.[75] Exogenous tumor promoters can determine the target site for tumor formation, and the promoting action of UVR may in part contribute to skin targeting for tumors when germline mutations produce an initiated state in multiple cell types. In general, initiated cells respond differently to promoters than normal cells, allowing for clonal selection of an initiated population.[76] Pre-malignant progression in an initiated cell clone occurs spontaneously but is accelerated by additional exposures to genotoxic agents, including some cancer chemotherapeutic drugs.[77] Pre-malignant progression in chemically induced mouse skin carcinogenesis is associated with nonrandom, sequential chromosomal aberrations, including amplifications, duplications, deletions, and loss of heterozygosity,[78] suggesting repeated episodes of cell selection, producing specific chromosomal aberrations that become modally dominant within the progressing focus. Thus, at least one function of the relevant genetic events in pre-malignant progression must result in a growth advantage for the affected cell. Epigenetic changes are also associated with malignant conversion, and upregulation of activator protein 1 (AP-1) transcriptional activity, alterations in cell cycle regulatory genes and secreted proteases, changes in gene splicing, and expression of modified cell surface molecules have all been reported. Together, these changes could facilitate migration and invasion that characterize the malignant phenotypes.

TABLE 110-4
Animal Models of Cutaneous Cancer Induction by Exogenous Agents

AGENT	SPECIES	COMMENTS
Basal Cell Carcinoma		
3-Methylcholanthrene	Rat	Other skin tumors
DMBA	Rat	SCC > BCC; lower DMBA doses may increase BCC incidence
Ionizing radiation	Rat	Other skin tumors
Dehydroretronecine	Mouse	BCC > SCC, also internal tumors
Squamous Cell Tumors		
(PAH, NA, AA) + promoter	Mouse, rat	Predominantly papilloma
(PAH, NA, AA) repeated	Mouse, rat	Predominantly SCC
Ultraviolet B	Mouse	*p53* mutations, immune suppression, SCC
Ultraviolet A	Mouse	Papillomas and SCC

AA = aromatic amines; BCC = basal cell carcinoma; DMBA = 7,12-dimethylbenz[a]anthracene; NA = nitrosamines; PAH = polycyclic aromatic hydrocarbons; SCC = squamous cell carcinoma.

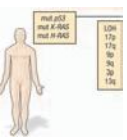
Alterations in methylation of DNA in tumor cells could also contribute to this stage of carcinogenesis.[79]

Pathogenesis of Basal Cell Carcinomas

Animal models for induction of skin tumors by chemical and physical agents have been extremely valuable for exploring mechanisms of carcinogenesis in an experimental setting (Table 110-4). Rats exposed to chemical carcinogens (methylcholanthrene, dimethyl benzanthracene) or ionizing radiation preferentially develop BCCs[80] that are phenotypically similar to human BCCs. In contrast, mice are resistant to BCC induction in the absence of genetic modification, although one study described mouse BCC development following either subcutaneous or topical exposure to dehydroretronecine,[81] an observation that has not been explored mechanistically.

As noted in General Principles, BCCs represent an intriguing exception to the rule of multistage cancer development. Individual tumors typically consist of homogeneous, slowly growing cells that very rarely metastasize, although they can cause extensive local damage (see Chap. 115). Even those rare BCCs exhibiting cellular atypia generally have a benign course,[82] suggesting that the full complement of factors driving malignant progression in SCCs and other neoplasms is not operating in these tumors. BCC cells exhibit abnormalities in growth control and terminal differentiation, induce clinically apparent angiogenesis, and invade their immediate surroundings. However, transplantation studies using human BCCs or transgenic mouse skin with BCC-like lesions[43] suggest that the tumor cells are critically dependent on adjacent stroma for survival. This property may help explain both the lack of BCC metastases and the difficulty in establishing BCC cell lines. Interestingly, in a recent study in which global gene expression profiling was performed on stromal cells derived from tumors versus normal tissue, the bone morphogenetic protein (BMP) antagonist, GREMLIN 1, was found to be highly expressed in BCC stroma but not normal skin.[83] BCCs express BMP 2 and 4, and GREMLIN 1 stimulates growth of cultured BCC cells in vitro, suggesting that GREMLIN 1 may be a key stromal factor needed to support BCC proliferation in vivo, by antagonizing growth-inhibitory effects of BMPs.

Studies performed using human and rodent BCCs have identified additional candidate molecules that may be important in the biology of these tumors. Upregulation of various matrix metalloproteases (MMPs), both in tumor cells and stroma, is likely to be important in the local invasion of BCC and may impact on growth control and other cellular functions given the emerging role of MMPs in regulating signaling at multiple levels.[84] Expression of several adhesion molecules is downregulated in BCCs, and this may account for the characteristic appearance of artifactual clefts between tumor cells and stroma in histologic sections, but the functional significance of this finding in BCC biology has not been established. The anti-apoptotic molecule BCL2 is consistently upregulated in BCCs probably because *BCL2* is an Hh target gene, but this does not appear sufficient to block apoptosis in these tumors as it does in other set-



tings. Indeed, the remarkably slow growth rate of BCCs has been attributed in part to baseline apoptotic cell loss. Expression studies in human BCCs and experimental models suggest the involvement of growth factor signaling pathways such as platelet-derived growth factor[85,86] and EGFR.[87] Several lines of evidence point to components of the cell cycle machinery as potentially critical targets in mitogenic responses to Hh signaling. Keratinocytes overexpressing Shh have enhanced proliferative potential and fail to undergo growth arrest in response to the cell cycle inhibitor p21[88]; in the absence of Shh, Ptch1 interacts with and may sequester cyclin B1, which is required for mitosis and cell cycle progression[89]; and Shh can drive proliferation of immature cerebellar cells by causing prolonged induction of cyclins D1, D2, and E.[90] In skin, Hh-driven proliferation of hair follicle epithelium is likely to be mediated by cyclin D2 and N-Myc.[91] As additional Hh target molecules are uncovered, their potential involvement in keratinocyte tumor biology can be tested using mouse models of BCC that are currently available.

Pathogenesis of Squamous Cell Carcinomas

In addition to deregulated growth control, there is a progressive loss in the capacity for terminal differentiation during SCC progression (see Fig. 110-1), culminating in a tumor with a spindle cell morphology that is indistinguishable from malignancies originating in mesenchymal tissues. Although the mechanisms responsible for defective differentiation at different stages of human skin cancer are not known, there is evidence that deregulation of the protein kinase C (PKC) family of enzymes plays a role in aberrant differentiation of mouse skin keratinocytes expressing the Ras oncogene.[72] PKCδ, which has been implicated in terminal differentiation of normal epidermal keratinocytes, is rendered inactive as a result of tyrosine-phosphorylation in ras-transformed keratinocytes. Restoring PKCδ to its native, non-tyrosine phosphorylated state reversed the block to terminal differentiation in ras-transformed keratinocytes. In addition, overexpression of PKCδ in the skin of transgenic mice inhibits the development of squamous papillomas and carcinomas.[102] In contrast, skin-targeted overexpression of PKCε resulted in less differentiated SCCs that rapidly metastasized to regional lymph nodes.[103] Additional work is needed to better understand the mechanism by which SCC tumor cells evade signals that trigger differentiation of normal keratinocytes.

Prostaglandin metabolism is activated by UVR and is constitutively induced in human SCCs, probably due to overexpression of the enzyme cyclooxygenase 2 (COX-2). Although the mechanism by which changes in prostaglandins influence skin cancer is not clear, they appear to operate at the tumor promotion stage. Telomerase activity is detected in a substantial proportion of human skin cancers, suggesting that these tumor cells are capable of evading cellular senescence, and telomerase-deficient mice are resistant to chemical carcinogenesis.[104] Additional contributors that are likely to be involved in SCC development and progression include mediators of angiogenesis, MMPs, and integrins, as well as other molecules involved in cellular adhesion and migration.

Spontaneous or carcinogen-induced tumor formation on genetically modified mice has revealed genes and pathways that appear to be important in skin cancer induction but would not have been apparent from hereditary cancer syndromes or analysis of human skin cancers. Suprabasal targeting of C-myc in transgenic mice permits suprabasal cells to cycle and produces the papilloma/actinic keratosis phenotype while basal cell targeting of C-myc is not oncogenic.[105,106] Deletion of the cyclin/CDK inhibitor $p21^{waf1}$, a downstream effector of p53, increases the number of benign tumors but not the rate of pre-malignant progression.[107,108] TGF-β suppresses pre-malignant progression but is required for progression from SCC to a spindle cell phenotype.[109–112] Two AP-1 transcription factors influence distinct stages of skin tumor development, where c-Jun is essential for papilloma and c-Fos is essential for SCC development.[113,114] Inhibition of AP-1 activity in benign papillomas prevents progression to carcinomas, but instead converts these lesions into benign sebaceous adenomas,[115] supporting the concept that squamous tumors are derived from progenitor cells with multilineage potential. Additional molecules now implicated in SCC development are ornithine decarboxylase, $p16^{Ink4a}$, $p15^{Ink4b}$, E-cadherin, STAT3, C-myc, Notch, α-catenin, nuclear factor kappa B, and Smad3.[116–124]

Constitutional Modifiers of Carcinogenesis

Inbred mouse strains differ in susceptibility to particular carcinogenic exposures by several orders of magnitude, and transplantation studies indicate sensitivity resides in the target tissue rather than systemically. Genomic scans of backcrossed mice among sensitive and resistant mouse strains indicate that constitutional determinants are multigenic and distinct for benign tumor formation or progression.[125,126] Similar studies indicate genetic loci determine the survival potential for tumor bearing animals.[127] Although the classical genetic approaches are frequently difficult and complex because multiple interacting loci are likely to be involved,[128] use of these methods to identify genes involved in susceptibility and resistance in animal models is likely to reveal determinants important for human skin cancer risk. For example, the identification of a susceptibility gene for mouse skin cancer, Aurora2 (*Stk6*), led to the discovery of a variant of the homologous human gene (*STK15*) that is likely to contribute to cancer development in the colon[129] and other organs.[130] These reports underscore the power of this experimental approach and the concept that studies in skin may be highly relevant to understanding tumorigenesis at other sites, because common mechanisms underlie cancer development in different organs.

Analysis of genetically modified mouse models has also revealed pathways associated with skin tumor susceptibility. Alterations in p53,[64] drug metabolizing enzymes,[131] T-cell function,[132] and DNA repair[59] modify risk for experimental skin cancer induction. Remarkably, polymorphisms in drug metabolizing enzymes and DNA repair pathways,[133,134] and variable responses in the p53 tumor suppressor pathway or in T-cell immunity after exposure to skin carcinogens[135,136] modify the human risk for skin cancer.

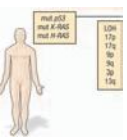
Exogenous Modifiers of Carcinogenesis

In experimental models, antioxidants and agents that alter microsomal metabolism of carcinogens can reduce or prevent tumor initiation by inhibiting the formation of ultimate carcinogens or accelerating their detoxification (Table 110-5). Similar mechanisms may influence ultraviolet light or ionizing radiation mutagenesis through inhibition of mutagenic oxyradicals produced endogenously following exposure. Scavengers prevent reactive mutagens from reaching critical targets. Cell cycle in-

TABLE 110-5
Modifiers of Carcinogenesis

Inhibitor Class	Examples
Inhibitors of initiation	
Antioxidants, scavengers	Butylated hydroxyanisole; butylated hydroxytoluene; selenium; vitamin C; vitamin E; ellagic acid
Inducers of mixed function of oxidase	Polycyclic aromatic hydrocarbons; TCDD; PCB
Inhibitors of mixed function oxidase	α-Napthoflavone; glucocorticoids
Cytotoxic agent	Sulfur mustard
Suppressor of tumor development	Retinoids
Inhibitors of promotion	
Antiproliferative	Anti-inflammatory steroids: dexamethasone, fluocinolone acetonide; inhibitors of arachidonic acid metabolism: indomethacin, celecoxib; inhibitors of polyamine metabolism: α-difluoromethylornithine
Antioxidant	Antioxidants: tert-butylhydroxyanisole, selenium; protease inhibitors: leupeptin, tosyl lysine chloromethylketone; superoxide dismutase; copper (II) 3,5-diisopropylsalicyclic acid
Natural products and dietary factors	Retinoic acid; vitamin D; green tea; silymarin; resveratrol; ursolic acid; caffeic acid phenethyl ester; curcumin; 1,25-dihydroxyvitamin D_3

PCB = polychlorinated biphenyl; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.



hibitors prevent fixation of mutations, allowing for DNA repair while cytotoxic agents kill initiated cells before their expansion into a tumor mass.

A number of agents are effective in the post-initiation phase of experimental tumor development, and some are being clinically evaluated.[137] Inhibitors of COX-2 (celecoxib, indomethacin) and ornithine decarboxylase (difluoromethylornithine) prevent both UVR and chemically induced tumors.[138,139] Although the mechanism of action of retinoids as modifiers of tumor development is not clear, retinoids are effective inhibitors of benign tumor formation in mouse skin carcinogenesis studies and show promise as inhibitors of actinic keratoses and cutaneous tumors in human studies. Predictable and parallel alterations in retinoid receptors in mouse and human cutaneous SCC indicate that the retinoid pathway must be central to cancer development in epidermis.[140,141] Considerable interest has developed in dietary factors that modify skin carcinogenesis. Restricted fat/energy diets reduce papilloma incidence in mouse models[142] and decrease the frequency of actinic keratoses in human populations.[143] Diverse dietary or natural factors, such as green tea, caffeic acid phenethyl ester from honey bee hives, resveratrol from grapes, silymarin from milk thistle, ginger extract, crocetin, and ursolic acid from the rosemary plant, are among natural products shown to be effective inhibitors of skin tumor formation by topical application or systemic exposure.[144] Several of these agents are believed to be antioxidants, but the precise mechanism of inhibition and their effectiveness as chemopreventive agents for human skin cancer remain to be established. Finally, immune response modifiers, such as imiquimod, may be effective for treating some types of skin cancer by modulating cytokine expression.[145]

NOVEL MOLECULAR TARGETS BASED ON NEW MECHANISTIC DATA

The substantial progress in our understanding of factors involved in skin tumor pathogenesis holds the promise of new approaches to treatment and prevention. In addition to the identification of new therapeutic targets, improved strategies are being developed for altering gene and protein function in skin with great selectivity. The abundance and unrivaled accessibility of skin cancers and pre-cancers makes them prime targets for rigorous translational studies and clinical trials. Based on the basic research studies outlined in this chapter, potential therapeutic targets include p53; COX-2; telomerase; EGFR or other receptor tyrosine kinases, and intracellular signaling elements such as SOS; Ras; ornithine decarboxylase; the DNA repair machinery; MMPs; PKC; molecules involved in cell cycle progression, such as cyclins D1 and D2, CDK4, $p^{16INK4a}$, and E2F1; retinoid receptors; and c-Fos. In all cases, the potential efficacy of the proposed treatments would need to be carefully evaluated in animal models or human tissues grown in immune-deficient mice. Because the great majority of cutaneous SCCs are effectively treated using surgery or radiation therapy, perhaps the greatest utility of these studies for dermatology patients would be in the identification of agents capable of preventing the appearance of pre-malignant lesions or blocking neoplastic progression to SCC in predisposed individuals. Along these lines, a double-blind study reported a significant reduction in the development of actinic keratoses and BCCs in XP patients treated topically with the DNA repair enzyme T4 endonuclease V, administered over a 1-year period.[146]

In contrast to the multiple genetic and biochemical changes associated with SCC development, the majority of BCCs have mutations in *PTCH1* or *SMO*, and essentially all of these tumors exhibit uncontrolled activation of the Hh pathway. Because several experimental models suggest that deregulated Hh signaling plays a central role in BCC development and maintenance, this pathway is a prime target for mechanism-based drug development. Cyclopamine and related molecules block Hh signaling by inhibiting SMO function,[147] and have been shown to inhibit growth of BCC-like tumors[148,149] and other "Hh-activated" tumors in pre-clinical studies.[150,151] However, Hh is a crucial embryonic signaling pathway[152] whose inhibition causes profound developmental defects, so attempts to treat or prevent human BCCs by modulating this pathway will need to be approached with care. Given the recent advances in our understanding of NMSC, it seems likely that new, rationally designed medical approaches for intervention will soon be available for these common neoplasms.

CHAPTER 111

Oncogenes, Tumor Suppressor Genes, and Viral Carcinogenesis

Nicole Basset-Séguin
Celeste Lebbé
Charlotte Proby
Alan Storey

This chapter discusses major viruses implicated in skin cancer (Table 111-1), the evidence of their role, what is known about their mechanism of action, and how they can be controlled by preventive and/or therapeutic approaches.

INTRODUCTION TO ONCOGENES AND TUMOR SUPPRESSOR GENES

Studies looking at the mechanisms by which viruses induce tumors discovered oncogenes critical for cell transformation. Oncogenes derive from normal cellular genes referred to as *pro-oncogenes* that encode for various proteins involved in positive control of cell proliferation, such as growth factors, growth factor receptors, signal transduction proteins, and transcription factors.[1] These genes were first identified by studying retroviruses in animal models.[2] Retroviruses belong to the class of RNA viruses and convert their genetic information into DNA after infection of the host cell. Later, the human counterparts of retroviral oncogenes were recognized. Other retroviruses lack their own viral oncogene but integrate their viral DNA near a proto-oncogene, leading to its deregulated expression. It has been recognized for some time that retroviruses acquired their viral oncogenes by their capacity to integrate into and then be excised from the DNA of the host cell, allowing the virus to pick up and modify cellular genes through amplification, mutation, and deletion, thus converting them into transforming genes when reintroduced back into a host cell. The oncogenes of retroviruses derive from genes that are highly conserved in evolution. Deregulation of one or more proto-oncogenes, rendering them constitutively active, occurs in a wide variety of human and animal tumors, regardless of etiology.

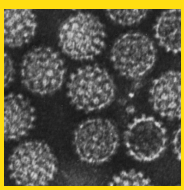
In contrast to retroviruses, DNA viruses contain oncogenes that are not derived from cellular proteins. Examples include the epidermal growth factor homolog of pox viruses or the middle T antigen of polyomavirus that can activate proteins encoded by cellular proto-oncogenes. Large DNA tumor viruses have genes with cellular homologues, but small DNA tumor viruses have instead small multifunctional proteins with no cellular homolog.

Other genes identified initially from genetically susceptible cancer-prone patients or family cancer syndromes, such as retinoblastoma (Rb)[3] or Li-Fraumeni syndrome (p53), have been characterized and are called *tumor suppressor genes*. The physiologic role of these genes is to negatively control cell growth. Studying the relationship of

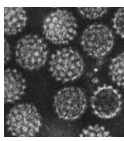
TABLE 111-1
Virus-Associated Cancer in Humans

Virus Group	Virus	Cancer
Hepadnavirus	Hepatitis B	Hepatocellular carcinoma
Hepadnavirus	Hepatitis C	Hepatocellular carcinoma
Herpesvirus	Herpesvirus type 4 (Epstein-Barr virus)	Burkitt lymphoma, nasopharyngeal carcinoma
Herpesvirus	Herpesvirus type 8	Kaposi sarcoma lymphoma
Papillomavirus	Oncogenic types, especially 5, 8, 16, 18, 31, 33, 35, 58	Cervical, vulval, vaginal, penile, and anal carcinoma; cutaneous squamous skin carcinoma in epidermodysplasia verruciformis, and perhaps other non-melanoma skin carcinomas
Retroviruses	Human T-cell lymphotropic virus type 1, human immunodeficiency virus	T-cell lymphoma and leukemia
Simian virus	SV40	Ependymoma, plexus choroid tumors, mesothelioma, bone tumors

VIRUSES AND CANCER AT A GLANCE

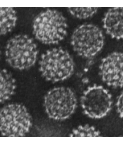


- At least 10 percent to 15 percent of human cancers are induced by viruses. Viruses may directly induce malignancy via introduction of a viral oncogene or inactivation of a host tumor suppressor gene.
- Iatrogenic immunosuppression, solar irradiation, or other factors may cooperate with viral infection to cause malignancy.
- Viral vaccines may reduce the incidence of specific cancers.



specific tumor suppressor genes with certain viral proteins increased greatly the knowledge of how viruses can be implicated in cancer in general and more particularly in skin cancer. For example, the large T antigen of SV40 virus or the E1A and E1B proteins of adenoviruses and, of more importance in dermatology, the E6 protein of oncogenic human papillomaviruses (HPVs), bind to and functionally inactivate cellular tumor suppressor genes, turning off the physiologic negative control of cell growth, thus promoting cell transformation.

VIRUSES IN DERMATOLOGIC TUMORS



Human Papillomaviruses (See Chap. 196)

HUMAN PAPILLOMAVIRUS: STRUCTURE AND MECHANISMS OF ACTION IN TRANSFORMATION HPV can be categorized according to sequence variations in E1, L1, E6, and E7 viral genes.[4] To date, more than 120 HPV types have been characterized and classified into five subgroups—A, B, C, D, and E—with differing host specificity, tissue tropism, and oncogenic potential. A and B families include mucosal and cutaneous HPV types. A and B families include mucosal and cutaneous HPV types. These two families contain both high-risk HPV, such as mucosal HPV-16, -18, -31, -33, -35, and -58, as well as HPV-5 and -8 associated with epidermodysplasia verruciformis (EV), and low-risk HPV found in benign condyloma (HPV-6, -11) or common cutaneous viral warts (such as HPV-1 and -2).

In vitro studies have allowed the demonstration of the transforming role of E6 and E7 proteins of high-risk HPVs, particularly those of mucosal viruses. In anogenital lesions, HPV DNA is often found in an episomal state in benign lesions and is frequently integrated in invasive lesions. This integration may play a role in transformation, as it frequently disrupts the coding sequences of E1 and E2 genes. Because the E2 transcriptional regulator binds to cognate recognition sequences in HPV promoters to regulate expression of the E6 and E7 genes, its disruption can lead to dysregulated E6 and E7 expression.

The transforming property of the E7 protein of high-risk HPV was the first to be demonstrated. E7 binds a member of the Rb family, p105Rb, which dissociates p105Rb-E2F complexes by inducing proteosomal degradation of p105Rb and liberates transcription factors involved in the beginning of the cell cycle.[5] Interestingly, it has been shown that substitution of a single amino acid in the E7 protein, affecting its ability to bind and degrade Rb protein family members, could explain the difference in transforming capacity of E7 between high- and low-risk HPV.[6,7]

The E6 protein of high-risk HPV is also implicated in transformation. It was first demonstrated that cooperation between the E6 and E7 protein was more efficient in inducing cell transformation than either protein alone.[8]

The first target of the E6 protein that was identified was the p53 tumor suppressor gene protein, a key regulator of the cell cycle often referred to as the "guardian of the genome." It was demonstrated that the E6 protein of high-risk mucosal HPV is able to induce p53 degradation through its association with an E3 ubiquitin ligase of the HECT (homologous to E6-AP carboxyl terminus) domain family known as *E6-AP*.[9,10] The degradation of p53 abolishes the p53-dependent induction of cell cycle arrest or apoptosis. Thus, elimination of p53 allows HPV-infected cells to escape apoptosis, thus providing a background in which normal growth restraints are absent. Similar to the E7 protein, it has been shown that only the E6 protein of high-risk HPV but not that of low-risk HPV was able to degrade p53. Moreover, it has been shown that E6 can sequester the p53 protein in the cytoplasm, inactivating it without inducing its degradation.[11]

Additionally, HPV E6 proteins of cutaneous HPV types that, in marked contrast to anogenital viruses, do not promote p53 proteolysis are nevertheless able to inhibit p53-induced apoptosis. An additional anti-apoptotic activity of the E6 protein is its inhibition of the Bak protein, a key regulator of the mitochondrial apoptotic pathway (reviewed in ref. 12).

A cross-talk between the Rb and p53 pathways and the interaction of E6 and E7 proteins in both pathways add to the synergic role for E6 and E7 in cell transformation. Cooperation between E6 and E7 proteins and the ras family of oncogenes has also been shown. Other cellular targets are probably involved in the transforming capacity of E6 and E7 proteins.

Besides their role in the control of cell cycle key regulators, E6 proteins of high-risk HPV have been shown to play an important role in genomic stability and, more precisely, DNA repair. Skin cells expressing the high-risk HPV-5 E6 protein are defective in ultraviolet (UV) B–induced DNA damage repair.[13]

Transgenic animal models for HPV have also been generated. The first one was developed by Tinsley et al.[14] in 1992 by expressing the early gene region of HPV-1, inducing plantar warts under the K6 promoter. The transgenic murine skin showed epidermal hyperproliferation and abnormal keratinocyte differentiation. More recently, a transgenic mouse model was generated expressing the complete early region of EV-associated HPV-8 in basal keratinocytes under the control of the K14 promoter. Over 90 percent of the transgenic mice spontaneously developed benign skin tumors with significant conversion to squamous cell carcinomas (SCCs),[15] which is remarkable compared to many other HPV-transgenic mice previously developed.

HPV-associated skin diseases are frequent[4] and are discussed in more detail in Human Papillomavirus and Skin Cancers and Human Papillomavirus and Epidermodysplasia Verruciformis.[16]

HUMAN PAPILLOMAVIRUS AND CERVICAL CANCER The close relationship between infection with certain HPV types and the risk of developing cervical cancer was noted initially by zur Hausen in 1977[17] and later confirmed by many fundamental molecular and epidemiologic lines of evidence. It is now thought that 99.7 percent of invasive SCC of the cervix contain high-risk HPV types.[18] Cervical cancer is therefore the first tumor recognized to be almost exclusively virus-induced.[19]

Epidermoid cervical cancers are the major form of cervical cancer (80 percent to 95 percent) and represent a major public health problem, especially in developing countries.

The importance of oncogenic HPV in cervical cancer renders HPV typing an important clinical tool for the treatment and follow up of patients with HPV-associated cervical morphologic abnormalities.[20]

However, it is more the persistence of oncogenic HPV rather than its simple detection that is a major carcinogenic factor.[21,22] Viral load also seems to be important to consider, as the level of high-risk HPV-16 detected by quantitative polymerase chain reaction (PCR) is higher in severe dysplasia when compared to moderate or low dysplasia and even more when compared to normal tissue. However, the importance of the viral load remains controversial and awaits further clarification.

Numerous vaccine strategies have been developed and are currently under clinical application, particularly in countries and populations with high oncogenic HPV prevalence.[23] Prophylactic HPV subunit vaccines based on the ability of the viral L capsid protein to form virus-like particles inducing high levels of neutralizing antibodies have recently been approved by the U.S. Food and Drug Administration. The vaccines target both HPV-16 and HPV-18, between them accounting for approximately 70 percent of cervical cancers. The vaccines have an excellent safety profile, are highly immunogenic, and have conferred complete type-specific protection against persistent infection and associated lesions in fully vaccinated women. The key issues are the definition of the ideal target population and the cost of the vaccines, which need to be sufficiently low for widespread implementation in the developing world where 80 percent of cervical cancer occurs. Other considerations include the length of protection afforded by the current vaccines and whether observed cross-reactivity with other HPV types can be sufficiently protective to prove beneficial.

HUMAN PAPILLOMAVIRUS AND OTHER GENITAL CANCER In external anogenital cancers (e.g., vulvar or penile cancer), the role of oncogenic mucosal HPV is also well established, and the same mechanisms of action in transformation as identified in cervical cancer are implicated. However, unlike cervical cancer, HPV is not the only carcinogenic factor involved in external anogenital cancers: the inflammatory dermatosis, lichen sclerosus (see Chap. 63), is also implicated. In HPV-derived external anogenital cancer, little or no mutation of cell cycle regulator genes, such as p53 and the $p^{16ink4\text{-}ARF}$ locus, is observed, whereas in lichen sclerosus–derived tumors, mutations of both pathways are common and may relate to the aggressive nature of such tumors.[24]

HUMAN PAPILLOMAVIRUS AND SKIN CANCERS As with cervical cancers, HPV DNA is detected frequently in skin carcinomas of immunocompetent (30 percent to 35 percent) and immunocompromised (75 percent) individuals. However, many different HPV types have been found in these tumors, and no pattern of high-risk or low-risk HPV types has yet emerged for skin cancer. Furthermore, although HPV DNA is frequently detected in swab samples collected from the superficial layers of skin tumors, significantly less HPV DNA is found in incisional biopsies of the same tumors (reviewed in ref. 25), advising cautious interpretation. A possible explanation is that tape stripping would remove the outer epidermal layers that contain the productive viral infection and so might be expected to reduce the viral DNA present. Perhaps of more significance are in situ hybridization studies[26] and viral load studies, both of which find that detection of active viral infection in skin tumors is patchy and suggest that DNA detection studies may be overly sensitive and not necessarily a reliable reflection of active HPV infection. EV-associated HPV types (now termed *β-HPVs*) are also frequently reported in normal skin, in hair follicles, or even in benign dermatoses such as psoriasis. In both immunocompetent and immunosuppressed patients, the role of HPV in skin cancer remains controversial, but evidence for a viral role promoting the mutagenic effects of UV damage is increasing. The presence of β-HPVs may be considered a risk factor together with the pattern and amount of sun exposure, sun sensitivity (skin color), country of residence, and number of sunburning episodes. In immunosuppressed patients, the duration and type of immunosuppressive drugs used are important additional factors. Most recent studies confirm a prevalence of β-HPVs of 70 percent to 80 percent in organ transplant–associated SCC and approximately 30 percent of immunocompetent SCC (reviewed in ref. 27). In skin cancer, the typical high-risk mucosal HPV (HPV-16) is found only in in situ or invasive epidermoid periungual carcinoma (see Chap. 114). In that situation, the presence of high-risk HPV-16 is thought to be by contact with the genital area and is equivalent to a sexually transmitted disease state.

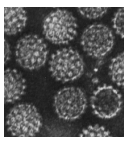
HPV-38 has been detected significantly more often in skin tumors (50 percent) than in normal skin (10 percent). Additionally, HPV-38 has been found in vitro to actively support immortalization of cultured human keratinocytes.[28] However, the importance of HPV-38 in skin tumor development awaits further elucidation.

Overall, the role of HPV in skin cancer is still unclear, although a role in combination with UV radiation seems likely in the early stages of tumor development.

HUMAN PAPILLOMAVIRUS AND EPIDERMODYSPLASIA VERRUCIFORMIS (See Chap. 196) EV is a rare autosomal recessive disease characterized by an early onset and lifelong occurrence of multiple flat warts, pityriasis-like macular lesions, and occurrence of skin cancer, mostly on sun-exposed skin. EV-type HPV integration is rare in skin cancer except in metastases. Additionally, the E6 protein of EV HPV does not degrade p53, and its E7 protein has little transforming potential in vitro,[29] although the E7 gene of HPV-5, another β-HPV type, was shown to induce the invasion of keratinocytes into the dermis in a skin-equivalent model. The invasion was accompanied by the destruction of basement membrane components, most likely through the induction of specific matrix metalloproteinases.[30] The E6 protein of β-HPV may interact with the pro-apoptotic Bak protein to promote cell transformation, but this needs to be further understood.[12,16]

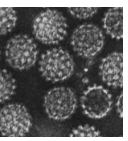
The first breakthrough in functional studies was the demonstration that a number of different HPV E6 proteins can effectively block the epidermal apoptotic response to UVR,[31] suggesting a mechanism whereby a diverse group of HPV types might promote tumor development in cooperation with the mutagenic effects of UVR. Corresponding in vivo studies have shown that the balance between proliferation and apoptosis is altered by HPV status: HPV-positive tumors have significantly reduced apoptotic rates compared to HPV-negative lesions,[32] apparently related to degradation of Bak.[33] Bak is located in the outer mitochondrial membrane and assembles into multimeric complexes during apoptosis, acting as a "gateway" to allow transit of apoptotic effector molecules, such as cytochrome c, thereby controlling initiation of the apoptotic cascade.[12]

Additional type-specific viral activities that interfere with the cellular response to UVR can be postulated. For example, keratinocytes expressing high-risk HPV-5 E6 protein, but not the E6 protein of benign cutaneous HPV types -10 and -77, take longer to repair UV-induced thymine dimers and therefore enter the cell cycle harboring such DNA damage, specifically bypassing the G1/S checkpoint[13] (see Chap. 112). Of the HPV types tested, only the cancer-associated HPV-5 E6 and not the E6 proteins of non–cancer-associated EV HPVs, such as types -23, -24, and -49, displayed this phenotype. Similarly, E6 proteins of HPV-1 and HPV-8 have been shown to interact with the XRCC1 protein that is involved in the repair of DNA single strand breaks.[34] Perhaps E6 can help cells overcome cell cycle checkpoints, allowing the propagation of UV-induced DNA damage that, in



turn, increases the likelihood of accumulating errors in key genes and the acquisition of genetic instability, both driving skin tumorigenesis in the context of continuing UV exposure.[16]

Two susceptibility loci have been identified in EV patients, on chromosomes 17q and 2. In the EV1 locus, Ramoz et al. identified two new genes, EVER1 and EVER2, in which mutation seems to segregate with the disease.[35] In unaffected individuals in whom EV HPV type can be found in normal skin, no mutation in EVER1 or EVER2 is found, and therefore no EV lesion is seen, whereas in EV patients bearing EVER1 or EVER2 mutations, EV lesions develop. The long splice isoforms of EVER1 and EVER2 are identical in sequence and genomic localization to the transmembrane channel–like (TMC) proteins TMC6 and TMC8.[36] Additionally, it has been shown that EV patients have a deficiency in cellular immunity against EV HPV, which adds another carcinogenic immunologic factor to explain transformation in such patients.[37]



Herpesvirus in Skin Tumors

HUMAN HERPESVIRUS 8 AND KAPOSI SARCOMA AND LYMPHOMA Kaposi sarcoma herpesvirus 8 (KSHV) or human herpesvirus 8 (HHV-8) is, together with Epstein-Barr virus, a member of the herpesvirus family known for its ability to induce neoplasia in natural or experimental hosts. Strong epidemiologic studies favored the role of a sexually transmissible agent involved in KS pathogenesis (see Chap. 128). It was only in 1994 that Chang et al.,[38] using representational difference analysis, identified two fragments of an unknown herpesvirus in a biopsy from an acquired immunodeficiency syndrome–related KS, soon to be classified as the first human 2-herpesvirus or rhadinovirus.

HHV-8 has evolved into five variants (A through E) that probably emerged after population migrations over the last 40,000 years. Such variants may have functional implications, although no association between variants and pathologies have been identified so far.[39,40] HHV-8 has a long unique region of approximately 145 kilobases, with at least 87 genes and a variable number of terminal repeats. Apart from genes involved in structure, virion maturation, DNA replication, nucleotide metabolism, and gene regulation, HHV-8 encodes for human gene homologues probably acquired from human cellular complementary DNA. Due to structural modifications, some of these pirated genes have become constitutively active and are oncogenes. After infection, HHV-8 remains in a latent state in the host cell (circular episomes), with minimal gene expression (latent genes). Lytic infection can occur in vivo and can be reproduced in vitro using pharmacologic agents such as histone deacetylase inhibitors.[41]

HHV-8 cellular homolog genes can be classified according to their biologic function as cell cycle regulators; stimulators of mitosis; anti-apoptotic, pro-angiogenic, immune-response inhibitors; and stimulators of transdifferentiation.[42]

HUMAN HERPESVIRUS 6, HUMAN HERPESVIRUS 8, AND LANGERHANS CELL HISTIOCYTOSIS Langerhans cell histiocytosis (see Chap. 148) is a disease characterized by Langerhans cell infiltration of skin and bone, with sometimes severe and multifocal infiltration of many organs, in which case it is best considered a malignant disease. The role of HHV-6 has recently been proposed but remains unproved.[49,50] A recent study searching for an association of HHV-8 with Langerhans cell histiocytosis has failed to demonstrate a causal role of that virus.[51]

HUMAN HERPESVIRUS 1 AND SKIN CANCER One study of the presence of HHV-6 and HHV-1 in DNA samples from 120 nonmelanoma skin cancers and 41 normal skin tissues showed that the risk for individuals with HHV-1 to have basal cell carcinoma and SCC was increased eight and six times, respectively. However, the small number of samples studied as well as the very high prevalence of HHV-1 infection in the normal population precludes firm interpretation of this correlation.[52]

VIRUS-DERIVED FUTURE STRATEGIC THERAPIES

Besides in vaccines such as those developed for "high-risk" HPV infections, the use of viral vectors has now expanded from relatively safe, non-replicating viruses to the use of viruses that replicate preferentially in cancer cells versus normal cells and belong to the so-called *oncolytic viruses*. As these viruses replicate, they lyse their host cells. Cancer cells are ideal hosts for many viruses because they have inactivated the anti-viral interferon pathway or have mutated tumor suppressor genes, enabling viral replication. Adenovirus and herpesvirus simplex specifically mutated to replicate faster in cancer cells are the main replicating human pathogenic viruses used in the clinic. It is hoped that the use of selective replicating viruses that could avoid immune clearance and allow systemic administration will be available in the future for antitumoral treatment strategies. However, specific guidelines are urgently needed for clinical use of such oncolytic viruses.[53]

CHAPTER 112

Carcinogenesis: Ultraviolet Radiation

Douglas E. Brash
Timothy Heffernan
Paul Nghiem

ULTRAVIOLET RADIATION AS A CARCINOGEN

Skin cancer offers our clearest picture of how a carcinogen causes human neoplasia. The basic principles of carcinogen exposure and slow development were discovered when Sir Percivall Pott traced scrotal cancers in adults to childhood employment as a chimney sweep[1] and they also apply to sunlight-induced cancers.[2,3] The process begins with carcinogen exposure, DNA damage, and failure to repair DNA or to apoptotically eliminate a damaged cell.[4–7] A mutant gene arises in a single cell which then expands into a mutant clone.[8] Rare cells of the clone repeat this carcinogenesis cycle to generate mutations in additional genes. Sunlight acts at each of these steps.

Epidemiologic Observations

The lifetime expectation of skin cancer in Australia is ~60 percent.[9] In the southern United States and Hawaii, non-melanoma skin cancers exceed all other cancers combined.[10–12] Basal and squamous cell carcinomas (BCCs and SCCs), and an SCC precursor, actinic keratosis (AK), are most frequent on sun-exposed skin, in outdoor workers, and at lower latitudes.[13–16] SCCs increase more quickly with dose or nearness to the equator than BCCs, and occur later in life, implying that SCC requires more sun-related steps.[16–20] In contrast, one-third of BCCs occur on body sites having only intermittent sun exposure, such as the trunk and legs.[16,21]

Melanoma also depends on sunlight. The relation to latitude is clear,[22–25] yet it is often stated that the predilection for the back and lower legs makes the relation to sunlight uncertain. This predilection reflects the large surface area of back and legs. When expressed as lesions per unit area, melanomas are 10- to 20-fold more frequent on the face and male ears than on intermittently exposed sites such as the lower legs in women, shoulders, back, or neck.[25,26] Melanomas are rare on the buttocks and soles. Melanoma appears to have two distinct origins:

1. A chronic sun damage (CSD) etiology affects the head and neck and is associated with chronic elastosis—a classic indicator of CSD—as well gene amplification of the cell cycle genes *CDK4* and *CCND1*.[27] The slow-growing lentigo maligna melanoma and its precursor, lentigo maligna occur on habitually exposed body sites of light-skinned individuals.[28]
2. A non-CSD route involves intermittent sun exposure of sites such as the trunk. Non-CSD melanomas carry mutations in the *BRAF* or *NRAS* oncogene—upstream regulators of cell cycle genes—and the patients have variant alleles of the melanocortin 1 receptor.[27,29,30] Intermittently exposed body sites are the location of the melanoma increase in recent decades, melanomas in patients younger than age 50 years, and the additional melanomas seen near the equator.[23,25,31] Recreational sunburn may explain these and the twofold higher melanoma incidence in office workers compared to outdoor workers.[32,33]

Sunlight is also implicated by the susceptible population: both classes of skin cancer are more frequent in light-skinned individuals with blonde or red hair who burn rather than tan.[13,34] Compared to black-skinned individuals, non-melanoma skin cancer risk rises ~10-fold in Asians and ~100-fold in Caucasians, with a further 2- to 12-fold risk for blonde or, especially, red hair.[13,34–37] The divergence is less for melanoma, about 1:1:15.[38] In black skin, BCC is rare even in patients with the hereditary nevoid BCC syndrome (NBCCS or Gorlin syndrome).[39] Skin tumors in black patients are often scar-related, but these may be associated with sunlight as well.[36] Melanin-related effects result from less melanin in light skin,[40] less shielding by pheomelanin than eumelanin, and greater production of photosensitized reactive oxygen from pheomelanin.[41–43]

Molecular epidemiology has provided the most direct evidence for ultraviolet radiation (UVR) as the active component of sunlight: UVB signature mutations are present in human BCC, SCC, and AK (see Ultraviolet Radiation Signature Mutations). Mutant cells are associated with elastotic dermis, indicating chronic sun exposure.[44] UVB's effectiveness is due to its ability to partially penetrate the ozone layer and stratum corneum and then be absorbed by DNA.[45] The ozone layer absorbs all but 1 part per million of UVC (used in germicidal bulbs), which otherwise would be lethal; UVA penetrates well but is poorly absorbed by DNA.[45,46] Nevertheless, chronic UVA can induce tumors in mice[47] and malignantly transforms predisposed human cells.[48] The cumulative dose of sunlight required to cause BCC or SCC in adults is fairly large, approximately 10,000 and 70,000 hours of exposure, respectively.[16] Psoriasis patients receiving < 100 UVB treatments [and who had low psoralen and UVA light (PUVA) exposure] had a risk of SCC or BCC on sun-shielded sites slightly above background, and risk was threefold higher with > 300 UVB treatments.[49]

ULTRAVIOLET RADIATION CARCINOGENESIS AT A GLANCE

- Ultraviolet radiation (UVR) from the sun is the most prevalent carcinogen in humans, particularly among Caucasians.
- Annual increases continue in the incidence of all types of skin cancer.
- The importance of exposure timing, dose rate, and total UVR exposure differ between the types of skin cancer.
- Sunlight leaves characteristic mutations that identify key molecular and cellular steps in skin tumor development.
- DNA repair, apoptosis, and cell signaling pathways are critical to preventing skin cancer, and UVR affects each of these processes.
- Genetic polymorphisms in genes for DNA repair, melanin, and free radical scavenging affect skin cancer risk.
- Novel, pathway-based approaches to prevent or treat skin cancer are being developed.
- Educational and behavioral approaches are key to minimizing skin cancer rates in the future.

Some melanomas appear to be independent of sunlight: tumors of the mucosa, palms, soles, and nail beds are equally frequent in whites and blacks, have remained constant while melanomas of the skin have become epidemic, and are not associated with precursor nevi.[50] Ocular melanomas are more frequent in whites than blacks, but do not depend on latitude and have not increased in the last few decades.[51]

The Skin Cancer Epidemic

The incidence of melanoma and non-melanoma skin cancers has doubled each decade since the 1930s.[10,23,25] AK, lentigo maligna, and lentigo maligna melanoma—typically lesions of the middle-aged and elderly—are now seen in young adults. But because cancer requires several events, it is not guaranteed that this increase in skin cancer is caused by an increase in one of the sun-related events. The best evidence for sun exposure is that increases have been greatest for intermittently sun-exposed sites, such as the trunk and limbs, with little change in melanomas of the head and neck.[23,25] Increased recreational exposure is usually blamed. Another suspect has been ozone depletion; because of a steep absorption curve in the UVB region, small changes in ozone concentration greatly affect UVB penetration. (UVC is fortunately still blocked). The Antarctic ozone hole caused a 50 percent ozone reduction over southern Chile and Argentina in the last two decades, with UVB increasing up to 40-fold. Yet skin cancers in these areas are increasing at the same rate as elsewhere.[52,53] The Arctic ozone hole has been offset by screening from air pollutants, yet skin cancers in Scandinavia are rising.[54]

An iatrogenic source of increased skin cancer incidence is PUVA therapy for psoriasis, which increases the risk of SCC eightfold; in some but not all patient cohorts it raises melanoma > 14-fold[55] (see Chap. 239). BCC is not affected. Cancer is now increasing as a result of tanning beds. Individuals whose first sunbed exposure occurred as a young adult, or who had long durations or high frequencies of tanning bed exposure, already have a 70 percent higher risk of melanoma.[56]

CHARACTERISTICS OF ULTRAVIOLET RADIATION–INDUCED CANCERS AND PRECANCERS

In the United States, ~1,000,000 BCCs are diagnosed annually, as well as 100,000 SCCs and 60,000 melanomas.[11,12] Survival differs strikingly. Fewer than 1 in 10,000 BCCs will metastasize and threaten the patient (see Chap. 115). This number increases to 1 in 40 for SCC, with clinical experience indicating that SCCs on sun-exposed skin are less likely to metastasize than those arising in scars.[57] One in seven invasive melanomas is lethal (see Chap. 124). Merkel cell carcinoma (see Chap. 120) is a sun-induced cutaneous neuroendocrine cancer that will kill one in three patients diagnosed with it. Its incidence has tripled in the past 15 years to approximately 1000 per year in the United States.[57a]

The type of exposure preferentially leading to each malignancy differs. Cumulative lifetime sun exposure is strongly associated with SCC incidence.[16,20] BCC and AK instead seem to depend on reaching a certain threshold of UV exposure, often attained in youth, such that sensitive individuals develop BCC at a relatively early age, and the incidence does not increase with further exposure.[16,20,58] Case-control studies link melanoma with intense exposure early in life, with one or two blistering sunburns doubling the melanoma risk (see Chap. 124 and ref. 59). This effect may be an underestimate if, as mentioned in Epidemiologic Observations, melanoma has two origins, one depending on CSD and one on intermittent exposure and sunburns.

Children are particularly sensitive to sunlight: moving from England to Australia before age 20 years confers the higher Australian incidence of AK, SCC, BCC, and melanoma, but the risk is much less when adults immigrate.[60,61] This is not simply due to children spending more time outdoors, as < 25 percent of lifetime exposure occurs before age 18 years.[62] One explanation may be that mutant cells created in youth have more years in which to acquire the additional genetic requirements for cancer.

Precursor lesions for SCC (AK) and melanoma (nevi) are also usually related to sun exposure.[14,15,63–65] Accounting for roughly 3 million physician visits each year in the United States, AKs (see Chap. 113) are the fourth leading cause for a visit to a dermatologist.[66] They typically manifest as 1- to 3-mm scaly papules that involve erythema but often are easier felt than seen. They proceed to SCC in ~1 percent of cases if left untreated.[67] Actinic cheilitis is an analogous precancerous state on the sun-exposed lip. The importance of ongoing sun exposure is made apparent by clinical studies indicating that reducing sun exposure can reduce the number of AKs over a span of months. In randomized sunscreen studies, statistically significant decreases in AKs were seen in the sunscreen group over brief periods.[68,69] Common nevi and especially clinically atypical nevi can be precursors of malignant melanoma, with abundant nevi conferring a 10-fold risk for cancer.[22,70] Acquired melanocytic nevi begin to appear at age 1 to 5 years in proportion to sunlight exposure and are most frequent in individuals with freckles and red hair.[63,64,71] Acquired nevi carry the *BRAF* mutations seen in non-CSD melanomas, but congential nevi instead have *NRAS* mutations.[72]

ULTRAVIOLET RADIATION–INDUCED GENETIC ALTERATIONS

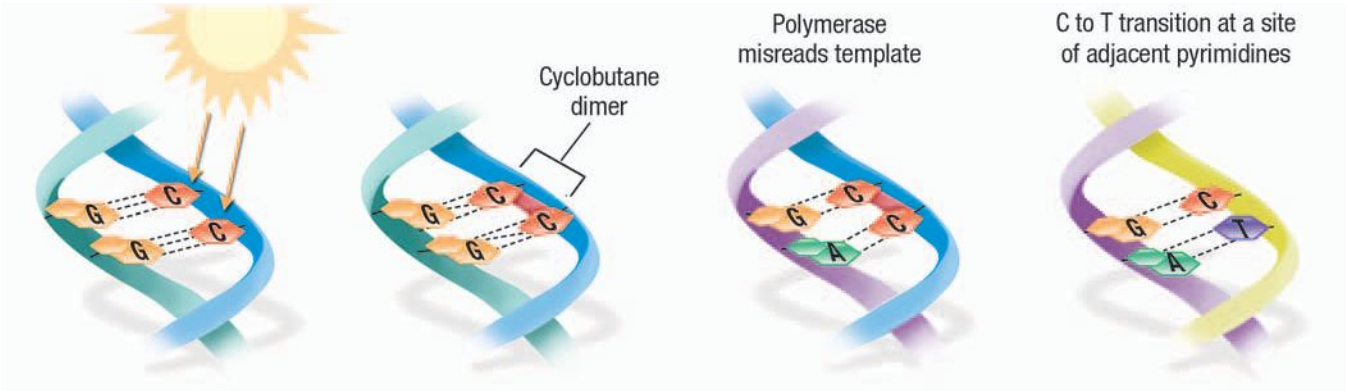
Ultraviolet Radiation–Induced DNA Damage and Repair

DNA PHOTOPRODUCTS The first molecular step in sunlight-induced carcinogenesis occurs when UVB photons induce DNA photoproducts. UVB and UVC tend to be absorbed at the 5-6 double bond of pyrimidines (thymine and cytosine), allowing the bond to open.[73] If two adjacent pyrimidines are activated, their open bonds cross-react. Creating two single bonds (5-5 and 6-6) results in a cyclobutane pyrimidine dimer (Fig. 112-1). The most frequent is TT, but TC and CC cyclobutane dimers are also made. A single bond between the 6 position of one pyrimidine and the exocyclic group of the other instead creates a pyrimidine-pyrimidone (6-4) photoproduct.[74] Both photoproducts distort the DNA helix and are recognized by DNA repair enzymes.

UVA is 20-fold more frequent in sunlight but requires 1000-fold greater doses for its biologic effects.[45–47,75,76] UVA induces T-containing cyclobutane dimers and lesser numbers of oxidized purines and pyrimidines and single-strand breaks.[77] UVA generates these lesions indirectly by photosensitization (see Chap. 88). UVA also efficiently photoisomerizes UVB-induced (6-4) photoproducts to their poorly repaired and highly mutagenic Dewar isomers.[77]

Ultraviolet Radiation Signature Mutations

UVR leaves a characteristic signature when it interacts with DNA, and this



▲ **FIGURE 112-1** Ultraviolet radiation (UVR)–induced C to T "signature mutation." UVR causes adjacent pyrimidines on the same strand to form a cyclobutane dimer. If not repaired, the C in the dimer can be misread by the DNA polymerase or can degrade to uracil such that it erroneously pairs with adenine. The net change is that a cytosine in the sequence is converted to thymine. If both cytosines mutate, the result is CC to TT. (Modified from a Scientific American article by Brash & Leffell, 1996.)

signature remains in the tumor decades later. It has been used to answer many questions about the origin of cancer. A cyclobutane dimer or (6-4) photoproduct can lead to a mutation in two ways (see Fig. 112-1). When the lesion is copied during DNA replication, the DNA polymerase may read a damaged cytosine as a thymine and insert an adenine opposite it. At the next round of replication, the polymerase correctly inserts thymine across from adenine, with the result being a C→T substitution. Although the TT cyclobutane pyrimidine dimer is the best known and most frequent photoproduct, the thymines are not mutagenic because the *XPV* gene encodes a specialized polymerase (Pol eta) that adds adenines across from a T-containing cyclobutane dimer.[83] Alternatively, a mutation can arise because cyclobutane dimers accelerate deamination of their cytosines to uracil (or 5-methylcytosine to thymine), leading to a C→T substitution; no polymerase error is involved.[84] In either case, C→T mutations occur only where a cytosine lies next to a thymine or another cytosine, because the major UV photoproducts join adjacent pyrimidines. If two adjacent cytosines mutate, the result is CC→TT. This distinctive pattern of mutation, C→T where the C lies next to another pyrimidine, including CC→TT, is unique to UVR and is called the *UV signature*.[85]

UV signature mutations provide a tool for deducing backward from mutations found in tumors to the original carcinogen. Nearly all experimentally created UVB or UVC mutations are located at adjacent pyrimidines, and about two-thirds are signature mutations.[85] The remaining third, typically C→A and T→C substitutions or one to two base insertions or deletions, are still caused by UV but probably arise by photosensitized production of reactive oxygen. Because this oxidative class is caused by many carcinogens, these mutations cannot identify whether their source was UVB, UVA, tobacco smoke, or intracellular oxidative phosphorylation. A set of tumors carrying the classic UV signature mutations must, however, also have some tumors with these UV-induced oxidative mutations. UVA, in contrast, only weakly induces UVB signature mutations by photosensitization but also generates oxidation-like mutations and T→G changes. The latter are rare with UVB or other carcinogens and have been proposed to be a UVA fingerprint.[86]

p53 UV signature mutations identified *p53* as critical for preventing SCC and BCC but not melanoma.[85,87] The p53 protein is a transcription factor that controls genes involved in the cell cycle, apoptosis, and DNA repair; it also acts directly on apoptosis proteins.[7] The *p53* gene is mutated in about one-half of all human cancers and is termed a *tumor suppressor gene* because cancer arises from losing its normal function rather than gaining an abnormal function as oncogenes do. Over 90 percent of SCC in U.S. patients contain these mutations, as well as three-fourths of AK. Although nearly all BCCs overexpress p53 protein, only half carry *p53* mutations. Each mutation changes the amino acid, indicating that the mutation was selected for and contributed to tumor development, rather than being simply an indicator of sun exposure. These *p53* mutations are most frequent at nine mutation hotspots in important functional regions of the protein. Compared to internal cancers, some skin cancer hotspots are displaced several nucleotides to lie at a site of adjacent pyrimidines.[87] Some sites may be hotspots because repair is slower there.[88] Other skin hotspots, like internal cancer hotspots, lie at 5-methylCG sites where body temperature slowly deaminates 5-methylcytosine to thymine; UVR accelerates this process.

The *p53* mutations in AK indicate that these dysplasias are clonal; patients with multiple AKs have different mutations in each lesion.[89–91] The similarity of AK and SCC mutations supports the idea that AKs can progress to SCC. Aggressive skin tumors from patients exposed to both sun and chemicals contain multiple unrelated *p53* mutations, as if multiple tumors arose in an abnormal field and merged.[92] XP tumors contain very frequent CC→ TT mutations, perhaps because slow repair allows more time for cytosine deamination.[93,94] Double-base mutations are also seen in conjunctival SCC, a tumor associated with human immunodeficiency virus (HIV) in sunny areas.[95] Sunscreens reduce the level of UV signature mutations.[96] In contrast, arsenic-induced BCC and SCC have non-UV *p53* mutations; *p53* mutations in BCCs from sun-shielded body sites resemble those seen with oxidative damage.[97,98]

Sunlight mutates *p53* early.[89,99] Normal sun-exposed skin carries ~60,000 clones of p53-mutant keratinocytes, three to 3000 cells in size.[100] By hematoxylin and eosin staining, the cells in these mutant clones appear completely normal.[44] The early appearance of *p53* mutations makes it possible to trace lineages in tumor development. Microdissecting lesions containing AK, carcinoma in situ, and SCC reveals that each stage contains the same *p53* mutation.[101] Although this result shows that

each stage arose from the same founder lesion, it does not show that the stages derived from each other. To show a lineage, it is necessary to find additional mutations that appear in succession. In microdissected BCCs, one *p53* mutation is present throughout the tumor, with various second mutations in different regions of the tumor.[102] Once both *p53* alleles are mutated, the cell is prone to aneuploidy,[103,104] increasing the likelihood of a mutator phenotype.

HEDGEHOG PATHWAY Nearly all sporadic BCCs have inactivating mutations in the *PTCH* tumor suppressor gene, a part of the hedgehog pathway (see Chap. 116); the remainder have activating mutations in its target, *SMO*. The hedgehog pathway appears to be a "gatekeeper" for basal cell carcinogenesis, needing to be mutated early in BCC: minute BCCs have *PTCH* mutations, as do all histologic subtypes; no BCCs have loss on other chromosomes without involvement of *PTCH*; and a congenital lesion that can progress to BCC, the sebaceous nevus, has *PTCH* allelic loss in 40 percent of cases.[105–107]

In sporadic BCCs, about three-fourths of *PTCH* mutations are UVR-like (either UV signature mutations or the expected UVR-induced oxidative mutations) and a further 15 percent are one or two base insertions or deletions, often adjacent to a C→ T at a dipyrimidine site.[108] BCCs from XP patients contain UVR-like *PTCH* and *SMO* mutations, with CC→ TT mutations overrepresented.[109,110] About 20 percent of the mutations in sporadic BCCs are not UVR-like and resemble germline mutations seen in basal cell nevus syndrome patients—deletions or insertions larger than two base pairs. This finding may relate to the clinical observation that one-third of BCCs occur on parts of the body that are not chronically sun-exposed, as well as the correlation between truncal BCC and defects in the glutathione radical-scavenging system (see Genetic Risk Factors). *PTCH* mutations tend to code for stop codons or frameshifts that completely inactivate the protein. In hereditary BCCs, nearly all tumors arose after losing the normal allele. This allelic loss appears related to sunlight, as NBCCS tumors are most frequent on sun-exposed skin and are rare in blacks.[39] UVB rarely causes this type of large genetic rearrangement so, in analogy to the x-ray sensitivity of NBCCS patients, UVA-photosensitized reactive oxygen may be important.

PSORALEN AND ULTRAVIOLET A LIGHT TUMORS (See Chap. 239) In psoralen-treated cells, UVA forms adducts at TA, TG, or TT sequences, as well as cross-links between the two DNA strands at these sites. In human PUVA-induced keratoses, SCCs, and BCCs, about one-fourth of mutations in *p53* or *HRAS* are psoralen-like mutations at the T of TA, TG, or TT; this proportion increases as the PUVA dose increases.[111,112] The majority of mutations, however, are UV signature mutations. The UVR-like mutations could have arisen from the UVA in PUVP, UVB treatment for psoriasis, or environmental UVB.

Melanoma Mutations (See Chap. 124)

Despite the correlation between melanoma and sunlight, genes with UV signature mutations are not prevalent. The *CDKN2A* locus is frequently mutated or deleted in familial and sporadic melanoma (see Chap. 124). Its two distinct tumor suppressor proteins, INK4A (also known as P16) and ARF, inhibit cell cycle progression via RB and p53, respectively. INK4A inhibits CDK4/6's inactivation of the retinoblastoma protein, RB. ARF inhibits MDM2-mediated degradation of p53. Germline mutations in *CDKN2A* are observed in ~25 percent to 40 percent of familial melanomas.[113,114] In sporadic melanoma, allelic loss of *CDKN2A* is more common than the rare *INK4A* inactivating mutations[115–117] or inactivation of *INK4A* by promoter methylation.[118] The role of sunlight in these genetic events is unknown.

Oncogene mutations are found in the RAS-BRAF-MEK-ERK mitogen-activated protein kinase (MAPK) signaling pathway. This signaling cascade is normally activated on growth factor stimulation, and its sequential phosphorylation regulates cell proliferation and differentiation. Activating mutations in MAPK signaling remove the growth factor requirement. *RAS* mutations are present in 10 percent to 20 percent of melanomas and have been correlated with UVR exposure.[119–121] The most prevalent *RAF* mutation in melanomas, the *BRAF* V600E point mutation, renders the kinase constitutively active and enhances ERK activation.[119] This mutation is present in nearly ~80 percent of acquired melanocytic nevi, suggesting a potential early role of BRAF in melanoma development.[121] The V600E mutation is not UVR-like and is associated with intermittent sunlight exposure.[27,29]

ULTRAVIOLET RADIATION–INDUCED STEPS IN CANCER AND CANCER PREVENTION

Skin tumors arise on a background of sun-damaged skin. To prevent sun damage, the skin reacts to acute and chronic UVR exposure by multiple stress responses.

DNA Damage Signaling (See Chap. 89)

A cell with damaged DNA upregulates normal p53 protein.[121a,121b] UV signaling is initiated by cyclobutane dimers and (6-4) photoproducts specifically in the small minority of actively transcribed genes, with stalled RNA polymerase both recruiting excision repair proteins and initiating signaling.[6,7] In an unknown way, this activates ATR and CHK1 kinases, which phosphorylate p53 at sites that make it resistant to proteasomal degradation mediated by HDM2. p53 then transcriptionally activates a large repertoire of genes, including the repair proteins P48, which is required for GGR and is defective in XP group E, and GADD45. Additionally, p53 functions as a chromatin accessibility factor, modifying the structure of damaged DNA and making it more accessible to repair factors. p53 also transactivates the cell cycle arrest protein P21, although in keratinocytes UVR induces P21 even without p53.[122] UVR primarily slows down S phase ("S phase delay") and induces a modest G_2 arrest, unlike ionizing radiation, which uses p53 to induce G_1 arrest. It is often said that cell cycle arrest facilitates DNA repair and survival, but there is little evidence supporting this concept; deleting the P21 cell cycle arrest protein has no effect on repair after UVR exposure.[123] These "guardian of the genome" roles of p53 are complemented by a "cellular proofreading" role in which p53 erases aberrant cells by apoptosis rather than repairing them: it transcriptionally activates the death receptor Fas and pro-apoptotic effectors Bax (Bcl-2–associated X protein), Bak, Bid, and PUMA; it directly activates Bax protein at the mitochondrion; and it inactivates E2F1, which otherwise inhibits anti-apoptotic Bcl-2.[8] This suite of UV responses is lost when p53 is mutated by sunlight. DNA damage also activates the cytoplasmically sequestered transcription factor nuclear factor κB, which then activates pro-inflammatory cytokines such as interleukin 10, growth signals, and

anti-apoptotic signals.[124,125] Finally, DNA photoproducts trigger UVR-induced systemic immunosuppression and suppression of dendritic cell antigen-presenting activity, but not inflammatory edema.[126,127]

Cytoplasmic Signaling

"The UV response" initially referred to the p53-independent activation of JNK, its target c-JUN, and, via the FOS-JUN transcription factor AP-1, induction of genes for collagenase, metallothionein, and c-JUN and c-FOS themselves.[128] The signal begins when reactive oxygen species generated by UVB or UVA photosensitization inactivate phosphatases by converting a highly sensitive cysteine residue in the catalytic site to sulfenic acid.[129,130] Dephosphorylation of growth factor receptor dimers and death receptor trimers is slowed, leading within minutes to more phosphorylated active receptors. Activated death receptors (involved in apoptosis) such as Fas and tumor necrosis factor-α (TNF-α) receptor then cluster even without a ligand, recruiting the adapter proteins DAXX and FADD and activating cytoplasmic kinases and scaffold proteins.[131–136] These activate ASK1 and MEKK 4,7 kinases and their target, JNK.[137] Phosphatase inhibition can activate JNK directly. In parallel, AP-1 also induces genes for the death receptor ligands, FasL and TNF-α.[138–140] These ligands, together with UV upregulation of FAS receptor via p53,[141] create a delayed feedback loop that, as with ionizing radiation,[142] appears to prolong the rapid but transient response triggered by UVR's inactivation of phosphatases. Without this prolongation, UVR-activated nuclear factor kappa B quickly terminates the JNK response.[143,144] This loop is important because transient JNK activation leads to cell proliferation, but constitutive JNK activation induces apoptosis.[145,146] AP-1 also induces immunomodulatory cytokines, such as interleukin 12, which facilitates NER[147]; the AP-1–induced metalloproteinases degrade dermal extracellular matrix molecules, such as collagen, and may contribute to photoaging.[148] UVR also blocks initiation of protein translation, via kinases that inactivate elongation factor eIF2α.[149]

Cellular Responses

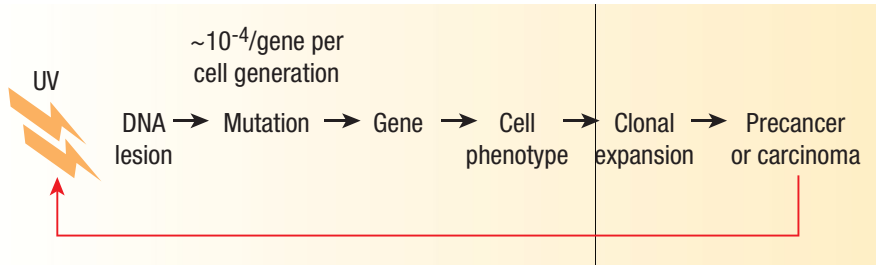
APOPTOSIS UV signaling generates sunburn cells—basal and suprabasal keratinocytes with dense, pyknotic nuclei and intensely eosinophilic cytoplasm (see Chap. 89). This apoptotic morphology is accompanied by pathognomic DNA double-strand breaks and cleaved caspase 3. UVR-induced apoptosis requires signals from both DNA damage and the cytoplasm: DNA photoproducts in active genes trigger p53 and its regulator Mdm-2,[89,150] but apoptosis also requires JNK and is partially blocked by antioxidants.[151,152] Although TNF-α is required, injecting TNF-α does not lead to sunburn cells, so UV-induced cytoplasmic signaling is not sufficient.[153,154] In fibroblasts, keratinocytes, or melanocytes with normal p53 and irradiated with physiologic UVB or UVC doses, apoptosis proceeds through the intrinsic mitochondrial pathway rather than the death-receptor/caspase 8 pathway.[152,155]

Apoptosis then prevents cancer by removing UVR-damaged cells, termed "cellular proofreading."[156] Mice accumulate mutations at a rapid rate if they are defective in apoptosis due to a defect in *p53* or Fas ligand, or due to overexpressing the anti-apoptotic protein Survivin.[140,157,158] In Survivin's case, this increases SCC. The epidermal hyperplasia that occurs several days after UVR exposure may replace cells lost by apoptosis or may remove additional damaged or mutant cells by desquamation. The signal for hyperplasia involves both DNA photoproducts and the epidermal growth factor receptor.[159]

STEM CELL POPULATIONS In chronically UVB-exposed human skin, *p53*-mutant clones are found at both sites of epidermal stem cells (see Chap. 44): the hair follicle, whose bulge region contributes to follicle development and transiently to wound repair, and the interfollicular epidermis, which maintains epidermal homeostasis and can also generate follicles.[100,160,161] SCCs are thought to originate in interfollicular epidermis, whereas histologic evidence and the expression pattern of PTCH indicate that BCCs originate in the follicles.[162,163] Hedgehog signaling through PTCH is crucial for maintaining skin stem cell populations and for regulating hair follicle and sebaceous gland development.[164] Chronically UV-irradiated human or mouse skin contains scattered basal cells with unusually high levels of DNA photoproducts.[165] The tumor promoter TPA (12-*O*-tetradecanoylphorbol 13-acetate), which induces skin stem cells to proliferate,[166] causes these cells to disappear and be replaced by clusters of *p53*-mutant keratinocytes. This behavior resembles that of stem cells that are quiescent and poorly repaired, at least on the parental DNA strand, until triggered to divide.[167] The immortalization-promoting enzyme telomerase is normally present only in the epidermal basal layer but is elevated in sun-exposed skin, skin precancers, and cancers.[168,169]

CLONAL EXPANSION OF MUTANT CELLS A single mutant cell must clonally expand to reach a clinical size. Less obviously, clonal expansion facilitates the multiple genetic hit mechanism of cancer. Physiologic UVR doses create mutations at a frequency of ~10^{-4}/gene per cell division[170] (Fig. 112-2). The specific mutations needed to activate an oncogene would be rarer. Spontaneous mutations, which reflect errors by the replication machinery or DNA damage due to body temperature, are also rare, on the order of 10^{-5}.[170] The probability of mutating five genes, such as an oncogene and both alleles of two particular tumor suppressor genes, is then at best 10^{-20}. With 10^6 proliferating keratinocytes per cm^2 in human skin,[171] and ~1 m^2 exposed, fewer than 1 person in 10^{10} would have a tumor. Accounting for the 60 percent lifetime expectation of skin cancer in Australia solely in terms of genetic hits in one cell is impossible. In contrast, clonal expansion increases by 1000-fold the number of targets for the next mutation.

A stem cell's clonal expansion is normally limited to its stem cell compartment.[172] Sunlight is a key driver of clonal expansion beyond this point. The *p53*-mutant clones in human skin are larger in chronically sun-exposed skin.[100] In mice, clones stop growing and regress when UVB treatment ends, indicating that clone expansion is due to a UVR-induced physiologic event rather than an irreversible mutation.[172,173] One of these physiologic events is UVR-induced apoptosis.[158] Once a *p53* mutation arises, the cellular proofreading mechanism backfires: subsequent UVR exposures eliminate damaged normal cells but spare apoptosis-resistant mutants. A mutant normally restrained within its stem cell compartment then escapes to colonize the newly vacated compartment. Repeating this process results in quantized clonal expansion. Apoptosis retards or accelerates skin cancer depending on the stage: it prevents new *p53* mutations, accelerates the expansion of *p53*-mutant clones and papillo-



▲ **FIGURE 112-2** The carcinogenesis cycle. Ultraviolet radiation (UVR) makes chemical changes in DNA that create mutations when DNA is copied. Some mutations alter the function of the gene in which they occur and lead to a new cell phenotype. The abnormal cell expands into a clone that becomes the target of further DNA damage.

mas, and prevents the mutations that convert a papilloma to SCC.[140,158]

Cell–Cell Communication

Cell–cell interactions prevent abnormal cells from proliferating inappropriately. In human autotransplant experiments, BCCs transferred from their original site regressed—suggesting that an abnormal underlying dermis is required for the tumor to persist.[174] Dermal fibroblasts suppress transformed keratinocytes by secreting transforming growth factor-β that induces squamous differentiation.[175] Normal keratinocytes also suppress their transformed neighbors, and UVR interferes with these signals. Normal human keratinocytes eliminate adjacent transformed keratinocytes (mutated in *p53* and *HRAS*) by inducing cell cycle arrest and differentiation.[176] Physiologic doses of UVB cause apoptosis and differentiation in the normal cells, but not in the transformed keratinocytes, allowing the latter to clonally expand.[177] Other intercellular signals are mediated by integrins—membrane receptors for extracellular matrix proteins such as collagen ($\alpha_2\beta_1$ integrin), laminin ($\alpha_3\beta_1$), and fibronectin ($\alpha_5\beta_1$). In keratinocytes, integrins bound to such ligand provide a "do not differentiate" signal through MAPK pathways, suppressing keratinocyte apoptosis and allowing a stem cell pool to be maintained.[178,179] Integrin receptors are often dysregulated in tumors. UVB irradiation downregulates the β_1 integrin subunit. UVA downregulates the gap junction communication protein connexin 43, resembling the action of the tumor promoter TPA.[180,181]

Melanocyte proliferation is normally regulated by keratinocytes via cell–cell adhesion receptors such as E-cadherin, P-cadherin, and desmogleins; these receptors are lost in vertical growth phase melanomas.[182] UVR stimulates keratinocytes to secrete endothelin-1, which then downregulates melanocyte E-cadherin and upregulates their N-cadherin.[183] This E- to N-cadherin switch diverts melanocyte interactions away from keratinocytes and toward fibroblasts and melanocytes.[182] Endothelin also downregulates the α_6 integrin subunit,[184] upregulates the $\alpha_v\beta_3$ and $\alpha_2\beta_1$ integrins that anchor melanocytes to dermal collagen and are associated with vertical growth–stage melanoma, inhibits gap junction communication by phosphorylating connexin 43, and activates metalloproteinases associated with basement membrane invasion.

Immune Surveillance

In humans, the primary evidence cited for immune surveillance in preventing UVR-induced skin cancer is the 10- to 20-fold increase in AK and SCC on previously sun-exposed skin in transplant patients receiving chronic immune suppression to prevent organ rejection. In one Australian study, 27 percent of deaths in a heart transplant cohort were due to skin cancer.[185] The increase begins months to a few years after immune suppression is initiated, and both the AKs and SCCs are unusually aggressive.[186–190] Melanomas are also increased.[191] Several lines of evidence mar the interpretation as immune surveillance: Cyclophosphamide is a well-known mutagen. Cyclosporine promotes tumor growth in vitro and in immune-deficient mice in which there is no immune system to be suppressed.[192] Azathioprine is a mutagen when followed by UVA irradiation.[193] HIV patients do have a modestly increased incidence of SCC, but these tumors at sun-shielded sites are associated with human papillomavirus (HPV).[194] Skin cancers are often said to develop in patients who are immunodeficient due to leukemia or lymphoma. Most published reports lack controls or patient data, but an eightfold elevation in chronic lymphocytic leukemia seems valid.[195,196] Most of these patients had received immunosuppressive drugs, or radiation, so the mutagenicity caveat applies.

In contrast, Merkel cell carcinoma may be truly sensitive to immune function because its incidence increases 10- to 20-fold not only in solid-organ transplant recipients but also in HIV patients (~13-fold) and in chronic lymphocytic leukemia (see Chap. 120). The chance of metastasis and mortality also increases in all types of immunosuppressed patients. Regardless of why immune-suppressed patients are at increased risk of skin cancer, it is critical that they be monitored closely because, when caught early, even tumors in immunosuppressed patients are curable.

ANIMAL MODELS OF SKIN CANCER: CLINICAL IMPLICATIONS

GENETIC RISK FACTORS FOR ULTRAVIOLET RADIATION CARCINOGENESIS

Pigmentation and Initial Damage

Melanin has a large role in resistance to skin cancer. The Fitzpatrick skin phototypes (see Chap. 89) are determined not only by baseline pigmentation but also by a person's response to UVR (always burns, tans easily, or rarely burns). This simple UVR skin response scale can account for up to a 100-fold difference in susceptibility to skin cancers.[233] Similarly, the many molecular etiologies of oculocutaneous albinism, which result in a deficiency of normal melanin, markedly increase the risk of skin cancer (see Chap. 71). Increased skin cancer among albinos is mostly non-melanoma skin cancer, but melanomas seem elevated as well.[234] Another hereditary risk factor, red or blonde hair, is now understood at a molecular level as commonly caused by polymorphisms in the melanocortin 1 receptor[235] (see Chap. 70). This receptor is a G-protein coupled receptor that binds melanocyte-stimulating hormone and lies at a key point in melanogenesis. Certain mutations in this receptor render it insensitive to normal pigmentation signals, resulting in pheomelanin instead of eumelanin. This is an important distinction in terms of skin cancer prevention. Red or yellow pheomelanin is a markedly less effective free radical scavenger;

indeed, UVR-exposed pheomelanin is degraded with a net formation of superoxide.[42,236] Therefore, pheomelanin can act as a photosensitizer, even inducing apoptosis in nearby cells.[43] Decreased protection and increased damage from pheomelanin in the epidermis may partly underlie the markedly increased risk of skin cancer associated with red-haired individuals.

Reactive oxygen species are largely absorbed by radical scavengers, such as glutathione, before they cause significant membrane or DNA damage. Specific polymorphisms in the genes for glutathione *S*-transferase confer a twofold risk for truncal AK, SCC, and BCC.[237] This genetic risk increases to sixfold in patients with high sun exposure and 12-fold in sun-exposed transplant patients.

DNA Repair and Apoptosis

XP (see Chap. 109) highlights the association between DNA repair capacity and skin cancer. Although defects in any of the XP genes result in some defect in NER, the severity of the XP disorder—number of skin tumors and life expectancy—correlates with DNA repair capacity.[82,238] The correlation between repair capacity and cancer incidence is also present in the general population. Patients with AK have a 30 percent to 50 percent reduced excision repair in their normal fibroblasts or lymphocytes.[239–241] Cells from BCC patients have reduced excision repair compared to cells from control individuals.[242] These data suggest that relatively subtle variability in DNA repair capacity contributes to an individual's risk of developing skin cancer.

Viral Sensitivity

In the rare inherited sensitivity to HPV infection termed *epidermodysplasia verruciformis* (see Chaps. 111 and 196), roughly one-half of patients will develop SCC. These SCCs are typically on sun-exposed body sites and occur decades earlier than in the general population.[243] HPV may be important in UV carcinogenesis in immunosuppressed transplant patients, as it is detected twice as frequently in SCCs from these patients as in immunocompetent controls.[244]

PREVENTION

The potential of education and sunscreen to control skin cancer remains largely unproven due to the long latency between sun exposure and skin cancer appearance. Adult sunscreen use can reduce AK by twofold.[68,69] Randomized studies of school children who aggressively applied sunscreen indicate that common nevi can be reduced.[245] A regimen of sun protection longer than the typical 2- to 4-year study would likely decrease nevi and subsequent melanoma risk more impressively. Encouraging data are emerging from Australia where education campaigns, covered sidewalks, and covered playgrounds at schools have led to a stabilization of the incidence of non-melanoma skin cancers.[9] Clearly, an effective campaign to reduce skin cancer needs to begin with school-age children. This is due to the combined factors that children younger than the age of 18 years spend a significant portion of their time in outdoor recreation, and sun damage sustained early in life has more time to contribute to UV carcinogenesis.

One could ask "how much sun is too much?" The answer will vary immensely depending on many factors such as pigmentation, whether sun exposure occurs in modest doses or large exposures, the immune status of the individual, and subtle differences in DNA repair capacity. Although highly controversial, there may be some benefit to sun exposure. Several studies have suggested twofold better survival after a diagnosis of invasive melanoma among patients with extensive sun exposure as compared to those with less exposure.[246] A potential explanation is greater vitamin D synthesis induced by UVR.

NOVEL THERAPEUTIC APPROACHES

Despite the use of sunscreens and public awareness of the effects of long-term exposure to UVR, the incidence of both melanoma and non-melanoma skin cancers continues to increase. This has led to investigation of novel chemopreventive agents that interfere with the development of cancer through diverse mechanisms. Perhaps the most important recent advance in this area is the use of imiquimod (see Chap. 221), an activator of the innate immune system through the TLR7 receptor. Imiquimod has recently been approved for treating AKs and superficial BCCs, and reports of imiquimod effects also exist for atypical melanocytic proliferations such as lentigo maligna.[247]

In terms of foods, tea appears to have chemopreventive activity. Orally administered green or black tea reduces UVR-induced skin cancers in mice to less than one-half of control levels.[248] Polyphenols and caffeine appear to be the major chemopreventive components. Topical application of caffeine was similarly effective in mice.[249] The protective effect of caffeine is attributed to its ability to induce apoptosis after UV irradiation.

Low-fat diets have been well studied as an approach to preventing skin cancer. Animal studies have shown that high-fat diets shorten the time between UVR exposure and tumor formation and markedly increase the number of tumors per animal.[250] In human trials of patients with non-melanoma skin cancer, restricting calories from fat reduced the appearance of AKs by two-thirds and the development of new non-melanoma skin cancers by one-half.[251]

Chronic UVB exposure induces inflammatory responses that have been linked to tumor formation. Inflammation induces cyclooxygenase enzymes and prostaglandins. Because prostaglandins promote keratinocyte proliferation and block differentiation, inhibiting prostaglandin formation is expected to be chemoprotective. Topical application of a nonsteroidal anti-inflammatory drug (Diclofenac) is effective in treating AKs, with 50 percent of target lesions resolving after Diclofenac treatment versus 20 percent in placebo.[252] Celecoxib, a systemic inhibitor of cyclooxygenase 2, inhibits the development of UVR-induced skin tumors in mice by twofold.[253,254] Given the side-effect profile of systemic cyclooxygenase 2 inhibitors, it appears unlikely that they will be developed for this indication.

An inducible repair process has been observed using DNA oligonucleotides that share sequence with the telomere.[255] In animal models and cell culture, these oligonucleotides can initiate multiple cellular responses, including melanin production and p53 activation, apparently in the absence of DNA damage. Topical application of these oligonucleotides to UV-irradiated mice diminished UVR-induced mutations and malignant lesions by fourfold.[256] If a therapeutically appropriate mechanism can be devised to activate this pathway, it may have utility in reversing DNA damage and preventing malignancies.

A recent development in the area of chemoprevention is the ability to augment normal DNA repair pathways. If one could increase DNA repair capacity, the mutations, chromosomal aberrations, and cell death known to be causal

for skin tumors should be reduced. The most direct application of this concept is the use of a viral enzyme (T4 endonuclease V) capable of recognizing cyclobutane dimers and accelerating the initial incision step of the NER pathway. This enzyme has been formulated into a liposomal preparation, allowing penetration into the relevant layers of skin. Indeed, studies in XP patients have shown efficacy in decreasing the residual DNA damage as well as the number of actinic keratoses.[257] There are thus diverse emerging approaches by which chemopreventive therapies may increasingly serve as an adjunct to classical UVR protection with sunscreens and avoidance of UVR exposure to skin.

SECTION 21

EPIDERMAL AND APPENDAGEAL TUMORS

CHAPTER 113

Epithelial Precancerous Lesions

Karynne O. Duncan
John K. Geisse
David J. Leffell

A precancerous or pre-malignant lesion is one that has a strong likelihood of transforming into a malignancy. There is much debate about the validity of the concept of precancerous lesions.[1–4] Lesions discussed in this chapter are those that have a clinically demonstrated potential to become invasive carcinomas and demonstrate histologic atypia confined to the epidermis. The focus is only on the precancerous keratinocyte lesions and not on those of other epithelial cells such as the melanocyte, Merkel, and appendageal cells. Discussion of malignancies and pre-malignancies associated with these cells can be found in Chaps. 124, 120, 119, and 121, respectively.

- Bowen disease or squamous cell carcinoma in situ
- Erythroplasia of Queyrat
- Leukoplakia
- Erythroplakia

PUVA = psoralen plus ultraviolet A radiation therapy.

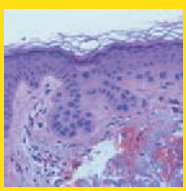
A common feature of all pre-malignant epithelial tumors (Table 113-1) is that they have the potential to become invasive squamous cell carcinoma (SCC). These precancerous lesions and SCC are considered by many to represent a continuum of disease with dysplasia at one end of the spectrum and invasive carcinoma at the other.

ACTINIC KERATOSES

Actinic keratoses (AKs) are cutaneous neoplasms consisting of proliferations of cytologically aberrant epidermal keratinocytes that develop in response to prolonged exposure to ultraviolet (UV) radiation. AKs have historically been considered precancerous or pre-malignant lesions with a potential for developing into SCCs. In recent years, however, there has been an effort to redefine AKs as malignant neoplasms, because these lesions are essentially intraepithelial SCCs in evolution. Although not all AKs become SCCs, AKs are the initial lesion in a disease continuum that may progress to SCC. This concept of a progression along a spectrum is analogous to that of cervical carcinoma, for which cervical intraepithelial neoplasia is the initial, "precancerous" lesion.[8]

AKs are clinically important lesions, not only because of their potential to develop into SCC, but because they are one of the strongest predictors that an individual may subsequently develop melanoma or non-melanoma skin cancer (NMSC).[9–11] With the increasing incidence and prevalence of melanomas and NMSCs (discussed in Chaps. 124 and 115), persons with AKs are the perfect candidates for close longitudinal observation for prevention and early treatment.

ACTINIC KERATOSES AT A GLANCE



- Precancerous lesions on a spectrum from photodamaged skin to squamous cell carcinoma (SCC).
- Strongest predictors of subsequent development not only of non-melanoma skin cancer but also melanoma.
- Risk factors include individual susceptibility, cumulative ultraviolet (UV) radiation exposure, immunosuppression, prior history of skin cancers, genetic syndromes.
- Long-term and cumulative UV radiation exposure is the most important contributing factor for development of actinic keratoses (AKs).
- Risk of progression of AK to SCC varies from less than 1 percent to 20 percent.
- AKs should be treated because their course is unpredictable, they are often symptomatic, and they can progress to SCC if untreated.
- Treatment methods include cryotherapy, topical agents, electrodesiccation and curettage, and photodynamic therapy.

Epidemiology

AKs are second to acne vulgaris as the most common reason for patients to see a dermatologist. The National Am-

bulatory Medical Care Survey data for 1990 to 1999 indicate that AKs were diagnosed in more than 47 million physician visits over that 10-year period and were found to occur in 14 percent of patients visiting a dermatologist.[12] In the northern hemisphere, 11 percent to 25 percent of adults are thought to have one or more AKs.[12] In Australia 40 percent to 60 percent of adults are thought to have one or more AKs.[13]

Various risk factors have been identified for the expression of AKs. The two major ones are individual susceptibility and cumulative UV radiation exposure (Table 113-2). One of the most important susceptibility risk factors is age, because all the epidemiologic studies indicate that AKs increase in prevalence with increasing age, with rates ranging from less than 10 percent in white adults aged 20 to 29 years to 80 percent in white adults aged 60 to 69 years. Males appear to have more AKs than females in most epidemiologic studies, which presumably reflects greater cumulative sun exposure in males than in females.[14] This gender differential is more pronounced at younger ages. Other individual susceptibility risk factors include a phenotype of fair skin that easily burns and freckles, and rarely tans; blue or light-colored eyes; and red or blond hair.[14] Another individual risk factor is immunosuppression, because it is well known that organ transplant recipients are at increased risk of developing AKs and SCCs. Last, individuals with certain genetic syndromes, namely, albinism and xeroderma pigmentosum, and possibly Rothmund-Thomson and Bloom syndromes, are at greater risk of developing AK.

TABLE 113-2
Risk Factors for Development of Actinic Keratoses

- Individual susceptibility
  - Older age
  - Male gender
  - Fair skin that easily burns and freckles
  - Blond or red hair
  - Light-colored eyes
- Cumulative ultraviolet radiation exposure
- Immunosuppression
- Prior history of actinic keratoses or other skin cancers
- Genetic syndromes
  - Xeroderma pigmentosum
  - Bloom syndrome
  - Rothmund-Thomson syndrome

Cumulative exposure to UV radiation, including tanning beds, is the other major risk factor for developing AKs. Evidence that sun exposure plays a role in the development of AKs is the fact that over 80 percent of all AKs are distributed on habitually sun-exposed areas of the body, such as the scalp, head, neck, forearms, and dorsal hands.[14] Variables that affect a person's cumulative UV radiation exposure include age, gender, occupation, recreational activities, and place of residence. As previously stated, the older the individual, the greater the prevalence of AKs and, intuitively, the greater the cumulative exposure to UV radiation. The age at which a person received the greatest amount and intensity of exposure to UV radiation appears to be significant, with such exposure in childhood apparently posing the greatest risk. In migration studies in Australia, British immigrants who moved to Australia before the age of 20 had fewer AKs than the native white Australians early in life, but they had the same rate of AKs as the native Australians in later years. British immigrants who moved to Australia after the age of 20 years never showed the same rate of AKs as the native Australians or the British immigrants who arrived at a young age.[15]

Etiology and Pathogenesis

Although genetic and environmental factors may play a role in the development of AKs and SCC, it has long been recognized that the most important contributing factor is habitual exposure to UV radiation, namely, sunlight exposure. UV radiation is responsible for the development of AK, and eventually SCC, in two ways: first, it causes mutations in cellular DNA that, when unrepaired, lead to unrestrained growth and tumor formation; and second, it acts as an immunosuppressant to prevent tumor rejection[16] (see Chaps. 109, 110, 111, and 112).

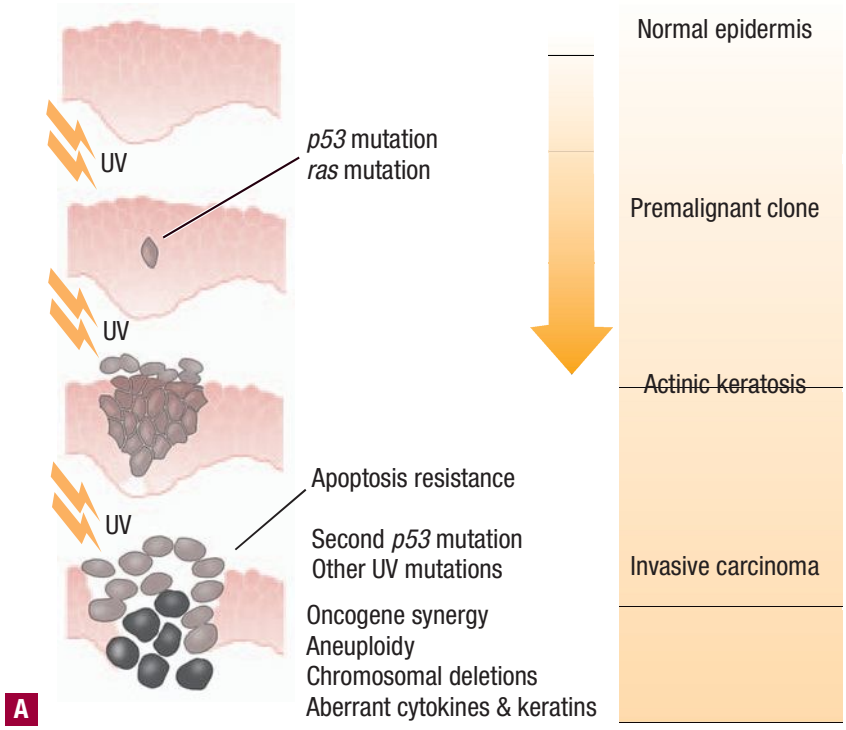
UV radiation–induced mutations in the tumor suppressor gene p53 play a pivotal role in the initiation of AKs and their development into SCC (Fig. 113-1; see Chap. 112). Multiple UV radiation–induced cellular insults to the skin result in a pathway to SCC that begins with photodamaged skin, progresses to the development of AKs, and eventually leads to some SCCs. AKs on photodamaged skin clinically represent expanded clones of genetically mutated cells that have escaped apoptosis and immune surveillance and have gone on to proliferate into clinically evident pre-malignant lesions.

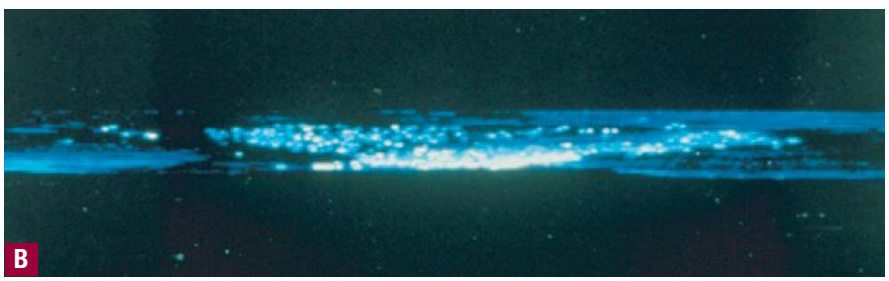
Clinical Findings

The typical patient with AKs is an older, fair-skinned, light-eyed individual who has a history of significant sun exposure, who burns and freckles rather than tans, and who has significant solar elastosis on examination (Fig. 113-2). AKs can be seen in younger individuals if these individuals have sustained sufficient sun exposure over their lives. Eighty percent of AKs are found on habitually sun-exposed sites of the body, such as the head, neck, forearms, and dorsal hands. Common signs and symptoms include pruritus, burning or stinging pain, bleeding, and crusting. The typical AK lesion, sometimes called the *erythematous AK*, presents most commonly as a 2- to 6-mm erythematous, flat, rough, or scaly papule. It is usually more easily felt than seen. AKs can vary in size and sometimes reach to several centimeters in diameter. They are most often found against a background of photodamaged skin or dermatoheliosis, with solar elastosis, dyspigmentation, yellow discoloration, ephelides, telangiectases, and sagging skin notably prominent. At times the number and confluence of AKs are so great that the patient appears to have a rash.

In addition to the typical erythematous AK, there are several other clinical sub-types (Table 113-3). The hypertrophic AK (HAK) presents as a thicker, scaly, rough papule or plaque that is skin colored, gray, or erythematous (Fig. 113-3A). It can be found on any habitually sun-exposed site on the body but has a propensity for the dorsal hands, arms, and scalp. A typical erythematous AK can progress into an HAK. At times, it is difficult to distinguish an HAK from an SCC clinically, and a biopsy is necessary. Induration or thickness, pain, and ulceration are the main clues to the transition of AK to SCC.

Cutaneous horn, also known as *cornu cutaneum*, refers to a reaction pattern and not a particular lesion (Fig. 113-4). In reference to AKs, a cutaneous horn is a type of HAK that presents with a conical hypertrophic protuberance emanating from a skin-colored to erythematous papular base. In classic definitions of a cutaneous horn, the height is at least one-half of the largest diameter. Thirty-eight percent to 40 percent of all cutaneous horns represent AKs.[17] In fact, on examination of biopsy specimens, the





▲ **FIGURE 113-1** **A.** Development of clonal expansion of ultraviolet (UV) radiation–mutated p53 gene in epithelium. In the multistage model of carcinogenesis, UV radiation–induced mutations provide selective growth advantage to neighboring cells, which leads to clonal expansion. (Adapted from Grossman D, Leffell DJ: The molecular basis of nonmelanoma skin cancer. *Arch Dermatol* **133**:1263, 1997.) **B.** Confocal microscopy revealing expansion of UV radiation–induced clone of abnormal keratinocytes in sun-damaged skin. ▲ **FIGURE 113-2** Severe solar damage of the face revealing telangiectasias as well as actinic keratoses at different stages of development, including the flat, pink macules and hyperkeratotic papules.

base of a cutaneous horn can be a number of different lesions, such as AK, SCC, seborrheic keratosis, filiform verruca vulgaris, trichilemmoma, or keratoacanthoma. The most common underlying lesion in elderly, fair-skinned persons is an HAK.

Actinic cheilitis represents confluent AKs on the lips, most often the lower lip (Fig. 113-5). Persons with this condition have red, scaly, chapped lips, and at times erosions or fissures may be present. The vermillion border of the lip is often indistinct, focal hyperkeratosis and leukoplakia may also be seen. Individuals with this condition often complain of persistent dryness and cracking of the lips, and the diagnosis of actinic cheilitis should always be suspected in elderly patients with such complaints.

TABLE 113-3
Clinical and Histopathologic Variants of Actinic Keratoses

Clinical Variants of Actinic Keratoses
- Erythematous actinic keratosis
- Inflamed actinic keratosis
- Hypertrophic actinic keratosis
- Cutaneous horn
- Actinic cheilitis
- Pigmented actinic keratosis
- Spreading pigmented actinic keratosis
- Proliferative actinic keratosis
- Conjunctival actinic keratosis

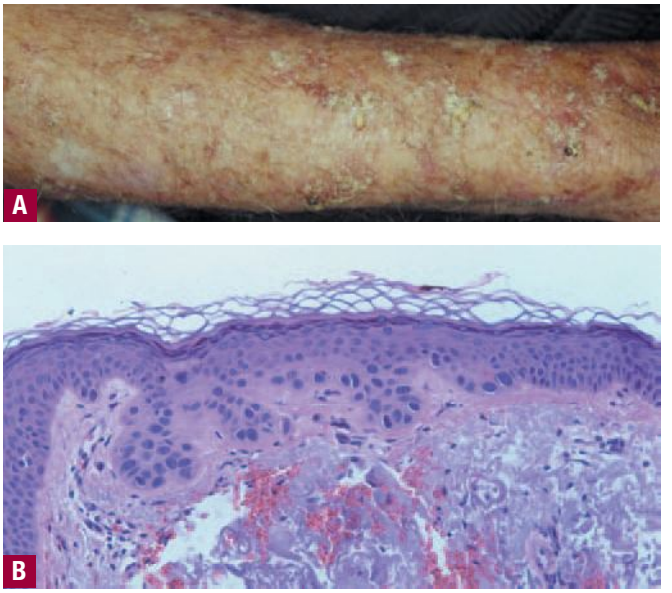
Histopathologic Variants of Actinic Keratoses
- Inflamed actinic keratosis
- Hypertrophic actinic keratosis
- Cutaneous horn
- Atrophic actinic keratosis
- Bowenoid actinic keratosis
- Pigmented actinic keratosis
- Proliferative actinic keratosis
- Lichenoid actinic keratosis
- Acantholytic actinic keratosis
- Clear cell actinic keratosis

Persistent ulcerations or indurated areas on the lip require biopsy to ensure that SCC is not present.

Unusual variants of AK include pigmented AK, spreading pigmented AK, proliferative AK, and conjunctival AK. The pigmented AK presents as a flat, tan to brown, scaly papule. Clinically, and many times dermatoscopically, it can be difficult to distinguish from a solar lentigo or lentigo maligna.[18] Spreading pigmented AK is a particular lesion that is often found on the face or scalp. It is typically a large lesion, often reaching more than 1 cm in diameter, and presents as a scaly, verrucous, or smooth plaque with variable colors. Proliferative AK is seen as an expanding, red, oval, scaly plaque that reaches up to 4 cm in diameter. It has poorly defined borders. Conjunctival AK is classified as a type of pinguecula or pterygium. It appears as a wedge-shaped, opaque thickening near the limbus, and it may extend onto the cornea from the scleral conjunctiva.

Histopathology

The typical erythematous AK has characteristic architectural and cytologic histopathologic features. All of the abnormalities are confined to the epidermis, although dermal solar elastosis is usually present and an inflammatory dermal infiltrate may also be seen. The classic histopathologic findings include foci of atypical, pleomorphic keratino-



▲ **FIGURE 113-3** **A.** Severe solar damage of the dorsal arm demonstrating hypertrophic actinic keratoses and actinic keratoses. **B.** Histopathologic preparation of actinic keratosis demonstrates atypical cells along the basal layer with sparing of adnexal epithelium.

▲ **FIGURE 113-4** **A.** Cutaneous horn of the ear. Only biopsy will confirm whether this is an actinic keratosis or a squamous cell carcinoma. **B.** Cutaneous horn of the cheek.

cytes along the basal cell layer and protruding as buds into the papillary dermis. The basal cell layer appears more basophilic because of crowding of the atypical keratinocytes. Overlying these foci of abnormal cells, one often sees irregular acanthosis, hyperkeratosis, and parakeratosis. There is notable sparing of the adnexal epithelium, with orthokeratosis overlying these structures, which gives rise to the characteristic pattern of alternating orthokeratosis and parakeratosis (see Fig. 113-3B). Cytologically, there is an increased nucleus-cytoplasm ratio in the atypical keratinocytes in addition to nuclear pleomorphism and mitoses.

An important point to remember about making the diagnosis of AK histopathologically is that if the physician has a strong clinical suspicion of SCC or basal cell carcinoma (BCC) and the initial cuts reveal AK, it is prudent to section more deeply into the block of tissue to ensure that an SCC or BCC is not missed. In one study additional diagnostic findings were present on step sections in 23 of 69 specimens (33 percent) initially diagnosed histopathologically as AK. Of these additional findings, 13 percent were indicative of Bowen disease (BD), 4 percent of BCC, and 3 percent of invasive SCC. Three variables that correlated with the discovery of malignancy on step sections were ulceration on the first level, a clinical diagnosis of skin cancer, and a history of skin cancer confirmed previously by biopsy examination.[21]

Diagnosis and Differential Diagnosis

The diagnosis of AK is accurately made by clinical examination in most instances when the examiner is familiar with AK and skilled in making such diagnoses. Some investigators, however, have commented on the difficulty of accurate and consistent counting of AK lesions by experts involved in AK research studies.[22] In practice, very few AKs are histopathologically confirmed, and thus few data exist on the accuracy of clinical diagnosis. The accuracy of clinical diagnosis is higher in a clinical referral setting than in the general community setting. One study involving a referral setting revealed a diagnostic accuracy of 94 percent, based on the correct histopathologic diagnosis of 34 of 36 clinically suspect, typical AKs.[23] Another study in a community-based setting reported a diagnostic accuracy of approximately 80 percent when random clinically diagnosed AKs were subject to histopathologic confirmation.[24]

The clinical features of typical erythematous AKs are not unique to these lesions. The differential diagnosis includes other common lesions as noted in Box 113-1. Of the clinical AK variants, pigmented AK is difficult to distinguish from solar lentigo and sometimes lentigo maligna; spreading pigmented AK, from lentigo maligna or a large seborrheic keratosis; HAK, from

◀ **FIGURE 113-5** Actinic cheilitis of the lower lip in a young man with a marine occupation. The patient is at risk for developing squamous cell carcinoma of the lip. Preventative treatment of the actinic cheilitis can include laser, cryosurgery, and topical treatment.

Box 113-1

Clinical Differential Diagnosis of Actinic Keratosis

Most Likely

- Erythematous actinic keratosis
  - Benign lichenoid keratosis
  - Irritated seborrheic keratosis
  - Psoriasis
  - Seborrheic dermatitis
- Hypertrophic actinic keratosis
  - Verruca vulgaris
  - Squamous cell carcinoma
  - Discoid lupus erythematosus
  - Keratoacanthoma
  - Porokeratosis
- Cutaneous horn
  - Seborrheic keratosis
  - Verruca vulgaris
  - Squamous cell carcinoma
- Pigmented actinic keratosis
  - Solar lentigo
  - Flat seborrheic keratosis
  - Lentigo maligna
- Spreading pigmented actinic keratosis
  - Large seborrheic keratosis
  - Lentigo maligna
- Actinic cheilitis
  - Dry, chapped lips
  - Lichen planus
  - Other variants of cheilitis

Always Rule Out

- Inflamed actinic keratosis
  - Bowen disease
  - Squamous cell carcinoma
  - Basal cell carcinoma
- Hypertrophic actinic keratosis or cutaneous horn
  - Squamous cell carcinoma
  - Keratoacanthoma
- Pigmented or spreading pigmented actinic keratosis
  - Lentigo maligna

SCC; and cutaneous horn, from the many entities it may represent.

Clinically, the greatest challenge is to distinguish an AK from an SCC, because the latter portends a more serious prognosis and requires different treatment. There are no reliable clinical criteria for distinguishing between these two entities, but findings of induration, pain, larger size, marked hyperkeratosis, ulceration, bleeding, rapid growth, and recurrence or persistence after treatment make the diagnosis of SCC more likely.

Prognosis and Clinical Course

The prognosis of AK includes three possible outcomes. It can persist, regress, or undergo malignant transformation into invasive SCC. It is impossible to predict which path any given AK may take. The relative risk of progression to SCC depends on factors related to the AK itself, such as the length of time an AK has been present and the number of baseline AKs that are on the skin. In addition, the risk for SCC increases with increased UV radiation exposure and with certain individual patient characteristics, such as suppressed immune status.

Several studies have attempted to determine the risk for the progression of AK to SCC, but most of them are inadequate in one respect or another. The risk for progression of AK to SCC reported in the literature varies from less than 1 percent[25] to 20 percent.[26] In a review of five clinical research studies carried out between 1988 and 1998, Glogau found that the published risk of progression of AK to SCC for individual lesions ranged from 0.025 percent to 16 percent per year.[27] Extrapolation from these clinical studies suggests a rate of risk of progression of AK to SCC of approximately 8 percent, computed as an average of the cited statistical rates.[27] Berhane et al. observed that before an AK progresses to SCC it may become clinically tender and inflamed. Histopathologic examination of such clinically inflamed AKs revealed the actual presence of overt SCC in 50 percent.[28] Thus, pain and inflammation in an AK may be a marker of progression to SCC.

The risk of malignant transformation can also be assessed by evaluating the percentage of SCCs that arise from preexisting AKs. Several studies have approached this issue by histopathologically examining invasive SCC specimens and determining the percentage of cases in which an associated or contiguous AK could be identified. An associated AK was identified at the periphery or within the SCC in 60 percent,[25] 82.4 percent,[29] 97 percent,[30] 97.2 percent,[31] and 100 percent[32] of reviewed cases in various studies. There has been one prospective study in which all SCCs treated by the authors in one calendar year were evaluated histopathologically to see if an AK was present in the specimen. They found a contiguous AK within a histopathologically confirmed SCC in 72 percent of cases.[33]

Spontaneous regression of an AK is impossible to predict for any particular lesion. One study reported that up to 25 percent of AKs remitted over a 1-year period, especially if sun exposure was limited during that time.[34] Another study found that more AKs regressed in individuals who routinely wore sunscreen.[24]

Not only do these three basic outcomes exist for individual lesions, but AKs are also sensitive clinical markers for predicting the future development of NMSC. The presence of AKs indicates long-term sun damage and identifies a group of people who are at high risk for developing SCC, BCC, and, to a lesser extent, melanoma.[9,10,11]

The estimated rates of metastases arising from actinically derived SCC have ranged from 1 percent to 2 percent to 20 percent depending primarily on depth of invasion, with the lip, ear, and scalp representing the sites of highest risk.[35]

Treatment

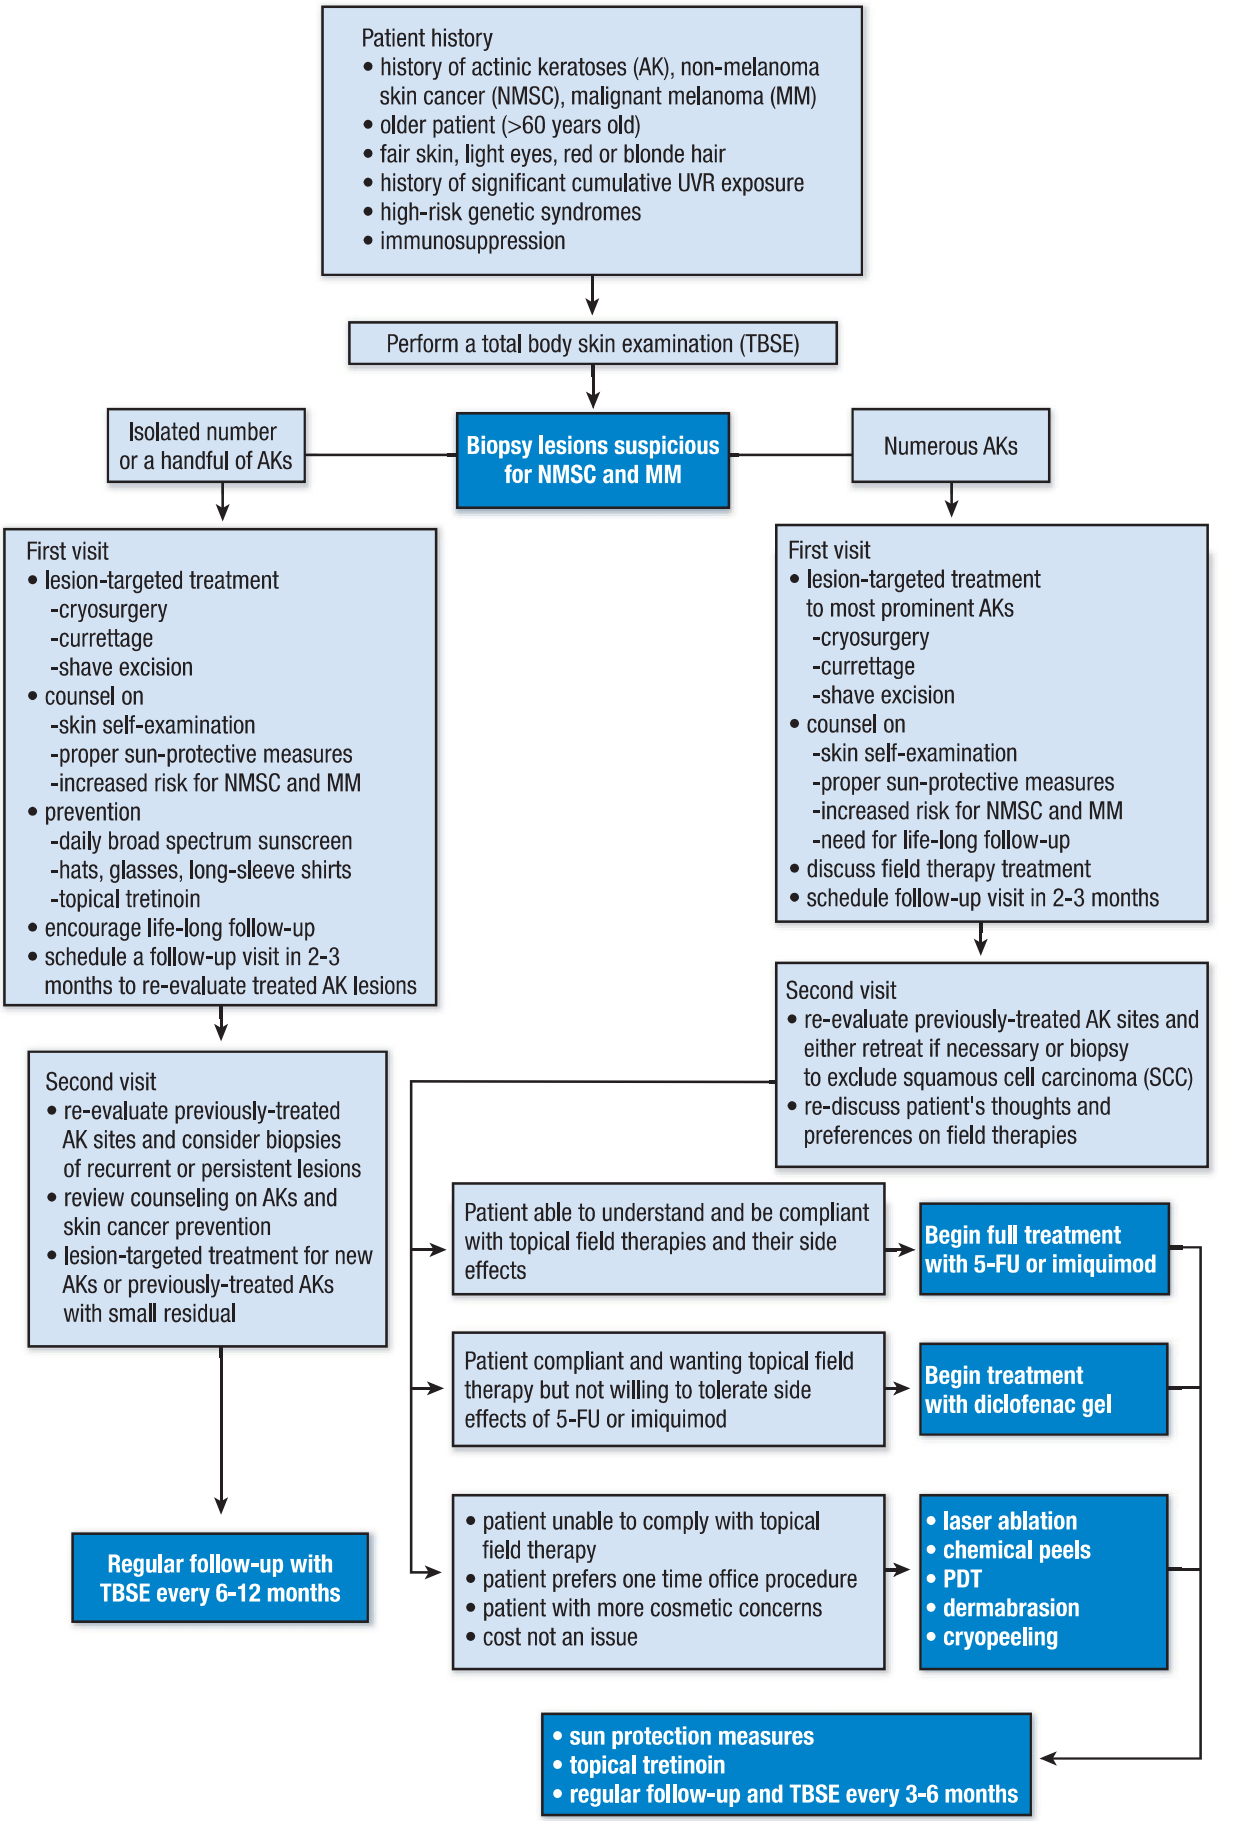
The inability to predict which AKs will persist, regress, or become SCCs makes treatment of these lesions equally confusing. Although some clinicians have argued that because of the low malignant transformation risk, treatment of AKs is unnecessary, most dermatologists advocate the treatment of AKs to avoid any chance of progression to invasive SCC.[36,37] Treatment of this disease is also warranted to minimize symptoms in affected patients with painful and pruritic AKs.

In selection of the proper treatment, there are no absolute guidelines or algorithms because published studies vary considerably in their design, measured outcomes, and follow-up time (Fig. 113-6). The clinical diagnosis of AK even by expert dermatologists can be inconsistent.[22]

The ideal treatment for AK lesions would be 100 percent effective and durable, resulting in complete clearance of clinical and sub-clinical AKs. It would also be affordable, easy to administer by the clinician and/or use by the patient, convenient and free of discomfort or downtime for the patient, and have a great cosmetic outcome. No one such therapy exists. Which treatment a physician chooses depends on personal skill level and individual patient characteristics as well as the size, location, and number of AKs present.

Treatment modalities for AKs can be broadly divided into lesion-targeted therapies and field therapies (Box 113-2).

LESION-TARGETED TREATMENTS FOR ACTINIC KERATOSIS The majority of the lesion-targeted therapies for the treatment of AKs are destructive—that is, they work by physically removing the AK. Such



▲ **FIGURE 113-6** Approach to the management of actinic keratoses. 5-FU = 5-fluorouracil; PDT = photodynamic therapy; UVR = ultraviolet radiation.

Box 113-2

Treatment of Actinic Keratoses

LESION-TARGETED THERAPIES

- Liquid nitrogen cryotherapy
- Curettage with or without electrocautery
- Shave excision

FIELD THERAPIES

- Topical
  - 5-fluorouracil cream and solution
  - 5% imiquimod cream
  - 3% diclofenac gel
- Procedural
  - Cryopeeling
  - Dermabrasion
  - Medium-depth chemical peel
  - Deep chemical peel
  - Laser resurfacing
  - Photodynamic therapy

destructive treatments are the most common methods used to treat AKs.[38]

Liquid Nitrogen Cryosurgery. Liquid nitrogen cryosurgery is the most common destructive procedure and is typically administered with a spray device or a cotton-tipped applicator (see Chap. 247).

The benefits of cryosurgery are its ease of administration in trained hands, the lack of need for anesthetic, and the lack of reliance on patient compliance other than in post-treatment care of lesions. Potential disadvantages of the use of cryosurgery include pain or discomfort for the patient, the presence of unsightly blisters and crusted wounds for a week or longer, hypopigmentation, scarring, and possible alopecia in treated areas.[40] In rare cases serious injury to underlying tendons and nerves may occur with deep or prolonged liquid nitrogen application to the hands. Most important, cryosurgery is best used to treat a limited number of clinically perceptible or symptomatic lesions.

Curettage. Curettage, with or without electrocautery, is another destructive treatment for AKs. This procedure and cryosurgery together constitute approximately 80 percent of all treatments for AKs in the United States.[38] A curette is used to mechanically scrape away the atypical keratinocytes of the AK. Electrocautery may or may not be used to further destroy atypical cells and to provide hemostasis. If cautery is employed, minimal use is advised to enhance the final cosmetic result. A local anesthetic is needed for this procedure, and hemostatic agents such as aluminum chloride can be used to stop the bleeding if electrocautery is not to be used.

Shave Excision. The third lesion-targeted destructive therapy for AKs is shave excision. This technique involves injection of a local anesthetic followed by tangential excision of the lesion with a surgical blade (see Chap. 243). Hemostatic agents must also be used to stop the bleeding. No data exist on the cure rate with the use of this technique, but as with curettage, anecdotal experience says it is effective. Healing time may be 1 to 2 weeks, and potential complications include infection, scarring, and dyspigmentation. Use of this technique is most indicated when a clinically apparent AK is suspicious for SCC and histopathologic examination is needed.

FIELD THERAPIES FOR ACTINIC KERATOSIS

Field therapies treat larger areas of photodamaged skin that have both clinical and subclinical AK lesions. Field therapies can be categorized further into topical or medical, and procedural field therapies. Such treatments are best used in patients with moderate to severely photodamaged skin and numerous AKs that would be too burdensome and painful to treat with the lesion-targeted therapies. Many patients with AKs, on close inspection, are found to be extensively affected with early disease in sun-exposed areas, which may make field therapy the more rational approach to this difficult problem.

Topical Field Therapy. Several topical agents are available and approved by the U.S. Food and Drug Administration (FDA) for the generalized treatment of AKs, including 5-fluorouracil (5-FU), 5 percent imiquimod cream, and 3 percent diclofenac gel (Box 113-3).

5-FU therapy has been a mainstay of topical treatment for AKs since the 1960s (see Chap. 220). 5-FU acts selectively to cause cellular destruction in actinically damaged cells but not in normal skin. 5-FU treatment of sun-damaged skin usually causes a brisk inflammatory reaction, which is felt to contribute to its overall efficacy.

Although many different treatment regimens have been proposed and used with topical 5-FU, the historical standard FDA-approved method consists of twice-daily application of 5-FU cream or solution to the entire affected region, typically for 2 to 4 weeks.

Anecdotally, topical 5-FU has been thought to be 75 percent effective—that is, 7 or 8 out of 10 treated AKs will resolve with appropriate therapy.[42] The long-term remission rates after 5-FU treatment vary, but the condition frequently recrudesces in a few years and severely affected patients return to baseline.

Patients should expect discomfort, pruritus, and burning at the sites of application, as well as erythema, erosion, crusting, and ulceration beginning at around 1 week into treatment (Fig. 113-7). These and other adverse reactions to 5-FU are further discussed in Chap. 220. Areas of the skin that seemingly have no visible evidence of AKs may also become quite inflamed during treatment, because the 5-FU is uncovering incipient AKs in these treated areas. Such outcomes portend a good prognosis for resolution of AK lesions. Much lower cure rates are seen when patient compliance is poor and the expected endpoints are not reached.

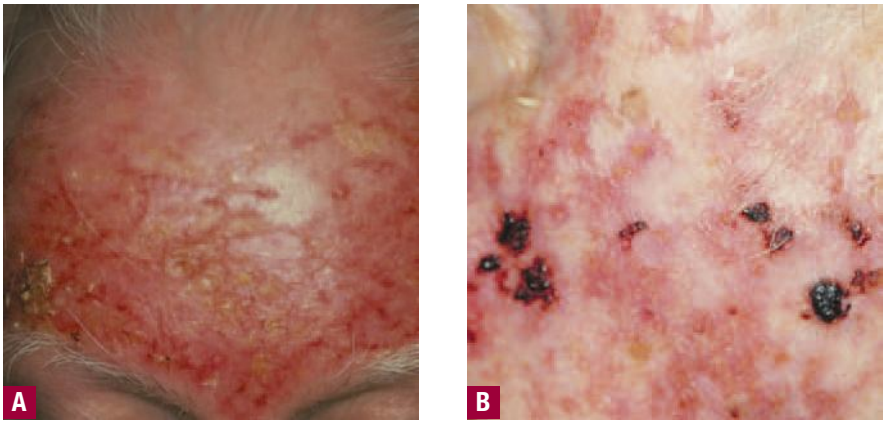
The second agent available for topical field treatment of multiple AKs is 5 percent imiquimod cream (see Chap. 221). First approved in 1997 by the FDA for the treatment of genital and perianal warts, it was approved in 2004 for the treatment of non-hypertrophic AKs on the face and scalp in immunocompetent adults. It is also approved for treatment of superficial BCC (see Chap. 115).

The ideal frequency and duration of imiquimod treatment for AKs have not been determined. Currently, the FDA-approved regimen calls for twice-weekly (e.g., Monday and Thursday) night-time application of a thin layer of

Box 113-3

Topical Field Therapies of Actinic Keratoses

MEDICATION	TOPICAL PREPARATION	DOSAGE
5-Fluorouracil	1% solution	Twice daily for up to 4 wk
	2% solution	
	5% solution	
	1% cream	
	5% cream	
	0.5% micronized cream	Once daily for 4 wk
Imiquimod	5% cream	Twice per week for 16 wk
Diclofenac	3% gel	Twice daily for 90 days



▲ **FIGURE 113-7** **A.** Erythema and crusting secondary to treatment with 5-fluorouracil (5-FU). **B.** Superficial hemorrhage in a patient taking warfarin (Coumadin) who was treated with 5-FU.

imiquimod cream to the affected area, which is the regimen used in clinical trials. After 1 to 2 weeks of therapy patients should begin to see an eruption of erythematous, crusty, eroded papules and plaques in the treated areas. If the reaction is too severe or uncomfortable, patients can take a 1- or 2-week break from the application of imiquimod and then restart therapy. Treatment should be continued for 16 weeks.

Treatment with imiquimod cream is associated with adverse reactions, most notably local skin reactions such as erythema, scabbing, flaking, erosion, weeping, and vesicle formation. Such reactions are actually a foreshadowing of better clearance of the AKs. In fact, the greatest resolution of the AKs has been seen in patients with the most severe reactions.[45–47] Systemic absorption is minimal, and overall excellent safety margins have been demonstrated with the topical administration of imiquimod cream.[48] Systemic adverse effects, including interferon-like side effects such as flu-like symptoms, headaches, and myalgia, have been infrequently reported.

No long-term safety issues have been discovered.

The third FDA-approved topical field therapy for treating AKs is 3 percent diclofenac gel. Diclofenac is a nonsteroidal anti-inflammatory drug whose mechanism of action is not completely understood but is thought to involve inhibition of cyclooxygenase (COX), a rate-limiting enzyme in the synthesis of prostaglandins. Diclofenac appears to have greater affinity for the COX-2 enzyme than for the COX-1 isoform. One theory regarding its role in eradicating AKs relates to the finding that the production of prostaglandins from arachidonic acid may contribute to UV radiation–induced NMSC. Thus, inhibition of this cascade by diclofenac may also explain its efficacy in treating AKs.[54]

The FDA-approved regimen for diclofenac in the treatment of AKs is twice-daily application for 90 days. Compared with imiquimod and 5-FU, diclofenac does not cause as much inflammation, irritation, or downtime for the patient. Adverse effects include mild local site reactions, such as erythema, pruritus, flaking, and possible contact dermatitis. In a study involving 96 patients, at 30 days after the conclusion of therapy complete clearance of AKs was observed in 50 percent of the diclofenac-treated group and in 20 percent of the vehicle-treated group.[55]

The best general approach to managing widespread AKs likely involves a combination or sequential strategy. For example, at the first visit with the patient, a handful of the largest, most notable AKs may be selected for biopsy to rule out SCC or treated with cryosurgery, and the clinician can discuss AKs and present topical field therapy options to the patient. At a subsequent visit for follow-up examination of the AKs that have been treated, another discussion can address which topical therapy is best suited to this particular patient. The next phase of treatment, involving a topical therapy, can be pursued.

Procedural Field Therapy. The second category of field therapies for treating diffuse AKs is the procedural field therapies. These include cryopeeling (see Chap. 247), dermabrasion, medium and deep chemical peels (see Chap. 252), laser resurfacing (see Chap. 240), and photodynamic therapy (PDT) (see Chap. 239).

Cryopeeling consists of extensive liquid nitrogen cryosurgery to the areas of discrete AKs as well as to the surrounding normal-appearing skin.

Dermabrasion is an older technique that is quite effective in the treatment and prophylaxis of AKs but is rarely used for this purpose. It causes physical destruction of the AKs with abrasion using either drywall sanding sheets or an electric dermabrasion device (see Chap. 252).

Medium-depth chemical peels using Jessner's solution and 35 percent trichloroacetic acid (TCA) are moderately effective in treating diffuse AKs, especially when a series of such peels are administered over time (see Chap. 252).[56,57] A combined peel in which 35 percent TCA is used after Jessner's solution has been shown to be equivalent in efficacy to 5-FU therapy.[58]

Deep chemical peeling using phenol or high concentrations of TCA is more effective in treating appendageal epithelial atypia but is rarely used because of the potential cardiac and renal toxicity of phenol, the greater risk of scarring and infection, and the dramatic hypopigmentation that can be seen after treatment.

Laser resurfacing for the treatment and prophylaxis of AK is another procedural field therapy that has been explored. The carbon dioxide (CO_2) laser and the erbium:yttrium-aluminum-garnet (er:YAG) laser are the two laser systems that have primarily been investigated for these purposes (see Chap. 240).

PDT using topical 5-aminolevulinic acid (ALA) is another procedural therapy that has been gaining popularity in the treatment of multiple and diffuse AKs. Topical PDT was approved by the FDA in 1999 for the treatment of non-hypertrophic AK lesions on the face and scalp (see Chap. 239). With PDT the topically applied ALA accumulates preferentially in the more rapidly dividing atypical cells and is converted to protoporphyrin IX, a heme precursor and a photosensitizer. When the ALA-treated skin is then exposed to a light source of the appropriate wavelength several hours later, the accumulated protoporphyrin IX generates a phototoxic reaction that destroys the treated cells.[63–67]

Patients can expect some discomfort with PDT, including erythema, edema, and burning or stinging during exposure to the light source. In a subgroup of patients with severe sun damage ALA-PDT can create intolerable pain that requires premature discontinuation of treatment. Allergic reactions to ALA have also been reported. Severe phototoxic reactions can occur if patients do not follow the protocol and practice strict sun avoidance for the prescribed

period after ALA application. Ultimate cosmetic outcomes have been good to excellent.

Prevention

Avoidance of UV radiation is the single most effective means of decreasing the risk of AK. A strategy designed to limit the amount and intensity of sun exposure, starting in childhood and continuing throughout the person's life, will likely decrease the number of AKs an individual will develop. Because complete avoidance of the sun is impractical, the next best preventive measures are to avoid exposure to intense midday sun; consistently apply and reapply broad-spectrum sunscreens; wear UV-protective clothing, hats, and sunglasses; and install UV-protective windows where indicated.

Application of SPF (sun protection factor) 15 sunscreen to mouse skin before UV irradiation has been shown to reduce the frequency of p53 mutations by 88 percent to 92 percent.[69] Sunscreens also reduce the number of tumors induced experimentally in animals exposed to UV irradiation and reduce the development of AKs in humans.[24]

There is limited evidence that adhering to a diet low in fat may decrease the incidence of AKs[70] and NMSC.[71,72] Topical retinoids have been shown to reduce the number of AKs after long-term consistent use.[73,74] More recently, long-term treatment with topical retinoic acid was shown to reduce keratinocyte and melanocyte atypia in photoaged skin.[75] Thus, topical retinoids may play a role in chemoprevention of AKs or maintenance of skin after more effective treatment of existing AKs. Oral retinoids are effective in preventing NMSC and AKs, especially in high-risk patients such as organ transplant recipients and patients with xeroderma pigmentosum, but they are effective only as long as the patient is taking the medication. The combination of low-dose 13-*cis*-retinoic acid (10 mg every other day) and topical tretinoin has been advocated for prophylaxis of both AKs and NMSC in renal transplant recipients.[76] Topical imiquimod is increasingly being used to prevent SCC in the transplant population.[77]

ARSENICAL KERATOSES

Arsenical keratoses (ArKs) are precancerous lesions found in association with chronic arsenicism. These lesions have the potential to develop into invasive SCC. Arsenic is a ubiquitous element that has no color, taste, or odor. It has the potential to cause characteristic acute and chronic syndromes in persons exposed to it, and such exposures are typically obscure because medicinal, occupational, and environmental sources exist. Detection of acute and chronic arsenicism is important, because the acute form can be fatal and the chronic form is associated with a variety of cutaneous and internal malignancies. ArKs are associated with chronic arsenicism.

Epidemiology

Knowledge of the medicinal benefits and poisoning potential of arsenic dates back to ancient times. Arsenic was introduced into the *United States Pharmacopoeia* in 1850, and before its use was discontinued around 1965, it was employed medicinally in the United States and Europe in the form of Fowler's solution, Donovan's solution, and Asiatic pills for treatment of various illnesses such as psoriasis, asthma, and syphilis. Medicinal exposure is now basically limited to treatment of tropical diseases, such as African trypanosomiasis, and more recently to treatment of various hematologic malignancies.[67] Arsenic in opium has been and is still used for medicinal and recreational purposes in India, and inorganic arsenic is still found in some traditional Chinese herbal preparations.[78] Unfortunately, these substances can be easily purchased and are increasingly being used again as homeopathic remedies, which results in modern day cases of what once was primarily a disease of historical interest.

Arsenic exposure can occur in a variety of occupations, either by direct exposure to arsenic or through indirect exposure from contaminated water and landfills. In 1973, it was estimated that more than 1.5 million workers in the United States were potentially exposed to arsenic in the workplace.[79] Occupations that carry risk of exposure include jobs in the mining, smelting, agricultural, computer microchip, forestry, electroplating, semiconductor, and glassmaking industries. Environmental exposure is often obscure and insidious, because there may be latent periods of up to 50 years before manifestations of chronic arsenicism appear. Arsenic is routinely found in soil, and it is found in much higher levels in the well water of certain regions where smelting and mining activities predominate, such as Taiwan, Sweden, and Argentina.[78] Other routes of environmental exposure include some illegally produced alcoholic beverages and the burning of pressure-treated lumber that has been pretreated with chromated copper arsenate. In all forms of medicinal, occupational, and environmental exposures, longer duration of exposure and higher cumulative dose are associated with a higher risk for the development of ArKs.

ARSENICAL KERATOSES AT A GLANCE

- Arsenical keratoses (ArKs) are precancerous lesions associated with chronic arsenicism.
- ArKs have the potential to become squamous cell carcinomas (SCCs).
- Chronic arsenicism has resulted from medicinal, occupational, and environmental exposures.
- Clinical appearance is of punctuate, keratotic, yellow papules overlying pressure points on palms and soles.
- Chronic arsenicism is associated with ArKs, Bowen disease, basal cell carcinoma, SCC, and internal malignancies, with latency periods of up to 40 years.
- No standard recommendations for treatment; most lesions are followed clinically or treated symptomatically.

History

Etiology and Pathogenesis

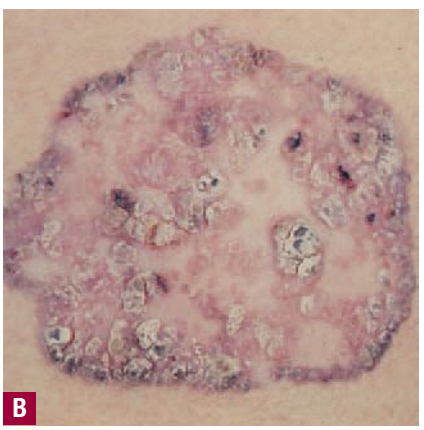
Arsenic is present as either organic or inorganic compounds as well as in three potential oxidative states: metalloid, trivalent, and tetravalent. Trivalent arsenicals are the most common and hazardous to humans. The toxicity of these compounds depends on the accumulation of arsenic in target tissues and its metabolism and elimination. Organic arsenicals are excreted rapidly. Trivalent inorganic arsenicals are the most acutely and chemically toxic compounds. Because arsenic is metabolized and detoxified in the liver via methylation, pa-

tients with pre-existing liver disease may be at greater risk for arsenic-related toxicity.

The mechanisms of arsenic-induced keratoses and malignancy are not fully understood. Arsenic reacts with the sulfhydryl groups in certain tissue proteins and subsequently affects many different enzymes that are essential to cellular metabolism. Arsenic has been found to cause chromosomal mutations, chromosomal breaks, sister chromatid exchanges, and mutations in p53.[83,84]

Clinical Findings

ArKs typically begin as pinpoint papules that are more easily felt than seen. They develop into small, 2- to 10-mm, punctate, yellow, keratotic papules most commonly seen on the palms and soles in areas of constant pressure or repeated trauma (Fig. 113-8A). They preferentially arise on the thenar and lateral borders of the hands, the sides of the fingers, and sometimes on the dorsal aspects of the fingers, overlying the joints. Although it is unusual, ArKs can be found on more widespread body areas such as the trunk, extremities, eyelids, and genitalia. ArKs may also present as slightly elevated, erythematous, scaly or pigmented plaques. ArKs on the palms and soles are more likely to be seen in individuals with chronic arsenicism caused by medicinal exposure than in those with arsenicism due to occupational exposure. Also, individuals with arsenical-related cancer are more likely to have palmar and plantar ArKs. The mean latency period for the development of ArKs varies considerably from 9 to 30 years.[85]



▲ **FIGURE 113-8** **A.** Arsenical keratoses of the palm. (Used with permission from James E. Fitzpatrick, MD, University of Colorado, Department of Dermatology.) **B.** Arsenical-induced in situ squamous cell carcinoma.

Other cutaneous neoplasms associated with chronic arsenicism include BD or SCC in situ, SCC (see Chap. 114), and BCC (see Chap. 115). Mean latency periods for the development of BD and SCC can also be as long as 40 years.[85] With arsenic as the carcinogen rather than UV radiation, these neoplasms, like ArKs, are distributed in more widespread, random, and nonphotodamaged areas. Arsenical BD often begins as a small flesh-colored to pink papule with a thick horny layer or crust. When this crust is removed, the underlying skin appears erythematous and oozing. Over time, unlike the relatively stable ArKs, these lesions increase in size, forming nodular and plaque-like lesions (see Fig. 113-8B) that often group together. Approximately one-third of patients have multiple lesions of BD.[78]

Arsenic-induced BCCs are also usually multiple, and the majority are of the superficial type, although small nodular BCCs are sometimes seen. These BCCs are found in a random, scattered distribution, primarily on the trunk and in hair-bearing regions. Clinically, the superficial BCCs are often indistinguishable from BD. Arsenic-related SCC can arise de novo or from malignant transformation of ArKs and BD lesions. In one study, 55 percent of SCCs arose from pre-existing ArKs or BD lesions.[85] Patients with SCC are more likely to have been exposed to arsenic earlier in life than are those without SCC.[85] They also are more likely to have multiple lesions of BD and more numerous palmar and plantar ArKs. The majority of SCCs have been found on the distal extremities of the hands and feet, and it has been hypothesized that irritation and trauma in these areas may increase the risk of malignant transformation. Clinically, ArKs that show progression to SCC often present with pain, bleeding, fissuring, and later ulceration. They tend to gradually expand in diameter, forming a large erosion or ulceration, and they sometimes reach sizes of up to 20 cm.

Other signs of chronic arsenicism include hyperpigmentation primarily affecting the nipples, axillae, groin, and other pressure points. Within these hyperpigmented patches are often seen small areas of hypopigmentation, resembling "raindrops in the dust." Diffuse alopecia of the scalp may be present. Longer term, patients may develop "blackfoot disease," which is a peripheral vascular disorder affecting the lower extremities that eventually results in gangrene. Hepatic cirrhosis can also occur. A variety of internal malignancies have been associated with chronic arsenicism, with long lag periods of 20 to 50 years reported. The internal malignancies linked with chronic arsenicism include lung, urinary tract, and hepatic tumors, hepatic angiosarcoma, leukemia, and lymphoma.

Histopathology

The histopathologic features of ArKs are essentially the same as those of AKs. No reliable histopathologic criteria can distinguish between the two. Some cases of ArKs are characterized by marked vacuolation of the epithelial cells and keratin horn formation. Also, solar elastosis is usually absent, and a chronic dermal lymphocytic infiltrate is commonly seen. Likewise, arsenic-related BD, BCC, and SCC are histopathologically indistinguishable from their non–arsenic-induced counterparts.

Diagnosis and Differential Diagnosis

ArKs may be mistaken for other types of punctate keratoses, such as disseminated punctate keratoderma, Darier disease, corns, and verruca vulgaris. Disseminated punctate keratoderma usually appears earlier in life. It has also been reported that on removal of the keratinous plugs in punctate keratoderma, small crater-like pits are left behind, whereas no pits are seen on removal of the keratin plugs in ArKs. Darier disease presents with characteristic lesions elsewhere. Corns are usually not so numerous and not so common on the hands. Warts often demonstrate evidence of thrombosed capillaries on removal of the surface keratin.

A diagnosis of ArKs and chronic arsenicism should be considered when numerous characteristic keratoses are seen on the palms and soles or when multiple lesions of BD, SCC, or BCC are found on an individual, especially when these lesions are in non–sun-exposed regions of the body. In most patients with

such neoplasms, palmar and plantar keratoses will also be present. Such patients should be questioned about previous occupations, living conditions, and environmental and medicinal exposures to elicit a history of potential arsenic exposure anywhere from 10 to 40 years previously. Biopsy of any changing ArK or erythematous nodule or plaque on the body should be performed to ensure that BD, BCC, or progression to SCC is not present.

Prognosis and Clinical Course

ArKs and arsenical-induced BD tend to persist for many years, and progression to invasive SCC is believed to be relatively rare. Invasive SCCs that arise in ArKs, however, are more locally aggressive and have a greater chance of metastasis than SCCs arising in AKs.[78] In lesions of arsenical-induced BD, locally invasive SCC has been seen histopathologically in up to 20 percent of cases. Once invasive SCC has occurred in BD, it is said that at least one-third will demonstrate evidence of metastasis unless adequate treatment is provided.[86]

Treatment

Management of patients with chronic arsenicism and ArKs should include regularly scheduled total-body skin examinations and general physical examinations, possibly every 6 months.[85] The exact incidence of internal malignancies associated with chronic arsenicism is unknown, so there is no standard protocol for the evaluation of potential internal malignancies. Exhaustive evaluations to detect such malignancies have not been recommended. Biannual detailed history taking and physical examination, yearly chest radiography, and selective testing when clinically indicated are probably reasonable recommendations.

Treatment of ArKs likewise is not standard and not mandatory, although treatment of these lesions is sometimes initiated to relieve the associated discomfort that some patients experience. Available localized treatment options include surgical excision, cryosurgery, curettage with or without electrocautery, CO_2 laser treatment, and topical chemotherapy with 5-FU, although 5-FU therapy is less successful in treating ArKs than in treating AKs.[78] PDT with ALA has also been used to treat these lesions. Oral retinoids may be useful in reducing the hyperkeratosis associated with ArKs. One can assume that imiquimod may be effective, but there are no studies of its use to date.

THERMAL KERATOSES

Etiology and Pathogenesis

Thermal keratoses (TKs) are keratotic lesions produced in the skin by exposure to infrared radiation. They have the potential to develop into SCC. Various sources of heat are implicated in causing these lesions, and several classic syndromes have been reported. Most notable are the kangri basket cancers in Kashmir, the kang cancers in China, the railway cancers in Britain, and the peat fire cancers in Ireland. The kangri is a pot that contains some type of fuel, such as charcoal, which is held against the thigh or lower abdomen as a source of warmth. In Kashmir, the malignancies would arise in the skin over the lower abdomen and thighs, where the baskets were in contact with the body. Kang are brick beds used primarily in the northeastern part of China that are usually heated by pipes connected to coal-burning stoves. The skin overlying the greater trochanter is where the cancers were most likely to develop. Heat was reported to be responsible for cancer of the skin overlying the shins of railway engine drivers in England. In Ireland, more than 150 women were reported to have lesions of erythema ab igne and SCC on the lower legs. These women all reported many years of sitting close to an open fire of burning peat to stay warm. Because peat is a less efficient fuel than coal, these women had to sit closer to the source to attain adequate warmth. The men did not experience the same cutaneous effects because they primarily wore thick, long trousers. In the United States, TKs, BD, and the development of SCCs have been noted in persons after long-term exposure to coal- and wood-burning stoves used as sources for heat and cooking.[87] The incidence and prevalence of TKs are not known. Likewise, the pathogenesis of these lesions is not fully understood, and the percentage of TKs that will progress to invasive SCC is also unknown. Erythema ab igne, the precursor lesion, has been reported as a result of long-term exposure to laptop computers and electric heating pads.[88]

Clinical Findings

Prolonged exposure to infrared radiation and to sources of heat can clinically produce the characteristic lesion of erythema ab igne, which manifests as an erythematous to brownish, fixed, thick, reticulated patch on the skin overlying the area that has been habitually exposed to heat (see Fig. 73-23 in Chap. 73). It differs from livedo reticularis in that it is more brownish, usually non-blanchable, and fixed. The sites of predilection are the back and abdomen from exposure to hot water bottles and heating pads or blankets, and the lower legs from exposure to fires or heating units as sources of warmth. After many years of such exposure, TKs may appear within these patches of erythema ab igne. SCC in situ within such patches has also been reported, and as with solar-induced AKs, progression to invasive SCC from TKs can occur. Clinically, TKs present as hyperkeratotic papules and plaques.

THERMAL KERATOSES AT A GLANCE

- Precancerous lesions that result from long-term exposure to infrared radiation; can progress to squamous cell carcinoma (SCC).
- Sources of infrared radiation include open fires, railway engines, wood-burning stoves, heating pads and blankets, and laptop computers.
- Precursor lesion is erythema ab igne; biopsy should be performed on any hyperkeratotic papule or plaque within such a patch.
- Risk of progression of thermal keratosis to SCC is unknown.

Histopathology

The histopathologic features of TKs are similar to those of AKs, including alternating hyperkeratosis and parakeratosis, keratinocyte atypia, sparing of the appendageal units, and, interestingly, even dermal elastosis and vascular ectasia. In one study, biopsy specimens from erythema ab igne patches without apparent TKs showed evidence of keratinocyte atypia.[89] Merkel cell carcinoma has also been reported to arise alongside SCC within a patch of erythema ab igne.[90]

Diagnosis and Differential Diagnosis

Biopsy should be performed on hyperkeratotic papules or plaques that de-

velop within a long-standing patch of erythema ab igne to confirm the diagnosis and to rule out progression to SCC.

Prognosis and Treatment

There is a paucity of information in the literature regarding the risk of progression of TK to invasive SCC and the general prognosis of thermal SCC. Similarly, little has been written about the treatment of these lesions. Surgical excision, curettage with or without electrocautery, cryosurgery, and possibly laser therapy appear to be reasonable therapeutic options. Patients with erythema ab igne should be counseled about the need to discontinue exposure to whatever heat source they have been in contact with, and they should be followed long term with physical examinations to identify early changes suggestive of TK or SCC.

HYDROCARBON KERATOSES

Etiology and Pathogenesis

Hydrocarbon keratoses (HKs), also known as *tar keratoses*, *pitch keratoses*, and *tar warts*, are precancerous keratotic skin lesions that occur primarily in persons who are exposed occupationally to polycyclic aromatic hydrocarbons (PAHs). SCC and keratoacanthoma have also been linked to such exposures. PAHs are produced by the incomplete combustion and distillation of coal, natural gas, and oil shale. They are found in tar, fuel oils, lubricating oils, oil shale, and bitumen.[80] Workers at risk for exposure to such compounds include workers in tar distillation and shale extraction, and workers exposed to creosotes, which are one of the main distillate fractions of coal tars and coal tar pitches.[91] Creosotes are used extensively as wood preservatives. Roofers, asphalt workers, road pavers, and highway maintenance workers are exposed to PAHs from fumes formed during the heating of bitumen.[91] Other groups of workers at risk for exposure to coal tar products include railway workers, brick masons, and diesel engineers.[80] Finally, persons exposed to mineral oils, cutting oils, and coolants also are at risk for the development of HKs and SCC.[91]

Clinical Findings

HKs present as small, oval to round, gray, flat papules that are easily removed without residual bleeding. These papules can then become larger and more verrucous in appearance, and eventually may develop into invasive SCC. Sites of predilection include the face, nostril rims, upper lip, forearms, volar wrists, dorsal feet, lower legs, vulva, and scrotum.[93] Of note, the lesions on the nostril rims, upper lip, genitalia, and forearms are not in the typical sun-exposed sites of the body. Thus, keratoses or malignancies in these regions should prompt the physician to inquire about potential occupational hazardous exposures. Other cutaneous findings related to PAH skin exposure include patchy hyperpigmentation, acne, and telangiectases at sites of exposure. The presence of acneiform lesions on the forearms and thighs should alert one to the possibility of PAH exposure. Facial features associated with long-term tar exposure include periocular fibromas, brownish or slate-gray discoloration, comedones, and hair follicle plugs.[93]

PAHs have also been reported to cause internal malignancies, such as lung and bladder cancers.[91]

Histopathology

Histopathologically, HKs appear similar to AKs and ArKs, as previously described. Often, HKs show more of a progression to full-thickness atypia or a bowenoid appearance. In early HKs, it has been said that distinction between benign and malignant epidermal changes can be difficult.

Diagnosis and Differential Diagnosis

HKs, with their grayish keratotic appearance, may be mistaken for verruca vulgaris, stucco keratoses, or even ArKs. A high index of suspicion is needed to make the diagnosis of HKs, because histopathologically they are difficult to distinguish from AKs and ArKs. The distribution of the lesions and other cutaneous findings of tar-exposed skin can aid in the diagnosis and lead to further, pointed questioning of the patient.

Prognosis and Treatment

The exact risk that an HK will progress to SCC is unknown. Most recommendations in the literature call for biopsy and surgical removal of HKs, especially in the vulvar and scrotal regions and on mucosal surfaces, where the risk of early metastasis from SCC is greater. Cryosurgery and curettage with or without electrocautery are probably reasonable treatment options for HKs at other cutaneous sites. Prevention is the key for workers exposed to PAHs in their occupations. Long-term follow-up of individuals with previous known PAH exposures is essential for early diagnosis and treatment of lesions and for early detection of internal malignancy in those at risk.

HYDROCARBON KERATOSES AT A GLANCE

- Hydrocarbon keratoses (HKs) are also known as *pitch keratoses*, *tar keratoses*, and *tar warts*.
- They occur in persons who are occupationally exposed to polycyclic aromatic hydrocarbons (PAHs).
- Occupations at risk include tar distiller, shale extractor, roofer, asphalt worker, road paver, highway maintenance worker, brick mason, diesel engineer, and chimney sweep.
- HK can progress to SCC, but the rate of progression and risk is unknown.
- Latency periods between PAH exposure and development of HK or SCC range from 2.5 to 45 years.
- Presence of atypical keratoses on the nostril rims, upper lip, and genitalia should prompt a search for occupational exposures to PAHs.
- Other skin findings include patchy hyperpigmentation, acne, and telangiectases.

CHRONIC RADIATION KERATOSES

Chronic radiation keratoses (CRKs) are precancerous keratotic lesions that may arise on the skin many years after exposure to ionizing radiation. They have been described in persons exposed to x-ray therapy, including grenz ray therapy for benign skin disorders such as acne vulgaris and tinea capitis; in medical personnel, dentists, and physicians who have administered x-rays over many years[80]; in other professionals who handle radioactive materials in their workplaces; on the fingers of persons who unknowingly wore gold rings contaminated by radioactivity (Fig. 113-9)[95]; in survivors of the atomic bomb in Japan[96]; and in the victims of nuclear accidents such as the one in Chernobyl, Ukraine.[97] For the purpose of the following discussion, *radiation* refers to

CHRONIC RADIATION KERATOSES AT A GLANCE

- Chronic radiation keratoses (CRKs) are precancerous lesions that may arise at irradiated sites years after such exposure and may progress to squamous cell carcinoma (SCC).
- Ionizing radiation sources include x-rays, grenz rays, and contaminated gold rings.
- Common sites are the palms, soles, and mucosal surfaces.
- Clinically present as hyperkeratotic papules or plaques within areas of chronic radiation dermatitis.
- Latency for the development of CRKs can be up to 56 years after exposure.
- Ionizing radiation–induced SCC can be extremely aggressive.
- Patients with ionizing radiation exposure and CRKs are also at risk for internal malignancies.

ionizing radiation; thus, the UV and infrared spectra of radiation are excluded.

Clinical Findings

The primary neoplasms resulting in the skin from exposure to ionizing radiation are CRKs, BCCs, and SCCs. Cutaneous sarcomas rarely occur. CRKs and BCCs are seen more commonly than SCCs, but any given CRK can potentially evolve into invasive SCC. The site and penetration of the ionizing radiation determine which type of tumor develops; palms, soles, and mucosal surfaces are said to be favored locations for CRK. The neoplasms that develop are often multiple, heal poorly, and recur frequently.[80] CRKs usually develop within areas of chronic radiation dermatitis or in persistent ulcerations arising in such chronically damaged areas of the skin. They appear as hyperkeratotic papules or plaques (see Fig. 113-9). The latency period from the time of exposure to the development of CRKs and radiation-induced skin cancers is typically long, having been reported to range up to 56 years. The latency period for the development of these tumors is inversely proportional to the radiation dose. Patients exposed to ionizing radiation are also at risk for the development of internal malignancies, such as those of the breast, bone, soft tissue, uterus, larynx, pharynx, thyroid, and maxillary sinus.[80]

▲ **FIGURE 113-9** Chronic radiation keratoses and squamous cell carcinoma on the thumb of an elderly radiologist who had not used gloves when doing fluoroscopic work.

Histopathology

Histopathologically, CRKs display keratinocyte dyskeratosis with hyperchromatic nuclei and abnormal mitoses. The dermis often demonstrates findings consistent with long-term radiation-induced changes, such as hyalinization of the collagen bundles, thickening and occlusion of deep dermal blood vessels, endothelial cell atypia, and destruction of the pilosebaceous units.

Prognosis and Treatment

Surgical excision is often the treatment of choice, because radiation-induced SCCs have a higher potential for metastases. Persons with ionizing radiation exposure should be followed with skin examinations at regular intervals for the rest of their lives, because the latency period for the development of cutaneous neoplasms is quite long, and the number of skin cancers in such patients tends to increase with time after irradiation. Evaluation for the development of internal malignancies, for which this exposure carries high risk, should also be considered in the long-term follow-up of these patients. Finally, these patients should be counseled to avoid other potential carcinogens, such as UV radiation.

CHRONIC SCAR KERATOSES

Chronic scar keratoses (CSKs), also known as *chronic cicatrix keratoses*, are precancerous keratotic lesions that arise in long-standing scars. CSKs can arise in association with a number of different chronic scarring processes, such as chronic ulcers, burn scars, pilonidal sinuses, draining sinuses, chronic osteomyelitis, vaccination scars, chronic hidradenitis suppurativa, old frostbite scars, and scarring acne vulgaris.

History

Etiology and Pathogenesis

The pathogenesis of a pre-malignant keratosis or a carcinoma arising in a

CHRONIC SCAR KERATOSES AT A GLANCE

- Chronic scar keratoses (CSKs), or cicatrix keratoses, are precancerous lesions that arise in long-standing scars from various causes.
- *Marjolin's ulcer* describes malignant changes within a burn scar but can also refer to such changes in chronic ulcers or sinus tracts.
- Approximately 2 percent of burn scars will undergo malignant changes.
- Most burn scar carcinomas are squamous cell carcinomas, but basal cell carcinomas, melanomas, sarcomas, and malignant fibrous histiocytomas have also been described.
- Acute Marjolin's ulcer develops within 1 year of the time of injury; chronic Marjolin's ulcer develops more than 1 year after an injury, with an average latency period of 36 years.
- Sites of predilection are the extremities and overlying joints.
- Any persistent lesion, erosion, or ulceration within a scar requires biopsy.
- Prevention includes excellent wound care, early skin grafting, avoidance of contractures, and early excision of any tissue showing degenerative changes.

chronic scar is not known. Proposed mechanisms for malignant degeneration within a burn scar include production of a carcinogenic toxin with the burn injury; immunologic privilege within scarred tissue that allows unchecked tumor growth; chronic irritation leading to malignancy; multi-step carcinogenesis involving initiation, promotion, and progression; and burn-induced DNA damage leading to malignant transformation. Characteristics of the burn scar that predispose to malignant transformation include a prolonged healing phase, repetitive trauma, and graft rejection.

Clinical Findings

CSKs present as hyperkeratotic papules, plaques, or erosions within the scarred skin. In terms of burn scars, two clinical types of carcinoma have been described. The more common presentation is of a flat, ulcerative, indurated lesion with elevated borders and surrounding induration. The less common type is an exophytic, papillomatous lesion resembling granulation tissue.[100] Bleeding, pain, and a foul odor may also be present. Typically, chronic and recurrent ulcerations have been present in the burn scar before malignant degeneration, and the malignancy often develops at an ulcer margin. One important fact about burn scar carcinomas is that usually only a portion of the ulcer undergoes malignant transformation. The remaining ulcer persists as a nonhealing wound, and thus the rate of false-negative results from biopsies of the ulcer is quite high.[99] Sites of predilection for burn scar carcinomas are the extremities and areas overlying joints, presumably because of repeated trauma in these areas.

Histopathology

Histopathologically, most scar keratoses range in pattern from several atypical keratinocytes to full-thickness epidermal atypia or in situ SCC. The majority of burn scar carcinomas are of the well-differentiated squamous cell type. When the diagnosis is based on histopathologic features, scar keratoses may be confused with pseudoepitheliomatous hyperplasia, a benign reactionary process.

Diagnosis

Biopsy should be performed on any persistent lesion, erosion, or ulceration within a scar. In addition, for burn scar carcinomas, because only a portion of the ulcer may be malignant, multiple biopsies or excisional biopsies are recommended if the suspicion of carcinoma is high, so the diagnosis will not be missed.

Prognosis and Clinical Course

CSKs may show a gradual progression to in situ carcinoma and frank SCC. Prompt diagnosis of these lesions is important, because once invasive SCC develops in a scar, it can quickly become aggressive, and the risk for metastasis is high. For burn scar carcinoma, the metastatic rate is estimated at approximately 35 percent, much higher than for actinically induced SCC.[100] Lesions occurring on the lower extremities have the highest rates of metastases, averaging 50 percent,[102] whereas those on the head, neck, and upper extremities fare better. Lymph node metastasis on presentation is the single most important indicator of poor prognosis.

Treatment and Prevention

Burn scar carcinoma may be prevented by meticulous burn wound care, early skin grafting, prompt treatment of infections, avoidance of contractures, and early excision of any degenerative changes within the scarred area, with step sections through the specimen to ensure that a malignancy has not been missed. Excision with wide margins (at least 2 cm) is the treatment of choice for burn scar carcinoma.[100,102] Radiation therapy and topical chemotherapy have not been beneficial in the treatment of these lesions.[100,102]

REACTIONAL KERATOSES

Reactional keratoses (RKs) are pre-malignant keratotic lesions that may arise in a variety of long-standing, non-scarring, inflammatory processes such as cutaneous lupus erythematosus, necrobiosis lipoidica, porokeratosis, erythema elevatum diutinum, granuloma inguinale, epidermolysis bullosa variants, pemphigus vulgaris, lichen sclerosis, lichen planus, and chronic deep fungal infections. Clinically, RKs present as hyperkeratotic papules or plaques. As with other precancerous keratotic lesions, a continuum from RK to SCC in situ to invasive SCC may be seen. Once invasive SCC has appeared, there is a significant risk that metastatic disease will develop, similar to that with scar keratoses. The main diagnosis to consider in the clinical and histologic differential is pseudoepitheliomatous hyperplasia.

PUVA KERATOSES

Psoralen plus ultraviolet A (PUVA) keratoses are precancerous keratotic lesions that arise in individuals exposed to PUVA for the treatment of a variety of cutaneous conditions. UVA light alone is thought to play a role in skin cancer formation, but the combination of UVA with psoralen is associated with a dose-dependent increased risk of pre-malignant keratoses and other cutaneous malignancies, such as SCC, melanoma, and, possibly, Merkel cell carcinoma (see Chaps. 112 and 239).

VIRAL KERATOSES

Viral keratoses, otherwise known as *warts*, are some of the most common keratotic lesions in humans. These lesions are caused by infection with the human papillomavirus (HPV). The role of HPV as an etiologic agent in the development of pre-malignant and malignant neoplasms is discussed further in Chaps. 111 and 196.

Bowenoid Papulosis

Bowenoid papulosis (BP) is characterized clinically by the presence of pigmented verrucous papules and plaques primarily on the genitalia of predisposed individuals, and histopathologically by the presence of SCC in situ–like changes (Fig. 113-10) (see also Chap. 75).

BP is caused by infection with HPV, and numerous HPV types have been linked to BP, including types 16, 18, 31 to 35, 39, 42, 48, and 51 to 54 (see Chap. 196). Lesions are pink, reddish brown, or violaceous (see Fig. 113-10). Differential diagnosis includes early condylomata acuminata (see Chaps. 75 and 76).

Histopathologically, the epidermis is usually hyperplastic with atypia, disordered maturation, scattered mitotic figures, and dyskeratotic keratinocytes.

The course of BP is variable, ranging from spontaneous regression to persistence of lesions to transformation into BD and invasive SCC. Patients with BP and their sexual partners should be followed and examined periodically, because of the risk of developing SCC, cervical, and vulvar neoplasia.[106] Patients with persistent disease should probably undergo testing for altered immune status. Treatment of BP is recommended, and it typically responds well to local therapy, although recurrences are common. Therapeutic options include local destructive measures such as curettage

VIRAL KERATOSES AT A GLANCE

- Two viral keratoses with the potential for malignant transformation are bowenoid papulosis (BP) and epidermodysplasia verruciformis (EV).
- BP is a precancerous condition of the genitalia caused by infection with human papillomavirus (HPV); oncogenic types 16, 18, and 33 are most commonly involved.
- BP may regress spontaneously, persist, or transform into Bowen disease or squamous cell carcinoma (SCC).
- Treatment options include topical imiquimod, curettage, excision, and laser vaporization.
- Sexual partners of patients must be examined and followed closely for development of cervical, vulvar, or penile carcinoma.
- EV is a rare autosomal recessive disease associated with mutations in the EVER1 and EVER2 genes.
- Affected individuals show a propensity toward infection with certain strains of HPV-5 and HPV-8.
- Clinical presentation is widespread flat wart-like papules and plaques in childhood; risk of developing SCC later in life is high.
- Sun avoidance, sun-protective measures, regular dermatologic follow-up, and screening of family members for the disease is important.

with or without electrocautery, CO_2 laser, neodymium:YAG laser, cryosurgery, and excision. Topical tretinoin, topical 5-FU, and topical cidofovir have been used in anecdotally reported cases with mixed results.[107] More recently, topical 5 percent imiquimod cream has shown promising results in a few case reports and would be the logical choice given its efficacy against HPV.[108–111]

Epidermodysplasia Verruciformis (See Chap. 196)

Epidermodysplasia verruciformis (EV) is a rare autosomal recessive genetic disease that manifests in childhood with disseminated flat, wart-like papules and plaques. These individuals are at high risk for the development of SCC in these wart-like lesions, which result from an abnormal propensity to infection with certain HPV sub-types, most notably HPV-5 and HPV-8 (see Chaps. 111 and 196). A susceptibility locus for EV was localized to chromosome band 17q25 in 1999,[112] and mutations in two novel genes from this same region (EVER1 and EVER2) were identified and associated with EV more recently.[113]

These patients present with numerous thin, pink, flat papules and plaques that resemble verruca plana. They also may have widespread scaly, erythematous, or hypopigmented macules and flat papules that appear similar to tinea versicolor.

SQUAMOUS CELL CARCINOMA IN SITU (BOWEN DISEASE)

BD is SCC in situ, originally described in 1912 by John T. Bowen, a Boston dermatologist.[114] It affects both skin and mucous membranes and has the potential to progress to invasive SCC.

Epidemiology

BD may occur at any age in adults, but it is rarely seen in individuals younger than 30 years. The typical patient with BD is older than 60 years. The disease is said to occur with an equal incidence in men and women, although most studies report a slight preponderance in women.[115] BD can be found on any body site, including both sun-exposed and non–sun-exposed regions of the body, although it appears to have a predilection for sun-exposed surfaces such as the head and neck and for the lower legs of women, in particular. The exact incidence of BD in the United States is unknown, but in one population study in Hawaii, the incidence was estimated at 142 per 100,000 persons.[116] Lesions of BD are usually solitary but are multiple in up to 10 percent to 20 percent of individuals.

Etiology and Pathogenesis

A number of different factors have been implicated in the development of BD, including a history of significant sun exposure, arsenic exposure, ionizing radiation, immunosuppression, and certain types of HPV infection. Up to 30 percent of extragenital BD lesions have been found to harbor HPV DNA.[117,118] The age group and sites of predilection of BD suggest a strong association with sun exposure. BD is also rare in more heavily pigmented individuals, and it has been described with increased frequency in patients undergoing PUVA therapy. The association with arsenic exposure has already been discussed. SCC in situ is seen commonly in organ transplant recipients after years of immunosuppressive drug therapy. Infection with HPV has been implicated in causing certain sub-types of BD. In particular, HPV-16 has been detected in many cases of anogenital BD and in some cases of finger and periungual BD.[119]

Clinical Findings

BD typically presents as a discrete, slowly enlarging, pink to erythematous thin plaque with well-demarcated, irregular borders and overlying scale or crust (Fig. 113-11A) resembling a psoriatic plaque. Hyperkeratotic and verrucous surface changes may be seen, and a pigmented variant of BD has been reported in fewer than 2 percent of cases.[120] Indi-

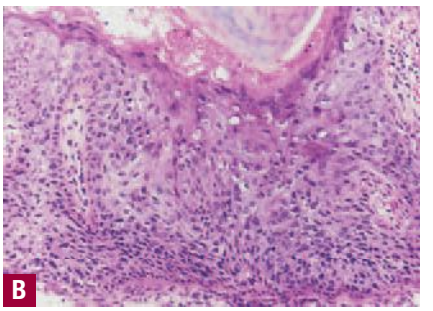
SQUAMOUS CELL CARCINOMA IN SITU (BOWEN DISEASE)

AT A GLANCE

- Bowen disease (BD) is squamous cell carcinoma (SCC) in situ, with the potential to progress to SCC.
- Etiologic factors include ultraviolet radiation exposure, chronic arsenicism, previous therapy with psoralen and ultraviolet A radiation, immunosuppression, exposure to ionizing radiation, and infection with human papillomavirus.
- Clinical variants are pigmented, intertriginous, periungual, and subungual BD.
- Histopathologic features include full-thickness epidermal atypia with adnexal involvement.
- Lesions progress to invasive carcinoma in 3 percent to 5 percent of cases.
- Treatment methods include excision and Mohs micrographic surgery, which permit histopathologic evaluation to exclude invasive SCC.
- Curettage treatment of BD may miss appendageal involvement.
- Topical therapy may be used in areas that are difficult to treat with other methods.

vidual lesions may measure up to several centimeters in diameter, and multiple lesions are not uncommon. As previously mentioned, sites of predilection include sun-exposed areas such as the head and neck and lower legs, although any body site may be affected.

A few clinical variants of BD deserve special mention. Intertriginous BD can present as an oozing, erythematous, dermatitic plaque or as a pigmented patch or plaque. BD involving the periungual region may appear as an erythematous, scaly, thin plaque around the cuticular margin, a crusted erosion, nail discoloration or onycholysis, a verrucous plaque, or destruction of the nail plate. BD of the mucosal surfaces can present as verrucous or polypoid papules and plaques, erythroplakia, or a velvety erythematous plaque. These last two entities are discussed separately in the sections Erythroplakia (Erythroplasia) and Erythroplasia of Queyrat.



▲ **FIGURE 113-11** **A.** Large plaque of Bowen disease of the leg. **B.** Bowen disease showing full-thickness atypia of epithelium.

Histopathology

The epidermis displays full-thickness atypia, including in the intraepidermal portions of the adnexal structures (see Fig. 113-11B). Involvement reaches from the stratum corneum down through the basal cell layer, although the basement membrane remains intact. Characteristically, parakeratosis and hyperkeratosis are present, as is acanthosis, with complete disorganization of the epidermal architecture. At times the hyperkeratosis and parakeratosis are so pronounced that a cutaneous horn is present. Throughout the epidermis are numerous atypical, pleomorphic, hyperchromatic keratinocytes. These cells are sometimes vacuolated and have a prominent pale-staining cytoplasm, reminiscent of the cells in Paget disease. These cells show loss of maturation and polarity, in addition to numerous mitotic figures. Individually keratinized cells with large, rounded, eosinophilic cytoplasm and hyperchromatic nuclei can be found in the epidermis, as can multinucleated cells. These atypical cells also are seen throughout the pilosebaceous units, within the acrotrichia, follicular infundibula, and sebaceous glands. The upper dermis is typically infiltrated by numerous cells associated with chronic inflammation, including lymphocytes, plasma cells, and histiocytes.

Diagnosis and Differential Diagnosis

Clinically, BD is most often mistaken for superficial BCC; patches of dermatitis, psoriasis, or lichen planus; AK; benign lichenoid keratosis or lichen planus–like keratosis; irritated seborrheic keratosis; or amelanotic melanoma (Box 113-4). More hyperkeratotic or verrucous lesions of BD may be difficult to distinguish clinically from viral warts, seborrheic keratoses, and SCC, and pigmented BD lesions can be mistaken for melanoma. Superficial BCC can sometimes be distinguished by its raised, subtle, translucent border.

Prognosis and Clinical Course

The risk that untreated BD will progress to invasive carcinoma has been estimated in one older study at approximately 3 percent to 5 percent.[117] Estimates are that once invasive carcinoma occurs in BD [see thumbnail image in Squamous Cell Carcinoma In Situ (Bowen Disease) At a Glance box], approximately 13 percent of these carcinomas will metastasize, and, of these cases, 10 percent will end in death from widespread dissemination.[122]

The presence of BD in any given individual is a marker for a high risk of developing a subsequent NMSC.[123] In studies addressing the association between the presence of BD and the risk of other NMSCs, approximately 30 percent to 50 percent of BD patients had either previous or subsequent NMSC. Another study estimated the incidence ratio for subsequent NMSC to be 4.3.[123] Previous studies also claimed that the presence of BD is a marker for internal malignancy, although a significant number of other investigations have been unable to substantiate this association. Critical analysis and meta-analysis of these past studies do not support the need for routine investigation for internal malignancy in persons with BD. The one exception to this position is in cases of BD related to previous arsenic exposure, in which the possibility of internal malignancy is real, as previously discussed. Also, BD involving the vulvar region in females has been associated

- Eccrine carcinoma
- Merkel cell carcinoma
- Sebaceous carcinoma
- Bowenoid papulosis
- Podophyllin-induced changes in a wart

with an increased risk of uterine, cervical, and vaginal cancer, possibly due to HPV infection, as discussed.[86,124]

Treatment

A number of different modalities are available for the treatment of BD. Such treatments can be divided into three main categories: surgical and destructive therapies, topical therapies, and non-surgical ablative therapies (Box 113-5). Surgical and destructive therapies include excision, Mohs micrographic surgery, curettage with or without electrocautery, chemoablation with TCA, and cryosurgery. Topical therapies include 5-FU and 5 percent imiquimod cream (see Chap. 221). Non-surgical ablative therapies are laser ablation, radiotherapy, and PDT (see Chap. 239). Although some of these modalities have reported cure rates that are better than others, no one treatment is right for all forms of BD. Therapy must be guided by the size and location of the BD, in addition to individual patient characteristics, such as age and healing capability.

Box 113-5

Treatment of Bowen Disease

SURGICAL AND DESTRUCTIVE THERAPIES

- Excision
- Mohs micrographic surgery
- Curettage with or without electrocautery
- Liquid nitrogen cryosurgery

TOPICAL THERAPIES

- 5-Fluorouracil (5% cream bid for 6–16 wk)
- 5% imiquimod (daily for 16 wk)

NON-SURGICAL ABLATIVE THERAPIES

- Laser ablation
- Radiotherapy
- Photodynamic therapy

ERYTHROPLASIA OF QUEYRAT

ERYTHROPLASIA OF QUEYRAT AT A GLANCE

- Erythroplasia of Queyrat (EQ) is an in situ squamous cell carcinoma (SCC) involving the mucosal surfaces of the penis in uncircumcised males.
- EQ is clinically distinct from Bowen disease.
- Human papillomavirus types 8 and 16 are identified in most cases.
- EQ progresses to invasive SCC in approximately 10 percent of cases.
- Preventive measures include circumcision and excellent hygiene.
- Recommended treatment is Mohs micrographic surgery. Excision, CO_2 laser vaporization, and topical 5-fluorouracil are secondary alternatives.

Etiology and Pathogenesis

Erythroplasia of Queyrat (EQ) is an in situ SCC affecting the mucosal surfaces of the penis in uncircumcised males. This condition was described by Queyrat in 1911 as "erythroplasie du gland."[125] The term *erythroplasia of Queyrat*, rather than simply SCC in situ or BD, is preferred for this condition because it is clinically distinct, presenting as a well-demarcated, shiny, velvety, bright red plaque. EQ occurs in uncircumcised men between the ages of 20 and 80 years, although the majority of cases are seen between the third and sixth decades. Risk factors for the development of this condition in uncircumcised males include poor hygiene, accumulation of smegma, heat, friction, trauma, and genital herpes simplex virus infection.[126] Co-infection with HPV subtypes 8 and 16 was identified in almost all EQ lesions that were investigated in one study.[126] Additional co-infection with HPV sub-types 39 and/or 51 was seen in several of these lesions. This study proposed that EQ differs from BD and other genital neoplasias in that co-infection with HPV-8 and other carcinogenic genital HPV types occurs in EQ.

Clinical Findings

EQ presents as a glistening, red, velvety plaque on the glans penis, the prepuce, or the urethra (Fig. 113-12). It begins as a solitary plaque in approximately 50 percent of cases, and as multiple plaques in the remainder.[86] Affected males complain of localized pain, pruritus, difficulty retracting the foreskin over the glans, bleeding, and crusting (see Chap. 75).

▲ **FIGURE 113-12** Erythroplasia of Queyrat. (Used with permission from James E. Fitzpatrick, MD.)

Histopathology

Histopathologically, EQ is similar to BD as previously described. In addition, there may also be epidermal hypoplasia and many more plasma cells in the dermal infiltrate, as is often seen in other processes affecting mucosal surfaces.

Diagnosis and Differential Diagnosis

The differential diagnosis includes other benign inflammatory conditions such as psoriasis, seborrheic dermatitis, lichen planus, lichen sclerosus, candidiasis, plasma cell balanitis (Zoon balanitis), lymphogranuloma venereum, granuloma inguinale, syphilis, and drug eruptions. If the diagnosis of EQ is under consideration, a biopsy should be performed.

Prognosis and Clinical Course

Lesions of EQ persist and enlarge slowly, and they typically have been present for several years (an average of 3.4 years in one study)[127] before a biopsy is taken. Progression of EQ to invasive SCC is more common than for the lesions of BD and is said to occur in approximately 10 percent of cases.[126,128] Once invasive SCC has occurred, approximately 20 percent of patients will display evidence of regional lymph node involvement or more distant metastases.[86]

Treatment and Prevention

Prevention of EQ in uncircumcised males may be maximized by adherence to good personal hygiene regimens, and early circumcision may also reduce the incidence of this disease. Several treatment options are available, including excision, Mohs micrographic surgery, CO_2 laser ablation, topical 5-FU, and topical imiquimod. Because of the strong association of EQ with HPV infection, topical imiquimod would intuitively seem a likely treatment choice for EQ. Several case reports have demonstrated its efficacy in treating EQ,[117] but no large, well-designed studies have been published to date to confirm its efficacy in treating this disease. Review of current data indicates that PDT does not yet seem to be as effective as a lone treatment modality for EQ.[129]

LEUKOPLAKIA

Leukoplakia is a clinical term that refers to a predominantly white lesion of the oral mucosa that cannot be rubbed off or characterized by any other definable lesion or known disease.[130] Leukoplakia is the most common precancerous lesion of the oral mucosa, with the potential to become oral SCC (OSCC).[131] Oral leukoplakia (OL) is in the same clinical spectrum of disease as oral erythroplakia (OE), but unlike OE it is a much more frequently diagnosed lesion with a much lower rate of malignant transformation.

Epidemiology

The reported prevalence of OL varies from 0.2 percent to 5 percent, although such rates vary significantly among different geographical areas and demographic groups.[132] In a worldwide systematic review of OL that included multiple studies involving more than 1000 subjects, prevalence rates varied between 0.50 percent and 3.46 percent.[133] The pooled prevalence estimate of OL in this study was between 1.49 percent and 4.27 percent.[133]

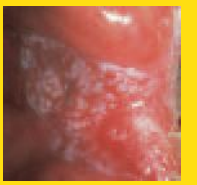
In addition to potentially becoming a malignant growth, OL, and for that matter OE, have come to be viewed as risk factors or markers for other epithelial cancers of the oral cavity and upper aerodigestive tract. The concept of field cancerization applied to the oral mucosa implies that its entire surface can be affected by carcinogens. Indeed, approximately 20 percent of patients with SCC of the head and neck will develop another malignancy or precancerous lesion within 5 years of the first diagnosis.[134]

Etiology and Pathogenesis

Given the current definition of leukoplakia, identification of an etiologic factor for a given white lesion would exclude this diagnosis. Two factors in this setting are tobacco use and candidiasis. Tobacco use is believed to be a strong risk factor for the development of OL. Tobacco-related white lesions of the oral mucosa have been identified and then subsequently found to disappear once the habit of tobacco use has been discontinued. By current definitions and standards, such tobacco-related white lesions are thought to be different entities than true OL, which would not disappear with cessation of tobacco use.

Likewise, there has been much debate as to whether or not *Candida* infection is a cause of leukoplakia or a superimposed infection within a pre-existing OL lesion. If one adheres to the strict and accepted definition of leukoplakia, a white lesion that disappears upon treatment of *Candida* infection is not leukoplakia. Thus, it is probably best to make a preliminary diagnosis of leukoplakia and then treat any underlying candidal infection and have the patient discontinue use of any tobacco products to see if the white lesion resolves. If such a lesion then resolves, it is not true leukoplakia.

LEUKOPLAKIA AT A GLANCE



- Leukoplakia is a clinical diagnosis of exclusion for a fixed white lesion in the oral cavity that does not resolve spontaneously.
- Oral leukoplakia (OL) is the most common precancerous lesion of the oral mucosa, with the potential to become oral squamous cell carcinoma (OSCC).
- Prevalence is 0.2 percent to 5.0 percent.
- Approximately 50 percent of OSCCs are associated with precancerous lesions.
- OL and oral erythroplakia are markers for increased risk for additional oral or upper aerodigestive tract malignancies.
- Risk factors for OL are the use of any tobacco product, concomitant alcohol use, history of previous OSCC or premalignant lesions, and infection with certain human papillomavirus sub-types.
- No consensus exists on how best to treat OL.

Clinical Findings

OL is clinically divided into two subtypes: homogeneous OL and non-homogeneous OL. Homogeneous OL has been defined as a mostly white, flat, uniform lesion that may have shallow cracks and a smooth, wrinkled, or corrugated surface that is consistent throughout.[137] Non-homogeneous OL has been defined as a mostly white or white and red lesion (erythroleukoplakia) that may be either irregular and flat, nodular (speckled), ulcerative, or verrucous. Non-homogeneous OL purportedly has a risk of malignant transformation that is four to five times higher than that of homogeneous OL. Another clinical sub-type of OL is proliferative verrucous leukoplakia, which

is most often found in patients who do not use tobacco products. This sub-type has a high rate of transformation to malignancy.[138]

Histopathology

If the provisional diagnosis of OL is at all in doubt and/or a waiting period to assess for possible regression or disappearance of a white lesion after eliminating possible causative factors has not resulted in resolution of the lesion, the next advisable step in evaluating the oral white lesion is to obtain a biopsy specimen for histopathologic diagnosis. This is where the concepts of epithelial dysplasia and carcinoma in situ enter the picture.

In relation to the oral mucosa, epithelial dysplasia has been defined as a "precancerous lesion of stratified squamous epithelium characterized by cellular atypia and loss of normal maturation and stratification short of carcinoma in situ."[143] Carcinoma in situ of the oral cavity has been described as "a lesion in which the full thickness, or almost the full thickness, of squamous epithelium shows the cellular features of carcinoma without stromal invasion."[143] Criteria have been put forth for diagnosing these changes, and the more prominent and numerous the designated features are, the more severe the grade of dysplasia.[131,137]

Diagnosis and Differential Diagnosis

A diagnosis of leukoplakia is made when a fixed white lesion of the oral mucosa is detected and cannot be identified as any other definable lesion or condition. Some suggest distinguishing between a provisional clinical diagnosis of OL and a definitive diagnosis of OL.[130] A provisional diagnosis of OL is made at the time of the initial examination when no other diagnosis for the white lesion is obvious. At this point, other possibilities to consider in the differential diagnosis are tobacco-associated lesions, *Candida*-associated lesions, lichen planus, leukoedema, lupus erythematosus, Epstein-Barr virus–associated oral hairy leukoplakia, oral white sponge nevus, mechanical or frictional irritation, contact lesions, cheek/lip/tongue biting, linea alba, aspirin burn, OSCC, and verrucous carcinoma (Box 113-6). If causative factors for the white lesion are suspected, it is recommended that these factors be eliminated for a period of 2 to 6 weeks to observe for regression of the white lesion. If on re-evaluation the white lesion persists, biopsy should be performed. If the lesion is a clinically high-risk one, biopsy should be performed before such a waiting period.

Box 113-6

Clinical Differential Diagnosis of Oral Leukoplakia and Oral Erythroplakia

CLINICAL DIFFERENTIAL DIAGNOSIS OF ORAL LEUKOPLAKIA

- Atrophic lichen planus
- Lupus erythematosus
- Pemphigus
- Cicatricial pemphigoid
- Kaposi sarcoma
- Chronic contact or allergic contact dermatitis
- Chronic mechanical trauma
- Thermal or mechanical injury
- Squamous cell carcinoma
- Amelanotic melanoma

Prognosis and Clinical Course

Once a definitive diagnosis of OL has been made, the risk of transformation to OSCC needs to be evaluated. The rate of malignant transformation of OL into OSCC has been found to vary from almost 0 percent to 20 percent in 1 to 30 years.[144] A study based on European epidemiologic data investigated the natural limit of malignant transformation of OL to OSCC. This study concluded that the upper limit of the annual malignant transformation rate of OL is unlikely to exceed 1 percent.[132]

DNA aneuploidy has shown the most promise as a prognostic indicator. DNA content (DNA ploidy) of a cell roughly estimates the amount of genetic instability and aberrant DNA. In malignancies the genetically stable diploid and tetraploid cells are replaced by genetically unstable aneuploid cells. In some studies DNA aneuploidy was a powerful predictor of the development of OSCC in OL lesions, whereas normal DNA content indicated a low risk.[145] A more recent study showed that additional oral malignancies consistently arose in patients whose dysplastic OL was marked by aneuploidy and that these individuals also had worse survival rates.[146] In addition, these investigators found that surgical removal of these dysplastic OL lesions with histologically clear margins did not result in better outcomes. They proposed that it is aneuploidy that best predicts poor survival in dysplastic OL.

Treatment and Prevention

There is no consensus on the most appropriate treatment for OL. Some recommend the following approach: if no or mild epithelial dysplasia exists histopathologically, pursue treatment if the OL is in a high-risk location or is large; if moderate or severe dysplasia exists histopathologically, then active treatment to remove the entire lesion is recommended.[137]

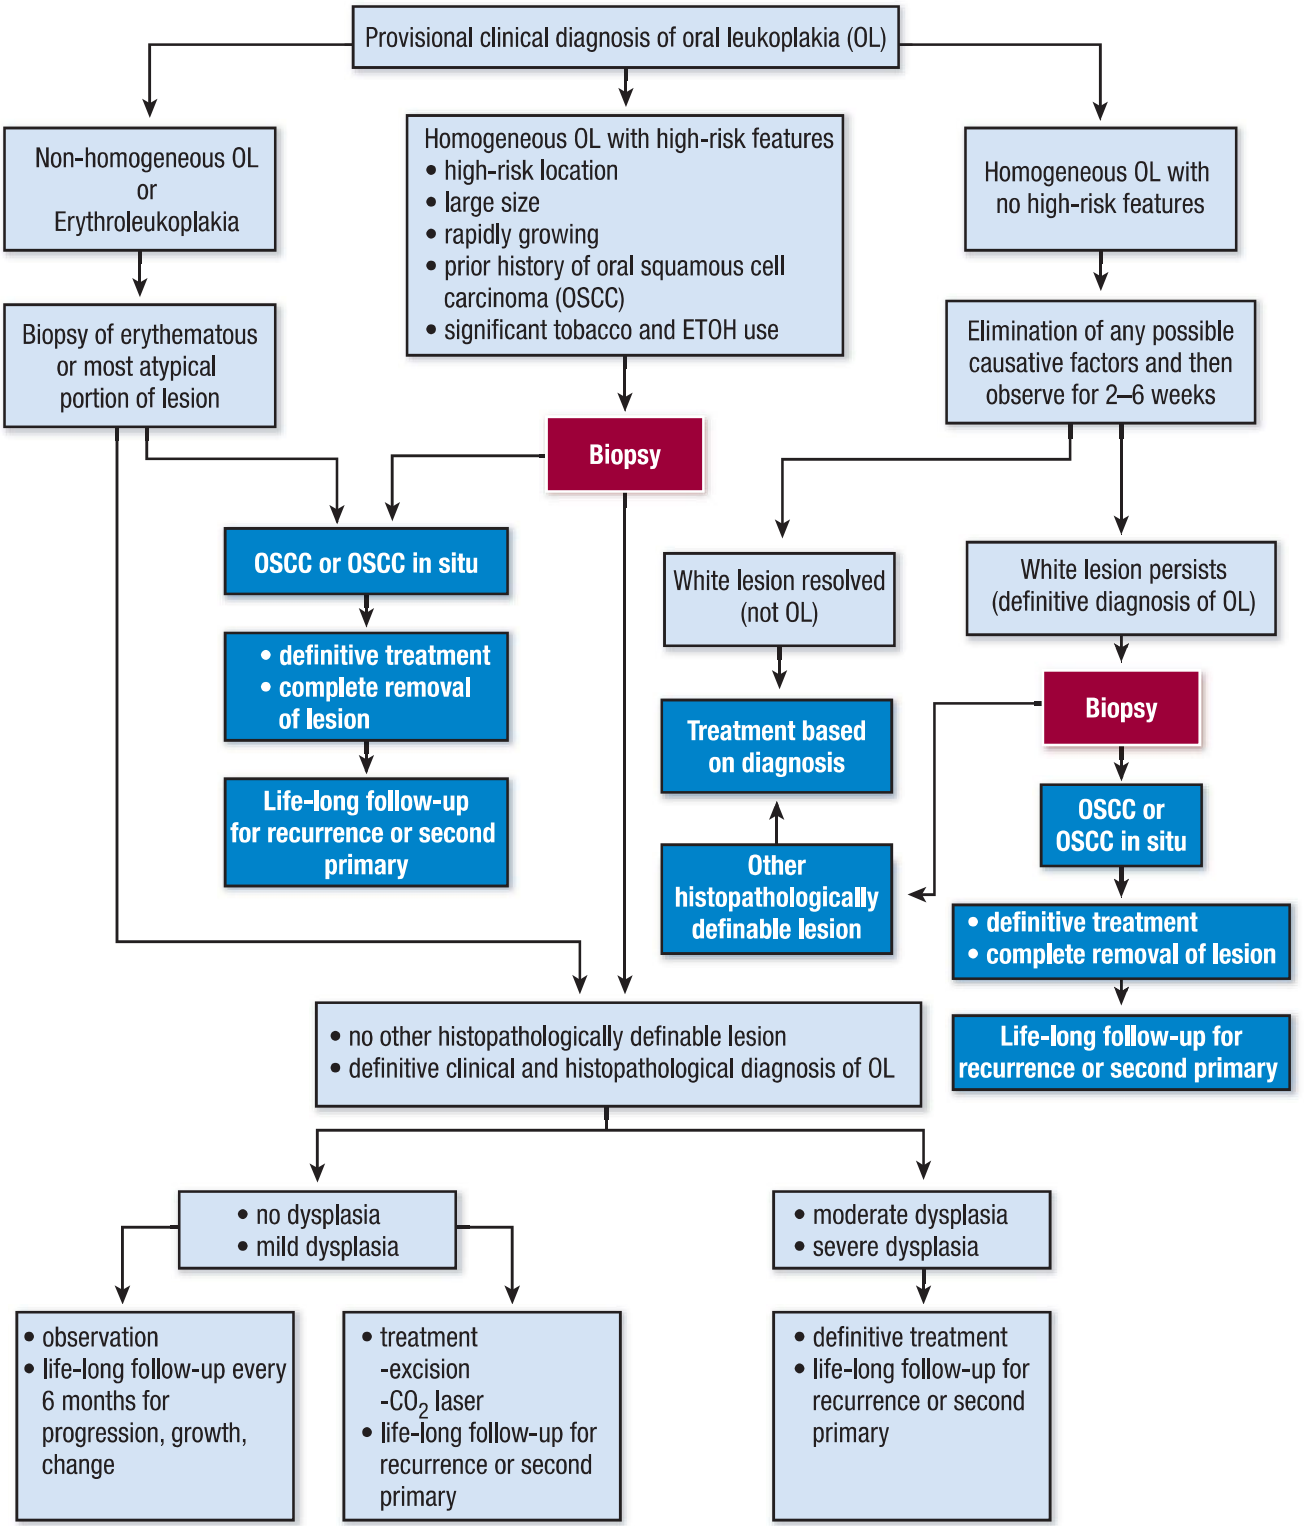
Because the recurrence of OL after treatment is common, because the risk of OSCC is present with or without treatment, and because patients with OL are at increased risk for additional head and neck malignancies, these patients need to be followed at regular intervals with thorough examinations and potentially with additional sampling biopsies. Follow-up intervals may vary from every 3 months in individuals at high risk to every 6 months in those at lower risk, for the rest of the patients' lives.

Despite all the controversies and inconsistencies surrounding OL, standard historical, clinical, and histopathologic findings are still the most important factors for predicting the possibility of malignant transformation of precancerous oral lesions. Evaluation for DNA aneuploidy in dysplastic OL may represent a useful tool in the near future for predicting potential aggressiveness and poor outcomes, but it is not yet available in mainstream clinical practice.

Treatment plans are guided mostly by findings from careful clinical and oral examinations, especially in individuals at high risk, and by histopathologic evaluation for the presence and degree of epithelial dysplasia (Fig. 113-13).

ERYTHROPLAKIA (ERYTHROPLASIA)

Erythroplakia, or *erythroplasia*, is a clinical term used to describe a red macule or



▲ **FIGURE 113-13** Approach to the management of oral leukoplakia. ETOH = ethanol.

patch on a mucosal surface that cannot be categorized as any other known disease entity caused by inflammatory, vascular, or traumatic factors. Histopathologically, it almost always displays either findings of SCC in situ or focal areas of invasive SCC, and thus is considered at least a precancerous lesion in most instances. Erythroplakia can involve any mucosal surface, but most commonly, in more than half of all cases, the lesions are on the oral mucosa. Of all oral precancerous lesions, it is considered to be the most dangerous and carries the greatest risk of progressing to or harboring invasive carcinoma.

Epidemiology

Erythroplakia is an uncommon lesion in the oral cavity, and it is said to be one of the least commonly diagnosed lesions among the group of oral lesions that may or may not become malignant.[148] The prevalence, based on a small num-

ERYTHROPLAKIA (ERYTHROPLASIA)

AT A GLANCE

- Erythroplakia is a clinical diagnosis of exclusion for a persistent fixed red patch in the oral cavity.
- It is the least common of all oral precancerous lesions but has the greatest potential to harbor or become oral squamous cell carcinoma.
- Risk factors are use of tobacco products and alcohol use.
- Histopathologic features include dysplasia, in situ carcinoma, or invasive carcinoma, seen in 40 percent to 50 percent of oral erythroplakia lesions.
- Early and effective treatment is important.
- Treatment for severely dysplastic lesions or in situ carcinoma is complete excision or Mohs micrographic surgery.

ber of worldwide studies, is between 0.02 percent and 0.83 percent.[149]

Etiology and Pathogenesis

Clinical Findings (See Chap. 74)

OE is found either intra-orally or on the vermillion surface of the lower lip. The most common areas in the oral cavity in which OE has been described are the soft palate, the floor of the mouth, and the buccal mucosa. OE presents as a subtle, asymptomatic, erythematous macule or patch. Most often it is less than 1.5 cm in its widest diameter, but lesions up to 4 cm in diameter have been described.[149] Characteristically it is sharply demarcated from the surrounding pink mucosa, and its surface is most often smooth and homogeneous in color. On occasion lesions of erythroplakia demonstrate a pebbled or stippled surface change and on palpation may have a soft and velvety feel. Induration indicates the presence of invasive carcinoma in many instances. Erythroplakia is commonly seen in association with leukoplakia, a condition termed *erythroleukoplakia*. Overwhelmingly, it is the red patches of erythroleukoplakia that are most likely to contain or develop into a malignancy.

Histopathology

Diagnosis and Differential Diagnosis

OE is a diagnosis of exclusion. The onus is on the clinician to rule out all other erythematous oral lesions before the term *oral erythroplakia* can be applied. Other entities that should be considered in the differential diagnosis include acute and chronic mechanical trauma, thermal or chemical injury, erythematous candidiasis, atrophic lichen planus, lupus erythematosus, pemphigus, cicatricial pemphigoid, Kaposi sarcoma, amelanotic melanoma, chronic contact or allergic dermatitis, submucosal hemorrhage, and various forms of glossitis (see Box 113-6). Of all of these possibilities, erythematous candidiasis and atrophic lichen planus are the most important considerations. In general, biopsy of any OE lesion should be performed if the cause is not obvious, if the lesion is in a high-risk location in the oral cavity, or if the lesion does not resolve over a period of several weeks.

Prognosis and Clinical Course

OE has the greatest risk for malignant transformation of all pre-malignant oral lesions. This elevated risk for malignant transformation is mostly based on the fact that histopathologic evaluation of OE usually reveals invasive SCC, SCC in situ, or severe dysplasia, as previously discussed. The rate at which in situ carcinoma of the oral cavity progresses to invasive SCC is not known exactly. The transformation rate for OSCC in situ or lesions with severe dysplasia has ranged from 14 percent to 50 percent, with an average of 26 percent.[148] In individuals at high risk, such as heavy smokers or drinkers, up to 80 percent of OE lesions on biopsy may contain focal areas of invasive carcinoma.[154]

Treatment and Prevention

Because OE has been shown to have the highest risk for malignant transformation, early and effective treatment of these lesions is thought to be important. The definitive treatment is controversial, and studies of the treatment of OE lesions by themselves are lacking. Recurrence rates after treatment of OE lesions are even less clear.

For severely dysplastic or in situ carcinoma lesions of erythroplakia, surgical excision or Mohs micrographic surgery is generally recommended, because the entire lesion can be removed with histopathologic confirmation of the diagnosis and adequate margins. The proper management of mildly or moderately dysplastic OE lesions is less clear, with some advocating excision and others promoting a more conservative, observational approach.

CHAPTER 114

Squamous Cell Carcinoma

Douglas Grossman
David J. Leffell

Cutaneous squamous cell carcinomas (SCCs) are malignant neoplasms derived from suprabasal epidermal keratinocytes. These and basal cell cancers are the non-melanoma skin cancers that represent the most common malignancies in humans. Whereas basal cell carcinoma (BCC) (see Chap. 115) is thought to arise de novo, SCC probably evolves in most cases from precursor lesions of actinic keratosis (AK) and Bowen disease (SCC in situ) (see Chap. 113). This chapter focuses on clinical aspects of invasive SCC. Cutaneous SCC represents a broad spectrum of disease ranging from easily managed, superficially invasive cancers to highly infiltrative, metastasizing tumors that can result in death. The clinical presentation can be variable despite the existence of easily identified typical lesions. The cellular and molecular aspects of SCC carcinogenesis are discussed elsewhere (see Chap. 112).

HISTORICAL ASPECTS

EPIDEMIOLOGY

Incidence

The precise incidence of BCC and SCC is unknown, because these cutaneous malignancies are not generally documented by the National Cancer Institute or most state cancer registries. It is generally accepted, however, that well over 1 million cases are diagnosed in the United States each year, with approximately 200,000 representing SCC.[10] Although less common than BCC, SCC carries a risk of metastasis and thus accounts for the majority of the several thousand deaths attributable to non-melanoma skin cancer each year. By comparison, cutaneous melanoma accounts for only 60,000 cases, but approximately 9000 deaths, annually.[11] Similar trends for SCC have been noted in Australia[12] and the Caribbean.[13]

SCC is strongly associated with advanced age, and a sharp increase in incidence is seen after age 40 years.[14] Today, the lifetime risk of SCC among whites is approximately 15 percent, almost double that of two decades ago. Increased exposures to ultraviolet (UV) radiation (through greater use of tanning salons, increased time spent outdoors, changes in clothing styles, and ozone depletion) and greater longevity have been suggested as possible causes for the increase in disease. It is likely that this trend will continue as a result of further depletion of the ozone layer and the aging of the U.S. population. The rising incidence of SCC over the past several decades has been paralleled by a 20 percent decrease in mortality, attributed largely to increased public awareness and aggressive treatment of high-risk lesions.[15] After a diagnosis of SCC, patients have a 44 percent to 50 percent cumulative risk of developing another non-melanoma skin cancer (18 percent to 30 percent risk of SCC) in the subsequent 3 to 5 years.[16] In addition, these patients are at increased risk for extra-cutaneous cancers.[17]

Demographics

Squamous cell cancer is twice as common in men as in women, probably as a result of greater lifetime UV exposure in men. Similarly, longer hairstyles and use of lipstick may account for the lower frequency of SCC on the ears and lips of women. There is an inverse relationship between skin pigmentation and SCC incidence, largely because of the protective effect of eumelanin. Thus, persons with white skin, blue eyes, fair complexion, red hair, and Celtic ancestry who tan poorly are at greatest risk. Increased pigmentation is associated not only with a lower incidence of SCC, but also with an inversion in the BCC/SCC ratio. In comparison with whites, the incidence of SCC is decreased by 30-fold in American blacks and the BCC/SCC ratio falls to 0.8:1.[14] Tanzanian albinos all develop SCC by young adulthood, and the ratio of BCC to SCC is only 0.2:1. Asians and Polynesians, with intermediate skin pigmentation, have correspondingly intermediate levels of SCC. A gene (MC1R) involved in melanogenesis that encodes the melanocortin 1 receptor is a major determinant of skin pigmentation and hair color. The MC1R gene is highly polymorphic, with more than 20 variants described.[18] Several variant MC1R alleles are associated with increased risk of SCC that is independent of skin type and hair color.

SQUAMOUS CELL CARCINOMA AT A GLANCE

- With basal cell carcinoma, most common human malignancy.
- Diagnosis is by biopsy.
- Caused by ultraviolet radiation in most cases.
- Precursor lesion is actinic keratosis.
- Treatment options are excision, Mohs microscopically controlled surgery, and radiation.

ETIOLOGY AND PATHOGENESIS

Predisposing Factors

There are a number of factors, including both acquired and genetic skin conditions, that may predispose to SCC (Table 114-1). Patients often demonstrate a multiplicity of factors that together are sufficient to induce SCC development. For example, a given skin site may be exposed to both UV radiation and another environmental carcinogen.

PRECURSOR LESIONS Most SCCs develop from precursor lesions such as AKs or Bowen disease (see Chap. 113).

ULTRAVIOLET RADIATION EXPOSURE UV radiation is considered the predomi-

TABLE 114-1
Predisposing Factors for Squamous Cell Carcinoma

- Precursor lesions (actinic keratosis, Bowen disease)
- Ultraviolet radiation exposure
- Ionizing radiation exposure
- Exposure to environmental carcinogens
- Immunosuppression
- Scars
- Burns or long-term heat exposure
- Chronic scarring or inflammatory dermatoses
- Human papillomavirus infection
- Genodermatoses (albinism, xeroderma pigmentosum, porokeratosis, epidermolysis bullosa)

nant risk factor for SCC. Importantly, there is a linear correlation between the incidence of SCC and exposure to UV radiation. The incidence of SCC has been reported to double with each 8- to 10-degree decline in geographic latitude and is highest at the equator.[19] World War II veterans stationed in the Pacific developed much higher rates of SCC than did their colleagues who served in Europe.[20] Similarly, SCC is more prevalent in Japanese people who emigrated to Hawaii than in those who remained in Japan.[21] Excessive UV radiation appears to be related more to the development of SCC than to the development of BCC. Rates of SCC rise more rapidly than those of BCC with increasing UV exposure,[22] and UV radiation–induced skin cancers in mice are almost exclusively SCCs rather than BCCs.[23] Moreover, in patients receiving long-term therapy with psoralen plus ultraviolet A (UVA) radiation for treatment of psoriasis there is an associated 30-fold increase in non-melanoma skin cancers, most of which are SCCs.[24]

IONIZING RADIATION There is a strong association between SCC and exposure to ionizing radiation. In one survey of SCC patients, an association with radiation therapy was observed only in those whose skin was likely to sunburn (see Chap. 113).

ENVIRONMENTAL CARCINOGENS Numerous occupational and environmental carcinogens, such as arsenic and aromatic hydrocarbons, predispose to the development of SCCs. With the exception of 3-methylcholanthrene and anthramine, chemical carcinogens generally produce SCCs rather than BCCs.[25] Exposures to insecticides and herbicides have also been associated with SCCs. In addition, smoking and alcohol use are strongly associated with SCCs of the oral cavity.

IMMUNOSUPPRESSION Chronic immunosuppression may lead to an increase in SCCs, primarily on sun-exposed sites.[26] An 18-fold increase in SCC has been reported in renal transplant patients[27]; these tend to appear 3 to 7 years after the onset of long-term immunosuppressive therapy, with corticosteroids, azathioprine, and cyclosporine most frequently implicated. With the increase in the total number of organ transplant patients, management of SCCs in this population is becoming more important. In patients with leukemia and lymphoma, SCCs are both increased and more aggressive.[28] Although multiple SCCs have been described in patients infected with human immunodeficiency virus, advanced human immunodeficiency virus infection has generally not been associated with an increased incidence of SCC, possibly because many patients do not live long enough to develop them.

SCARS AND UNDERLYING DISEASES Historically, SCC was associated with both burn scars and chronic ulcers as noted earlier, but such associations are seldom seen today. Also rare but reported is the development of SCCs in the context of chronic infections, particularly those associated with draining sinuses and scarring, such as perianal pyoderma, osteomyelitis, chromomycosis, hyalohyphomycosis, granuloma inguinale, lupus vulgaris, and leprosy. Chronic inflammatory processes, particularly those associated with scarring, such as venous ulcer, snakebite ulcer, discoid lupus erythematosus, oral lichen planus, morphea, lichen sclerosus, pilonidal cyst, acne conglobata, hidradenitis suppurativa, Hailey-Hailey disease, dissecting folliculitis of the scalp, and necrobiosis lipoidica, all can give rise to SCCs. An exception is vaccination scars, which are associated with BCCs rather than SCCs. SCCs have also been observed in transplanted skin, epidermal cyst, dental cyst, and dermoid cyst.

THERMAL FACTORS Long-term heat exposure can lead to SCCs. The role of thermal radiation in the development of skin cancer has long been recognized in many cultures, where common practices include placing hot ashes under the clothes to keep warm in winter or smoking opium while lying on heated beds. The incidence of SCCs is increased in persons who habitually sit in front of heating stoves and at sites of erythema ab igne (see Chap. 113).

HUMAN PAPILLOMAVIRUS INFECTION There is a role for human papillomavirus (HPV) infection in some types of SCCs. Verrucous carcinoma appears to be associated with several HPV types, as noted later. Head and neck and periungual SCCs are frequently associated with HPV-16. Patients with epidermodysplasia verruciformis are chronically infected with HPV, most commonly type 5, and one-third of these patients ultimately develop SCCs (see Chaps. 113 and 196).

GENODERMATOSES A variety of heritable diseases predispose to SCC development. Patients with oculocutaneous albinism develop predominantly SCCs (rather than BCCs) at an early age (see Chap. 71). Xeroderma pigmentosum (see Chaps. 109 and 140), a disorder of DNA repair, is also characterized by early development of SCCs. SCCs have been reported to develop in the Mibelli, disseminated superficial actinic, and palmaris et plantaris disseminata forms of porokeratosis (see Chap. 50), and in oral lesions of dyskeratosis congenita. As noted in Human Papillomavirus Infection, lesions of epidermodysplasia verruciformis can degenerate into SCCs (see Chap. 196). Finally, patients with the dystrophic form of epidermolysis bullosa are at increased risk for SCC (see Chap. 60).

Molecular Aspects

As in most cancers, the development of SCC from normal keratinocytes begins with mutations in the cellular DNA and genomic instability. Alterations in gene expression lead to loss of growth controls, penetration of the basement membrane, and ultimately invasion into surrounding tissue. Along the pathway to SCC, keratinocytes become resistant to apoptosis (programmed cell death) and immune attack.

GENETIC ALTERATIONS Most analyses of genetic alterations in SCCs have been performed in cases of oral or head and neck SCCs. Chromosomal deletions (loss of heterozygosity) commonly involve chromosomes 3, 9, 11, and 17; the regions most commonly identified include 9p21 and 17p13 where the INK4A (p16/Arf) and p53 tumor suppressors, respectively, are located.[29] Similar genetic lesions were found in a study of young patients (younger than 40 years of age).[30] It is unclear whether these genetic markers will serve as useful prognostic indicators.

P53 IN THE DEFENSE AGAINST SKIN CANCER A role for p53, cyclin D1, human telomerase reverse transcriptase, p16, and thrombospondin 1 has been identified in the multi-step process of human skin carcinogenesis.[31]

Apoptosis of keratinocytes that have sustained UV radiation–induced DNA damage, termed *sunburn cells*, requires the p53 tumor suppressor and represents a key protective mechanism against skin cancer by removing premalignant cells that have acquired mutations. In keratinocytes, UV radiation up-

regulates p53,[32] which delays cell cycle progression until DNA damage can be repaired or facilitates cell elimination by apoptosis.[33] Compromise of p53 function could undermine this apoptosis-based defense mechanism, giving UV-damaged cells a selective advantage to survive additional cycles of UV exposure.[34] Further impairment of p53 and other genes through additional UV radiation–induced mutations may then lead to even greater resistance to apoptosis, increased proliferation, and ultimately development of SCC. The increased susceptibility of p53-deficient mice to UV radiation–induced SCC[35] highlights this protective role of p53.

P53 MUTATIONS IN SQUAMOUS CELL CARCINOMA Consistent with the scenario described in p53 in the Defense Against Skin Cancer, mutations in the p53 gene are a common finding in SCC.[36] In most cases, these are C→T single base and CC→TT tandem transition mutations at dipyrimidine sequences—that is, "UVB-signature" mutations.[37] Most SCCs exhibit loss of heterozygosity with respect to p53 and isolated mutations on the remaining allele. In one study, the p53-apoptosis pathway was disrupted in 50 percent of oral SCCs. With respect to SCC precursors, p53 mutations were found in up to 75 percent of AK and SCC in situ lesions.[38] Interestingly, although different p53 mutations were found in separate AKs, all cells within a single precursor lesion had the same mutation.[31] Mutations in p53 can also be detected in keratinocytes from clinically normal sun-exposed skin.[39] Keratinocytes with p53 mutations occur in clonal patches that are larger and more frequently in sun-exposed skin.[40] These findings substantiate a clonal basis for UV radiation–induced SCC and suggest that p53 mutation is an early event in the development of SCC.

In addition to undergoing mutation, p53 can be compromised in keratinocytes infected with HPV. The E6 protein encoded by oncogenic HPV types binds p53 and targets it for rapid degradation, which disables the p53-apoptosis pathway. This is a primary mechanism by which HPV infection predisposes to SCC (see Chap. 196).

OTHER APOPTOTIC REGULATORS IN SQUAMOUS CELL CARCINOMA In addition to dysregulation of p53, dysregulation of other apoptotic regulatory proteins has been described in SCC. In a study of vulvar SCC, expression of the apoptotic inhibitor Bcl-2 correlated with metastasis.[41] Similarly, in esophageal SCC, expression of the apoptotic inhibitor Bcl-XL correlated with tumor invasion and metastasis.[42] In SCC of the tongue, low apoptotic index and decreased expression of the pro-apoptotic Bcl-2–associated X protein (Bax) correlated significantly with poor prognosis, whereas low Bcl-2 expression was associated with a favorable clinical outcome.[43] Expression of the anti-apoptotic Bcl-2–associated athanogene 1 (BAG-1) was associated with nodal metastasis in oral SCC.[44] Consistent with these observations, transgenic mice expressing Bcl-2 and Bcl-XL in the skin exhibit increased susceptibility to chemical-induced tumorigenesis. In addition to these Bcl-2 family members, the inhibitor of apoptosis protein survivin is expressed in both SCC and precursor lesions,[45] and in one study its expression correlated with aggressive tumor phenotype.[46] Interestingly, survivin may be negatively regulated by the binding of p53 to its promoter.[47] More recent studies in transgenic mice have yielded paradoxical results, which suggests that apoptosis may be required in the initial phase of UV radiation–induced clonal expansion.[48]

IMMUNE EVASION Working with UV radiation–induced SCCs in mice, Kripke and colleagues first demonstrated the importance of immunosuppression in UV radiation–induced SCC in the 1970s (see Chap. 88). They found that although UV radiation–induced SCC was promptly rejected when transplanted into genetically identical recipient mice, the transplanted tumors grew rapidly, and rejection did not occur if recipient mice were first treated with a subcarcinogenic dose of UV radiation. These experiments suggested that UV radiation not only induced SCC but also impaired the ability of host animals to mount protective immune responses against foreign tumor antigens.

CLINICAL FINDINGS

In white men and women, the majority of SCCs arise on sun-exposed areas such as the head, neck, and dorsal hands. SCC of the legs is more common in women.[49] In blacks, on the other hand, SCCs tend to be distributed equally on sun-protected and sun-exposed areas.[50] SCC typically presents in solitary fashion, arising from precursor lesions as noted earlier. An exception is in immunosuppressed patients, who may manifest eruptive SCCs.

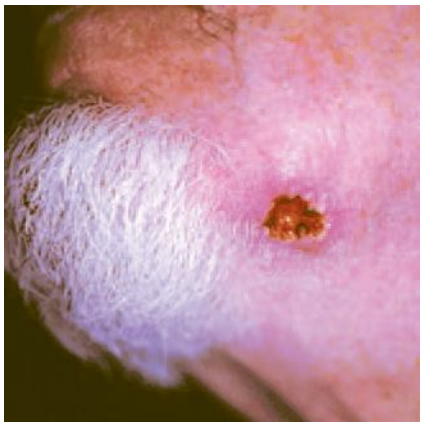
Development from Precursor Lesions (See Chap. 113)

AKs often occur as a multiplicity of lesions, ranging in size from pinpoint to over 2 cm, and the borders are usually ill defined. A dry adherent scale gives them a rough, gritty texture. By contrast, lesions of Bowen disease are usually solitary, sharply demarcated, scaling papules or plaques, often initially mistaken for eczema, psoriasis, or lichen simplex. The latter disorders are often pruritic, whereas Bowen disease is usually not. In sun-protected sites, Bowen disease may have a noneczematous appearance. For example, it may appear verrucous in the anogenital area, nail bed, and eyelid, and as a dark patch or oozing erythematous plaque in intertriginous areas. These precursor lesions are usually asymptomatic, and the development of tenderness, induration, erosion, increased scale, or enlarging diameter may herald evolution into SCC. Typically a patient with multiple AKs may present with a single lesion that gradually becomes more prominent than the rest (Fig. 114-1), or with a solitary, persistent, non-pruritic, scaling patch that is unresponsive to treatment with topical steroids.

Squamous Cell Carcinoma Morphologies

A firm, flesh-colored or erythematous, keratotic papule or plaque is most com-

▲ **FIGURE 114-1** Papular squamous cell carcinoma (SCC) of the ear. The differential diagnosis includes chondrodermatitis nodularis helicis, which, unlike SCC, is associated with pain.



▲ **FIGURE 114-2** Ulcerative squamous cell carcinoma of the jaw. In this region, extension of the cancer can invade the marginal mandibular nerve.

mon (see Fig. 114-1), but SCCs may also be pigmented. Other presentations include as an ulcer (Fig. 114-2), a smooth nodule (Fig. 114-3), or a thick cutaneous horn. SCC may also be verrucous or present as an abscess, particularly if in a periungual location (see Fig. 113-9 in Chap. 113). The margins may be indistinct. With enlargement, there is usually increased firmness and elevation. Progressive tumor invasion ultimately results in fixation to underlying tissues. Especially in the head and neck region, an enlarged lymph node nearby that is firm and non-tender may indicate tumor metastasis (Fig. 114-4).

Oral Squamous Cell Carcinoma

SCC of the oral cavity usually occurs in patients with a long history of cigarette smoking, tobacco chewing, or alcohol use, but it has now been documented in younger adults without these traditional risk factors. There is a male predominance, and the palate and tongue are the most common sites. Oral SCC most commonly evolves from lesions of erythroplakia and is usually asymptomatic (see Chap. 113). Distinct patterns include a persistent rough red patch or granular velvety red plaque that ultimately becomes firm and nodular. Surprisingly, the risk of transformation to SCC does not appear to correlate with the degree of epithelial dysplasia.[51] The floor of the mouth, ventrolateral tongue, and soft palate are considered high-risk sites. It may also present as a peritonsillar abscess.

▲ **FIGURE 114-4** Preauricular mass resulting from metastasis of cutaneous squamous cell carcinoma (SCC). Involvement of the parotid gland can result from metastasis of SCC in the temple and ear region.

Lower Lip Squamous Cell Carcinoma

SCC of the lower lip begins as a roughened papule of actinic cheilitis or scaly leukoplakia, with slow progression to a tumor nodule (Fig. 114-5). Clinical clues associated with evolving SCC include persistent lip chapping with localized scale or crust, red and white blotchy atrophic vermilion zone of the lip, indistinct or "wandering" vermilion border, and small fissuring or ulceration within an area of indurated actinic cheilitis. Symptoms of underlying pain or altered sensation should be investigated as a potential sign of perineural invasion.

Genital Squamous Cell Carcinoma

SCC of the vulva most commonly occurs on the anterior labia majora, beginning as a small warty nodule or an erosive erythematosus plaque. These lesions may be asymptomatic but more often are associated with pruritus or bleeding. Lesions of lichen sclerosus are another common precursor of SCC of the vulva. SCC of the cervix is associated with HPV infection, most commonly with type 16. SCC of the scrotum begins as a small pruritic verrucous lesion that becomes friable with increasing size. SCC of the penis usually occurs in uncircumcised males (see eFig. 114-5.1 in on-line edition) and, although very uncommon in Western countries, may account for 10 percent of cancers in places where genital hygiene is poor. A distinct precursor of penile SCC is erythroplasia of Queyrat (see Chap. 113), characterized by a velvety red plaque. In addition to lack of circumcision, penile SCC has been associated with a history of condyloma and phimosis and lichen sclerosus et atrophicus (see Chaps. 63 and 75). The genitalia were once thought to be a common location for SCC after long-term therapy with psoralen and UVA radiation, but this complication can be avoided by shielding the genitalia during treatment, and such an association is rarely seen today. Perianal SCC may also occur (Fig. 114-6).

Scar Squamous Cell Carcinoma

SCCs arising in scars typically begin decades after injury, with skin breakdown and persistent erosion. Most commonly this occurs on the lower extremities at sites of chronic pyogenic or venous sta-

▲ **FIGURE 114-3** Nodular squamous cell carcinoma of the forehead. This lesion is recurrent and can be seen arising in the previous surgical scar. It should be considered high risk.

◀ **FIGURE 114-5** Squamous cell carcinoma of the lower lip that developed in the setting of habitual sun exposure and actinic cheilitis. There is a large but subtle nodule, better felt than seen, on the lower lip. There are areas of hyperkeratosis and ulceration. Metastasis to draining lymph nodes can occur.

▲ **FIGURE 114-6** Perianal squamous cell carcinoma (SCC) in situ. Identification of these lesions requires thorough proctoscopic examination and monitoring for invasive SCC.

sis ulcers. Gradually nodularity develops, although detection is often delayed because of concealment by surrounding indurated scar tissue. When SCC arises in chronic sinuses, however, nodularity may not be present. The development of increased pain, drainage, or bleeding alone should raise concern and warrants further investigation.

Keratoacanthoma (For full discussion, see Chap. 117)

The hallmark of keratoacanthoma is rapid growth, up to several centimeters in weeks, and then gradual involution over a period of months in most cases (see Chap. 117). The typical presentation is in an elderly patient on a sun-exposed site, particularly an extremity. Morphologically, keratoacanthoma is usually a large, smooth, dome-shaped, verrucous nodule with a central keratotic crater. Although historically viewed as a benign neoplasm because of its tendency toward spontaneous resolution, keratoacanthoma can be locally destructive and aggressive and must be viewed as a clinical sub-type of SCC. This tumor may occur in association with sebaceous neoplasms and gastrointestinal malignancies in Muir-Torre syndrome.

Verrucous Carcinoma

Verrucous carcinoma is a form of SCC that encompasses several clinical entities, all characterized by slow-growing exophytic tumors with a cauliflower-like appearance that develop at sites of chronic irritation.[52] They may be clinically mistaken for giant warts. Four subtypes are recognized based on site of occurrence. Type I consists of oral tumors on the buccal mucosa of elderly male tobacco chewers and has been referred to as *oral florid papillomatosis* (Fig. 114-7). Representing 2 percent to 12 percent of all oral cancers, these tumors are most commonly found on the buccal mucosa, tongue, gingiva, and floor of the mouth. Type II is the anogenital type, as described by Buschke and Loewenstein. It occurs on the glans penis of young uncircumcised males, on the scrotum, on the perianal region in both sexes, and, less commonly, on the female genitalia. Type III, also known as *epithelioma cuniculatum*, is a malodorous tumor often found on the plantar area in elderly men (Fig. 114-8). It usually involves the skin underlying the first metatarsal head and tends to form draining sinuses that are caniculated (like rabbit burrows) in appearance. Finally, type IV occurs at other sites, including the scalp, trunk, and extremities. Detection of sequences from HPV types 6, 11, 16, and 18 in epithelioma cuniculatum and type 11 sequences in oral verrucous carcinoma raises the possibility that these tumors evolve from verruca vulgaris.

Metastatic Squamous Cell Carcinoma

Metastatic SCC in the skin can have a variety of presentations. It may be signaled by a palpable lymph node near the site of treatment of a previous SCC.

▲ **FIGURE 114-7** Verrucous carcinoma presenting as a thick plaque arising on the buccal mucosa. This type of tumor was formerly called *oral florid papillomatosis*.

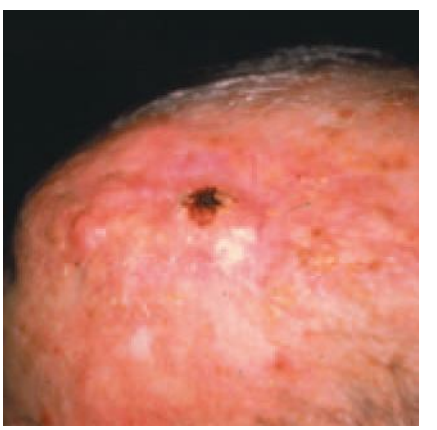
▲ **FIGURE 114-8** Epithelioma cuniculatum, verrucous carcinoma of the foot.

On the other hand, it may present as large keratotic papules or nodules resembling the primary lesion (Fig. 114-9). Metastatic SCC on the skin may be the first sign of internal malignancy, initially presenting in the skin as clusters of firm pink or red papules that may be keratotic centrally.

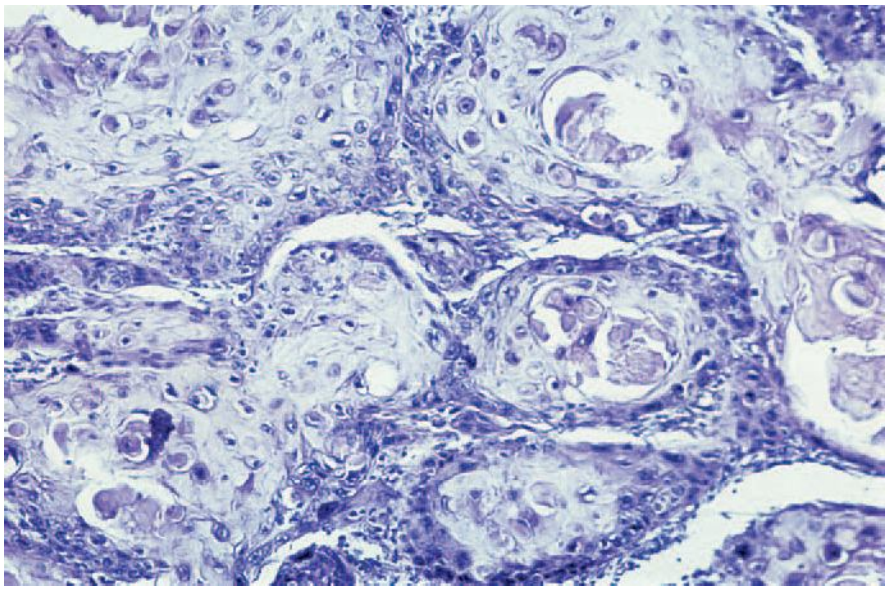
HISTOPATHOLOGY

General Considerations

The hallmark of invasive SCC is the extension of atypical keratinocytes beyond the basement membrane and into the dermis (Fig. 114-10). The absence of a connection between tumor cells and the epidermis should raise concern for metastatic SCC, although this may simply reflect undermining from adjacent tumor. In every case, it is important to note clues that may indicate a precursor lesion or particular etiology. For example, the presence of solar elastosis and keratinocyte atypia at the margins would suggest that the SCC is actinically derived. On the other hand, the presence of scar



▲ **FIGURE 114-9** Squamous cell carcinoma metastatic to skin.



▲ **FIGURE 114-10** Squamous cell carcinoma demonstrating invasive cancer with atypical keratinocytes and foci of keratinization.

tissue may indicate recurrent disease or a sinister scar-associated SCC. These considerations have important implications for treatment and prognosis, as discussed in Treatment.

Basic Features

The tumor may appear as single cells, small groups or nests of cells, or a single mass. The inferior border may broadly impose on the dermis or be represented by individual foci of microinvasion. Invasive tumor is usually confined to the dermis, and subcutaneous involvement is unusual. There are typically varying proportions of normal-appearing and atypical squamous cells, the latter characterized by increased mitoses, aberrant mitotic figures, nuclear hyperchromasia, and loss of intercellular bridges. Squamous differentiation is seen as foci of keratinization in concentric rings of squamous cells called *horn pearls*. Loss of differentiation is associated with decreased keratin production.

Grading

Histologic grading of SCC is based on the degree of cellular differentiation. Low-grade tumors are comprised of uniform cells, resembling mature keratinocytes, with intracellular bridges and keratin production. High-grade SCCs, by contrast, are characterized by atypical cells, loss of intracellular bridges, and minimal or absent keratin production. Another feature of higher-grade tumors is a less distinct demarcation between malignant cells and adjacent normal stroma. In 1932, Broders[53] introduced a formal grading system based on keratinocyte differentiation that is still used today. Tumors are graded on a scale of 1 to 4 based on increasing percentages of undifferentiated cells (Table 114-2). In addition to grade, the depth of penetration, tumor thickness, and hair follicle involvement should also be reported.

Histologic Sub-Types

There are many histologic sub-types of SCC.[54] In the adenoid (or pseudoglandular) SCC, there is a tubular microscopic pattern and keratinocyte acantholysis. In clear cell SCC, the keratinocytes appear clear as a result of hydropic cytoplasmic swelling and accumulation of lipid vacuoles. Spindle cell SCC reveals spindle-shaped atypical cells. Signet-ring cell SCC is a rare variant characterized by concentric rings composed of keratin and large vacuoles corresponding to markedly dilated endoplasmic reticulum. In addition, a basaloid variant has been described. In verrucous carcinoma, the superficial component resembles verruca vulgaris with prominent acanthosis and papillomatosis, whereas the deeper component extends downward, displacing collagen bundles. Finally, keratoacanthoma reveals a symmetric keratin-filled crater, with the epidermis on each side extending over to form a distinct lip.

TABLE 114-2
Broders' Grading System for Squamous Cell Carcinoma

Grade	% Undifferentiated Cells	Other Features
1	< 25	Keratinization
2	< 50	
3	< 75	
4	> 75	Atypia, loss of intracellular bridges

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Determination of the Diagnosis

The diagnosis of SCC is always made by skin biopsy. Any persistent, enlarging, or nonhealing lesion, particularly if on a sun-exposed site, warrants biopsy evaluation. It is important that the biopsy be of sufficient depth so that invasive SCC can be distinguished from in situ disease. If a lesion is flat or minimally elevated (less than 1 mm), the superficial shaving technique can be used to minimize wound size and scarring and is usually adequate. For elevated lesions, the punch technique or a deep shave excision should be used to ensure that a specimen of adequate depth is taken. Because the diagnosis of keratoacanthoma depends largely on overall architecture, performing excisional biopsy or taking an incisional ellipse through the entire lesion is recommended. A tangential excision through the deep dermis also usually suffices.

Differential Diagnosis

Clinically, the differential diagnosis of SCC is long, but it can be narrowed based on lesion morphology. For verrucous or scaly lesions, benign conditions to consider include wart, seborrheic keratosis, AK, melanocytic nevus, pyogenic granuloma, eccrine poroma, and deep fungal infections such as chromomycosis. The entity "erosive pustular dermatosis of the scalp" is a benign condition that is often initially mistaken for SCC but responds to potent topical steroids.[55] Other malignant verrucous lesions include atypical fibroxanthoma, BCC, Bowen disease, verrucous melanoma, Merkel cell carcinoma, and, of course, metastatic SCC. Pigmented SCC in particular may mimic melanoma. For ulcerative lesions, additional diagnoses include trauma, BCC, and herpes virus infection (with either herpes simplex virus or varicella-zoster virus).

Histologically, the differential diagnosis of well-differentiated SCC includes

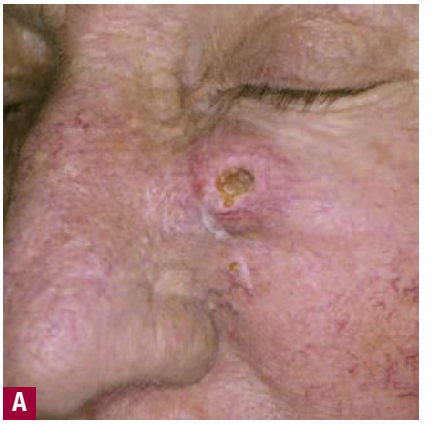
verruca vulgaris and inverted follicular keratosis. In addition, reactive epidermal hyperplasia (pseudoepitheliomatous hyperplasia) secondary to mycosis, eruptions in response to halogenated drugs (bromoderma and iododerma), and even mechanical trauma can mimic SCC. In these hyperplasias, however, the keratinocytes usually remain well differentiated; the margins of the proliferating epidermis are often pointed or irregular, rather than bulbous; there is leukocyte invasion with occasional keratinocyte disintegration; and granulomas or intraepidermal abscesses may be present.[56] Some adenoid SCCs may demonstrate a pseudovascular pattern, with erythrocytes in pseudovascular spaces, and may be confused with angiosarcoma; these tumors do not express factor VIII antigens or bind ulex agglutinin. Clear cell SCC may simulate adnexal tumors with sebaceous differentiation or sebaceous carcinoma. Distinguishing spindle cell SCC from atypical fibroxanthoma is difficult. The differential diagnosis of poorly differentiated SCC also includes fibrosarcoma, Merkel cell carcinoma, and melanoma. In most cases, SCC can be distinguished from these others by special stains for various cytokeratins, but in difficult cases electron microscopy may be needed to establish the diagnosis. In general, SCC does not stain for melanocyte (S100 protein, homatropine methylbromide) or smooth muscle (vimentin, actin) markers.

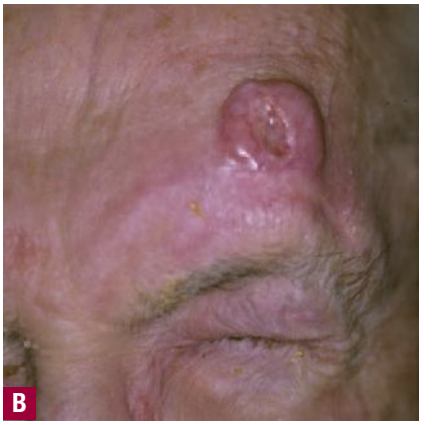
RECURRENCE AND METASTASIS

SCC, like BCC, may cause local tissue destruction, but it also has significant potential for metastasis. Metastases, when they occur, are generally to regional lymph nodes and are detected 1 to 3 years after initial diagnosis and treatment.[19] In many cases, metastasis is preceded by local recurrence at the site of the primary lesion. Historically, the reported rate of metastasis for SCC has ranged from 0.5 percent to 6 percent,[57] and metastasis tends to occur with tumors that are large, recurrent, and involve deep structures or cutaneous nerves (Fig. 114-11).

High-Risk Lesions

In a classic study, Rowe et al.[58] reviewed all major series of SCC dating back to 1940 to determine risk factors associated with recurrence and metastasis. Table 114-3 summarizes the characteristics of "high-risk" lesions. With respect to size, tumors smaller than 2 cm in diameter are low risk, with an overall metastatic rate of roughly 1 percent. In one study,[59] the metastatic rate increased to 9.2 percent and 14.3 percent for tumors of 2 to 5 cm and larger than 5 cm, respectively. With respect to depth and invasion, tumors less than 4 mm deep and rated as Clark levels I to III have limited metastatic potential, whereas close to half of those deeper than 4 mm and at Clark levels IV or V were metastatic in some series. Tumor involvement of bone, nerve, or muscle tissue is strongly associated with metastasis. With respect to anatomic site, SCC of the ear has the highest rate of recurrence (18.7 percent), whereas lip SCC has the highest rate of metastasis (13.7 percent), with half of lip metastases present at the time of initial diagnosis. All SCCs arising in scars are high risk, with metastatic rates approaching 40 percent in some series.[60] By contrast, SCCs arising in actinically damaged skin are of considerably lower risk, with an average metastatic rate of 5.2 percent. Poorly differentiated SCCs (Broders grade 3 or 4) demonstrate a recurrence rate of 28.6 percent and a metastatic rate of 32.8 percent, compared with 13.6 percent and 9.2 percent, respectively, for well-differentiated tumors.





▲ **FIGURE 114-11** **A.** Infiltrative squamous cell carcinoma (SCC) demonstrating retraction of underlying tissue of the left cheek, where extension might involve infraorbital nerve. **B.** SCC of left side of forehead, where extension to bone with invasion or along the supraoptic nerves might lead to death.

TABLE 114-3
High-Risk Squamous Cell Carcinoma

- Diameter > 2 cm
- Depth > 4 mm and Clark level IV or V
- Tumor involvement of bone, muscle, nerve
- Location on ear, lip
- Tumor arising in scar
- Broders grade 3 or 4
- Patient immunosuppression
- Absence of inflammatory infiltrate

The prognosis is particularly poor for spindle cell SCCs.[61] Immune status is another important consideration. One study[62] found that 23 percent of patients with metastatic SCC were immunosuppressed. A heavy inflammatory response appears to be a favorable prognostic sign, because absence of infiltrate has been correlated with higher rates of recurrence and metastasis.

TREATMENT

Box 114-1 summarizes the various modalities available for treatment of SCCs. Treatment selection is directed largely by assessment of tumor risk for recurrence and metastasis, as discussed in the previous section. Ablative techniques such as electrodesiccation and curettage, liquid nitrogen cryotherapy, carbon dioxide laser, intralesional chemotherapy, and photodynamic therapy are superficial, do not allow histologic margin control, and thus are generally inappropriate for treatment of invasive SCCs. An exception may be the use of topical 5-fluorouracil for treatment of conjunctival SCCs.[63]

Surgical Excision

Conventional surgical excision is viewed by many as the treatment of choice for small primary SCCs. Recommended margins are 4 mm for low-risk lesions or

Box 114-1
Treatment of Squamous Cell Carcinoma

- Non-excisional ablative techniques (in situ disease only, or in special circumstances)
- Mohs surgery
- Conventional surgical excision
- Radiation therapy

TABLE 114-4
Indications for Mohs Surgery

- Infiltrative squamous cell carcinoma (SCC)
- Poorly defined clinical margins
- Location on lip, ear, nail bed, nasal tip, eyelid, genitalia
- History of radiation at site
- Involvement of nerve, bone, muscle
- Immunosuppressed patient
- Recurrence of large SCC
- Verrucous carcinoma
- SCC arising from chronic scarring conditions

SCCs with a depth of less than 2 mm; for lesions with a depth of more than 6 mm or a diameter larger than 1 cm, Mohs microscopically controlled surgery (MMCS) is recommended.[64] MMCS is also recommended in specific circumstances when the highest cure rate and minimal tissue destruction are desired (Table 114-4). Specifically, tumors involving the periocular or periauricular areas; recurrent or large tumors; lesions with poorly defined clinical margins; tumors at sites where tissue preservation is important (nasal tip, lip, eyelid, ear, genitalia); deeply infiltrative tumors; lesions at sites that were previously irradiated; tumors with involvement of underlying structures (nerve, bone, muscle); tumors in immunosuppressed patients; and lesions at sites associated with high recurrence rates should strongly be considered for MMCS.[65] Additional indications include verrucous carcinomas and high-risk SCCs such as those arising from chronic scarring conditions.

Radiation

Radiation can be used to treat superficially invasive to moderate-risk lesions and serves as an important adjuvant to excisional surgery in treating residual microscopic disease and providing prophylaxis against metastatic disease. It has been shown to be particularly useful for SCCs of the external auditory canal,[66] although radiation therapy may lead to hearing loss.[67] Radiation therapy is not advised for verrucous carcinoma, in which there is an associated low rate of anaplastic transformation. Radiation may also be used as adjuvant therapy in cases in which perineural SCC was identified in surgical pathologic specimens but treatment failures occurred.

Recurrence Rates

Many risk factors for recurrence and metastasis have been identified.[68] In their review noted in High-Risk Lesions, Rowe et al.[58] also assessed responses to treatment. They reported increasing combined rates of recurrence for each of the following treatment modalities (for primary cancers): MMCS (3.1 percent), electrodesiccation and curettage (3.7 percent), excisional surgery (8.1 percent), and radiation (10 percent). A review of the use of MMCS to treat SCC with 4-year follow-up reported a cure rate of 92 percent.[69] The surprisingly low rate of recurrence for electrodesiccation and curettage likely reflects its judicious use for treatment of low-risk lesions. Similarly, the recurrence rates for both MMCS and excisional surgery may be somewhat skewed by their use in treating high-risk lesions. For lip SCC, the overall recurrence rate was 2.3 percent with MMCS compared with 10.5 percent with other treatment modalities; for ear SCC, the recurrence rates were 5.3 percent and 18.7 percent, respectively. For all recurrent tumors, cure rates were 76.7 percent with excision, compared with 90 percent with MMCS. For low-risk SCCs, overall recurrence rates were 1.9 percent with MMCS versus 16.5 percent with all other modalities. Overall 5-year survival rate for patients with metastatic SCCs was 26.8 percent, with poorer outcomes among patients with lip lesions[70] and those treated with surgery alone (and no radiation).

Treatment of High-Risk Lesions

Management of high-risk lesions is reviewed elsewhere.[71] Oral 5-fluorouracil has been used to treat aggressive lesions refractory to conventional therapies. Additional treatments, including β-carotene, interferon, and retinoids, have been employed with variable results. High-risk lesions may require formal staging. Computed tomography or magnetic resonance imaging may be useful in the detection of advanced perineural involvement of head and neck SCC.[72] Sentinel lymphadenectomy has been combined with MMCS.[73] Involvement of lymph nodes may warrant radical lymph node dissection and radiation therapy. Elective cervical lymphadenectomy may be indicated for high-risk lesions of the lip.[74] When a clinical lymph node examination yields negative results, further intervention may still be indicated if the tumor is considered sufficiently high risk.

Patient Follow-Up

After a diagnosis of SCC, all patients should be considered at high risk for developing additional lesions of SCC as well as BCC. They should be seen at regular intervals, ranging from 3 and 12 months, depending on the degree of risk of prior lesions, status of precursor lesions, and individual patient compliance. A complete skin examination should be performed at each visit, including examination of the oral mucosa. In addition, sites of previous lesions and treatments should be assessed for signs of recurrence. Finally, a lymph node examination is indicated to monitor for metastatic disease.

PREVENTION

Those at risk for SCC—namely, persons with a prior history of non-melanoma skin cancer or any of the predisposing conditions discussed earlier—should be monitored closely. They should receive complete skin examinations on a regular basis.

Sun Protection

The most effective preventive measure is protection from sun exposure. It is likely that adequate sun protection beginning in early childhood could prevent most SCCs.[75] This requires establishing patterns of behavior at an early age, such as applying sunscreen repeatedly, wearing hats and protective clothing, and avoiding the sun during the hours of peak intensity. However, the importance of sun exposure prevention in childhood should not be construed to mean that sun protection later in life will be of no benefit. There is evidence that aggressive sun protection throughout life can prevent the development of SCC precursor lesions and cancers themselves.

Treatment of Precursor Lesions

Treatment of precursor lesions is expected to reduce the incidence of SCC. Several options are available for treatment of AK (see Chap. 113). Isolated lesions can often be effectively removed by liquid nitrogen cryotherapy. For patients with many AKs or areas of skin with a multitude or confluence of lesions, topical chemotherapy using 5-fluorouracil is an option. Topical diclofenac and imiquimod have now been introduced as therapies for widespread AK.

Other Preventive Measures

A number of additional preventive measures can be taken that may reduce the

incidence of SCC in individual patients. For example, the use of condoms can prevent transmission of HPV and may thereby reduce the risk of genital SCC. Decreased alcohol consumption and smoking cessation is likely to reduce the risk of oral SCC. Several years ago there was great interest in the use of both retinoids and interferons as systemic chemopreventive agents. Low-dose etretinate (10 mg/day) has been used successfully in renal transplant patients.[76] A more recent recommendation is isotretinoin (Accutane; 10 mg every day or every other day) in addition to topically applied tretinoin.[77] Topical application of a DNA repair enzyme in liposomes was shown in one experimental trial to reduce the incidence of new AK in xeroderma pigmentosum patients, but further clinical studies have not been published and the potential clinical role of the repair enzyme is unknown.[78] Finally, the introduction of a vaccine for the prevention of infection with HPVs and of precancerous lesions of the cervix may one day translate into the prevention of all HPV-induced precancerous lesions of the skin.[79]

CHAPTER 115

Basal Cell Carcinoma

John A. Carucci
David J. Leffell

Basal cell carcinoma (BCC) is a malignant neoplasm derived from nonkeratinizing cells that originate in the basal layer of the epidermis. If left untreated, BCC will continue to invade locally and may result in substantial tissue damage that compromises function and cosmesis. Metastasis is an extremely rare event.

EPIDEMIOLOGY

BCC is the most common cancer in humans. It is estimated that over 1 million new cases occur each year in the United States.[1] BCC is more common in elderly individuals but is becoming increasingly frequent in people younger than 50 years of age. Christenson et al. noted a disproportionate increase in BCC in women under age 40.[2] The malignancy accounts for approximately 75 percent of all non-melanoma skin cancers and almost 25 percent of all cancers diagnosed in the United States.[1] The tumor characteristically develops on sun-exposed skin of lighter-skinned individuals, with 20 percent occurring on the nose. Men are affected slightly more often than are women. Levi et al. reported that the incidence of BCC rose steadily in the Swiss Canton of Vaud between 1976 and 1998 to levels of 75.1 in 100,000 in males and 66.1 in 100,000 in females.[3,4] A study of non-melanoma skin cancers in Aruba supported these findings.[5] In that study, BCC was the most common type of skin cancer diagnosed between 1980 and 1995. Tumors were more frequent in patients older than 60 years of age, and 57 percent were in men. The highest percentage of lesions occurred on the nose (20.9 percent), followed by other sites on the face (17.7 percent).

Risk factors for BCC have been well characterized and include ultraviolet light (UVL) exposure, light hair and eye color, northern European ancestry, and inability to tan.[1] Patients with BCC are at increased risk for melanoma but not for other internal malignancies. Bower et al. reported that individuals with BCC had a threefold increased risk for melanoma but no increased risk for any other type of cancer.[6]

ETIOLOGY AND PATHOGENESIS

The pathogenesis of BCC involves exposure to UVL, particularly the ultraviolet B spectrum (290 to 320 nm) that induces mutations in tumor suppressor genes.[7,8] Some studies indicate that intermittent brief holiday exposures may place patients at higher risk than occupational exposure.[9] Ramani and Bennett reported a significantly higher incidence of BCCs in World War II servicemen stationed in the Pacific theater than in those stationed in Europe.[10] This suggests that several months or years of intense exposure to UVL may have deleterious long-term effects. Other factors that appear to be involved in the pathogenesis include mutations in regulatory genes,[11] exposure to

BASAL CELL CARCINOMA AT A GLANCE

- Most common cancer in humans.
- Caused by exposure to ultraviolet light; associated with PTCH gene mutation in many cases.
- Incidence increasing in younger populations.
- Locally destructive.
- Treated by surgical excision, electrodesiccation and curettage, Mohs surgery, and occasionally irradiation.

ionizing radiation,[12] and alterations in immunosurveillance.[13]

The propensity to develop multiple BCCs may be inherited. Included among heritable conditions predisposing to the development of this epithelial cancer are nevoid basal call carcinoma syndrome or basal cell nevus syndrome (BCNS),[14] Bazex syndrome,[15] and Rombo syndrome.[16] Patients with BCNS may develop hundreds of BCCs and may exhibit a broad nasal root, borderline intelligence, jaw cysts, palmar pits, and multiple skeletal abnormalities. BCNS occurs due to mutations in the tumor suppressor PTCH gene (see Chap. 116).[17,18]

Bazex syndrome is transmitted in an X-linked dominant fashion.[15] Patients have multiple BCCs, follicular atrophoderma, dilated follicular ostia with ice-pick scars, hypotrichosis, and hypohidrosis. In contrast, Rombo syndrome is transmitted in an autosomal dominant fashion.[16] Patients have vermiculate atrophoderma, milia, hypertrichosis, trichoepitheliomas, BCCs, and peripheral vasodilation. Hypohidrosis is not a feature of Rombo syndrome (see Chap. 65).

The role of the immune system in the pathogenesis of skin cancer is not completely understood. Immunosuppressed patients with lymphoma or leukemia[19] and patients who have received an organ transplant[13] have a marked increase in the incidence of squamous cell carcinoma but only a slight increase in the incidence of BCC. Bastiaens et al. found that transplant recipients developed more BCCs on the trunk and arms than did nonimmunosuppressed patients.[20] Patients with human immunodeficiency virus infection develop BCCs at the same rate as immunocompetent individuals, based on similar risk factors.[21] Immunosuppressed long-term alcoholics tend to develop infiltrative BCCs with increased frequency.[22]

A potential link between UVL and decreased immunity has been suggested by Gutierrez-Steil et al., who demonstrated that UVL-induced BCCs express Fas ligand (CD95L).[23] They further showed that these cells were associated with CD95-bearing T cells undergoing apoptosis. This represents a potential mechanism by which UVL might help tumor cells avoid being killed by cytotoxic T lymphocytes.

CLINICAL MANIFESTATIONS

Presentation

The presence of any friable, non-healing lesion should raise the suspicion of skin cancer. Frequently, BCC is diagnosed in patients who state that the lesion bled briefly then healed completely, only to recur. BCC usually develops on sun-exposed areas of the head and neck but can occur anywhere on the body. Features include translucency, ulceration, telangiectasias, and the presence of a rolled border. Characteristics may vary for different clinical sub-types, which include nodular, superficial, morpheaform, and pigmented BCCs and fibroepithelioma of Pinkus (FEP).

▲ **FIGURE 115-1** Nodular basal cell carcinoma presenting with a translucent ulcerated nodule.

▲ **FIGURE 115-3** Pigmented basal cell carcinoma (BCC), a variant of nodular BCC.

Basal Cell Carcinoma Sub-Types

NODULAR BASAL CELL CARCINOMA Nodular BCC is the most common clinical sub-type of BCC (Fig. 115-1).[24] It occurs most commonly on the sun-exposed areas of the head and neck and appears as a translucent papule or nodule depending on duration. There are usually telangiectasias and often a rolled border. Larger lesions with central necrosis are referred to by the historical term *rodent ulcer* (Fig. 115-2). The differential diagnosis of nodular BCC includes traumatized dermal nevus and amelanotic melanoma.

PIGMENTED BASAL CELL CARCINOMA Pigmented BCC is a sub-type of nodular BCC that exhibits increased melanization. Pigmented BCC appears as a hyperpigmented, translucent papule, which may also be eroded (Fig. 115-3). The differential diagnosis includes nodular melanoma.

SUPERFICIAL BASAL CELL CARCINOMA Superficial BCC occurs most commonly on the trunk and appears as an erythematous patch (often well demarcated) that resembles eczema (Fig. 115-4).[24] An isolated patch of "eczema" that does not respond to treatment should raise suspicion for superficial BCC.

MORPHEAFORM (SCLEROSING) BASAL CELL CARCINOMA Morpheaform BCC is an aggressive growth variant of BCC with a distinct clinical and histologic appearance. Lesions of morpheaform BCC may have an ivory-white appearance and may resemble a scar or a small le-

▲ **FIGURE 115-2** Rodent ulcer with central necrosis.

▲ **FIGURE 115-4** Superficial basal cell carcinoma, which can mimic the appearance of an isolated inflammatory lesion.

▲ **FIGURE 115-5** Morpheaform basal cell carcinoma, which may resemble a scar.

sion of morphea (see Chap. 62) (Fig. 115-5). Thus, the appearance of scar tissue in the absence of trauma or previous surgical procedure or the appearance of atypical-appearing scar tissue at the site of a previously treated skin lesion should alert the clinician to the possibility of morpheaform BCC and the need for biopsy.

FIBROEPITHELIOMA OF PINKUS FEP classically presents as a pink papule, usually on the lower back.[25] It may be difficult to distinguish from an acrochordon or skin tag.

BIOLOGIC BEHAVIOR

Local Invasion

The greatest danger of BCC results from local invasion (Fig. 115-6). In general, BCC is a slow-growing tumor that invades locally rather than metastasizes.[26,27] The doubling time is estimated to be between 6 months and 1 year. If left untreated, the tumor will progress to invade subcutaneous tissue, muscle, and even bone. Anatomic fusion planes appear to provide a low-resistance path for tumor progression. Tumors along the nasofacial or retroauricular sulcus may be extensive. In one informative case, a patient documented the progression of his own tumor with photographs over a 27-year period.[28] The lesion, which encompassed an entire side of the face, including the maxillary sinus, apparently doubled over a 10-year period and grew rapidly in the 2 years before hospital admission. This scenario occurs in the context of physical or psychiatric disability that interferes with judgment or access to health care. In another case, a 35-cm BCC on the back of a 65-year-old man recurred after wide local excision and x-ray therapy (XRT), resulting in spinal cord compression.[29] Lethal extension to the central nervous system from aggressive scalp BCC has been reported.[30]

▲ **FIGURE 115-6** Massive local tissue damage from multiply recurrent basal cell carcinoma.

▲ **FIGURE 115-7** Orbital invasion by basal cell carcinoma, which requires extensive surgery.

Perineural Invasion

Perineural invasion is uncommon in BCC and occurs most often in histologically aggressive or recurrent lesions. In one series, Niazi and Lamberty identified perineural invasion in fewer than 0.2 percent of cases.[31] In that series, perineural BCC was seen most often with recurrent tumors located in the preauricular and malar areas. Ratner et al. found a higher incidence in their study (3.8 percent).[32] Leibovitch et al. reported perineural spread in more than 50 percent of periocular BCCs eventuating in orbital invasion. These tumors required extensive surgery and in some cases exenteration (Fig. 115-7).[33] Perineural spread may manifest as pain, paresthesias, weakness, or paralysis. The presence of focal neurologic symptoms at the site of a previously treated skin cancer should raise concern about nerve involvement.

Metastasis

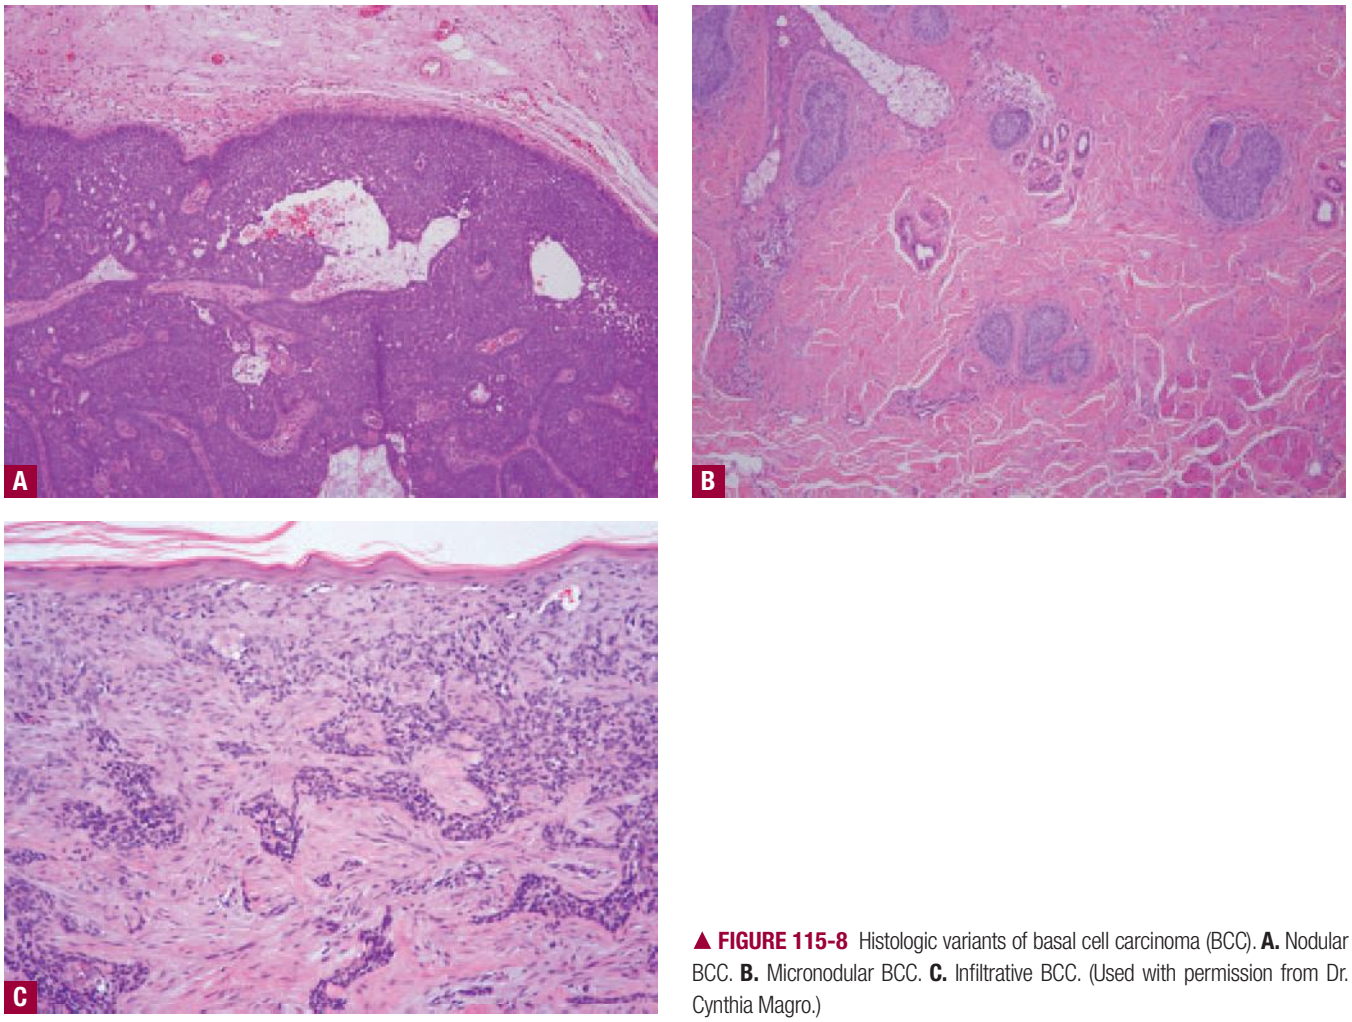
Metastasis of BCC occurs only rarely, with rates varying from 0.0028 percent to 0.55 percent.[34–36] Involvement of lymph nodes and lungs is most common. Von Domarus et al. reported five cases of metastatic BCC in which perineural or intravascular invasion had been noted in three.[37] Squamous differentiation was not observed in the primary tumors in the cases they presented but was noted in two of five cases of metastatic cancer. Overall, squamous differentiation was present in 15 percent of the primary or metastatic tumors from the 170 cases reviewed. Aggressive histologic characteristics, including morpheaform features, squamous metaplasia, and perineural invasion, have been identified as risk factors for metastasis.[36]

DIAGNOSIS

Diagnosis of BCC is accomplished by accurate interpretation of the skin biopsy results. The preferred biopsy methods are shave biopsy, which is often sufficient, and punch biopsy. A sterilized razor blade, which can be precisely manipulated by the operator to adjust the depth of the biopsy specimen, is often superior to a No. 15 scalpel for shave biopsies. A punch biopsy may be useful for flat lesions of morpheaform BCC or for recurrent BCC occurring in a scar.

HISTOPATHOLOGY

Histopathologic features vary somewhat with sub-type, but most BCCs share some common histologic characteris-



▲ **FIGURE 115-8** Histologic variants of basal cell carcinoma (BCC). **A.** Nodular BCC. **B.** Micronodular BCC. **C.** Infiltrative BCC. (Used with permission from Dr. Cynthia Magro.)

tics.[38] The malignant basal cells have large nuclei and relatively little cytoplasm. Although the nuclei are large, they may not appear atypical. Usually, mitotic figures are absent. Frequently, retraction of stroma from tumor islands is present, creating peritumoral lacunae that are helpful in histopathologic diagnosis.

Nodular Basal Cell Carcinoma

Nodular BCCs account for half of all BCCs and are characterized by nodules of large basophilic cells and stromal retraction (Fig. 115-8A). The term *micronodular BCC* is used to describe tumors with multiple microscopic nodules smaller than 15 μm (see Fig. 115-8B).

Pigmented Basal Cell Carcinoma

Pigmented BCC shows histologic features similar to those of nodular BCC but with the addition of melanin.[38] Approximately 75 percent of BCCs contain melanocytes, but only 25 percent contain large amounts of melanin. The melanocytes are interspersed between tumor cells and contain numerous melanin granules in their cytoplasm and dendrites. Although the tumor cells contain little melanin, numerous melanophages populate the stroma surrounding the tumor.

Superficial Basal Cell Carcinoma

Superficial BCC is characterized microscopically by buds of malignant cells extending into the dermis from the basal layer of the epidermis.[38] The peripheral cell layer shows palisading. There may be epidermal atrophy, and dermal invasion is usually minimal. This histologic sub-type is encountered most often on the trunk and extremities but may also appear on the head and neck. There may be a chronic inflammatory infiltrate in the upper dermis.

Morpheaform Basal Cell Carcinoma

Morpheaform or infiltrative BCC consists of strands of tumor cells embedded within a dense fibrous stroma (see Fig. 115-8C).[38] Tumor cells are closely packed and, in some cases, only one cell thick. Strands of tumor extend deeply into the dermis. The cancer is often larger than the clinical appearance indicates. Recurrent BCC may also demonstrate infiltrating bands and nests of cancer cells embedded within the fibrous stroma of scar.

Fibroepithelioma of Pinkus

In FEP, long strands of interwoven basiloma cells are embedded in fibrous stroma.[38] Histologically, FEP shows features of reticulated seborrheic keratoses and superficial BCC.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for BCC is summarized in Box 115-1.

TREATMENT

Management of BCC is guided by anatomic location and histologic features. Approaches include Mohs micrographic surgery (MMS), standard surgical excision, destruction by various modalities, and topical chemotherapy.[38] The best

- Fibroepithelioma of Pinkus
  - Skin tag
  - Papillomatous dermal nevus
  - Fibroma

chance to achieve cure is through adequate treatment of primary BCC, because recurrent tumors are more likely to recur and to cause further local destruction. An algorithmic approach to management is summarized in Fig. 115-9.

Mohs Micrographic Surgery (See Chap. 245)

MMS offers superior histologic analysis of tumor margins while permitting maximal conservation of tissue compared with standard excisional surgery.[39] Rowe, Carroll, and Day report a recurrence rate of 1 percent for primary BCCs treated by MMS.[40] This was superior to the rate for other modalities, including standard excision (10 percent), curettage and desiccation (C&D) (7.7 percent), XRT (8.7 percent), and cryotherapy (7.5 percent). Recurrent BCCs treated by MMS reappeared at a rate of 5.6 percent, which was again superior to the rate for other modalities, including excision (17.6 percent), XRT (9.8 percent), and C&D (40 percent).[41] MMS is the treatment of choice for morpheaform, poorly delineated, incompletely removed, and otherwise high-risk primary BCCs. It is the preferred treatment for recurrent BCC and for any BCC that occurs at a site where tissue conservation is desired. MMS is particularly useful in treating BBCs at high-risk anatomic sites, including the embryonic fusion planes represented by the nasofacial junction and retroauricular sulcus (Table 115-1).

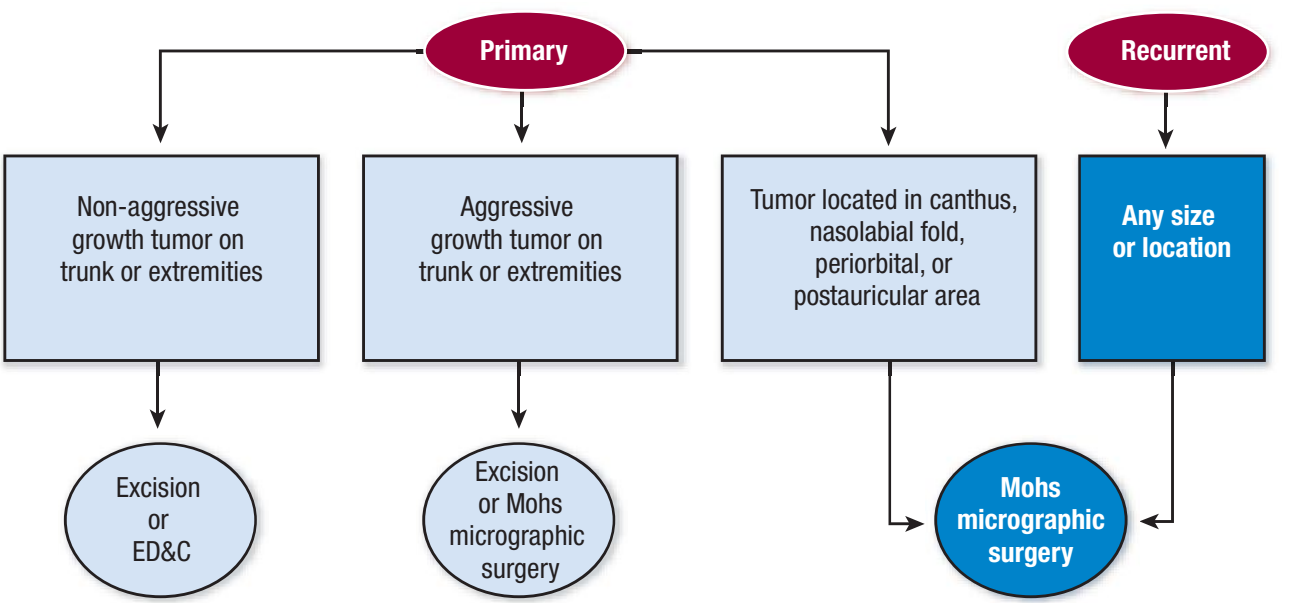
Standard Excision (See Chap. 244)

Compared with non-excisional techniques, standard surgical excision offers the advantage of histologic evaluation of the removed specimen. Although standard excision is appropriate for many BCCs, cure rates for standard excisional surgery are inferior to those for MMS in cases of primary morpheaform BCCs, recurrent BCCs, and tumors located in high-risk anatomic sites.[40,41] Wolf and Zitelli demonstrated that margins of 4 mm were adequate for 95 percent of nonmorpheaform BCCs smaller than 2 cm in diameter when treated by standard excision.[42] Johnson, Tromovitch, and Swanson reported a 96.7 percent cure rate when the excision included a 2-mm margin beyond the area defined by curettage.[43] Tumor was present in 64 of 403 curette margins and in 12 of 403 excision

TABLE 115-1

Indications for Mohs Surgery for Basal Cell Carcinoma

- Location on a high-risk anatomic site including mask area of face, scalp, anatomic fusion planes, periorbital area/eyelid
- Tumor > 2 cm
- Aggressive histologic sub-type
- Recurrent tumor
- Incompletely excised basal cell carcinoma
- Location on previously irradiated skin
- Immunosuppression of patient after solid organ transplantation
- Indistinct clinical border
- Situation requiring conservation of normal tissue to preserve function and cosmesis
- Situation requiring highest achievable probability of cure to preserve function and cosmesis



▲ **FIGURE 115-9** Management of basal cell carcinoma is guided largely by anatomic site and histologic sub-type of the lesion. ED&C = electrodesiccation and curettage.

margins. The histologic sub-type was aggressive in 11 of 12 cases with positive excision margins. Margins of 5 mm are necessary for primary morpheaform BCC or recurrent BCC. Excision of primary BCC should extend to fat to ensure adequate tumor removal.

Curettage and Desiccation (See Chap. 247)

C&D is one of the most frequently used treatment modalities for BCC.[44] That C&D is operator dependent was shown by Kopf et al., who identified a significant difference in cure rate between patients treated by private practitioners (94.3 percent) and those treated by residents (81.2 percent).[45] Spiller and Spiller reported a cure rate of 97 percent in 233 patients.[46] Cure rate decreased as a function of primary lesion size: for lesions smaller than 1.0 cm, the cure rate was 98.8 percent; for lesions between 1.0 and 2.0 cm, 95.5 percent; and for lesions larger than 2.0 cm, 84 percent. Recurrences were noted most often on the forehead, temple, ears, nose, and shoulders. C&D is not recommended for large primary BCC, morpheaform BCC, or recurrent BCC.

Cryosurgery (See Chap. 247)

Cryosurgery is another destructive modality that has been used in the treatment of BCC.[47] Two freeze-thaw cycles with a tissue temperature of –50°C (–58°F) are required to destroy BCC. In addition, a margin of clinically normal tissue must be destroyed to eradicate sub-clinical extension. Cryosurgery lacks the benefit of histologic confirmation of tumor removal. Kuflik and Gage reported 99 percent cure rates in 628 patients followed for 5 years.[48] Possible complications of cryosurgery include hypertrophic scarring and post-inflammatory pigmentary changes. Another serious potential adverse outcome is the obscuring of tumor recurrence by fibrous scar tissue. Any recent change in a cryosurgery scar after normal healing is completed should raise the suspicion of recurrent BCC.

Topical Treatment

IMIQUIMOD Imiquimod (5 percent cream) (see Chap. 221) has been used in the treatment of skin cancers.[49] Imiquimod is a Toll-like receptor 7 agonist and is believed to induce interferon-α and other cytokines to boost T helper 1 type immunity. In two double-blind, randomized, vehicle-controlled trials, clinical and histologic clearance rates for dosing five and seven times per week were 75 percent and 73 percent, respectively, for superficial BCC.[50,51] In another study, 10 of 19 nodular BCCs (approximately 53 percent) cleared after treatment with imiquimod.[52] In general, adverse side effects are limited to local skin reactions. Follow-up in case series has generally been shorter than that in retrospective studies of recurrence rates after definitive surgical management.

5-FLUOROURACIL (See Chap. 220) 5-Fluorouracil (5-FU), a topically applied chemotherapeutic agent used in the treatment of actinic keratoses, has also been used to treat BCCs. In one series, Epstein showed a 5-year recurrence rate of 21 percent after 5-FU treatment, which was reduced to 6 percent when curettage was performed initially.[53] 5-FU is metabolized by dihydropyrimidine dehydrogenase, and its use is contraindicated in patients deficient in that enzyme.[54,55] The use of 5-FU to treat BCC should be considered carefully and should include an evaluation of the risk of recurrence and treatment failure.

Photodynamic Therapy (See Chap. 239)

Photodynamic therapy involves the activation of a photosensitizing drug by visible light to produce activated oxygen species that destroy the constituent cancer cells.[56] Exogenous δ-aminolevulinic acid increases intracellular production of the endogenous photosensitizer protoporphyrin type IX, which preferentially accumulates in tumor cells. Morrison et al.[59] reported an 88 percent initial clearance of 40 large (> 2 cm) BCCs after one to three treatments. The time of follow-up was between 12 and 60 months. Reports of higher recurrence rates by others suggest that this method may be best reserved for select situations in which better established methods are not feasible.[57] Marmur et al. reviewed photodynamic therapy for non-melanoma skin cancer and reported recurrence rates ranging from 0 percent to 31 percent for BCC.[57]

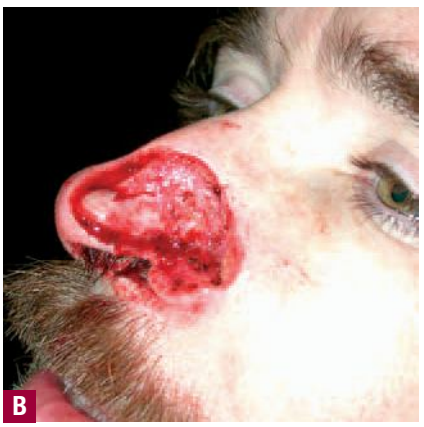
Radiation Therapy (See Chap. 241)

XRT may be useful in cases of primary BCC or in cases in which postsurgical margins are positive for cancer. Advantages include minimal patient discomfort and avoidance of an invasive procedure for a patient unwilling or unable to undergo surgery. Potential disadvantages include lack of histologic verification of tumor removal, prolonged treatment course, cosmetic result that may worsen over time, and predisposition to aggressive and extensive recurrences. Local control rates of 93 percent to 97 percent have been reported[58,59]; however, cosmesis has been rated inferior to results achieved surgically.

Special Management Issues

INCOMPLETELY EXCISED BASAL CELL CARCINOMA Based on data from the 1960s suggesting that 50 percent to 70 percent of incompletely excised BCCs do not recur, some physicians adopted a "wait and see" approach.[60] In some cases, flap and graft repair may have been performed before confirmation of negative margins, so that the anatomy was distorted. This confounds identification of positive margins for definitive treatment. Incomplete resection was addressed by Robinson and Fisher,[61] who reported on 994 patients consecutively referred for treatment of incompletely excised BCCs with subsequent clinical recurrence. Of these, only 32 were referred for MMS for complete tumor removal at the time the original operating surgeon received the pathologic confirmation of positive excision margins. For the remaining 962 recurrent BCCs, the nose was the most common anatomic site (43 percent), and flap repair was the most common form of reconstruction (52 percent). The authors recommend MMS for the treatment of incompletely excised BCC. Ideally, patients should receive treatment at the time of diagnosis, because delay will likely result in increased local tissue damage (Fig. 115-10). Patients unable to undergo re-excision to achieve clear margins should be evaluated for XRT.

NEUROTROPIC BASAL CELL CARCINOMA Perineural invasion by BCC is a rare event (< 0.2 percent of cases).[32,33] When perineural invasion is detected, every effort should be made to clear the tumor, preferably by MMS. Patients with gross perineural invasion manifested by neurologic symptoms would benefit from preoperative magnetic resonance imaging to assess extent of tumor spread. Classic examples include brow paralysis due to involvement of the temporal branch of the facial nerve and mid-face paresthesias secondary to involvement of the trigeminal nerve.



▲ **FIGURE 115-10** Incompletely excised basal cell carcinoma (BCC) resulting in extensive spread after observation rather than immediate definitive management. **A.** Recurrent BCC after skin graft placement over tumor-bearing area. **B.** Intraoperative view during Mohs surgery to achieve a tumor-free plane before reconstruction.

METASTATIC BASAL CELL CARCINOMA Although it is exceedingly rare, the possibility of metastatic disease exists and may need to be addressed.[36] If nodal disease is suspected on surgical examination, lymph node biopsy and imaging studies, as well as evaluation by medical and surgical oncologists, are indicated. Platinum-based chemotherapy has been used with modest results in treatment of metastatic BCC; however, rapid clinical response was reported using a combination of cisplatin and paclitaxel.[62]

COURSE AND PROGNOSIS

With appropriate treatment, the prognosis for most patients with BCC is excellent. Control rates as high as 99 percent have been achieved by MMS. Although tumor control rates for primary tumors are high, patients must be monitored for recurrence and development of new primary BCCs. The risk for development of a second primary BCC ranges from 36 percent to 50 percent.[63] Periodic full-body skin examinations and counseling about sun protection are recommended for any patient with a history of BCC. This is especially important because patients with a history of BCC are at increased risk for melanoma.

The prognosis for patients with recurrent BCC is favorable, although recurrent tumors are more likely to appear again and to behave aggressively. Patients with a history of recurrent disease must be monitored more frequently for the development of further recurrences and new primary tumors. For the rare patient with metastatic disease, prognosis is poor, with a mean survival of 8 to 10 months from the time of diagnosis.

CHAPTER 116

Basal Cell Nevus Syndrome

Anthony E. Oro

Basal cell nevus syndrome (BCNS), also known as *nevoid basal cell carcinoma syndrome* and *Gorlin syndrome* [Online Mendelian Inheritance in Man (OMIM) #109400], is a rare autosomal dominant disorder associated with a panoply of phenotypic abnormalities that can be divided into developmental anomalies and postnatal tumors, especially basal cell carcinomas (BCCs).[1] Although individual aspects had been reported previously, their syndromic association was first appreciated widely in the late 1950s.[2,3]

EPIDEMIOLOGY

The prevalence of BCNS is variously estimated to be 1 in 60,000 and 1 in 120,000 persons.[4,5] The syndrome affects both sexes and occurs in a wide variety of cultural groups, and therefore does not have a predilection for a particular skin type. The condition appears to have complete penetrance and variable expressivity of traits, which makes clinical presentation among families variable. Further, as with many dominantly inherited conditions, new mutations are common. As a result, in many cases, patients may have no apparent affected ancestors or siblings.

ETIOLOGY AND PATHOGENESIS

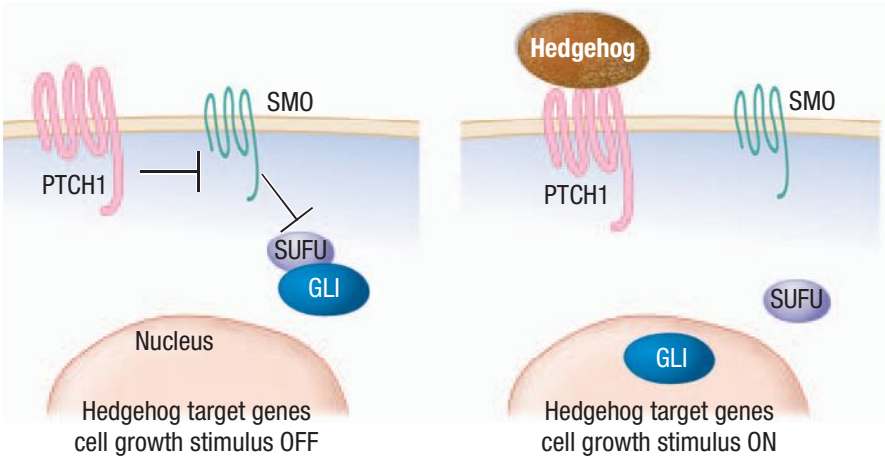
Genetic Abnormality

All known BCNS patients thus far carry mutations in the *PATCHED1* (*PTCH1*, UniGene Hs.494538) gene residing on the long arm of chromosome 9.[6,7] PTCH1 plays a central role in the hedgehog signaling pathway that is essential for the establishment of normal body and limb patterning in metazoan organisms.[8] The PTCH1 locus behaves like a classic tumor suppressor gene (Fig. 116-1). The appearance of BCCs in small numbers at an older age in sporadic cases and in larger numbers at a younger age in patients with BCNS is reminiscent of differences in sporadic and hereditary cases of retinoblastoma.[9] BCNS, like other tumor susceptibility syndromes, is inherited in an autosomal dominant manner, with inheritance of a loss-of-function allele followed by somatic loss of the remaining copy before tumor formation.

Identification of the gene mutation responsible for BCNS facilitated a molecular verification of the tumor suppressor prediction.[6,7] In BCNS, patients inherit

BASAL CELL NEVUS SYNDROME AT A GLANCE

- A rare autosomal dominant disorder with phenotypic abnormalities that include developmental anomalies and postnatal tumors, especially basal cell carcinomas (BCCs).
- The three most characteristic abnormalities are tumors such as medulloblastomas or BCCs, pits of the palms and soles, and odontogenic cysts of the jaw.
- Related findings include calcification of the falx cerebri, enlarged body habitus, and skeletal abnormalities of the ribs and skull.
- Diagnosis is suggested to the dermatologist in a patient with multiple BCCs arising at an unexpectedly early age on non–sun-exposed skin, with an average age of onset of 21 years.
- Histologic features are similar to those of sporadic infundibulocystic BCCs or medulloblastomas.



▲ **FIGURE 116-1** The mammalian hedgehog signaling pathway. PTCH1 is the receptor for the growth factor hedgehog and inhibits the function of smoothened (SMO). SMO inhibits Suppressor of Fused (SUFU), which in turn inhibits the GLI transcription factors.

one defective PTCH1 allele, but their tumors contain an additional somatic mutation. As with other tumor suppressor genes, PTCH1 mutations have also been found in older adults with sporadic BCCs and other sporadic tumors known to be over-represented in BCNS patients (e.g., medulloblastomas and meningiomas), which supports the idea that two somatic "hits" are required in sporadic tumors.

Are PTCH1 mutations the only cause of BCNS? Despite direct sequencing of *PTCH1* exons in patients, somatic mutations are found in fewer than half of BCCs and constitutional mutations in fewer than 100 percent of BCNS patients.[13,14] On the one hand, this suggests that mutations in other unidentified genes may underlie the disease. On the other hand, early linkage studies found strong association with the PTCH1 locus. Moreover, although mutations are not found in PTCH1 exons in some patients, hedgehog signaling pathway abnormalities are still present in these tumors. This indicates that either mutations in another PTCH1-like gene or insensitivity or incompleteness of the screening methods explain the discrepancy.

PTCH1 Function[15]

PTCH1 protein plays a critical role in the hedgehog signaling pathway. Genetic and biochemical studies in *Drosophila* and mammals indicate that PTCH1 protein inhibits this signaling pathway by inhibiting the function of the central G protein–coupled receptor smoothened (SMO), and that the extracellular ligand hedgehog reduces this inhibition. Signaling by SMO results in the activation of the GLI family of zinc finger proteins that mediate all the transcriptional effects of hedgehog signaling. Three GLI proteins mediate activation and suppression of hedgehog target genes, with GLI1 and GLI2 acting as activators and GLI2 and GLI3 as suppressors. SMO signaling tips the balance towards activation and away from target gene suppression. In mammals, GLI activity is controlled by the novel cytoplasmic protein Suppressor of Fused (SUFU), which promotes the transcriptional repression and inhibits activation.[16] SMO functions to inhibit SUFU activity, thus releasing GLI proteins to become transcriptional activators. When hedgehog binds to PTCH1, PTCH1 inhibition of SMO is relieved and the pathway is activated. The loss of PTCH1 function that allows unregulated SMO activity forms the basis of the tumor induction.

How PTCH1 functions as a tumor suppressor is still under investigation. A significant aspect of PTCH1 function is inhibition of SMO, although how PTCH1 accomplishes this is unknown. PTCH1 acts in an enzymatic manner, with only a few molecules able to inhibit several-fold times more SMO.[17] Moreover, PTCH1 and SMO are thought not to physically interact and exist in distinct endosomes in the cell. One clue is that SMO activity appears to be linked to its sub-cellular location, because loss of PTCH1 or mutations that trap SMO at the membrane result in SMO phosphorylation and increased activity.[18] Another clue is that PTCH1 shares homology with sterol-sensing domain–containing proteins such as the cleavage activation protein SREBP (sterol regulatory element–binding protein) and β-hydroxy-β-methylglutaryl–coenzyme A reductase.[19] It also shares significant structural identity with the resistance-nodulation-division (RND) permease family of small-molecule transporters, which suggests that it acts like a molecular pump. This evokes the tantalizing hypothesis that PTCH1 regulates SMO localization by regulating the production or distribution of small-molecule second messengers in the cell.

Mutations in Sonic Hedgehog Pathway in BCCs

Supporting the central role of Sonic Hedgehog (Shh) target gene induction in BCC pathogenesis is the finding of mutations in members of the Shh pathway in both BCNS patients and in sporadic BCCs. Identified mutations involving PTCH1 are by far the most common and are found in approximately 40 percent of tumors.[23] Epidemiologic evidence implicates ultraviolet light in the

pathogenesis of sporadic BCCs. The particular type of mutation found in PTCH is consistent with mutation caused by ultraviolet light, which provides additional evidence for PTCH and sunlight in cancer development.[24]

Mutations of SMO protein have been identified in approximately 10 percent of BCCs, and these mutations appear to render SMO protein resistant to PTCH1 inhibition.[25] Indeed, experimental transfection of cells with mutant SMO sequences can transform them to a malignant phenotype. This finding that BCCs may have upregulation of hedgehog target gene expression due to mutations in either PTCH1 or SMO argues that it is the upregulation of hedgehog signaling rather than the specific mutation that is crucial to BCC formation. Consistent with this is the finding that mutations in the gene encoding SUFU have been reported to underlie formation of medulloblastomas.[26]

The identification of these molecular abnormalities in BCCs for the first time has permitted the development of mouse models of this tumor. Previously, insults to mouse skin—ultraviolet or ionizing radiation or carcinogenic chemicals—have produced papillomas and carcinomas of the squamous, but not the basal cell, lineage. Mouse models that show spontaneous development of BCC-like tumors include those with epidermal overexpression of hedgehog,[27] of mutant SMO,[25] or of GLI1[28,29] or GLI2.[30] In addition, *ptc1*$^{+/-}$ mice, which, like BCNS patients, have one instead of two functioning alleles of *PTCH1*, not only develop BCCs and related tumors but also develop plantar pits, medulloblastomas, and rhabdomyosarcomas, as do BCNS patients. The mouse BCCs (mimicking BCCs in BCNS patients) occur spontaneously in low numbers and in small sizes, but in much higher numbers and of larger size in mice exposed to ultraviolet or ionizing radiation.[11,30,31]

CLINICAL FINDINGS

Cutaneous Lesions

Hedgehog signaling plays a critical role in the expansion of progenitor cells in a wide variety of tissues in both invertebrate and vertebrate organisms. PTCH1 normally is expressed both during development and in the adult, which suggests an ongoing role postnatally. Studies involving experimental models inappropriately expressing components of the hedgehog signaling pathway have revealed significant developmental anomalies.[31] The resemblance of these anomalies to those characteristic of BCNS implies that aberrant activation of the hedgehog signaling pathway is a sufficient explanation for the developmental and tumorigenic anomalies of BCNS, even if the precise pathogenic mechanisms have yet to be elucidated.

Patients with BCNS show multiple abnormalities, none of which is unique to this syndrome[5,13,14] (Table 116-1). The three abnormalities considered to be most characteristic of the syndrome are tumors such as medulloblastomas or BCCs, pits of the palms and soles, and odontogenic cysts of the jaw.

BCCs in patients with BCNS cannot be distinguished individually from those in sporadic cases (see Chap. 115), which is not surprising in view of the similar pathogenesis in familial and sporadic cases. What is distinguishing is their appearance in large numbers starting at an early age. They may be banal appearing and confused grossly with nevocytic nevi—hence the name *basal cell nevus*. They may also have a translucent, papulonodular appearance more characteristic of sporadic basal cell carcinomas and may invade locally. In rare cases, they may even metastasize, causing the patient's death. Although the ratio of sun-protected to sun-exposed BCCs may be higher in BCNS than in sporadic cases, sunlight and ionizing radiation clearly accelerate BCC formation in BCNS patients, and darkly pigmented BCNS patients may have few to no BCCs (Figs. 116-2, 116-3, and 116-4).

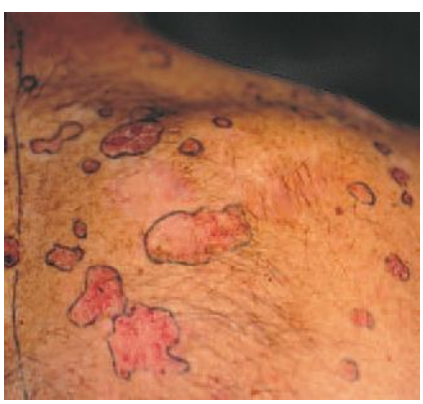
▲ **FIGURE 116-2** Face of a man with severe scarring from growth and treatment of multiple basal cell carcinomas (BCCs). Note multiple outlined new BCCs despite extensive and frequent surgery.

Palmo-plantar pits are small defects in the stratum corneum and may be pink or, if dirt has accumulated, dark in color (Fig. 116-5). They appear early in life and can be a valuable aid in diagnosis in addition to jaw cysts or medulloblastoma. Their basis is poorly understood, but they are thought to be due to aborted attempts to generate hair follicles in the palms. They are also seen in mouse PTCH1 heterozygotes.[31]

Related Physical Findings

Tissue overgrowth, which is also a feature of hedgehog signaling pathway activation in *Drosophila*, often is manifested by an overall body size larger than that of other family members. Limbs may be particularly long, giving a marfanoid appearance (Fig. 116-6), and a large head circumference (at least in probands) and frontal bossing are often described.



▲ **FIGURE 116-3** Upper back of man with basal cell nevus syndrome with innumerable basal cell carcinomas, some of which are nodular and most of which are flat, erythematous patches.

▲ **FIGURE 116-4** Basal cell carcinoma (BCC) on the toe of a patient with basal cell nevus syndrome (BCNS), which illustrates that the whole skin surface of BCNS patients is susceptible to BCC formation.

Jaw cysts often are the first detectable abnormality[5,13,14] (Fig. 116-7). They may be asymptomatic and therefore diagnosed only radiologically. However, they also may erode enough bone to cause pain, swelling, and loss of teeth. They occur more often in the mandibular jaw than in the maxillary jaw.[32] They presumably form from inappropriate Shh induction of dental epithelium, can recur often, and can be the most debilitating aspect of the syndrome.[33]

Table 116-1 lists the phenotypic abnormalities that have been reported often enough that they probably are true components of the syndrome. These include tissue overgrowth seen in other epithelial organs such as the meninges or ovary that give rise to meningiomas or ovarian fibromas. Variation in clinical severity is typical even within a single kindred, and this heterogeneity is likely due to both environmental differences (e.g., exposure to ultraviolet and ionizing radiation) and genetic background differences.

Of interest is the finding that Shh signaling plays a key role in up to 25 percent of all human cancers, including small cell lung cancer, pancreatic cancer, and prostate cancer.[34] This finding suggests a wider role for hedgehog signaling than that seen in BCNS patients. Although BCNS is a rare syndrome and exhaustive controlled studies have not been performed, no excess of these associated cancers has been documented in BCNS patients. This might reflect a distinct mechanism of action, because these other tumors demonstrate hedgehog ligand overexpression rather than the loss of PTCH1. Alternatively, pathway induction in older adults may have different consequences than pathway activation in younger individuals.

DIAGNOSIS

Because the individual abnormalities are not unique to BCNS patients, it is possible to diagnose BCNS clinically only when multiple typical defects are present (Table 116-2). The severity of abnormalities may differ markedly among members of a single kindred, and diagnostic certainty may be difficult for specific individuals even if they be-

▲ **FIGURE 116-5** **A.** Unusually florid palmar pits in a patient with basal cell nevus syndrome (BCNS). **B.** Larger magnification showing that these lesions in BCNS are really punched-out pits.

long to a kindred with known BCNS.[35] Generally, the diagnosis is suggested to the dermatologist when multiple BCCs arise in a patient at an unexpectedly early age and in unexpectedly large numbers, with the average age of onset in the early 20s.

Further evaluation should include (1) questions about whether other family members have had abnormalities consistent with BCNS (although perhaps 25 percent to 30 percent of patients with BCNS have no affected ancestors) and whether the patient is taller and heavier than his or her relatives; (2) examination for palmo-plantar pits and skin cysts and assessment of body and head size; and (3) radiologic evaluation for jaw cysts (which often appear around the start of the second decade and frequently recur after surgery), calcification of the falx (which occurs in nearly all adults with BCNS and may be present in early childhood in BCNS patients, thus suggesting the diagnosis of BCNS in patients with early-onset medulloblastomas), and abnormalities of the ribs, spine, and phalanges (flame-shaped lucencies), each of which is present in one-third to one-half of BCNS patients.[5,13,14,36] Kimonis and colleagues proposed a set of major and minor criteria for presumptive diagnosis of BCNS, which has since been modified (see Table 116-2).[13] For cases in which the diagnosis is in doubt, or for genotyping of other family members, identification of *PTCH1* gene mutations is now available commercially through GeneDX (Gaithersburg, MD).

DIFFERENTIAL DIAGNOSIS

Other syndromes exist that are characterized by the development of multiple BCCs. These include Bazex syndrome (OMIM 301845),[37] Rombo syndrome (OMIM 180730),[38] and a syndrome observed in a family with BCCs, milia, and coarse, sparse hair.[39] Hair abnormalities are present in all three syndromes, which is a finding of interest in view of the often-repeated suggestion that BCCs arise from hair follicles rather than from interfollicular epidermis. The exact nosologic relationships among these three syndromes are uncertain, but patients with BCNS have normal hair, and all three syndromes seem quite different from BCNS.

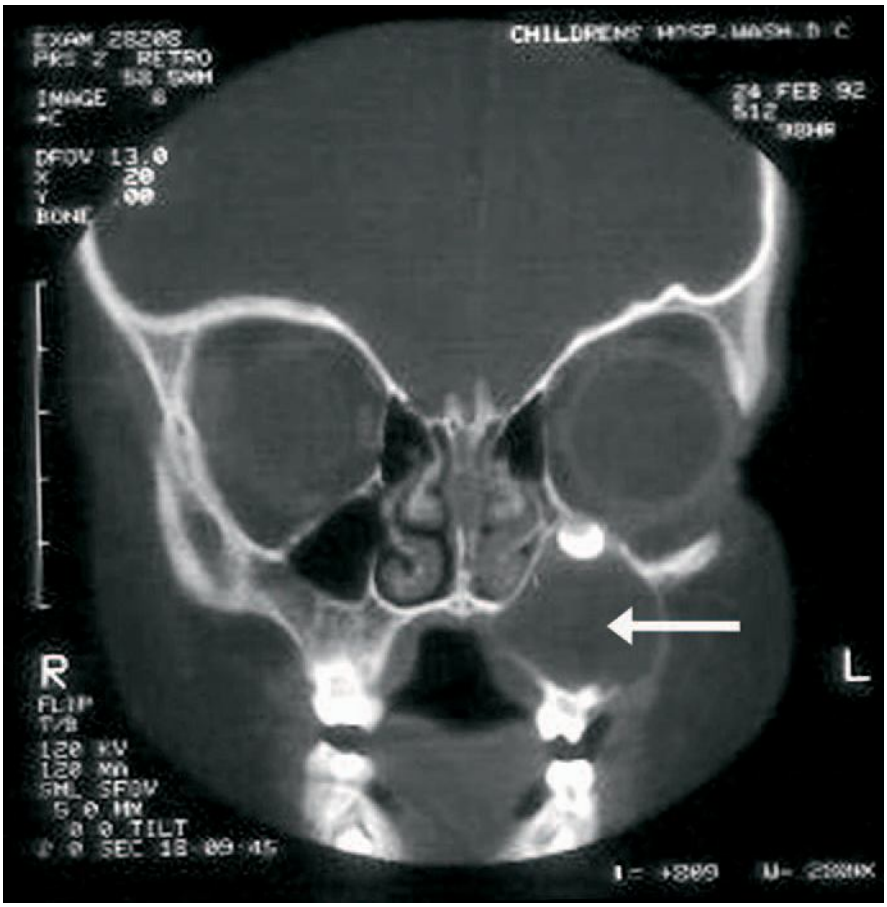
Two other syndromes that have been described include multiple hereditary infundibulocystic basal cell carcinoma[40] and generalized basaloid follicular hamartoma.[41] Both demonstrate histologic variants of BCCs, with more hamartomatous lesions, and are characterized by palmar pits and milia. The latter syndrome is acquired and associated with autoimmune disease, which suggests an immunologic stimulation of the hedgehog pathway. The former appears to be linked to the PTCH1 locus and thus may be due to a PTCH1 allele.

Patients with long-term arsenic ingestion may have multiple BCCs. Their dyschromia and lack of other phenotypic abnormalities differentiate them from BCNS patients (see Chap. 113). Patients with xeroderma pigmentosum develop multiple BCCs but are readily differentiated from BCNS patients by their severe photosensitivity and other phenotypic abnormalities (see Chap. 140).

The most challenging patients are those who have a marked propensity to develop multiple BCCs early in life, sometimes sporadically or in rare cases after therapeutic irradiation (e.g., for Hodgkin disease) without showing any of the other signs of BCNS. These cases occasionally produce diagnostic confusion because, due to the variable expressivity of individual PTCH1 alleles, it is not known whether their defect is related to the hedgehog pathway, to DNA repair, to an unknown toxin, and/or to undescribed mechanisms. One insightful study argues against constitutional PTCH1 mutations as the cause of multiple BCCs, because PTCH1 mutations have not been found in individuals who do not have at least one other key manifestation of BCNS.[42]

COMPLICATIONS, PROGNOSIS, AND CLINICAL COURSE

Although disease pathogenesis involves abnormalities in Shh signaling, the wide variability in clinical course among fam-



▲ **FIGURE 116-7** Radiographic findings of odontogenic keratocyst (*arrow*).

TABLE 116-2
Diagnostic Criteria for Basal Cell Nevus Syndrome (BCNS)

Major Criteria
1. Basal cell carcinoma before age 20 yr
2. Odontogenic keratocysts before age 15 yr
3. Three or more palmar and/or plantar pits
4. Bilamellar calcification of the falx cerebri (if younger than 20 yr)
5. Fused, bifid, or markedly splayed ribs
6. First-degree relative with BCNS
7. *PTC* gene mutation in normal tissue

Minor Criteria
1. Macrocephaly determined after adjustment for height
2. Congenital malformations: cleft lip or palate, frontal bossing, "coarse face," moderate or severe hypertelorism
3. Skeletal abnormalities: Sprengel deformity, marked pectus deformity, or marked syndactyly of the digits
4. Radiologic abnormalities: bridging of the sella turcica; rib anomalies such as bifid or splayed ribs; vertebral anomalies such as hemivertebrae, fusion, or elongation of the vertebral bodies; modeling defects of the hands and feet; or flame-shaped lucencies of the hands or feet
5. Ovarian fibroma
6. Medulloblastoma

Data from Kimonis VE et al: Clinical manifestations in 105 persons with nevoid basal cell carcinoma syndrome. *Am J Med Genet* **69**:299, 1997; and First BCCNS Colloquium, St. Louis, May 2005.

ilies, and even between generations of the same family, make prediction of clinical course difficult. If BCNS is suspected or confirmed, physicians should also screen for the most frequent sequelae of the disease during childhood or adolescence. (Fig. 116-8). No large-scale survival studies have been performed to determine whether BCNS patients die earlier because of their disease.[13,43] The major complications are associated with developmental abnormalities that result in developmental delay or physical impairment in children and the childhood tumors that arise, such as medulloblastoma. The latter often occur within the first 5 years of life and are frequently the initial sign of BCNS. Complications arising from medulloblastoma treatment (radiation, shunt placement) are relatively common, and multidisciplinary teams of physicians are required to optimally treat these patients.

In the skin, BCCs that arise are locally aggressive but very rarely metastasize.[44] No reports document an increased risk for metastatic BCCs, which suggests that the basic character of the tumor is similar to that seen in sporadic BCC cases. However, because of the high numbers and wide distribution of the tumor, even in the absence of sun exposure, involvement of key epithelial surfaces or membranes is likely and can be disfiguring for the patient.

TREATMENT

Therapy must be directed at the individual lesions as they arise, and the most important aspect of management is frequent examination, enthusiastic counseling about avoidance of sun exposure, and early treatment of small tumors. In animal models of BCNS, small clinically undetectable tumors arise throughout the skin. This suggests that many more tumors form than are detectable visibly by the clinician.[29] This has several therapeutic ramifications. One is that clinicians caring for BCNS patients should become confident in their clinical acumen so that they can diagnose and treat tiny BCCs without histopathologic confirmation. This would eliminate multiple scar-inducing biopsies in addition to potentially disfiguring treatments. Another is that invasive treatments should be focused on those lesions that are potentially most harmful, such as those invading mucous membrane or adjacent structures. Repetitive surgical treatments run the risk of severe disfigurement for the patient. Finally, clear surgical margins may be difficult to achieve when using Mohs surgery, so aggressive pursuit of a clear margin needs to be balanced against other factors in treating these patients.

Non-surgical approaches to BCC treatment should be used aggressively in BCNS patients when possible. Because the key is to convince the patient to accept frequent treatments, minimization of discomfort and scarring is a major goal. Approaches that may be of benefit are topical treatment with 5-fluorouracil (with or without occlusion, depending on the degree of inflammation produced),[45] the Toll-like receptor agonist imiquimod,[46] and photodynamic therapy.[47] Oral therapy with retinoids also may be of value, but often only at a dosage that causes severe side effects.

Studies have now identified a natural antagonist of the hedgehog pathway derived from the *Veratrum californicum*

Approach to a patient with known or suspected BCNS

Pediatric patients

- baseline MRI of brain, repeat yearly (if asymptomatic) until age 8
- baseline dermatologic exam, repeat yearly until first BCC develops, then every 6 months or more frequently as needed) throughout life
- digital panorex of jaw at age 3 or 4 years (or as soon as tolerated), then yearly until first jaw cyst develops. Repeat yearly (or more frequently as needed), until age 21
- pelvic u/s in girls at menarche (or earlier if symptomatic)
- molecular diagnosis, (if desired) for patients with family history and known mutation
- baseline scoliosis assessment at 1 year of age and then annually for progression if present
- routine developmental screening and referral for all children who do not meet developmental milestones

Adult patients

- baseline MRI of brain (if not done at age 8 or later)
- dermatologic exam at 4 months (or more frequently if new lesions present at each exam)
- digital panorex of jaw twice yearly until cyst free for two years, then yearly or less frequently (depending on patient's concern about radiation)
- prenatal or preconception counseling if desired

▲ **FIGURE 116-8** Approach to the patient with known or suspected basal cell nevus syndrome (BCNS). BCC = basal cell carcinoma; MRI = magnetic resonance imaging; u/s = ultrasonography. (Data from Kimonis VE et al: Clinical manifestations in 105 persons with nevoid basal cell carcinoma syndrome. *Am J Med Genet* **69**:299, 1997; and First BCCNS Colloquium, St. Louis, May 2005.)

plant called *cyclopamine*.[12] This substance binds and antagonizes SMO activity and has been shown to be effective in animal models of BCCs. Other small-molecule hedgehog pathway antagonists with similar properties have been identified and are currently being tested for their clinical efficacy.[48] These bring the promise of a specific therapy for BCCs and other hedgehog signaling–dependent tumors.

The x-irradiation of BCCs has been advocated in otherwise normal patients who are not surgical candidates. However, excessive radiation should be avoided if possible, because enhanced radiation-induced carcinogenesis (e.g., in the skin of the portals of irradiation for childhood medulloblastomas) is characteristic of BCNS. Patients with BCNS who receive radiation have developed an unusually large number of basal cell tumors in the irradiated area a short time after exposure (Fig. 116-9). Radiosensitivity in PTCH heterozygotes has also been detected at the cellular level, although the mechanism is poorly understood.[49]

Genetic counseling is appropriate. With the availability of direct sequencing of the PTCH1 locus, genotyping for prenatal diagnosis is potentially achievable for interested families. Because PTCH1 is transmitted with complete penetrance, half of the children of affected individuals are expected to develop BCNS.

ACKNOWLEDGMENTS

I would like to thank Drs. Sheri Bale and Thierry Magnaldo for patient information and Ray Herrman for administrative help.

CHAPTER 117

Keratoacanthoma

Lorenzo Cerroni
Helmut Kerl

Keratoacanthoma is a common epithelial tumor of the skin characterized by rapid growth, histopathologic features similar to those of cutaneous squamous cell carcinoma, and a certain tendency toward spontaneous regression. The exact nosology and classification of keratoacanthoma are a matter of debate. Some authors regard keratoacanthoma as a benign cutaneous tumor that is the prototype of a "pseudomalignant" tumor of the skin, whereas others maintain that it is a malignant neoplasm and should be regarded as a variant of cutaneous squamous cell carcinoma.

The authors of this chapter believe that keratoacanthoma represents a peculiar variant of squamous cell carcinoma, based on the rare but well-known potential for distant metastases, and the capability for local destruction of important structures.

EPIDEMIOLOGY

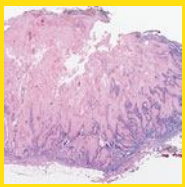
The exact incidence of keratoacanthoma is unknown. The tumor is more frequent in light-skinned persons, and rarer in dark-skinned and Japanese persons. The relative frequency in comparison with squamous cell carcinoma of the skin is controversial, but most studies show a lower incidence of keratoacanthoma than of squamous cell carcinoma. Discordant results may be explained, at least in part, by differences in classification of these lesions.

Studies on gender distribution reveal that both sexes are affected equally, possibly with a slight predilection for men. Keratoacanthoma occurs mostly in adult life, with a peak between the ages of 55 and 65 years; it has been observed rarely in younger patients. The familial type of keratoacanthoma occurs often during adolescence, and a neonatal case has been reported.[8] Although the incidence was thought to remain stable after a peak in the sixth decade, a study conducted in a defined population in Hawaii revealed that keratoacanthoma increases with age, in a fashion similar to that observed for cutaneous basal and squamous cell carcinomas.[9]

Relationship to Squamous Cell Carcinoma

The authors of earlier reports considered keratoacanthoma to be a form of epithelial cancer of the skin, and named it accordingly. However, since the introduction of the concept of keratoacanthoma as a benign, self-healing neoplasm distinct from squamous cell carcinoma, the relationship between these two epithelial tumors has been the subject of debate. In their paper published in 1950, Rook and Whimster wrote, "This disease is evidently not cancerous or precancerous."[2] On the other hand, Kwittken, in 1975, stated, "I have come to the firm conclusion that all of these lesions are malignancies and that the formerly accepted concept of a self-healing squamous cell carcinoma of the skin is a correct one,"[10] and in 1979, even Rook amended his initial concept by writing, "…transformation from keratoacanthoma to squamous cell carcinoma occurs frequently."[11] Cases of typical keratoacanthoma with metastases have been observed,[12] and four possible explanations for this phenomenon have been suggested: an initial misdiagnosis of keratoacanthoma; the presence of both keratoacanthoma and squamous cell carcinoma in the same lesion; the malignant transformation of keratoacanthoma into squamous cell carcinoma; and, finally, the possibility that keratoacanthoma may be a peculiar variant of squamous cell carcinoma.[13] The debate is not settled yet, and some authors still maintain that keratoacanthoma represents a benign epithelial tumor, distinct from squamous cell carcinoma,[14] whereas others hold that it is a variant of squamous cell carcinoma with tendency to spontaneous regression, but with the potential for giving rise to lethal distant metastases.[15] Two studies of large numbers of cases highlighted the impossibility of reliably differentiating keratoacanthoma from squamous cell carcinoma using histopathologic criteria alone.[16,17] Recently, a patient under infliximab therapy developed multiple squamous cell carcinomas as well as keratoacanthomas, suggesting a common pathogenetic pathway on immunosuppression.[18] In addition, multiple keratoacanthomas and multiple squamous cell carcinomas may be observed at the same skin site ("field cancerization") (Fig. 117-1). Keratoacanthomas have a higher proliferation rate than squamous cell carcinomas.[19] Other investigations pointed at similarities among squamous cell carcinoma and keratoacanthoma in the expression of oncogenetic and cell-cycle–regulating proteins as well as regarding the presence of trisomy 7 in a subset of tumors in both groups, thus suggesting a close relationship between these two entities.[20–25] On the other hand, studies on loss of heterozygosity, on expression of angiotensin type 1 receptor and of desmogleins 1 and 2, on adhesion molecules vascular cellular adhesion molecule and intercellular adhesion molecule, on telomerase activity, on apoptotic and cell adhesion markers, and on chromosomal aberrations assessed by comparative genomic hybridization showed differences among keratoacanthomas and squamous cell carcinomas.[26–32] Using different molecular techniques, both similarities and differences between keratoacanthoma and squamous cell carcinoma have been recently demonstrated.[33] In short, at present, and in spite of the great amount of clinical and experimental data collected over the decades, the exact nosology of keratoacanthoma is not clear, and the term *abortive malignancy* has been proposed.[34]

KERATOACANTHOMA AT A GLANCE



- A common, rapidly growing epithelial tumor with histopathologic features similar to squamous cell carcinoma and a tendency to spontaneous regression.
- Considered a variant of squamous cell carcinoma because of potential of metastases and local tissue destruction if untreated. Considered by others a *pseudocancer*, but this issue is unresolved.
- Clinically, keratoacanthoma is a hyperkeratotic solitary tumor. Multiple keratoacanthomas occur.
- Predilection for sun-exposed areas.
- May be associated with Muir-Torre syndrome.
- Pathology reveals a central keratotic plug surrounded by an epithelial proliferation with atypical keratinocytes and mitoses; neurotropism may be observed.

▲ **FIGURE 117-1** Multiple keratoacanthomas and invasive squamous cell carcinomas on the upper chest of a 90-year-old man.

ETIOLOGY AND PATHOGENESIS

Different etiologic factors are probably involved in the development of keratoacanthomas in different patients, and it seems likely that these different factors act synergistically to induce the onset of a lesion in a given patient. The role of chronic ultraviolet (UV) light exposure in the etiology of keratoacanthoma is well documented by the frequent occurrence on sun-exposed areas, as well as by the presence of keratoacanthomas in patients with xeroderma pigmentosum and after prolonged psoralen and UVA light (PUVA) treatment. In patients with multiple keratoacanthomas, PUVA treatment accelerates the development of the tumors,[35] but the risk for keratoacanthoma after therapy with PUVA seems lower than that for squamous or basal cell carcinoma.[36] An etiologic link to UV light has been confirmed also by experimental studies in mice.

The relationship of keratoacanthoma to chemical carcinogens has been well documented in humans and in several animals.[37] In fact, the incidence of keratoacanthoma is higher in industrial towns, and among industrial workers coming in contact with pitch, mineral oils, and tar. Chemical carcinogens may act in conjunction with UV rays to induce the onset of keratoacanthomas. Smokers seem also to be more affected than nonsmokers.[37]

Keratoacanthomas have been reported at the site of injury. The association with trauma is also documented by the report of cases occurring after skin grafting, at both the donor and the recipient sites, and at the site of arterial puncture and vaccination.[38–40] The role of human papillomavirus (HPV) remains controversial. Recently, evidence of HPV infection was documented by the highly sensitive polymerase chain reaction technique,[41,42] but other studies failed to detect viral material within lesions of keratoacanthoma.[43] Some studies found an association with HPV-25, and HPV-19 and HPV-48 have been isolated in a lesion arising in a human immunodeficiency virus (HIV) patient.[44,45] Several other types of HPV have been linked to keratoacanthoma, including types 6, 9, 14, 16, 19, 35, 37, 58, and 61.

Genetic factors probably play a major role in the familial type of keratoacanthoma. In the other variants of keratoacanthoma, it seems likely that genetic aspects interplay with other etiologic factors (i.e., UV rays, trauma, infections) by providing the genetic predisposition for the development of the tumor. Keratoacanthomas are commonly observed in patients with Muir-Torre syndrome, suggesting that the genetic defect(s) of this syndrome also plays a role in the development of keratoacanthoma.[46–49] In addition, keratoacanthomas have been observed in patients affected by a variety of skin diseases including psoriasis, lupus erythematosus, lichen planus, atopic dermatitis, herpes zoster, acne conglobata, and pemphigus foliaceus, among others.[38]

Keratoacanthomas also have been observed in patients under immunosuppression as a result of bone marrow transplantation, cyclosporine treatment, or infection with HIV, thus suggesting that immunosuppression may play an etiologic role in some cases. In these patients, most lesions of keratoacanthoma tested for presence of HPV proved positive, suggesting that immunosuppression may contribute by decreasing the immune response against possible causative agents.[50] Similarly, UV light may act not only by direct carcinogenesis, but also by virtue of the local immunosuppression caused by sun exposure (see Chap. 89).

Little is known about the pathogenesis of keratoacanthoma, and about the exact mechanisms of regression in the absence of any treatment. Studies on p53 oncoprotein expression and p53 gene mutations revealed expression of p53 oncoprotein in the great majority of tested cases, and association with a point mutation in the p53 gene in slightly more than 10 percent of these cases, suggesting a possible role of p53 gene in the development of some keratoacanthomas.[21,25]

Multiple keratoacanthomas of the Ferguson-Smith type show a familial distribution and are transmitted in an autosomal dominant fashion. The gene responsible for this syndrome is localized to chromosome 9q. The majority of the cases have been described in some Scottish families, and in these patients, the syndrome is thought to be caused by a single genetic mutation that occurred before 1790.[57]

CLINICAL FINDINGS

Keratoacanthomas occur mostly on sun-exposed skin of the face, forearms, and dorsal aspects of the hands (see eFig. 117-1.1 in on-line edition and Fig. 117-2). Actinic damage is commonly found in the surrounding skin. In most instances, they are located on hairy skin, but lesions with similar clinicopathologic aspects have been described in the oral cavity, the subungual region, the genital mucosa, and the conjunctiva.

The stereotypic example of keratoacanthoma is represented by a solitary lesion growing rapidly within a few weeks, and subsequently showing a slow involution over a period of a few months. Three clinical stages have been described: proliferative, mature, and resolving.[38] Lesions in the proliferative stage are rapidly enlarging erythematous papules that grow up to a dimension of 1 to 2 cm or more. In this stage, the lesions are symmetric and firm and show a smooth surface. In the mature stage there are symmetric, firm, erythematous or skin-colored nodules with a central keratotic core (see Fig. 117-2). The central part can appear crateriform if the keratotic core is removed. Ghadially divided mature keratoacanthomas into three main morphologic types: type 1, or bud-shaped; type 2, or dome-

▲ **FIGURE 117-2** Mature keratoacanthoma on the temple of a 93-year-old woman. Note central keratotic core giving a white-yellowish appearance to the superficial part of the lesion.

shaped; and type 3, or berry-shaped.[39] Regressing lesions are characterized by a keratotic, partly necrotic nodule that becomes progressively flat upon elimination of the keratotic plug, eventually leaving a hypopigmented scar (Fig. 117-3; Box 117-1).

Systemic Associations

Keratoacanthomas may be associated with multiple internal cancers in patients with Muir-Torre syndrome and the related hereditary nonpolyposis colorectal cancer syndrome. Patients with multiple keratoacanthomas should always be evaluated for the presence of typical traits of Muir-Torre syndrome, where cutaneous sebaceous tumors and low-grade visceral malignancies can be observed (most commonly carcinomas of the gastrointestinal tract, but also carcinomas of the lung and genitourinary system, and, occasionally, colonic polyps). It has been suggested that at least some of the patients with multiple keratoacanthomas of the Ferguson-Smith type may have an incomplete form of the Muir-Torre syndrome.

Keratoacanthomas may also occur in patients with xeroderma pigmentosum (see Chap. 140) and, rarely, in patients with lymphomatoid papulosis (see Chap. 146).

▲ **FIGURE 117-3** Regressing keratoacanthoma on the lower leg of a 59-year-old man. There is a whitish flattened plaque with superficial ulceration in the center.

Box 117-1

Clinical Differential Diagnosis of Keratoacanthoma

Most Likely

Consider

- Well-developed tumors
  - Common warts
  - Molluscum contagiosum
  - Prurigo nodularis
  - Metastatic carcinoma
- Regressing tumors
  - Regressing lesions of lymphomatoid papulosis
  - Regressing lesions of anaplastic large cell lymphoma
  - Amelanotic melanoma

Variants

Several variants of keratoacanthoma have been described, and different morphologic types of keratoacanthoma have been observed in a single patient.[58]

Giant Keratoacanthoma

In some instances, keratoacanthomas may reach dimensions of several centimeters (see eFig. 117-3.1 in on-line edition), and even a tumor reaching 15 cm in its diameter has been observed. Giant keratoacanthomas show a predilection for the nose and the dorsum of the hands. In some cases, the growth of the tumor may be associated with destruction of underlying tissues (Fig. 117-4).

Keratoacanthoma Centrifugum Marginatum

Keratoacanthoma centrifugum marginatum is characterized by multiple tumors growing on a localized area, usually on the face, trunk, or extremities (Fig. 117-5).[59] Tumors are annular, polycyclic, or circular in morphology. The area affected may reach 20 cm in diameter, and resolution may be slower than in solitary keratoacanthoma.

▲ **FIGURE 117-4** Giant keratoacanthoma on the tip of the nose of a 52-year-old man. Note the destructive appearance of the tumor.

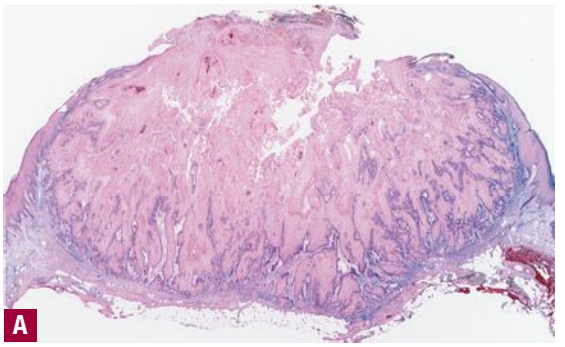
▲ **FIGURE 117-5** Multiple keratoacanthomas with an annular arrangement and central, keratin-filled craters on the back of the hand (keratoacanthoma centrifugum marginatum). This 42-year-old male patient also had lupus erythematosus.

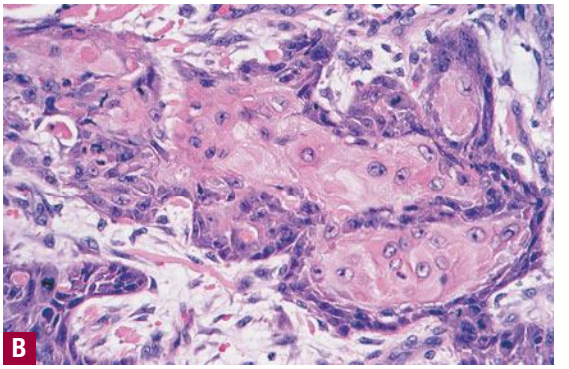
Multiple Keratoacanthomas of the Ferguson-Smith Type

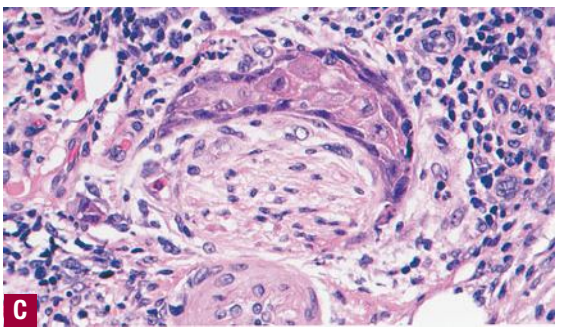
The Ferguson-Smith type is a familial form of keratoacanthoma that affects both sexes with approximately equal severity, which is characterized by the appearance of multiple, sometimes hundreds of keratoacanthomas, each with the clinicopathologic aspects of a solitary keratoacanthoma. The disorder is inherited in an autosomal-dominant manner, and the majority of the cases have been described in a few Scottish families. Patients develop keratoacanthomas during adolescence and early adulthood, but onset during childhood is not infrequent. It has been suggested that at least some of these patients may have an incomplete form of the Muir-Torre syndrome.

Generalized Eruptive Keratoacanthomas of Grzybowski

Keratoacanthomas of Grzybowski is a variant characterized by the presence of hundreds to thousands of tiny follicular keratotic papules disseminated all over the body, with predominance on sun-exposed areas. Facial involvement is usually severe, and coalescence of lesions around the eyes may cause ectropion. The mucosal regions (oral, genital) may be affected, whereas palms and soles are usually not involved. The age of onset is similar to that of solitary keratoacanthoma, and clustering in families has not been observed.







◀ **FIGURE 117-6** Mature keratoacanthoma. **A.** Low-power magnification revealing a symmetric lesion with a central keratotic core. **B.** Tumor complexes with large eosinophilic cells admixed with atypical cells and a few mitoses. **C.** Perineural growth of tumor cells (neurotropism).

Subungual Keratoacanthoma

Subungual keratoacanthoma (see eFig. 117-5.1 in on-line edition) differs from the other types of keratoacanthoma by being persistent and often causing destruction of the underlying bone. The tumor originates in the distal nail bed, separating the nail plate from the nail bed, and can grow rapidly causing destruction of the entire phalanx.

Keratoacanthoma of the Mucosal Regions

Keratoacanthomas have been described in the oral mucosa, the conjunctiva, the nasal mucosa, and the genital mucosa. In fact, involvement of the oral and genital mucosa is common in the generalized eruptive keratoacanthomas of the Grzybowski type. Keratoacanthomas arising on mucosal regions, especially on the oral mucosa, present clinically as slowly growing crateriform lesions that tend to persist for many months or years.

PATHOLOGY

The histopathologic diagnosis of keratoacanthoma rests mainly on the silhouette of the tumor as assessed at scanning magnification; inadequate specimens (i.e., punch biopsies, shave biopsies, curettage) do not allow a diagnosis and differentiation from squamous cell carcinoma. Two large studies on the histopathologic criteria for diagnosis of keratoacanthoma emphasized the overlapping features between this tumor and squamous cell carcinoma, which render differentiation very difficult or even impossible in given cases.[16,17]

The histopathologic features of keratoacanthoma depend on the stage of evolution of the tumor. In early, proliferative lesions, the epithelium is markedly hyperplastic, and the central keratotic plug is not as pronounced as in fully developed lesions. The lesion has an overall symmetric aspect (see eFig. 117-5.2 in on-line edition). Although atypical cells do not represent the majority of the cells in typical keratoacanthoma, there may be atypical keratinocytes and mitoses, especially at the lower margin of the tumor. Nests of epithelial cells may detach from the main tumor mass and be found in the superficial reticular dermis. Fully developed, mature lesions are characterized by a large central core of keratin surrounded by a well-differentiated proliferation of squamous epithelium that in some cases may resemble squamous cell carcinoma (Fig. 117-6A). The epidermis at both sides of the central core extends over the keratotic area in a fashion that has been described as "lipping" or "buttressing," giving a distinct crateriform appearance to the lesion. Nests and strands of keratinocytes may be found apart from the main bulk of the tumor but usually do not extend lower than the level of sweat glands (Box 117-2).

Cytomorphologically, large keratinocytes with eosinophilic cytoplasm are commonly observed, together with atypical cells and mitoses (see Figure 117-6B). An inflammatory infiltrate containing lymphocytes, plasma cells, histiocytes, eosinophils, and neutrophils is a common feature, and in some instances may be conspicuous. Neurotropism and even vascular invasion can be observed in otherwise typical keratoacanthomas, but the prognosis does not seem to be affected by these histopathologically worrisome features (see Fig. 117-6C).[14]

PROGNOSIS

Solitary keratoacanthoma behaves as a benign tumor in the majority of the cases, but lymph node and visceral metastases have been observed in a small number of patients. Central facial keratoacanthoma may behave aggressively. There are no clear-cut features to predict the biologic behavior of a given tumor, but persistent and recurrent lesions should be managed by complete surgical excision. Histopathologic features that are associated with a poor prognosis in common squamous cell carcinoma, such as neurotropism and vascular invasion,

Box 117-2

Histopathologic Differential Diagnosis of Keratoacanthoma

Most Likely

- Squamous cell carcinoma

Regressing Tumors: Consider

- Other regressing epithelial tumors
- Regressing lesions of lymphomatoid papulosis
- Regressing lesions of anaplastic large cell lymphoma

do not seem to have prognostic implications in keratoacanthomas.[14] Ungual keratoacanthomas do not show a tendency to spontaneous regression and often are the cause of massive bone destruction.[60] In spite of aggressive local behavior, however, distant metastases have not been observed in ungual and mucosal types of keratoacanthoma.

TREATMENT (Box 117-3)

Keratoacanthomas show a tendency to spontaneous regression, and, in typical cases, an acceptable therapeutic option may be to adopt the so-called watchful waiting strategy. However, because of the uncertainty regarding the exact nosology of this tumor, as well as the difficulty to differentiate it clinically from squamous cell carcinoma, complete conservative excision is advised in most cases, especially in those of solitary keratoacanthoma and in keratoacanthoma of the face. Removal by shave excision below the base to preserve architecture for diagnostic purposes followed by electrodesiccation and curettage are being increasingly performed for keratoacanthoma.[62] Punch biopsies never allow differentiation of keratoacanthoma from well-differentiated squamous cell carcinoma and should be avoided. For diagnostic purposes, a longitudinal biopsy that includes normal skin at both margins of the lesion as well as the underlying fat tissues is acceptable. Mohs micrographic surgery has been adopted for difficult cases such as recurrent lesions, lesions in the central facial area, giant lesions, or lesions of keratoacanthoma centrifugum marginatum that may cover a large area of the body.[61] Therapy by laser vaporization, electrodesiccation, and cryosurgery with liquid nitrogen does not allow the histopathologic verification of the clinical diagnosis.

Keratoacanthomas have been treated by radiotherapy (electron beam, or the voltage radiation, superficial x-ray) with excellent results.[63] This type of treatment is particularly indicated for lesions that can be difficult to manage surgically. Intralesional instillation of chemotherapeutic agent (methotrexate, bleomycin, and 5-fluorouracil) has also proved therapeutically successful,[38,64] and 5-fluorouracil has been applied also topically.[65] Some keratoacanthomas have been treated by intralesional injection of interferon-α 2a,[66,67] and others have been successfully treated with intralesional application of triamcinolone. Successful topical treatment has been performed with podophyllin, either alone or in combination with other treatment modalities. However, podophyllin is also capable of inducing keratoacanthomas. Multiple keratoacanthomas have been treated successfully with oral retinoids in several cases, but larger studies have not been performed.[68] Systemic treatments include chemotherapy with methotrexate, cyclophosphamide, or 5-fluorouracil.

A further treatment option for keratoacanthoma of both solitary and multiple types is represented by photodynamic therapy with δ-aminolevulinic acid (see Chap. 239). The treatment is simple and has been shown to achieve good therapeutic and cosmetic results.[69,70] Topical imiquimod has been reported to induce regression of keratoacanthoma.[71]

Box 117-3

Treatment for Keratoacanthoma

FIRST LINE

- Complete surgical excision

SECOND LINE

- Curettage followed by electrodesiccation
- Radiotherapy
- Intralesional chemotherapeutic agents, intralesional interferon
- Oral retinoids
- Photodynamic therapy

Specific types of keratoacanthomas may require other treatment modalities (e.g., generalized eruptive keratoacanthomas of Grzybowski)

PREVENTION

Preventive measures against the development of keratoacanthomas are similar to those applied for basal and squamous cell carcinoma of the skin. In predisposed subjects (i.e., fair skin, history of multiple actinic keratoses, basal and/or squamous cell carcinomas, Muir-Torre syndrome), avoidance of direct sun exposure should be achieved, and skin protection creams applied.

Benign epithelial tumors comprise a large and disparate group of tumors commonly seen by dermatologists and primary care physicians. No single classification system unifies these lesions under one theme, as their cells of origin and clinical presentation can vary substantially. In this chapter, the clinical entities are grouped by clinical or histologic features to better understand them from a practical diagnostic and treatment point of view (Table 118-1).

SEBORRHEIC KERATOSIS

Etiology

The precise etiology of seborrheic keratoses (SKs) is unknown. Genetics, sun exposure, and infection have all been implicated as possible factors. Many individuals with SKs have a positive family history for the condition. SKs demonstrate irregularities in the expression of the apoptosis markers p53 and Bcl-2, though no genetic locus or chromosomal imbalance has been detected to date.[1,2] The higher prevalence of SKs on sun-exposed skin implies a possible causative role.[3]

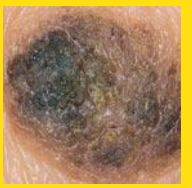
Viral infection has also been considered a possible cause of SKs based on occasional clinical similarities to warts. Although no human papillomavirus (HPV) DNA was detected in a study of 40 genital SK biopsies, non-genital skin yielded different results. Epidermodysplasia verruciformis-associated HPV DNA has been demonstrated in 42 of 55 (76 percent) non-genital SK biopsies compared to only 13 of 48 (27 percent) healthy controls ($p < 0.005$).[4] These findings indicate the possible role of viral infection in the development of SKs in non-genital skin.

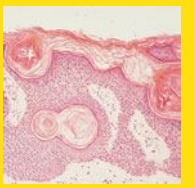
Although the etiology of SKs remains unknown, the monoclonal nature of these neoplasms has been established in 2001.[5] By tracking polymorphisms in a human androgen receptor, researchers found that more than half of the 38 SKs sampled, regardless of subtype, were clonal in nature.[5] The development of SKs has also been associated with circulating epidermal growth factors and melanocyte-derived growth factors in addition to the local increased expression of tumor necrosis factor-α and endothelin-converting enzyme.[6] The latter two are associated with an increased expression of the keratinocyte melanogen, endothelin-1, resulting in hyperpigmentation within SKs.

Epidemiology and Clinical Features

SKs are the most common benign epidermal tumor of the skin and a frequent focus of patient concern because of their variable appearance. These lesions are common in middle-aged individuals and can arise as early as adolescence.[7] Although there are many clinical variants of the lesions, these lesions usually begin as well-circumscribed, dull, flat, tan, or brown patches. As they grow, they become more papular, taking on a waxy, verrucous, or "stuck-on" appearance (Figs. 118-1 and 118-2). Many lesions display distinctive pseudohorn cysts that represent plugged follicular orifices. SKs may arise on any non-mucosal surface, and multiple lesions may be distributed in a "Christmas tree" pattern along skin folds or in Blaschko's lines.[8] The color of these lesions ranges from pale white to black. At times, distinguishing these lesions from a nevus or melanoma can be clinically challenging. Because melanoma, basal cell carcinoma, and other cutaneous malignancies have been reported to arise in SKs, care must be taken to critically evaluate

SEBORRHEIC KERATOSES AT A GLANCE





- Seborrheic keratosis is the most common benign epidermal tumor.
- Usually begin as well-circumscribed, dull, flat, tan, or brown patches with pseudohorn cysts.
- Rapidly-growing, symptomatic, or atypical lesions should be biopsied to rule out malignancy such as basal cell carcinoma, squamous cell carcinoma, or melanoma.
- Clinical and histopathologic variants include the common seborrheic keratosis, reticulated seborrheic keratosis, stucco keratosis, clonal seborrheic keratosis, irritated seborrheic keratosis, seborrheic keratosis with squamous atypia, melanoacanthoma, and dermatosis papulosa nigra.
- Hallmark histopathologic findings: Acanthosis, papillomatosis, pseudohorn cysts, hyperkeratosis.
- Internal malignancy: Individuals can develop multiple, eruptive seborrheic keratoses (Leser-Trélat sign). Adenocarcinoma of the stomach is most common associated malignancy.

rapidly-growing, symptomatic, or unusual lesions.[9,10]

Clinicopathologic Variants

COMMON SEBORRHEIC KERATOSIS Common SK is classically a stuck-on, verrucous papule (see Figs. 118-1 and 118-2) with pseudohorn cysts (Fig. 118-3). Hyperkeratosis, acanthosis, and papillomatosis are hallmark pathologic findings. An increased number of melanocytes may also be present, giving lesions a tan or dark brown color. SKs are usually asymptomatic but may itch. Common SKs spare the palms, soles, and mucosa.

SKIN TAGS These rough, 1- to 2-mm, pedunculated papules are commonly located in areas of friction. The axilla, inframammary area, and neck are common locations where these papules commonly appear. Spontaneous regression can occur.

RETICULATED SEBORRHEIC KERATOSIS Reticulated SKs are also known as *adenoid SKs*. A solar lentigo usually precedes this often pigmented patch or papule. Histologically, there are small horn cysts suspended among interwoven strands of basophilic cells (Fig.118-4).[11]

STUCCO KERATOSIS Stucco keratoses are also described as *verrucous, serrated, hyperkeratotic,* and *digitate.* These lesions are commonly 1- to 3-mm, flat-topped, white to tan papules that adhere tightly to the skin on the lower legs (see eFig. 118-4.1 in on-line edition). No keratinocytic vacuolar changes or viral cytopathic changes are observed, thus distinguishing them from verruca plana.

CLONAL SEBORRHEIC KERATOSES Intraepithelial nests of basophilic keratinocytes of varying sizes with admixed melanocytes is the common histopathologic finding in clonal SKs (Fig. 118-5).

IRRITATED SEBORRHEIC KERATOSIS Irritated SKs represent SKs that have been mechanically or chemically irritated or are involved in immunologic responses. Although inciting trauma is occasionally associated with irritated SKs, spontaneous inflammation is common (Fig. 118-6). Histologically, the dermis underlying these lesions is filled with a dense inflammatory infiltrate predominantly of lymphocytes. This inflammation is occasionally lichenoid or neutrophil-rich. Swirled collections of eosinophilic keratinocytes can be seen in the epidermis.[12] Eczematous changes in or around the lesion, also known as *Meyerson phenomenon*, can also be seen.[13]

SEBORRHEIC KERATOSIS WITH SQUAMOUS ATYPIA Varying degrees of squamous atypia can be seen in SKs. Bowenoid transformation of benign SKs into squamous cell carcinoma in situ has also been documented. The development of basal or squamous cell carcinoma in a SK is rare.[14]

MELANOACANTHOMA Melanoacanthoma is also known as *pigmented SK*. This benign, slow-growing SK resembles melanoma and is located on the trunk, head, or neck of older individuals. The term *mel-*

▲ **FIGURE 118-5** Clonal seborrheic keratosis showing round nests of keratinocytes and some melanocytes.

anoacanthoma was introduced in 1960 to describe a pigmented lesion composed of nested melanocytes and keratinocytes.[15]

Dermatosis Papulosa Nigra. Dermatosis papulosa nigra are small dark brown to black papules that are commonly found on the face of individuals of Fitzpatrick skin phototype IV or greater. They are histologically identical to SKs, though clinically, these lesions resemble melanoacanthomas (Fig. 118-7).

Association with Skin Cancers. Lesions demonstrating the histology of both SKs and malignancies have been reported.[16,17] Although it is likely that most of these lesions represent collision tumors, malignant transformation of SKs into basal cell carcinomas, squamous cell carcinomas, and melanomas can occur. In a retrospective study of 813 lesions histologically diagnosed as SKs, 5.3 percent were associated with non-melanoma skin cancer. In this study, the most common malignancy was squamous cell carcinoma in situ, followed by basal cell carcinomas and invasive squamous cell carcinomas; no melanomas were observed.[17] Clinically atypical or rapidly growing SKs should be biopsied to rule out the possibility of malignancy.

LESER-TRÉLAT SIGN In the context of internal malignancy, individuals can develop multiple, eruptive SKs also known as the *Leser-Trélat sign*. Adenocarcinoma of the stomach is the most commonly associated malignancy,[18,19] though adenocarcinoma of the lung and colon have also been linked (see Chap. 154). Other diseases reported to occur with eruptive SKs are leukemia, lymphoma, lepromatous leprosy, human immunodeficiency virus infection, erythrodermic eczema, and melanoma.[20–23] Inflammation of eruptive SKs during chemotherapy, especially cytarabine, is known to occur (see Fig. 118-6).[24] The common presentation of eruptive SKs with acanthosis nigricans led many to speculate a common reactive mechanism.[25] Abnormal immune responses may also play a role in the development of this clinical sign.

▲ **FIGURE 118-6** Inflamed, irritated seborrheic keratoses occurring during cytarabine therapy. This is in the submammary region, and there are also pustules of *Candida* infection.

▲ **FIGURE 118-7** Dermatosis papulosa nigra.

Treatment

Symptomatic SKs or cosmetically undesirable lesions may require treatment. Destruction with cryotherapy, electrodesiccation followed by curettage, curettage followed by desiccation, or laser ablation have all been shown to be very effective. Reports of giant SKs measuring many centimeters have been treated successfully with either dermabrasion or topical fluorouracil.[26,27] Recurrence of the lesions may occur if destruction of the perimeter is not fully achieved. Common complications of these destructive measures include scarring, pigmentary alteration, incomplete removal, or recurrence. It is not uncommon to require multiple treatments to ensure the complete destruction of the initial lesion. Surgical excision of the lesion is also an accepted treatment modality, especially if the lesion is pedunculated and can be transected at its base. It is preferable to ensure that the method of removal of these benign lesions minimizes the risk of scarring.

The concern for malignant lesions appearing as SKs or possible collision lesions between a SK and a malignant lesion necessitates histopathologic examination before destruction or removal. Thus, for any lesion with a possibility of malignancy, removal must be done in a fashion to yield tissue for evaluation. Rapid growth, atypical morphologic features, unusual lesion location, or symptomatology should all be considered when evaluating SKs, and care should be taken not to destroy a lesion that begs further pathologic examination.

EPIDERMAL NEVUS

Epidermal nevus is a generalized term for hamartomatous proliferations of epithelium. Sub-types of this tumor differ according to the distribution of the lesions or the predominant histologic cell type: keratinocyte (verrucous epidermal nevus), sebaceous gland (nevus sebaceous), pilosebaceous unit (nevus comedonicus), eccrine gland (eccrine nevus), or apocrine gland (apocrine nevus). Table 118-2 provides a classification of one framework to discuss this large and diverse entity. Currently, there are six different epidermal nevus syndromes described: Proteus, congenital hemidysplasia with ichthyosiform nevus and limb defect syndrome, phakomatosis pigmentokera-

EPIDERMAL NEVUS AT A GLANCE

- Epidermal nevi are hamartomatous proliferations of the epithelium, including keratinocytes, sebocytes, pilosebaceous units, eccrine glands, or apocrine glands.
- Six different epidermal nevus syndromes: Epidermal nevi present with developmental abnormalities of the nervous, cardiovascular, urogenital, or skeletal systems.
- Linear configurations common on limbs following Blaschko's lines or in relaxed skin tension lines. Tend to appear between birth and adolescence.
- Epidermal nevus presenting with pruritus, erythema, scaling is likely a variant known as *inflammatory linear verrucous epidermal nevus*.
- Differential diagnosis: Lichen striatus, linear Darier disease, linear porokeratosis, linear lichen planus, linear psoriasis, verrucous stage of incontinentia pigmenti.

▲ **FIGURE 118-8** Verrucous epidermal nevus.

totica, sebaceous nevus, Becker's nevus, and nevus comedonicus.[28]

Epidemiology

Epidermal nevi occur in 1 in 1000 live births.[29] Eighty percent of lesions appear within the first year of life, with the majority of lesions appearing by age 14 years. There are rare reports of adult onset of epidermal nevi, with the oldest patient being a 60-year-old woman.[30] Such late-developing epidermal nevi probably represent lesions that have always been present sub-clinically, but recent growth resulted in clinical recognition.[31] There is an equal male–female prevalence, and most cases are sporadic. However, some familial cases have been documented.[32]

TABLE 118-2
Classification of Epidermal Nevi

Epidermal Nevus Variant	Predominant Structure	Morphology	Extent
Verrucous epidermal nevus	Surface epidermis	Verrucous	
Localized			Localized
Systematized			Widespread
Nevus unius lateris			Widespread unilateral
Ichthyosis hystrix			Widespread bilateral
Inflammatory linear verrucous epidermal nevus		Inflamed	Localized
Nevus sebaceous	Sebaceous glands	Yellow verrucous	Localized, rarely diffuse
Nevus comedonicus	Hair follicles	Grouped comedones	Localized, rarely diffuse
Eccrine nevus	Eccrine sweat glands	Nondescript papule	Localized
Apocrine nevus	Apocrine sweat glands	Nondescript papule	Localized
Becker's nevus	Surface epidermis Hair follicles, + smooth muscles, melanization	Pigmented, hairy	Localized
White sponge nevus	Mucosal epithelium	Gray-white plaque	Localized or diffuse

▲ **FIGURE 118-9** Verrucous epidermal nevus showing linear configuration.

Verrucous Epidermal Nevus

Verrucous epidermal nevus is also known as linear verrucous epidermal nevus or *linear epidermal nevus*.

CLINICAL FEATURES Verrucous epidermal nevi are characterized by localized or diffuse, closely set, skin-colored, brown, or gray-brown verrucous papules, which may coalesce to form well-demarcated papillomatous plaques (Fig. 118-8). Linear configurations are common on the limbs as is distribution in Blaschko's lines or in relaxed skin tension lines (Fig. 118-9).

Extensive distribution of a verrucous epidermal nevus is termed *systemized epidermal nevus*. Variants of this type of nevus include nevus unius lateris (Fig. 118-10), epidermal nevi distributed on one-half of the body; and ichthyosis hystrix, epidermal nevi distributed bilaterally. Commonly, systematized nevi take on a transverse configuration on the trunk and linear configuration on the limbs.

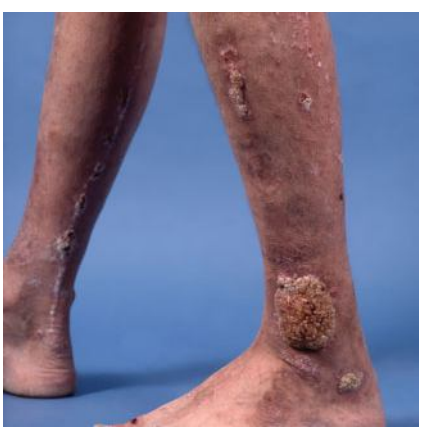
An epidermal nevus presenting with pruritus, erythema, and scaling is likely a variant of the epidermal nevus termed an *inflammatory linear verrucous epidermal nevus* (ILVEN) (Fig. 118-11). These lesions are found most commonly on the buttocks and lower extremities and may resemble linear psoriasis.

COURSE AND COMPLICATIONS Linear epidermal nevi tend to appear between birth and adolescence. Although congenital lesions tend not to expand significantly, lesions that present after birth

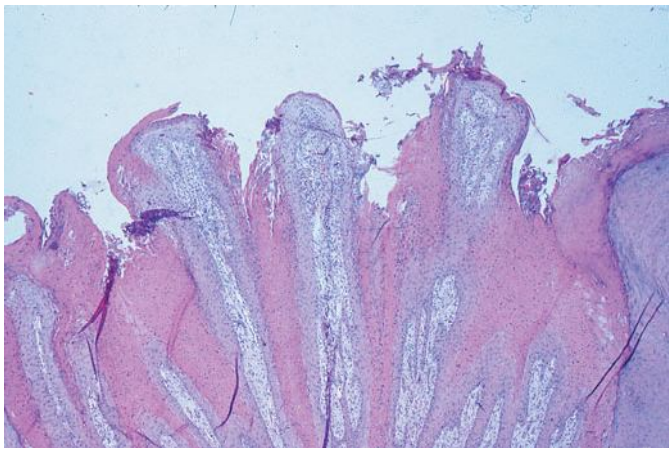
▲ **FIGURE 118-10** Nevus unius lateris. Epidermal nevus affecting one-half of body.

may expand during childhood, stabilizing in size at or around puberty.[33] Although intertriginous lesions may become macerated and secondarily infected, the majority of epidermal nevi remain quiescent after adolescence. Rare cases of basal cell carcinoma and squamous cell carcinoma arising within epidermal nevi has been reported. This malignant transformation is most common in middle-aged or elderly individuals, though the youngest reported case occurred in a 17-year-old woman.[34]

Epidermal nevi may present in conjunction with other epidermal lesions such as café-au-lait macules, congenital hypopigmented macules, and congenital nevocellular nevi.[33] Extensive lesions may be associated with abnormalities in other systems (see Epidermal Nevus Syndrome).



▲ **FIGURE 118-11** Inflammatory linear verrucous epidermal nevus showing psoriasiform erythema, scaling, and hyperkeratosis. The nodule on the left leg was a giant wart.



▲ **FIGURE 118-12** Epidermal nevus showing hyperkeratosis, acanthosis, papillomatosis, and elongation of rete ridges.

Rarely, patients with epidermal nevi have offspring with epidermolytic hyperkeratosis (EHK), a condition resulting from a mutation in keratin 10 (K10). Paller et al.[35] investigated three families with this occurrence. The analysis of skin samples of parents and offspring with EHK demonstrated a parental mutation in one of the two K10 alleles within the epidermal nevus; non-lesional skin showed no mutation. Offspring showed the same K10 mutation as their parents.[35] The presence of two genetically distinct cell lines in the parents, also known as *mosaicism*, is a result of postzygotic mutation during embryogenesis.[35a] If histopathologic evaluation of an epidermal nevus reveals findings consistent with EHK, the patient is at risk of having a child with EHK. Prenatal counseling may be very important for these patients.

PATHOLOGY There are 10 histologic variants of the epidermal nevus, with over 60 percent of lesions displaying acanthosis, papillomatosis, and hyperkeratosis (Fig. 118-12).[36] Rare variants may have features similar to SKs, with thin, elongated rete ridges; or EHK, with compact orthokeratosis, vacuolization of the granular layer of the epidermis, and large keratohyaline granules within or outside cells.[37] Epidermal hyperkeratosis may be a more common finding in ichthyosis hystrix. ILVEN is a histologically distinct variant of the epidermal nevus that displays a chronic dermal inflammatory infiltrate, psoriasiform epidermal hyperplasia, and alternating bands of ortho- and parakeratosis. In this variant, the granular layer is absent underlying the areas of parakeratosis.[38]

DIFFERENTIAL DIAGNOSIS (Box 118-1) Lichen striatus, linear Darier disease, linear porokeratosis, linear lichen planus, linear psoriasis, and the verrucous stage of incontinentia pigmenti may all have similar clinical presentations as the linear verrucous epidermal nevus. Lichen striatus may mimic ILVEN clinically, but is self-limited and pruritic as compared with epidermal nevi. Histology may be useful in differentiating these entities. Linear Darier disease and linear porokeratosis can be differentiated pathologically with linear Darier disease having the distinct pathologic findings of acantholytic dyskeratosis, and linear porokeratosis having coronoid lamellae. Although some consider linear lichen planus and linear psoriasis to be variants of the ILVEN, the genetics and the immunology has yet to be fully characterized.[39–41] Incontinentia pigmenti can be distinguished clinically based on the transient nature of this phase and the preceding verrucous phase. Histologically, this entity can be distinguished by its dyskeratosis, pigment incontinence, eosinophilic exocytosis, and basal layer vacuolization.

TREATMENT Complete excision of an epidermal nevus to the level of the deep dermis is necessary to prevent recurrences. Based on the size and distribution of the

Box 118-1

NEVUS SEBACEOUS AT A GLANCE

- Linear, hairless, yellow, waxy, and verrucous plaque presenting from birth to adolescence.
- Benign tumor of sebaceous gland: Immature sebaceous glands located high in the dermis and malformed pilosebaceous units are key features.
- Most common benign tumors arising within a nevus sebaceous: Syringocystadenoma papilliferum, trichoblastoma.
- Differential diagnosis: Epidermal nevi, aplasia cutis, congenital triangular alopecia.
- Rapidly growing papules or nodules: Require pathologic evaluation to rule out malignancy but excision should be considered on a case-by-case basis.

lesion, however, excision may not be an appropriate treatment option. Multiple other surgical and medical treatments are available to treat or destroy these lesions. Laser ablation, electrofulguration, cryotherapy, and medium to full-depth chemical peels may offer partial or full destruction of lesions. Although topical retinoids and calcipotriene offer little relief, these medications can be used as an adjunctive therapy to increase the efficacy of the surgical intervention. Systemic retinoids and anti-psoriatic agents may offer some clinical improvement. There are reports of successful treatment of ILVEN with etanercept.[42] If malignant transformation is confirmed within an epidermal nevus, the lesion should be completely excised.

Nevus Sebaceous

Nevus sebaceous is also known as *nevus sebaceous of Jadassohn* and *organoid nevus*.

CLINICAL FEATURES Nevus sebaceous presents as a linear, hairless, yellow, waxy, and verrucous plaque (Fig. 118-13). It can be flat at birth, becoming plaque-like under the hormonal influences of puberty. These nevi are common in the scalp, but there are reports of lesions on the face, chest, and in oral mucosa. Tumors can arise within nevus sebaceous. The most common benign tumors are syringocystadenoma papilliferum and trichoblastoma.[43] Other benign tumors reported to arise in a nevus sebaceous are the leiomyoma, syringoma, spiradenoma, hidradenoma, and keratoacanthoma.[44] It was once believed that individuals with this tumor were at increased risk of basal cell carcinomas, but a retrospective review of 596 cases by Cribier et al. revealed that most lesions initially diagnosed as basal cell carcinoma were actually trichoblastomas.[45] A second retrospective study of 757 tumors confirmed this finding.[46] This does not exclude the possibility of the development of basal cell carcinoma in these lesions. Rarely, malignant tumors such as apocrine carcinoma, squamous cell carcinoma, and malignant eccrine poromas may arise within nevus sebaceous.[47]

▲ **FIGURE 118-13** Nevus sebaceous.

Nevus sebaceous syndrome is the very rare association of an extensive, congenital nevus sebaceous with ocular abnormalities and cerebral defects such as mental retardation or seizures. This syndrome is also known as *Schimmelpenning-Feuerstein-Mims syndrome* or *organoid nevus syndrome*.[48,49]

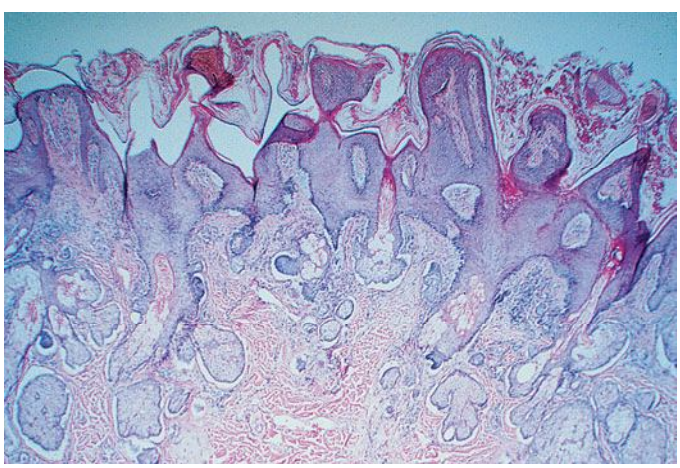
PATHOLOGY Immature sebaceous glands located high in the dermis and malformed pilosebaceous units are features of nevus sebaceous (Fig. 118-14). Vellus hairs are more common than terminal hairs in these lesions. Epidermal acanthosis, hyperkeratosis, and pseudoepitheliomatous hyperplasia can also be seen.

DIFFERENTIAL DIAGNOSIS Epidermal nevi, aplasia cutis, and congenital triangular alopecia may be clinically similar to nevus sebaceous but biopsy can easily distinguish between these entities.

TREATMENT Excision of nevus sebaceous was common when these lesions were thought to carry an increased risk of basal cell carcinoma. Rapidly growing papules or nodules demand pathologic evaluation to evaluate for rare malignancies, but excision should be considered on a case-by-case manner.[47]

Nevus Comedonicus

Nevus comedonicus is also known as *comedo nevus*, *nevus follicularis keratosis*, *nevus acneiformis unilateralis*, and *nevus zoniforme*.[50] Nevus comedonicus is a rare hamartoma of the pilosebaceous unit.[51,52] Clinically, comedo-like dilated pores with keratinaceous plugs present in a linear, nevoid, bilateral, or zosteriform pattern (Fig. 118-15).[51] An inflammatory variant also exists, with suppurative cysts and acne-like lesions. These lesions appear on the face, chest, or upper arms at birth or during childhood.[28] Nevus comedonicus syndrome is the association of nevus comedonicus with non-cutaneous findings such as



▲ **FIGURE 118-14** Nevus sebaceous showing epidermal hyperplasia and increased numbers of sebaceous glands and apocrine glands in the dermis.

NEVUS COMEDONICUS AT A GLANCE

- Presents as comedo-like dilated pores with keratinaceous plugs; linear, nevoid, bilateral, or zosteriform pattern.
- Nevus comedonicus syndrome: Association of nevus comedonicus with non-cutaneous findings such as skeletal defects, cerebral abnormalities, and cataracts.
- Hallmark findings: Keratin-filled epidermal invaginations associated with atrophic sebaceous glands or follicles.
- Differential diagnosis: Acne vulgaris, acne neonatorum, milia nevus sebaceous, linear Darier disease.
- Inflammatory variant can result in significant suppuration and pain, requiring medical or surgical intervention.

skeletal defects, cerebral abnormalities, and cataracts.[53]

COURSE AND COMPLICATIONS Nevus comedonicus lesions follow a noninflammatory or inflammatory course and do not resolve spontaneously. The inflammatory course may result in scarring. Nevus comedonicus syndrome results in developmental, cerebral, skeletal, or ocular defects that present by the age 15 years.[54]

PATHOLOGY The hallmark findings in nevus comedonicus are keratin-filled epidermal invaginations associated with atrophic sebaceous glands or follicles. EHK may be seen.[55]

▲ **FIGURE 118-15** Nevus comedonicus consisting of linear closely set comedones.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of this lesion includes acne vulgaris, milia, acne neonatorum, nevus sebaceous, and linear Darier disease.

TREATMENT The noninflammatory variant of nevus comedonicus is usually asymptomatic, with treatment based on the cosmetic concerns of the patient. The inflammatory variant can result in significant suppuration and pain, requiring medical or surgical intervention. Inflammation may be controlled with tazarotene cream or other retinoids, tacrolimus ointment, calcipotriene cream, and intralesional steroids.[56] Keratolytics may be of some help. Systemic antibiotics may help to control infection or inflammation. Surgical interventions, such as extraction, excision, dermabrasion, or laser resurfacing, may result in good clinical results.[57,58]

Eccrine Nevus

An eccrine nevus, the simplest form of eccrine hamartoma, is characterized by an increase in the number or size of eccrine coils.[59–62] These lesions do not always display hyperhidrosis, however. Fewer than 20 cases of eccrine nevi have been described in the literature. Commonly distributed on the trunk, arms, or legs, these lesions occur equally in men and women. Although there seems to be a childhood predominance, the onset ranges from birth to the eighth decade.[63] The morphology of eccrine nevi may vary, appearing clinically as tan papules or normal skin.[64,65] Treatment is targeted at the control of hyperhidrosis. Agents such as aluminum chloride solution, anticholinergics, antidepressants with anticholinergic activity, botulinum toxin, iontophoresis, or sympathectomy have been reported to help control the hyperhidrosis. Surgical excision of the lesion is also an acceptable treatment.[66,67]

Apocrine Nevus

Apocrine nevi are hamartomatous proliferations of mature apocrine glands often found within a nevus sebaceous. Clinical presentation varies, but they can be found as soft nodules or papules in the axilla or on the upper chest. Histologically, the apocrine glands extend from the epidermis to the fat. These lesions can be surgically excised if desired.[68]

EPIDERMAL NEVUS SYNDROME AT A GLANCE

- Epidermal nevus syndrome is the association of any type of epidermal nevus with various cutaneous, ocular, neurologic, skeletal, cardiovascular, or urogenital developmental abnormalities.
- Historically, six epidermal nevus syndromes described: Proteus syndrome, congenital hemidysplasia with ichthyosiform nevus and limb defects, phakomatosis pigmentokeratotica, sebaceous nevus, Becker's nevus, and nevus comedonicus.
- Affects men and women equally, and presents within the first 40 years of life.
- Patients with extensive epidermal nevi or those with epidermal nevi and systemic abnormalities should be suspected of having the epidermal nevus syndrome.
- Evaluation and management: Require multidisciplinary team approach involving the dermatologist, pediatrician, ophthalmologist, neurologist, plastic surgeon, and orthopedic services.

Epidermal Nevus Syndrome*

Epidermal nevus syndrome is also known as *Schimmelpenning syndrome*, *Feuerstein-Mims syndrome*, and *Solomon syndrome*. Epidermal nevus syndrome is the association of any type of epidermal nevus with various cutaneous, ocular, neurologic, skeletal, cardiovascular, or urogenital developmental abnormalities. Historically, there have been six epidermal nevus syndromes described: Proteus syndrome, congenital hemidysplasia with ichthyosiform nevus and limb defects, phakomatosis pigmentokeratotica, sebaceous nevus, Becker's nevus and nevus comedonicus. Some authors argue that epidermal nevus syndrome is a collection of many different distinct clinical syndromes.

*This follows the discussion of this syndrome by SG Silver and V Ho in *Dermatology in General Medicine* (6th edition).[58]

Happle[69] proposed that the epidermal nevus syndrome is not a single entity but consists of at least six distinct diseases that differ in genetic origin and share the common feature of mosaicism. The entities include Schimmelpenning syndrome; nevus comedonicus syndrome; pigmented hairy epidermal nevus syndrome; Proteus syndrome; congenital hemidysplasia, ichthyosiform dermatitis, and limb defects syndrome; and phacomatosis pigmentokeratotica.

EPIDEMIOLOGY Epidermal nevus syndrome affects men and women equally and presents within the first 40 years of life. Inheritance is sporadic, although anecdotal reports of familial transmission has been reported.[69] Although the exact incidence of epidermal nevus syndrome is unknown, a study of 119 cases of epidermal nevi showed that 33 percent of patients showed one or more extra-cutaneous abnormalities, 16 percent showed two or more abnormalities, 10 percent showed three or more abnormalities, and 5 percent showed five or more abnormalities.

CLINICAL FEATURES Solomon and Esterly provided a detailed account of the spectrum of epidermal nevi seen in the epidermal nevus syndrome.[29] They described seven types of lesions. The majority of patients had nevus unius lateris; 20 percent of patients had ichthyosis hystrix; and another 20 percent had what the authors termed the *acanthotic form* of epidermal nevus. These lesions presented as large, unilateral, brown, slightly scaly patches. About 10 percent of patients had linear nevus sebaceous involving the scalp and face. Localized linear verrucous nevus and a velvety epidermal nevus in the axilla similar to acanthosis nigricans were seen in a minority of cases. Some patients had a mixture of several types of lesions.

Table 118-3 lists the mucocutaneous changes other than epidermal nevus that may be seen in patients with epidermal nevus syndrome.[70] Hemangiomas and pigmentary changes are found in 10 percent to 20 percent of patients. Less common findings are hair abnormalities, dental abnormalities in association with mucosal epidermal nevi, and dermatomegaly. This last condition involves an increase in skin thickness, warmth, and hairiness. As discussed earlier, various cutaneous tumors may develop within the epidermal nevus.

A wide range of skeletal abnormalities has been reported (Table 118-4).[69–71] The incidence of skeletal changes has ranged from 15 percent to 70 percent.

Neurologic abnormalities occur in 15 percent to 50 percent of cases (Table 118-5).

From 9 percent to 30 percent of patients with epidermal nevus syndrome have ocular abnormalities (Table 118-6).[72]

As in isolated epidermal nevi, malignant transformation may occur within the epidermal nevi in patients with epidermal nevus syndrome. This occurrence is most common in those with nevus sebaceous. Perhaps less well known is the association of visceral malignancies with the epidermal nevus syndrome. The following tumors are reported to occur at a higher frequency and at an earlier age in patients with epidermal nevus syndrome: tumors of the genitourinary system (Wilms' tumor, nephroblastoma, metastatic transitional cell carcinoma of the bladder, and rhabdomyosarcoma of the bladder); tumors of the gastrointestinal tract (hepatic adenoma, salivary gland adenocarcinoma, and carcinoma of the esophagus and stomach); and tumors of the central nervous system (astrocytoma, mixed glioma, and meningioma). Breast carcinoma, mandibular ameloblastoma, chondroma, odontoma, and endometrioma are other tumors associated with epidermal nevus syndrome.[40] However, these associations have not been confirmed by case-controlled studies.

MANAGEMENT Patients with extensive epidermal nevi or those with epidermal nevi and systemic abnormalities should be suspected of having the epidermal nevus syndrome. Evaluation and management of patients with epidermal nevus syndrome requires a multi-disciplinary team approach involving the dermatologist, pediatrician, ophthalmologist, neurologist, plastic surgeon, and orthopedic services. These patients require a careful history with particular attention given to developmental history, attainment of

milestones, history of seizures, and abnormalities of the bones, eyes, and urinary tract. Thorough mucocutaneous, neurologic, ophthalmologic, and orthopedic examinations are necessary. Depending on the findings on history and physical examination, further investigations may be indicated. These may include biopsy of the epidermal nevus, electroencephalography, computed tomography, magnetic resonance imaging, intravenous pyelography, and radiographic evaluation of bones. A regular follow-up program should be planned for the patient.

LICHEN STRIATUS

Lichen striatus is a rare, idiopathic, linear, papular eruption that usually resolves in 1 to 2 years.

Etiology and Epidemiology

Lichen striatus, which is also known as *Blaschko linear acquired inflammatory skin eruption*, most commonly affects individuals from 4 months to 15 years of age.[73] The etiology is unknown. This self-limited dermatosis occurs most commonly on the limbs in females. Distribution on the face and trunk has been reported, however.[74] Nail changes are uncommon.[75] Most cases are distributed in Blaschko's lines, though axial distributions have been reported. A retrospective analysis of 155 cases of children with lichen striatus revealed an association with atopic dermatitis in 70 of the cases.[76]

Clinical Features[77]

Lichen striatus is an eruption characterized by the sudden onset of flat-topped, 1 to 3 mm, pink, tan, or hypopigmented papules in a linear configuration or Blaschkoid distribution (Fig. 118-16). Bilateral eruptions have been reported, though unilateral lesions are the norm. These flat-topped papules may have an associated scale. Longitudinal ridging and nail plate thinning can be seen. This eruption is usually self-limited, lasting from a few months to two years before spontaneously regressing.

Pathology

Lichen striatus is characterized by a lichenoid, lymphocytic infiltrate involving three to four adjacent dermal papillae with overlying epidermal acanthosis, dyskeratosis, hyperkeratosis, and occasional parakeratosis.[77,78] Intraepidermal vesicles containing Langerhans cells can be seen in half of the cases.[79]

LICHEN STRIATUS AT A GLANCE

- Lichen striatus is a rare, idiopathic, linear, papular eruption that usually resolves in 1 to 2 years.
- Occurs most commonly on the limbs of females.
- Eruption is characterized by the sudden onset of flat-topped, 1 to 3 mm, pink, tan, or hypopigmented papules in a linear configuration or Blaschkoid distribution.
- Differential diagnosis: Lichen planus, psoriasis, linear porokeratosis, lichen nitidus, Darier disease, inflammatory linear verrucous epidermal nevus.

Differential Diagnosis

Lichen planus, psoriasis, linear porokeratosis, lichen nitidus, Darier disease and ILVEN can have similar morphology and distribution to lichen striatus. These clinical entities can usually be separated based on histopathology. ILVEN can be distinguished clinically because of its earlier onset and lack of spontaneous regression.[79]

Treatment

Symptomatic control of pruritus with topical steroids may be necessary. Otherwise, treatment is generally not necessary for this self-limited condition.

▲ **FIGURE 118-16** Lichen striatus. Linear configuration of slightly scaling papules in Blaschkoid distribution on the leg.

CLEAR CELL ACANTHOMA

Epidemiology

Clear cell acanthoma is most commonly found equally in men and women ages in the sixth to eighth decade.

Etiology and Pathogenesis

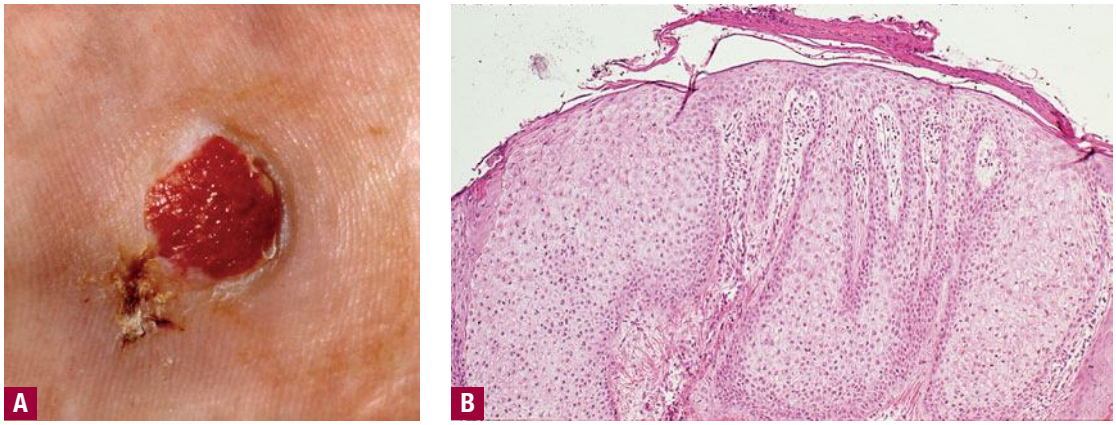
The etiology of clear cell acanthoma, also known as *Degos acanthoma* and *pale cell acanthoma*, is unknown. When initially described by Degos et al. in 1962, the lesion was thought to be benign tumor of epithelial origin.[80] Although initially thought to be of follicular or sweat-gland origin, the expression of involucrin and epithelial membrane antigen by clear cell acanthomas indicates an epithelial origin.[81–83] The cytokeratin staining patterns, interestingly, reveal staining patterns commonly found in inflammatory dermatoses such as lichen planus, psoriasis, and discoid lupus.[84] The presence of clear cell acanthomas on psoriatic plaques has led many to question the role of inflammation in the development of these lesions.[85]

Clinical Features

Clear cell acanthoma is commonly a solitary, shiny, erythematous to brown, well-demarcated papule or nodule that blanches almost fully with pressure (Fig.

CLEAR CELL ACANTHOMA AT A GLANCE

- Clear cell acanthoma is a tumor of epidermal origin.
- Solitary, shiny, erythematous or orange to brown, blanching, well-demarcated papule or nodule with collarette of scale.
- Composed of distinctive, glycogen-rich keratinocytes.
- Differential diagnosis: Lichenoid keratosis, basal cell carcinoma.



▲ **FIGURE 118-17** **A.** Clear cell acanthoma presenting as a flat orange nodule on the sole. **B.** Histologically, it is a well-circumscribed epidermal tumor composed of clear (glycogen-rich) cells.

118-17A). Surrounding the lesion is a collarette of scale. These lesions range from 5 mm to 2 cm, although the giant clear cell acanthoma can measure greater than 5 cm.[86] The lesions are usually found on the legs but can be located on the trunk and face. Although commonly solitary, multiple lesions have been reported. The dermatoscopic findings of the clear cell acanthoma is similar to that seen in psoriasis, with vascular puncta prominent in the lesion.[87] These lesions bleed with trauma.

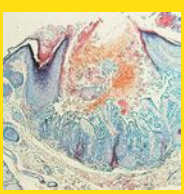
Pathology

Pale-staining keratinocytes within a background of epidermal psoriasiform hyperplasia is characteristic in clear cell acanthoma (see Fig. 118-17B). Other epidermal findings include suprapapillary plate thinning, neutrophils, and sparing of adnexal epidermis. A mixed inflammatory infiltrate, papillary dermal edema, and enlarged vessels can be seen in the dermis. The glycogen-rich keratinocytes in the epidermis stain distinctively with periodic acid-Schiff and periodic acid-Schiff with diastase.[88]

Treatment

Cryotherapy, curettage and electrodesiccation, laser ablation, or surgical excision have been used to successfully treat this lesion.[89]

WARTY DYSKERATOMA AT A GLANCE



- Solitary focus of acantholytic dyskeratosis
- Lesions: Solitary, skin-colored, umbilicated papules located on the head or neck
- Histology: Cup-shaped epidermal invagination with acantholysis and dyskeratosis filled with keratinaceous material
- Differential diagnosis: Actinic keratosis, squamous cell carcinoma
- Treatment: Excision

WARTY DYSKERATOMA (ISOLATED DYSKERATOSIS FOLLICULARIS)[90]

ACANTHOMA FISSURATUM

CYSTS OF EPIDERMAL ORIGIN

Epidermoid Cyst

An epidermoid cyst, also known as a *keratin cyst, epidermal cyst, epidermal inclusion cyst, sebaceous cyst,* or an *epithelial cyst,* is a keratin-filled epithelial-lined cyst.

EPIDEMIOLOGY Epidermoid cysts are found most commonly in adult men and women. Genetic disorders, such as Gorlin syndrome (nevoid basal cell carcinoma syndrome), pachonychia congenita type 2 (Jackson-Lawler type), and Gardner syndrome, may predispose individuals to having this type of cyst.

ETIOLOGY AND PATHOGENESIS Epidermal cysts are most commonly the result of plugged pilosebaceous units. These cysts express the same cytokeratin profile as the follicular infundibulum.[96] Epidermal cysts can also be caused by the traumatic implantation of epidermal cells into deeper tissues or by the proliferation of viable epidermal remnants along embryonic fusion planes.[97,98] Epidermoid cysts can be located anywhere on the body and are characterized by their distinctive pathology. Recently, HPV type 57 and 60 DNA has been detected in palmoplantar epidermoid cysts.[99,100]

CLINICAL PRESENTATION Epidermoid cysts are classically dermal or subcutaneous mobile nodules with a central punctum (Fig. 118-18). Lesions not associated with trauma are commonly located on the upper chest, upper back, neck, or head. Traumatic lesions are more common on the palms, soles, or buttocks. The punctum, when present, represents the plugged pilosebaceous unit from which cheesy debris may be expressed. These lesions can be skin-colored, yellow, or

ACANTHOMA FISSURATUM AT A GLANCE

- Fissured or ulcerated, usually retroauricular nodule that appears in areas of friction, as with ill-fitting eyeglasses
- Differential diagnosis: Basal cell carcinoma, squamous cell carcinoma, chondrodermatitis nodularis helicis
- Usually resolve after correction of ill-fitting appliance

CYSTS OF EPIDERMAL ORIGIN

AT A GLANCE

- Epidermoid cysts are a keratin-filled epithelial-lined cysts.
- Result most commonly from a plugged pilosebaceous unit.
- Classically dermal or subcutaneous mobile nodules with a central punctum.
- Brisk, foreign-body giant cell reaction is possible if epidermoid cysts rupture into surrounding tissue.
- Trichilemmal cysts are keratin-filled, epithelial-lined cysts usually on the scalp arising from outer root sheath of the hair follicle. These pilar cysts are mobile, firm, well-circumscribed nodules. Pathology: Cyst wall without a granular layer.
- Milia: Thought to be the result of pilosebaceous or eccrine sweat duct plugging.
- Pathology similar to epidermal cyst that is smaller in scale.
- Steatocystoma multiplex: Numerous, epithelial-lined, sebum-filled dermal cysts with characteristic sebaceous glands in the cyst walls.
- Dermoid cysts: Collections of epidermis located along embryologic fusion planes most commonly on the forehead, lateral eye, or neck.
- Branchial cysts: Asymptomatic cysts caused by the occlusion of branchial cleft sinuses that are located along the angle of the mandible if arising from the first branchial cleft and the middle to lower third of the anterior border of the sternocleidomastoid in cases arising from the second branchial cleft.
- Preauricular cysts or sinuses: Epithelial invaginations located in the preauricular area that arise from the incomplete fusion of the first and second branchial arches in the preauricular area.
- Rupture or secondary infection are the most common complications of epidermal cysts.
- Removal of the entire cyst wall is required to prevent cyst recurrence.

▲ **FIGURE 118-18** Epidermoid cyst presenting as a dome-shaped protuberance of the cheek.

white. Cysts are usually slow-growing and asymptomatic, though rupture is common.

COMPLICATIONS A brisk, foreign-body giant cell reaction is possible if epidermoid cysts rupture into surrounding tissue. This foreign-body reaction may mimic that of secondary bacterial infection. However, polymicrobial infection of a cyst with aerobic or anaerobic organisms may occur. Common aerobes include *Staphylococcus aureus*, group A *Streptococcus*, and *Escherichia coli*, while common aerobes include *Peptostreptococcus* species and *Bacteroides* species. Polymicrobial infection is most common. Although the clinical course of epidermoid cysts is benign, basal cell carcinoma, squamous cell carcinoma, epithelioid carcinoma, and other malignancies have been reported to occur in conjunction with these cysts, though malignant transformation is rare.[101–103]

PATHOLOGY An epidermoid cyst has a stratified, squamous lining with an intact granular layer (Fig. 118-19). These cysts contain central, eosinophilic, keratinaceous debris that can incite a foreign-body reaction of multinucleated giant cells and histiocytes when released into the dermis and surrounding tissue.

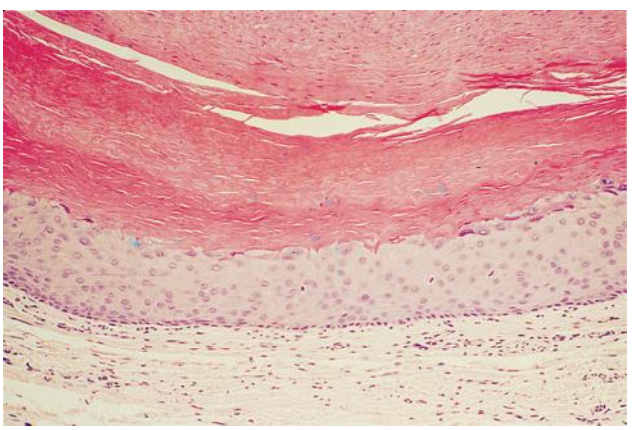
DIFFERENTIAL DIAGNOSIS Steatocystoma multiplex, pilar cysts, and lipomas can all mimic epidermoid cysts. Clinically, however, steatocystoma multiplex usually express a liquid rather than a cheesy material, pilar cysts are most commonly on the scalp, and lipomas are softer, deeper, and without a punctum. Pathology also distinguishes between these lesions.

TREATMENT Removal of the entire cyst wall is required to prevent cyst recurrence. Intralesional steroids at a concentration of 5 mg/mL can be used to control small, inflamed, symptomatic lesions. If the cyst becomes inflamed, painful, or purulent, infection must be considered. Incision and drainage with oral antibiotic therapy to treat *S. aureus* should be initiated. Wound cultures with directed therapy may be indicated, based on the clinical presentation of the lesion. Complete excision or destruction of the cyst lining is the definitive treatment. If the cyst has ruptured or has become infected, excision of the lesion should be deferred until the inflammation has decreased. This will decrease the likelihood of wound dehiscence.

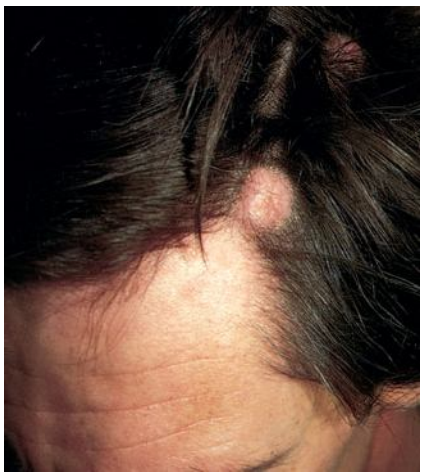
Trichilemmal Cyst (Pilar Cyst)

Trichilemmal cysts are keratin-filled, epithelial-lined cysts usually on the scalp that arise from the outer root sheath of the hair follicle.

EPIDEMIOLOGY Trichilemmal cysts can be found in 5 percent to 10 percent of the population, most commonly in middle-aged women.



▲ **FIGURE 118-19** Epidermoid cyst lined by stratified epithelium with a granular layer. Within the cyst, the keratinous material is arranged in laminated layers.



▲ **FIGURE 118-20** A trichilemmal (pilar) cyst on the scalp.

ETIOLOGY AND PATHOGENESIS Pilar cysts arise from the epithelium located between the orifice of the sebaceous gland and the arrector pili muscle. This squamous epithelium undergoes rapid keratinization resulting in a cyst wall without a granular layer.

CLINICAL FEATURES Pilar cysts are mobile, firm, well-circumscribed nodules located overwhelmingly in the scalp (Fig. 118-20). These lesions can also be found on the face, head, and neck. Most patients have more than one lesion, with 10 percent of people having more than 10 lesions. Rapid growth is abnormal and can be a sign of infection or malignant transformation.[104]

COMPLICATIONS Although these lesions largely remain asymptomatic, rupture and infection can occur. Proliferating trichilemmal tumors are a variant of this benign lesion and are commonly found on the scalp of elderly women. This lesion can destroy adjacent lesions and ulcerate, mimicking skin cancer. Malignant degeneration of pilar cysts into malignant proliferating trichilemmal cysts can occasionally occur.

PATHOLOGY The hallmark finding of these cysts is the absence of a granular layer within the cyst wall (Fig. 118-21). The cyst content is usually eosinophilic keratin, but basophilic areas of calcification may occur in the lumen of these lesions. If lobules of squamous epithelium are seen in the walls of the lesion, it is most likely a proliferating trichilemmal cyst. Invasion of the cyst lining into the surrounding tumor indicates malignancy.

DIFFERENTIAL DIAGNOSIS See Differential Diagnosis under Epidermoid Cyst.

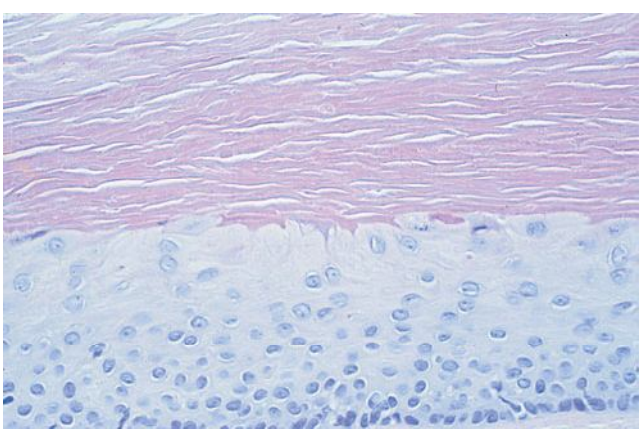
TREATMENT The treatment is the same as with epidermoid cysts. Because the cyst wall of these tumors is clinically more firm than that of epidermoid cysts, it is possible to extract the lesion through a small incision made with a dermal punch trephine.

Milium

Milia are minute epidermoid cysts, lined with epidermis and filled with keratin.

Epidemiology. Milia are common congenital and acquired lesions in both infants and adults. Men and women are affected equally.

ETIOLOGY AND PATHOGENESIS Milia are thought to result from pilosebaceous or eccrine sweat duct plugging. These superficial lesions can be primary or secondary, with the latter resulting from injury to the skin. Secondary lesions are common in sub-epidermal blistering diseases such as epidermolysis bullosa and porphyria cutanea tarda, burns, after dermabrasion or ablative laser resurfacing, or in conjunction with topical therapy such as glucocorticoid therapy or 5-fluorouracil treatment.[105–108]



▲ **FIGURE 118-21** Trichilemmal cysts showing an epithelial lining that lacks a granular layer.

▲ **FIGURE 118-22** Primary milium. A 3-mm, hard, seed-like white papule.

CLINICAL FEATURES Milia are 1- to 2-mm, white, domed papules commonly located on the cheeks and eyelids of adults (Fig. 118-22). In infants, milia are common on the face and the mucosa. Epstein's pearls are milia on the palate. Eruptive milia have been reported, though this is a rare occurrence.[108] *Milia en plaque* is a plaque-type, inflammatory variant of milia that is commonly located on the ear.[109] Acquired milia (see eFig. 118-22.1 in on-line edition) can be located anywhere the predisposing trauma or other factors have occurred.

PATHOLOGY The pathology of a milium is similar to that of an epidermoid cyst, but the small size and occasional connection to eccrine ducts or vellus hair follicles distinguish these two entities. Bacteria are not usually seen in milia.

TREATMENT Congenital milia tend to spontaneously resolve. Acquired milia can resolve spontaneously as well, but can also be removed by disrupting the overlying epidermis with light electrodesiccation or an 11-blade and expressing the keratin contents.

Steatocystoma Multiplex

Steatocystoma multiplex are numerous, epithelial-lined, sebum-filled dermal cysts with characteristic sebaceous glands in the cyst walls.

ETIOLOGY AND PATHOGENESIS Steatocystoma multiplex, (sebocystomatosis, epidermal polycystic disease) can be a sporadic or autosomal-dominant disorder. These lesions can also be found in syn-

▲ **FIGURE 118-23** Steatocystoma multiplex. Multiple skin-colored cystic lesions on the trunk.

dromes such as Alagille syndrome and pachyonychia congenita type II (see Chap. 48). In the latter, lesions are associated with mutations in K17. Sporadic solitary lesions are termed *steatocystoma simplex*.

CLINICAL FEATURES These lesions present as asymptomatic, yellow or skin-colored dermal papules or cysts located most commonly on the trunk, upper arms, scrotum, or chest (Fig. 118-23). Oily material can be expressed from these lesions when incised. These lesions can become infected and suppurate, resulting in sinus formation and scarring.

PATHOLOGY The cyst walls of steatocystoma multiplex are composed of stratified, squamous epithelium with an absent granular layer. Sebaceous glands are located in the cyst wall (see eFig. 118-23.1 in on-line edition). There is an eosinophilic cuticle on the luminal side of this wall with keratin, oil, and hairs in the lumen.

DIFFERENTIAL DIAGNOSIS Eruptive vellus hair cysts can mimic steatocystoma multiplex clinically. They may have a tuft of hairs protruding from the cyst centrally, with findings of vellus hairs in the lumen with follicles in the wall. Epidermal inclusion cysts also have to be excluded. The pathogenesis of steatocystoma, epidermal inclusion cysts, and eruptive vellus hair cysts may be similar.[110]

TREATMENT Removal of these lesions can be successfully achieved with simple excision or drainage of the cyst with manual removal of the cyst wall which, at times, results in the clinical resolution of lesions.[111,112] Inflamed lesions have been reported to respond to intralesional steroids, carbon dioxide laser, oral retinoids, or cryotherapy.[113]

Dermoid Cyst

Dermoid cysts are epithelial-lined cysts containing various appendageal structures resulting from retained epithelium along embryonic fusion planes. These cysts are either congenital or develop in childhood. The prevalence is equal in men and women.

CLINICAL FEATURES Dermoid cysts are smooth, occur in the midline, and commonly possess a deep sinus tract that connects to the epidermis. They can measure between 1 cm and 4 cm, and are most commonly located on the forehead, lateral eye, or neck.[114,115] A superficial dermoid cyst located on the dorsal nose is referred to as *fistula of the dorsum of the nose* and is characterized by a central tuft of hair or communication intracranially. Dermoid cysts can be located deep in the subcutaneous tissue, intracranially, or intraorbitally.[116]

COMPLICATIONS Infections, rupture, and abscess formation from the manipulation of these cysts are possible serious complications.

PATHOLOGY Stratified squamous epithelium with a variety of adnexal structures may be present in the walls of dermoid cysts. Smooth muscle, pilosebaceous units, apocrine or eccrine glands, or goblet cells may also be present in the cyst walls. These cysts contain keratin and hairs.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of dermoid cysts includes gliomas, encephaloceles, hemangiomas, soft tissue sarcomas, and other epidermal cysts such as branchial cleft cysts and thyroglossal duct cysts.

TREATMENT Imaging studies that help to characterize the extent of the tumor are necessary before excision is undertaken. Consultation with neurosurgery, otolaryngology, or plastic surgery may be indicated.

Branchial Cyst (Branchial Cleft Cyst)

Sequestration of first or second branchial cleft membranes results in these cysts, sinuses, or tags.

EPIDEMIOLOGY Branchial cleft cysts are largely sporadic, but autosomal dominant cases have been reported. There is no gender predominance. Ten percent of lesions are bilateral.

ETIOLOGY AND PATHOGENESIS These cysts result from the occlusion of branchial cleft sinuses.

CLINICAL FEATURES These asymptomatic lesions are located along the angle of the mandible if arising from the first branchial cleft and the middle to lower third of the anterior border of the sternocleidomastoid in cases arising from the second branchial cleft. They may present after an upper respiratory infection as a painful mass. These lesions tend to drain internally, but communication with the epidermis can occur. Branchial cysts may become complicated by infection.

PATHOLOGY Branchial cleft cysts are lined with epithelium containing lymphoid follicles, mucous glands, or smooth muscle. A dense lymphocytic infiltrate may also be seen. The cyst contents contain mucin.

TREATMENT Excision is the treatment of choice. Infected cysts may require incision and drainage or antibiotic therapy.

Preauricular Cyst and Sinus (Congenital Auricular Fistula, Ear Pits)

Preauricular cysts or sinuses are epithelial invaginations located in the preauricular area.

CHONDRODERMATITIS NODULARIS HELICIS

Clavus helicis CNH is a chronic, solitary, tender, ulcerated nodule on the helix of the ear, first described in 1915.[124]

Etiology and Pathogenesis

Many etiologic factors have been suggested for CNH. It is thought to be a disease of degenerated collagen that undergoes trans-epithelial elimination.[125] Vascular insufficiency, pressure, injury to the cartilage, sun-exposure, and low temperature have all been implicated in inciting cartilage damage. Recently, Magro et al. described 24 patients with early-onset CNH who had concomitant microvascular disease, strengthening the argument for the role of ischemia in the development of this process.[126] Re-

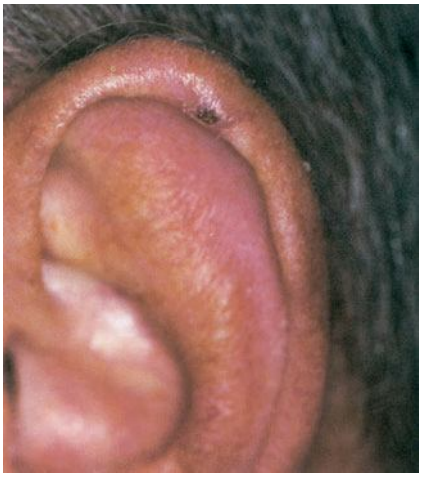
CHONDRODERMATITIS NODULARIS HELICIS

AT A GLANCE

- Chondrodermatitis nodularis helicis is a chronic, solitary, tender, nodule on the helix of the ear. Sometimes ulcerated.
- Thought to be a disease of degenerated collagen that undergoes transepithelial elimination.
- Often: History of a suddenly-appearing, skin-colored to pink papule or nodule on the ear that grew rapidly and subsequently remained quiescent.
- Differential diagnosis: Basal cell carcinoma, keratoacanthoma, wart, rheumatoid nodules, squamous cell carcinoma, clavus, tophus.
- Treatment: Conservative, includes pressure-relieving pillows with a "doughnut," steroid injection. If needed: Excision.

ports of CNH in association with the pressure from cell phone use has also been documented.[127] The finding of solar elastosis histologically at the periphery of many lesions along with the prevalence of CNH in lightly-pigmented populations raise the possible link between sun-exposure and CNH.[128]

CLINICAL FEATURES This disorder is found overwhelmingly in adult men over the age of 50, with the male-female prevalence being greater than 2:1.[129] Two cases of CNH in children have been reported.[130,131] Patients present with a history of a suddenly appearing, skin-colored to pink papule or nodule on the ear that grew rapidly and subsequently remained quiescent. These lesions tend



▲ **FIGURE 118-24** Painful nodule of the ear: a typical lesion of chondrodermatitis nodularis helicis.

to be on the right helix, measure less than 1 cm, and are associated with pain (Fig. 118-24). The pain can be paroxysmal or associated with changes in ambient temperature. The lesion may have a central ulceration with an adherent hemorrhagic or scale crust. Spontaneous resolution of CNH is unlikely. A possible subset of CNH may be seen in elderly women who have a history of prior trauma. For these women, spontaneous regression is not uncommon.

Differential Diagnosis

Basal cell carcinoma, keratoacanthoma, warts, rheumatoid nodules, squamous cell carcinoma, clavus, and tophus are all within the differential of CNH.

Pathology[132]

In the epidermis, there is commonly hyperkeratosis and parakeratosis; ulceration may be present. Occasionally, degenerated collagen is seen in the epidermis, indicating a trans-epidermal elimination process. A brisk, predominantly lymphocytic infiltrate is noted in the dermis with admixed histiocytes and few neutrophils. Telangiectasias and solar elastosis are often noted in the adjacent dermis. The perichondrium shows inflammation and fibrous thickening. The cartilage may show hyalinization, necrosis, and, at times, ossification.

Treatment

Conservative treatment includes pressure-relieving pillows with a "doughnut" shape that are commercially available. In a recent study examining the role of such pressure-relieving devices, 13 of 15 patients (87 percent) were healed at follow-up after 1 month of conservative treatment.[133] High-potency steroids, intralesional steroids, and laser ablation may also be used to induce symptom control or regression of the lesion.[134] Excision of CNH nodules using a shave or excisional technique through and around the affected cartilage is also an accepted treatment option, though recurrences may occur at the edge of the lesion.[135]

CHAPTER 119

Appendage Tumors and Hamartomas of the Skin

R. Stan Taylor
Jennifer B. Perone
Steven Kaddu
Helmut Kerl

GENERAL CONSIDERATIONS

Appendage tumors of the skin differentiate from epithelial components of normal (embryonal or mature) adnexal structures. During embryologic development, eccrine differentiation is independent of development of the hair follicle, apocrine system, and sebaceous glands (pilosebaceous units; Table 119-1).[1–6] Therefore, when considering appendageal tumors, differentiation from these adnexal units is used to classify the lesion.

Adnexal neoplasms may occur singly or multiply. Solitary lesions generally reveal no distinctive clinical features; however, site can be used as an aid in diagnosis. The anatomic distribution corresponds with the normal distribution of the adnexal structure from which the neoplasm differentiates. Appendage tumors arising as multiple lesions frequently display a characteristic distribution. They are often inherited in an autosomal dominant fashion and may be associated with other cutaneous and extra-cutaneous pathology.

Histopathology is the most important tool for diagnosis and classification of appendage skin tumors given the nondescript clinical appearance of many of these neoplasms. Assessment of architectural and cytomorphologic characteristics as well as determination of which normal adnexal structures the differentiation of the tumor most closely resembles are the cornerstones of microscopic evaluation.[1–6] On routine hematoxylin and eosin–stained sections, diagnostic criteria are apparent in the vast majority of cases, although the degree of involvement may vary greatly within the same tumor. A careful and adequate sampling of the specimen is therefore essential.

Immunohistologic analyses are occasionally necessary for interpretation of the tumors (Table 119-2). Interestingly, there is a significant overlap of immunohistologic features among tumors with ductal differentiation (apocrine and eccrine tumors) and certain visceral malignancies. Ultrastructural studies are of limited value in routine diagnosis of these tumors.

Cytogenetic and molecular studies have shed some light on the pathogenesis of several cutaneous appendage tumors. For instance, *p53* mutations have been detected in a number of neoplasms, suggesting an etiologic role for ultraviolet light exposure.[7] Mutation of the human homolog of *Drosophila patched* (*PTC*) gene has been shown to be the molecular defect in follicular appendage tumors arising in patients with nevoid basal cell carcinoma syndrome (Gorlin syndrome; see Chap. 116).[8] Germline mutations have consistently been reported in other familial syndromes, suggesting a role for these aberrations in pathogenesis. For example, mutations of *PTEN*, a tumor-suppressor gene, have been identified in tumors from patients with Cowden (multiple hamartoma) syndrome[9] (see Chap. 154). Microsatellite instability as well as mutations of the *hMSH2* and *hMLH1* mismatch repair genes have also been detected in neoplasms from patients with Muir-Torre syndrome[10] (see Chaps. 109 and 154).

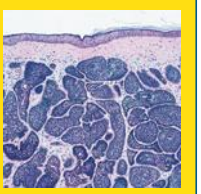
DIFFERENTIAL DIAGNOSIS

Differential diagnosis largely depends on the histologic findings. Ductal differentiation characterizes apocrine and eccrine tumors. Features of apocrine secretion (i.e., decapitation secretion) are seen in ductal structures of apocrine neoplasms, whereas ductal structures in eccrine tumors are lined by a flattened epithelium.[1] Follicular tumors show a range of morphologic features that recapitulate specific portions of normal hair and hair follicle[3] such as the infundibulum, isthmus, stem, and bulb (see Chap. 84). The finding of matrical cells reflects differentiation toward follicular bulbs. Trichohyalin granules and blue-gray corneocytes indicate differentiation toward the inner root sheath. Differentiation toward the outer root sheath is manifested by the presence of either clear columnar cells aligned in a palisade (outer root sheath differentiation at the bulb), subtly cornified cells with pink cytoplasm (outer root sheath differentiation at the stem), or fully cornified cells with red cytoplasm ("trichilemmal keratinization"), which corresponds to outer root sheath differentiation at the level of the isthmus.

Sebaceous tumors reveal areas with sebocytes (cells with vacuolated cytoplasm and scalloped nuclei) and tubular structures.[2] Some tumors may display one or more lines of differentiation, making even histopathologic diagnosis challenging at times.

Determination of whether an appendage neoplasm is benign or malignant requires assessment of architectural and cytomorphologic characteristics. Great care is necessary when applying traditional morphologic criteria of malignancy such as asymmetry, poor circumscription, and presence of epithelial aggregations with prominent atypia and mitotic activity. Some malignant and aggressive adnexal neoplasms [e.g., microcystic adnexal carcinoma (MAC)] show deceptively bland appearances. Furthermore, there are certain neoplasms whose malignant potential is not always predictable on morphologic grounds alone.

APPENDAGE TUMORS AT A GLANCE



- Differentiate from cutaneous adnexal structures into eccrine, apocrine, hair follicle unit, or sebaceous tumors.
- Clinical diagnosis is difficult, as most present as nodules. Anatomic location, presence of single or multiple lesions, knowledge of distribution of adnexal structures should be considered in development of a differential diagnosis.
- Risk of malignant degeneration varies with individual lesions.

CLASSIFICATION AND PATHOGENESIS

The number of current classifications of appendage tumors of the skin indicates how little consensus exists about their grouping and their etiology and pathogenesis.[1–6] There is also no unanimity among authors as to whether particular tumors are truly neoplasms, hyperplasias, or hamartomas. In this chapter, we categorize appendage tumors of the skin as cysts, hamartomas, hyperplasias, and benign or malignant neoplasms, and arrange them alphabetically (see Table

TABLE 119-1
Classification of Appendage Tumors of the Skin

Tumors with Apocrine Differentiation	Tumors with Eccrine Differentiation	Tumors with Follicular Differentiation	Tumors with Sebaceous Differentiation
Cysts	*Cysts*	*Cysts*	*Cysts*

• Syringocystadenocarcinoma papilliferum			

119-1). A cutaneous cyst is defined as an epithelium-lined, round, or oval sac-like lesion. The term *cutaneous hamartoma* refers to an embryologic malformation characterized by an abnormal arrangement of "normal" cutaneous tissues. Cutaneous hyperplasia represents an increase in the number of normal cells but with relatively normal arrangement. A benign neoplasm has no potential to metastasize. A malignant neoplasm possesses the potential for local destruction and metastasis.

TREATMENT

A diagnostic biopsy of a suspicious lesion yielding a correct diagnosis is usually the first step in appropriate management of patients with appendageal skin tumors. A number of tumor-related and patient-related factors influence the choice of treatment. Tumor-related factors include the type, size, and anatomic location. Patient-related factors include life expectancy, comorbid conditions, and cosmetic concerns.

Specific treatment of benign appendage tumors is sometimes unnecessary. In some cases, removal of the tumor is indicated for cosmetic reasons only. Treatment of choice for the majority of benign appendage tumors and relatively

TABLE 119-2

– = no reaction; ± = weak reaction; + = strong reaction.

non-aggressive, malignant appendage neoplasms is excisional surgery. A variety of superficial ablative techniques (electrodesiccation and curettage and cryotherapy) have proved to be effective in selected patients. A number of other alternative treatment options, including the use of systemic retinoids, lasers, and photodynamic therapy, have also been advocated for use in some cases; however, most do not have sufficient data for universal application.

Treatment of malignant appendage tumors aims mainly at eradication of the cancer, preservation or restoration of normal function, and cosmesis. High-risk patients with tumors known to have a high rate of recurrence or metastasis most frequently require wide excisional surgery, Mohs micrographic surgery, and/or radiotherapy. Notably, sentinel node biopsy is sometimes valuable in staging of patients with eccrine and apocrine carcinomas.[11]

APPENDAGE TUMORS WITH APOCRINE DIFFERENTIATION

Appendage tumors with ductal differentiation (sweat gland tumors) have traditionally been divided into apocrine and eccrine. However, over the years, it has become increasingly recognized that distinction between apocrine and eccrine is not always possible, as classic features of apocrine differentiation are sometimes observed in tumors traditionally categorized as eccrine.

Generally, the anatomic distribution of apocrine tumors reflects that of normal glands manufacturing apocrine secretion, which are confined to the head and neck, axillae, and genital or perianal skin. The vast majority of apocrine tumors are benign.[1] Malignant neoplasms show varied and diverse morphologic features and biologic potential.

Cysts: Hidrocystoma

EPIDEMIOLOGY Hidrocystoma (cystadenoma) is a relatively common cystic lesion presenting mostly in middle-aged or elderly individuals.

ETIOLOGY Hidrocystoma shows features of either apocrine (apocrine type) or eccrine (eccrine type) differentiation.

CLINICAL FINDINGS Hidrocystoma is a solitary, small- to medium-sized, skin-colored, reddish or bluish cystic nodule situated on the head or neck, especially in the periorbital region[1,4–6,12] (Fig. 119-1A). Unusual presentations include multiple lesions, giant tumors (up to 7 cm), and lesions occurring in childhood. Hidrocystoma occasionally develops within a nevus sebaceus (see Chap. 118). Multiple apocrine hidrocystomas on the upper and lower eyelid margins bilaterally may be a feature of a rare variant of ectodermal dysplasia (Schopf-Schulz-Passarge syndrome).[13]

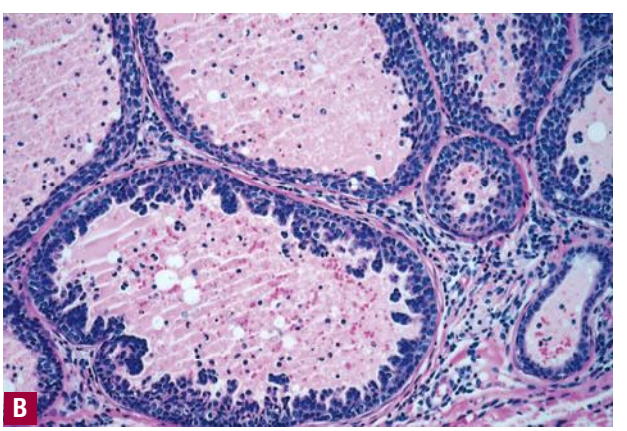
HISTOPATHOLOGY On histologic examination, there is a unilocular or occasionally a multilocular cyst located in the dermis. The epithelial lining displays either features of apocrine (decapitation secretion) or eccrine (single or double layered, cuboid often flattened epithelium) differentiation.[1] Prominent papillations protruding into the lumen are noted in a subset of cases (see Fig. 119-1B). Secretory products contain lipofuscin, melanin, and/or hemosiderin.

TREATMENT Treatment of choice in solitary lesions is simple surgical excision. Multiple lesions may be removed using a carbon dioxide or nonablative diode laser,[14] electrodesiccation, local infiltration of trichloroacetic acid,[15] or surgery with blepharoplasty.

Hamartomas

APOCRINE NEVUS ***Epidemiology.*** Apocrine nevus is a rare hamartoma that consists of proliferation of normal-appearing apocrine glands in the dermis.

Clinical Findings. Pure apocrine nevus presents as a unilateral or bilateral, soft, lobulated, dermal mass in the axilla or as a circumscribed area on the scalp.[1,4–6,12] Two variants are recognized: (1) a type occurring as a part of nevus sebaceus



◀ **FIGURE 119-1** Apocrine hidrocystoma. **A.** Reddish-brown to bluish cystic nodule. **B.** Multilocular tumor with papillary projections ("apocrine secretion").

and (2) an extremely rare type arising independently (pure apocrine nevus). Cases of apocrine nevus occurring as multiple, firm papules on the chest have been reported.[16]

Histopathology. Histologically, there are numerous, discrete, closely spaced tubular structures in the dermis and/or the subcutaneous fat. The tubules are lined by typical apocrine glandular epithelium and contain a homogeneous or vacuolated pink material (apocrine secretion). An apocrine nevus developing within a pre-existing nevus sebaceus usually arises in the deeper portion, sometimes in association with a syringocystadenoma papilliferum or trichoblastoma.[17]

SUPERNUMERARY NIPPLE ***Epidemiology.*** Lesions present mainly in young individuals.[1] Males and females are equally affected.

Etiology. Most cases are sporadic, but some lesions show a genetic transmission.

Clinical Findings. Supernumerary nipple is characterized by the presence of solitary or multiple rudimentary nipples developing along the embryonal milk line. They occur commonly as solitary, asymptomatic, soft, brown papules with a dimple, resembling dermatofibromas, fibromas, or melanocytic nevi. Less frequently, patients show supernumerary nipples with an appearance of an areola (polythelia areolaris), a patch of hair (polythelia pilosa), or a subcutaneous mass with or without areola. Rare cases present as a pedunculated or dermal mass in the axilla or vulva. Supernumerary nipples have also been reported in association with adenoma of the nipple (erosive adenomatosis)[1,18]; with renal abnormalities, including renal cell carcinoma; and with cardiovascular disorders, including congenital heart abnormalities.[19]

Histopathology. A dome-shaped lesion consisting of variable components of a normal nipple, including sebaceous lobules and ducts (Montgomery's tubercles). A rudimentary vellus follicle, various lactiferous ducts, dilated venules, and fascicles of smooth muscle can be observed.

Treatment. Treatment is by simple surgical excision if desired.

Hyperplasia: Fibroadenoma

EPIDEMIOLOGY Fibroadenoma is the most common cause of a breast mass in women younger than 25 years of age.

ETIOLOGY AND PATHOGENESIS The etiology is unknown, but the condition probably results from a proliferation of breast tissue in response to excessive circulating estradiol over progesterone.

CLINICAL FINDINGS Rarely, the tumor arises along the embryonic milk line or in other locations.[1,20] Lesions commonly present as single or multiple firm, rubbery, smooth, mobile, painless infiltrates ranging up to 2 cm in diameter that can be bilateral. A distinct juvenile type that arises in teenage females presents with large tumors measuring 15 to 20 cm that can grow rapidly, often leading to extensive stretching of the skin and distortion of the nipple.

HISTOPATHOLOGY Histopathologic examination reveals a variably hyalinized or mucinous, fibrous stroma surrounding a proliferation of ductal structures with apocrine secretion.

SPECIAL TESTS Routine mammography may reveal smaller lesions.

TREATMENT Treatment is complete local surgical excision. Conservative management has also been proposed.[20]

Benign Neoplasms: Adenoma of the Nipple

EPIDEMIOLOGY Peak incidence is in the fifth decade in women; however, the lesion may present at any age. Men are occasionally affected.

ETIOLOGY AND PATHOGENESIS Adenoma of the nipple (florid papillomatosis, erosive adenomatosis, papillary adenoma) is a rare, benign neoplasm currently thought to originate from terminal lactiferous ducts and subareolar breast tissue.

CLINICAL FINDINGS Patients sometimes complain of pain or an itchy, burning sensation within the lesion. Clinically, there is usually a unilateral enlargement and/or induration of the nipple that contains a palpable, firm, subareolar nodule.[1,5,6,12] The surface is occasionally erythematous, ulcerated, or crusted, and may ooze a serous, serosanguineous, or bloody discharge. Importantly, the overall clinical appearance is often indistinguishable from that of mammary Paget disease (see Chap. 121). Bilateral tumors have been reported. The lesion has also been observed to develop in association with a supernumerary nipple.[18]

HISTOPATHOLOGY An endophytic proliferation of tubular structures in the dermis with a verrucous or ulcerated surface is usually found. Some of the tubular structures exhibit cystic dilatations with discrete papillations. They are lined by an inner apocrine secretory epithelium and an outer myoepithelial layer and are separated by a fibrous stroma.

TREATMENT The treatment of choice is complete surgical excision. Persistence or recurrences are common. Mohs micrographic surgery may be beneficial for conservation of the nipple.[21] Cryosurgery may be useful in the treatment of some patients.

Hidradenoma Papilliferum

EPIDEMIOLOGY Hidradenoma papilliferum (papillary hidradenoma) is a relatively uncommon benign neoplasm in adult women.

CLINICAL FINDINGS This lesion usually occurs as a unilateral, small (up to 1 cm in diameter), asymptomatic, skin-colored nodule on anogenital skin.[1,4–6,12] There are, however, a few reports of similar neoplasms arising on the eyelid[22] and external auditory canal.

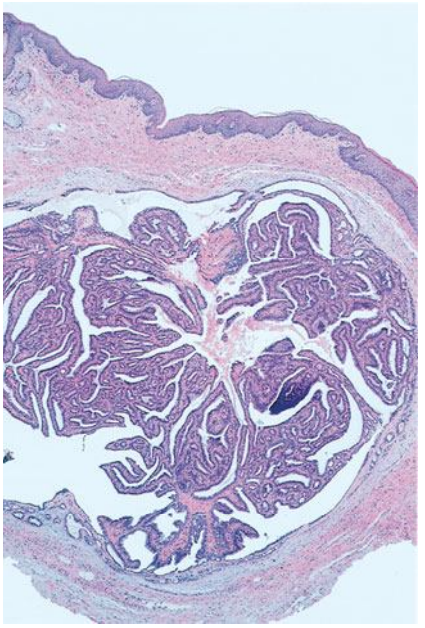
PROGNOSIS AND CLINICAL COURSE Malignant transformation has been reported. A fatal metastasizing squamous carcinoma arising in a hidradenoma papilliferum has also been reported.[23]

HISTOPATHOLOGY Histopathologic examination reveals a partly solid or solid-cystic lesion, usually without an epidermal connection. The tumor shows a complex pattern, with anastomosing papillary structures and tubules as well as some glandular areas (Fig. 119-2). The papillary structures are interconnected in a trabecular pattern. The epithelial lining consists of an inner layer of tall and columnar cells with eosinophilic cytoplasm and features of decapitation secretion. A thin, outer myoepithelial layer is frequently present, with a surrounding lymphoplasmacytic infiltrate.

TREATMENT Treatment is by simple surgical excision. In perianal tumors, consultation with a colorectal surgeon is advised to assure preservation of normal sphincter function.

Mixed Tumor of the Skin

EPIDEMIOLOGY Lesions are seen in middle-aged and elderly men.



▲ **FIGURE 119-2** Hidradenoma papilliferum. Cystic tumor with papillary and glandular areas.

ETIOLOGY AND PATHOGENESIS Mixed tumor of the skin (chondroid syringoma) is a group of adnexal neoplasms with ductal differentiation and a fibromyxochondroid stroma.[1,4–6,12] Apocrine or eccrine features predominate in individual cases.

CLINICAL FINDINGS Skin lesions present usually as solitary, firm, non-ulcerated, shiny, or waxy nodules measuring from 2 mm to several centimeters in diameter, situated on the head and neck[24] (Fig. 119-3A). Mixed tumors may occasionally develop on a variety of other anatomic sites, including genitalia.

HISTOPATHOLOGY There is a well-circumscribed dermal and/or subcutaneous lesion composed of elongated, partly ramifying tubular structures and/or complex solid nests as well as cords (see Fig. 119-3B). The epithelial component is typically embedded in an abundant stroma of spindled and stellate cells, mucin, and chondroid material. The apocrine type reveals, at least focally, small tubular lumina and cystic structures with apocrine secretion. A homogenous material is sometimes noted within the cystic cavities. Foci of polygonal, plasmacytoid, pale, and clear cells may be observed. Occasional cases display follicular and sebaceous differentiation, fat metaplasia, and/or collagenous spherulosis.[1,25] The eccrine type is characterized by tubulocystic spaces with cuboidal cell linings attached to solid elements, resembling the tadpole configuration seen in syringomas.

Notably, some mixed tumors reveal atypical histologic features, including an infiltrative margin, satellite tumor nodules, and tumor necrosis. These atypical histologic appearances do not generally correspond with aggressive potential.

PROGNOSIS AND CLINICAL COURSE To date, there are no convincing reports of malignant transformation of benign mixed tumor in the literature.[1,5]

TREATMENT Complete surgical excision is the treatment. Chondroid syringoma of salivary origin requires complete surgical excision.

Syringocystadenoma Papilliferum

EPIDEMIOLOGY Syringocystadenoma papilliferum occurs in adults.

ETIOLOGY AND PATHOGENESIS Most authors consider syringocystadenoma papilliferum to be a benign tumor,[5,6] whereas others categorize it as a hamartoma.[1] The lesion develops either independently or arises in association with a nevus sebaceus.[17] Syringocystadenocarcinoma papilliferum may develop from long-standing syringocystadenoma (see Syringocystadenocarcinoma Papilliferum).

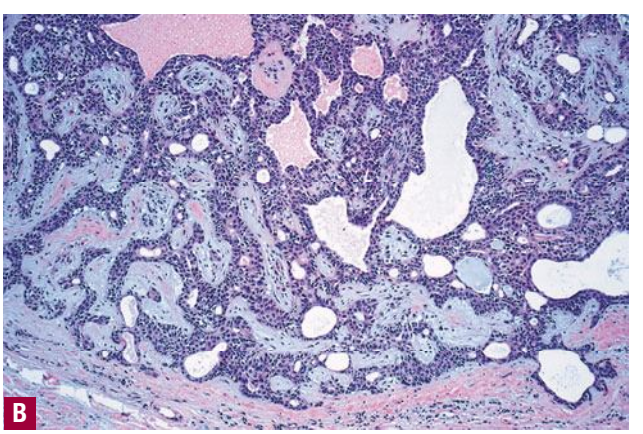
CLINICAL FINDINGS Solitary syringocystadenoma papilliferum occurs as a single, papillomatous, verrucous, sometimes erosive plaque or nodule measuring 1 to 3 cm in diameter, situated on the head and neck of adults[1,4–6,12] (Fig. 119-4A). A small fistula discharging a clear, bloody, or malodorous exudate may be noted. Less common presentations include childhood tumors, lesions located on unusual anatomic sites (e.g., trunk, upper arms, vulva, and thighs), and lesions arising as multiple or linearly arranged cutaneous nodules.

HISTOPATHOLOGY There is a crateriform epidermal invagination, with the upper portion lined by squamous epithelium and the lower portion lined by apocrine epithelium (see Fig. 119-4B). The surrounding epidermis usually reveals papillomatosis, hypergranulosis, and hyperkeratosis. Foci with variously sized papillations covered by a squamous epithelium are frequently observed within the epidermal invagination. In the dermis, cystic structures with villous projections exhibiting apocrine secretion may be present. The lesion is often surrounded by a variable lymphoplasmacytic infiltrate. Syringocystadenoma papilliferum arising in nevus sebaceus (see Chap. 118) sometimes co-exists with trichoblastomas or basal cell carcinoma and has been reported with verrucous carcinoma.[17,26]

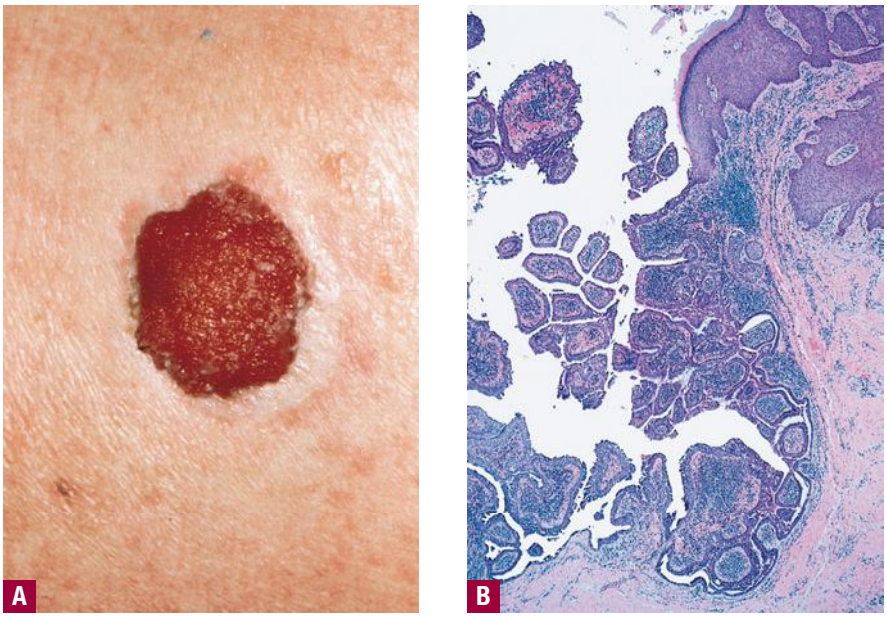
TREATMENT Treatment of choice is surgical excision. Carbon dioxide laser may be effective in removing tumors on anatomic sites unfavorable to surgical excision.

Malignant Neoplasms

APOCRINE ADENOCARCINOMA ***Epidemiology.*** Apocrine adenocarcinoma (apocrine carcinoma) is a rare, poorly documented, aggressive adnexal neoplasm. Lesions present predominantly in adults.



◀ **FIGURE 119-3** Mixed tumor. **A.** Mixed tumor on the nose. **B.** Solid cords and tubular structures in a background of a fibromyxoid stroma.



▲ **FIGURE 119-4** Syringocystadenoma papilliferum. **A.** Erosive nodule on the forehead. **B.** Epidermal invagination with papilliferous projections.

Clinical Findings. Apocrine adenocarcinoma presents as either solitary or multiple nodules and plaques measuring 2 to 8 cm in diameter situated in the axilla or anogenital area.[1,4,12] Occasional cases may involve the fingers, nipples, eyelid, or chest. Lesions occasionally develop in association with nevus sebaceous (see Chap. 118), apocrine hamartoma, or extramammary Paget disease (see Chap. 121).[1,27] Eyelid apocrine adenocarcinoma tumors are considered to be derived from Moll's gland.[28]

Histopathology. Histopathologic examination reveals a dermal/subcutaneous non-encapsulated tumor with infiltrative margins. The epithelial component shows variable papillary, solid, or mixed patterns. Foci of partly anastomosing tubular structures exhibiting apocrine (decapitation) secretion and infiltrating cords of neoplastic cells can be observed, but not ubiquitously. Neoplastic cells display variable pleomorphism and mitotic activity, as well as abundant, sometimes granular or vacuolated, eosinophilic cytoplasm. Myoblastomatoid adenocarcinoma of the breast is a variant of apocrine adenocarcinoma with neoplastic cells with foamy, granular cytoplasm.[29] It is particularly important to differentiate apocrine adenocarcinoma from cutaneous metastases from other organs, especially from the breast.

Prognosis and Clinical Course. Apocrine adenocarcinoma (apocrine carcinoma) is aggressive. Regional lymph node metastases and fatal visceral metastases have been recorded.[30]

Treatment. Surgical excision with adequate margins should be performed.

DUCTAL CARCINOMA ***Epidemiology.*** Ductal carcinoma occurs in elderly patients, preferentially in men.[31]

Etiology and Pathogenesis. The term *ductal carcinoma* has been suggested to denote a rare type of malignant sweat gland carcinoma characterized by prominent, closely packed tubular structures with either apocrine or eccrine features.[1,31]

Clinical Findings. Tumors present usually as solitary, asymptomatic nodules in the axilla.[31] Occasional cases arise as multiple lesions or are situated on unusual sites, including face, scalp, sternal region, and nipple. Clinical presentation can mimic Paget disease.[32] Tumors developing within a pre-existing nevus sebaceus have been reported.[27]

Histopathology. There is a deep dermal and/or subcutaneous proliferation composed of numerous closely packed, tubular structures, sometimes with cystic and solid aggregations of neoplastic cells. The tubular and solid elements are composed of atypical neoplastic cells with abundant eosinophilic cytoplasm, hyperchromatic nuclei, and frequent mitotic figures. Features of apocrine or eccrine differentiation can be observed in individual cases.[1,31]

Prognosis and Clinical Course. Metastases, especially to regional lymph nodes, lungs, and to other organs, can develop. Recurrences are common.

Treatment. Treatment is by surgical excision with adequate margins.

EXTRAMAMMARY PAGET DISEASE See Chap. 121.

HIDRADENOCARCINOMA PAPILLIFERUM ***Epidemiology.*** Hidradenocarcinoma papilliferum is a rare appendage tumor presenting mainly in middle-aged women.

Etiology and Pathogenesis. This tumor most often arises from a pre-existing, usually long-standing, benign hidradenoma papilliferum.[1,33] It presents as a solitary, small, often ulcerated nodule in the anogenital region and, rarely, in the axilla. Most lesions are asymptomatic, but a few patients complain of slight pain or a brownish, watery discharge. Lesions have occasionally been observed in association with extramammary Paget disease.[34]

Histopathology. Histopathologically, unlike hidradenoma papilliferum, this malignant tumor often shows asymmetry and high cellularity. It consists of tubules and cystic cavities with features of apocrine differentiation surrounded by compressed fibrous stroma. Papillations with a central fibrovascular tissue core are noted projecting in the cyst cavities.

Prognosis and Clinical Course. Fatal metastases, often initially involving lymph nodes, have been recorded. Sentinel node biopsy may be valuable in staging of these patients.

Treatment. Local surgical excision is the treatment of choice.

MALIGNANT MIXED TUMOR ***Epidemiology.*** Malignant mixed tumor presents in middle-aged adults, most commonly in women.

Etiology. This malignant counterpart of benign mixed tumor appears mainly to develop de novo.[1,5,35]

Clinical Findings. Malignant mixed tumor shows predilection for the trunk and extremities,[1,5,36] anatomic sites not usually involved by benign mixed tumors. It appears as a solitary, occasionally painful, firm or cystic, non-ulcerated cutaneous or subcutaneous nodule measuring 2 to 10 cm in diameter.[1,4–6,12,36]

Histopathology. The tumor shows lobulated epithelial aggregations with tubular structures, cords, and solid elements. The epithelial component is surrounded by a fibrous stroma with myxomatous and cartilaginous areas. Neoplastic cells display polygonal, plasmacytoid, or cuboidal appearances with variable pleomorphism and scattered mitotic figures. Tubular structures show either apocrine or eccrine differentiation.

Treatment. Treatment of choice is total surgical excision. Local and distant metastases, especially to lymph nodes, are common. Prophylactic removal of regional lymph node chains and/or adjuvant radiotherapy may facilitate long-term survival.[5]

MUCINOUS CARCINOMA ***Epidemiology.*** Primary mucinous carcinoma of the skin (colloid, gelatinous, or adenocystic carcinoma) is a rare, low-grade carcinoma.

Etiology. This lesion bears close morphologic resemblance to mucinous carcinoma of the breast.

Clinical Findings. It presents as a solitary, slowly growing, soft to firm, grayish, reddish, or bluish smooth-surfaced nodule measuring up to 3 cm in diameter.[1,4–6,12,37] Lesions tend to occur in older adults (particularly men) on the head and, particularly, around the eyelids.[37] Scalp tumors may occur as a patch of alopecia.

Laboratory Tests. There are solid and cystic aggregations of neoplastic cells within the dermis, often with extension to the subcutis, embedded in large pools of mucin. Mucinous areas are typically separated by fibrous septae.

Prognosis and Clinical Course. Recurrences have been reported in about 28 percent of cases.[37] Metastases are rare and involve mostly regional lymph nodes.

Treatment. Treatment is by wide surgical excision.

SYRINGOCYSTADENOCARCINOMA PAPILLIFERUM ***Etiology.*** Syringocystadenocarcinoma papilliferum is a rare neoplasm that usually arises in a long-standing syringocystadenoma papilliferum and occasionally in a nevus sebaceus.[1,12,38,39]

Clinical Findings. The tumor preferentially involves the scalp of adult women. A few cases have been reported on the chest.

History. Patients may give a history of sudden enlargement of long-standing clusters of skin-colored or yellowish, sometimes ulcerated, papules or nodules.[39]

Histopathology. Syringocystadenocarcinoma papilliferum superficially resembles syringocystadenoma papilliferum on scanning magnification. However, the malignant tumor is characteristically asymmetric and poorly circumscribed, with extension deep into the subcutis. It consists mainly of papillations that project above the skin surface into cystic cavities. Cells are crowded and atypical, with numerous mitotic figures. Tubular structures with apocrine secretion are noted in some sections.

Prognosis and Clinical Course. The neoplasm occasionally gives rise to regional lymph node metastases.[39]

Treatment. Treatment of choice is surgical excision, but Mohs micrographic surgery has been used.[40]

APPENDAGE TUMORS WITH ECCRINE DIFFERENTIATION

Eccrine tumors show a wider anatomic distribution than do apocrine tumors.[41] This is due to the broader distribution of normal eccrine glands in virtually all topographic sites, in contrast to normal apocrine glands, which are confined to the head and neck, axillae, genital, and perineal skin.

Histopathologically, eccrine tumors comprise a large spectrum of lesions with differentiation to various portions of normal eccrine apparatus, including intraepidermal (acrosyringium), dermal, and secretory ducts.[41] There are no uniform criteria for diagnosis. The most important feature is the tendency to form lumina with a flattened epithelium. Distinction from apocrine tumors is not always straightforward, as the ducts of each gland type are similar and "decapitation" can be observed in certain tumors traditionally classified as "eccrine."

Cyst: Hidrocystoma

CLINICAL FINDINGS Eccrine hidrocystomas can be either solitary (Smith type) or multiple (Robinson type).[42] Clinically, they have a generic appearance as domed, skin colored, or translucent papules most commonly on periorbital skin. Multiple eccrine hidrocystomas have been associated with warm climates, hyperhidrosis, and Graves disease.[43]

HISTOPATHOLOGY The cyst lining is a double layer of cuboidal epithelium lacking decapitation secretion. Eosinophilic contents may be seen.

TREATMENT Treatment is similar to apocrine hidrocystoma. Use of topical atropine,[44] botulinum toxin,[45] and pulsed dye laser[46] has also been reported.

Hamartoma: Eccrine Hamartoma

EPIDEMIOLOGY Eccrine hamartoma occurs in children.

ETIOLOGY AND PATHOGENESIS The term *eccrine hamartoma* is employed for a number of conditions characterized by an increase in size and/or number of normal intradermal eccrine ducts and coils, including eccrine nevus, eccrine angiomatous hamartoma, and porokeratotic eccrine ostial and dermal duct nevus.[12,41] It may be congenital.

CLINICAL FINDINGS Eccrine nevus usually presents as a solitary, well-circumscribed area of hyperhidrosis on the extremities of children. A few cases occurring as linear papules and multiple plaques have been reported. Eccrine angiomatous hamartoma commonly shows a solitary, flesh-colored, hyperhidrotic, painful papule or plaque appearing at birth or during childhood.[47,48] A few cases arising as multiple, symmetrically located lesions have been reported. Porokeratotic eccrine ostial and dermal duct nevus typically presents as congenital keratotic papules and plaques located on the distal extremities. Lesions may show a linear arrangement.

HISTOPATHOLOGY There is an increase in size and/or number of normal eccrine ducts and coils in the dermis.

TREATMENT Most patients require no specific treatment. Surgical excision is indicated for painful eccrine angiomatous hamartomas. Successful treatment of eccrine nevus with botulinum toxin has been reported.[49] Carbon dioxide laser therapy has been employed in some cases of porokeratotic eccrine ostial and dermal duct nevus.[47]

Hyperplasias: Syringolymphoid Hyperplasia

EPIDEMIOLOGY Males are preferentially affected.

ETIOLOGY AND PATHOGENESIS Syringolymphoid hyperplasia is a chronic skin condi-

tion that may present either as an isolated lesion or in association with cutaneous T-cell lymphoma.[50]

CLINICAL FINDINGS Patients usually show patches of hairless, anhidrotic, reddish-brown papules with pseudofollicular hyperkeratosis.

HISTOPATHOLOGY Hyperplastic eccrine structures are surrounded by a dense lymphocytic infiltrate with "syringotropism." Lesions associated with mycosis fungoides occasionally reveal a perifollicular lymphocytic infiltrate and follicular mucinosis (see Chap. 146).

PROGNOSIS AND CLINICAL COURSE Careful follow-up with biopsy of persistent lesions is recommended in apparently idiopathic cases to exclude lymphoma.

Benign Neoplasms

CYLINDROMA ***Epidemiology.*** Women are more commonly affected than men.

Etiology. Multiple cylindromas are often familial and inherited as an autosomal dominant trait, mainly in the setting of Brooke-Spiegler syndrome (familial autosomal dominant cylindromatosis).

Clinical Findings. Two main clinical forms of cylindroma are recognized; namely, a common, solitary type and a less-frequent form showing multiple lesions. Solitary cylindromas occur as slowly growing, asymptomatic, or painful, skin-colored, reddish, or bluish papules, nodules, or tumors on the head and neck region of adults.[4–6,12,41]

Multiple cylindromas occur as numerous papules, nodules, or variously sized tumors distributed mostly on the scalp and sometimes on the face or trunk. They show a tendency to confluence and may cover the entire scalp (so-called *turban tumors*; Fig. 119-5A) or display a linear arrangement. Rarely, patients reveal widespread nodules, a clinical picture that mimics neurofibromatosis. Patients with Brooke-Spiegler syndrome show multiple cylindromas and trichoepitheliomas, occasionally in association with multiple basal cell adenomas of the parotid glands, milia, organoid nevi, basal cell carcinomas, and spiradenomas (see Spiradenoma). The susceptibility gene has been mapped to chromosome 16q12-q13 and has features of a recessive oncogene/tumor-suppressor gene.[51]

Histopathology. There is usually a well-circumscribed dermal and/or subcutaneous lesion composed of irregularly shaped tumor islands and cords of basaloid cells arranged in a jigsaw puzzle–like pattern (see Fig. 119-5B). Islands of basaloid cells are surrounded by a prominent rim of uniformly thickened periodic acid-Schiff (PAS)–positive basement membranes. They consist of two types of basaloid cells, namely, a central population with large nuclei and abundant cytoplasm and a peripheral population with smaller nuclei, arranged in a palisade at the periphery.

▲ **FIGURE 119-5** **A.** Cylindroma or turban tumor. **B.** Cylindroma with irregularly shaped aggregations of basaloid cells arranged in a "jigsaw puzzle" pattern.

Treatment. Cylindromas may recur if incompletely excised. Local aggressive behavior and malignant transformation has occasionally been observed, especially in long-standing turban tumors of the scalp.[52]

HIDRADENOMA ***Epidemiology.*** Hidradenoma (eccrine acrospiroma) presents mainly in adults, primarily in women.

Clinical Findings. Hidradenoma presents as a slowly growing, firm, solitary, smooth-surfaced, usually bluish-red, movable dermal and/or subcutaneous papule or nodule.[4–6,12,41] Lesions are located mostly on the scalp, face, trunk, and abdomen, and, occasionally, on the extremities (Fig. 119-6A). Unusual presentations include childhood neoplasms, large or rapidly growing lesions,[53] painful and/or ulcerated lesions, as well as pedunculated tumors.

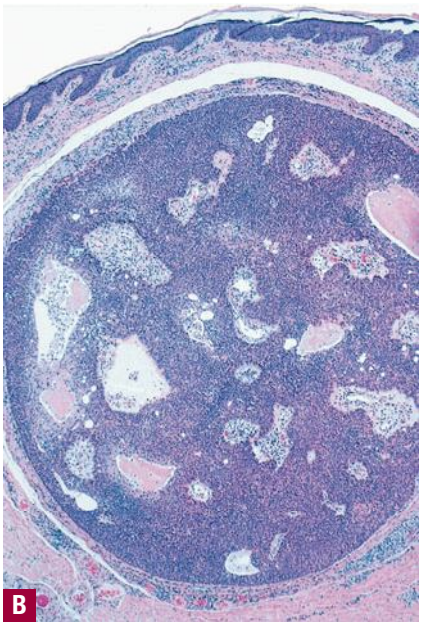
Histopathology. A nodular, solid, or solid-cystic lesion in the dermis, sometimes with extension to the subcutis (see Fig. 119-6B). The epithelial component consists of closely packed aggregations of round, fusiform, or polygonal cells with either eosinophilic or clear cytoplasm. Individual lesions show a variable cellular composition. Clear cells predominate in about one-third of cases. Mitotic figures are sometimes noted within the epithelial component, a feature that does not generally indicate malignancy. The cystic spaces are often filled with mucin.

Prognosis and Clinical Course. Hidradenoma shows a high rate of local recurrence and may rarely undergo malignant transformation.[54]

Treatment. Treatment is complete surgical excision.

POROMA ***Etiology.*** The term *poroma* refers to a group of rare cutaneous appendage tumors composed of cells (cuticular and poroid cells) similar to those of the acrosyringium. Poromas are traditionally subcategorized histopathologically based on their location in relation to the epidermis into three main variants; namely, hidroacanthoma simplex, eccrine poroma, and dermal duct tumor.[4–6,41] Some authors add poroid hidradenoma to this group.[41] There are also reports of "poromas" with differentiation toward the follicolosebaceous–apocrine unit.

Clinical Findings. Clinically, hidroacanthoma simplex presents mostly in middle-aged and elderly individuals, preferentially in women as a solitary, hyperkeratotic plaque, with predilection for the extremities. Eccrine poroma occurs commonly as a solitary, slowly growing, skin-colored, or pigmented sometimes bright red, itchy, or painful pedunculated, sessile papule or nodule, situated mostly on the soles and palms of adults (see eFig. 119-6.1 in on-line edition).



▲ **FIGURE 119-6** Hidradenoma. **A.** Dome-shaped nodule on the leg. **B.** Well-circumscribed, dermal nodule composed of two cell types.

Histopathology. Hidroacanthoma simplex shows sharply demarcated aggregations of cuboid to ovoid cells confined to the epidermis. Eccrine poroma reveals aggregations of uniform basaloid cells that radiate from the basal layer of the epidermis into the dermis (Fig. 119-7). Dermal duct tumor consists of several sharply circumscribed, mainly dermal nodules composed of poroid and cuticular cells. Ductal structures are frequently observed. Poroid hidradenoma is characterized by intradermal, solid, and cystic aggregations of poroid cells.

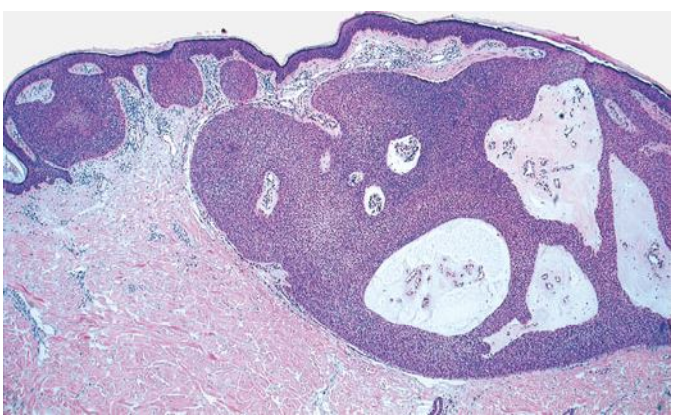
Prognosis and Clinical Course. Eccrine poroma is rarely observed to precede the development of porocarcinoma.

Treatment. Treatment of choice is total surgical excision.

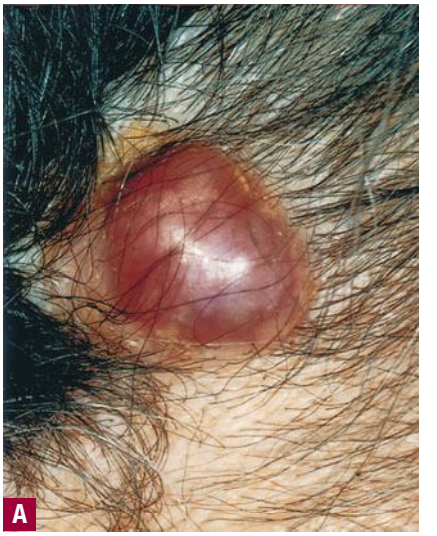
SPIRADENOMA ***Epidemiology.*** Spiradenoma occurs in young and middle-aged adults.

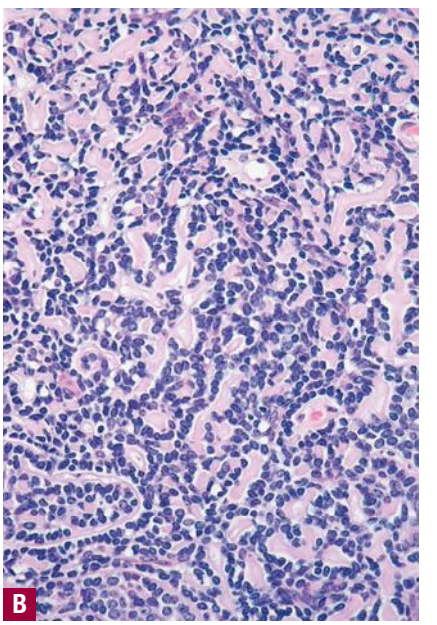
Clinical Findings. Spiradenoma usually presents as a solitary, slowly growing, sometimes painful, reddish-brown, intradermal, or deeply subcutaneous nodule[4–6,12,41,55] (Fig. 119-8A). Eccrine spiradenomas may be seen in Brooke-Spiegler syndrome (an autosomal dominant condition) in association with multiple cylindromas and trichoepitheliomas.

Histopathology. There are one or several well-circumscribed, basophilic nodules in the dermis, sometimes with extension to the subcutis. Nodules show epithelial cell aggregates arranged in sheets and cords or in a trabecular pattern (see Fig. 119-8B). They consist of two types of cells; namely, small, dark-staining basaloid cells located at the periphery, and larger cells with a pale nucleus situated mostly in the center. Tubular or cystic structures are occasionally noted within the epithelial aggregations. Some areas of the tumor contain a PAS-positive hyaline material.



▲ **FIGURE 119-7** Eccrine poroma. Nodular aggregations of basaloid cells extend from the epidermis into the superficial dermis.



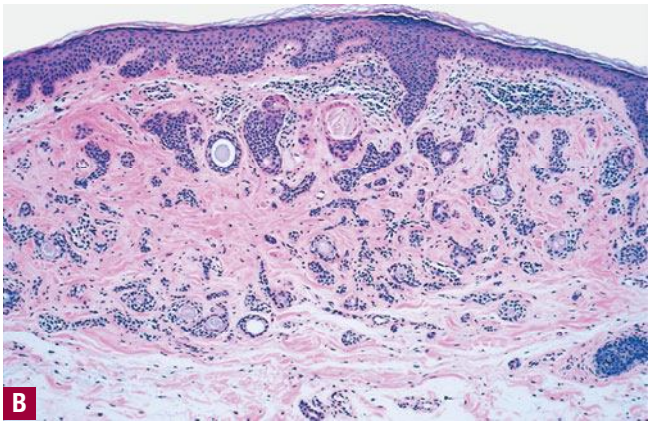


▲ **FIGURE 119-8** Spiradenoma. **A.** Reddish-brown tumor on the scalp. **B.** Tumor cells arranged in a trabecular pattern. Note hyaline material in the background.

Prognosis and Clinical Course. Malignant transformation is infrequent and presents with ulceration.[52]

Treatment. Complete surgical excision is the treatment of choice.

SYRINGOMA ***Epidemiology.*** Common. Adult women are most commonly affected, but these can occur in all adults.



▲ **FIGURE 119-9** Syringoma. **A.** Multiple, small papules on the periorbital skin of a young woman. **B.** Solid, tubular, and cystic structures in the upper dermis. Note "tadpole"-like morphology of tumor lobules.

Etiology. Syringoma is a benign neoplasm with differentiation toward eccrine acrosyringium.

Clinical Findings. Syringomas present as numerous, small, firm, smooth, skin-colored, or slightly yellowish papules situated on the face, particularly around the lower eyelids of adults, but can develop in other anatomic sites[4–6,12,41] (Fig. 119-9A). Women are more commonly affected. Scalp lesions often present as non-scarring alopecia. Syringomas occasionally show a unilateral, linear, or bathing trunk–type distribution. Familial cases have been recorded. There appears to be an increased frequency of syringomas in patients with Down syndrome. Eruptive syringomas represent a distinctive, occasionally familial form presenting mainly in pubescent or adolescent girls as successive crops of numerous, disseminated, sometimes confluent papules. These lesions tend to involve the upper half of the body, particularly the anterior aspect of the neck, chest, trunk, axillae, inner aspects of the upper arms, and umbilical area.

Histopathology. Numerous epithelial aggregations of small, tadpole-shaped solid nests, cords, and tubular structures in the upper half of the dermis (see Fig. 119-9B). The epithelial areas are commonly surrounded by thickened, closely packed, collagen bundles.

Treatment. Some patients seek removal of the lesions because of cosmetic concerns. Surgical excision generally produces less than satisfactory cosmetic results. Alternative therapeutic approaches may include dermabrasion, electrodesiccation with curettage, and laser resurfacing.[56]

TUBULAR ADENOMA ***Epidemiology.*** Tubular adenomas are found in middle-aged adults as solitary, slowly growing, well-circumscribed nodules, situated mostly on the extremities. Black women appear to be preferentially affected.

Etiology. The term *tubular adenoma* defines a group of benign appendage tumors histopathologically characterized mainly by numerous cystic, dilated, and branching tubular structures in the dermis surrounded by a compressed fibrous stroma.[12,41,57] Lesions show either eccrine (tubular eccrine adenoma) or apocrine (tubular apocrine adenoma) differentiation.

Clinical Findings. Unusual presentations include their occurrence during childhood, large tumors, and lesions with verrucous or eroded surfaces. Some cases arise in association with a preexisting nevus sebaceus or syringocystadenoma papilliferum.

Histopathology. This lesion demonstrates a relatively well-circumscribed dermal nodule consisting of numerous cystic, dilated, and branching tubules, surrounded by compressed or focally hyalinized fibrous tissue.

Prognosis and Clinical Course. Tubular adenomas sometimes recur after surgical excision, but malignant transformation has not been observed.

Treatment. Treatment is by simple surgical excision.

Malignant Neoplasms

AGGRESSIVE DIGITAL PAPILLARY ADENOMA AND ADENOCARCINOMA ***Epidemiology.*** Aggressive digital papillary adenoma and adenocarcinoma are rare neoplasms presenting mainly in middle-aged adults, primarily in white males.

Clinical Findings. These tumors are characterized mainly by an acral localization and a tendency to recur.[1,4,12,58] *Aggressive digital papillary adenoma* has been the term used to represent the less-aggressive end of the spectrum, whereas *aggressive digital papillary adenocarcinoma* has been reserved for more aggressive tumors with metastatic potential. The neoplasms present as single, flat, or slightly elevated, often ulcerated, crusted, or bleeding nodules measuring up to 2 cm in diameter. The volar surface of the fingers and toes and the adjacent parts of the palms and soles are predominantly involved. Adherence to underlying deeper tissues is often apparent.

Histopathology. There is usually a dermal and/or subcutaneous lobular proliferation of ductal and glandular structures with focal solid and cribriform zones.[58] Epithelial components are separated by a fibrocollagenous stroma. Ductal structures show variable dilatations forming cystic spaces in which several intraluminal papillary projections are present. Solid and ductal structures are composed mainly of polygonal cells. Squamous metaplasia and spindle cells as well as apocrine or sebaceous differentiation can be found. An inflammatory infiltrate consisting predominantly of lymphocytes and plasma cells is sometimes noted.

Prognosis and Clinical Course. Approximately 50 percent of aggressive digital papillary adenomas recur locally. Metastases, when they occur, involve mainly the lungs, but have occasionally been observed in other tissues such as lymph nodes, brain, skin, bone, and kidney.

Treatment. Standard treatment is surgical excision.

CYLINDROCARCINOMA ***Epidemiology.*** Cylindrocarcinoma is a very rare appendage tumor that presents in middle-aged and elderly individuals (mean age, 66 years). Women are more commonly affected than men.

Clinical Findings. Cylindrocarcinoma is a rapidly growing ulcerated or bleeding nodule on the scalp.[36,41,60]

Histopathology. The vast majority of cylindrocarcinomas show a remnant of a benign cylindroma (see Cylindroma). The cylindrocarcinomatous areas consist of irregularly shaped, poorly circumscribed, focally confluent nests and cords of atypical basaloid cells.

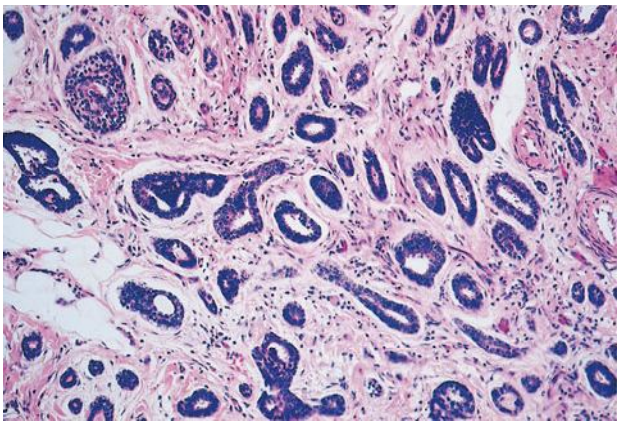
Prognosis and Clinical Course. There is a tendency for local destructive growth and the potential for metastasis to lymph nodes in particular but also to liver, lung, and bone. This aggressive tumor develops most commonly in patients with multiple cylindromas.

Treatment. Treatment is surgical excision.

ECCRINE CARCINOMA ***Etiology.*** *Eccrine carcinoma* is a term used for a group of rare, malignant, eccrine neoplasms with a great diversity in histomorphologic features and wide differences in biologic behavior.[5,12,31,41] The common histopathologic denominator is the presence of variable areas of basaloid cells with tubular structures. These tumors have previously been described under different names, including basal cell tumor with eccrine differentiation (eccrine epithelioma), syringoid carcinoma, and eccrine syringomatous carcinoma.

Clinical Findings. Lesions show no distinctive clinical features. They present as slowly growing, solitary, nodules, plaques, and tumors on the scalp, extremities, or trunk of older adults.

Histopathology. There is a wide spectrum of histopathologic features. Some tumors show confinement to the dermis, whereas others reveal involvement of the subcutis and deeper soft tissues. Lesions may display relatively well-differentiated features with areas of clear-cut ductal differentiation. A subset of lesions exhibits anaplastic features, with only subtle signs of ductal differentiation. Relatively well-differentiated tumors are characterized by basaloid aggregations arranged in strands, solid nests, and dilated or branching tubular structures (Fig. 119-10). Foci with syringomatous features may be present. Perineural invasion is a common finding.



▲ **FIGURE 119-10** Eccrine carcinoma with nests and tubular structures. Note focal syringomatous features.

Prognosis and Clinical Course. Eccrine carcinoma can be invasive and destructive, with frequent recurrences. Local recurrences are common. Lymph node and distant metastases are observed in some patients.

Treatment. Treatment is by wide surgical excision. Sentinel node biopsy may be valuable in diagnosis of lymph node metastases.

HIDRADENOCARCINOMA ***Epidemiology.*** Hidradenocarcinoma (clear cell hidradenocarcinoma, malignant clear cell hidradenoma, solid-cystic hidradenocarcinoma, malignant acrospiroma, malignant clear cell myoepithelioma, clear cell eccrine carcinoma) occurs in middle-aged or elderly individuals.

Clinical Findings. This tumor presents as a solitary, ulcerated nodule on the head/neck, trunk, and extremities of middle-aged or elderly individuals[1,12,41,54] (Fig. 119-11).

Histopathology. A non-encapsulated, dermal/subcutaneous nodule consisting of irregularly shaped lobules of predominantly large, atypical, polygonal cells with eosinophilic cytoplasm and foci of clear cells (due to glycogen) are frequently observed. Cords and nests of tumor cells may infiltrate surrounding tissues. Mitotic figures are frequent. Ductal structures with either eccrine (usual) or apocrine differentiation are seen. Areas with basaloid or squamoid features are may be noted.

Prognosis and Clinical Course. Hidradenocarcinoma is a rare aggressive tumor. Local recurrence is common despite treatment. Distant metastases via lymphatic spread are not uncommon.

Treatment. Wide surgical excision is the treatment of choice.

MICROCYSTIC ADNEXAL CARCINOMA ***Etiology.*** MAC is also known as *syringomatous carcinoma* and *sclerosing sweat duct carcinoma*.

Epidemiology. MAC is a rare, locally aggressive tumor with a high potential for local recurrence.

◀ **FIGURE 119-11** Hidradenocarcinoma. Large ulcerated tumor.

Clinical Findings. MAC usually presents in elderly individuals as a solitary, slowly growing, firm, indurated plaque on the face, particularly around the upper lip or orbit.[1,4,5,12] For unclear reasons, the tumor tends to occur on the left side of the face. Lesions may occasionally be found on extra-facial locations, including the nipple, axilla, and lower extremities.

Prognosis and Clinical Course. Local recurrences are common (about 50 percent of cases) and may develop several years after initial diagnosis and therapy. Prolonged follow-up is therefore usually necessary.

Treatment. Treatment of choice is surgical. A more favorable cure rate (up to 89 percent) has been achieved with Mohs micrographic surgery. Regional and distant metastases are rare.[61]

POROCARCINOMA ***Epidemiology.*** Porocarcinoma is a rare, potentially aggressive neoplasm presenting in elderly individuals.

Etiology. It has been suggested that porocarcinoma is a malignant transformation of an eccrine poroma or hidroacanthoma simplex due to the frequent history of a long-standing nodule at the site where the cancer develops.

Clinical Findings. Porocarcinoma is the malignant counterpart of eccrine poroma (or malignant eccrine poroma). It presents as a partially ulcerated, verrucous plaque or polypoid tumor on the lower extremities.[4–6,12,41,62,63] Other common anatomic sites are the head and neck,[62] trunk, and, less frequently, the upper extremities, and genitalia.

Histopathology. Histopathologically, primary porocarcinoma can appear alone or as a component of benign eccrine poroma or a hidroacanthoma simplex component.

Prognosis and Clinical Course. A generally poor response to treatment is seen, with frequent local recurrences (up to 20 percent of cases), lymph node metastases, and, occasionally, distant metastases. Distant metastases can develop in the lung, breast, mediastinum, peritoneum, spine, and liver.

Treatment. Wide local surgical excision or Mohs micrographic surgery is the treatment of choice. Metastatic porocarcinoma is very resistant to adjunctive chemotherapy or radiation, and such patients have a high mortality rate.[62] Despite previous disease patterns, mounting evidence indicates that porocarcinoma may not be as aggressive as previously thought.[63]

SPIRADENOCARCINOMA ***Epidemiology.*** Spiradenocarcinoma presents mainly in middle-aged and elderly individuals and is very rare.

Etiology. Spiradenocarcinoma is a malignant, sometimes aggressive, appendage tumor that usually arises from a benign spiradenoma.[12,41,64]

Clinical Findings. Typically, patients report a single, large nodule on the extremities, trunk, or abdomen with slow growth for many years and recent rapid size increase, color change, pain, or possible ulceration.

Histopathology. The tumor usually shows a carcinomatous area, representing spiradenocarcinoma, in association with a typical, benign spiradenoma.

Prognosis and Clinical Course. Local recurrences and/or lymph node involvement are frequent, and fatal metastases have been reported in about 20 percent of cases.[36]

Treatment. Wide surgical excision is the preferred treatment.

APPENDAGE TUMORS WITH FOLLICULAR DIFFERENTIATION

The follicular cysts, hamartomas, and neoplasms reviewed in this section show predominantly histopathologic features that resemble different portions of a normal hair follicle, hair shaft, and/or perifollicular fibrous sheath. They exhibit a wide range of morphologic features and may display variable degrees of differentiation. Consequently, uniform diagnostic criteria do not exist for a number of entities.[3–6,12]

Cysts

EPIDERMAL CYST (See Chap. 118) Multiple epidermal cysts may be a feature of Gardner syndrome.[4,5,66] Gardner syndrome, caused by mutations in the *adenomatous polyposis coli* (*APC*) gene, is a rare, inherited, autosomal dominant trait characterized by multiple epidermal cysts and pilomatricomas, soft-tissue proliferations (fibromatosis, lipomas, leiomyomas), multiple craniofacial osteomas, bilateral pigmented ocular fundus lesions (congenital hypertrophy of the retinal epithelium), and intestinal (colorectal) polyposis. If intestinal polyposis is undetected or untreated, virtually all patients develop colonic carcinoma at a young age. The cutaneous cysts frequently predate the intestinal polyps.

HYBRID CYST Hybrid cysts occur in all age groups. Follicular hybrid cyst has been reported to occur within a nevus sebaceous.[67] They present usually as solitary, cystic nodules situated on the head and neck.[4,68]

Histologically, there is a cystic lesion displaying a mixed type of epithelial lining with a stratified squamous epithelium in its upper portion and outer sheath differentiation with trichilemmal cornification in its lower portion.

KERATOCYST Cutaneous keratocysts present typically in patients with basal cell nevus syndrome[66,69] (see Chap. 116).

They have been observed on the trunk and extremities independent of basal cell nevus syndrome[70] and show similar histopathologic features to the jaw keratocysts of patients with this syndrome.

There is a cystic structure with a corrugated or festooned configuration. The epithelial lining reveals several layers of squamous epithelium without a granular zone. A lanugo hair is observed within the cyst cavity of some lesions.

PIGMENTED FOLLICULAR CYST Pigmented follicular cyst shows differentiation toward the infundibular portion of the hair follicle. This cyst usually presents as a solitary, relatively small (0.4- to 1.5-cm), pigmented papule or nodule situated on the head and neck region of adult males.[4,66,71] Vulvar lesions have also been reported. Histopathologically, there is a cystic structure filled with numerous, heavily pigmented hair shafts. The cyst is lined by a stratified squamous epithelium.

TRICHILEMMAL CYST (See Chap. 118)

VELLUS HAIR CYST Lesions are either sporadic or inherited in an autosomal dominant fashion. The cysts show differentiation toward the infundibular portion of the hair follicle and typically contain numerous vellus hairs. Multiple, small (1- to 3-mm), asymptomatic, pigmented, reddish, or grayish papules are distributed on the chest, abdomen, and

axilla (eruptive vellus hair cysts) and, occasionally, on the face, neck, and extremities.[5,6,66] Familial cases present most commonly at birth or in early infancy. Sporadic lesions tend to develop in the first or second decades of life. Eruptive vellus hair cysts may be associated with steatocystoma multiplex, trichostasis spinulosa, anhidrotic ectodermal dysplasia,[72] and pachyonychia congenita, as well as some neurologic disorders. Histopathologic examination reveals a cystic structure located in the middle or upper dermis. It is lined by a stratified squamous epithelium with focal features of outer root sheath differentiation at the level of the follicular isthmus and trichilemmal cornification. Several vellus hair shafts and keratin material are present within the cystic lumen. Eruptive vellus hair cysts are difficult to treat surgically. Patients may benefit from therapy with isotretinoin, pulsed carbon dioxide, and erbium: YAG-laser ablation.[73] Spontaneous regression has occasionally been observed.

Hamartomas

BASALOID FOLLICULAR HAMARTOMA Basaloid follicular hamartoma occurs either as a solitary, sporadic tumor or as multiple, hereditary lesions.[74,75] Familial, multiple, basaloid follicular hamartomas manifest as numerous, small (1 to 2 mm in diameter), flesh-colored papules located predominantly over the central face, and occasionally elsewhere on the head and neck. Lesions have been reported in association with myasthenia gravis, alopecia, hypohidrosis, facial sclerosis, systemic lupus erythematosus, or cystic fibrosis.[74,75] Solitary forms of basaloid follicular hamartoma are commonly found on the face and scalp. Localized linear and unilateral variants have also been documented. Histopathologically, there are anastomosing strands of basaloid cells with numerous epidermal connections. Central areas of epithelial aggregations occasionally reveal cells with a squamoid appearance. Features of follicular differentiation, including horn cysts, rudimentary germs, and follicular papillae, are variably present.

HAIR FOLLICLE NEVUS Hair follicle nevi have been reported in all age groups.[3,12,76] There is currently disagreement as to whether "hair follicle nevus" ("congenital vellus hamartoma") represents a distinct entity or a variant of trichofolliculoma.[3] Hair follicle nevi occur as slightly dome-shaped, skin-colored papules and nodules on hair-bearing skin, particularly on the face.[76] Cases with a linear arrangement have been documented. A number of specific conditions have been included as variants of hair follicle nevus by different authors; namely, the so-called *faun-tail* (a cutaneous lesion characterized by the presence of a patch of hairs arising over the lower sacral area), hair follicles arising on the palms and soles, and Becker's pigmented hairy nevus.[12,77]

Histologically, the upper dermis reveals a well-circumscribed area with numerous closely packed mature vellus follicles. Hair follicles are surrounded by prominent sheaths of perifollicular connective tissue. Clefts are usually observed bordering the perifollicular connective tissue. Some lesions display sebaceous lobules. Treatment of choice is surgical excision.

LINEAR UNILATERAL BASAL CELL NEVUS Linear unilateral basal cell nevus presents at birth or in infancy as numerous, cutaneous papules or nodules distributed unilaterally, sometimes in a zosteriform fashion. Lesions often show comedone plugs and closely resemble nevus comedonicus. One patient with diffuse osteoma cutis, unilateral anodontia, and abnormal bone mineralization has been reported.[78] Histopathologic features simulate those of basal cell carcinoma. Lesions are characterized by a lattice-like pattern of basaloid cells attached to the undersurface of the epidermis. Hints of follicular differentiation are usually present.

NEVUS COMEDONICUS (See Chap. 118)

NEVUS SEBACEUS (See Chap. 118)

Benign Neoplasms

DESMOPLASTIC TRICHOEPITHELIOMA ***Epidemiology.*** Desmoplastic trichoepithelioma (sclerosing epithelial hamartoma) is a relatively uncommon tumor. The tumor shows a predilection for young and middle-aged adults, more commonly in women.

Clinical Findings. Desmoplastic trichoepithelioma presents as a small (up to 1 cm in diameter), asymptomatic, firm, oval, oblong, or annular papule or plaque on the face (Fig. 119-12), particularly around the angle of the lip.[3–6,12] Plaques often reveal a raised border and depressed center. Familial cases have been reported.

Histopathology. Histopathologic examination reveals a relatively well-circumscribed lesion in the upper two-thirds of the dermis with a focal epidermal connection. It is composed of basaloid aggregations arranged predominantly in columns and cords and admixed with infundibulocystic structures, surrounded by a dense, hypocellular desmoplastic stroma. It may occasionally be difficult to distinguish this entity histologically from malignant desmoplastic lesions such as aggressive growth basal cell carcinoma or MAC.

▲ **FIGURE 119-12** Desmoplastic trichoepithelioma located on the infraorbital region.

Treatment. Local surgical excision is the preferred treatment.

DILATED PORE OF WINER Although classified as a neoplasm in this section, there is currently some debate as to whether dilated pore represents a type of follicular (infundibular) cyst or a neoplastic process.[3,5,6,79]

The lesion presents usually as a solitary, comedo-like, keratin-filled structure on the head and neck of elderly individuals.[79] In some cases, lesions arise in the setting of cystic acne or actinic damage. Histologically, a single or several contiguous, markedly dilated infundibula are observed in the upper dermis, sometimes with extension to the lower dermis. The epithelial lining reveals focal acanthosis and finger-like projections radiating into the surrounding dermis. Dilated infundibula contain cornified cells arranged in basket-weave and laminated patterns. Heavy pigmentation of the epithelium can be observed in some cases.

If desired, local surgical excision can be performed to remove the lesion.

FIBROFOLLICULOMA Fibrofolliculoma is a rare tumor that presents in middle age. Fibrofolliculoma presents with multiple, small papules measuring 2 to 4 mm in diameter, situated on the head and neck, upper trunk, and arms.[3,5,6] Multiple, fa-

milial fibrofolliculomas occurring in association with trichodiscomas, perifollicular fibromas, and skin tags are a feature of Birt-Hogg-Dubé syndrome.[80] Patients with this autosomal dominant syndrome show a tendency to develop colonic polyposis, spontaneous pneumothorax, and a range of internal neoplasms (e.g., renal carcinoma).

Fibrofolliculoma is histologically characterized by a dome-shaped lesion with a central, relatively well-formed hair follicle displaying a single or several contiguous, dilated, keratin-filled infundibula. The infundibula are connected to several thin, focally anastomosing epithelial strands that extend in a radial fashion into the connective tissue. The lesion is often surrounded by a well-circumscribed fibrillary collagenous or mucinous stroma with scant or no elastic tissue. Surgical excision may be useful in the treatment of solitary lesions. Carbon dioxide laser or other destructive modalities may be practical in removal of multiple lesions. Patients should be screened for other features of Birt-Hogg-Dubé syndrome.

FIBROUS PAPULE Currently, there is some disagreement as to whether fibrous papule represents a neoplastic process or a hamartoma.[3] Fibrous papule (perifollicular fibroma) presents mainly as a solitary papule or as several dome-shaped, skin-colored, pigmented, or reddish lesions situated on the face, particularly around the nose of adults.[3,5,6,12] Multiple fibrous papules can be seen in patients with tuberous sclerosis. Multiple fibrous papules occurring in association with fibrofolliculomas and trichodiscomas are a feature of Birt-Hogg-Dubé syndrome.[80] Histologically, a dome-shaped or polypoid lesion consists of one or more poorly formed hair follicles surrounded by cellular fibrous stroma in the upper dermis. The epidermis sometimes reveals an increased number of large, single melanocytes located along the dermal–epidermal junction. There is usually a proliferation of small vessels within the dermis. Spindle- and stellate-shaped, sometimes multinucleated fibroblasts can be found within the stroma. Several histologic variants have been described, including classic, hypercellular, clear cell, pigmented, pleomorphic, and inflammatory.[81] Treatment of choice is surgical excision. Carbon dioxide laser is useful in removing multiple lesions.

INVERTED FOLLICULAR KERATOSIS Inverted follicular keratosis occurs most often in middle-aged and older men. Because of the wart-like morphology, it has been suggested that inverted follicular keratosis may represent a manifestation of human papillomavirus infection rather than a true follicular neoplasm.[3] Inverted follicular keratosis presents as an asymptomatic, small (3 to 10 mm in diameter), solitary papule or nodule, most often on the face.[4–6,12] Most lesions are located around the cheek and upper lip, but may occur on the eyelid. Histopathologic examination reveals an endophytic or exophytic–endophytic lesion consisting of several large epithelial lobules extending into the dermis. Four distinctive histopathologic patterns are recognized; namely, papillomatous, keratoacanthoma-like, solid, and cystic. The center of the epithelial lobules is composed of squamous cells focally arranged in a whorled pattern (squamous eddies). The periphery is sometimes occupied by basaloid cells. Additional features in some lesions include foci of trichilemmal differentiation, mucinous areas with spongiosis, and melanin pigmentation. A mild lymphohistiocytic inflammatory infiltrate often surrounds the lesion. Treatment is by surgical excision.

PANFOLLICULOMA Panfolliculoma is a recently described benign neoplasm that shows differentiation toward portions of both the upper and lower segments of a normal hair follicle.[3] The tumor reveals several morphologic similarities to trichoblastoma. Clinically, cystic, skin-colored or reddish, dome-shaped papules, situated on the head, trunk, and lower limbs of adults, can be found. Histologically, the tumor is characterized by several closely packed, solid, solid-cystic, or cystic aggregations of epithelial cells in the dermis, sometimes extending into the subcutis. They are surrounded by a fibrous stroma with focal clefts between the stroma and adjacent "normal" dermis or subcutaneous fat. Neoplastic cells reveal a spectrum of morphologic features reflecting bulbar, stem, isthmic, and infundibular differentiation. These include the presence of germinative and matrical cells (bulb), cells with trichohyalin granules and blue-gray corneocytes (inner root sheath), and cells with abundant pale and clear cytoplasm (outer root sheath). Cystic structures are lined by infundibular epithelium with a granular zone and filled with blue-gray corneocytes arranged in basket-weave, laminated, and compact patterns. Treatment is surgical excision.

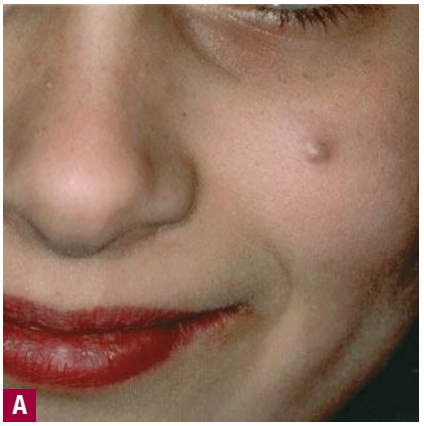
PILAR SHEATH ACANTHOMA Middle-aged and elderly individuals are commonly affected. Pilar sheath acanthoma is characterized by a small (5 to 10 mm in diameter), solitary, skin-colored papule situated on the head and neck, particularly around the upper lip.[3–6,82] A central, occasionally keratin plugged pore is often present. Histologically, there is a crateriform depression in the epidermis representing a widely dilated, keratin-filled infundibulum or closely set infundibula contiguous at the base with numerous epithelial lobules of pink keratinocytes. The epithelial lobules radiate into the dermis, sometimes with involvement of the subcutis. They are surrounded by a narrow rim of fibrous tissue. The epithelium shows similar features to those of the isthmus of a normal hair follicle. Small infundibulocystic structures, tubular structures, and foci of sebaceous differentiation (ducts or sebaceous lobules) are variably observed in individual cases. Treatment is surgical excision.

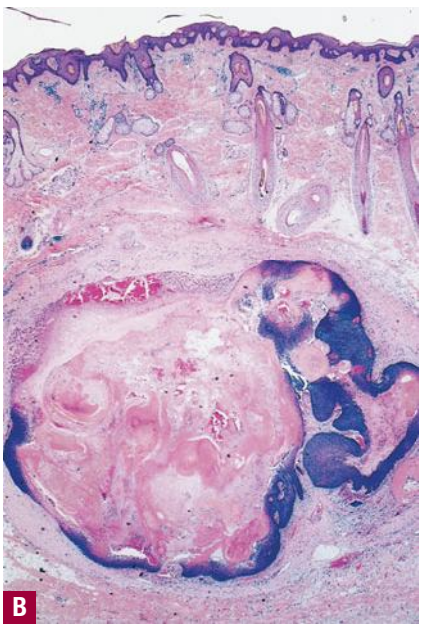
PILOMATRICOMA ***Epidemiology.*** Pilomatricoma most commonly occurs in children and young persons.[3–6,12] Some tumors arise in older adults. Mutation of the β-catenin gene, a mediator in the Wnt signal transduction pathway, is common in pilomatricomas.

Etiology. Pilomatricoma (calcifying epithelioma of Malherbe) is a relatively common appendage tumor that predominantly shows differentiation toward the matrical portion of a normal hair follicle at the level of the bulb.

Clinical Findings. Lesions present as solitary, skin-colored, or pigmented cystic or firm nodules on the head and neck (Fig. 119-13A) and upper extremities. Unusual clinical features include rapidly growing tumors, lesions associated with overlying striae or anetodermic changes, and tumor arising in a nevus sebaceus. Several variants, including multiple pilomatricomas, bullous or giant tumors, and lymphangiectatic variants, have been reported.[83,84] Multiple pilomatricomas have also been reported in patients with Gardner syndrome.[4,66]

Histopathology. Pilomatricoma shows a spectrum of morphologic features that mainly reflect different evolutionary stages.[85] Early and well-developed pilomatricomas reveal variably sized, round to oval cystic lesions lined by a basaloid epithelium at the periphery and filled in the center with masses of eosinophilic, faulty hair matrix material containing "shadow" ("ghost") cells (see Fig. 119-13B).





▲ **FIGURE 119-13** Pilomatricoma. **A.** A tumor in a young girl. **B.** Cystic lesion lined focally at the periphery by basaloid epithelium and filled with masses of eosinophilic, cornified material with shadow cells.

Basaloid (matrical) cells show monomorphous round nuclei with one or more distinctive nucleoli and variable numbers of mitotic figures. Foci of squamoid epithelium are sometimes noted within the epithelial lining. Regressing pilomatricomas display haphazardly arranged foci of basaloid cells and shadow cells as well as an inflammatory infiltrate with multinucleated histiocytic giant cells. Granulation tissue is sometimes noted. Old pilomatricomas reveal no basaloid component but show irregularly shaped, partially confluent masses of shadow cells with foci of calcification or ossification. Melanin deposition, trans-epidermal elimination, and extramedullary hematopoiesis have been described in some pilomatricomas. A peculiar variant with relatively large areas of basaloid cells and small foci of shadow cells ("proliferating pilomatricoma") is occasionally observed in older adults.

Treatment. Surgical excision is the most common treatment. Some lesions show spontaneous regression. Local recurrences may occasionally develop after surgical excision. Malignant transformation has been rarely described.[86]

PROLIFERATING PILAR TUMOR (See Chap. 118) ***Epidemiology.*** Women are approximately two times more commonly affected than men.

Etiology. Rarely, the neoplasm has been reported in association with nevus sebaceus or basaloid follicular hamartoma.

The exact nature of proliferating pilar tumor is still debatable. Traditionally, the tumor has been regarded as a benign follicular neoplasm. There are, however, several well-documented reports demonstrating that proliferating pilar tumor is capable of undergoing frank carcinomatous transformation, even with development of distant metastases. This has prompted some authors to advance the view that proliferating pilar tumor represents a low-grade type of squamous cell carcinoma ("proliferating trichilemmal cystic squamous carcinoma").[3]

Clinical Findings. Clinically, lesions present as solitary, slowly growing, cystic, or lobulated nodules and tumors on the scalp and trunk, as well as on the extremities of older adults.[3,5,12] A few patients show multiple, sometimes familial, lesions. Occasional tumors may be ulcerated or occur as relatively large extracranial masses (up to 25 cm in diameter; Fig. 119-14).

▲ **FIGURE 119-14** Proliferating pilar tumor. Ulcerated giant nodule on the scalp.

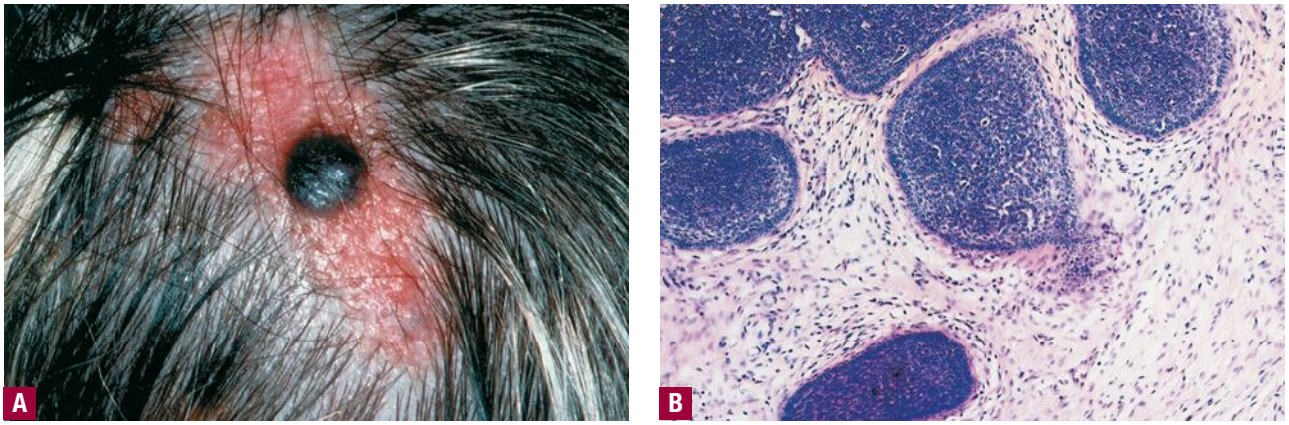
Histopathology. Histopathologic examination usually reveals a sharply circumscribed, round or oval, cystic neoplasm occupying the lower dermis and subcutis. There is an epithelial component lining nearly the whole lesion and extending within it in a radial fashion. The epithelium forms several partially interconnecting solid and cystic lobules. A zone of fibrous stroma with clefts between the stroma and surrounding normal tissue encompasses the tumor. Tumor nests are composed mainly of squamous cells with some areas of clear cells containing glycogen. A characteristic feature is the presence, in the center of lobules, of trichilemmal cornification—that is, abrupt formation of compact eosinophilic keratin without granular layer interposition. Foci with keratohyaline granules, small horn pearls and squamous eddies, calcification, stromal calcium deposition, ossification, and shadow cells, as well as a palisading arrangement of the nuclei at the periphery of the lobules, are observed in individual tumors.

Prognosis and Clinical Course. Local recurrences and metastatic spread have been observed even in histopathologically typical cases.

Treatment. Treatment is by complete excision. Accurate follow-up is recommended in all patients.

TRICHOADENOMA Trichoadenoma (of Nikolowski) is a rare follicular tumor that some authors consider a neoplastic process, whereas other authors consider it a malformation.[3–6,12] These lesions occur most commonly in adults. Clinically, trichoadenoma presents as solitary, slowly growing, grayish nodules measuring up to 1.5 cm in diameter. They are mainly situated on the face and trunk. Histopathologically, a dome-shaped, sharply defined nodule composed of numerous, round to oval, infundibulocystic structures is observed in the dermis. Involvement of the subcutis may be noted in some cases. Infundibulocystic structures are lined by a squamous epithelium with a clear-cut basal layer, spinous zone, and granular layer. They contain corneocytes arranged in a laminated pattern. A conspicuous collagenous stroma often surrounds the tumor cell nests. A subset of cases shows prominent verrucous hyperplasia of the epidermis. Treatment is surgical excision.

TRICHOBLASTOMA Trichoblastomas are best subdivided according to the pre-



▲ **FIGURE 119-15** Trichoblastoma. **A.** Pigmented type arising in a nevus sebaceous. **B.** Nodular aggregations of basaloid cells surrounded by abundant fibrous stroma. Note prominent peripheral palisading of nuclei and a focus with a follicular germ and papilla.

dominant morphologic pattern into large nodular (including pigmented), small nodular (including adamantinoid or lymphadenoma), retiform (giant solitary trichoepithelioma), cribriform (classic trichoepithelioma), racemiform (nonclassic trichoepithelioma), and columnar (desmoplastic trichoepithelioma) variants.[3] Exact subclassification is difficult in some lesions because of the presence of more than one predominant morphologic pattern. Here we focus mainly on "conventional" trichoblastomas.

Clinical Findings. Clinically, trichoblastomas present as solitary, non-ulcerated, skin-colored to brown or bluish-black papules/nodules situated mostly on the head and neck, particularly on the scalp and face of adults. Trichoblastomas are also commonly observed in association within a pre-existing nevus sebaceus[17,88] (Fig. 119-15A) or may occasionally coexist with a basal cell carcinoma.[3] Cutaneous lymphadenoma (adamantinoid trichoblastoma) is a rare appendage tumor classified as a variant of trichoblastoma.[3] It presents mainly in adults in the fourth to fifth decades as a solitary, skin-colored nodule situated on the head and neck.[3,4,12,89]

Histopathology. Lesions are characterized by several dermal/subcutaneous, smooth-bordered aggregations of basaloid (germinative) cells arranged in different morphologic patterns, including cribriform, nodular, racemiform, and retiform. Epithelial aggregations are surrounded by a variable sclerotic or partly hyalinized stroma. They typically reveal peripheral palisading and several foci with rudimentary follicular papillae and germs (see Fig. 119-15B). The basaloid cells are relatively monomorphous and exhibit dark-staining nuclei with large prominent nucleoli and scanty, pale, or eosinophilic cytoplasm. A few mitotic figures and single necrotic cells are sometimes noted. Additional findings in some cases include heavy melanin pigmentation, horn cysts, and amyloid deposits.

Treatment. Treatment is by complete excision.[3]

TRICHODISCOMA Multiple trichodiscomas may be inherited in an autosomal dominant fashion in the setting of Birt-Hogg-Dubé syndrome.[80] Trichodiscoma is a rare tumor that presents as multiple, asymptomatic, small, skin-colored papules situated on the face, arms, trunk, and, sometimes, the legs.[3,5,6,12] Recently, the cutaneous lesions in Birt-Hogg-Dubé syndrome (fibrofolliculomas and trichodiscomas) have been interpreted as different developmental stages of one single tumor with sebaceous differentiation, called "mantleoma." Histopathologic examination reveals a well-circumscribed, non-encapsulated, dome-shaped nodule in the dermis consisting of a zone of loose, finely fibrillar connective tissue with bundles of collagen, fibrocytes, and venules. The lesion is encircled by collarettes of infundibular epithelium that are focally continuous, with epithelial cords radiating into the stroma. The epithelial cords sometimes contain sebaceous cells. A hair follicle or nerve fibers may be noted at the edge. Treatment of choice in solitary lesions is surgical excision. Carbon dioxide laser is useful in removal of multiple lesions. Patients should be screened for other features of Birt-Hogg-Dubé syndrome.

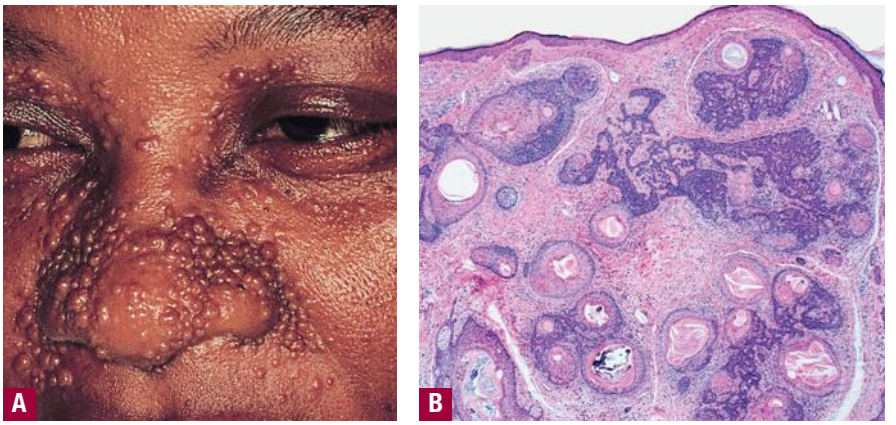
TRICHOEPITHELIOMA ***Etiology.*** Trichoepithelioma shows a spectrum of histopathologic features reflecting mainly differentiation toward hair and hair follicle, particularly follicular germs.[3–6,30] This neoplasm is therefore best regarded as a distinct variant of trichoblastoma (described in the section Trichoblastoma).

Clinical Findings. Three distinctive forms of trichoepitheliomas are recognized; namely, solitary, multiple, and desmoplastic.[3]

Solitary trichoepithelioma occurs mainly as a small (5 to 8 mm in diameter), skin-colored papule situated on the face, especially around the nose, upper lip, and cheeks of adults.[4–6,12] Occasional lesions develop on the trunk, neck, scalp, and lower extremities.

Multiple trichoepitheliomas present usually in adolescents as numerous, small papules distributed on the face, with predilection for the area around the nasolabial folds, forehead, chin, and preauricular area (Fig. 119-16A). A few patients reveal plaques, nodules, or tumors due to coalescing of several lesions. Multiple trichoepitheliomas are mostly transmitted as an autosomal dominant trait in patients with Brooke-Spiegler (epithelioma adenoides cysticum) syndrome. In this syndrome, patients show predisposition for developing multifocal cylindromas, spiradenomas, and milia.[90] Multiple trichoepitheliomas have also rarely been associated with a number of other systemic conditions, including Rombo syndrome (atrophoderma, milia, hypotrichosis, basal cell carcinomas, and peripheral vasodilatation),[91] systemic lupus erythematosus, and myasthenia gravis.

Histopathology. This is a dome-shaped, sharply circumscribed lesion composed of aggregations of relatively monomorphic basaloid (germinative) cells in the upper dermis surrounded by abundant fibrous stroma with intrastromal clefts (see



▲ **FIGURE 119-16** Trichoepithelioma. **A.** Multiple familial type. **B.** Well-circumscribed, multi-lobular dermal tumor consisting of solid and branching basaloid aggregations admixed with horn cysts surrounded by abundant fibrous stroma. Note a focal cribriform pattern.

Fig. 119-16B). The basaloid aggregations are mainly arranged in a cribriform pattern but may show other architectural patterns, including nodular, racemiform, and retiform. They typically reveal peripheral palisading and several foci with rudimentary follicular papillae and germs. In some lesions, other findings include infundibulocystic structures, shadow cells, sebaceous glands, amyloid, calcification, melanin pigmentation, and mucin deposition. A lymphohistiocytic infiltrate with small foreign-body granulomas is sometimes present.

Treatment. Surgery is usually effective in removing solitary lesions. However, surgical treatment of multiple trichoepitheliomas is generally disappointing. Alternative therapies have included cryotherapy, electrodesiccation, and carbon dioxide laser.

TRICHOFOLLICULOMA Trichofolliculoma is a rare tumor that presents mainly in adults. It presents as a small, solitary, dome-shaped papule or nodule situated on the face, particularly around the nose.[3–6,12] A central, dilated keratin plugged ostium with vellus hair(s) is often present (Fig. 119-17). Histologically, the lesion is basically centered on one or, less frequently, on several contiguous, variably dilated, primary follicles lined by infundibular and isthmus type epithelium and opening to the skin surface. Numerous, smaller, secondary (vellus) follicles bud from the wall of the central follicle in a radial fashion. The central follicle is commonly filled with cornified cells and sometimes contains vellus hairs. The secondary follicles often reveal differentiation toward germinative epithelium or formation of hair. They are surrounded by a prominent fibrous stroma. Surgical excision is the treatment of choice.

TRICHOLEMMOMA Tricholemmoma lesions usually present in adulthood. A tumor-suppressor gene (designated *PTEN/MMAC1*) has been demonstrated to play a causative role.[9] Recently, some authors have proposed tricholemmoma to represent an old viral wart.[3] Tricholemmoma (trichilemmoma) shows differentiation toward the outer root (trichilemmal) sheath of a normal hair follicle at the level of the bulb. Clinically, tricholemmomas are solitary, small (3 to 8 mm in diameter), asymptomatic, keratotic, or smooth-surfaced papules on the face, particularly around the nose and upper lip.[3–6,12] Some cases arise in association with nevus sebaceus.[88] Multiple facial tricholemmomas represent an important cutaneous marker for Cowden syndrome, which is discussed in Chap. 154. Patients with Cowden syndrome show a tendency to develop particular internal malignancies, especially involving the breast, colon, and thyroid.

▲ **FIGURE 119-17** Trichofolliculoma. Papule on the forehead with a hair emanating from its central pore.

Histologically, lesions show a lobular, folliculocentric, exo-endophytic proliferation of polygonal, pale-staining, glycogen-containing squamoid cells. The epidermal surface often reveals parakeratosis with scale crusts and sometimes a cutaneous horn (trichilemmal horn). The periphery of the lobules is bordered by columnar cells arranged in a palisade. Foci with small squamous eddies are occasionally observed within the center of tumor lobules. A conspicuous basement membrane usually surrounds the lesions. Desmoplastic tricholemmoma represents a special variant with prominently hyalinized or desmoplastic stroma.[92] Treatment is by surgical excision.

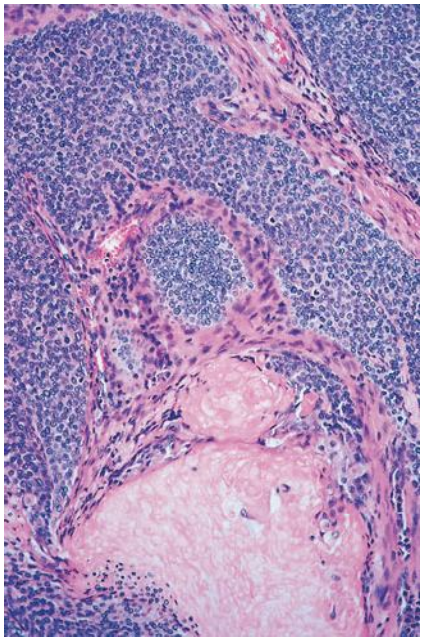
TUMOR OF THE FOLLICULAR INFUNDIBULUM Middle-aged and elderly individuals are most commonly affected by tumor of follicular infundibulum. Despite its name, tumor of the follicular infundibulum shows mainly differentiation toward the isthmus of a normal hair follicle rather than the infundibulum. Lesions present as solitary, small (5 to 10 mm in diameter), asymptomatic, smooth, or keratotic papules on the head and neck.[3,5,12] A small subset of cases occur as multiple lesions (infundibulomatosis, eruptive infundibulomas). Tumors developing in association with Cowden syndrome or with a pre-existing nevus sebaceus have been reported.

Histologically, there is a horizontally oriented, plate-like tumor in the upper dermis with an epithelial component showing multifocal connections to the epidermis or hair follicles. The epithelium typically reveals a fenestrated pattern with interconnecting cords and columns. Infundibulocystic structures are focally present. Cells display small, monomorphic nuclei and abundant pale to pink-staining cytoplasm. The tumors are sometimes surrounded by a collagenous stroma with a network of elastic fibers. Variable areas with single necrotic cells, clear cells, rudimentary papillae and germs, ductal structures, and features of sebaceous differentiation are observed in some cases. Surgical excision may be used to remove the lesions.

Malignant Neoplasms

BASAL CELL CARCINOMA WITH FOLLICULAR DIFFERENTIATION (See Chap. 115)

PILOMATRICAL CARCINOMA Pilomatrical carcinoma (matrical carcinoma) is a rare tumor found on the head and neck of



▲ **FIGURE 119-18** Pilomatrical carcinoma. Irregular aggregations of atypical basaloid cells continuous with an area of cornified material containing shadow cells.

older adults.[3–6,12] Clinical appearances are generally not distinctive. Most cases probably develop de novo, but malignant transformation from a benign pilomatricoma has been reported.[86] Histopathologic examination shows irregularly sized and variously shaped cutaneous/subcutaneous epithelial islands of basaloid (matrical and supramatrical) cells with conspicuous foci of shadow cells (Fig. 119-18). The basaloid cells reveal nuclear atypia and mitoses, as well as areas of geographic necrosis.

Pilomatrical carcinoma is primarily locally aggressive, but distant metastases, especially to lungs, bones, and lymphatics, have rarely been reported. Treatment of choice is surgical excision with adequate margins.[86]

APPENDAGE TUMORS WITH SEBACEOUS DIFFERENTIATION

Apart from sebaceus hyperplasia, sebaceous tumors appear to be less common and to show less morphologic diversity than other types of appendage tumors. Terminology is still controversial. Benign sebaceous neoplasms were conventionally divided into sebaceous hyperplasia, sebaceous adenoma, and sebaceous epithelioma, and malignant sebaceous neoplasms into basal cell carcinoma with sebaceous differentiation and sebaceous carcinoma.[5,6] Recently, the existence of sebaceous epithelioma as a distinctive neoplasm was challenged.[2] The term *sebaceoma* has been recommended for the most common benign neoplasm with sebaceous differentiation, whose malignant counterpart is sebaceous carcinoma. Furthermore, it has been proposed that sebaceous adenoma represents a superficial sebaceous carcinoma rather than a benign neoplasm. This section adopts this classification.

Cyst: Steatocystoma (See Chap. 118)

Hamartomas

FOLLICULOSEBACEOUS CYSTIC HAMARTOMA Folliculosebaceous cystic hamartoma is a cutaneous hamartoma that is comprised of follicular, sebaceous, and mesenchymal elements. Lesions present as solitary, long-standing, asymptomatic papules or nodules measuring 0.5 to 2.0 cm or more in diameter situated on the head and neck.[12,93] The face, especially the region around the nose, is mainly involved. Some lesions show a slightly depressed area with a centrally located crateriform pore.

Histologically, a dome-shaped nodule with a mature infundibular structure to which numerous rudimentary hair follicles and/or sebaceous units are attached is observed. The follicular structure is typically surrounded by abundant fibrous and elastic tissue. Adipocytes, nerves, and blood vessels are frequently found within the stroma. Treatment is by simple surgical excision.

FORDYCE'S SPOTS (FORDYCE DISEASE) AND MONTGOMERY'S TUBERCLES Fordyce's spots are found on adult women. Fordyce's spots and Montgomery's tubercles represent the occurrence of sebaceous glands on the lips and buccal mucosa, and on breast areola, respectively.[2] Despite the ectopic locations, both conditions reveal sebaceous glands with a "normal" histopathologic appearance and are therefore best regarded as hamartomas. Clinically, Fordyce's spots present as tiny, white or yellowish, focally grouped papules on the lip near the vermilion or on a buccal mucosa of adults. Rare lesions develop on the genital mucosa. Montgomery's tubercles arise as tiny papules distributed in a circle near the periphery of the breast areola.

Fordyce's spots show similar features to those in Montgomery's tubercles. They consist of a single sebaceous gland or lobule located in the upper submucosa or dermis, respectively. Some lesions reveal no accompanying sebaceous duct.

NEVUS SEBACEUS (See Chap. 118)

Hyperplasia: Sebaceous Hyperplasia

Males are more commonly affected than females by sebaceous hyperplasia, a common tumor. Rare cases show a familial pattern. Sebaceous hyperplasia presents commonly as solitary or multiple, small (less than 3 mm in diameter), yellowish papules on the face, particularly on the forehead of middle-aged individuals.[2,4–6,12] Lesions often reveal a central dell (Fig. 119-19). Clinically, lesions are often suspected to be basal cell carcinomas. Unusual presentations of sebaceous hyperplasia include linear and zosteriform lesions, giant and diffuse tumors, and lesions confined to the areola or genital (vulva) region. Rhinophyma (see Chap. 79) is currently widely considered to represent a special form of sebaceous hyperplasia.[2]

Histologically, sebaceous hyperplasia reveals large mature sebaceous lobules clustered around discrete, often dilated, infundibula located mainly in the upper dermis. The infundibulum is sometimes filled with debris and bacteria, and may contain a vellus hair.

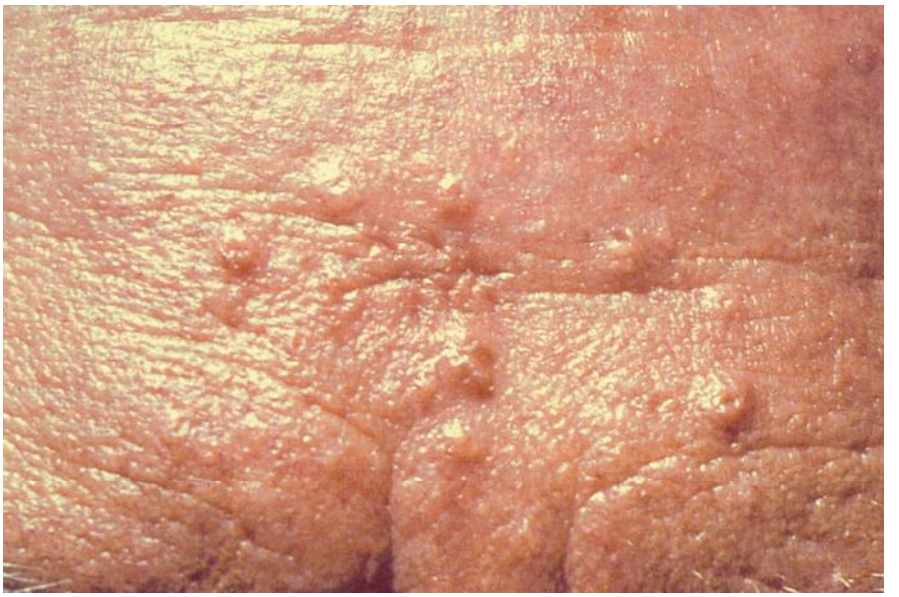
A variety of treatment options exist including electrodesiccation, CO_2 laser surgery, cryosurgery, and shave excision with curettage.

Benign Neoplasms

MANTLEOMA Mantleoma (see also Fibrofolliculoma) is a recently described benign tumor that shows differentiation toward the sebaceous mantle.[3]

Mantleomas occur either as solitary or as multiple tumors.[3,12] Solitary mantleomas appear to be sporadic. They present as small papules on the face, frequently mimicking basal cell carcinomas or dermal nevi. As far as multiple mantleomas are concerned, it was proposed that both fibrofolliculomas and trichodiscomas arising in patients with Birt-Hogg-Dubé syndrome actually represent different developmental stages of mantleoma. Multiple mantleomas in these patients occur as numerous, small papules located mainly on the head and neck, as well as the trunk.

Mantleomas show various histopathologic features. Some lesions consist only of cords and columns of undifferentiated epithelial cells that radiate



▲ **FIGURE 119-19** Sebaceous hyperplasia. One- to 3-mm smooth papules with central umbilication on the forehead.

from an infundibulum. Other lesions reveal interconnected cords with sebocytes and sebaceous ductal structures.

Solitary lesions may be excised. Management of multiple mantleomas is that of multiple fibrofolliculomas and trichodiscomas.

RETICULATED ACANTHOMA See the earlier section Appendage Tumors with Apocrine Differentiation.

SEBACEOMA ***Epidemiology.*** Sebaceoma usually occurs in older individuals and in the Muir-Torre syndrome (see Malignant Neoplasms: Sebaceous Carcinoma and Neoplasms in the Muir-Torre Syndrome).

Etiology. Sebaceoma represents the most common benign neoplasm with sebaceous differentiation.

Clinical Findings. Sebaceoma usually presents as a solitary, slowly growing, asymptomatic, yellowish papule or small nodule on the face or scalp[2,90] (Fig. 119-20A). Women appear to be more commonly affected than men. Occasional tumors arise in association with nevus sebaceus or seborrheic keratosis.

Histopathology. Lesions are centered in the dermis and consist of relatively symmetric, well-circumscribed, and smoothly bordered lobular aggregations of epithelial cells with focal connections to preexisting infundibula.[2,94] Involvement of the subcutis is observed in some cases. Epithelial aggregations are composed of basaloid cells with relatively monomorphous nuclei admixed with variable foci of discernible sebocytes and sebaceous ductal structures (see Fig. 119-20B). Some cases reveal entirely immature sebocytes—that is, cells with small monomorphous nuclei and scant cytoplasm but without vacuoles. Other cases display a variable mixture of immature and mature sebocytes with highly vacuolated abundant cytoplasm and nuclei exhibiting scalloped borders. Scattered mitoses are observed in some cases. Additional features may include a "ripple-like" pattern and cystic as well as ductlike structures containing sebaceous secretion.

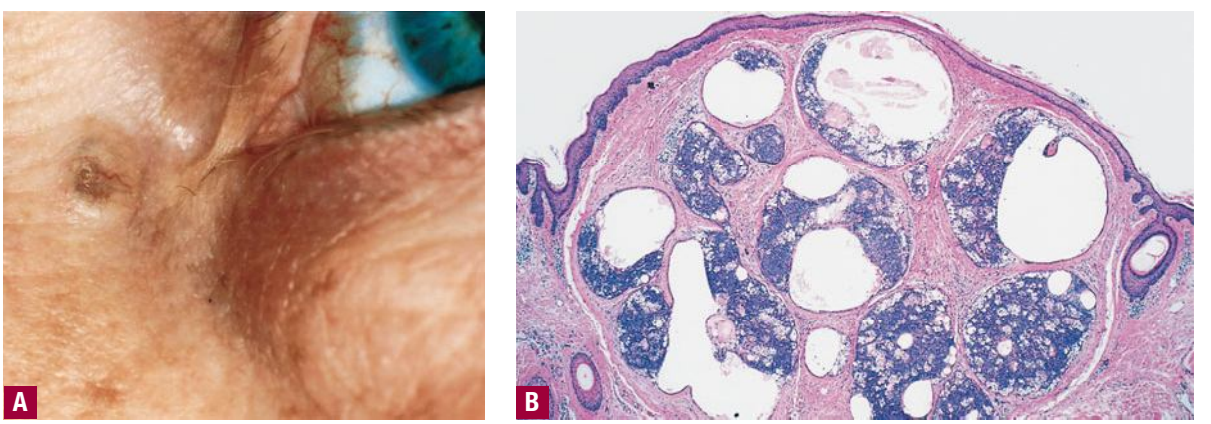
Treatment. Treatment of choice is simple surgical excision. Electrodesiccation, curettage, and cryotherapy are effective in some cases.

Malignant Neoplasms: Sebaceous Carcinoma and Neoplasms in the Muir-Torre Syndrome

EPIDEMIOLOGY Sebaceous carcinoma occurs more commonly in women than in men, and there may be a history of radiation. Rare cases have been observed in young individuals infected with human immunodeficiency virus.

ETIOLOGY Sebaceous carcinoma represents a spectrum of rare malignant appendage tumors with sebaceous differentiation that have a potential for aggressive behavior.[2,4–6,12,94] They have traditionally been divided into ocular and extraocular types. Of these, the ocular type is the most common.

CLINICAL FINDINGS The ocular type of sebaceous carcinoma usually presents in older adults as a small, solitary papule or nodule on the eyelid, particularly around the meibomian glands and glands of Zeiss of the upper eyelid.[2] Lesions are often suspected to be chalazions.



▲ **FIGURE 119-20** Sebaceoma. **A.** Yellowish nodule near the inner canthus of the eye. **B.** Well-circumscribed tumor composed of basaloid aggregations admixed with sebocytes and ductal as well as cystic structures.

Extraocular sebaceous carcinoma occurs mostly as a yellowish, firm, often ulcerated nodule on the head and neck of elderly individuals. Other anatomic sites, such as the foot and genital regions (labia and penis), may occasionally be involved. Lesions often mimic pyogenic granuloma, hemangioma, or squamous cell carcinoma.

Sebaceous carcinoma represents an important cutaneous marker of Muir-Torre syndrome[95] (see Chap. 154). In this syndrome, the tumors occur as single or multiple, skin-colored, yellowish or reddish-brown, sometimes ulcerated papules with the appearance of sebaceus hyperplasia and nodules, situated commonly on the face. They may coexist with keratoacanthomas and/or epidermal cysts. There is still controversy regarding the nature of sebaceous tumors arising in patients with Muir-Torre syndrome. Previous examples have mostly been considered as benign neoplasms ("sebaceous adenomas" or sebaceomas) and less commonly as sebaceous carcinomas. Based mainly on morphology, some authors recently proposed that the vast majority of sebaceous tumors arising in these patients are, in fact, sebaceous carcinomas.[94]

HISTOPATHOLOGY Sebaceous carcinoma is characterized by an asymmetric lesion centered in the dermis and consisting of variously sized and irregularly shaped aggregations of neoplastic cells.[2,94] Involvement of the subcutaneous tissue and/or underlying muscle is observed in some cases. Neoplasms may be relatively well-differentiated, with prominent sebaceous lobules and/or sebaceous ductal structures, or show undifferentiated features, with neither readily discernible cytoplasmic vacuoles nor ductal differentiation. The nuclei of the neoplastic cells, especially along the periphery of the tumor nests, tend to be crowded and pleomorphic and may exhibit marked atypia, as well as increased mitotic figures. Sections often reveal areas with geographic necrosis. A peculiar variant with cystic features may be difficult to differentiate from sebaceoma.

Treatment of choice is surgical excision with adequate margins. Radiation therapy may be effective in some patients with eyelid neoplasms. Up to one-third of patients with the ocular type of sebaceous carcinoma show lymph node metastases, particularly to the preauricular and cervical nodes, and the 5-year mortality rate is about 20 percent. Histopathologic features suggestive of a poor prognosis include the presence of vascular and lymphatic invasion, orbital extension, poor differentiation, an infiltrative growth pattern, and large tumor size. In contrast to ocular tumors, extraocular sebaceous carcinoma very rarely reveals nodal or visceral metastases. Sebaceous carcinomas arising in Muir-Torre syndrome, like visceral malignancies in these patients, also seem to be less aggressive than their ocular counterpart, which is unassociated with the syndrome.[95]

CHAPTER 120

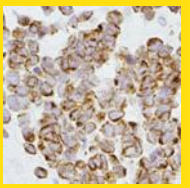
Merkel Cell Carcinoma

Paul Nghiem
Natalia Jaimes

Merkel cell carcinoma (MCC) is a neuroendocrine carcinoma of the skin. Although it is 40 times less common than malignant melanoma, it has a higher mortality (33 percent) than melanoma (15 percent). From 1986 to 2001 there was a rapidly increasing incidence in reported cases of MCC, with a tripling in the rate over this 15-year period. Management of MCC is challenging and optimal therapy is controversial, at least in part due to a lack of quality data on which to base treatment decisions.

MCC is a relatively recently described entity, although the Merkel cell was described more than 100 years ago. In 1875, human Merkel cells were first described by Friedrich S. Merkel (1845–1919). He named these cells *Tastzellen* (touch cells) assuming that they had a sensory touch function within the skin due to their association with nerves. In 1972, Toker described five cases of "trabecular cell carcinoma of the skin." In 1978, Tang and Toker found dense core granules on electron microscopy that were typical of Merkel cells and other neuroendocrine cells. In 1980, the name *MCC* was first applied to this tumor. In 1992, antibodies to cytoker-

MERKEL CELL CARCINOMA AT A GLANCE



- Higher mortality (33 percent) than melanoma (15 percent).
- Incidence tripled from 1986 to 2001.
- Affects elderly/whites/immunosuppressed.
- Consider in differential diagnosis of any rapidly growing, nontender nodule on sun-exposed area.
- Sentinel lymph node biopsy, surgery, and radiation are indicated in most cases.
- Imaging (computed tomography/magnetic resonance/positron emission tomography): poor sensitivity and specificity at time of diagnosis and in early stages.
- Management: challenging; therapy is unique and controversial.
- Avoid over-aggressive surgery: adjuvant radiation therapy highly effective.
- Adjuvant chemotherapy: high morbidity, no proven benefits.
- Optimum care: multidisciplinary coordination between dermatologists, surgeons, radiation, and medical oncologists.

atin-20 allowed for the first time specific and relatively easy diagnosis of MCC to be made through immunohistochemistry. Since that time, electron microscopy is essentially no longer used to make the diagnosis. Most recently, in 2004, an elegant transgenic mouse model was used to isolate normal Merkel cells from mouse skin and find that they possessed excitable calcium channels and were capable of neurotransmitter release, suggesting that they do indeed play a role in touch sensation within the skin.[1]

EPIDEMIOLOGY

Over the 15-year period between 1986 and 2001, the incidence of MCC tripled from 0.15 per 100,000 to 0.44 per 100,000.[2] There are likely two factors that contribute to this increase in incidence that is more rapid than that of any other type of skin cancer. One factor is an increase in the accurate diagnosis of this malignancy through the routine use of cytokeratin-20 immunohistochemistry and the improved recognition of this malignancy by dermatopathologists. In the past, many MCCs were no doubt mischaracterized as lymphoma, melanoma, or undifferentiated carcinoma in the era before immunohistochemistry. A second likely reason is an increase in the number of people over age 65 years with extensive sun exposure history and prolonged immune suppression. Each of these factors is a known risk factor for MCC and several will be discussed in the section Etiology and Pathogenesis.

Recent studies have indicated that the number of MCC cases within the United States is between 600 and 1000 cases per year depending on the particular tumor registry analyzed.[3,4] This cancer is far more common in whites than in blacks, consistent with a known role for ultraviolet radiation in the pathogenesis. Specifically, the rates in whites have been reported as 0.23 per 100,000 as compared to 0.01 per 100,000 for blacks.[5] Although not specifically reported, rates in Hispanics and Asians are likely intermediate between those in blacks and whites. MCC tends to be more common in men than in women (2:1 in ratio).[3]

ETIOLOGY AND PATHOGENESIS

There are several known risk factors for MCC that will likely continue to lead to an increase in the incidence of this disease.

Age Greater Than 65 Years

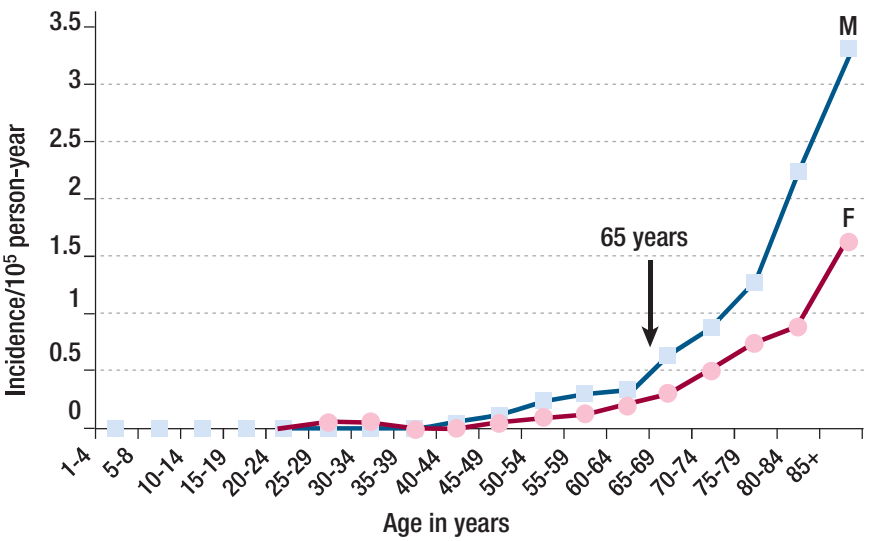
The median age for diagnosis of MCC is 70 years, and there is a 5- to 10-fold increase in incidence after age 70 as compared with age less than 60 years, as shown in Fig. 120-1. Indeed, only about 5 percent of MCC cases present in patients under age 50 and it is extremely rare in childhood.[6]

Sun Exposure

Sunlight, prolonged ultraviolet exposure, and photochemotherapy are all associated with an increased risk of MCC. The vast majority of MCC present on sun-exposed skin. It is clear, however, that sun is not required for MCC to develop. MCC cases can occur on sun-protected skin, including buttocks and vulva as well as portions of the scalp that are covered by hair.

Immune Suppression

The role of the immune system in preventing and fighting MCC is apparent within several different populations of immune-suppressed patients. Solid organ transplant recipients make up approximately 8 percent of all MCC cases.[7] There is thus approximately a 10-fold increase in MCC in the solid organ transplant population as compared to a control population.[5] In organ transplant recipients, the median age of presentation of MCC is far younger with almost half of patients presenting at less



▲ **FIGURE 120-1** Frequency of Merkel cell carcinoma by age and sex. The most significant risk factor for Merkel cell carcinoma is age. M, male (■); F, female (●). than 50 years of age as compared to only 5 percent in the typical population.[6] In transplant recipients, MCC is more aggressive than melanoma with 68 percent of these patients developing lymph node metastases as compared to 20 percent for melanoma.[6] The death rate due to MCC in this population is 60 percent as compared to 29 percent for melanoma.[6,7] The ratio of post-transplant melanoma to MCC is 6:1 as compared to 65:1 in the general population,[5] indicating the relative importance of the immune system in suppressing MCC as compared to melanoma.

Several of the drugs used to suppress the immune system in transplant recipients, including cyclosporine, have previously been shown to act directly on certain tumor cells to augment their growth and aggressive behavior. Data from several other populations suggest, however, it is likely the immune suppression itself that is most important for MCC and not the direct effects of drugs such as cyclosporine acting on the tumor. Specifically, among human immunodeficiency virus–positive patients, there is a relative risk of 13-fold for the development of MCC as compared to the general population.[8] Similar to solid organ transplant recipients, in human immunodeficiency virus–positive patients, this disease also behaves more aggressively and presents at a younger age than in the general population. An increased incidence has also been noted in patients with chronic lymphocytic leukemia which is well known to cause profound and prolonged immune suppression, particularly in the T lymphocyte arm of the immune system.

Molecular Genetics

At the molecular level, virtually nothing is known about MCC. It shares histologic features with another neuroendocrine carcinoma, small cell lung cancer, but it is unclear if these similarities at the histologic level extend to the genetic level as well. Thus far there is no clear tumor suppressor gene or oncogene that has been conclusively implicated in MCC. Diverse chromosomal abnormalities have been reported, including in chromosomes 1, 6, 7, 11, 12, and 18, but these are low-resolution genetic abnormalities and the specific tumor suppressors, or oncogenes, associated with these have not been identified. The p53 gene has been studied in MCC and no significant elevation in p53 mutations has been noted, suggesting that p53 mutation does not play an important role in the development or progression of MCC.[9]

TABLE 120-1
Clinical Features of Merkel Cell Carcinoma

Firm; red, purple, or skin-colored, nontender papule or nodule (see Figs. 120-2A and B)
Most lesions are < 20 mm in diameter at diagnosis
Rapid growth within 1–3 mo
Usually on a sun-exposed location (but not always)
Ulceration is rare
Locally aggressive, with local discontinuous and distant lymphatic spread (see Fig. 120-2B)

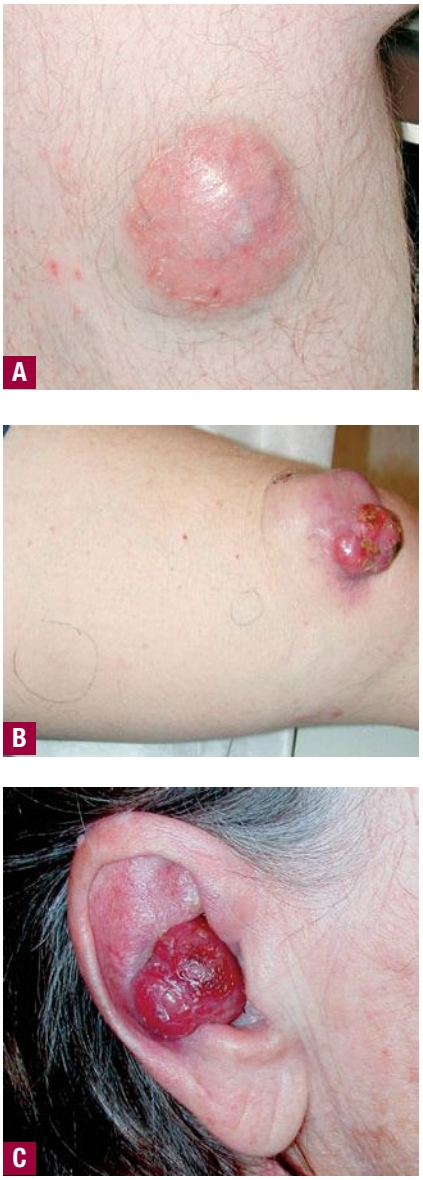
CLINICAL PRESENTATION OF MERKEL CELL CARCINOMA

Although there have been no large studies to describe the clinical presentation of MCC, based on our observations among over 100 cases,[13] we have generated a list as shown in Table 120-1. In distinction to melanoma, there are no clear "ABCD" features that alert a clinician to whether they are looking at an MCC or not. However, if several of the features shown in Table 120-1 are present, it is clearly appropriate to carry out a biopsy to evaluate for MCC or a separate malignant process. In our population,[13] we have analyzed the biopsy reports of more than 70 patients in which the clinician had submitted a presumed diagnosis at the time of biopsy. Strikingly, the clinician listed as clinical impression a benign diagnosis in over one half of cases. In particular, a cyst or acneiform lesion was the single most common of these (Box 120-1 and Figs. 120-2A and B) and -melanoma skin cancer was also relatively frequent as a presumptive diagnosis (Fig. 120-2C).

Box 120-1
Differential Diagnosis of Merkel Cell Carcinoma

Most Likely
- Cyst
- Basal cell carcinoma
- Squamous cell carcinoma (see Fig. 120-2C)
- Amelanotic melanoma
- Cutaneous lymphoma
- Adnexal tumor

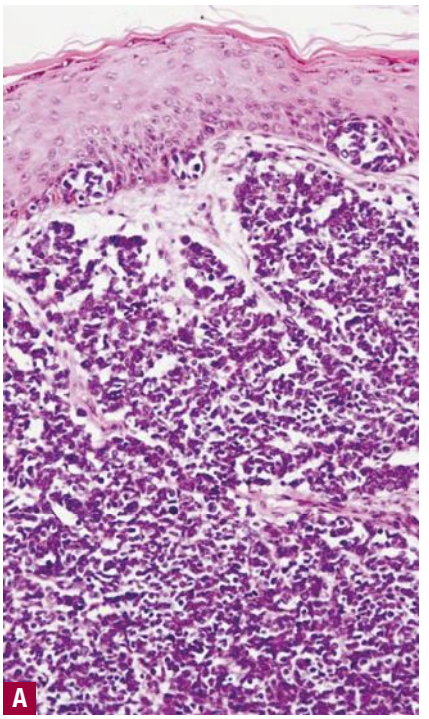
Consider
- Metastasis
- Dermatofibromasarcoma protuberans
- Keratoacanthoma
- Neuroblastoma

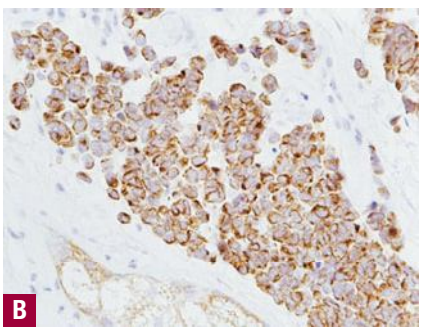


▲ **FIGURE 120-2** Clinical appearance of Merkel cell carcinoma (MCC). **A.** MCC frequently has a "cyst-like" appearance. This is reflected in the differential diagnoses given by clinicians at the time of the biopsy, with cyst/acneiform lesion being the most common clinical impression. **B.** MCC on the knee of a 70-year-old woman with chronic lymphocytic leukemia. For 6 months this lesion was thought to be a "cyst"; consequently, diagnosis and treatment were delayed. Pen marks indicate palpable satellite metastases that developed several months after the primary lesion, presumably tracking via lymphatics. **C.** MCC on the ear of an 87-year-old woman. The lesion grew rapidly and was non-tender. After approximately 3 months, it was biopsied by a clinician who listed squamous cell carcinoma as the presumptive diagnosis.

PATHOLOGY

Merkel cells are thought to be mechanoreceptors involved in fine touch lo-





▲ **FIGURE 120-3** Merkel cell carcinoma pathology. **A.** Hematoxylin and eosin. There is diffuse dermal as well as intraepidermal involvement with Merkel cell carcinoma. This case was seen in consultation, with an initial diagnosis of cutaneous T-cell lymphoma. **B.** Cytokeratin-20. Showing the pathognomonic "perinuclear pattern" of cytokeratins (CAM5.2). (Reprinted from Nghiem P, Mckee P, Haynes H: Merkel cell (cutaneous neuroendocrine) carcinoma, in *Skin Cancer, Atlas of Clinical Oncology*, edited by A Sober, F Haluska, American Cancer Society, 2001, with permission.)

cated within the basal epidermis. This is based on their close association with cutaneous nerves as well as recent data that show Merkel cells are excitable cells with calcium channels and capable of release of neurotransmitters.[1] Although it has not been formally shown, it is widely agreed that Merkel cells in the skin are the precursor cells to MCC. As shown in Fig. 120-3A, the classic histologic features of MCC include sheets of small basophilic cells with scant cytoplasm, fine chromatin, and no nucleoli. There are numerous mitotic figures and occasional individual necrotic cells. Lymphovascular invasion is a very common feature and often can be found when it is specifically searched for even in a "negative" margin. This helps to explain the high local recurrence rate in MCC for narrow or even relatively wide margin excision when adjuvant radiation therapy is not given.

TABLE 120-2
Immunohistochemistry Panel

	Cytokeratin-20	Cytokeratin-7 and thyroid transcription factor-1	Leukocyte common antigen	S-100

Small cell lung carcinoma	–	+	–	–
Lymphoma	–	–	+	–
Melanoma	–	–	–	+

Hematoxylin and Eosin Stain

Three histologic patterns have been described up to now and none is clearly associated with a better or worse prognosis. The most common type is the "intermediate type." This has uniform small cells with minimal cytoplasm, pale nuclei, and a dispersed chromatin appearance. On hematoxylin and eosin staining, the differential diagnosis for this presentation is that of the small, blue-cell tumors including melanoma and lymphoma. The second most common pattern is the "small cell type." This takes its name from small cell lung carcinoma, which is the principal differential diagnosis for this pattern. It shows irregular, hyperchromatic cells with scant cytoplasm and malignant cells that are arranged in linear patterns infiltrating stromal structures. The least common but perhaps most histologically distinctive type is the "trabecular" type. This is the pattern originally described by Toker in 1972. It has a lattice-like, or network appearance, and the differential diagnosis includes metastatic carcinoid tumor.

Immunohistochemical Stains

The use of antibody-based stains has greatly facilitated the ease and specificity of MCC diagnosis (Table 120-2). The single most useful of these stains to rule in MCC is cytokeratin-20.

Cytokeratin-20

Intermediate filament protein is expressed in MCC as well as in adenocarcinomas of the colon, stomach, and pancreas. Within the skin, however, the expression of cytokeratin-20 is limited to Merkel cells. A "perinuclear dot" pattern of cytokeratin is essentially pathognomonic for MCC (see Fig. 120-3B).

Antibodies to CAM5.2

CAM5.2, a cocktail of antibodies that detects multiple human cytokeratin epitopes, typically reacts with both MCC and small cell lung carcinoma. Although it is useful as an initial screening tool to detect tumors of squamous origin, its lack of selectivity relative to cytokeratin-20 means that it cannot be used to definitively diagnose MCC.

Thyroid Transcription Factor-1

Thyroid transcription factor-1 is negative in MCC and positive in small cell lung cancer and thus useful for the differential diagnosis between these two tumors that can look identical by routine histology.

Cytokeratin-7

Cytokeratin-7 has the same staining pattern as thyroid transcription factor-1, that is, negative in MCC and positive in small cell lung carcinoma; it is also expressed in epithelial cells of the lung, ovary, and breast.

Neuron-Specific Enolase

Neuron-specific enolase is positive in MCC and other neoplasms derived from neural or neuroendocrine tissue. In some cases, neuron-specific enolase is released by neuroendocrine carcinomas including MCC and can be detectable in the blood.

Leukocyte Common Antigen

Leukocyte common antigen is useful to differentiate between lymphomas and carcinomas, as it is positive in lympho-

mas and negative in carcinomas including MCC.

S-100

S-100 is positive in most melanomas and glial cell tumors and negative in MCC.

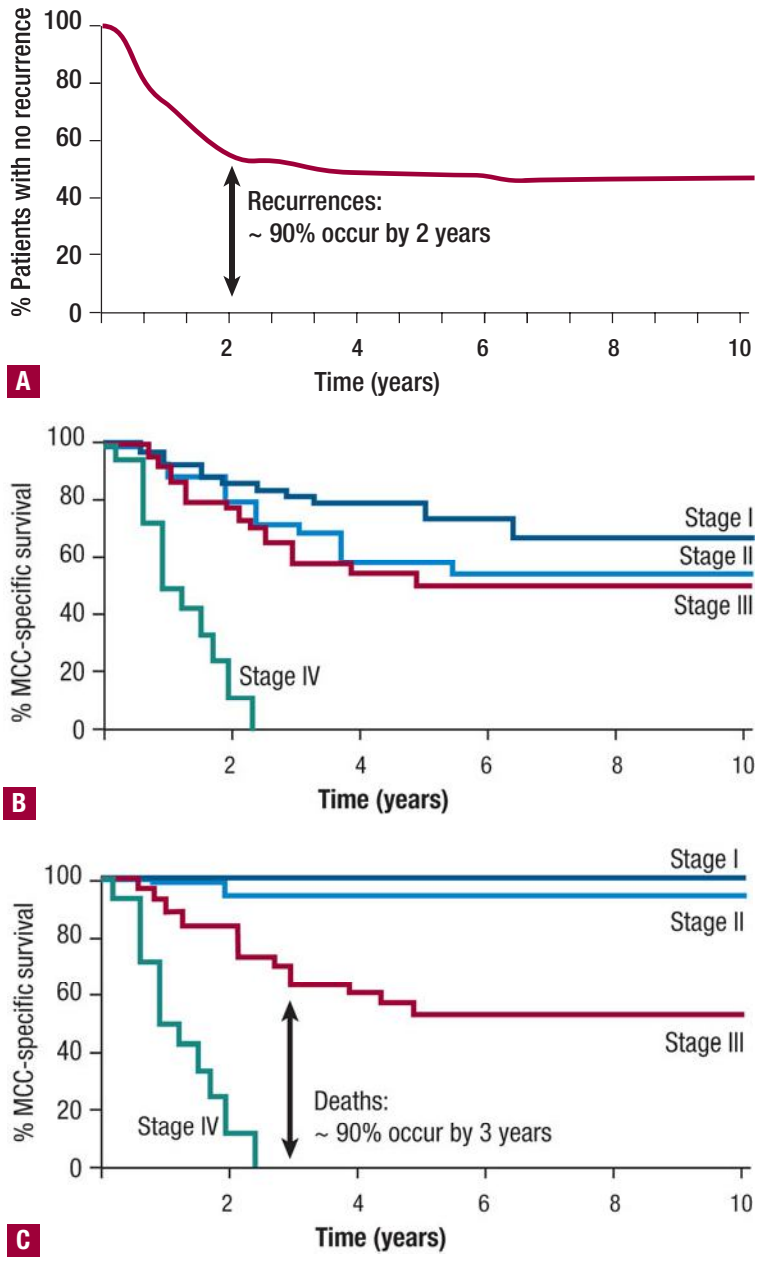
Before cytokeratin-20 and cytokeratin-7, many MCC cases were misdiagnosed as lymphoma, small cell lung carcinoma metastases, or undifferentiated carcinoma. Currently, if immunohistochemistry is carried out properly, MCC diagnosis is typically definitive.

STAGING AND PROGNOSIS

According to the American Joint Committee on Cancer, there are four clinical stages for MCC based on features at time of presentation. Localized disease is either Stage I (primary lesion ≤ 2 cm) or Stage II (primary lesion > 2 cm). Nodal spread of MCC is stage III, whereas patients presenting with metastatic disease beyond the local node bed have Stage IV disease. Survival after a diagnosis of MCC is highly dependent on the stage at presentation. Patients with truly local only disease have a greater than 90 percent chance of survival, which decreases to approximately 60 percent with nodal involvement, and below 10 percent among those presenting with metastatic disease. Unlike malignant melanoma, if MCC recurs it tends to do so rapidly with 90 percent of recurrences occurring within 3 years of diagnosis (Fig. 120-4A).[10]

Sentinel Lymph Node Biopsy and Staging of Merkel Cell Carcinoma

Over the past 20 years, sentinel lymph node biopsy (SLNB) has become quite common in staging malignant melanoma presenting with a depth of greater than 1 millimeter. More recently, several studies have indicated that SLNB is also a sensitive test for detecting MCC spread to the lymph nodes.[11–13] SLNB clearly has less morbidity than an elective lymph node dissection. Interestingly, MCC has a much higher rate of involving the lymph nodes (approximately 30 percent of all cases) than melanoma (approximately 5 percent of all cases). If an SLNB is to be carried out properly, it needs to be performed at the time of the wide resection as opposed to after the wide excision when local lymphatics have been disturbed. The importance of SLNB in determining prognosis in MCC can be seen by comparing Figs. 120-4B and 120-4C. The essential difference is that one-third of patients with local only disease as determined by clinical palpation of lymph nodes, in fact, have microscopic disease in the lymph nodes that very much affects their subsequent survival.[13] The 5-year survival rate of pathologically staged node-negative patients was 97 percent compared with 5-year survival of node-positive patients of 52 percent.[10]



▲ **FIGURE 120-4** Prognosis of Merkel cell carcinoma depends on stage at presentation. **A.** Fraction of patients with Stage I, II, or III disease with no recurrence. Approximately 90 percent of patients who experienced a recurrence did so within 2 years of diagnosis (n, 237 patients). **B.** Disease-specific survival for patients who underwent clinical staging only. Clinical node staging does not provide optimal information for prognosis and treatment (n, 180 patients). MCC = Merkel cell carcinoma. **C.** Disease-specific survival for patients who underwent pathologic staging. Pathologic staging can be done by sentinel lymph node biopsy or other lymph node surgery. At 5 years, patients with no lymph node disease (Stage I or II) had a 97 percent survival rate. Those with lymph node disease (Stage III) had a 52 percent survival at 5 years (n, 145 patients). (Adapted from Allen PJ et al: Merkel cell carcinoma: prognosis and treatment of patients from a single institution. *J Clin Oncol* **23**:2300, 2005, with permission.)

Radiologic Imaging Studies

Although most patients who present for management of MCC have not had an

SLNB, the majority have had computed tomographic (CT) scans. We studied our own series of patients to determine the sensitivity and specificity of CT scans in patients presenting with MCC.[13] We found that scans were not sensitive at all (missing 90 percent of positive cases) in terms of detecting nodal involvement of MCC as compared with SLNB. Among patients who had low-risk disease (negative sentinel lymph nodes or very small primary tumors) all of the "positive" scan results were, in fact, false positives.[13] We therefore reserve CT scans for patients presenting with more advanced disease, such as positive nodal involvement or clinical evidence of metastatic disease.

TREATMENT

Optimal therapy for MCC is controversial and there is no broad consensus on how to manage this disease. One summary of multi-institution management is available through the National Comprehensive Cancer Network (http://www.nccn.org). The National Comprehensive Cancer Network generates a treatment algorithm for MCC with annual updates. The best outcome for MCC is clearly obtained when multidisciplinary management is carried out by an experienced team. Each major treatment modality is summarized below.

Surgery at Primary Site

The initial management in almost all cases of MCC is surgical excision of the tumor. When carried out without subsequent adjuvant radiation, surgery has a relatively high recurrence rate depending on the margins chosen. Surgery alone with 0.5 centimeter margins resulted in a 100 percent recurrence rate in 38 patients.[14] When wide local excision was carried out with 2.5 centimeter margins, the recurrence rate fell to 49 percent.[15] For Mohs surgical excision, the local recurrence rate was 16 percent, which was reduced further to 0 percent in patients who had adjuvant radiation therapy as well.[16] There are no data to suggest that extremely wide excision margins improve overall survival. Depending on the location of the tumor, significant morbidity can result when 2 to 3 centimeter margins are taken. Numerous studies show that if surgery is the sole treatment, recurrence rates are significantly higher than if radiation therapy is added to the regimen. Excision with narrow but clear margins (carried out at the time of SLNB) followed by adjuvant radiation therapy is a reasonable approach to management. Overly aggressive surgery, including amputation, or very wide margins in cosmetically sensitive areas, decreases quality of life, increases morbidity, delays time to initiation of adjuvant radiation, and does not appear to improve survival or local cure rates.

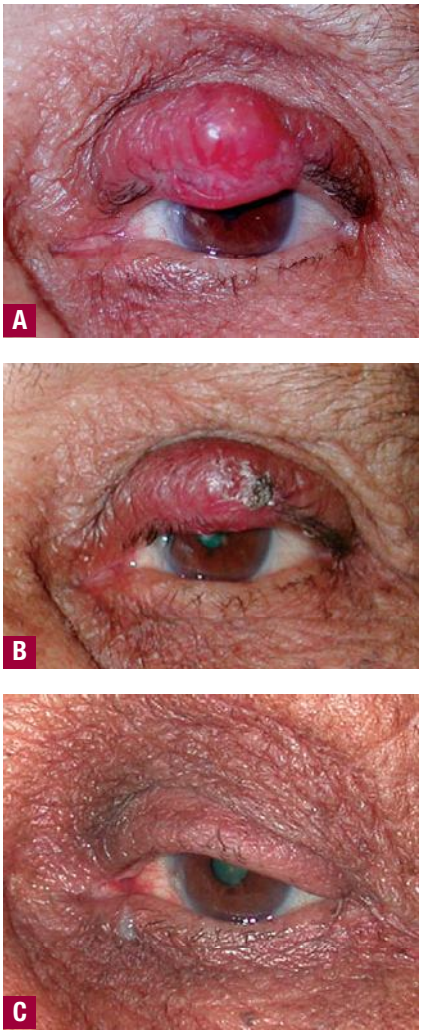
Surgery at the Draining Node Bed

The role of completion lymphadenectomy is controversial. It is typically carried out if there is gross involvement of the draining node bed clinically or if the SLNB is positive. One study showed a benefit of elective lymph node dissection in decreasing nodal recurrences but this was not associated with overall improved survival and clearly has significant morbidity associated with it.[17,18] The relatively greater morbidity of completion lymphadenectomy in combination with relatively frequent nodal recurrences after complete nodal dissection has led us to favor radiation therapy to the lymph node bed rather than surgical therapy.

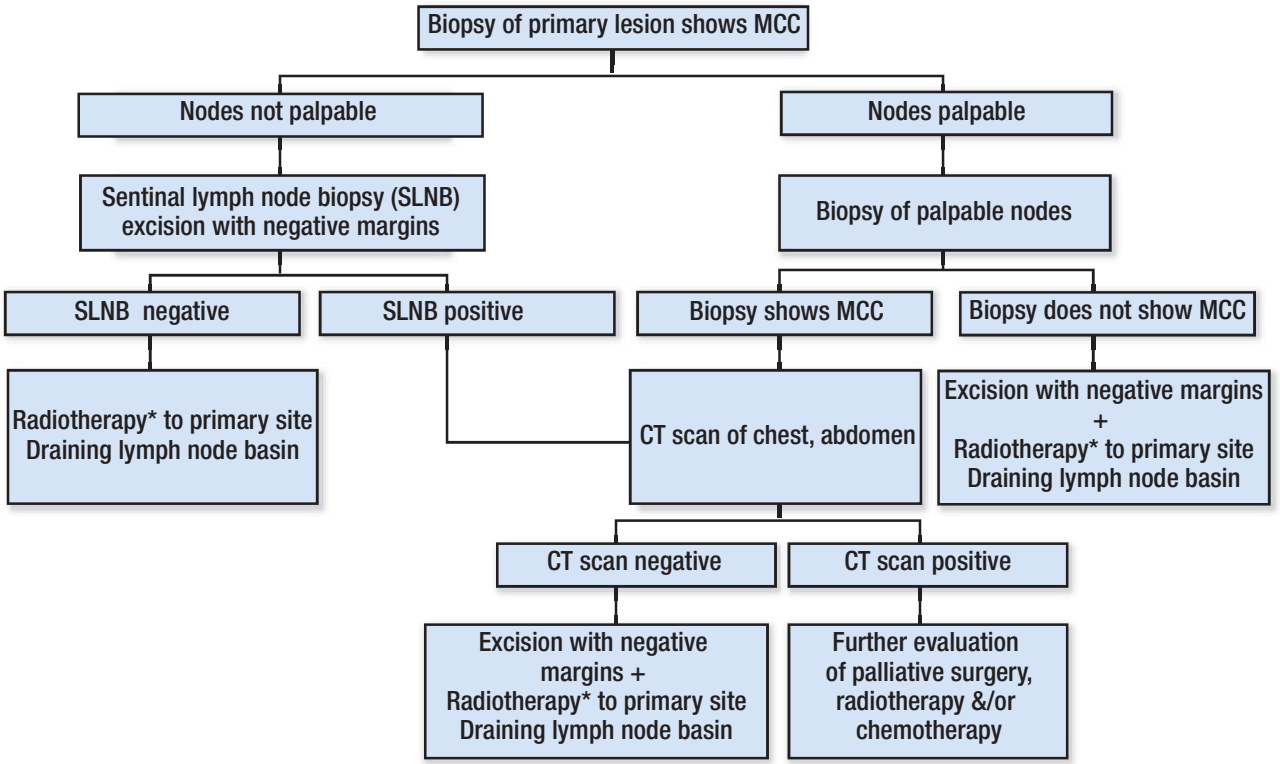
Radiation Therapy

MCC is an unusually radiosensitive tumor.[14,19] Recently, there have been reports of successful treatment of MCC with radiation as monotherapy. With a 3-year median follow up, there was 0 percent disease recurrence in 9 patients treated with radiation monotherapy.[19] One case treated with radiation monotherapy is shown in Fig. 120-5. In most of these cases, the lesion was felt to be inoperable and radiation was given for palliation, but resulted in at least local cure in almost all cases. Data to support radiation as monotherapy remain very scant at this time.

The much more common use of radiation is as an adjuvant to surgery. Adjuvant radiation clearly is critical if surgical margins are positive or if margins are relatively narrow. Adjuvant radiation therapy to the draining node bed is an excellent means of treating sentinel lymph node–positive patients. Numerous studies, although mostly retrospective case studies, indicate a statistically significant improved local and nodal rate of control in this cancer if radiation is added.[20] The typical doses of radiation for MCC are shown in the legend of Fig. 120-6. Acute side effects from radiation therapy include erythema at the site and mild-to-moderate fatigue that peaks towards the end of radiation and usually resolves within 1 to 2 months of completing a 5-week course. Chronic radiation skin changes include temporary or permanent alopecia within the irradiated field, epidermal atrophy, loss of adnexal structures leading to skin or mucosal dryness, and risk of subsequent secondary skin cancers in the irradiated region in patients with a life expectancy of greater than 20 years after the radiation treatment. Perhaps the most significant potential side effect is lymphedema. This is more commonly an issue in lower extremities, when radiation therapy is given to the inguinal lymph nodes, especially after surgery has also been carried out in that region.



▲ **FIGURE 120-5** **A.** Merkel cell carcinoma on the eyelid arising 3 months before biopsy. The lesion was initially presumed to be a chalazion or cyst. **B.** Using a thin lead shield to protect the globe, the eyelid, the surrounding tissues, and draining lymph node bed were treated with radiation monotherapy. **C.** The patient remains recurrence-free at 2.5 years after diagnosis, and thus has a greater than 95 percent chance of cure at this point.



▲ **FIGURE 120-6** Approach to the patient with Merkel cell carcinoma (MCC). *Recommended radiation therapy dose (National Comprehensive Cancer Center Guidelines for MCC, 2006): 45–50 Gy for primary site with negative excision margins and node bed with no palpable disease. 55–60 Gy for primary site with positive excision margins and node bed with palpable disease. Radiation therapy given in 2-Gy fractions, 5 times/week over 4–6 weeks. CT = computed tomography.

Chemotherapy

The most commonly used regimen in MCC is the combination of carboplatin and etoposide. Chemotherapy is without a doubt useful in palliation for symptomatic disease that is otherwise inoperable. Most patients who have not received chemotherapy yet have a significant response with shrinkage of the tumor. Unfortunately, in almost all cases, the tumor grows back and is resistant to chemotherapy even if entirely different agents are used on a subsequent round of chemotherapy. After careful analysis of the literature, we currently do not recommend adjuvant chemotherapy for patients whose MCC has been treated with surgery, radiation therapy, or both. There are six reasons why we currently do not recommend adjuvant chemotherapy.

1. Mortality: there is a 4 to 7 percent acute death rate due to adjuvant chemotherapy in MCC partly due to the fact that these patients are often elderly.[21,22]
2. Morbidity: Neutropenia occurs in 60 percent of patients with fever, and sepsis in 40 percent.[23]
3. Decreased quality of life: this is quite severe in this older population, including fatigue, hair loss, nausea, and vomiting.
4. Resistance to chemotherapy: MCC that recurs after chemotherapy is less responsive to later palliative chemotherapy.
5. Immunity: Chemotherapy suppresses immune function, and this is known in general to be very important in preventing and controlling MCC.
6. Apparent poorer outcomes: Among patients with nodal disease, there was a 60 percent survival if chemotherapy was not given among 53 patients. In contrast, survival was only 40 percent among node positive MCC patients who did receive adjuvant chemotherapy.[10] Although this is not a randomized trial and was not statistically significant, it certainly does not suggest a survival benefit for administrating adjuvant chemotherapy.

Optimal Treatment for Merkel Cell Carcinoma

In general, optimal treatment for MCC should involve obtaining pathologically clear margins by surgery, typically with 1- to 2-centimeter margins as possible, depending on the site. More narrow margins or even positive margins can often be effectively treated by local radiation, typically extending 3 to 5 centimeters beyond the tumor bed. We also recommend treating the draining lymph node bed, likely with radiation therapy, for patients with high-risk disease including a positive SLNB, immune suppression, or a tumor greater than 2 centimeters in diameter. Fig. 120-6 summarizes a treatment plan for patients with MCC.

CLINICAL COURSE AND COMPLICATIONS

In more than 90 percent of cases, MCC is an unanticipated diagnosis at the time the pathology results become known. Most commonly, the lesion in question was thought to be a cyst or acneiform lesion. Although most patients and physicians are not familiar with this disease or its specific management, this disease can be lethal and there is a need to initiate therapy rapidly. Because of the rarity of this cancer, patients and physicians increasingly resort to the internet for medical information. One website, http://www.merkelcell.org, is devoted to aiding patients and physicians by presenting current data and referral center availability.

Among patients who experience a recurrence of their MCC, 90 percent of these happen within 2 years of diagnosis. The most common site of recurrence is

the draining nodal basin or adjacent skin.[10] The chance of developing metastasis and subsequent death is highly associated with the stage of disease at presentation, varying from greater than 95 percent chance of cure to less than 10 percent chance of cure. For those who have recurrences, the locations and frequencies are skin (28 percent), lymph nodes (27 percent), liver (13 percent), lung (10 percent), bone (10 percent), brain (6 percent), bone marrow (2 percent), pleura (2 percent), and other sites (4 percent).[22] Once MCC has spread to viscera, it is essentially incurable.

Fortunately, for more than 50 percent of patients, a good outcome can be anticipated. Those who have had no recurrences for 3 to 5 years, unlike melanoma, are considered cured. The complications for those who do not experience a metastasis depend very much on the therapy they received. We believe that treatment with surgical excision and radiation therapy as outlined in this chapter has relatively minimal complication rates and the best possible chance of cure based on current literature. However, for those who receive very aggressive surgical excision, amputation or chemotherapy for low-risk disease, complication rates tend to be higher without improved outcomes.

CHAPTER 121

Mammary and Extramammary Paget Disease

Isaac M. Neuhaus
Roy C. Grekin

EPIDEMIOLOGY

Mammary Paget disease (MPD) represents approximately 1 percent to 3 percent of breast neoplasms.[1] The peak incidence is between 50 and 60 years of age. MPD in males is extremely rare; almost all reported cases occur in women.

Extramammary Paget disease (EMPD) is a rare neoplasm that affects apocrine gland–bearing skin, such as the vulva, perianal region, scrotum, and penis. The majority of patients are women in the sixth through eighth decades of life.[2,3] The vulva is the most commonly affected area, and EMPD represents 2 percent of all vulval malignancies.[3]

ETIOLOGY AND PATHOGENESIS

MPD is almost always associated with underlying in situ or invasive intraductal adenocarcinoma of the breast (up to 98 percent of cases in some studies).[4,5] Malignant cells directly extend from the underlying tumor into the epidermis via the lactiferous ducts. Rare cases are reported to have originated primarily in the epidermis of the nipple.[6]

Unlike MPD, in which almost all cases have a documented underlying neoplasm, EMPD does not have a uniform histogenesis, and several different forms have been described. Primary EMPD is the most common type and accounts for the majority of all patients with this disease. Underlying carcinoma is not present, and these cases represent a primary intraepithelial neoplasm. The malignant cells are thought to originate from intraepidermal apocrine glands or from pluripotential cells of the epidermis. The neoplasm can then invade the dermis and metastasize via lymphatic spread. In contrast, a smaller proportion of EMPD cases are associated with an underlying apocrine carcinoma or internal malignancy (secondary EMPD). These cases are due to epidermotropic spread of malignant cells from the underlying tumor. Approximately 15 percent of cases are associated with an underlying internal carcinoma. The most common visceral malignancies associated with EMPD are carcinomas of the rectum, bladder, urethra, cervix, and prostate.

CLINICAL FINDINGS

History

Both MPD and EMPD often present with a long-standing history of pruritic, erythematous, scaly patches on the breast and in the groin, perineum, and axilla, respectively. Frequently there is a delay in diagnosis of many months to years as treatment with topical steroids and antifungal agents for presumed inflammatory or infectious dermatitis are initiated. After continued failure to respond to these medications, a diagnostic biopsy is ultimately performed.

MAMMARY AND EXTRAMAMMARY PAGET DISEASE AT A GLANCE

- Rare intraepithelial adenocarcinoma occurring primarily in women.
- Erythematous, scaly, eczematous plaque frequently misdiagnosed as inflammatory or infectious dermatitis.
- Most commonly affected sites: Unilateral nipple/areola complex [mammary Paget disease (MPD)], vulva, perianal skin, scrotum, and penis [extramammary PD (EMPD)].
- Most cases are associated with underlying breast carcinoma (MPD); EMPD not usually associated with underlying neoplasm but may be present in minority of cases.

▲ **FIGURE 121-1** Paget disease of the nipple. Sharply circumscribed erythematous and scaly plaque involving the nipple and areola.

▲ **FIGURE 121-2** Extramammary Paget disease. Moist, well-demarcated, eroded, oozing plaque on the scrotum and inguinal fold in an older man.

Cutaneous Lesions

MPD frequently presents as a unilateral, erythematous, scaly plaque or patch involving the nipple and occasionally the areola (Fig. 121-1). Ulceration and weeping with an eczematous appearance is frequently present. Nipple erosion and discharge may occur. Retraction of the nipple can be seen. Pain, burning, and pruritus are frequently reported by patients. See Box 121-1 for differential diagnosis of MPD and EMPD.

Lesions of EMPD are clinically similar to MPD and often present as a well-defined, moist, erythematous, scaly, eczematous patch. Hypo- and hyperpigmentation can occur. Burning and intense pruritus are commonly reported. Lesions typically involve apocrine gland–bearing skin (i.e., groin and axilla); the most frequent site is the vulva, but perineal, scrotal (Fig. 121-2), perianal (Fig. 121-3), and penile skin are also common areas. Rarely, ectopic EMPD has been reported in areas that are relatively free of apocrine glands, such as the chest, abdomen, thigh, eyelids, face, and external auditory canal.[7–11] Given the unclear association with underlying carcinoma in EMPD as compared to MPD, a palpable mass is much less frequently found on examination.

Related Physical Findings

Up to one-half of all patients with MPD have a palpable underlying breast mass.[4,5,12,13] Of those patients with a palpable underlying tumor, half have axillary adenopathy due to lymph node metastasis.[4,5] Palpable lymph nodes are much less frequently present in EMPD. Complete physical examination is required in all cases of MPD and EMPD for indications of metastases and underlying malignancy. Patients may present with symptoms and physical findings associated with any underlying carcinoma.

Laboratory Tests

PATHOLOGY The intraepidermal adenocarcinoma of EMPD and MPD has a similar histologic appearance. There are groups, clusters, or single cells within the epidermis that show nuclear enlargement with atypia, prominent nucleoli, and well-defined ample cytoplasms (Fig. 121-4).[12] Intercellular bridges are absent. The cells can be within all levels of the epidermis and can compress but preserve the basal layer without junctional nest formation. The cells can extend into the contiguous epithelium of hair follicles and sweat gland ducts. Acanthosis, hyperkeratosis, and parakeratosis are often present. These cells have a "pagetoid" appearance and simulate other intraepidermal malignancies, including melanoma, pagetoid squamous cell carcinoma in situ, mycosis fungoides, cutaneous adnexal carcinomas (sebaceous carcinoma, porocarcinoma, and others), Merkel cell carcinoma, Langerhans cell histiocytosis, and other epidermotropic cutaneous metastases. The cells of MPD and EMPD can be pigmented, which should not necessarily indicate they are melanocytic.

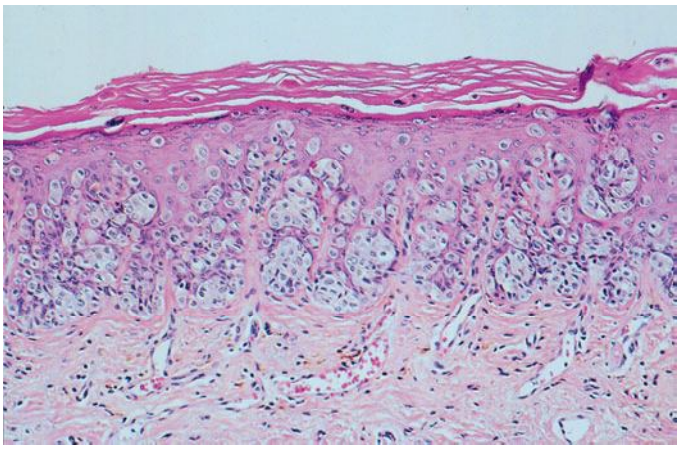
Paget's cells have intracellular mucopolysaccharides, with EMPD having a greater amount of mucin as compared

Box 121-1

Differential Diagnosis of Mammary (MPD) and Extramammary Paget Disease (EMPD)

	Most Likely	*Consider*	*Always Rule Out*
MPD	Nipple eczema	Hailey-Hailey disease	Bowen disease
	Erosive adenomatosis	Pemphigus	Basal cell carcinoma
	Psoriasis		Malignant melanoma
	Dermatophyte infection		
EMPD	Candidiasis	Lichen sclerosus et atrophicus	Bowen disease
	Tinea cruris	Pemphigus	Erythroplasia of Queyrat
	Psoriasis	Lichen simplex chronicus	Malignant melanoma
	Seborrheic dermatitis	Lichen planus	
	Nummular dermatitis	Drug eruption	

▲ **FIGURE 121-3** Perianal Paget disease presenting as moist, superficially eroded patch. (Used with permission from Robert Spencer, MD.)



▲ **FIGURE 121-4** Paget disease, hematoxylin and eosin stain. Paget's cells have distinctive pale-staining cytoplasm and are usually randomly dispersed throughout the epidermis.

to MPD. As a result, cells frequently show positive staining for periodic acid-Schiff and diastase resistance, mucicarmine, Alcian blue at pH 2.5, and colloidal iron (see eFig. 121-4.1 in online edition). However, there are can be focal "skip areas" that are devoid of mucin, resulting in negative stains.

Immunohistochemistry is a useful adjunct in making the correct diagnosis. Low-molecular-weight cytokeratin stains cytokeratin 7 (CK7) and anti-cytokeratin (CAM 5.2) are sensitive markers for both MPD and EMPD (see eFig. 121-4.2 in online edition). They are not completely specific, however, with both Toker and Merkel cells showing CK7 positivity. The cells of MPD and EMPD may stain with carcinoembryonic antigen and epithelial membrane antigen. The most useful keratin markers for Paget disease are CAM 5.2 and CK7, as they stain more than 90 percent of Paget's cells but do not react with epidermal or mucosal keratinocytes.[13,14] The cells of pagetoid squamous cell carcinoma in situ typically do not stain with CK7 and CAM 5.2. S100 and HMB-45 are useful markers to exclude melanoma, as both are typically negative in MPD and EMPD.

CK20 positivity has been found more frequently in cases of secondary EMPD with underlying carcinoma as compared to those cases of primary intraepithelial EMPD ($CK7^+/CK20^-$).[15]

Gross cystic disease fluid protein-15 (GCDFP-15) is a marker for apocrine epithelium and is typically positive in primary EMPD not associated with underlying neoplasm. In contrast, GCDFP-15 is frequently negative in those cases of secondary EMPD with an associated malignancy.[16]

Mucin core protein (MUC) expression is useful in the diagnosis of MPD and EMPD.[17] MUC1 positivity is noted in both MPD and EMPD. MUC2 expression is generally negative in primary EMPD, but may be expressed in those cases of secondary EMPD with an associated underlying gastrointestinal adenocarcinoma. MUC5AC is frequently positive in primary EMPD and less commonly noted in secondary EMPD or those cases of primary intraepithelial EMPD that becomes invasive.

SPECIAL TESTS Diagnosis of MPD and EMPD should be accompanied by a thorough search for underlying malignancy. Mammography is indicated in all cases of MPD, with biopsy of any underlying breast mass.

In cases of EMPD, workup is directed toward the possibility of an underlying gastrointestinal or genitourinary neoplasm. Imaging of the abdomen and pelvis, colonoscopy, barium enema, cystoscopy, intravenous pyelogram, chest x-ray and mammogram (for the rare association of EMPD and MPD), and blood work are appropriate tests. Some reports have suggested that positron emission tomography scans may be useful for cases of invasive EMPD to evaluate for lymph node involvement and metastases.[18,19]

COMPLICATIONS

Failure to identify and adequately treat cases of MPD can lead to metastatic disease with a poor prognosis. EMPD, if left untreated, can become invasive with a less favorable outcome.

PROGNOSIS AND CLINICAL COURSE

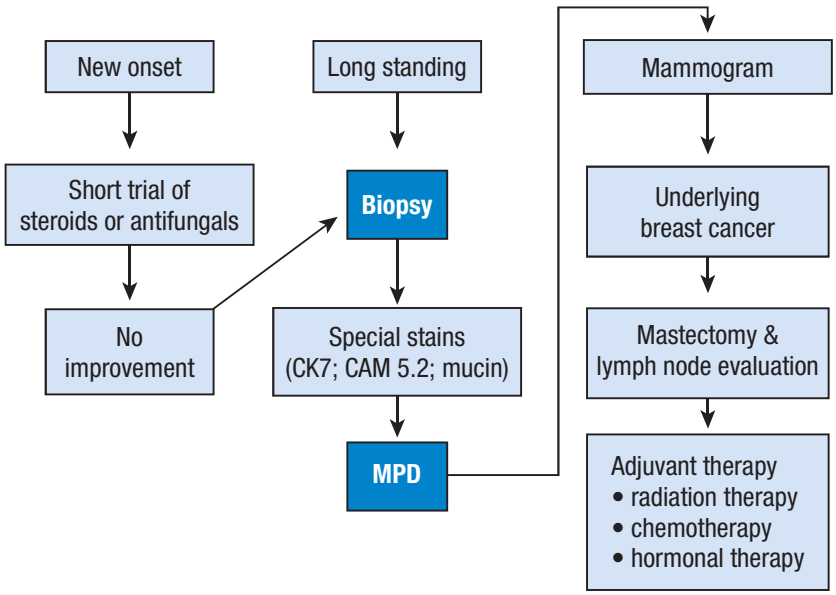
Overall survival in patients with MPD is affected by lymph node status and the presence of an underlying breast mass. Patients with negative lymph nodes have been shown to have a 10-year survival rate of 75 percent to 95 percent, whereas those with positive lymph nodes have a survival rate of 20 percent to 45 percent.[4] Patients with a palpable breast mass have a 5-year survival probability of 35 percent to 51 percent, as compared to 75 percent to 82 percent in patients without a palpable mass.[5]

The prognosis for primary EMPD confined to the epidermis is excellent with appropriate treatment. Careful monitoring for early detection of local recurrence is critical given the multifocal pattern often present in EMPD. In contrast, invasive EMPD has a high rate of metastasis and carries a poor prognosis. The depth of invasion appears to be an important prognostic factor, with microscopic invasive disease (less than 1 mm) having a more favorable prognosis as compared to those with deeper invasion.[20,21] Lymphovascular invasion and regional lymph node metastases markedly reduces overall survival rate and indicates a very poor prognosis. Clitoral EMPD has been shown to have a higher incidence of death from the disease as compared to other vulvar EMPD locations.[20] In cases of secondary EMPD, the prognosis is related to the underlying carcinoma.

TREATMENT

Mammary Paget Disease (Fig. 121-5)

Treatment of MPD is surgical. However, optimal surgical management of MPD remains to be defined, and treatment choice is frequently based on the presence or absence of an underlying breast mass. Mastectomy remains the standard definitive treatment. However, evidence suggests that MPD treated with breast-conserving surgery results in local control and survival rates similar to those achieved with mastectomy.[22,23] Proper preoperative imaging is required to rule out multi-focal disease that would make breast-conserving therapy less effective and favor mastectomy.[24] Lymph node evaluation via axillary dissection or sentinel lymph node biopsy must be considered in MPD. Adjuvant therapy with radiation, chemotherapy, or hormonal therapy is recommended based on lymph node status and specific features of the primary tumor.[4] All diagnoses of MPD require referral to a physician with expertise in the management of breast cancer.



▲ **FIGURE 121-5** Approach to the patient with mammary Paget disease (MPD). CAM 5.2 = anti-cytokeratin stain; CK7 = cytokeratin 7 stain.

Extramammary Paget Disease (Fig. 121-6)

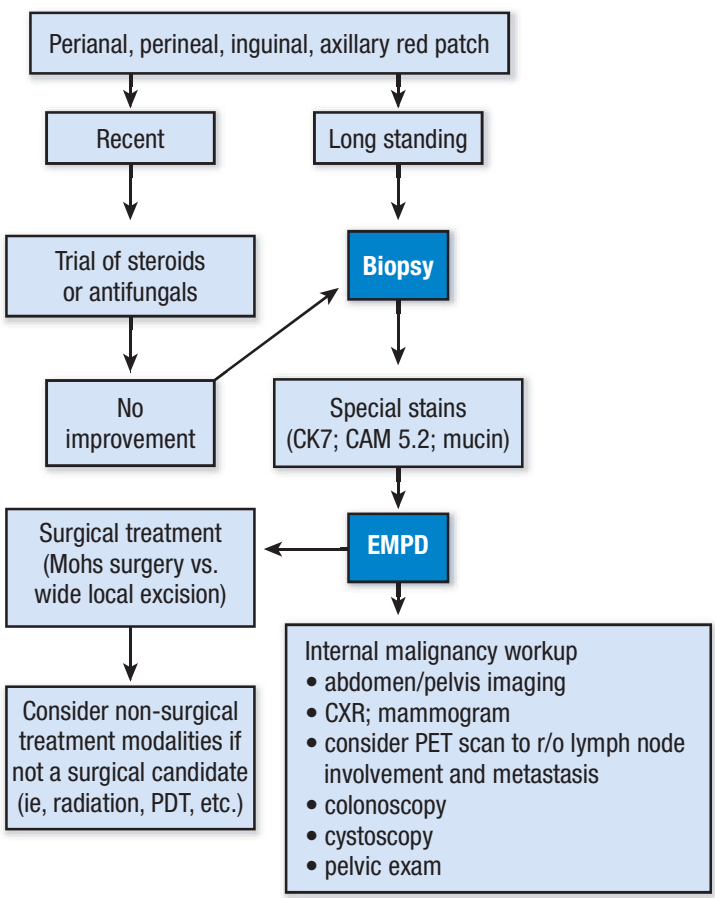
EMPD has been treated with a variety of different modalities. Although surgical management of the disease is the most frequently used method, various other treatments have a role for non-surgical candidates and as adjuvant therapy.

SURGERY Surgery remains the treatment of choice for EMPD when tolerated by the patient. However, high local recurrence rates are seen after standard surgical excision, even with wide margins. This is most likely due to the irregular margins, multi-focal nature of the condition, and subclinical involvement of apparently unaffected skin.

Several reviews have shown an overall recurrence rate of up to 44 percent with wide local excision,[2,25] The local recurrence rates are higher in cases of invasive disease as compared to those limited to intraepithelial involvement. In addition, more radical and extensive surgeries are associated with lower rates of local recurrence. Patients with primary vulvar EMPD treated with radical vulvectomy, radical hemivulvectomy, and wide local excision have reported recurrence rates of 15 percent, 20 percent, and 43 percent, respectively.[25]

Multiple scouting biopsies to help delineate the extent of the disease before surgery can be a useful adjuvant technique.[26] Intraoperative staining with CK7 is the preferred immunostain for intraoperative tissue evaluation.[27] Sentinel lymph node biopsy has been described in the treatment of EMPD.[28] Although this technique has been limited to a small number of reported patients and most cases of EMPD have in situ disease, sentinel lymph node biopsy may prove beneficial for those patients with increased risk of lymph node involvement and metastasis (i.e., dermal invasion of Paget's cells).[29]

MOHS MICROGRAPHIC SURGICAL EXCISION Given the high rates of local recurrence and the significant morbidity associated with radical and repeated surgeries, Mohs micrographic surgical excision (MMS) has been used to improve cure rates and for tissue sparing of critical genitourinary anatomic structures as compared to wide local excision.[2,27,30,31] The recurrence rate after treatment with MMS has been reported as 16 percent for primary EMPD and 50 percent for recurrent EMPD. Ninety-seven percent of the cases treated with MMS required margins of 5 cm from the clinical tumor margin. However, if surgical margins of only 2 cm were used, as may be the case because wider margins may not be feasible when operating on the genitalia, only 59 percent of



▲ **FIGURE 121-6** Approach to a patient with extramammary Paget disease (EMPD). CAM 5.2 = anti-cytokeratin stain; CK7 = cytokeratin 7 stain; CXR = chest x-ray; PDT = photodynamic therapy; PET = positron emission tomography; r/o = rule out.

the tumors would have been cleared. The 40 percent expected recurrence rate with 2-cm margins is consistent with what is seen in various reports of EMPD treated with standard wide excision. This further validates a potential benefit of frozen horizontal sectioning to evaluate 100 percent of the surgical margin and reduces the possibility of residual tumor, which may result from narrow margins in standard excision.

RADIOTHERAPY Although surgery remains the traditional treatment for EMPD, radiotherapy may be indicated in those patients who are poor surgical candidates or are concerned with the morbidity of genitourinary function due to extensive surgery that is often required for curative treatment.[32–34] In addition, radiotherapy has been described as useful for local recurrence after surgery or as an adjuvant therapy in those patients with a high risk of recurrence.[34,35] No randomized controlled studies comparing surgery to radiotherapy have been performed to date.

TOPICAL CHEMOTHERAPY AND IMMUNOMODULATORS Topical agents, including 5-fluorouracil (5-FU) and imiquimod, have been used to treat EMPD with varying degrees of success.

5-FU may be useful as a preoperative adjunctive treatment to highlight the subclinical extent of disease before MMS or for early postoperative detection of recurrence.[36] However, topical 5-FU has not proven to be a reliably curative agent in the treatment of EMPD.[37] This is likely due to the limited penetration of the drug and the inability to reach the deeper epidermal layers and adnexal structures that are frequently involved in EMPD.

Imiquimod has been reported to result in clinical and histologic cure in several case reports.[38–42] Given the limited number of patients treated with this medication, further studies and long-term follow-up in a larger cohort is necessary.

SYSTEMIC CHEMOTHERAPY Systemic chemotherapy has been used to treat patients with invasive and metastatic disease and may be considered in rare cases in which surgery and radiotherapy are contraindicated. Limited reports of systemic chemotherapy for the treatment of EMPD have been described, including a combination of low-dose 5-fluorouracil and cisplatin[43]; a combination of 5-FU, cisplatin, mitomycin C, epirubicin, and vincristine[44,45]; and docetaxel.[46,47]

PHOTODYNAMIC THERAPY Given the patchy nature of EMPD and extension beyond clinically visible tumor, photodynamic therapy (PDT) is a potentially useful treatment modality. Although the limited number of studies and reports makes further investigation necessary, PDT may be considered in patients who are poor surgical candidates, are at risk for significant functional morbidity due to the anatomic location of the disease, or have recurrent postsurgical disease.[48–51] Limiting treatment to intraepithelial disease is prudent given the limitations of current PDT technology. PDT has been described as an adjuvant to surgical treatment to better define clinical margins and improve recurrence rates.[27]

PREVENTION

Both EMPD and MPD are not preventable diseases. Rather, early diagnosis is the key to a favorable prognosis, and any unilateral eczematous rash on the breast or in the groin that does not respond to an appropriate course of topical treatment warrants a biopsy. Routine mammography may allow early detection of underlying breast carcinoma in women of appropriate screening age.

SECTION 22

MELANOCYTIC TUMORS

CHAPTER 122

Benign Neoplasias and Hyperplasias of Melanocytes

James M. Grichnik
Arthur R. Rhodes
Arthur J. Sober

Benign melanocytic proliferative lesions form a spectrum of disorders ranging from a massive accumulation of cells in multiple tissue elements to epidermal foci with a simple increase in epidermal melanocyte number. Here these lesions are separated into *melanocytic neoplasias* and *melanocytic hyperplasias.* The term *melanocytic neoplasia* is used to describe the presence of melanocytic cells in epidermal nests (defined as three or more melanocytic cells in direct contact (also known as *thèque*), within the dermis, or in other tissues. The melanocytic neoplasms are referred to as nevi (singular: nevus) and the melanocytic cells forming these nevi are referred to as *nevomelanocytes*. The term *melanocytic hyperplasia* is used to indicate increased melanocytes confined to the basal layer of the epidermis.

The specific molecular events causing melanocytic neoplasias and hyperplasias are still largely unknown. Given the identification of specific mutations (such as B-RAF)[1] and the clonal nature of nevi,[2–4] it is likely that these lesions are derived from a single progenitor cell and are the result of the dysregulation of specific cellular pathways. Given the presence of immature (less melanized) cells in many melanocytic neoplasias, it seems likely that specific underlying mutations disrupt normal melanocytic development and result in accumulation of the nevomelanocytic cells that do not complete typical migration and differentiation. The melanocytic hyperplasias are comprised of epidermal melanocytes at an increased concentration and thus alterations of normal melanocytic homeostatic mechanisms appear to be operative. These alterations could be due to a primary melanocytic defect (such as an ultraviolet-induced mutation) or homeostatic signaling changes in the local environment (possibly driven by mutations within the local keratinocytes, fibroblasts, or other resident cells).

Until discrete molecular markers are better defined, definitive subclassification of these melanocytic lesions is not possible. This heterogeneous group of disorders is currently loosely subcategorized based on clinical features and microscopic characteristics. The neoplasias described include congenital nevomelanocytic nevi (CNNs), nevus spilus, common acquired nevomelanocytic nevi (excluding atypical/dysplastic nevi covered in Chap. 123), blue nevi, pigmented spindle cell nevi (PSCN), Spitz nevi, and nodal nevi. Cutaneous melanoma is covered separately in Chap. 124. The benign melanocytic hyperplasias described in this chapter include lentigo simplex (including agminated lentigines) and solar lentigines.

CONGENITAL NEVOMELANOCYTIC NEVI

Epidemiology

The vast majority of CNNs noted at birth are small and singular, and no gender predilection has been demonstrated. The most reliable prevalence rate for CNN in a homogeneous ethnic group was obtained by biopsying all pigmented lesions in 841 white infants examined within 72 hours of birth: Of 21 infants with pigmented lesions, 7 babies (0.83 percent of 841) had a biopsy-confirmed nevomelanocytic nevus.[5] Many other series have yielded equivalent results. CNNs of 99 mm or more in diameter occur in only 1 of every 20,000

CONGENITAL NEVOMELANOCYTIC NEVUS AT A GLANCE

- Melanocytic neoplasm often exhibiting extensive nevomelanocytic infiltration of the dermis with potential involvement of the underlying adipose and muscular tissue.
- The lesions may be small or cover a substantial portion of the body surface. They are generally darker than the surrounding skin, have a rugated or smooth elevated surface, and may demonstrate long, darker, thicker hairs.
- Present at birth (or shortly thereafter—tardive congenital nevomelanocytic nevus).
- Large lesions have a significant risk of melanoma development. Cranial or midline lesions and large congenital nevomelanocytic nevus lesions with satellite lesions have an increased risk of leptomeningeal involvement.
- Synonyms: garment nevus, nevus pigmentosus et pilosus, giant nevus, verrucous nevus, and giant pigmented nevus.

▲ **FIGURE 122-1** Familial aggregation of small congenital nevomelanocytic nevi. Note small congenital nevus on the thigh of a 3-year-old white boy and on the back of his 5-year-old male sibling.

newborns, and CNNs with a garment distribution occur in only 1 of every 500,000 newborns.[6] Familial aggregation has been demonstrated for both large and small varieties of CNN (Fig. 122-1). Discordance for giant CNNs has been demonstrated for identical twins in at least three cases and for non-identical twins in two cases.

Etiology and Pathogenesis

CNNs represent a developmental abnormality of normal melanocytic development. This is presumably due to mutation (potentially NRAS)[7] that occurs in a progenitor cell that results in the abnormal extensive accumulation of melanocytic cells along migration pathways during normal development. The events leading to the nevomelanocyte accumulation may also have effects on the surrounding tissue (i.e., increased length/darker hair) possibly due to changes in the local cytokine environment of the nevomelanocytic cells. Clinical findings such as a congenital divided nevus of the eyelid (Fig. 122-2) can give us insight into when these events occur.[8] The eyelids form at between 5 and 6 weeks in utero, begin to fuse at about 8 to 9 weeks, and reopen during the sixth uterine month.[9] Because of the contiguous nature of this lesion on the upper and lower eyelids, it may be presumed that the nevomelanocytes migrated into this location sometime during or after eyelid fusion but before the eyelids split.

Clinical Findings (Fig. 122-3)

HISTORY Most CNNs are present at birth; however, there are also rare varieties of relatively large nevomelanocytic nevi (> 1.5 cm) that appear for the first time between 1 month and 2 years of life, according to parental observations and corroborated by photographs (tardive congenital nevi).

▲ **FIGURE 122-2** Congenital divided nevomelanocytic nevus of the eyelid. The nevus is contiguous when the eyelids are closed, suggesting that the lesion was formed in the developing fetus before the eyelids split (i.e., before 24 weeks).

As a child grows, the CNN should grow relatively proportionally[10] and continue to "mature." History of disproportionate growth, especially after 6 months, or change in a non-uniform manner is of concern for possible melanoma.

Both small and large varieties of CNNs have been associated with loss of pigmentation, halo depigmentation, and even regression.

CUTANEOUS LESIONS Although CNNs are on average larger than acquired nevi, for lesions less than 1.5 cm in diameter there is no specific size limitation that can be used to predict reliably whether a given nevus is congenital or acquired. Lesions attaining a diameter of 1.5 cm or more are likely to be congenital, atypical melanocytic nevi, or melanoma.

There is no completely satisfactory way to categorize CNNs as small or large. Definitions have been based on ease of removal and termed *small* if they can be excised and the wound defect closed primarily without significant deformity. Arbitrary size criteria have also considered small (< 1.5 cm; see eFig. 122-3.1 in on-line edition), medium (1.5 to 19.9 cm), and large (≥ 20 cm). Size, of course, is all relative to the location and the patient. *Giant* has been variously defined as a lesion as large as the patient's palm if it occurs on the head and neck (and twice that area for other anatomic sites), 30 percent of the body surface, or 900 cm^2 in adults (or smaller if it involves a major anatomic area) (see Congenital Nevomelanocytic Nevus At a Glance figure). Depending on the definition used, lesions that are regarded as small or medium in the newborn period may be designated medium or large, respectively, by late childhood or adulthood, given that CNNs appear to grow in proportion to the affected anatomic site.[10]

Pigmented lesion present at birth, macular or papular, may be extensive.
If diagnosis is not clear a small biopsy may be indicated.
Differential diagnosis includes café au lait macule (CALM), dermal melanocytosis (Mongolian spot), and epidermal nevus

↓

Cranial or midline large CNN and large CNN with satellite lesions, have an increased risk of neurocutaneous/leptomeningeal involvement.
MRI may be indicated

↓

When deciding whether lesion is to be excised or observed, one must weigh risk of melanoma, cosmetic and functional issues against anesthesia, surgical and scarring risks.

↓

Any lesion that is non-uniform in appearance on a single examination or demonstrates a non-uniform change over time must be considered for excision to rule out melanoma

▲ **FIGURE 122-3** Approach to the patient with congenital nevomelanocytic nevus (CNN). MRI = magnetic resonance imaging.

The contour of CNNs is usually smooth, regular, and sharply demarcated, and skin markings distort the skin surface at least slightly when assessed by oblique lighting. Some CNNs are relatively hairless. However, coarse, long, darkly pigmented hair may be present at birth, appear within the first year or two of life, or be delayed for several years. Lesions may have a smooth, pebbly, rugose, verrucous, cerebriform, or grossly lobular surface. CNNs with a cerebriform appearance may present as cutis verticis gyrata.

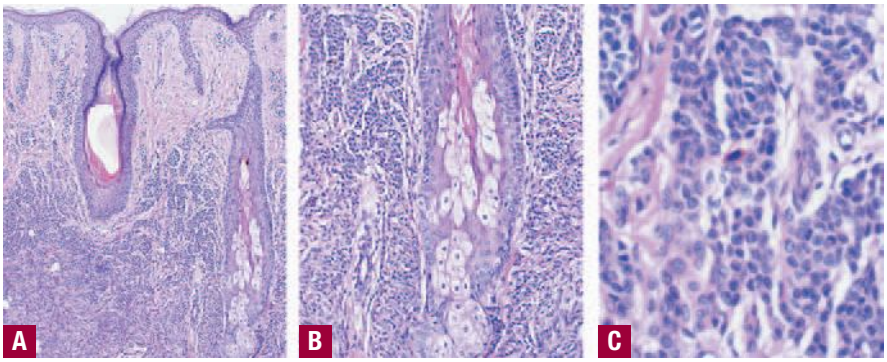
Dermoscopy may reveal a reticular pattern or globular/cobblestone pattern and may be useful in the identification of small foci of melanoma. In large congenital nevi, there can be significant variability in pigmentation and structure, and melanomas may develop in the deep components potentially reducing the utility of dermoscopy in these lesions.

Unique varieties of CNNs may have an atypical appearance and be striking for their haphazard, very dark-brown, black, or blue-black pigmentation or discontinuous pigmentation and poorly demarcated and/or irregular outlines, often associated with atypical histopathologic features. Very darkly pigmented CNNs are distinctly uncommon in whites and should suggest the possibility of atypical histopathologic features. In darkly pigmented infants, CNNs are usually darkly pigmented.

RELATED PHYSICAL FINDINGS CNNs of the head, neck, or posterior midline, and/or the presence of multiple satellite lesions associated with large CNN may be complicated by underlying cranial and/or spinal leptomeningeal melanocytosis. This phenomenon may be asymptomatic or may give rise to communicating or noncommunicating hydrocephalus, seizures, focal neurologic deficits, mental retardation, or even melanoma. CNNs need not be giant to be associated with this underlying disorder.

There is a significant association between neurofibromatosis and giant CNNs. In a study by Crowe et al.,[11] 3 of 223 patients with neurofibromatosis had extensive CNNs. In his monograph on neurofibromatosis, von Recklinghausen described 1 of 28 patients as having a giant CNN.[12] Tumors indistinguishable from neurofibroma in the absence of von Recklinghausen neurofibromatosis may develop in association with giant varieties of CNN.

Malignant degeneration of large CNNs may be associated with the relatively sudden appearance of a dermal or subcutaneous nodule, very dark pigmentation, itching, pain, bleeding, or ulceration. Often, CNN-associated melanomas appear to have evolved in nonepidermal locations.[13] Therefore, early detection of melanoma in association with a giant CNN may be difficult and not recognized until a dermal nodule or metastatic disease appears. The prognosis for patients who develop melanoma in association with giant CNNs is usually grave.[13] Unlike melanoma in general, there is no ethnic predilection for melanoma developing in giant CNN. There have been multiple cases of lethal melanoma developing in association with giant CNNs in black children.



▲ **FIGURE 122-4** Histopathologic features of congenital nevomelanocytic nevus. Nevomelanocytes in the low-magnification image (**A**) reveal dense accumulation in the lower two-thirds of the dermis; at medium magnification (**B**), these cells encroach on dermal adnexal structures (follicular and eccrine); and higher magnification (**C**) reveals dense collections of small nevomelanocytic cells.

Laboratory Tests

HISTOPATHOLOGY CNNs are characterized by the presence of nevomelanocytes in the epidermis as well-ordered thèques and/or nevomelanocytes in the dermis which are present as sheets, nests, cords, and/or single cells. Although histopathologic features are cited as being useful in distinguishing nevi as congenital or acquired, there are no known features with absolute specificity and sensitivity. The histopathologic features of very large CNNs may be divided into nevomelanocytic, neuroid, epithelioid cell and/or spindle cell, blue, and mixed types.

In the nevomelanocytic type of large CNN, the histopathologic appearance may be identical to typical acquired nevi, with nevomelanocytes in the epidermis as well-defined thèques and/or nevomelanocytes in the papillary dermis as sheets, cords, or nests. CNNs are more likely than acquired nevi to have nevomelanocytes in the lower two-thirds of the reticular dermis and to be associated with appendageal and neurovascular structures (Fig. 122-4). There may be preferential involvement of one or more epithelial structures in CNN, such as eccrine ducts, and these structures may be abundant and malformed. Veins may be preferentially involved, with an "inflammatory" appearance showing nevomelanocytes within and around blood vessel walls. Subendothelial protrusion by nevomelanocytes in lymphatic vessels may be prominent. Arrector pili may be malformed, large, and infiltrated by nevomelanocytes. Hair follicles are often quite large and frequently associated with abundant melanin in the hair bulb. Nevomelanocytes in the deep reticular dermis may be distributed as single cells or as a single-file array insinuating among collagen bundles, sheets of cells, or combinations of patterns.

Unique to the very large CNN is the occasional presence of nevomelanocytes within the substance of muscle, bone, placenta, umbilical cord, cranium, and dura mater. Very extensive CNN may be intermixed with elements of vascular malformation, hemangiomas, increased numbers of mast cells, cartilage, calcification, and even bone. There may be sparse mononuclear cell infiltrates associated with some giant CNNs. In addition to melanoma, associated tumors developing in CNN include schwannoma, neuroid tumor, lipoma, rhabdomyosarcoma, neurofibroma, sebaceous nevus, hemangioma, lymphangioma, and mastocytoma. A possible explanation for these mixed neoplasms containing melanocytic, neuronal, and other elements is that the CNN precursor cell, at least in some cases, is a pluripotent stem cell that has the capacity to give rise to multiple cell types.

In giant CNNs, nevomelanocytes have been found in regional lymph nodes

without further evidence of progressive metastatic disease. Whether this deposition occurred during the migration of the cells through the dermis or was secondary to migration from the skin after the neoplasm developed is unknown. The presence of nevomelanocytes in the nodal tissue from these lesions does not imply malignancy (see nodal nevi).

CNNs may also give rise to proliferative nodules that may be difficult to differentiate from melanoma.[14]

SPECIAL TESTS For patients with concern of possible leptomeningeal involvement, magnetic resonance imaging should be considered. For patients with concern of melanoma, positron emission tomography scan may be considered.

Differential Diagnosis (Box 122-1)

Complications

The relationship between melanoma and large CNNs is well documented. The risk of melanoma development appears to be proportional to the size of the congenital nevus. The cumulative 5-year risk has been calculated to be 2.3 percent[15] and 5.7 percent[16] in patients with congenital nevi that involve over 5 percent of the body surface. The lifetime risk of melanoma for patients with very large CNNs has been estimated to be at least 6.3 percent, based on a questionnaire follow-up study of 151 persons with CNNs examined between 1915 and 1973 in Denmark.[17] Melanoma may develop in large CNNs at any time, but the diagnosis of melanoma was established in the first 3 to 5 years of life in approximately one-half of published cases in which patients ultimately developed melanoma in association with giant CNN.

A causal association between small CNNs and melanoma is more difficult to establish than for large CNNs. When histopathologic features were studied, 6 percent to 8 percent of primary melanomas were found to be in contiguity with nevi that had microscopic features characteristic of CNN.[18,19] These findings support the concept of melanoma risk even with small congenital nevi, given the expected chance association based on body-surface-area considerations.[20]

For cranial, midline, or CNN with multiple satellite lesions, there is a risk of leptomeningeal involvement. Symptomatic leptomeningeal melanocytosis carries a poor prognosis, even in the absence of malignant degeneration.

Box 122-1

Differential Diagnosis of Congenital Nevomelanocytic Nevus

- Café-au-lait macule
- Nevus spilus
- Lentigo simplex
- Nevus of Ota/Ito
- Dermal melanocytosis (mongolian spot)
- Becker's melanosis
- Arrector pili (smooth muscle) hamartoma
- Epidermal nevus
- Nevus sebaceous
- Solitary mastocytoma

Prognosis and Clinical Course

CNNs have a dynamic evolution during body growth. CNNs at birth usually distort the skin surface at least slightly when assessed by oblique lighting and may become more elevated over time. Surface pigmentation also may change. Lightly pigmented CNNs may become more darkly pigmented, and darkly pigmented CNNs eventually may become less pigmented. CNNs also may develop a halo of depigmentation, potentially heralding spontaneous regression. Loss of pigmentation has been associated with regression of underlying nevomelanocytes and the replacement with sclerosis in some cases. Relatively hairless CNNs at birth may develop long, dark, coarse hair or may maintain a relatively normal hair density. With few exceptions, CNNs generally expand in direct proportion to growth of a given anatomic zone, although disproportionately rapid area expansion of some congenital nevi may occur during early infancy.[10] Lesions in fully grown individuals should remain stable.

Treatment

The treatment of CNNs, large and small, depends on the perceived risk of melanoma plus cosmetic and functional considerations.

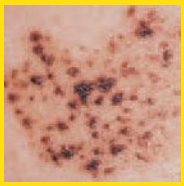
Melanoma may arise in very large CNNs even in the first several years of life. Therefore, excision of very large CNNs should be considered as early as possible, but it is probably prudent to wait until after the first 6 months of life to reduce surgical and anesthetic risks. Management of patients with very large CNNs must be individualized. Extensive involvement of the body surface, with little or no normal skin available for graft sites, may necessitate abandoning efforts at prophylactic excision and accepting lifelong surveillance to detect the earliest signs of malignant change. It may be impossible to remove every nevomelanocyte in very large CNNs, particularly when there is involvement of vital structures or deep anatomic zones. The treatment goal is to remove as much of the nevus as possible while preserving function and improving cosmetic appearance. Tissue expansion and artificial skin replacement are invaluable in repairing large wound defects. Other indications for surgical excision of very large CNNs include chronic pruritus, ulceration, and infection. Unlike surgical excision, dermabrasion and other modes of destructive therapy do not address the malignant potential of CNN; nevomelanocytes may still be left behind in the dermis, and the cosmetic results associated with destructive therapy are unpredictable. Melanoma has been reported after dermabrasion of large CNNs.[21] "Pseudomelanoma" has been described after laser treatment of a giant CNN.[22]

The approach to small CNNs needs to be considered carefully. It appears that the risk of melanoma development depends on CNN size, and therefore, smaller lesions appear to have less risk. However, due to the smaller size, complete excision of small congenital nevi may be relatively straightforward, resulting in excellent cosmetic results. Although atypical-appearing CNNs should be considered for immediate excision, careful surveillance without excision may be an option for clinically benign lesions depending on gross appearance, size, location, cosmetic and functional deficits (or improvement) resulting from excision, and general health issues. Given the risk of general anesthesia, for lesions perceived to be at low risk during the first decade of life it is appropriate to consider waiting until the child is old enough to tolerate local anesthesia. All CNNs should be documented at birth, preferably in the form of high-quality photographs that can be used to aid follow-up by parents and physicians. Follow-up is complicated by the natural evolutionary changes that take place in a nevus during body growth (i.e., surface, size, color, and hair), and periodic updates of photographs may be warranted. Suspicious changes in color, surface, or size require urgent evaluation.

Prevention

There is no known preventive approach to avoid the development of congenital nevi. Ultraviolet radiation (UVR)–induced mutations clearly play no role

NEVUS SPILUS AT A GLANCE



- Localized collection of melanocytic neoplasias forming in the background of a melanocytic hyperplasia. The neoplastic elements within the lesion tend to be histologically similar in appearance. In some lesions, the darker elements may only demonstrate increased hyperplasia compared to the background lesion.
- Clinically, the lesion appears as a hyperpigmented patch with scattered darker elements clinically similar in appearance.
- Background lesion may be present at birth but generally develops during infancy or early childhood. The neoplastic or hyperplastic elements may continue to develop within the lesion over time.
- Overall, risk is low but melanoma has been noted to develop in nevus spilus.
- Nevus spilus (derived from Greek *spilos*, meaning *spot*)—spotted nevus. Synonyms: speckled lentiginous nevus and zosteriform lentiginous nevus.
- Related variants with localized collection of nevomelanocytic neoplasias without the background of melanocytic hyperplasia are referred to as agminated nevomelanocytic nevi.
- Related variants with localized collection of melanocytic hyperplasias without the background of melanocytic hyperplasia are referred to as *agminated lentigines* (see Lentigo Simplex).

in the initial development of the lesions already present at birth. There is no current data on parental exposure that may give rise to congenital nevus formation in their offspring. The role of subsequent UVR exposure for secondary development of melanoma is unclear. However, it seems prudent to protect lesions from unnecessary UVR exposure.

NEVUS SPILUS

Epidemiology

Nevus spilus occurs in less than 0.2 percent of newborns, 1 percent to 2 percent of white school children, and 2 percent of white adults.[23] There are no prevalence data in darkly pigmented persons. There does not appear to be a gender predilection.[23] When viewed as a risk marker for melanoma, nevus spilus shows a trend for being more common in melanoma cases than in controls. Kopf et al.[23] detected nevus spilus in 5 (4.8 percent) of 105 white adults with melanoma compared with 14 (2.3 percent) of 601 dermatology outpatients.

Etiology and Pathogenesis

Nevus spilus may be postulated to develop along similar pathways as a congenital nevus, but instead of the underlying mutation creating a massive accumulation of nevomelanocytic cells in the dermis, the genetic defect creates a field of cells that are susceptible to a secondary event leading to the development of focal individual melanocytic neoplasms within the localized melanocytic hyperplasia. The specific mutations, chromosomal aberrations (mosaicism), and/or dysregulated pathways involved in this process are unknown.

Clinical Findings (Fig. 122-5)

HISTORY Rarely, nevus spilus may be present at birth. More commonly, the lesion becomes evident during infancy or early childhood. More darkly pigmented, flat, or raised elements are usually present when the lesion is first recognized, but new pigmented elements may appear over time.

CUTANEOUS LESIONS Clinically the lesion presents as a circumscribed macule/patch of tan pigmentation with features consistent with lentigo or café-au-lait macule including scattered, more darkly pigmented nevomelanocytic (or more hyperplastic) macular and/or papular elements (see figure in At a Glance box). The tan macular background pigmentation ranges from less than 1 cm to greater than 10 cm in diameter (Fig. 122-6). Although nevus spilus may occur anywhere, lesions have been noted primarily on the torso and extremities. A divided nevus spilus of the eyelid has been reported.[24] Lesions may be localized or have a segmental distribution. Giant varieties of nevus spilus may occur.

RELATED PHYSICAL FINDINGS Nevus spilus has been associated with other anomalies of vascular, central nervous system, or connective tissue origin. Multiple granular tumors and nevus flammeus have been associated with a giant nevus spilus.

Laboratory Tests

HISTOPATHOLOGY The tan background pigmentation usually consists of increased numbers of melanocytes in a lentiginous epidermal pattern. Routine and electron microscopic studies of nevus spilus may demonstrate melanin macroglobules in some cases. The flat, dark elements of nevus spilus may demonstrate foci of increased melanocytic hyperplasia or melanocytic dysplasia (architectural disorder and variable cellular atypia), whereas the raised elements usually contain collections of nevomelanocytes in the epidermis and/or dermis. The neoplastic elements of nevus spilus also may consist of epithelioid and/or spindle cell nevi, nevi with dysplastic features, or blue nevi.

SPECIAL TESTS There are no identified molecular tests of value, at least currently.

Differential Diagnosis (Box 122-2)

Complications

There are insufficient data to be certain of the natural history of nevus spilus or to comment specifically about its malignant

Background evenly hyperpigmented patch but also including scattered hyperpigmented foci. Wood's light may be required to visualize background hyperpigmention.

↓

New hyperpigmented foci may develop over time.
If one of the foci is unusual compared to the others, is non-uniform, and/or changing, it should be excised to exclude the possibility of melanoma.

▲ **FIGURE 122-5** Approach to the patient with nevus spilus.

▲ **FIGURE 122-6** Nevus spilus. **A.** Nevus spilus appearing first at age 3 years on the ankle and foot of a 25-year-old white woman. **B.** Congenital nevus spilus on the arm of a 10-year-old white male.

potential; however, caution must be exercised in affected individuals. Melanoma has been noted to develop in contiguity with nevus spilus, with some cases ending in metastatic disease and death.

Prognosis and Clinical Course

In general, nevus spilus is a benign lesion that may develop more spotted elements over time. Once developed, nevus spilus lesions are presumed to persist throughout life, although it is possible that some elements within the nevus spilus or even the entire nevus spilus itself could regress with time. There are no long-term follow-up studies of nevus spilus.

Treatment

No standard guidelines exist for the management of patients with nevus spilus. Clinical appearance (typical or atypical), history of stability or instability of pigmented elements, congenital or noncongenital onset, perceived risk of developing melanoma, and cosmetic concerns are considerations when determining whether to excise or recommend periodic clinical evaluation for life. Atypical-appearing new and/or unstable elements in nevus spilus should be evaluated by histopathologic examination to exclude melanoma. A nevus spilus with dysplastic or congenital features may have a greater risk of developing melanoma.[25,26]

Box 122-2

Differential Diagnosis of Nevus Spilus

- Agminated nevomelanocytic nevi
- Agminated lentigines
- Becker melanosis
- Congenital nevomelanocytic nevus
- Café-au-lait macule

Prevention

It is theoretically possible that increased UVR exposure results in the development of new nevomelanocytic proliferations or increased malignant potential of nevus spilus.

COMMON ACQUIRED NEVOMELANOCYTIC NEVUS

Epidemiology

Common (also called *typical*) acquired nevomelanocytic nevi develop after birth, slowly enlarge symmetrically, stabilize, and after a period of time may regress. The majority of common acquired nevi appear to develop during the second and third decades of life, although some lesions may appear in the first 6 to 12 months of life.

A number of studies have quantified the number of typical acquired nevi in different age groups. In 432 European whites between the ages of 4 days and 96 years, nevi that were 3 mm in diameter or larger were detected in females and males, respectively, at median numbers of 0 and 2 in the first decade, 10 and 16 in the second decade, 16 and 24 in the third decade, 10 and 19 in the fourth decade, 12 and 15 in the fifth decade, 4 and 12 in the sixth decade, and 2.0 and 3.5 in the seventh through the ninth decades.[27] In a series of Australian whites, the average number of nevi per person peaked at 43 for males and 27 for females during the second and third decades, respectively, and decreased to very few in the sixth and seventh decades.[28] A similar age-related prevalence rate for nevi has been documented in other countries. A difference in frequency distribution of nevi according to gender is not clear, although most series show a close to equal prevalence in males and females.

The prevalence of acquired nevi varies according to ethnicity. In African blacks, the overall prevalence of nevi (regardless

COMMON ACQUIRED NEVOMELANOCYTIC NEVUS AT A GLANCE

- A spectrum of nevomelanocytic neoplasias often subcategorized based on location of cells: cells in the epidermis (junctional), dermis (intradermal), or both areas (compound). Pathologically, the cells in the deeper dermis tend to be smaller in size and express melanocytic antigens at reduced levels.
- Clinically, the lesions tend to be uniform in appearance and relatively small in size.
- Primarily develop during childhood/young adulthood.
- Increased numbers of acquired nevi suggest an increased risk for melanoma development (see Chap. 124).
- Synonyms: nevus cell nevus, nevocellular nevus, nevocytic nevus, soft nevus, neuronevus, pigmented nevus, pigmented mole, common mole, melanocytic nevus, hairy nevus, cellular nevus, and benign melanocytoma.

of size) tends to be higher in those with lighter skin versus those with darker skin.[29] When prepubertal whites were examined for nevi, a significant association for excess nevi was documented for pale skin, blue or green eyes, blond or light-brown hair, and a tendency to sunburn, but not a tendency to freckle.[30] Other studies show variable relationships to these same parameters.

Environmental exposure to UVR appears to be a critical permissive or inciting factor for the development of nevomelanocytic nevi. In an Australian study, nevus density has been shown to increase with increasing sun intensity in the northern parts of the continent.[31] Furthermore, the use of UVR-blocking sunscreens has been shown to decrease the number of new nevi in children.[32]

Genetic factors appear to play a role in the development of nevomelanocytic nevi. The size, frequency, and distribution patterns of acquired nevi tend to aggregate in families. This observation is well documented for atypical nevi in the setting of familial cutaneous melanoma (see Chap. 124) and CNN.

Acquired nevi may be attacked by the patient's immune system, resulting in the development of a halo nevus (see History). Of 8298 whites aged 12 to 16 years, there were 51 males (1.2 percent) and 22 females (0.5 percent) who had one or more halo nevi, for an overall prevalence rate of 0.9 percent.[33] In one large series of halo nevus,[34] individuals ranged in age from 3 to 42 years (mean age, 15 years), with the vast majority of cases occurring before age 20 years.

Etiology and Pathogenesis

There has been an ongoing debate as to the origin of nevi. Although many theories have been proposed, and some supporting data are available, the critical events leading to nevus development remain a mystery. Current data suggest that nevomelanocytic nevi are clonal,[2–4] and a specific B-RAF[1] mutation has been identified and is likely to play a role in the majority of common acquired (including atypical) and congenital nevi. However, the B-RAF mutation does not seem to play a major role in blue nevi or Spitz nevi. H-RAS may play a role in some Spitz nevi, but it is clear that many more mutations are yet to be identified and correlated with the different nevus phenotypes.

Melanocytic "precursor" cells have been shown to be present in adult human skin,[39] and melanocytic stem cells have been identified in the epidermis in murine system.[40] It is assumed that these melanocytic stem cells accumulate mutations, and when needed to replenish melanocytes, they produce nevomelanocytes instead. Presumably, these nevomelanocytes then attempt to migrate along normal developmental pathways from the dermis into the epidermis. Dependent on the underlying mutation, some cells might also migrate aberrantly. The defect, timing, and local tissue influences could allow for the creation of a variety of different melanocytic neoplasias.

The clinical phenomenon of eruptive nevi also further confounds the location of the cell of origin issue. In these patients, there is the abrupt appearance of numerous similar appearing nevi often in the setting of immunosuppression or chemotherapy. Although it is generally assumed that these lesions all directly originate in the skin, drawing a comparison with epidermotropic metastatic melanoma leaves open the possibility of a circulating nevomelanocytic precursor.

Clinical Findings (Fig. 122-7)

HISTORY Acquired nevi primarily develop during childhood and early adulthood. Although nevi can clearly persist in a stable state for decades, many eventually regress. In a study following patients with dysplastic/atypical nevi, the highest rate of nevus development and nevus regression was present in patients younger than 30 years of age.[42] In later adult years, nevus counts are significantly less than those in young adulthood, and new nevi are rare, but melanoma is more prevalent. Thus, a growing lesion in an adult has a greater risk of being melanoma.

Spontaneous and concurrent development of scattered nevomelanocytic nevi often similar in appearance has been termed *eruptive nevi*. Often, these patients have experienced a blistering skin disease, immunosuppression, or chemotherapy. Eruptive nevi may have a pattern consistent with common acquired nevi, but Spitz nevi and blue nevi have also been described.

Patients may also present with the history of spontaneous development of a zone of depigmentation around a preexisting nevus. This phenomenon has been called a *halo nevus*. The halo phenomenon may be associated with acquired and CNN as well as with melanoma and non-melanocytic tumors. This phenomenon often, but not always, indicates the onset of involution and subsequent regression of the melanocytic nevus. Other names for this phenomenon include *leukoderma acquisitum centrifugum, Sutton's nevus, leukopigmentary nevus, perinevoid vitiligo,* and *perinevoid leukoderma*. Time for full evolution to depigmentation of the halo is not known, but patients report the phenomenon occurring over days to weeks, with little change occurring in the halo thereafter. The central nevus may persist or eventually disappear. Disappearance may take months to years. Areas of depigmentation that remain after the central nevus disappears may remain stationary for many years or re-pigment after months to years. There are lesions in which the nevus does not involute, and repigmentation of the depigmented halo may occur.

CUTANEOUS LESIONS Common acquired nevi vary considerably in their gross appearance. In general, appearance to the naked eye is orderly: The lesions have a homogeneous surface and coloration pattern, round or oval shape, regular outlines, and relatively sharp borders (Fig. 122-8). Common acquired nevi may be papillomatous, dome-shaped, pedunculated, or flat-topped and usually are flesh-colored, pink, or brown. More elevated acquired nevi tend to be more lightly pigmented, and flatter acquired nevi tend to be more darkly pigmented. More elevated and less pigmented lesions tend to have a prominent intradermal nevus component, whereas flatter and darker lesions have a more prominent junctional melanocytic or nevomelanocytic component and a less prominent dermal component. Very dark brown and black are unusual colors for common acquired nevi in lightly pigmented people. In contrast, dark pigmentation is usual for common acquired nevi in people who have darkly pigmented skin. Blue, gray, red, and white areas in a nevus are not typical features and ought to be viewed with suspicion. The surfaces of nevi may reveal hair that is less than, equal to, or greater than that of surrounding skin. Hair in nevi may be coarser, longer, and darker than that in surrounding skin (often these lesions reveal congenital features). Lesions on palms and soles are usually hairless. Size, shape, skin markings, and hair quality of nevi in darkly pigmented races are similar to those in whites.

Dermoscopy reveals a number of diagnostic patterns in common acquired nevi. In general, these lesions reveal a reticular or globular pattern. On the palms or soles, a parallel-furrow, lattice, or fibrillar pattern may be present. Non-

Acquired nevi are prevalent and benign. Melanoma is infrequent but deadly. One of the best tools for the differential diagnosis of an acquired lesion is dermoscopy.

↓

Dermoscopy

Step 1: establish whether a lesion is melanocytic or non-melanocytic

Classic melanocytic patterns
reticular, parallel, globular, homogenous, and starburst.

Classic non-melanocytic patterns
fingerprint, fissures, comedo-like and milia-like structures (as in seborrheic keratoses), red lacunas or sacular structures (as in hemangiomas), and spoke wheel, leaf, and ovoid structures (as in basal cell carcinaomas).

↓

Step 2: further evaluate lesions that are melanocytic or not clearly non-melanocytic for findings that may suggest melanoma. These findings may include a multi-component pattern, asymmetric dots, radial streaming, blue white veil, and irregular vascular structures. Lesions suggesting the possibility of melanoma should be excised.

↓

Dermoscopy will not be able to discriminate some of the early melanomas from acquired nevi. In order to identify these early melanomas, an additional three-step approach is recommended.

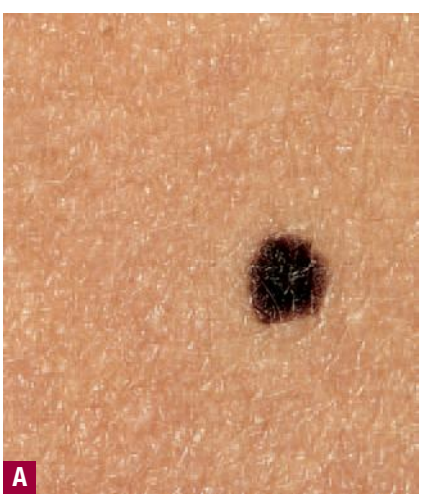
1. Is the lesion unusual? Unusual lesions would be those identified by patient as concerning, not matching the patient's average type of mole, and/or not displaying a clearly benign dermoscopic pattern.
2. Is the lesion growing? Patient history or photographic documentation may help. Baseline total skin photographs of patients at high risk for melanoma are invaluable for detecting new or changing lesions. Keep in mind that all acquired nevi are new and grow at some point, so growth alone is not a sufficient reason for excision.
3. Does the lesion have non-uniform features? As melanomas develop, they become more non-uniform. A lesion that is unusual and changing should be excised. In addition, if non-uniform features are also present, the concern for melanoma is further increased.

▲ **FIGURE 122-7** Approach to the patient with acquired nevomelanocytic nevus.

uniform patterns and parallel-ridge patterns are worrisome for melanoma.

Pigmented nevi of the nail apparatus may be a dark or light brown, extending from the nail matrix to the distal edge of the nail plate (see eFig. 122-8.1 in online edition; see Fig. 87-19 in Chap. 87); extension of the pigmentation onto the skin of the nail fold or beyond the distal nail groove should be considered suspicious for melanoma. Nevi on palms and soles, even compound nevi, may not distort the skin surface, perhaps because of a thickened stratum corneum in these sites.

The typical halo nevus has a pink or brown central nevomelanocytic nevus surrounded by a symmetric round or oval halo of depigmented skin. The central nevus may be small in typical acquired nevi, or large in acquired atypical or congenital nevi (Fig. 122-9). The halo of depigmentation is variable in size, usually a radial zone 0.5 to 5.0 cm around the central lesion. White hairs may be seen in hair-bearing depigmented areas. Alopecia areata surrounding a halo nevus has been reported. The number of halo nevi per person may be one or many, multiple lesions occurring in 25 percent to 50 percent of patients. For patients who have multiple lesions, only a few nevi are usually affected, but as many as 90 halo nevi have been reported in a single person. Any nevus in any anatomic site may be involved, but the posterior torso is involved most commonly. Lesions are usually asymptomatic. UVR may cause redness and even blistering in the perinevic halo. An atypical gross appearance of the central nevus or an asymmetric halo of depigmentation around a suspicious nevus, particularly in adults, should raise suspicion for melanocytic dysplasia or melanoma. The depigmented halo associated



◀ **FIGURE 122-8** Typical acquired nevomelanocytic nevi. **A.** Junctional nevus. A uniformly dark brown macule, round in shape, with smooth, regular border. **B.** Two compound nevi. A uniformly pigmented papule and domed nodule. The upper lesion is flatter and tan with slight central elevation. The lower lesion is older and is uniformly elevated due to an increased intradermal component.

▲ **FIGURE 122-9** Halo nevomelanocytic nevus. **A.** Acquired halo nevus on the chest of a 16-year-old white boy whose maternal grandmother had melanoma. **B.** Acquired halo nevi on the back of a 6-year-old white boy who has dysplastic nevi in the hairy scalp and a history of melanoma in his maternal grandmother. Scale in millimeters. **C.** Halo congenital nevomelanocytic nevus on the neck of a 4-year-old female of a black African-American mother and white father. This child also had scattered areas of vitiligo-like depigmentation in other sites. A 3-year follow-up after excision of the nevus revealed almost total repigmentation of the widely scattered previously depigmented areas.

with melanoma tends to be irregular and surrounds the tumor asymmetrically, and the central lesion usually has an atypical appearance.

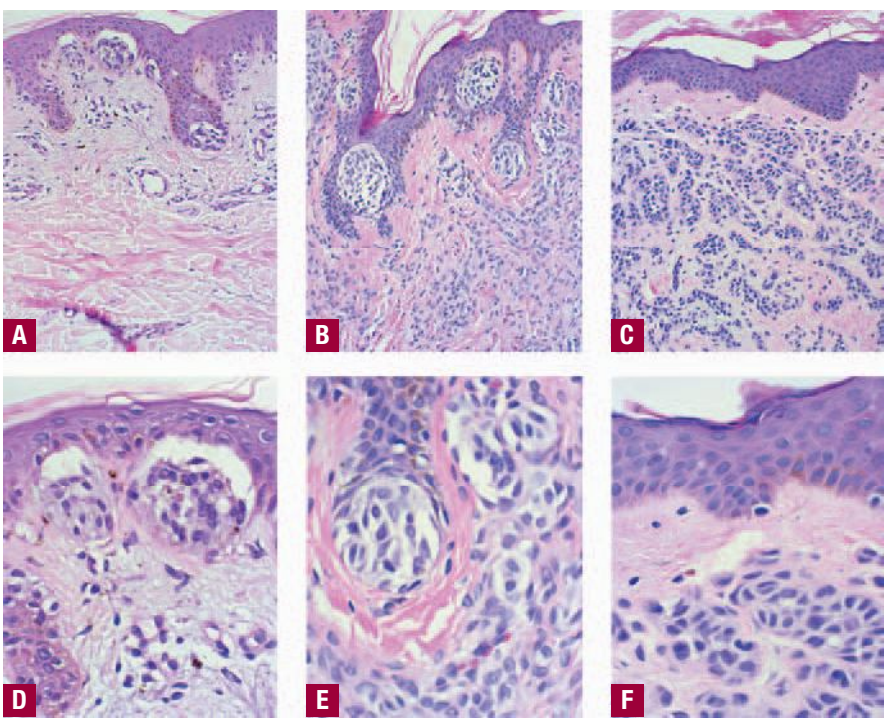
A second process that may provide some insight into factors involved in melanocytic interactions with the immune system is a process that results in the development of an eczematous dermatitis presenting as a red halo around nevi (halo dermatitis). Unlike halo nevi, regression of the nevus does not usually occur, and the eczematous changes clear over the course of several months.

RELATED PHYSICAL FINDINGS For patients with multiple nevi, there is an increased risk for cutaneous melanoma (see Chap. 124). This risk is further increased in the setting of atypical nevi and/or a personal or family history of melanoma. For patients with eruptive nevi, there may be findings suggestive of a blistering disease or immunosuppression. For patients with halo nevi, the most common associated condition is vitiligo, occurring in 18 percent to 26 percent of patients. Halo nevus may be associated with poliosis, Vogt-Koyanagi-Harada syndrome (see Chap. 72), pernicious anemia, and a personal or family history of melanoma (including ocular melanoma). Relatively large and numerous nevi are common in Turner syndrome and Noonan syndrome.

Laboratory Tests

HISTOPATHOLOGY Nevomelanocytes in the epidermis have a nuclear size similar to or larger than nuclei of epidermal melanocytes. Nevomelanocytes are arranged in nests surrounded by a smooth perimeter of epidermis and separated from nevomelanocytes by a retraction artifact (Fig. 122-10). Nevomelanocytes have abundant pale-staining eosinophilic cytoplasm and may have pseudopodic or dendritic extensions that are more evident when enzymatic or immunohistochemical techniques are used for visualization. Nuclei of nevomelanocytes are pale-staining, characterized as vacuolated or reticulated; a nucleolus is usually visible.[43] Epidermal melanocytes between junctional thèques of nevomelanocytes in typical nevomelanocytic nevi are disposed as single typical cells, with overall numbers equal to or slightly greater than that in adjacent sun-exposed skin (see Fig. 122-10).[44] The overlying epidermis is often normal in appearance but may be thickened in a lentiginous pattern (elongated and club-shaped rete ridges), with an appearance similar to seborrheic keratosis complete with horn cysts or epidermal verrucous hyperplasia similar to epidermal nevus.

The dermal component of nevi has an orderly progression from top to bottom, with larger epithelioid cells above (epi-



▲ **FIGURE 122-10** Histopathologic features of acquired nevi. Junctional nevus (**A**) and higher magnification (**D**). Compound nevus (**B**) and higher magnification (**E**). Intradermal nevus (**C**) and higher magnification (**F**). Well-formed nests of nevomelanocytes are present in the junctional and compound nevi. Sheets and cords of nevocytes are present in the dermis of the compound and intradermal nevi. A grenz zone free of nevomelanocytes is present just below the epidermis in the intradermal nevus (**C** and **F**).

dermis and superficial papillary dermis) blending into a pattern of smaller cells in the deeper dermis.

Some acquired lesions are found to have congenital features (reviewed earlier in Congenital Nevomelanocytic Nevi) suggesting that though these features may be present in congenital nevi, they are not limited to those present at birth. Others may be found to have atypical features (see Chap. 123).

Inflammatory cellular infiltrates in typical, stable acquired nevi are usually scanty[43] or absent. Melanin-laden macrophages are usually apparent in the superficial papillary dermis of nevi, their number usually proportional to degree of melanin production.[43] Blood vessel proliferation, eosinophilic fibrosis, and lamellar fibroplasia (features frequently seen in atypical melanocytic nevi) are usually not prominent in typical acquired nevi. Langerhans cell density overlying typical acquired nevi and atypical nevi is increased compared with adjacent skin.[46]

Intradermal nevi that have few or no junctional nests frequently have a grenz zone relatively free of nevomelanocytes just below the epidermis (see Fig. 122-10).

The *balloon cell nevus* is composed of peculiar foam cells comprising a portion or all of a given lesion. In addition to clear cells with single basophilic nuclei, multinucleated balloon cells and multinucleated giant cells are seen frequently. Electron microscopic studies suggest that the vacuolization of the nevomelanocytes is due to enlargement and destruction of melanosomes. There appears to be no distinguishing gross features of balloon cell nevi.

The *combined nevus* refers to the in-contiguity association of different types of melanocytic nevi. Most combined blue nevi are found in association with a benign compound nevus (acquired or congenital).

Recurrent melanocytic nevus (pseudomelanoma) is the name given to recurrent lesions after incomplete removal of a benign nevomelanocytic nevus.[47] Recurrent nevi are relatively common after superficial destructive procedures (i.e., shave biopsy or dermabrasion). A markedly atypical clinical and histopathologic appearance may accompany this recurrence, making these lesions worrisome for possible melanoma. Clinically, the recurrent nevus is confined to the scar but may be markedly irregular. Histopathologically, the recurrent lesions often demonstrate the presence of melanocytic hyperplasia in a lentiginous or junctional pattern (often to a greater extent than the original nevus). Moderate nuclear atypia may be present in 12 percent of recurrent nevi, mitotic figures in 8 percent, and pagetoid upward migration in 3 percent, raising concern about the potential biologic behavior of some recurrent lesions.[48] It is important to review the original histopathologic specimen when making re-excision and margin decisions.

No definitive pattern has been described for eruptive nevi beyond that for the nevus type.

For halo nevi, the usual histopathologic findings are a central nevomelanocytic nevus associated with a dermal band-like lymphohistiocytic infiltrate and a depigmented zone totally or almost totally devoid of epidermal melanocytes. Immunohistochemical staining [melanoma antigen recognized by T cells (Mart-1), S100 protein, or other melanocytic markers] may help to identify the residual epidermal melanocytes or the nevomelanocytes in the inflammatory infiltrate. The lymphocytes appear to be antigenically stimulated, and 80 percent are T lymphocytes, whereas B lymphocytes are scarce or absent. The T cells appear to belong to the $CD8^+$ population.[49]

The state of the nevus at the time of excision may also influence the histologic appearance. Nevi recently sunburned or traumatized may acutely have features worrisome for melanoma, and these changes resolve as the lesion heals.[52] It is also possible that nevi in their early growth phase also have more concerning features such as epithelioid cell appearance and pagetoid upward migration, but this has not yet been substantiated.

SPECIAL TESTS Special tests are not generally required. However, for patients who have eruptive nevi, given the association with immunosuppression, immunologic tests may be in order. Immunohistochemical profiles may be of value for difficult to diagnose lesions. Low Ki67 activity and loss of HMB45 in dermal (deeper) cells may help confirm a benign diagnosis. Compared to melanoma, common acquired nevi are genomically stable.[53] Gene chip analysis may be a useful way to discriminate these lesions in the future.

Differential Diagnosis (Box 122-3)

Complications

Multiple studies demonstrate that prominent numbers of nevi indicate an increased melanoma risk. Tucker et al.[54] noted a 3.4 (95 percent confidence interval: 2.0 to 5.7) adjusted relative risk for patients with 100 nevi or more (> 2 mm and < 5 mm) compared with those with fewer than 25 nevi. The relative risk was increased to 12 (95 percent confidence interval: 4.4 to 31.0) for patients with 10 or more atypical nevi compared with patients without atypical nevi. Absence of direct site specificity of nevi

  - Sarcoidosis
  - Psoriasis
  - Angioma

and melanoma suggests that nevus proneness per se indicates a general melanoma risk,[55] largely independent of hair and eye color and overall sun exposure.[56] Other traits, including skin color and freckles, may be multiplicative to the number of nevi in increasing melanoma risk.[57] The annual risk of a melanoma developing in a mole has been calculated to be approximately 1 in 200,000.[58] Furthermore, it has been reported that only 26 percent of melanomas are found in association with nevus elements.[59] Thus, it is possible that the majority of melanomas develop directly from normal skin (see Chap. 124). In patients with numerous nevi (and/or atypical nevi) these nevi are best viewed as risk markers, not precursors (or precancers) of melanoma.

Prognosis and Clinical Course

It is likely that acquired nevi evolve through a life cycle, first becoming apparent after infancy in the vast majority of cases, peaking in number during the second and third decades of life, and then disappearing by the seventh to ninth decades.[27,28,50] Regression of nevi is believed to occur by neuroid, fibrous, mucinous, or fatty degeneration.[49] Transepidermal elimination of nevomelanocytes has also been noted.[51,60] Nevi also may involute during the course of inflammatory halo depigmentation (halo nevi). The pathogenesis of the halo phenomenon is poorly understood. Available evidence suggests that both humoral and cellular factors may be responsible for nevus destruction. Atypical nevi, melanoma, and vitiligo may occur more frequently in individuals with halo nevus.

Eruptive nevi may occur as a spontaneous development of multiple nevi. These nevi are often similar in appearance to each other clinically and histopathologically. Reports generally link the initiating event to a blistering skin disease, systemic immunosuppression, chemotherapy, or treatment with "biologics."[61] The setting allowing for the eruptive nevi may also allow for melanoma development, as reported for some transplant patients, so such patients may need to be monitored carefully.

There may be relatively sudden changes in nevi that are unrelated to malignant transformation. Any single nevus that is noted to suddenly change independently should be cause for concern. Causes of sudden changes in a nevus (color, surface, or size, with or without pain, itching, ulceration, or bleeding) over days or weeks include cystic dilatation of a hair follicle, epidermal cyst formation, folliculitis, abscess formation, trauma, hemorrhage, and, in the case of a pedunculated nevus, strangulation and thrombosis. These benign causes of sudden change may require close observation for 1 to 2 weeks until resolution occurs, or excision for histopathologic examination.

The vast majority of acquired nevi are harmless. New nevi may continue to appear and disappear throughout life, but most develop during childhood and early adulthood. New or growing nevi in older individuals are more worrisome. Melanoma risk appears to be related to the number and size of nevi; patients with numerous nevi, atypical nevi, and a personal or family history of melanoma should be considered for periodic surveillance examinations for life.

Treatment

The vast majority of acquired nevomelanocytic nevi require no treatment. Indications for removal of benign-appearing lesions may include cosmetic concerns or continual irritation. Lesions with worrisome clinical features need to be excised for histopathologic examination. These features are further addressed in Chaps. 123 and 124. Dermoscopy may be used to differentiate benign and potentially malignant features. A photographic medical record can play a critical role in identifying change, or lack of change, in making risk assessments of particular nevi. All acquired nevi have an initial growth phase; other factors such as unusual features and/or non-uniformity must be considered when making a decision as to whether a particular lesion needs to be removed.[41,62]

Although a benign-appearing nevus associated with halo depigmentation need not be removed, it is reasonable to recommend periodic examination of affected individuals for atypical melanocytic nevi, vitiligo, and melanoma. Atypical-appearing central nevi, presence of an asymmetric halo, eccentric placement of a melanocytic lesion in the halo, or the setting of atypical melanocytic nevi and/or melanoma (personal or family) should suggest the need for histopathologic examination for melanoma. Cover-ups or sunscreens should be recommended for sun-exposed areas of depigmentation to prevent acute burn, chronic actinic damage, and carcinogenesis.

Complete removal of nevi is best accomplished by excision. Leaving a partially excised nevus, regardless of the initial pathology, is fraught with potentially concerning consequences of repigmentation and/or regrowth (pseudomelanoma).[47] Incisional biopsy, even for melanoma, is necessary at times, particularly for lesions that cannot be excised easily but require histopathologic diagnosis. Destructive modes of therapy (electrodesiccation, cryotherapy, dermabrasion, and laser) should be avoided and considered very carefully if used in the management of melanocytic and nevomelanocytic nevi. They have the disadvantage of not providing tissue for histopathology. Although dermabrasion has been used to eliminate pigmentation of nevomelanocytic nevi, residual nevomelanocytes in the dermis are to be expected, cosmetic outcome is often unpredictable, and recurrence with worrisome clinical features may complicate future management. Laser treatment of melanocytic and nevomelanocytic lesions has the theoretic risk of malignant transformation, but there is no proof for this.

Prevention

There appears to be a direct relationship between the number of acquired nevi and sun exposure, and a decrease with sunscreen use. Patients at increased risk should be reminded to minimize UVR overexposure. This can be done in a manner that should not impede day-to-day activities but will help reduce melanoma risk. This is best accomplished by first rearranging outdoor activities to the early morning or late afternoon/evening. This avoids the most intense UVR which hits the earth 2 hours either side of high noon. Second, cover-up clothing that blocks light transmission should be worn. Clothing is often easier to put on than sunscreen and does not rapidly wear off with sun exposure or sweating. Finally, sunscreens should be used as part of a comprehensive sun protection program.

BLUE NEVUS

Epidemiology

Blue nevi are present in fewer than 1 of 3000 newborns, in approximately 1 of 1000 aged 5 years or less, in 1 percent to 2 percent of white school children, in 3 percent of Japanese adults, and in 0.5 percent to 4.0 percent of healthy white adults. The vast majority of blue nevi are single, small, deep-blue macules or papules approximately 1 to 2 mm in diameter.

BLUE NEVUS AT A GLANCE

- Melanocytic neoplasia comprised of pigmented melanocytic cells in the mid-dermis. Includes common blue, cellular blue, combined blue, atypical, and large patch/plaque lesions.
- Lesions appear as blue, blue-gray, or blue-black papule, nodule, or plaques.
- Lesions are generally acquired but may be congenital.
- Cellular blue nevi may have an elevated risk for development of melanoma.
- Synonyms: benign mesenchymal melanoma, blue neuronevus, chromatophoroma, melanofibroma, Jadassohn-Tièche nevus, and dermal melanocytoma.
- Related lesions include nevus of Ota/Ito and mongolian spot.

Multiple blue nevi may be associated with lentigines, cardiac myxoma, and mucocutaneous myxomas [lentigines, atrial myxomas, mucocutaneous myxomas, and blue (LAMB) nevi, Carney complex]. Blue nevi have been associated with nodular mastocytosis, and a histogenic relationship has been claimed for melanocytes and mast cells.[63] Blue nevi have been reported to occur in oral mucosa, uterine cervix, vagina, spermatic cord, prostate, and lymph nodes.[64]

Etiology and Pathogenesis

The origin of common blue nevi and cellular blue nevi is unknown, but they may be derived from a mutant precursor cell resulting in the accumulation and differentiation of the melanocytic cells in the dermis instead of their normal location in the epidermis. Differentiation towards hair follicular melanocytes is possible. Some varieties of cellular blue nevi stain for CD34,[65] suggesting a potential "stem cell" origin. Bednar's tumors (dermatofibrosarcoma protuberans including cells with melanocytic marker expression) also express $CD34^+$ suggesting a similar stem cell origin for these tumors with different differentiation pathways.[66] Nevus of Ito/Ota is related to common blue nevi but represents an extensive localized acquired proliferation. The extension of these neoplasms along specific neural pathways may provide insight into the etiology of these dermal proliferations, including the possible role of certain neural factors. Although no specific mutations have been attributed to blue nevi, in the murine system a number of genes have been identified that result in the accumulation of dermal melanocytic cells,[67] and it is possible that some of these mutations may be involved in human dermal melanocytoses.

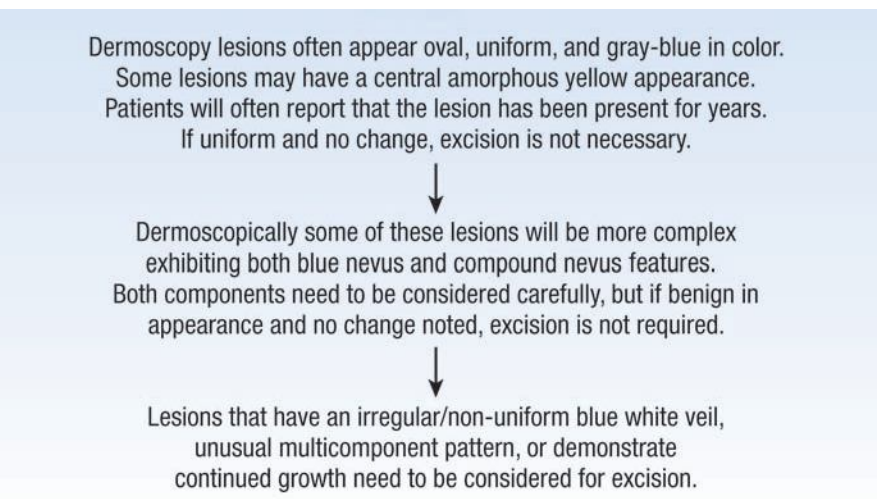
Clinical Findings (Fig. 122-11)

HISTORY Common blue nevi are usually acquired, and once developed should remain stable. Nevus of Ota and Ito may share similar underlying defects to blue nevi and are also often acquired (in early childhood, often before age 1 year or around puberty) but are far more extensive encompassing a portion of trigeminal (ophthalmic and maxillary) and brachial (posterior supraclavicular and lateral cutaneous) nerve distributions respectively. Dermal melanocytosis (mongolian spot) may also be related to blue nevi, but is usually present at birth or within the first few weeks of life and centered over the lumbosacral area. These lesions usually regress in early childhood but may persist in approximately 10 percent of cases.

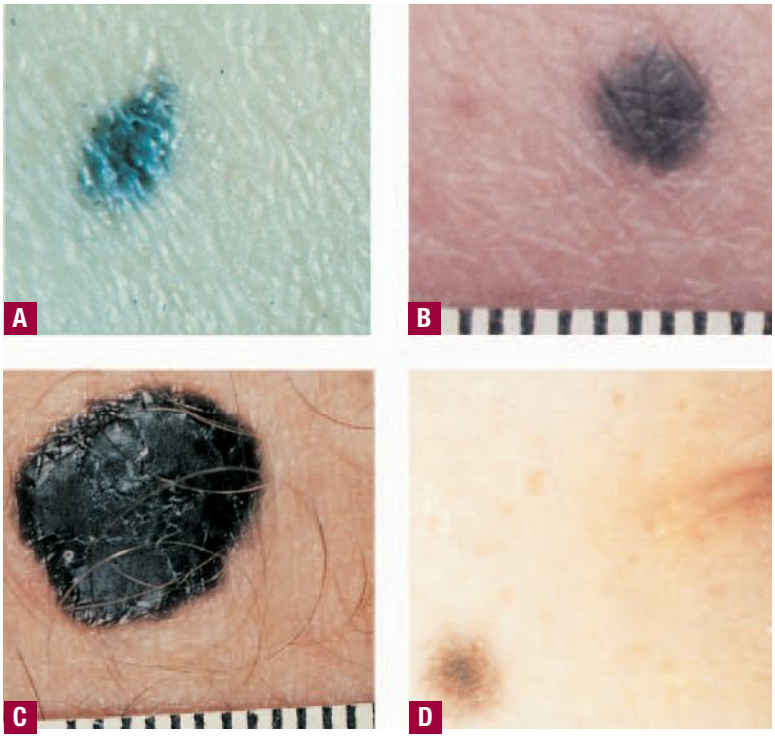
CUTANEOUS LESIONS Common blue nevi are usually solitary, asymptomatic blue, blue-gray, or blue-black papules, usually less than 10 mm in diameter (Fig. 122-12). The blue-gray color of blue nevi is an optical effect of blue light backscatter from the skin over the dermal melanin (Tyndall effect). Hypopigmented, target or targetoid, and combined blue nevi (compound nevomelanocytic nevus and a blue nevus) also exist. Common blue nevi occur anywhere, but about half the reported cases present on the dorsa of hands and feet. Usually, the common blue nevus is singular, but rarely, lesions may be multiple and agminated or arranged in large plaques consisting of multiple solitary papules or nodules with intervening areas of blue discoloration. Common blue nevi also occasionally may have satellite lesions that may be mistaken for melanoma metastasis.[68] Rare giant varieties of congenital blue nevus occur, often with multiple satellite lesions.[13] The large plaque blue nevus (pilar neurocristic hamartoma) may occasionally be associated with a background of lentigo simplex.

The deep penetrating nevus may be considered a unique form of blue nevus, but some would include this lesion in the category of Spitz nevus. Deep penetrating nevi are darkly pigmented, blue-black papules or nodules, mostly on the head and neck or upper extremities, 2 to 9 mm in diameter, and occurring predominantly in the first four decades of life, including childhood.[69]

Cellular blue nevi are blue-gray or blue-brown nodules or plaques 1 to 3 cm in diameter, occasionally larger (see Fig. 122-12C). Their surface is usually smooth but may be irregular. Approximately one-half the cases are located on the buttocks or sacrum. Cellular blue nevi may develop in association with CNN, occasionally with target appearance. Cellular blue nevus differs from the common blue nevus in that it is usually larger, more ele-



▲ **FIGURE 122-11** Approach to the patient with blue nevus.



▲ **FIGURE 122-12** Blue nevus. **A.** Common blue nevus appearing as an acquired blue-gray papule on the shoulder of an 18-year-old white woman. **B.** Common blue nevus appearing as an acquired blue-gray papule on the buttock of a 62-year-old white man. **C.** Cellular blue nevus appearing as a congenital blue papule on the low back of a 30-year-old white man. **D.** Combined common blue nevus–nevomelanocytic nevus appearing as a brown papule with a blue-gray center on the cheek of a 12-year-old white boy, beginning as a pinpoint dot at age 1 year and enlarging slowly over time. Scale in millimeters.

vated, more aggressive locally, and occasionally associated with lymph node "benign metastasis." Complicating the picture is the fact that melanoma may develop in a cellular blue nevus.

Malignant blue nevus (melanoma) may develop in contiguity with a cellular blue nevus, nevus of Ota, combined congenital blue nevus, or de novo. Malignant blue nevus presents as an expanding dermal nodule with or without ulceration. There is some dispute as to whether malignant blue nevus should be considered a separate entity from melanoma or simply referred to as a *melanoma developing in a blue nevus*.

RELATED PHYSICAL FINDINGS The presence of epithelioid blue nevi may warrant consideration of Carney complex/myxoma syndrome/LAMB syndrome, with evaluation for related findings, including atrial myxomas and endocrine tumors.

Laboratory Tests

HISTOPATHOLOGY In common blue nevi, dermal melanocytes appear as melanin-containing fibroblast-like cells grouped in irregular bundles admixed with melanin-containing macrophages, associated with excessive fibrous tissue in the middle or upper reticular dermis, occasionally extending downward to subcutaneous fat or upward to papillary dermis (Fig. 122-13). Elongated melanin-producing dermal melanocytes in common blue nevi usually lie with their long axis parallel to the epidermis. Except in the case of combined blue nevus (with a compound nevomelanocytic nevus component), the epidermis in common blue nevi appears normal. Combined blue nevi have been noted in 1 percent of melanocytic nevi excised for histopathologic examination.[70]

In cellular blue nevi, there is usually a component of a common blue nevus plus fascicles of spindle-shaped cells with ovoid nuclei and abundant pale cytoplasm with little or no melanin, and often epithelioid cells, present in the dermis and often in subcutaneous fat in nests, bundles, and neuroid forms with little or no intervening stroma (see Fig. 122-13C and D). Epithelioid cell and amelanotic varieties of the cellular blue nevus have been described. Epithelioid blue nevi have been reported in association with cardiac myxoma[73] or in isolation.[74] Histopathologic diagnosis may be difficult when the common blue nevus component and melanin production are sparse or inapparent. Differentiation of some cellular blue nevi from melanoma can be difficult. Occasionally, small groups of well-differentiated melanocytes are present in the marginal sinus or parenchyma of lymph nodes draining the anatomic site of the cellular blue nevus, making it difficult to differentiate true metastasis from pseudometastasis. It is likely that "inert" deposits of melanocytes in the capsules and peripheral sinuses of lymph nodes draining some varieties of cellular blue nevus are transported passively (see Nodal Nevi).

The malignant blue nevus is a variant of melanoma, distinguished from cellular blue nevus by invasiveness, cellular atypia, pleomorphism, atypical mitoses, and areas of necrosis.

SPECIAL TESTS Imaging tests of the heart may be required if there is concern for Carney complex/myxoma syndrome/LAMB syndrome.

Differential Diagnosis (Box 122-4)

Complications

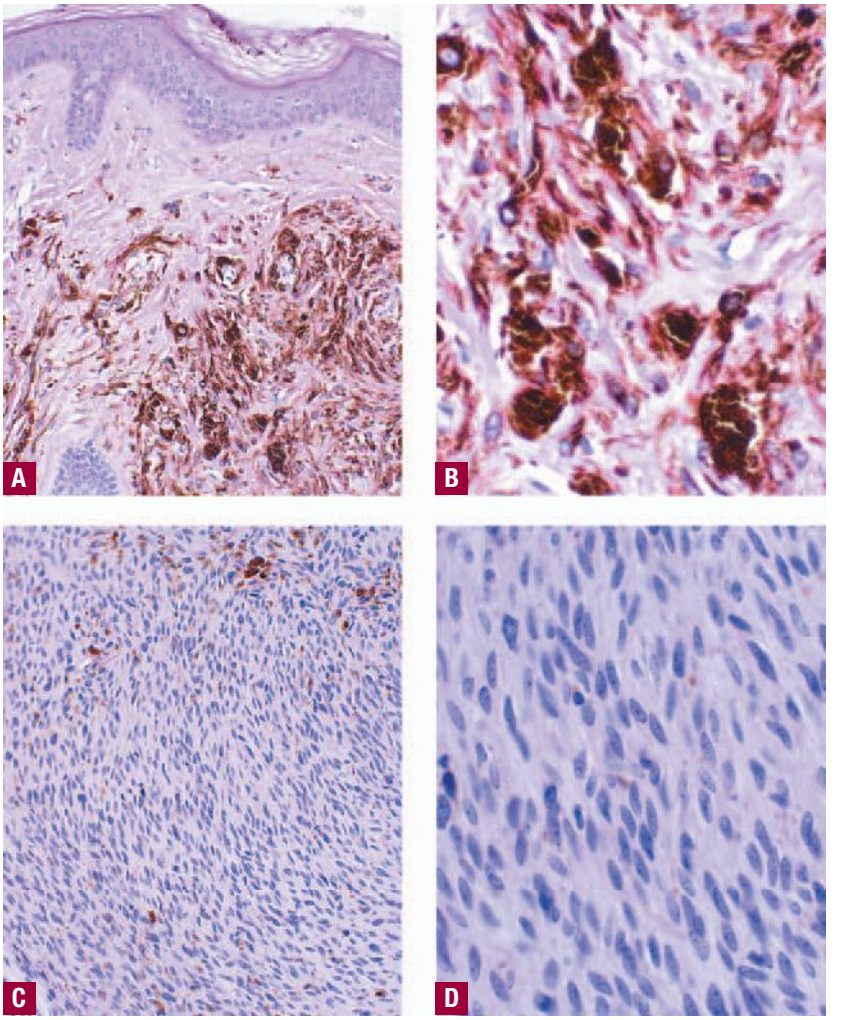
A major complication of blue nevi is the potential risk of melanoma. This risk appears to be highest for cellular blue nevi. Melanoma has been noted to evolve in large blue nevus patches or plaques and in associated with nevus of Ota and Ito.

Prognosis and Clinical Course

The natural evolution has not been studied for common blue nevi or cellular blue nevi. It is likely that once established, blue nevi remain unchanged or possibly regress over time. "Change" is worrisome for melanoma development.

Treatment

A common blue nevus that is stable for many years in an adult usually requires no therapy. Sudden appearance of a blue nodule, expansion of a pre-existing blue nodule, a congenital blue nodule, or a relatively large blue nodule or plaque greater than 10 mm in diameter should be considered for histopathologic examination. Excision should include subcutaneous fat to ensure complete removal of deep dermal melanocytes, which are frequently present in the subcutaneous tissue of cellular blue nevus. The large plaque blue nevus (pilar



▲ **FIGURE 122-13** Histopathologic features of common and cellular blue nevi. Common blue nevus (**A**) and higher magnification of the dermal component (**B**) revealing heavily pigmented, elongated melanocytes. Cellular blue nevus (**C**) and higher magnification (**D**) revealing sheets of melanocytes with ovoid nuclei.

neurocristic hamartoma) requires consideration for excision or periodic evaluation for suspicious change. Cellular blue nevus should be evaluated for excision because of its malignant potential.

Prevention

The causative factor in eruptive blue nevi has been attributed to sun exposure.[75] Thus, as with other nevi, it is reasonable to minimize excessive UVR exposure.

- Primary or metastatic melanoma
- Glomus tumor
- Pyogenic granuloma
- Sclerosing hemangioma
- Dermatofibroma
- Ochronosis

PIGMENTED SPINDLE CELL NEVUS

Epidemiology

The mean age of presentation has been reported as 25.3 years, ranging from 2.5 to 56.0 years of age.[76] Similar age ranges have been reported in other studies.[77] The majority of cases occur in the third decade of life. Female patients outnumber male patients with reported ratios of 2:1,[76] 1.4:1.0,[77] and 1.3:1.0.[78] The majority of these lesions are found on the extremities with reported frequencies of 67.0 percent,[76] 69.6 percent,[78] and 75.0 percent.[77] There is a preference for the lower extremity, especially the thigh, with the back being the next most common site.[77]

Etiology and Pathogenesis

It may be presumed that PSCN are derived from the same progenitor cells giving rise to epidermal melanocytes and nevomelanocytes. No known specific mutation has been identified.

PIGMENTED SPINDLE CELL NEVUS AT A GLANCE

- Acquired, benign melanocytic tumors comprised of heavily pigmented spindle-shaped melanocytic cells confined primarily to the epidermis.
- The pigmented spindle cell presents as a jet black lesion often with "starburst" appearance.
- These nevi are thought to develop quickly and then stabilize.
- Malignant degeneration is thought to be rare.
- Synonyms: Reed nevus, pigmented Spitz nevus.

Clinical Findings (Fig. 122-14)

HISTORY PSCN was first described by Reed in 1975.[79] These lesions are generally detected as acquired lesions, often during the third decade of life. At presentation, patients often note that the lesion has increased in size.[77,78] It is not known how quickly these lesions grow, but growth may be relatively rapid as one case report of a lesion on a 3-year-old child documented significant growth over a 3- and 6-month period.[80] Once fully developed, it is assumed that these lesions will remain stable, but the full natural history of these lesions is not well characterized.

CUTANEOUS LESIONS The PSCN is usually a sharply circumscribed, uniformly darkly pigmented papule[76–78] (Fig. 122-15). Dermoscopically, most of the lesions are jet black but may be blue-gray or brown. In the initial growth phase, the lesions may have a globular appearance[80] but the vast majority of these lesions are uniformly dark centrally, with a sharp interface with surrounding skin often exhibiting streaks/pseudopods and giving the lesion a starburst appearance.

Dermoscopically, this lesion is often diffusely jet black with a sharp well defined border. The border should interface with the skin in a similar (uniform) manner for the full circumference of the lesion. The pattern is often "starburst" in appearance.

↓

Non-uniform edge, active growth, and/or atypical features warrant excision

▲ **FIGURE 122-14** Approach to the patient with pigmented spindle cell nevus.

RELATED PHYSICAL FINDINGS No known association.

Laboratory Tests

HISTOPATHOLOGY PSCN consists of vertically oriented fascicles of spindle-shaped, pigment-producing melanocytes (Fig. 122-16); some pagetoid upward migration may be present, but the lesion can be distinguished from melanoma by uniform nuclei, uniform cellular detail, and distinctive pattern of growth. Almost all cases of pigmented spindle cell nevus have a lymphohistiocytic host response. Spindle cells extend down eccrine ducts in 40 percent and involve hair follicles in 22 percent of lesions.[76] There is an overlap of these lesions with Spitz nevi. In a review of 91 PSCN by Sagebiel et al.,[76] cells were predominantly spindle in 74 percent and mixed spindle cell and epithelioid cell in 26 percent of patients. There are atypical variants of PSCN in which there are architectural alterations and striking cellular atypia.[78]

SPECIAL TESTS No known specific mutation or genetic markers.

Differential Diagnosis (Box 122-5)

Complications

There are no reported complications, but misinterpretation of benign or malignant behavior of the lesion could result in unnecessary or insufficient treatment, respectively.

Prognosis and Clinical Course

The PSCN are thought to be benign. No local recurrence or distant spread was noted for 38 patients followed for an average of 14 months.[76] In another study, 57 patients were followed for an average of 6 years and again no local recurrence or metastasis was noted.[77]

Treatment

If there is clinical concern, these lesions should be excised with a narrow margin of normal skin.

Box 122-5

Differential Diagnosis of Pigmented Spindle Cell Nevus

- Spitz nevus
- Blue nevi
- Hematoma
- Atypical nevomelanocyte
- Melanoma

Prevention

The role of UVR exposure in the development of PSCN is unknown. Generally, it is best to avoid UVR overexposure.

SPITZ NEVUS

Epidemiology

An annual incidence rate of 1.4 cases of Spitz nevus per 100,000 individuals has been estimated in Australia, compared with 25.4 per 100,000 individuals for cutaneous melanoma during the same time interval.[81] Among melanocytic nevi excised in children, 1 percent to 8 percent of cases are interpreted as Spitz nevus.[82] In a case series of 308 patients with Spitz nevi reported by Allen,[83] 15 percent of lesions occurred in adolescents and adults, the oldest patient being 56 years of age. There appears to be no gender predilection for Spitz nevus. Published cases have been described primarily in whites.

Etiology and Pathogenesis

It may be presumed that Spitz nevi are derived from the same progenitor cells that give rise to epidermal melanocytes and nevomelanocytes. Unlike common

SPITZ NEVUS AT A GLANCE

- Spitz nevi represent a spectrum of unique, usually acquired lesions, exhibiting epithelioid and often spindle-shaped melanocytic cells with abundant eosinophilic cytoplasm and large nuclei. Often develop in the dermis with some involvement of the overlying epidermis. Atypical variants exist.
- Clinically, the lesion is often a pink, dome-shaped papule.
- Thought to develop quickly and then stabilize. Their clinical presentation and histopathology can cause diagnostic concern for melanoma.
- Synonyms: Spitz tumor, nevus prominens et pigmentosus, pseudomelanoma, spindle and epithelioid cell nevus, nevus of large spindle and/or epithelioid cells, and compound melanocytoma. The previously used terms *Spitz's juvenile melanoma*, *benign juvenile melanoma*, and *prepubertal melanoma* should not be used.

acquired nevi and congenital nevi, the B-RAF mutation does not appear to be involved. Amplifications of chromosome 11p and H-RAS and activating mutations of H-RAS have been noted in a subset of Spitz nevi.[84] Heritable genetic factors have not been investigated systematically, but there is a single report of multiple tumors in identical twin boys.[82] The role of trauma in the histogenesis of Spitz nevi is speculative. One case has been reported at the site of bacille Calmette-Guérin vaccination.[85]

Clinical Findings (Fig. 122-17)

HISTORY The rate of growth, period of stabilization, and rate of regression of Spitz nevi are not known. The duration of solitary Spitz nevus before presentation is usually less than 9 months. Lesions usually show an increase in radial size over time, some gradual and others rapid.[86] Based on patients with eruptive Spitz nevi, regression has been reported to occur and may even occur in some lesions while new lesions are appearing.[87]

CUTANEOUS LESIONS The most common variety of Spitz nevus is solitary, asymptomatic, pink or red, hairless, firm, and dome-shaped (Fig. 122-18). Some Spitz nevi may resemble a keloid. The surface is commonly smooth, and the borders may fade into surrounding skin. Verrucous, scaly, stippled, crusted, or (rarely) eroded lesions have been noted. Spitz nevi are usually asymptomatic, but pruritus, tenderness, and/or bleeding may occur.[82] A halo of depigmentation has been associated with several cases of Spitz nevus.[33,88] Spitz nevi are part of a spectrum in which some also include PSCN and deep penetrating nevi.

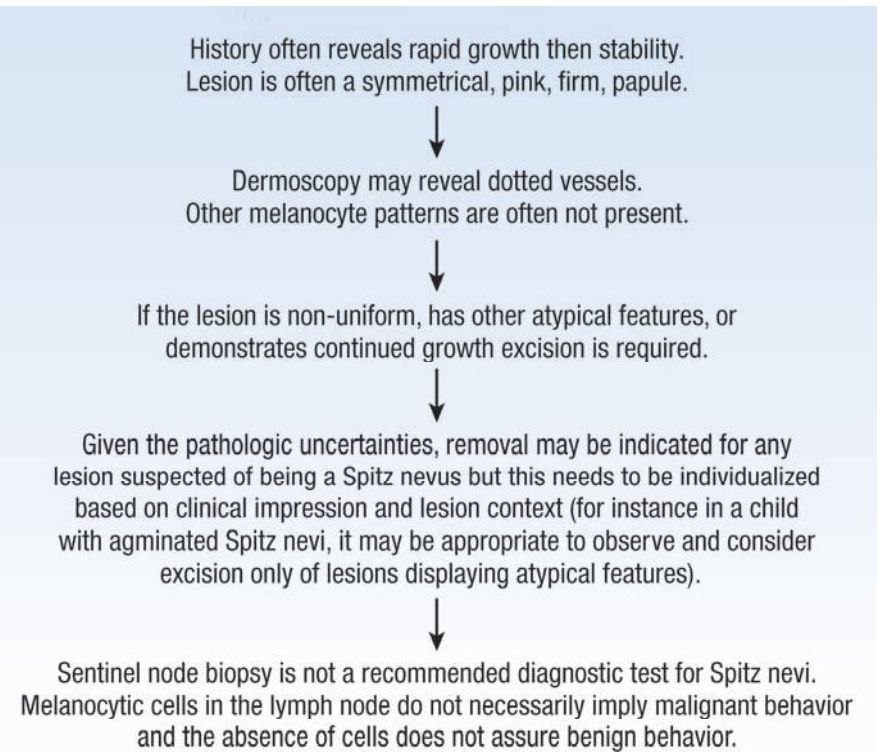
Spitz nevi can also present as widespread eruptive lesions or in a grouped manner as multiple agminated lesions consisting of red, red-brown, brown, or dark-brown papules or nodules, with a fine stippled surface (see Fig. 122-18C). Agminated Spitz nevi often occur in the early years of life within a background of congenital (sometimes acquired) macular pigmentation (nevus spilus) or occasionally within a hypopigmented plaque. Spitz nevi may also develop as single or multiple lesions in a large CNN.

The diameter of Spitz nevi ranges from several millimeters to several centimeters, the average being 8 mm in one series.[82] In 73 percent of patients in one series,[81] the tumor diameter was 6 mm or less, and in 94 percent of patients, the tumor diameter was less than 10 mm. Most cases are described as superficial papules or nodules, although subcutaneous involvement may occur.[87] In one series of 43 patients,[82] the anatomic location included the head or neck in 18, upper extremities in 9, torso in 9, and lower extremities in 7. Spitz nevi tend to spare palms, soles, and mucous membranes.

RELATED PHYSICAL FINDINGS There is no known association with other somatic abnormalities.

Laboratory Tests

HISTOPATHOLOGY Unlike ordinary nevi and melanomas, melanocytic cells in Spitz nevi are large—often twice the size of epidermal basal keratinocytes,[86] with prominent mononuclear or multinucleated giant cells in the epidermis and/or dermis (Fig. 122-19). Mitoses, usually few in number, are detected in one-half the cases,[88] whereas atypical mitoses are uncommon in Spitz nevi. In contrast to melanoma, the melanocytic cells in Spitz nevi show progressive maturation with increasing depth, becoming smaller and more similar to ordinary nevomelanocytes,[86,88] with the overall distribution of cells in the dermis being wedge-shaped, with narrowing of the wedge toward the subcutaneous fat.



▲ **FIGURE 122-17** Approach to the patient with Spitz nevus.

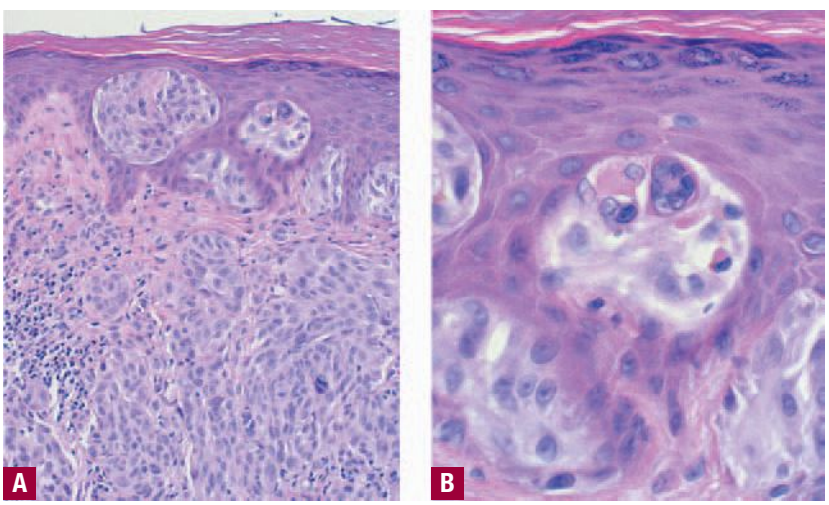
▲ **FIGURE 122-18** Spitz nevi. **A.** Pink plaque, which appeared de novo over an 8-week period, becoming more elevated with time, in the preauricular area of a 4-year-old white boy. **B.** Dome-shaped pink papule, which appeared de novo over a 2-week interval 4 months before, on the forehead of a 5-year-old white boy. **C.** Agminated Spitz nevi. Numerous grouped pink papules and plaques, appearing at age 6 months, on the face of a 4-year-old white boy.

Coalescent eosinophilic globules (Kamino bodies), periodic acid-Schiff–positive and diastase-resistant (resembling colloid bodies), have been reported in 60 percent of Spitz nevi[89] (see Fig. 122-19). Similar globules may be detected in 2 percent of melanomas and 0.9 percent of typical acquired nevi, but the globules are smaller in size, more difficult to find, single rather than coalescent, and commonly periodic acid-Schiff–negative.[89]

Melanocytic elements are usually arranged in well-circumscribed nests, although there may be permeation of the epidermis by single cells or small groups of cells. In those cases with epidermal nests, artifactual clefts are usually seen above the nests in half the cases, a finding rarely observed in melanoma.[81] The epidermis is usually hyperplastic, with elongated and bulbous pegs and knobs extending into the dermis, although thinning and even ulceration may occur rarely. The dermal inflammatory cell infiltrate may be slight or marked, band-like, and mainly at the base or patchy around blood vessels and/or intermixing with tumor cells. Although melanin was observed in all 13 patients originally described by Spitz,[86] more recent studies have determined that melanin was moderate in 10 percent of cases and heavy in 5 percent.[88]

Although the bizarre histopathologic features and frequent occurrence of dermal inflammation may cause diagnostic confusion, Spitz nevus usually can be differentiated from melanoma. The histologic features of Spitz nevus in children and adults are similar.

SPECIAL TESTS A subgroup of Spitz nevi have a gain of chromosome 11p and amplification or activation of H-RAS.[84] These markers are not routinely used in the clinical setting but may be helpful in the future for discriminating these nevi from other melanocytic neoplasias.



▲ **FIGURE 122-19** Histopathologic features of Spitz nevus (**A**) and higher magnification of the intraepidermal component revealing eosinophilic cytoplasmic changes (Kamino bodies) in several cells (**B**).

Differential Diagnosis (Box 122-6)

Complications

Misinterpretation of benign or malignant behavior of the lesion could result in unnecessary or insufficient treatment, respectively.

Prognosis and Clinical Course

The natural history of the Spitz nevus is largely unknown. Based on patients with eruptive Spitz nevi, it is clear that spontaneous regression can occur.[87] A

concern is that some lesions diagnosed as Spitz nevi may progress to melanoma or represent melanoma at the outset.[90]

Treatment

Complete excision with a clear margin of normal skin is generally sufficient treatment for Spitz nevi. Given the difficulty of confidently excluding the possibility of melanoma in certain cases, a wider margin of normal skin may be prudent for histopathologically worrisome lesions.[90] Incompletely excised lesions may recur in as many as 7 percent to 16 percent of patients.[82,91–93] Although some authors have advocated sentinel node biopsies in these lesions, this may only add to the confusion because Spitz nevus cells may be present in the regional lymph nodes but not necessarily indicate malignancy.[94] Management of patients who have numerous Spitz nevi requires individual judgment and periodic examination for new or unstable lesions.

Prevention

The role of UVR exposure in the development or progression of Spitz nevi is unknown.

NODAL NEVI

Epidemiology

Nevomelanocytes can be identified in lymph nodes with a frequency ranging from 0.3 percent to 7.3 percent in lymphadenectomies not related to melanoma and up to 22 percent in regional nodes removed because of melanoma.[95] When nevomelanocytes are evident in lymphadenectomies due to melanoma, it has been reported that 75 percent of the primary cutaneous melanomas had an associated nevomelanocytic nevus, often with congenital features.[96] A significant association has also been noted for the presence of cutaneous nevomelanocytic nevi in the zones of skin drained by lymph nodes that were found to include nevomelanocytes.[97] In most cases, the nevomelanocytes appear to be derived from common acquired nevi, but congenital nevi, blue nevi, cellular blue, and Spitz nevi have all also been reported to involve regional lymph nodes.[64]

Etiology and Pathogenesis

There are two prevailing theories as to the mechanism by which nevomelanocytes appear in regional lymph nodes.

NODAL NEVI AT A GLANCE

- A benign melanocytic neoplasia present in a lymph node. Nevomelanocytes are often located in the capsule but they may also be present in the parenchyma of the nodal tissue.
- Generally asymptomatic and found as a result of lymph node removal.
- Cells may be deposited passively into the node from a cutaneous melanocytic lesion. It is also possible that abnormal migration pathways result in the nevomelanocytes taking up residence in the nodes during embryonic development.
- The presence of these cells in nodal tissue creates difficulties for pathologists evaluating sentinel node biopsies.

The first theory is that during development, nevomelanocytes get trapped in the developing nodal tissues. Some support for this theory could be based on the fact that nodal nevi can be found in association with congenital nevi. This observation suggests that there is an opportunity for nevomelanocytes to be deposited during development. Further, blue nevus cells can be found in tissues such as prostate, cervix, vagina, spermatic cord, and seminal vesicles.[64] Thus, aberrant migration and differentiation of melanocytic cells do occur.

The second theory suggests that there may be passive transfer from the cutaneous lesion to the lymph node. Substances such as carbon, tattoo ink, and radioactive colloid are readily transferred to the draining lymph node. It is reasonable to assume that loosely adherent nevomelanocytes could also traverse the same path. In fact, nevomelanocytes have been noted in lymph channels.[64] Once in the lymph node, nevomelanocytes are generally identified in the capsule, but they can also be found in the parenchyma.[95] It is not known how nevomelanocytes get into the capsule, but it is reasonable to assume that these cells migrate from the parenchyma into the capsule. It is important to note that melanoma cells can also be found in the capsule,[98] so it is rational to assume that entry into the capsule is not limited to a developmental event. The fact that nevomelanocytes in regional lymph nodes are highly correlated with the presence of nevomelanocytic nevi in the skin, supports the concept that these cells arrive in the lymph nodes via dissemination from the benign cutaneous lesion.

Clinical Findings (Fig. 122-20)

HISTORY Generally, nodal nevi are identified in lymph nodes that are removed because of melanoma, but these benign cells are also identified in nodes removed for other reasons. Generally, the patient does not note symptoms related to the nodal nevus.

CUTANEOUS LESIONS Common acquired nevomelanocytic nevi, congenital nevomelanocytic nevi, blue nevi, and Spitz nevi have been noted to give rise to nodal nevi.[64]

RELATED PHYSICAL FINDINGS Due to concern for melanoma, patients should be

Lymph node often removed due to concern for melanoma, but could also have been removed for other reasons.

↓

Histopathologic evaluation is required. It is best to review the lesion in the skin draining to the node along with the node. Location of the nevomelanocytes and cellular appearance may be sufficient for diagnosis.

↓

Immunohistochemistry revealing a lack of proliferative component or high p16 level may help substantiate the benign diagnosis. Molecular PCR based tests do not generally differentiate between benign and malignant melanocytic cells.

▲ **FIGURE 122-20** Approach to the patient with nodal nevus. PCR = polymerase chain reaction.

Box 122-7

Differential Diagnosis of Nodal Nevi

- Melanoma
- Cells from other neoplastic source
- Foreign body deposit (tattoo ink, carbon)

evaluated for findings that might be worrisome for metastatic melanoma.

Laboratory Tests

HISTOPATHOLOGY Pathology often reveals nevomelanocytes largely confined to the nodal capsule. However, cells may also be noted in the parenchyma. These cells should bear resemblance to the cells in the cutaneous lesion. Lack of proliferative markers (Ki67) and possibly high levels of p16 immunohistochemistry markers support the benign diagnosis.[99]

SPECIAL TESTS The use of standard immunohistochemical tests may help identify the location and cellular features of the nevomelanocytes in the lymph node tissue sections. Reverse transcriptase–polymerase chain reaction tests do not discriminate benign from malignant melanocytic nodal disease.

Differential Diagnosis (Box 122-7)

Complications

Complications, such as scarring or lymphedema, may exist for the surgical procedure. A misinterpretation of benign nodal deposits as malignant could result in unnecessary regional lymph node dissection and treatment with systemic agents. An interpretation of malignant nodal cells as benign would not flag the patient as having a worse prognosis and may delay other treatments.

Prognosis and Clinical Course

If the lymph node deposits are determined to be benign, no further treatment is warranted.

Treatment

None required for benign nodal nevi.

LENTIGO SIMPLEX

Epidemiology

The frequency of lentigo simplex in children and adults has not been determined. There does not appear to be a racial or gender predilection. Lentigo simplex is the most common histopathologic pattern of darkly pigmented lesions excised from acral sites of darkly pigmented races.[28] Pigmented nail bands, noted in up to 20 percent of Japanese, may have histopathologic features of lentigo simplex.[100] For agminated lentigines, the population prevalence is unknown, but it is believed to be rare.

Etiology and Pathogenesis

The increased density of melanocytes in lentigines is presumably due to an underlying developmental or intrinsic defect in melanocyte homeostasis. In some lentigines, the presence of melanin macroglobules in melanocytes and keratinocytes suggests that defects affecting melanization pathways are also involved. The presence of lentigo simplex in association with somatic abnormalities in such diverse conditions as Peutz-Jeghers syndrome, LEPOARD syndrome (*l*entigines; *e*lectrocardiogram conduction defects; *o*cular hypertelorism; *p*ulmonary stenosis; *a*bnormalities of genitalia; *r*etardation of growth, and sensorineural *d*eafness), and LAMB/myxoma syndrome suggests that lentigo development may be influenced by a number of different genetic factors. For agminated lentigines, it is possible that chromosomal mosaicism plays a role in the development of the localized collection of lentigines.

Clinical Findings (Fig. 122-21)

HISTORY Unlike solar lentigines, lentigo simplex is thought to be largely UVR independent. Lentigo simplex may appear as early as the first decade and may occur anywhere on skin or mucous membranes.

Generalized lentigines may occur as an isolated phenomenon without known familial aggregation and first appear at birth, during infancy, or during adulthood. Familial clustering in an autosomal pattern also has been noted. A number of syndromes are recognized (see Chap. 73).

In Moynahan (LEOPARD) syndrome, lentigines are present at birth or shortly thereafter and may increase in number during childhood. In Peutz-Jeghers syndrome, numerous lentigines may be present at birth or appear during early childhood. Oral pigmentation usually persists in Peutz-Jeghers syndrome, whereas cutaneous lentigines usually fade after puberty. In LAMB syndrome, the lentigines on the lips and genital sites appear in early childhood and tend to persist.

Agminated lentigines first become manifest at birth or early childhood.

CUTANEOUS LESIONS Lentigo simplex usually is a sharply circumscribed, light-brown or dark-brown macule.

In Moynahan (LEOPARD) syndrome, lentigines occur on both sun-exposed and sun-protected sites, including genitalia, conjunctiva, oral mucosa, palms, and soles. In Peutz-Jeghers syndrome, lentigines are almost always present on the oral mucosa. Other common sites of involvement include lips, nose, eyelids, anus, nail bed, and dorsal and ventral surfaces of hands and feet.

LENTIGO SIMPLEX AT A GLANCE

- Includes a spectrum of melanocytic hyperplasias consisting of intraepidermal melanocytic hyperplasia and increased melanin formation. The extent of melanocytic hyperplasia can be quite variable, ranging from lesions in which the increased melanin content is notable but the increase in melanocyte number is marginal, to lesions in which accumulation of melanocytes is marked.
- Lesions consist of hyperpigmented macules and may be isolated, agminated (focal cluster), or multiple and present on skin, nails, and mucous membranes.
- May be congenital or acquired.
- Multiple lentigines may be associated with somatic abnormalities.
- Synonyms: simple lentigo, melanotic macule, lentiginosis. Other names for agminated lentigines include unilateral lentigines, partial unilateral lentiginosis, lentiginous mosaicism, and segmental lentiginosis.
- Other lesions in which epidermal melanocytic hyperplasia may be noted, and some overlap may exist with simple lentigines, include café-au-lait macules, melasma, and inflammatory/cytokine-induced proliferation.

Dermoscopy tends to reveal a simple well defined regular pigment network without any other dermoscopic findings, such as dots or globules, that might suggest junctional or dermal collections of nevomelanocytes.

↓

If lesions are multiple and in one focal location, agminated lentigines should be considered. Wood's light will help to exclude background hyperpigmentation that might indicate nevus spilus.

↓

If lesions are multiple and dispersed, consider possible associated syndromes and evaluate for associated abnormalities.

↓

If lesions are in an adult and in sun exposed (or tanning/UV box exposed) area, consider the possibility that the lesions are solar lentigines.

↓

A lesion not displaying uniform features, particularly if changing, needs to be considered for biopsy to exclude melanoma.

▲ **FIGURE 122-21** Approach to the patient with lentigo simplex. UV = ultraviolet.

Lentigines in the myxoma syndrome (LAMB) occur mainly on the face and genitalia as tan to black macules (Fig. 122-22). In centrofacial lentiginosis, the presence of pigmented macules is restricted to a horizontal band across the central face.

Agminated lentigines first become manifest at birth or early childhood as small, circumscribed, light-brown macules, 2 to 10 mm in diameter, confined to a localized area of the skin, often in a segmental distribution (Fig. 122-23) and frequently in a curvilinear or swirled pattern. Wood's lamp examination may be required to differentiate agminated lentigines from nevus spilus, because the macular background pigmentation is evident in the latter and absent in the former.

RELATED PHYSICAL FINDINGS If there is concern that the lentigines are part of a syndrome, further evaluation is appropriate, and should be guided by the physical findings and syndrome under consideration.

Laboratory Tests

HISTOPATHOLOGY Lentigo simplex consists of intraepidermal melanocytic hyperplasia in the basal layer of elongated epidermal rete ridges, without nest formation. At one end of the lentigo spectrum, lesions are more similar to café-au-lait lesions, in which the melanocyte number may only be minimally increased but pigmentary differences are marked; at the other end of the spectrum, the number of melanocytes is sufficiently increased to begin forming nests, appearing similar to a junctional nevus. Depending on the degree of keratinocytic hyperplasia, distinct separation from solar lentigo may not be possible based on histopathologic interpretation alone. Giant pigment granules (melanin macroglobules) may occur in lentigo simplex in isolation, and in association with multiple-lentigines (LEOPARD) syndrome.

In agminated lentigines, histopathologic studies reveal increased numbers of melanocytes in elongated epidermal rete ridges, similar to lentigo simplex, without nests of nevomelanocytes or cellular inflammation.

SPECIAL TESTS Mart-1, Mel-5, and DOPA histochemistry may be useful to demonstrate increased number of melanocytes confined to the basal layer and lacking junctional nest formation. If a syndrome is under consideration, imaging studies may be required.

Differential Diagnosis (Box 122-8)

Complications

There are no known complications from lentigo simplex. Complications arise from the associated syndromes. Atypical varieties of lentigo simplex (in any anatomic site) may be potential precursors or masqueraders of melanoma.

Prognosis and Clinical Course

The natural history of isolated lentigo simplex is not known. Once developed, the lesions are presumed to be relatively stable. There is no convincing evidence that lentigo simplex evolves to a nevomelanocytic nevus. As with any process in which melanocytes are present (including normal skin), it is possible for melanoma to arise in a lentigo, but an elevated risk has not been demonstrated conclusively for lentigo simplex.

The long-term course and malignant potential of agminated lentigines are unknown.

Treatment

There is no need to treat benign-appearing lentigo simplex. Cosmetic removal may be achieved with cryotherapy or

▲ **FIGURE 122-22** Lentigo simplex. **A.** Acquired darkly pigmented lentigines on the vulva of a 13-year-old white girl who has *l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas, and *b*lue nevi (LAMB, myxoma) syndrome. **B.** Multiple lentigines on the lips of the same patient. This patient died in her mid-20s of a malignant schwannoma.

other destructive approaches such as Q-switched laser. However, caution must be taken to ensure the lesion being treated is benign. Lesions that are significantly unusual, irregular, asymmetric, or changing in shape should be examined histopathologically to exclude melanoma. Wood's lamp examination is useful in defining margins of lentigo simplex.

Until the long-term course of agminated lentigines is known, it may be prudent to recommend periodic examinations to detect the earliest signs of possible malignant evolution.

Prevention

UVR is clearly associated with the development of solar lentigines, but its role in the different types of simple lentigines is not known. However, it is rational to limit UVR overexposure.

SOLAR LENTIGO

Epidemiology

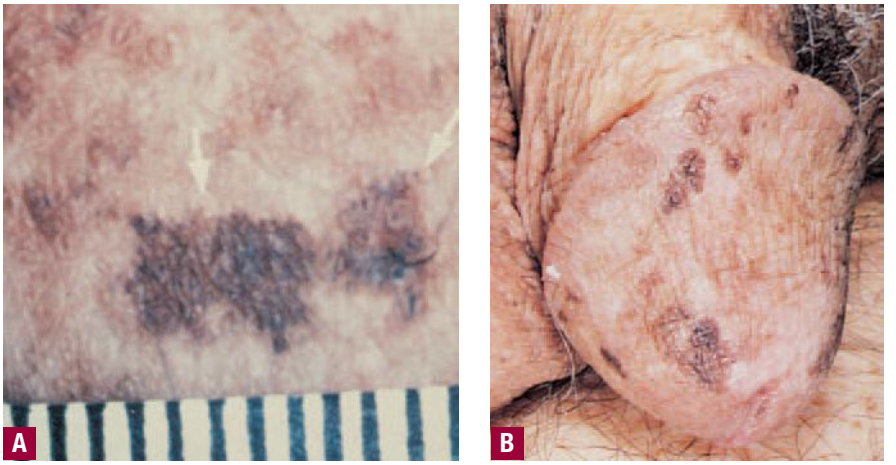
The prevalence of solar lentigines is correlated directly with increasing age, and they are present in 90 percent of white people over 60 years of age.[101] Solar lentigines are common in individuals who sunburn easily and do not tan, whereas they are uncommon among people who have darkly pigmented skin.[102]

Lentigines may be induced by photochemotherapy [psoralen and ultraviolet A light (PUVA) lentigo], occurring in 40 percent to 50 percent of patients an average of 5.7 years after starting therapy, their frequency and severity directly attributable to the total number of treatments (Fig. 122-24; see Chap. 239).[102] Darkly pigmented skin is associated with the lowest risk for PUVA-induced or solar-induced lentigines.[102] Lentigines have been associated with UVA tanning bed use.[103]

Lesions similar in gross and microscopic appearance to solar lentigo, freckle (ephelis), may occur in children and young adults.[104] They may appear within the first 5 years of life, tend to aggregate in families, and are significantly associated with red hair; their location and density correlate with sun sensitivity and sun exposure. The presence of freckles has been associated with a 2.5-fold increase in the rate of sunburn susceptibility and poor tanning

SOLAR LENTIGO AT A GLANCE

- Solar lentigo is distinguished from lentigo simplex histopathologically on the basis of shape and extent of epidermal hyperplasia. The epidermal hyperplasia is often more prominent in solar lentigines and may include "bud-like" structures at the base of rete ridges.
- Solar lentigines appear as circumscribed pigmented macules occurring singly or as multiple lesions and present on the skin surface exposed to natural or artificial sources of ultraviolet radiation. Distinct subtypes exist and include the ink spot lentigo.
- Most solar lentigines occur in adults.
- Solar lentigines are benign but caution must be taken to discriminate benign lesions from lentigo maligna.
- Outdated synonyms: sun-induced freckle, liver spot, lentigo senilis, and senile lentigo.



▲ **FIGURE 122-24** Photochemotherapy [psoralen and ultraviolet A light (PUVA)]-induced lentigines on the buttock (**A**) and penis (**B**) of a 57-year-old white man who had received PUVA for psoriasis several times per week for 5 years. The PUVA lentigines appeared between 1 to 2 years after PUVA therapy was begun. The current recommendation is to shield the male genitalia during PUVA therapy to prevent epithelial tumors of the penis and scrotum.

response and a three-fold greater likelihood of a lower minimal erythema dose in people who mostly burn and tan minimally or not at all.[105] The presence of dense sun-induced freckling increases the estimated risk for melanoma by three- to fourfold.[106]

Etiology and Pathogenesis

Solar lentigines are thought to represent a marker of intermittent high-intensity UVR, cumulative UVR, and/or a unique susceptibility to the proliferative, stimulatory, and/or mutagenic effects of UVR. Given the hyperplasia of both the keratinocytes and melanocytes, the primary defect in solar lentigines could be in either cell type eliciting a secondary proliferative response in the other.

There is a pronounced link between UVR exposure and the development of lentigines. Single exposures of experimental UVB radiation (320 mm) that is 6 to 10 times the minimal erythema dose induces "freckling" in susceptible individuals.[107] Phototoxic doses of PUVA may lead to the development of lentigines 6 to 8 months later.[108] In addition to the total dose of UVR received during photochemotherapy, individual susceptibility factors to lentigo development include race, age, and burning/tanning response to sunlight.[102]

Supportive of the underlying mutation being present in the melanocytes is the finding that epidermal melanocytic cellular atypia persists in lentigines developing in patients receiving chronic photochemotherapy for 1 to 2 years or longer after therapy is discontinued.[102]

In xeroderma pigmentosum (XP), in which patients have an increased sensitivity to UVR, hyperpigmented macules develop on light-exposed skin within the first 5 years of life (see Chap. 109), and these lesions demonstrate hyperplasia of variably atypical epidermal melanocytes (i.e., atypical lentigines). In one series of XP patients from Japan,[109] lentigo maligna melanoma was the predominant melanoma type, suggesting an association between this tumor subtype, sensitivity to UVR, and the presence of UVR-induced atypical solar lentigines, and supportive of the underlying mutation being in the melanocytic lineage.

Clinical Findings (Fig. 122-25)

HISTORY Solar lentigines appear as acquired lesions, generally in fair-skinned individuals, on sun-exposed skin surfaces. For the majority of solar lentigines, it is assumed that once present, they remain stable.

CUTANEOUS LESIONS Solar lentigo occurs as a pigmented macule on skin exposed to natural sunlight or artificial sources of UVR, usually in the presence of similar lesions in the same location (Fig. 122-26). Lesions may be tiny (< 1 mm in diameter) or large (up to a few centimeters in diameter), with a tendency to confluence in severely sun-damaged skin and with smooth or irregular outlines. Lesions are usually light brown, but varieties of solar lentigo are jet black, similar to an India ink stain (ink spot lentigo). Although solar lentigo usually occurs on sun-exposed skin, identical-appearing lesions may occur on sun-protected sites (including the penis and buttocks) that have been exposed to photochemotherapy (see Fig.

Dermoscopically these lesions are of uniform color and may have a prominent network pattern or a diffuse uniform very light brown pigmentation. The borders may have a jagged shape, but the interface between lesion and normal skin is generally visible. These lesions may occasionally be difficult to differentiate from a junctional nevus or a flat seborrheic keratoses.

↓

Solar lentigines are more likely to be found on fair skinned individuals with advancing age.

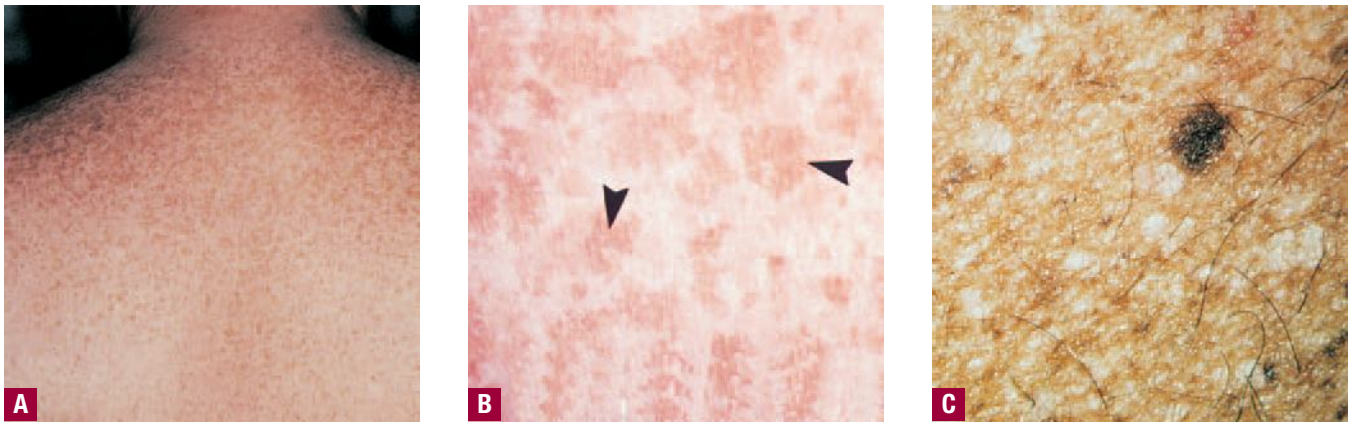
↓

The lesions should be found in areas of significant UVR exposure. Important to keep in mind, these lesions may even be present on genital skin in the setting of PUVA or other intense UVR exposures.

↓

Lesions appearing different than the others and changing, especially if non-uniform, need to be considered for biopsy to exclude melanoma (particularly the lentigo maligna subtype). On the face, dermoscopic structures that increase concern for melanoma include asymmetric follicular pigmentation, gray pigment network, and annular/granular and rhomboidal structures.

▲ **FIGURE 122-25** Approach to the patient with solar lentigo. PUVA = psoralen and ultraviolet A light; UVR = ultraviolet radiation.



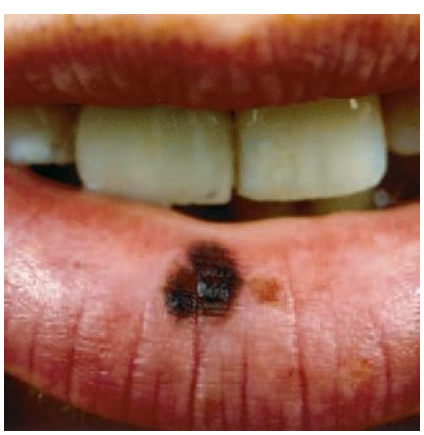
▲ **FIGURE 122-26** Solar lentigo. **A.** Uncountable solar lentigines on the back of a 30-year-old white man, appearing initially during early childhood after multiple sunburns. **B.** High magnification of lentigines in (**A**) showing light-brown macules with markedly irregular outlines. **C.** Solar lentigines on sun-damaged dorsal hand skin (hypopigmentation, wrinkling, and telangiectasia) of an elderly white man.

122-24). When examined by dermoscopy, solar lentigines reveal a uniform reticular network.[110] Lentigines in patients receiving PUVA and in individuals who have XP are often darkly and/or irregularly pigmented.

Solar lentigines not apparent in visible light may be visualized using Wood's lamp illumination.

The oral-labial melanotic macule has gross morphologic characteristics similar to solar lentigo (Fig. 122-27), but its relation to a sun-sensitive phenotype or excessive sun exposure has not been well documented.

A clinical distinction is made between a freckle (ephelis) and a solar lentigo. Freckles are common on the central face and often first noted in early childhood, presumably developing after significant sun exposure and are said to fade or even disappear when sun exposure is discontinued. Unfortunately, there are no longitudinal studies of ephelides or solar lentigines that document gross morphologic or time-course differences that would reliably allow a clinical distinction between ephelides and solar lentigines. According to L-3, 4-dihydroxyphenylalanine (DOPA) studies on epidermal sheets, ephelides have been reported to show increased melanogenesis but decreased melanocyte number, which implies a different pathologic basis.[107,111] However, counting melanocytes in DOPA-incubated epidermal sheets is unreliable for pigmented lesions, and these early studies must be questioned. Studies in DOPA-incubated tissue vertical sections demonstrate that melanocytes are increased in "ephelides" in children and young adults, similar to solar lentigines.[44,110]



▲ **FIGURE 122-27** Labial melanotic macule, appearing 5 years earlier, on the lower lip of a 26-year-old white woman.

RELATED PHYSICAL FINDINGS Patients with solar lentigines are more likely to be fair skinned, particularly those with red hair and or lighter eye color. Along with the lentigines, increased solar damage may be noted and other lesions such as idiopathic guttate hypomelanosis, actinic keratoses, and seborrheic keratoses may be present. The presence of solar lentigines is a risk factor for melanoma, basal cell cancer, and squamous cell cancer.

Laboratory Tests

HISTOPATHOLOGY Solar lentigines reveal elongated epidermal rete ridges with club-shaped or bud-like extensions, frequent branching and fusing of rete ridges, a thinned or atrophic epidermis between rete ridges, and increased numbers of epidermal melanocytes without nesting. The microscopic appearance suggests a concurrent proliferation of keratinocytes and melanocytes.[112] There is a scant to moderate perivascular mononuclear cell infiltrate in the dermis, usually associated with scattered melanin-laden macrophages.

Histopathologic characteristics of the labial melanotic macule (labial lentigo) are similar to those of solar lentigo, showing melanocytic hyperplasia but without cellular atypia. The presence of melanocytic hyperplasia in labial melanotic macule is not a uniform finding in all studies.

SPECIAL TESTS Mart-1 and DOPA histochemical studies may be useful to demonstrate increased number of melanocytes confined to the basal layer and a lack of junctional nest formation.

Differential Diagnosis (Box 122-9)

Complications

A potential complication is the discovery that an atypical solar lentigo is actually melanoma (often of the lentigo maligna variety).

Prognosis and Clinical Course

Solar lentigines may appear at any time of life. A solar lentigo may enlarge, darken, and become stable over time, but longitudinal studies of solar lentigines are lacking. It is possible that once formed, solar lentigines may persist indefinitely

Box 122-9

- Junctional nevomelanocytic nevus
- Pigmented actinic keratoses
- Lentigo maligna

or fade slightly with time. Solar lentigines may be a heterogeneous population that includes lesions that fade and lesions that do not fade after UVR avoidance. The presence of these lesions suggests an increased risk for melanoma and nonmelanoma skin cancers.

It has been proposed that some varieties of lichenoid keratosis (see Chap. 113) may be due to an acute inflammatory reaction targeting the solar lentigo, and that resolution of lichenoid keratosis may cause regression of the associated lentigo.[114]

The long-term course of atypical varieties of PUVA lentigo is unknown, but it is clear that PUVA lentigines (see Fig. 122-24) may persist 1 to 2 years or longer after therapy is discontinued[102] and that cellular atypia of epidermal melanocytes in these lesions may persist as well. It is also clear that these patients may be at increased risk for melanoma[115] and should be followed periodically for life.

Lentigo maligna (see Chap. 124) may masquerade as a solar lentigo early in its development or, alternatively, may evolve from a pre-existing solar lentigo. A solar lentigo not matching the patient's other lentigines and/or enlarging/darkening out of step should be examined histopathologically or followed closely.

Treatment

Solar lentigo usually requires no therapy, but importantly, its presence indicates sensitivity and/or excessive exposure to UVR. Bleaching creams containing hydroquinone are usually not effective. Cryotherapy or other superficial destructive techniques (such as Q-switched laser) may be an option if the lesion is clearly benign, but lesions may recur after therapy.

Prevention

It may be possible to prevent further solar lentigines by reducing sun exposure. This may be accomplished through avoidance, protective clothing, and sunscreens. Optimally, these measures should be initiated during early childhood and continued throughout life.

CHAPTER 123

Atypical Melanocytic Nevi

Margaret A. Tucker

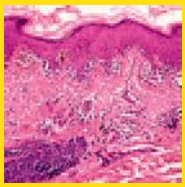
EPIDEMIOLOGY

The term *atypical melanocytic nevi* includes several clinical entities, including the common atypical dysplastic nevi, and rare atypical Spitz or spitzoid nevi, atypical genital nevi, and other unusual melanocytic nevi.[1] This chapter will focus on the common atypical/dysplastic nevi, which are relatively frequent melanocytic neoplasms.

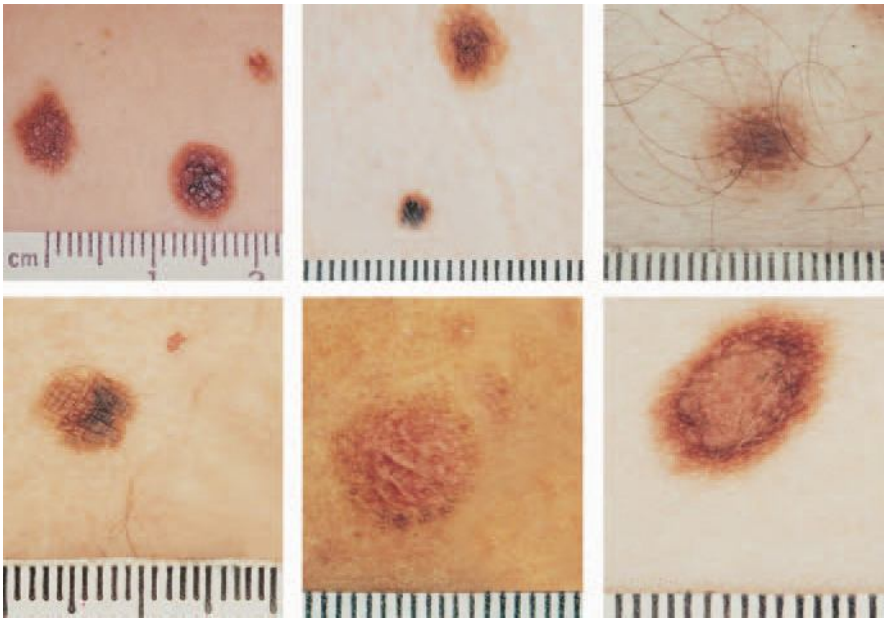
Atypical nevi were first recognized as distinct pigmented lesions during the clinical assessment of melanoma-prone families.[2] The nomenclature associated with these lesions also includes B-K moles (recognizing the first two families described whose surnames began with B and K),[2] familial atypical multiple mole and melanoma syndrome,[3] atypical mole syndrome,[4] Clark's nevus,[5] atypical moles, and nevus with architectural disorder (with varying degrees of melanocytic atypia).[6] The nomenclature has been contentious in the past. The term *dysplastic nevus* (DN) is more frequently used at present, both for clinical and histologic diagnoses,[7,8] and it is the personal preference of the author. Therefore, the term will be used throughout this chapter.

The usual clinical criteria for the diagnosis of a DN are two obligate features: Diameter in one dimension at least 5 mm and a prominent flat component, and two of three other features: Irregular, asymmetric outline, indistinct borders, and variable pigmentation (Fig. 123-1).[9] The histologic features include the presence of an immature or disordered growth pattern with a lymphocytic host response and random cytologic atypia in melanocytes (Fig. 123-2).[10] Multiple studies have demonstrated that the clinical

ATYPICAL/ DYSPLASTIC NEVI AT A GLANCE



- Prevalence among Caucasian young adults roughly 10 percent; varies by population
- Flat (totally or partially), large (> 5 mm) lesions with irregular shape, indistinct borders, and variable pigmentation
- Risk markers for melanoma and precursors of melanoma
- Most frequent on sun-exposed areas, especially intermittently exposed, such as back
- Associated with large numbers of common acquired nevi
- Majority of lesions will involute and disappear over time
- Histologic features include presence of immature, disordered growth pattern with a lymphocytic host response and random cytologic atypia in melanocytes



▲ **FIGURE 123-1** Atypical nevi have two obligate features: diameter in one dimension at least 5 mm and a prominent flat component, and two of three other features: irregular asymmetric outline, indistinct borders, and variable pigmentation.

and histologic criteria are each reproducible across observers.[11–14]

Most of the information on the epidemiology of DN has been obtained from studies of melanoma etiology. In virtually every study that has assessed risk of melanoma associated with DN, these nevi are associated with increased risk of melanoma.[15] Most of the epidemiologic studies have used the clinical diagnosis of DN as the risk factor analyzed. DN occur in approximately 10 percent of the adult populations of northern European descent based on the results of multiple case-control studies evaluating risk of melanoma associated with these lesions.[15] Among studies, the prevalence of DN in control populations has ranged from 7 percent to 24 percent. The studies occurred in different geographic regions, with varied control selection, and somewhat different criteria for the clinical diagnosis of DN. Given the differences in exposures and selection criteria for both study participants and nevi, the studies are remarkably consistent.

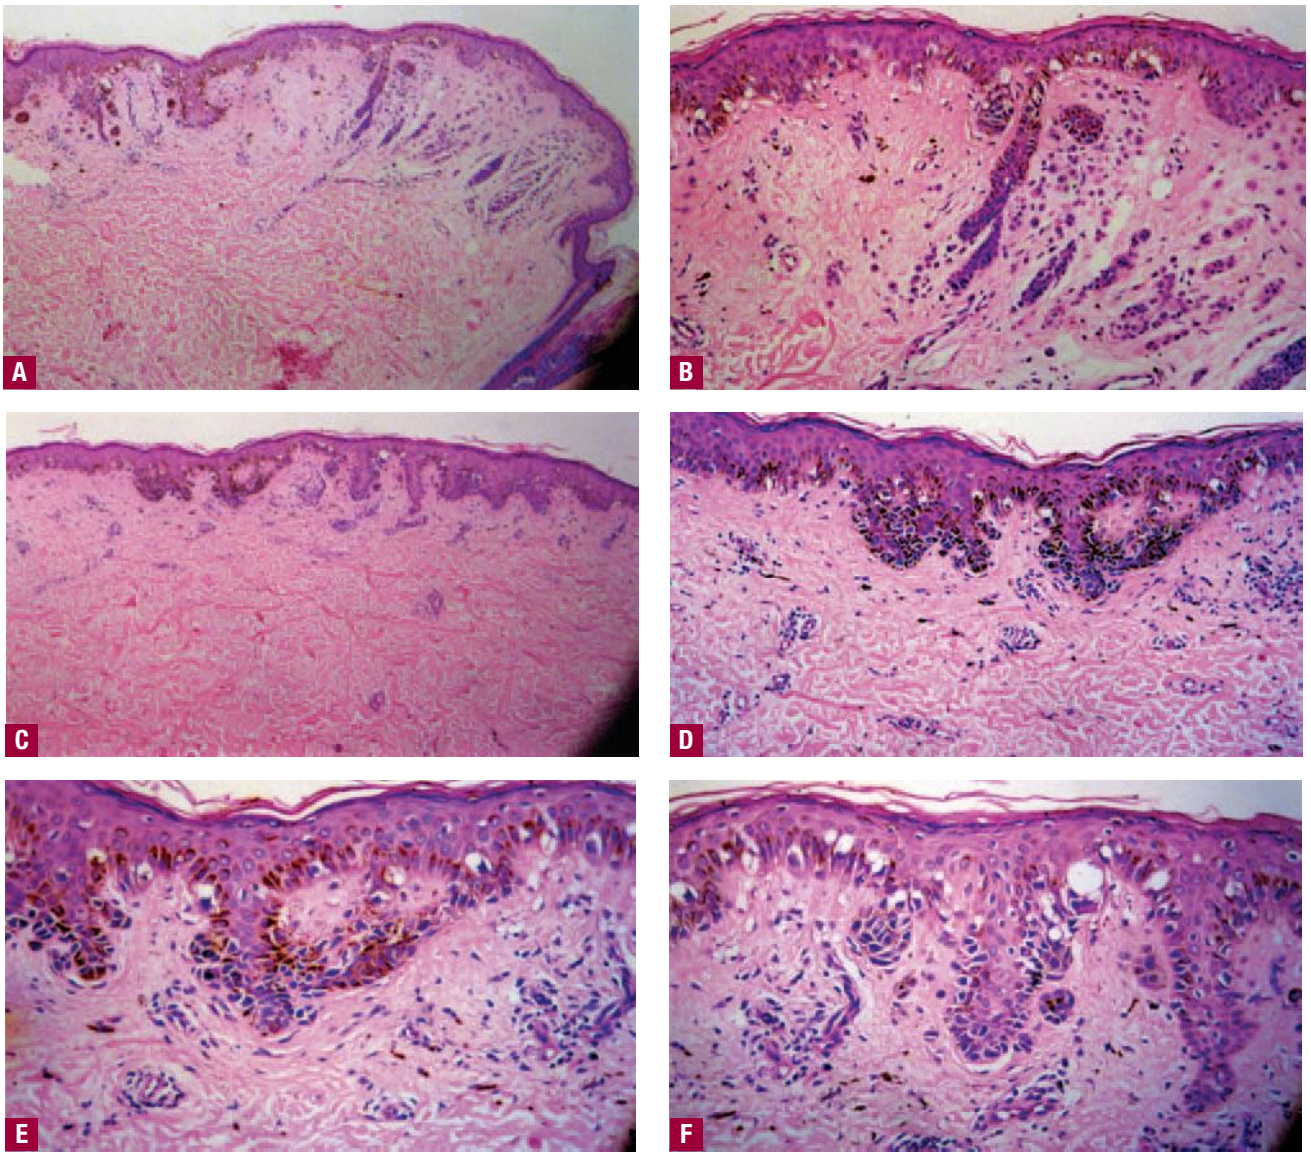
Limited data on the population prevalence of these lesions exist, and geographic and racial differences are likely. One early cross-sectional study in a New Zealand cohort (independent of melanoma) revealed DN in 9 percent of European descent adults.[16] A joint case-control study of nevi and melanoma in Australia and the United Kingdom demonstrated that DN were three times more frequent in the Australian controls (6 percent) than in the British controls (2 percent).[17] There are a few case reports of DN in Japanese, primarily in melanoma-prone families.[18]

DN are frequently found in melanoma-prone families in North America, Europe, and Australia.[19–27] They appear in the majority of Northern European families (from England, France, Holland, North America, Scotland, Sweden) and, to a somewhat lesser extent, in Spanish and Italian families. One of the differences in the Mediterranean families is that the nevi tend to be somewhat smaller than the 5-mm diameter criterion and may not be counted as dysplastic.

ETIOLOGY AND PATHOGENESIS

The etiology of DN is largely unknown, but there appears to be a genetic component of risk. DN occur in a familial pattern; limited segregation analyses suggest an autosomal dominant transition of the trait.[28] To date, no germline susceptibility genes have been identified for these lesions. Early on, it was hypothesized that melanoma and DN represented pleiotropic effects of a single gene.[29] After the first major melanoma susceptibility gene, cyclin-dependent kinase inhibitor 2A (*CDKN2A*), was identified, this hypothesis could be directly tested. Within melanoma-prone families with identified mutations in *CDKN2A*, DN do not consistently co-segregate with the mutation in the family.[30,31] This observation implies that the alteration in *CDKN2A* associated with risk of melanoma is not causal for DN. Within families having *CDKN2A* germline mutations, DN also appear to be an independent risk factor for melanoma.[22,31] Germline mutation testing of several other candidate genes for melanoma (e.g., *PTEN*, *BRAF*, *CDK4*) in individuals with DN, but not necessarily melanoma, has also not found mutations in the candidates selected.[32] Germline polymorphisms in *BRAF* were also not related to nevi or freckles in another study.[33] Although two groups have found evidence for linkage of a gene for increased number of nevi in the region around *CDKN2A* in twin studies,[34,35] a specific gene that is mutated has not yet been identified. One group also evaluated "atypical mole count" and found some areas of modest interest on chromosomes 1, 6, and X.[35] It is likely that DN, like melanoma, is a complex, heterogeneous trait.

One author has hypothesized that a single mutation in melanocyte precursors would be sufficient to explain the pathogenesis of nevi (not specifically DN).[36] Detecting novel characteristic somatic mutations in the atypical melanocytes within DN has been difficult,



▲ **FIGURE 123-2** The histopathology of the lesion shown in Figure 123-10. **A.** The low-power view shows a dermal nevus with dysplasia. **B.** A closer view of the dysplasia at the shoulder of the dermal nevus. **C.** Another area of dysplasia. **D.** On closer view, there is an increased number of melanocytes without an apparent increase in keratinocytes, with the melanocytes clustered on the sides and the ends of the retia. The nuclei of the melanocytes are quite atypical. **E.** At higher power, the nuclei of the melanocytes are atypical and enlarged, characteristic of epithelioid melanocytic dysplasia. **F.** Another area of the lesion with melanocytes in linear array, characteristic of lentiginous melanocytic dysplasia. The melanocytes are not as enlarged as in the area of epithelioid dysplasia. With > 30 atypical melanocytes and the level of disorganization of the architecture, the lesion is classified as severely dysplastic. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

even with microdissection, because of the small clusters of atypical melanocytes. On account of this technical difficulty, data are available for relatively sparse numbers of lesions. For instance, in a report assessing *BRAF* V600E (formerly V599E) mutations in 77 nevi, mutations were found in 82 percent of all nevi, but only five DN were included.[37] Among these, four (80 percent) had the mutation. Another method for evaluating V600E, the ligase detection reaction, does not require microdissection and can be performed on paraffin sections of formalin fixed tissue.[38] This method has been used to evaluate the presence of mutations within 6 DN, half of which had the V600E mutation in *BRAF*. Based on limited data, although the V600E mutation occurs early in melanocyte tumor progression (in benign nevi), the mutation is not distinctively associated with DN, nor does it appear to be more frequent than in common nevi.

Somatic mutations in *NRAS* have also been described in melanomas and in nevi.[39,40] These mutations are found in lesions that do not have *BRAF* mutations. There is a specific activating mutation in codon 61 of *NRAS* that was evaluated in Swedish individuals with germline *CDKN2A* mutations. Seven DN, 21 melanomas, and two common acquired nevi were studied. All but one of the melanomas and five of the seven DN had the *NRAS* mutation; neither of the common acquired nevi did.[39] An earlier study using microdissection in 13 common nevi and nine DN showed hemizygous deletion in the region of p16 in seven of nine DN and in none of the common nevi.[41] In a similar manner, three of seven of the DN had hemizygous loss in the region of p53; all three also had deletions in the region of p16. None of the common nevi had hemizygous loss in the p53 region.

Senescence is usually driven by telomere shortening and is associated with increased expression of p16, among other tumor suppressors. One group re-

cently explored whether *BRAF* mutations, particularly V600E, in nevi were associated with senescence.[42] They measured activity of senescence-associated acidic β-galactosidase, a common senescence marker, and p16 in congenital (not dysplastic) nevi and in melanocytes transduced with lentivirus expressing V600E. They found that senescence-associated acidic β-galactosidase was always expressed in the nevi (n = 23) and in 80 percent of the cultured melanocytes. All of the nevi had some melanocytes expressing p16, but none showed upregulation of p21 and p53. Eight of the congenital nevi had V600E mutations; the pattern of p16 expression was heterogeneous and similar in lesions with and without V600E mutations. These findings suggest that other mechanisms in addition to p16 are important in the growth arrest of congenital nevi.

Several lines of evidence suggest that sun or ultraviolet light (UV) exposure is important in the etiology of DN. First, the lesions occur most frequently in sun-exposed areas, particularly in those intermittently exposed, but DN may also occur in unexposed areas.[19,44–47] The most common area for DN is on the trunk, primarily the back (Fig. 123-3; see eFig. 123-10.1 in on-line edition). There is relative sparing of the more sun-protected lateral thoracic regions and the inner aspect of the arms. Fewer DN occur in doubly covered areas such as on the buttocks. In a comparison of Australian and British controls from a joint case-control study, the prevalence of DN was three times higher overall in the Australians, but the prevalence of nevi on non–sun-exposed areas was the same.[17] Second, several studies have also demonstrated, to varying degrees, that individuals with DN report more frequent sun exposure and sunburns, especially before age 20, than individuals without DN.[48–50] Individuals who tan well appear to develop fewer DN. Third, based on longitudinal studies of melanoma-prone families, individuals with DN who use sun protective measures consistently develop fewer new nevi, and the dysplastic and common nevi they have are more likely to involute and disappear.[47] Sun-protected children in these high-risk families also develop fewer nevi. None of the existing data, however, prove causality between UV exposure and DN. Over time, some of the cohort studies of nevi in children from the general population may yield important information about the etiology of DN.

▲ **FIGURE 123-3** **A.** A back view showing the distribution of dysplastic nevus and lesion to lesion variability, with an increased number of common acquired nevi also. **B.** A closer view of a cluster of lesions marked as #2 on the back. The lesions are different sizes, colors, shapes, with differing amounts of asymmetry, and indistinct borders. Only the largest lesion meets all of the criteria for a clinical dysplastic nevus.

Clinical Findings (Fig. 123-4)

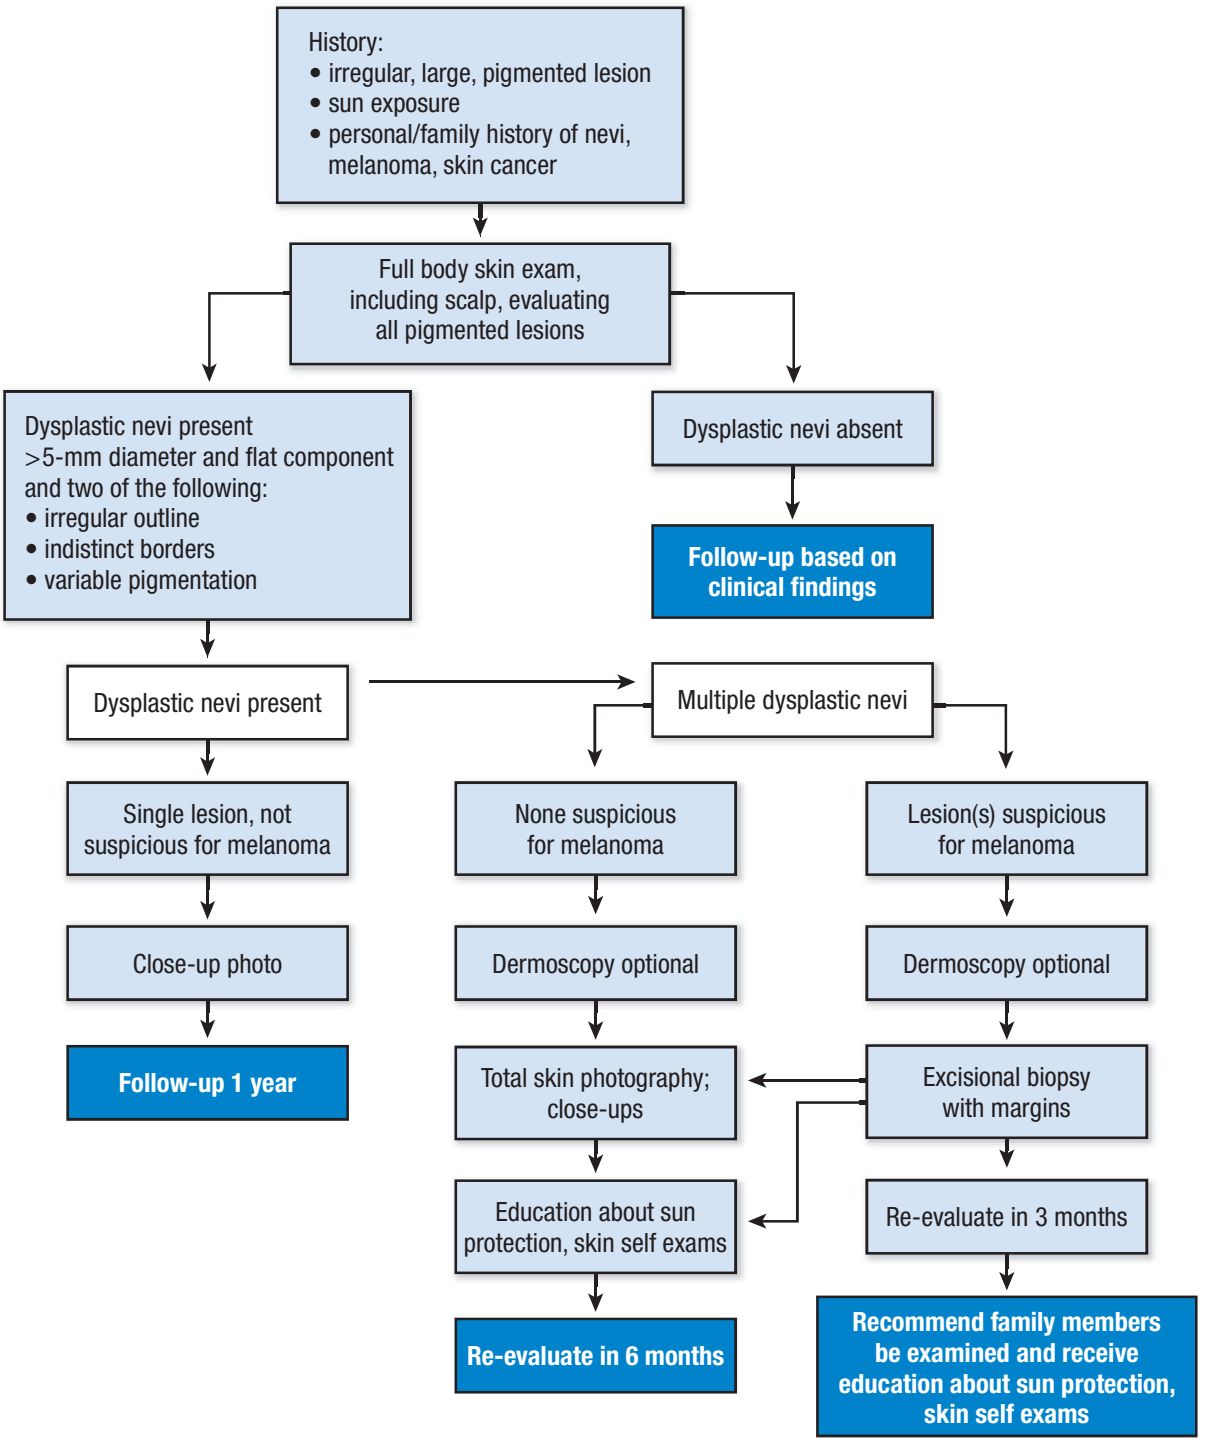
History

Many individuals with DN come to the attention of a clinician because they are worried about a changing mole. These individuals should be asked about their sun exposure patterns, their personal and family history of melanoma, other skin cancers, and other nevi. Most individuals with multiple DN consider themselves "moley" and often have "moley" family members. They will often report they have been "very moley all of their life." It is useful to ask if their moles changed during adolescence (puberty) or pregnancy.

Knowing the individual's sun exposure is important to understand both their nevus pattern and also, associated melanoma risk. Sun exposure patterns have several components. Although sun exposure at an early age is clearly a risk factor for nevi and melanoma, adult exposure is also important.[51] The practitioner should elicit residential history (e.g., ever lived in the southern half of the United States or in very sunny areas); recreational history (e.g., place and types of exposure); occupational exposure; sunburn (bad blistering) history; and tanning bed/solarium use. Individuals who burn easily may alter their exposure patterns as they age to minimize burning as they age. Time of day of exposure is also clearly important, as is shade-seeking behavior. Understanding current and past sun exposure patterns or sun-seeking behavior also helps personalize sun protection education.

Past history of melanoma or other skin cancer identifies individuals who have already had the exposure to make cancers and are at increased risk of developing another. Individuals who have had one melanoma are at substantially increased risk of developing another primary melanoma, especially within the first 5 years.[52] During this time period, individuals in the general population with melanoma have a 10-fold increased risk of melanoma. Having multiple nevi, especially DN, is one of the risk factors identifying those most likely to develop another primary melanoma.[53] A previous history of nonmelanoma skin cancer approximately doubles the risk for melanoma, especially in older men.[54] Members of melanoma-prone families with DN are at quite high risk of developing melanoma.[47] The risk of melanoma in individuals with multiple DN without a personal or family history of melanoma is also elevated,[9] but probably not as high as that of someone with such a history. It is important to know whether the patient has had multiple excisions of nevi in the past; if so, the current exam will not reflect their original nevus pattern. It is likely that their most atypical or largest nevi may have been removed; the pathology reports from these lesions are often quite useful. Despite the concern about melanoma in individuals with DN, most of these people will never develop melanoma.

For a specific lesion of concern, it is helpful to obtain information about the time period over which it has changed, what brought it to their attention, and whether there are sensations associated with it. It is also important to know if other lesions are also changing, because DN can have "bursts of activity" when

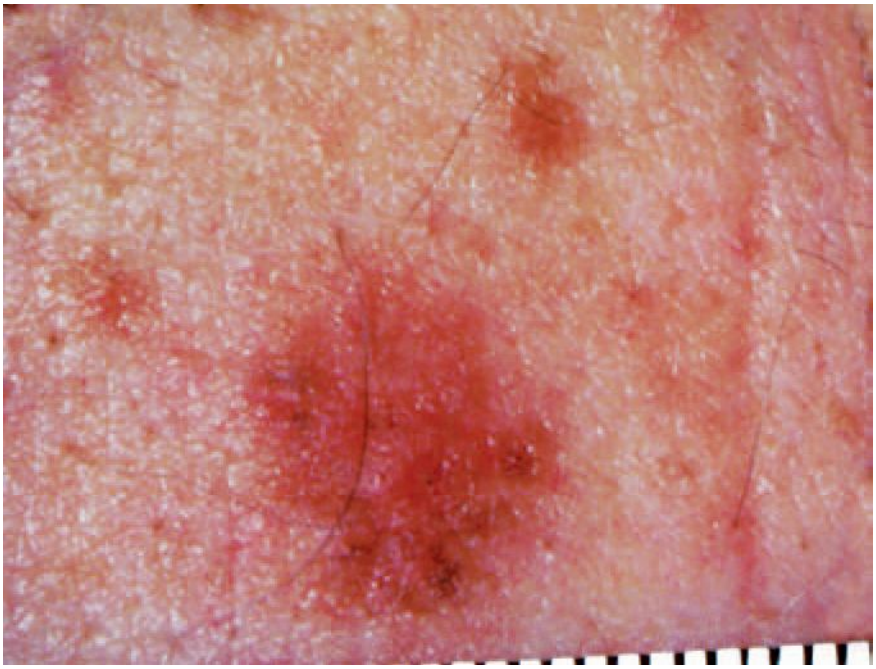


▲ **FIGURE 123-4** Approach to the patient with dysplastic nevi.

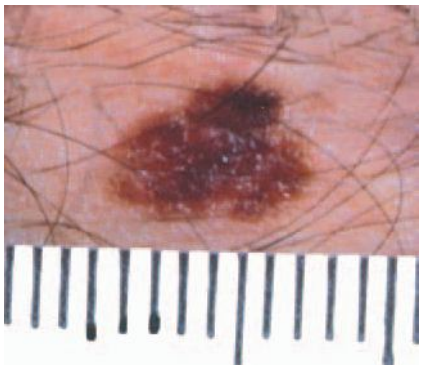
multiple lesions are changing. The reasons for the increased rate of change are not understood. Anecdotally, the changes can occur after increased sun or UV exposure (see Figs. 123-9 and 123-10), or in times of hormonal/growth changes such as puberty and pregnancy.[47]

Cutaneous Lesions

DN are large, flat, asymmetric lesions with irregular outline and variable coloration (see Fig. 123-1). Within an individual, there is lesion-to-lesion variability, but there tends to be some consistency in the appearance (see Fig. 123-3B). Between individuals, even within the same family, there can be very broad differences in appearance of DN.[47] Any specific lesion needs to be assessed in the context of where it is in its natural life history. By usual clinical criteria, to be a DN, the lesion must be at least 5 mm in one dimension. Some groups have used other sizes, such as 5 mm in all directions, 7 mm in diameter, or 8 mm in diameter. The most commonly accepted size now is 5 mm in at least one diameter. The requirement of 5 mm in all directions forces a relative symmetry which is not frequent in these lesions. DN tend not to be circular or smoothly ovoid. A DN must also have a flat component, which may be the dominant part of the lesion or might only be a remaining shoulder of the lesion (Fig. 123-5; see Fig. 123-1). Often, DN develop a somewhat "pebbly" surface, with several small papules (Fig. 123-6;



▲ **FIGURE 123-5** The largest diameter of this lesion is approximately 11 mm (from 12 to 6 o'clock); it is mostly flat with a plaque-like low papule off center to the lower right. All of the borders are indistinct; the outline is quite irregular; the lesion is asymmetric; the colors vary from pink to light tan. The lesion is from an individual with quite fair skin and hair who does not make dark pigment. There are also two small other nevi in the photo with the same range of pigmentation.

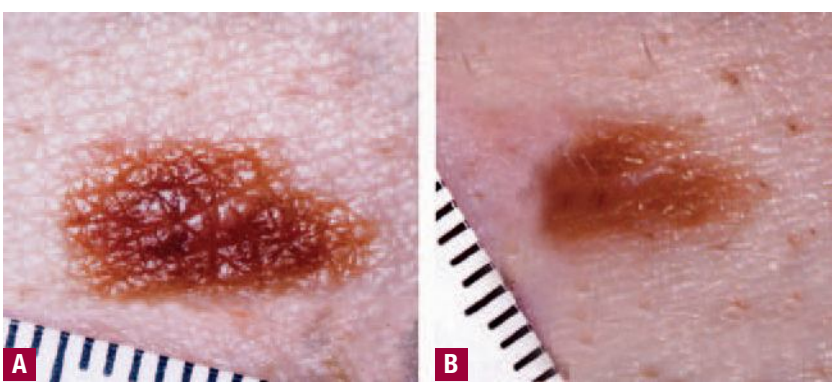


▲ **FIGURE 123-8** This lesion is 7 mm in greatest diameter and predominantly flat. It is quite irregular in outline and asymmetric. The borders are somewhat smudged in some areas; there is clear pigment variation. This person makes very dark nevi; this lesion was typical of many of the patient's nevi.

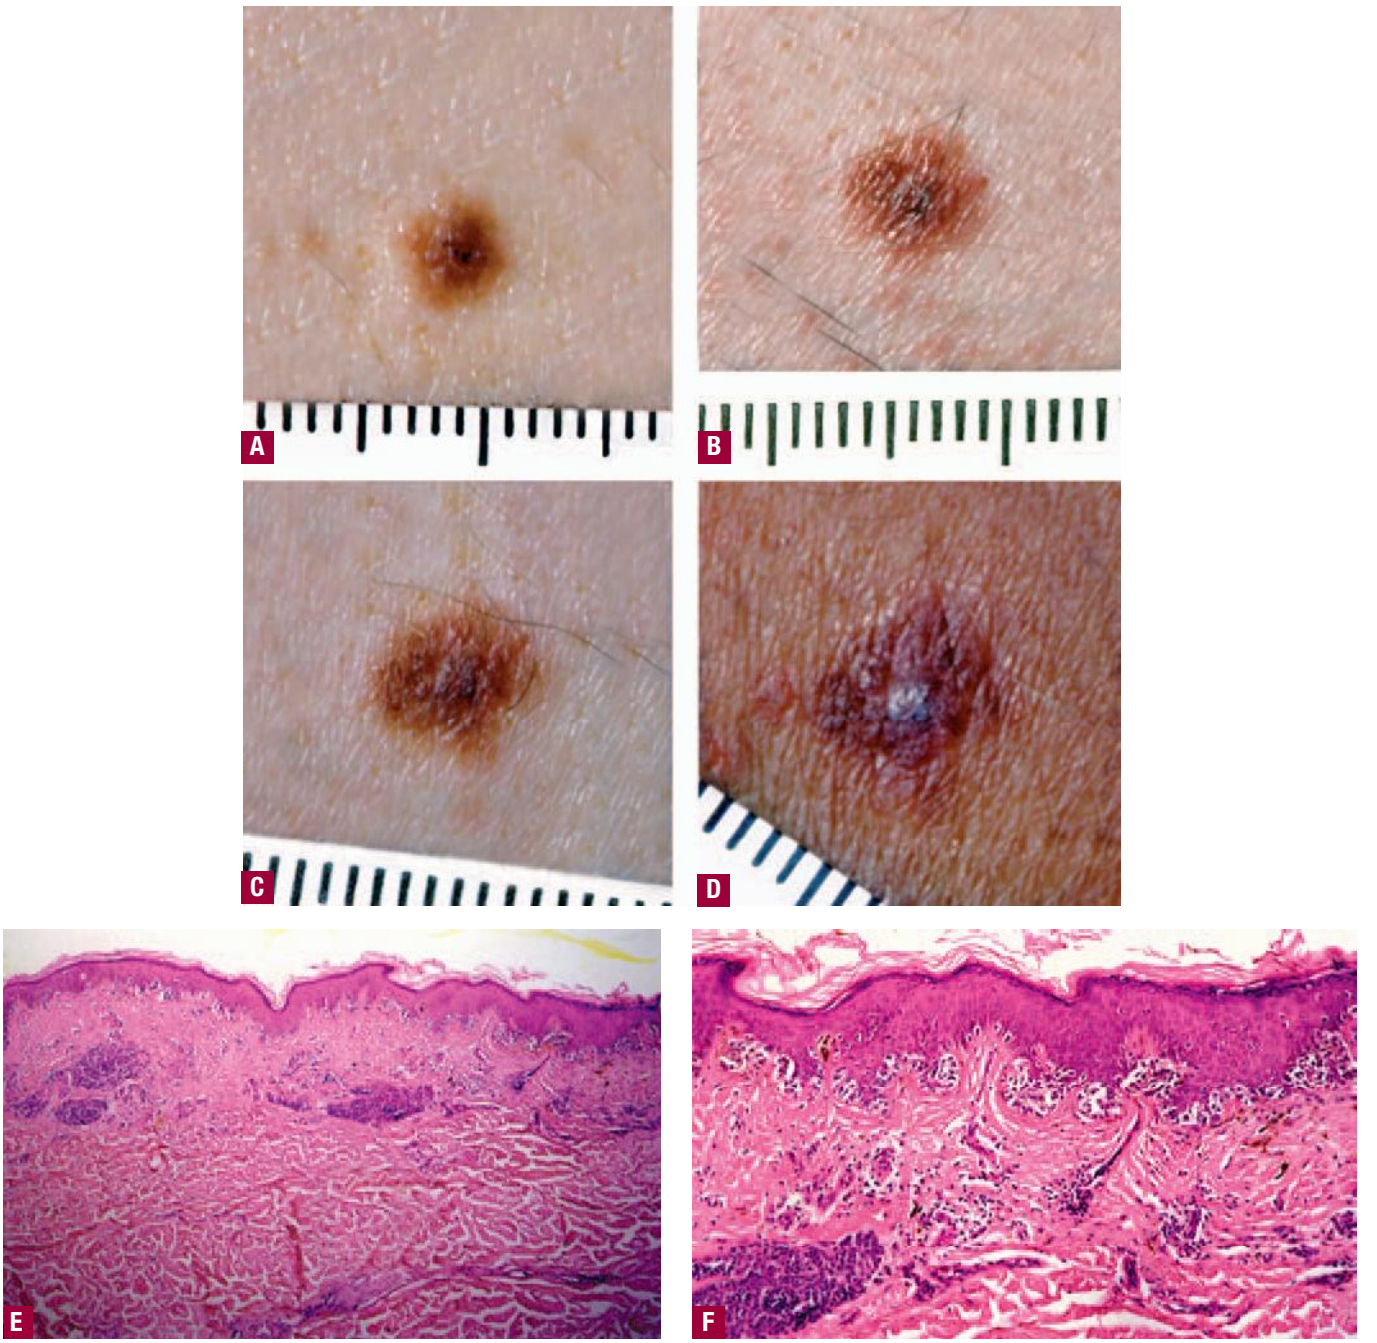
see Fig. 123-1). If a lesion is completely raised or papular, it is not a DN. Many DN, in the process of involution, become fully papular, and are no longer considered dysplastic. The surface of a DN usually retains fairly normal skin markings (Fig. 123-7A). If there is a papule without skin markings, one needs to think about an expansive process that distorts the architecture, such as a growing tumor. The lesions are asymmetric with an irregular outline. Often the outline is "geographic" and quite irregular. Lesions are frequently rhomboidal or polygonal; others may be almost ovoid or round, but have irregular projections into the surrounding skin (Fig. 123-8). The borders of the lesions are often smudged, with the pigment fading into the adjacent skin. Some of the border may be definitive; other areas may be indistinct. Color variation usually ranges from pink to very dark brown, but this needs to be evaluated in comparison with other pigmented lesions an individual has (see Fig. 123-3B). A very dark brown area in someone with a fair complexion may be suspicious for melanoma. Conversely, someone who is quite dark may make very dark nevi. A prominent erythematous component may correspond to an inflammatory infiltrate in the lesion. A disproportionate erythema in lesion in comparison with other lesions may also be suspicious for melanoma. Similarly, an area of central inflammation and pigment clearing in a DN may be suspicious for regressing melanoma.

Most DN start as ordinary appearing small, symmetric nevi (Fig 123-9A).[47] Unlike other nevi, they continue to enlarge in diameter over varying periods of time. Often, one of the first atypical

▲ **FIGURE 123-6** This lesion is 11 mm in diameter, with a "pebbly" central papular area and a several mm "shoulder" around the papular area. The borders are irregular and quite indistinct around the whole lesion. There is color variation from pinkish tan to medium brown.



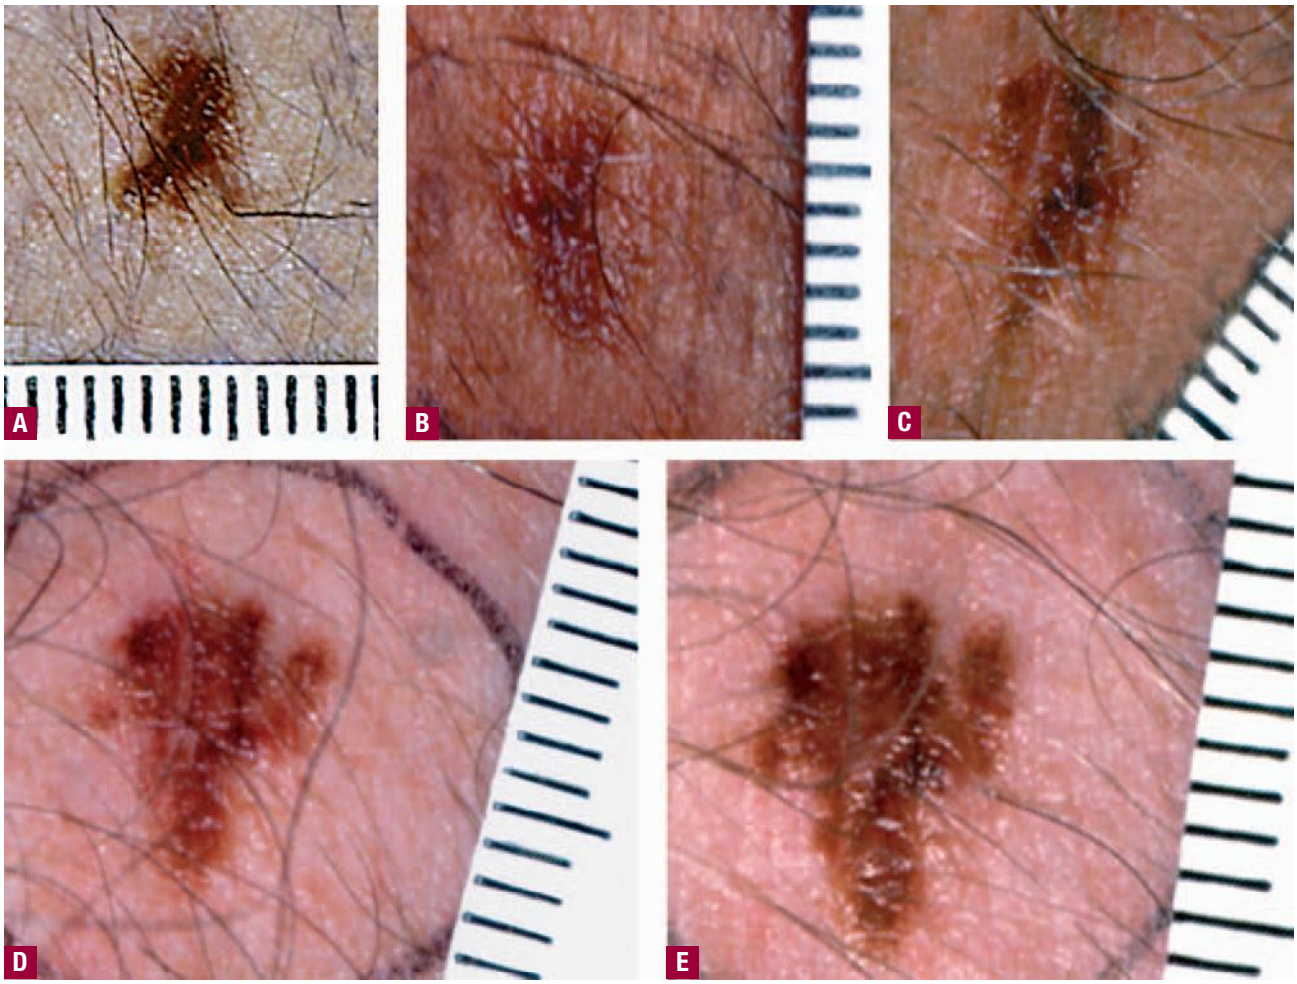
▲ **FIGURE 123-7** **A.** This is a lesion with largest diameter 8 mm, primarily flat with a central low papule, irregular outline, somewhat indistinct border at the upper left corner and far right protrusion, and variable pigmentation. The normal skin markings are well seen. **B.** The same lesion 4 years later after initiation of rigorous sun protection. The entire lesion is flatter. On the right side of the lesion in the area of the "shoulder," there is clear involution of the promontory and invagination of the shoulder area just above it. On the left, the outline has also invaginated toward the center. The entire lesion is also substantially lighter. This is an involuting dysplastic nevus.



▲ **FIGURE 123-9** **A.** A close-up was taken of this lesion because of increasing prominence in comparison with previous overview photographs. The lesion does not meet criteria for a clinical dysplastic nevus (DN). The largest diameter is not over 5 mm, but it is somewhat irregular in outline with indistinct borders and variable pigmentation. **B.** The same lesion 2 years later has increased in size to 6 mm; become more irregular with an indistinct border from approximately 4 to 6 o'clock and from 11 to 1 o'clock. The central hyperpigmentation has increased, and there is the beginning of central elevation. The lesion now meets criteria for a DN, but is not suspicious for melanoma. **C.** A year and a half later, the lesion now measures 7 mm and has become more irregular and asymmetric. The central papule is dark, but consistent with many other nevi. **D.** A year later, the patient had been using a sunbed for several months and was deeply tanned. The borders of the lesion are difficult to appreciate; the surface of the central papule is exfoliative and has lost the skin markings. The lesion was removed because of the continued changes. **E.**, **F.** There is a plaque of nevus cells at the base of the photomicrograph. Above this, there is an increased amount of connective tissue. Along the dermal-epidermal interface, there is proliferation of moderately atypical melanocytes. Below them is concentric eosinophilic fibroplasia. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

features is a smudging of the border of the lesion, followed by increasing irregularity of outline, and increasing asymmetry (see Fig. 123-9 B,C). Color variation may appear early. Some lesions will have growth arrest before reaching a diameter of 5 mm. Often the nevi will remain as relatively flat lesions over extended periods of time. Some will develop a central papule and evolve to a more typical compound or dermal nevus. As this occurs, the flat component generally recedes toward the papular component (see Fig. 123-7 A,B). Over time, most lesions involute and disappear, leaving no obvious trace.[47]

The most important clinical question in following each specific nevus is the determination of whether or not it is a melanoma (see Chap. 124). When using the "ABCDE" criteria in assessing a DN, each



▲ **FIGURE 123-10** The lesion's histopathology is demonstrated in Figure 123-2. **A.** The lesion was photographed because of increasing prominence on overview photographs. It meets all the clinical criteria for dysplastic nevus: It is larger in diameter than 5 mm; is asymmetric with irregular, indistinct borders; and has variable pigmentation. **B.** Four months later, after a couple months of sunbed use,[119] the lesion is somewhat darker, but it is difficult to see distinct boarders because of the deep tan. The outline generally looks similar to the previous photo. **C.** A year later, after continued sunbed use, the lesion is larger, darker, and more asymmetric. It had changed less than other lesions, and other, higher risk lesions were removed. **D.** Six months later, after stopping tanning, the lesion is much lighter. The darkest areas have lightened considerably. The upper pole of the lesion is expanding, and the whole lesion is asymmetric with some indistinct borders. **E.** Three months later, the darker areas were even darker and larger, and the lesion was excised. (Photomicrographs used with permission from Wallace H. Clark, Jr.)

characteristic will be a matter of degree, because DN share these characteristics with early melanoma (Asymmetry, Border irregularity, Color variegation, Diameter greater than 6 mm, and Evolving over time).[55–57] When assessing the evolution, change towards senescence or involution is not worrisome, but change towards morphology closer to melanoma is. Continuing change over several examinations out of proportion to changes in other lesions is also of concern for melanoma (Fig. 123-10).[47] Each lesion should be assessed within the context of the other lesions an individual has. For instance, a lesion on someone with red hair that has a quite dark brown area may be more suspicious for melanoma (because that individual doesn't usually make dark brown pigment) than a lesion with almost black pigmentation in a darker skinned individual. Some individuals have multiple lesions with severely atypical morphology, but the lesions have not changed over years.[47] These lesions usually do not need to be biopsied. If most lesions, including other DN, are in the process of involution, but a DN remains stably atypical or progresses and becomes even slightly more abnormal appearing, then it is reasonable to biopsy the lesion. Obviously, a new dark area in a previously relatively stable lesion is suspicious for melanoma. One becomes most suspicious of a lesion if it is disproportionately more atypical appearing than all of the other lesions. A recent survey of dermatologists[58] in Europe suggests that most dermatologists already use such a process. The recognition of melanoma is more of an overall pattern recognition and a differential recognition process, also known as the "ugly duckling sign," than an analytic criteria recognition (systematically going through all of the ABCDE criteria). The best predictors of melanoma were overall irregularity, the ugly duckling sign, and history of recent change.

Earlier recommendations suggested biopsy of a suspected DN at the time of initial examination to verify histologically that an individual has DN.[60] Over time, with the validation of epidemiologic studies identifying the clinically diagnosed DN as risk markers of melanoma and with the established reproducibility of the clinical diagnosis, it has become clear that the clinical diagnosis can generally be used for patient management. Many individuals with multiple DN will likely have excisional biopsy of lesions at some time in their clinical course; histologic information can be obtained at that time. This approach is also consistent with the rec-

ommendation that the only reason to biopsy a DN is to rule out melanoma.

Related Physical Findings

The major related physical findings in an individual with DN are the cutaneous phenotype and extent of solar injury, both of which are independent risk factors for melanoma.[54] Individuals who are heavily freckled and have DN are at higher risk of developing melanoma than those with DN who are not freckled.[9] In the nonfamilial setting, these effects appear additive. Recent melanoma studies have evaluated the variations in *MC1R*, the melanocortin 1 receptor gene, as a risk factor for melanoma.[61–65] Some variations in the gene are related to the freckling phenotype, fair skin, and red hair, the "red hair variants." Other, more common variants do not have a recognizable phenotype, but do increase melanoma risk. In melanoma-prone families, many individuals have information not only on the cutaneous phenotype, but on genetic variations in *MC1R* as well as the major melanoma susceptibility genes.[66–69] All the family studies showed an increase in risk of melanoma in *CDKN2A* mutation carriers associated with *MC1R* polymorphisms. Multiple alleles raised the risk higher. Only one study also evaluated DN. Within these families, DN and variations in *MC1R* both increase the risk of melanoma in *CDKN2A* mutation carriers.[69]

Evidence of chronic solar injury is also associated with an increased risk of melanoma in men with DN, especially in older men.[54]

Laboratory Tests

HISTOPATHOLOGY The major relevant diagnostic laboratory tests are the careful histologic examination of excised lesions. It is helpful to alert the pathologist to the particular area of concern that led to the biopsy. Sectioning through the area of most interest is essential to ensure that melanoma is not missed. The pathologist should also comment on the adequacy of the excision margins.

Histopathologic features are an immature growth pattern and random cytologic atypical of melanocytes (see Fig. 123-2) and a lymphocytic host response.

DN occupy a middle ground between common acquired nevi and early melanoma. As with virtually any biologic phenomenon, there is a continuum in melanocytic lesions between completely banal and malignancy. The difficulties in clinical and histologic diagnoses of DN lie in the border between common acquired nevi and nevi that barely meet criteria for DN (see Fig. 123-9E); and between severely DN and early melanoma (see eFig. 123-10.1 in on-line edition; see Figs. 123-2, 123-10F). The newly described *de novo intraepidermal epithelioid melanocytic dysplasia* is a variant that may lie within the severely DN-melanoma in situ continuum.[70]

The histologic diagnosis of DN can be considered in two components: architectural and cytologic.[71] The lesions are usually larger than common nevi; interpreting small lesions may be problematic. There is usually a junctional component which may be most of the lesion, or an edge or shoulder to a compound papule. The junctional component extends several retia beyond the dermal component. In the lesion, particularly in the junctional component, melanocytes are frequent, either singly or usually in small nests. Rete ridges are elongated, with the nests of melanocytes along the side or at the tips. Occasionally, the nests bridge between retia. There is fibroplasia in the dermis, often concentric eosinophilic fibroplasia or lamellar fibroplasia. Lymphocytes tend to be patchy and perivascular. Scattered melanocytes along the dermal-epidermal junction (at least 5 to 10) are atypical (random cytologic atypia). The atypical melanocytes are one-third to one-half larger than the melanocytes in the normal surrounding skin and have more abundant cytoplasm.[72] The nuclei of the normal melanocytes tend to be 4 to 6 μm, but those of the atypical melanocytes are 8 to 24 μm. The nuclei may be slightly irregular or folded with hyperchromasia and clumping of chromatin. Some may have prominent nucleoli. The melanocytes in DN are intermediate between ordinary nevus cells and early melanoma with regard to histologic characteristics, cell surface markers, and (often) somatic mutation detection. Several groups have proposed criteria for grading histologic dysplasia to help place a specific DN within the spectrum from almost normal nevus to melanoma.[13,73–75] Most of these systems, when evaluated, have good intraobserver reproducibility, but less interobserver reliability. It is often helpful for the clinician, however, for the pathology report to include an assessment whether the lesion is close to melanoma, because those lesions may need re-excision.

SPECIAL TESTS For clinical care of individuals with DN, full body photography is an essential tool.[47] Both overview photographs and close-up photographs of the most atypical nevi are extremely useful. These may be difficult to obtain in a practice with limited access to photography. The quality of the photography often reflects the frequency with which patients having pigmented lesions are seen and photographed, not just the quality of the photography equipment. Several algorithms for "covering" full skin surface areas have emerged, each with some advantages. In evaluating the different algorithms, it is useful to note how well each displays the anatomic regions with sufficient magnification and illumination to evaluate patterns, relative sizes, and pigmentary characteristics of nevi. Another important consideration is how reproducible the system is within one's practice. The usual system chosen may have to be altered for individuals with profuse dark body hair because the pattern and size of nevi with standard overviews may not be visible. The important uses of overviews in future examinations include (1) recognition of new lesions; (2) change in specific lesions in relation to others (see eFig. 123-10.2 in on-line edition); and (3) involution of lesions over time. There are commercially available photography management tools to aid in organizing the images for each patient. Each practitioner should evaluate what system works best in their practice and use this consistently.

Close-up photographs of the most atypical appearing nevi should be at 1:1 or 2:1 magnification with a ruler in the photograph (see Fig. 123-10). This allows careful comparison of the size, outline, color patterns, surface patterns, and skin markings at the time of the photograph with examinations in the future. In addition, photography of scalp nevi is also useful when they are not visible on overview photos. The location of each close-up photograph should be recorded to aid in identifying the specific nevus at future examinations. Again, commercially available management tools may be helpful. Many studies have demonstrated that the comparison of previous photography with the current skin examination aids in the recognition of changing lesions. Melanomas occurring in patients who are regularly followed using clinical photographs appear to be predominantly in situ or very thin invasive melanomas.[47,76–82]

In experienced hands, dermoscopy, or epiluminescence microscopy, is also a useful adjunct for examining specific lesions. Dermoscopy is a skill acquired through formal training, and it requires proficient pattern recognition and analy-

sis. It is more widely used and taught in Europe than in the United States. It is often impractical to examine every DN with dermoscopy during a routine evaluation, especially of someone with many DN. Most practitioners use dermoscopy only to examine select lesions.[82] Recent atlases have illustrated dermoscopy of DN and melanoma.[83,84] Several sets of criteria for differentiating nevi, including DN from melanoma, have been developed, including pattern analysis, ABCD (Asymmetry, Border, Color, Dermascopic structures) rule, Menzies method, and 7-point check list. These algorithms were compared among expert examiners.[85] Pattern analysis was the preferred method among most participants. It is not surprising, therefore, that the interobserver agreement was good for this method and that this method performed best, with highest sensitivity and specificity. There was substantial interobserver variation among the different variables in sets of criteria, but very high intraobserver consistency. This implies that the observers may interpret the components of the criteria differently but were very consistent in their interpretations. This analysis, however, did not focus specifically on DN.

Digital epiluminescence microscopy (digital dermoscopy) is also available, in which the digital dermoscopy images of specific pigmented lesions are stored and compared. Dermoscopic imaging in follow-up surveillance can thus be captured, similar to sequential photography of pigmented lesions. Sequential digital dermoscopy in compliant patients by experienced examiners increased the specificity of diagnoses.[90] Multiple different systems are available[86,90–92]; there are sparse data on direct comparisons between the systems. Some of the systems also include image analysis for automating diagnoses. Evaluation of the diagnostic precision of both dermoscopy by clinicians and digital dermoscopy with image analysis suggests that some systems may perform as well as or better than clinicians.[93] There is some evidence that these more quantitative comparisons may lead to higher specificity in the recognition of early melanoma. There is still major overlap, however, between DN and early melanoma.[94] Use of digital dermoscopy may also enhance confidence in care provided and an enhancement of self skin exams.[95] Use of digital epiluminescence microscopy is time consuming for the patients and the staff. The costs of the equipment at this time would likely limit the use of the modality to clinics having a high number of patients with pigmented lesions being followed.

New imaging techniques, such as confocal scanning laser microscopy, also hold much promise for identifying very early melanomas.[96,97] Confocal microscopy can visualize tissue architecture down to the papillary dermis at the individual cell level. Criteria for the diagnosis of melanoma are being developed. Specific criteria for DN should follow. Again, the technology is expensive, and the imaging is time consuming.

Box 123-1

Differential Diagnosis

Most Likely

- Common acquired nevus
- Congenital or congenital-type nevus
- Dermatofibroma
- Seborrheic keratosis

Consider

- Combined nevus
- Spitz nevus/Spitz variant
- Pigmented spindle cell nevus
- Blue nevus
- Pigmented actinic keratosis

Always Rule Out

- Melanoma in situ
- Superficial spreading melanoma
- Pigmented basal cell carcinoma

Differential Diagnosis (Box 123-1)

COMPLICATIONS

The major complication of DN is melanoma, but melanoma is a relatively uncommon event. These lesions are both risk markers for melanoma and precursor lesions for melanoma. Numerous studies have documented that DN are dynamic lesions, but only a small percentage progress toward or develop into melanoma.[79,82,89]

In most of the case-control studies evaluating risk of melanoma, the risk increases with more DN.[9,15,98,99] These risks are estimated based on the clinical recognition of DN. At this time, there are few data to address the risk of melanoma associated with only histologic evidence of DN. The correlation between the clinical and histologic diagnoses is not perfect; the optimal evaluation of this has not yet been done. It is likely that some of the discrepancies between histology and clinical diagnoses are in the border between normal and minimally dysplastic and between severely dysplastic and melanoma.

A continuum of risk of melanoma from the border of common acquired nevi to mild dysplasia to severe dysplasia is likely. In one large study, there was no risk associated with clinically very mild lesions that were at the borderline between normal and dysplastic where experienced observers disagreed about the diagnosis.[15] One unequivocal DN, however, increased risk of melanoma twofold. More than 10 increased the risk 12-fold [95 percent confidence interval (CI): 4.4–31]. A meta-analysis of 47 studies revealed the risk of melanoma associated with any atypical nevus was 10-fold increased (95 percent CI: 5.0–20.3).[99] The different studies used various criteria for the classification of a nevus as atypical or dysplastic. There was evidence of heterogeneity of the risks associated with DN according to the type of study (case-control vs. cohort), source of controls (hospital, population, or other), and exposure measure (dichotomous or not). Some of the heterogeneity in the combined data likely reflects the different diagnostic criteria for DN in the studies. When the analysis was limited to case-control studies, the risk of melanoma associated with five or more DN was sixfold increased (95 percent CI 3.8–10.3). Individuals with DN and melanoma are more likely to develop multiple primary melanomas than individuals who have melanoma, but not DN.[53] Individuals who are immunosuppressed, such as those with transplants[100,101] or those who have had lymphoma,[102] are at two- to eightfold more likely to develop melanoma. Where it has been investigated, the melanomas occur in individuals with DN.

Removal of all DN is not recommended for several reasons. Complete removal of all DN is not only unnecessary surgery; it also does not alter the need for continued surveillance of these individuals. Individuals with DN continue to develop new nevi until late middle age, and can develop melanoma de novo not associated with a nevus.[47] Some have hundreds of nevi, tens of which are dysplastic. Most nevi will undergo physiologic involution. Removal of all of the nevi does not change the need for careful sun protection, regular skin self exams, or routine professional examinations. Nevi need only be removed when clinically suspicious for melanoma.

PROGNOSIS AND CLINICAL COURSE

Much of the natural history information about DN derives from longitudinal studies of melanoma-prone families.[47] In

these families, DN may start to appear early in childhood. For some reason, atypical lesions may first appear on the scalp of young children, not usually in infancy or in toddlers.[103] For most children in melanoma-prone families who go on to develop DN, the first finding is an increased number of small typical nevi, most often in sun-exposed areas (see Fig. 123-10A).[104] Over time, some of these lesions grow in diameter, become more asymmetric with irregular, indistinct borders and variable pigmentation (see Fig. 123-10 B,C). Often by the time of puberty, characteristic DN exist. During puberty, individuals often develop more nevi and more atypical nevi. Children who have been carefully sun-protected tend to develop many fewer nevi. These findings are consistent with the epidemiologic studies which have shown that sun protection decreases the number of nevi that develop in children from the general population.[105]

Typically, DN are most frequent on intermittently exposed skin surfaces.[44–47] Epidemiologic studies have demonstrated that the most frequent site is the back; often the large irregular nevi are prominent on the lower back (see Fig. 123-3A), with relative sparing of the heavily sun-exposed upper back and shoulders. DN can, however, occur in minimally sun-exposed areas such as the doubly covered buttocks, breasts, scalp, and pubic regions. Individuals with DN may also develop nevi, not necessarily atypical, on palmar and plantar surfaces and in webspaces of hands and feet. It is uncommon for individuals with DN to have nevi on mucosal surfaces, but they do occur.

Individuals with DN continue to develop new nevi late into adulthood.[79,82,89] The majority of nevi in individuals with DN are ordinary common acquired nevi. In a longitudinal study (at least 5 years of follow-up) of individuals with DN in a pigmented lesion clinic, nevi were dynamic lesions.[79] One-third of individuals developed new nevi; most new nevi occurred in individuals under age 30. About one-half of the lesions with close-up photographs changed over time; 15 percent of lesions developed more atypical features; 35 percent became less atypical. Among these nevi, 2.4 percent disappeared. During the study period, 11 of 153 individuals developed new melanomas 0.25 to 0.85 mm thick. In a prospective study from Australia, nevi were also dynamic, but the study did not give specific information on DN, and the rates of change were highest in the individuals with over 20 DN at the first visit.[89]

Relatively few of an individual's total nevi are dysplastic (see Figs. 123-3A, 123-10C). Even in individuals from melanoma-prone families, the majority of DN involute and disappear over time.[47] Nevi and DN tend to have periods of relative stability and periods of increased activity, when several new nevi appear and existing nevi change in color, size, or appearance. The triggers for this activity are not well studied; anecdotally, sun exposure seems to stimulate nevus activity (see Figs. 123-9, 123-10, see eFig. 123-10.1 in on-line edition). After sun or UV exposure, new nevi may appear and existing nevi may enlarge, become more irregular, or darken. Pregnancy also seems to increase the number, size, and sometimes, pigmentation in DN. Long-term prospective studies documenting total changes in all nevi over decades (appearance, development, changes, involution) have not been done. The relationship of activity of nevi to molecular markers of senescence also has not been explored. Changes in tissue microenvironment or signaling may also be important in nevus changes.

Nevus counts and counts of DN in general decrease with age. In a longitudinal study of Australian individuals at increased risk of melanoma,[89] those over age 50 had fewer nevi develop or change. If lesions changed, however, they were more likely to be melanoma. Over age 50, most individuals do not have clinical DN.[15] Those who have remaining DN are at highly increased risk of melanoma. The lack of normal involution of these lesions may be a powerful risk marker for melanoma. About 20 percent of individuals who have had DN in their forties, though, continue to develop new nevi beyond age 50,[79] again indicating that they may have an "activated melanocyte system."[106]

The risk of melanoma has also been estimated among individuals with DN who have been followed in pigmented lesion clinics for a number of years.[79,82,89,107] In general, these patients were followed at least yearly. Overview and close-up photographs were used, and dermoscopy of suspicious lesions was also often used. Although the measures of level of risk of melanoma vary between studies, in general, the risk associated with the presence of DN was substantially elevated overall and increased with more DN. The risks tend to be highest in individuals with a personal and family history of melanoma; followed by those with a family history of melanoma, but no personal history; then those with a personal but no family history of melanoma; and lowest in those with neither personal nor family history of melanoma.

Although the familiarity of DN is not fully understood, it is reasonable to examine the first-degree relatives of individuals with multiple DN. If they are found to have DN, the same approach should be followed for their care.

The recommended frequency of regular health care provider examinations has not been systematically evaluated. Empiric recommendations have been suggested for individuals in melanoma-prone families,[47,108] but these have not been rigorously evaluated in a prospective study. The risk in these individuals is also likely to be higher than in individuals with DN without a family history of melanoma. For individuals having a large number of severe DN, it is reasonable to begin following them at 3-month intervals. If their nevi are relatively stable, this time can be extended to every 6 months, then to yearly. If an individual has few mild DN, yearly exams are reasonable. Whenever the activity of the nevi increases, new nevi are developing, and/or nevi are becoming darker and more irregular; it is important to increase the frequency of exams. The frequency of exams is also an interplay between what the individual patient will tolerate (with work absences, care expenses, etc.) and their reliability in performing skin self exams. If they are consistent in performing exams, and call for appointments when nevi are changing, the frequency of prescheduled exams can be more flexible.

Patients should receive copies of their overview and close-up clinical photographs for their use at home. A diagram of the close-up photos is helpful, especially for individuals with a large number of photographs. Patients should also undergo detailed instruction in skin self-examination using their photographs. The best methods for teaching the components of skin self-examination have not been systematically evaluated. Recent work has demonstrated that nurse instruction in skin self-examination using the patient's own photographs resulted in much better adherence to a program of regular self-exams.[109] There is also recent evidence that having patients map their moles on a body diagram may help improve self-exam accuracy.[110] The instruction about self-exams is also a good opportunity for reinforcing sun protective measures and the early recognition of melanoma. The determinants of continuing self-exams are not fully understood; women, highly educated individuals, people who have had skin cancers, and those who are confident about doing self-exams are more likely to do the exams.[111]

Education about sun protection is another component of the patient management. Although randomized clinical trial data are not available, a growing body of evidence supports the assumption that minimizing sun and UV exposure is prudent in individuals with multiple DN (see eFig. 123-10.1 in on-line edition). DN are both precursor lesions and risk markers for melanoma.[59] Minimizing exposure to the major environmental risk factor for melanoma, UV exposure, is warranted in this group. The suggestions for sun protection should be the same as those for the prevention of melanoma: avoidance of midday sun exposure, shade-seeking when out of doors, scheduling outdoor activity for early morning or late afternoon, use of protective clothing, and use of sunscreens. One of the important cohort studies that clearly established a risk of melanoma associated with use of UV tanning devices also demonstrated a high risk of melanoma in the women with large irregular nevi on their legs (14 percent of the cohort overall; 27 percent of cases).[112] Unfortunately, the authors did not report whether those with irregular nevi had a higher risk associated with using the tanning devices than those without the irregular nevi. Nonetheless, it seems sensible to advise that individuals with DN not use tanning devices.

Although there have been some reports of individuals with ocular melanoma being more likely to have DN, it is likely to be an extremely rare event. In a survey of usual practices among dermatologists, only 2.9 percent always recommended an exam for ocular melanocytic neoplasms.[113] Another 11.5 percent said they usually did. Most said that they recommended such an exam infrequently or never. It is reasonable to suggest that at the patient's next routine eye exam, they inform the ophthalmologist that they have DN. The ophthalmologist can, at that time, be alert for ocular pigmented lesions.

TREATMENT

Treatment of a DN that is suspicious for early melanoma is excisional biopsy of the entire lesion with visibly clear margins. Shave biopsies of these lesions are discouraged. Not infrequently, a shave biopsy does not fully excise the elongated rete, and the abnormal nests at the base of the rete are not removed. Repigmentation and re-growth can occur (see eFig. 123-10.1 in on-line edition). In melanoma-prone families, recurrences after shaves have sometimes been melanoma. The atypia in the melanocytes and nests is not uniform across the lesions. Because the major reason for removal of an DN is to rule out melanoma, it is important to completely remove the lesion to allow adequate histologic assessment of the lesion and the margins. One of the reasons commonly given for a shave biopsy is that the scarring will be less noticeable. If the shave is sufficiently deep to ensure removal of the entire lesion and to preserve the architecture for adequate histologic review, the scar will likely not be less noticeable. Because individuals with multiple DN may have a number of lesions removed over their lifetime, excisional biopsy with sutures may yield a much better cosmetic result for them. If the histology reveals severe dysplasia, reexcision to obtain adequate margins (usually 5 mm for severe dysplasia) may be required. In a survey of management of DN among dermatologists in practice that was conducted a number of years ago, 23 percent usually shaved a DN to fully remove it; 32 percent used saucerization, 12 percent used a punch, and 30 percent excised the lesion.[113]

Over the years, a number of different topical and systemic treatments have been tried to induce DN to differentiate or to remove them. One of the first agents was topical 5-fluorouracil (5 percent). Use of this agent on selected DN-induced inflammation, ulceration, and disappearance of the DN.[114] Parallel evaluations of topical and systemic antioxidants were then initiated. In a pilot study, topical retinoic acid–induced inflammation and clinical and histologic reversion toward common nevi.[115] Use of this agent, however, was limited by poor compliance due to skin irritation and inflammation. Another variation was adding cortisone to the treatment and using occlusive dressings.[116] A small randomized trial of oral β-carotene versus placebo for 3 years was conducted in 62 patients with numerous DN.[117] The endpoint was the number of new nevi that developed. At the time of analysis, there was no difference in the number of new nevi in the two groups. More recently, topical imiquimod cream (5 percent) was used three times a week for 20 weeks.[118] The endpoint was clinical response assessed by sequential confocal microscopy. There were difficulties in the comparison of the imaging techniques, but there were no obvious clinical changes in the treated lesions. The treated lesions showed a relative reduction of junctional and intraepidermal nevocytes with papillary fibrosis and some inflammation. The authors concluded that topical immune modulators may have some promise in chemoprevention of melanoma, but imiquimod did not warrant further investigation. In summary, although several promising topical agents have been tried, none have been efficacious and acceptable. These trials are difficult to design and conduct; there is a parallel large effect of removing UV exposure that affects the nevi and drives them toward regression/senescence. Documenting additional involution of nevi related to a medication can be problematic.

PREVENTION

The major preventive intervention for the development of dysplastic, as well as common acquired nevi, is likely decreased UV exposure, although this is not proven. With the growing body of evidence that childhood sun exposure is important in the number of nevi that develop,[105] it is important to initiate sun-protective behaviors early.

EPIDEMIOLOGY

The incidence of melanoma has increased significantly worldwide over the last several decades. In the United States, the lifetime risk of developing invasive melanoma was 1 in 1500 for persons born in 1935, 1 in 600 persons for those born in 1960, 1 in 150 persons for those born in 1980, and is estimated to be 1 in 62 persons for persons born in 2006 (1 in 34 including in situ melanoma). The American Cancer Society estimates that in 2006, 111,900 new cases of melanoma were diagnosed, including 49,710 in situ and 62,190 invasive cases (34,260 men and 27,930 women).[1] Melanoma had the greatest annual percent change in cancer incidence rate among the top 10 cancer sites by gender, all ages, and all races, between 1990 and 1997.[2] Invasive melanoma of the skin is the fifth most frequent site for cancer to occur in men and the sixth most frequent site in women, representing approximately 5 percent of all newly diagnosed cancers. Melanoma represents the most common cancer type in Caucasian women 25 to 29 years, second to thyroid cancer in women 15 to 24 years of age, and second to breast cancer in women 25 to 44.[3]

Mortality rates have also risen over the last several decades but not as quickly as incidence rates. The American Cancer Society estimates that in 2006, there were 7910 deaths (5020 men and 2890 women) due to melanoma.[4] Melanoma accounts for 79 percent of all skin cancer deaths. One American dies from melanoma approximately every hour. Melanoma is one of the leading cancers in terms of average years of life lost per death from disease. Although mortality rates have increased, survival for those diagnosed with melanoma have also increased. Based on U.S. Surveillance, Epidemiology, and End Results Program (SEER) data, the overall survival rates for melanoma were estimated at 60 percent in 1960 to 1963, 80 percent in 1974 to 1976, and 89 percent in 1992 to 1997.[5]

The mean age of diagnosis is relatively young at 52 years, which is 10 to 15 years earlier than the mean age of diagnosis in the more common tumors of the breast, lung, colon, and prostate. More than 25 percent of melanomas occur in persons less than 45 years of age. Incidence rises with age, especially in men. In the United States, women have a slightly higher incidence of melanoma before the age of 40 years. After age 40, men have a higher incidence, and the difference becomes remarkably large with increasing age. Mortality data parallel incidence data, with older men having the highest mortality rates. Although mortality rates in older persons, especially men, are rising, rates in younger persons and females have been steady or actually declined.[6] Lightly pigmented Caucasians have the highest incidence rates, much more than Hispanics, Asians, and African Americans.

ETIOLOGY AND PATHOGENESIS

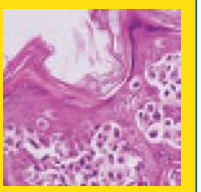
Risk Factors (Table 124-1)

SUN EXPOSURE Both genetic and environmental factors are related to melanoma pathogenesis and certainly not all melanomas are sun related. There is, however, clear convincing evidence that sun exposure, and more specifically ultraviolet (UV) exposure, is a major environmental cause of melanoma, especially in high-risk populations. Epidemiologic studies suggest that periodic, intense sun exposure (particularly during the critical time period of childhood and adolescence) rather than long, continued, heavy sun exposure is most important in melanoma causation, termed the *intermittent exposure* hypothesis. Sunburn history, notably blistering and peeling burns, serves as a surrogate measure of intermittent intense sun exposure. In one review of published literature, there was a significant positive association between sunburns during childhood and risk of melanoma development.[7] One blistering sunburn in childhood more than doubles a person's chances of developing melanoma later in life. Sunburns in adulthood have also been shown to contribute to melanoma risk.[8] Data from the behavior risk factor surveillance system of the Centers for Disease Control and Prevention show that nearly 32 percent of all adults aged ≥ 18 years, 58 percent between 18 and 29 years of age, and more than 40 percent of children report having had at least one annual sunburn defined as red skin for more than 12 hours.[9] Crude sunburn prevalence rates in white adults by state demonstrated higher sunburn rates among Caucasian adults living in the Midwest, possibly a reflection of a population that is more sun sensitive or less likely to practice sun-safe behaviors.

Migration studies generally indicate an increased melanoma risk in individuals who spent childhood in sunny geographic areas or emigrated to sunnier areas.[10] Younger migrants to sunny areas have an increased risk for melanoma as compared with adult immigrants. Lastly, there is an increased melanoma risk with longer duration of residence in the sunny locale.

Melanoma incidence and mortality among Caucasians correlate inversely with latitude of residence and dose of UV radiation, termed the *latitude gradient*.

MELANOMA AT A GLANCE



- Rising incidence worldwide; U.S. estimated lifetime risk of invasive melanoma is 1 in 1500 if born in 1935, 1 in 600 if born in 1960, 1 in 62 if born in 2006 (1 in 34 with inclusion of in situ melanoma).
- Risk factors: history of sunburns and/or heavy sun exposure, blue or green eyes, blonde or red hair, fair complexion, > 100 typical nevi, any atypical nevi, prior personal or family history of melanoma, *p16* mutation.
- Mean age of diagnosis: 52 years, 10 to 15 years younger than other more common cancers, (e.g., breast, lung, colon, and prostate).
- Most common location: back in men, lower extremities, then trunk in women.
- Features used for melanoma recognition: A (asymmetry), B (irregular borders), C (color variegation), D (diameter > 6 mm is most common use but others have changed D to difference-"ugly duckling" sign or different with respect to change in size, shape, color, or persistent lesional pruritus), E (evolving over time).
- Follows highly variable course and represents a heterogeneous disorder.
- Surgically curable if diagnosed and treated in early phase, but potentially lethal with increased risk when diagnosed and treated late.

TABLE 124-1
Risk Factors for Cutaneous Melanoma

- Ultraviolet radiation exposure
  - Blistering sunburns at any time in life; intermittent or sporadic high levels of exposure
  - Excessive chronic exposure to sunlight
- Phenotypic characteristics
  - Fair skin, inability to tan, tendency to sunburn or freckle (SPT I and II)
  - Blue or green eyes
  - Red or blond hair
  - Numerous typical nevi and/or more than one atypical nevus
  - Large congenital nevus
- History of prior melanoma
- Family history of melanoma
- Mutation in p16, BRAF, or MC1R
- Xeroderma pigmentosum
- Immune suppression (debatable)

The highest rates are nearest the equator. In areas as geographically diverse as the United States, New Zealand, and Australia, the incidence of melanoma is greater in regions closer to the equator. However, this gradient may be confounded by other risk factors for melanoma. In Italy, for example, more darkly pigmented persons reside in the South whereas more lightly pigmented persons live in the North, so that the latitude gradient is actually reversed.[3] Even in the United States, SEER data from 1992 to 2001 demonstrate that the latitude gradient applies only to non-Hispanic whites; melanoma incidence was not associated with latitude and UV index in African Americans, Hispanics, Asians, and Native Americans.[11]

The anatomic distribution of melanoma by body site demonstrates that intermittently exposed skin areas have the highest rates of developing melanoma. In men, the trunk, particularly the upper back, is the most common site for melanoma. In women, the lower legs, followed by the trunk, are the most common sites.[12] These intermittently exposed areas are the most common areas to develop melanoma in younger persons. In older persons, there is a greater incidence of melanomas located on chronically exposed areas with maximal cumulative sun exposure. The face is the most common location for melanoma in older persons, with the addition of the neck, scalp, and ears as well, in older men.[13,14]

Several forms of artificial light have been associated with the development of melanoma, particularly psoralen and ultraviolet A light (PUVA) and UVB, and tanning booths. The so-called *PUVA Follow-up Study* demonstrated increased rates of melanoma after PUVA exposure, with an incidence rate ratio of 9.3 approximately 20 years after PUVA therapy; these rates increased over time and were higher in patients exposed to high doses of PUVA.[15] However, the role of PUVA in the development of melanoma has been disputed (see Chap. 239). There is also rising concern over tanning beds and melanoma risk, especially as exposure to the artificial UV radiation is intermittent in nature. Any exposure to artificial tanning devices modestly, but significantly, increases the risk of cutaneous melanoma (odds ratio, 1.25), and longer duration of bed use, younger age at first exposure, and higher frequency of use are associated with a significantly elevated risk (odds ratio, 1.69).[16]

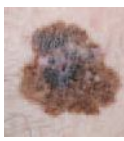
SKIN PHENOTYPE Light skin pigmentation, blond or red hair, blue or green eyes, prominent freckling tendency, and tendency to sunburn with Fitzpatrick skin phototype I–II are phenotypic features associated with an increased risk of melanoma. Melanoma occurs infrequently in type V–VI skin, suggesting that skin pigment plays a protective role.

MELANOCYTIC NEVI There is an increased risk of melanoma associated with nevi, both in a quantitative (i.e., number of nevi) and qualitative (i.e., typical vs. atypical nevi) manner. Adults with more than 100 clinically typical-appearing nevi, children with more than 50 typical-appearing nevi, and any patient with atypical nevi (see Chap. 123) are at risk. Tucker et al. found that the presence of a solitary dysplastic nevus doubled the risk of melanoma, while having 10 or more atypical nevi was associated with a 12-fold elevation of risk.[17] Nevi more often serve as a genetic marker of increased risk rather than a pre-malignant lesion, as most melanomas arise de novo. In a study of 1606 patients with melanoma, only 26 percent of the melanomas were histologically associated with nevi (43 percent of these atypical nevi, 57 percent other nevi).[18]

On the other hand, large congenital nevi are recognized potential precursors of melanoma, although the degree of risk varies depending on the size of the lesion (see Chap. 122).[19] Many series define large congenital nevi as greater than 20 cm in diameter in adulthood, and lifetime risks for developing melanoma are generally accepted to be in the 5 percent to 10 percent range. It is estimated that 70 percent of melanomas in large congenital nevi develop before the age of 10 years old and may occur deep within the nevus or even in the central nervous system, making detection of a thin lesion difficult. Patients with large congenital nevi located on the posterior axis (paraspinal, head, and neck regions) or in conjunction with multiple satellite lesions are at risk for neurocutaneous melanosis, with an increased risk of developing melanoma in the central nervous system. For small- to medium-sized congenital nevi, the melanoma risk is similar to any other area of skin; in this case, melanoma usually occurs later in life (after puberty), and arises at the dermal-epidermal junction, making early detection possible.[19] Thus, prophylactic excision of small- and medium-sized congenital nevi is usually unwarranted.

FAMILY HISTORY Patients with familial melanoma are estimated to account for 10 percent to 15 percent of all patients with melanoma. Having one first-degree relative with melanoma doubles the risk of melanoma, whereas having three or more first-degree relatives with melanoma increases the risk 35- to 70-fold.[20] Some of this risk may be attributed to shared risk factors such as skin phenotype, multiple nevi, and excessive sun exposure. The association between familial melanoma and multiple atypical nevi has historically been given various names, including *B-K mole syndrome*, *familial atypical multiple mole-melanoma syndrome*, and *dysplastic nevus syndrome* (see Chap. 123). Patients with familial melanoma typically have earlier onset melanoma and multiple primaries as well as atypical nevi. The molecular basis for some familial atypical multiple mole-melanoma syndrome kindreds will be discussed in Genetics.

PERSONAL HISTORY A previous history of melanoma increases the risk for another primary melanoma, with 5 percent to 15 percent of individuals developing multiple primary melanomas.[21,22] In patients with multiple primary melanomas, roughly one-half develop a second primary tumor in the same region of the body (i.e., trunk, extremity, head, and neck) and roughly one-half develop a second primary melanoma within the first year of initial diagnosis. However, subsequent primary melanomas may develop decades after diagnosis of the



initial lesion, stressing the need for long-term surveillance. Subsequent melanomas are thinner compared with the first melanoma in roughly 70 percent to 75 percent of cases.[21]

Immunosuppression has also been described as a risk factor for melanoma with a two- to fivefold increased incidence reported post-transplantation in a few studies.[3] The increased incidence of melanoma with immunosuppression, however, remains debatable. Finally, a history of actinic keratosis or non-melanoma skin cancer also confers a small increased risk of developing melanoma.

GENETICS ***CDKN2A-CDK4-TP53 Pathway.*** Germline mutations in the chromosome 9p21 tumor suppressor gene, cyclin-dependent kinase inhibitor 2A (*CDKN2A*), account for approximately 40 percent of hereditary melanoma cases (≥ 3 melanomas in one lineage) and confer a 76 percent chance of developing melanoma in the United States[23]; concordant with ambient rates, this risk is somewhat higher in Australia and lower in Europe. Individuals with germline *CDKN2A* mutations also exhibit a higher risk of pancreatic cancer; an estimated 15 percent of individuals with a mutant allele will develop pancreatic cancer in their lifetime.[24] Bona fide deleterious point mutations in *CDKN2A* are relatively uncommon in primary melanoma tumors although homozygous deletions of this gene may obscure the true rate of somatic loss in melanoma. *CDKN2A*, encodes two gene products: p16 (also known as *INK4a*, inhibitor of kinase 4a) and p^{14ARF} (alternative reading frame). p16 is a cell cycle regulator that binds and inhibits cyclin-dependent kinases CDK4 or CDK6, thereby inhibiting progression of cells through the G1 phase of the cell cycle. If p16 function is absent or inactivated by mutation, unrestrained CDK4 activity phosphorylates the retinoblastoma protein thereby releasing the transcription factor E2-F and inducing S-phase entry. This sequence culminates in enhanced cellular proliferation which, in the absence of checkpoint regulation, results in unrestrained growth and neoplasia.

The binding partner of the p16 protein is CDK4. Only a handful of families worldwide thus far have been reported to carry hereditary mutations in CDK4 while somatic mutations in this gene have also been detected in some melanoma cell lines. Functional studies suggest that mutations in CDK4 render the cyclin-dependent protein kinase resistant to p16 inhibition, resulting in a phenotype identical to that from p16 loss.

The p^{14ARF} protein from CDKN2A inhibits a cellular oncogene MDM2, which in turn accelerates the destruction of the p53 tumor suppressor gene.[25] Thus, complete loss of CDKN2A also leads to abrogation of p^{14ARF} and loss of p53 function. Thus, this single locus can impact both the retinoblastoma protein and p53 pathways and probably explains the low rate of direct *TP53* mutagenesis in melanoma.

RAS Signaling Pathway. Davies et al. first reported in 2002 a somatic mutation in the *BRAF* gene in 66 percent of melanomas.[26] B-raf is a serine/threonine kinase, which is a major player in the Ras-Raf-Mek-Erk mitogen-activated protein kinase (MAPK) signaling transduction pathway that regulates cell growth, proliferation, and differentiation in response to various growth factors, cytokines, and hormones. The stimuli activate the G-protein Ras by inducing the exchange of guanosine 5′-diphosphate for guanosine 5′-triphosphate, which then binds and activates Raf. Raf phosphorylates and activates Mek, which in turn phosphorylates MAPK (i.e., Erks). This signaling cascade serves to intracellularly amplify the extracellular signals mediated by growth factors. There are three functional Raf proteins in humans, A-raf, B-raf, and C-raf. B-raf has a much higher basal kinase activity than either A-raf or C-raf, and somatic mutations in B-raf occur with moderate to higher frequency in melanoma and colorectal, ovarian, and papillary thyroid carcinomas, implicating activating oncogenic mutations of B-raf as critical promoters of malignancy.[27]

BRAF mutations are significantly more common in melanomas occurring on skin subject to intermittent sun exposure, with 81 percent of melanomas on skin without chronic sun damage having *BRAF* or *NRAS* mutations.[28] On the other hand, the majority of melanomas from acral sites (palms, soles, subungual skin), mucosa, or chronically sun-damaged skin do not carry a mutation in either gene. There are also significant differences in the number of copies of genomic DNA in melanomas located in the various regions. Melanomas with wild-type *BRAF* or *RAS* frequently had increases in the number of copies of the genes for *CDK4* and *CCND1* (cyclin D1), two critical G1 cell cycle proteins and two genes that are transcriptionally induced by activated MAPK signaling.[28]

Mutations in *PTEN/MMAC1* tumor suppressor gene also lead to enhanced Ras pathway signaling.[29] This protein/lipid phosphatase downregulates signaling through the Akt arm of the Ras circuitry. When PTEN is inactivated, there is dysregulated Akt activity along with increased cellular survival.

Other Genes. **MICROPHTHALMIA.** Recently, somatic amplifications of the microphthalmia (*MITF*) gene in a subset of melanoma tumors were identified, and it was demonstrated that overexpression of *MITF*, in conjunction with ectopic expression of *BRAF*, resulted in melanocyte transformation.[30] The Mitf protein is a transcription factor that appears to be a master regulator of melanocyte differentiation, and amplification of this gene appears to contribute to a novel carcinogenic mechanism known as *lineage addiction*.

MELANOCORTIN-1-RECEPTOR. As mentioned above, red hair and sun sensitivity represent epidemiologically demonstrated risk factors for cutaneous melanoma. Recently, mutations in the melanocortin-1-receptor (*MC1R*) were shown to strongly contribute to the red hair/fair skin phenotype.[31] As such, germline mutations in the *MC1R* gene have also been shown to increase melanoma risk by approximately two- to fourfold in the general population[32]; it also confers risk for non-melanoma skin cancer. Because the prevalence of *MC1R* mutations is quite high in the white population, its attributable risk to melanoma is higher than the rarer high-risk *CDKN2A* mutations.

XERODERMA PIGMENTOSUM GENES. Xeroderma pigmentosum (XP) is a rare autosomal recessive genodermatosis comprised of at least seven complementation groups each defined by a separate gene. The XP genes are involved in excising DNA photoproducts in a reparative program termed *nucleotide excision repair*. Thus, heritable defects in these genes lead to increased mutagenesis and early carcinogenesis. Patients with XP harbor a 600- to 1000-fold increased risk for skin cancer, including cutaneous melanoma.

BREAST CANCER SUSCEPTIBILITY GENE. Carriers of the breast cancer susceptibility gene, *BRCA2*, appear to harbor an increased risk for melanoma (2.58-fold).[33] Although an interaction between breast cancer and melanoma risk has been suggested on epidemiologic

grounds, the genetic interaction between BRCA2 and melanoma risk remains to be fully determined.

Tumorigenesis and Tumor Progression

Five stages of malignant transformation and tumor progression in melanocytes have been suggested, based on clinical, histopathologic, immunopathologic, cytogenetic, and in vitro properties: (1) benign melanocytic nevi; (2) atypical nevi; (3) primary malignant melanoma, radial growth phase; (4) primary malignant melanoma, vertical growth phase; and (5) metastatic malignant melanoma. It is believed that with each successive step of tumorigenesis, a new clone of cells emerges with growth advantages over the surrounding tissue, resulting in "clonal expansion." It has been postulated that a critical step in tumor progression of melanoma may be the transition from radial to vertical growth phases. The radial growth phase consists of primarily intraepidermal proliferation of melanoma cells, but also invasion of the papillary dermis by small numbers of cells that have gained a growth advantage. These cells are thought to have the capacity for autonomous proliferation in this location, but not for aggregative growth. Radial growth phase cells are characterized by the presence of E-cadherin, an adhesion molecule that interacts with keratinocytes and impedes migration of the cells from their intraepidermal location[34] Melanomas in this phase are probably incapable of metastasis. The vertical growth phase is signaled by the property of aggregative growth, resulting in the formation of expansile nests or nodules of cells. Because the metastatic cascade comprises a complex range of numerous biochemical events, the vertical growth phase is likely an oversimplified correlate for the metastatic phenotype. Among other characteristics, vertical growth phase cells lose E-cadherin and express N-cadherin, a molecule that interacts with fibroblasts, macrophages and endothelial cells. This latter interaction may facilitate intravasation of the malignant cells.[34]

A discussion of tumorigenesis of melanoma must take into account several important clinical observations: (1) the association between precursor nevi and melanoma in approximately 30 percent of cases (an apparent absence of precursor nevi in 70 percent of melanoma); (2) the role of UV light in the pathogenesis of melanoma; (3) pigmentary phenotype of patients in whom melanoma develops; and (4) family history of melanoma and other genetic factors. When the above observations are considered in light of the multistep process of tumor progression of melanoma, at least two major pathways of tumorigenesis can be envisioned.

In the first pathway, melanomas, particularly superficial spreading melanomas (SSMs), at least in some cases, develop in association with melanocytic nevi. Nevi may represent the first stage of tumor progression of melanoma or an initiated clonal proliferation. The most likely initiating agent would be UV exposure, perhaps at an early age. There is epidemiologic evidence that sun exposure earlier in life may result in larger numbers of nevi. The number of precursor nevi may be important as greater numbers of initiated cells would increase the target population for another mutational event. As UV is believed to be a complete carcinogen, sunlight exposure, perhaps of intermittent nature, could lead to this second mutational event, resulting in tumor progression. A second pathway of melanoma development is exemplified by lentigo maligna melanoma (LMM). This form of melanoma results from cumulative sun exposure and a corresponding cumulative insult to the DNA of melanocytes on sun-exposed skin. The age-incidence rates show a steady increase with age, consistent with continuous exposure (initiation) to a carcinogenic agent such as UV light.

Curtin et al. compared genome-wide alterations in the number of copies of DNA and mutational status of *BRAF* and *NRAS* in melanomas from variable groups in which the degree of exposure to UV light differed.[28] The genetic alterations identified in melanomas at different sites with different levels of sun exposure indicated that there are distinct genetic pathways in the development of melanoma. This supports the hypothesis that the clinical heterogeneity notable for melanoma may be explained by genetically distinct types of melanoma with different susceptibility to UV light.[28] Certainly, other as yet unknown pathways may exist that are independent of UV light.

CLINICAL FINDINGS

Sub-Types of Melanoma

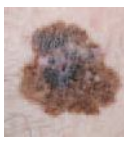
SUPERFICIAL SPREADING MELANOMA SSM is the most common sub-type, accounting for approximately 70 percent of all cutaneous melanomas. It is diagnosed most commonly in the fourth and fifth decades on intermittently sun-exposed areas, most frequently the lower extremity of women, and the upper back of men. Its classic clinical appearance best fits into the ABCD criteria (see Making a Diagnosis), with irregular borders and irregular pigmentation, but it may present subtly as a discrete focal area of darkening within a pre-existing nevus. The range of appearance of SSM is broad (Figs. 124-1 and 124-2). Although varying shades of brown typify most melanocytic lesions, striking aspects of dark brown to black, blue-grey, pink, red, and grey-white (which may represent regression) may be found in melanoma. SSM is the sub-type of melanoma most commonly associated with pre-existing nevi. The history of SSM is often of a lesion slowly changing over months to years. It may be mistaken for an atypical nevus or seborrheic keratosis.

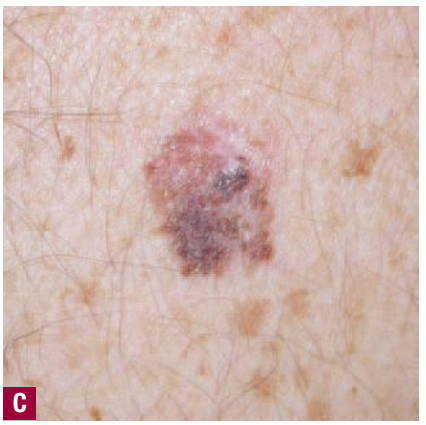
DIFFERENTIAL DIAGNOSIS (Box 124-1)

NODULAR MELANOMA Nodular melanoma (NM) is the second most common melanoma sub-type and accounts for approximately 15 percent to 30 percent of all melanomas. The median age of onset is 53 years, and the trunk is the most common site. NM is remarkable for rapid evolution, often arising over several weeks to months. NM clinically lacks an apparent radial growth phase. It is more common for NM to begin de novo than to arise in a pre-existing nevus. NM typically appears as a uniformly dark blue-black or bluish-red raised lesion, but 5 percent are amelanotic (Fig. 124-3). A substantial proportion of thick melanomas are of the nodular type.[35] Early lesions often lack asymmetry, have irregular borders, and are a size > 6 mm. Amelanotic lesions may be mistaken for basal cell carcinoma, pyogenic granuloma, or hemangioma, whereas pigmented lesions may be mistaken for blue nevi or pigmented basal cell carcinomas.

DIFFERENTIAL DIAGNOSIS (Box 124-2)

LENTIGO MALIGNA AND LENTIGO MALIGNA MELANOMA LM is a sub-type of melanoma in situ with a prolonged radial growth phase that may progress to invasive LMM with time. Invasive LMM constitutes 10 percent to 15 percent of cutaneous melanomas. LM and LMM are diagnosed most commonly in the seventh to eighth decades in an older population than other types of melanoma; they are uncommon before the





◀ **FIGURE 124-1** Superficial spreading melanoma (SSM). **A.** Classic clinical appearance with cardinal features of SSM: asymmetry, irregular scalloped borders, mottled variegate color, large diameter, and central elevation with surface distortion in a 45-year-old man, left chest, Breslow depth 1.25 mm. **B.** Another SSM with similar features but with pronounced areas of pink, shades of blue and white, with peripheral areas of black and brown in a 54-year-old woman, right lower abdomen, Breslow depth 3.5 mm, 26 mitoses/mm^2, ulceration focally present. **C.** Earlier detection in a 55-year-old man with many atypical nevi, patient unaware of the lesion, lesion noted by primary care physician during a routine physical examination, "different" than other nevi, right upper back, Breslow depth 0.50 mm. The pink/tan upper portion is an atypical nevus, the lower portion SSM arising in an atypical nevus. **D.** Still earlier detection with more subtle ABCDs (asymmetry, border, color, diameter/difference, elevation/evolving), forearm, Breslow depth 0.14 mm. The lesion was 0.8 cm in diameter with a history of a "brown spot," which grew in size, changed shape, and changed to a darker color over several months.

age of 40 years. The most common location is on the chronically sun-exposed face, on the cheeks and nose in particular; the neck, scalp, and ears are also involved in men. Its pathogenesis is thought to be related to cumulative sun exposure rather than intermittent exposure. LM is a flat, slowly enlarging, brown, freckle-like macule with irregular shape and differing shades of brown and tan, usually arising in a background of photodamage (Fig. 124-4). The life-

time risk of LMM developing from LM is estimated to be low but the invasive component is potentially lethal.[36] LMM is frequently larger than LM and may continue to be macular in early lesions, although a nodular portion is often seen within the patch later. Both LM and LMM often have clinically ill-defined borders, which may be obscured by background actinic damage consisting of lentigines, pigmented actinic keratoses, or ephelides. LM and LMM are associated with significantly higher rates of extensive sub-clinical lateral growth, resulting in higher recurrence rates with standard recommended margins and failure to completely excise the lesion. LM and LMM have the least common association with nevi, at 3 percent of cases, but the highest rate of association with desmoplastic melanoma (DM).

DIFFERENTIAL DIAGNOSIS (Box 124-3)

ACRAL LENTIGINOUS MELANOMA Acral lentiginous melanoma (ALM) is a sub-type of melanoma with distinct differences in frequencies seen between ethnic groups. ALM constitutes only 2 percent to 8 percent of melanomas in Caucasians but represents the most common form in darker-pigmented individuals (60 percent to 72 percent in blacks, 29 percent to 46 percent in Asians). Although the proportion of ALM seen in darker-pigmented individuals is higher, the incidence of ALM is similar for Caucasians and other ethnicities. ALM is diagnosed in an older population, with the median age of onset being 65 years old. The most common site for ALM is the sole, with the palm and subungual locations following (Fig. 124-5). Not all palmar or plantar melanomas are ALMs; a minority are SSMs or NMs. The clinical appearance of ALM can be brown, black, tan, or red with variegations in color and irregular borders; however, the most common color is brown-black. There is often a delay in the diagnosis of ALM, often misdiagnosed as a plantar wart or hematoma, leading to a more advanced lesion upon diagnosis associated with poorer outcomes.[37] ALM is not thought to be associated with sun exposure.

Subungual melanoma, considered a variant of ALM, generally arises from the nail matrix, most commonly on the great toe or thumb (Fig. 124-6). It appears as a brown to black discoloration or growth in the nail bed. A widening, dark, or irregularly pigmented longitudinal nail streak (melanonychia striata) with or without nail dystrophy and nail plate elevation may be seen. Hutchinson sign, the finding of pigmentation of the posterior nail fold, has been considered an ominous finding associated with advanced subungual melanoma. Benign lesions that can mimic subungual melanoma include

longitudinal melanonychia, subungual hematoma, or pyogenic granuloma or even onychomycosis with pigmentation or hemorrhage.

DIFFERENTIAL DIAGNOSIS (Box 124-4)

Other Variants

DESMOPLASTIC MELANOMA DM is an uncommon type of melanoma that is locally aggressive with high rates of local recurrence. It most commonly develops in older persons, usually in the sixth or seventh decade, and has a male predominance 2:1. The sun-exposed head and neck regions are the most common sites. The lesions typically have a firm, sclerotic, or indurated quality, and one-half are amelanotic (see eFig. 124-6.1 in on-line edition). Approximately one-half of the lesions arise in association with the LM histologic sub-type. Many DMs are deeply invasive at diagnosis and have a propensity to infiltrate perineurally, otherwise called *neurotropic melanoma*. Neurotropism enhances the likelihood of local recurrence. Occasionally, there are some lesions with prominent perineural invasion and no evidence of an intraepidermal component. These lesions are designated *neurotropic melanoma*. Although deeply invasive, DM is associated with lower metastatic rates than other sub-types of melanoma when matched for depth of invasion. A recent study has shown that lesions with fusiform and/or epithelioid melanoma cells had a higher metastatic rate than those with pure DM with only fibrosing component.[38] Results from a small study that involved 10 samples that investigated gene expression profiling demonstrated a molecular distinction between DM and nondesmoplastic melanoma.[39]

Box 124-3

MUCOSAL MELANOMA Melanoma infrequently can arise on mucosal surfaces. The most common sites are the head and neck (conjunctival, intranasal, sinus, and oral cavities), vulva, anorectal, or even urethral melanoma (Fig. 124-7). With the exception of the conjunctiva, patients present most often with delayed detection and a deeply pigmented, irregular lesion, but due to its location, may also present with bleeding or a mass lesion.[40] As most of these lesions present with a radial growth phase manifesting a macular pigmentation, any suspicious area in these sites should be biopsied. Lesions of the conjunctiva are easily visible and appear increased in patients with atypical nevus.[41,42]

NEVOID MELANOMA Nevoid melanoma describes a heterogeneous group of rare lesions that histologically resemble benign nevi by their symmetry and apparent maturation with descent in the dermis, thus with greater potential for misdiagnosis. Clues to their histologic diagnosis include marked hyperchromasia of the nuclei of the tumor cells, the presence of mitoses, and an expansile

growth of the dermal cells with effacement of the adventitia in affected areas. Clinically this may correspond to a tan papule or nodule, more often > 1 cm in diameter on a young adult.[43]

SPITZOID MELANOMA Spitzoid melanoma is a sub-type of melanoma that clinically and histologically resembles a Spitz nevus (see Chap. 122), but tends to be larger and have asymmetry and irregular coloration. Distinction between the two is sometimes extremely difficult, especially in the younger patient with mitoses favoring melanoma. In this tumor, the size of the lesion, greater than 1 cm in diameter; thickness of the invasive component, well over 2 mm; and quite numerous mitoses, many atypical; are helpful in identifying these lesions. The role of *BRAF* or *NRAS* is less clear in the pathogenesis of Spitzoid melanoma.[44]

OTHER RARE TYPES Several other rare and unusual types of melanoma are beyond the scope of this chapter, but previously reported in a comprehensive review, which include metaplastic melanoma, balloon cell melanoma, signet-ring cell melanoma, myxoid melanoma, rhabdoid melanoma, minimal-deviation melanoma, animal-type melanoma, malignant blue nevus.[43]

▲ **FIGURE 124-6** Subungual acral lentiginous melanoma (ALM). **A.** Extensive involvement of periungual skin (Hutchinson sign) with dystrophy and loss of the nail plate secondary to the tumor. **B.** ALM great toe, without notable Hutchinson sign, Breslow depth 3.4 mm, 6 mitoses/mm^2, two positive sentinel nodes identified, disease free at 2 years. **C.** Advanced subungual ALM with proximal periungual macular component and subungual and distal ulcerated nodular component. **D.** Subungual ALM, thumb nail bed streak, Breslow depth 0.5 mm. This was her fourth primary melanoma, other three located on the shoulder, cheek, and neck, the first 14 years prior.

Melanoma and Pregnancy

Melanoma is the second most common cancer in women of child-bearing age, and so it also constitutes one of the more common types of cancers diagnosed in pregnancy.[3,45] There has been much controversy regarding the effect of pregnancy on the clinical course of melanoma. The biologic basis of potential hormonal ef-

fects on melanoma includes the well-known hyperpigmentation associated with pregnancy, and the elevation of many endogenous hormones, including estrogens and melanocyte-stimulating hormone. However, the literature demonstrates that pregnancy before, during, or after a woman is diagnosed with melanoma does not appear to influence overall survival.[46] Overall survival in pregnant women is similar to nonpregnant women diagnosed with melanoma when corrected for prognostic factors; in addition, pregnancy subsequent to the diagnosis of primary melanoma is not associated with an increased risk of death.[47] There is no difference in the distribution of disease stage of melanoma, tumor thickness, lymph node positivity or assessment, and survival for pregnancy-associated melanoma (i.e., melanoma diagnosed during or within 1 year).[48] Pregnant women with melanoma should be offered the same surgical treatments, including sentinel lymph node (SLN) biopsy (usually with omission of blue dye), as nonpregnant counterparts; however, certain chemotherapeutic and immunologic regimens used in advanced melanoma may be contraindicated in pregnancy. After the initial diagnosis and treatment of melanoma, there are no standard, defined guidelines for patients who desire to become pregnant. Counseling recommendations should be comprehensive and individualized on a case-by-case basis, depending primarily on the risk of recurrence (related to the stage at diagnosis) and degree of personal desire to become pregnant relative to risk. Waiting for a period of up to 5 years is generally advised, depending on these factors.

Pediatric Melanoma

Melanoma in childhood and adolescence is rare. Of all newly diagnosed melanomas, 1 percent to 4 percent occur in patients younger than 20 years of age, and only 0.3 percent to 0.4 percent occur in prepubertal children.[49] However, melanoma is being increasingly diagnosed in this age group and being reported to occur more commonly without the classic predisposing risk factors of familial melanoma, congenital nevi, dysplastic nevi, and xeroderma pigmentosum.[50] Based on SEER data of 1255 melanoma patients less than 20 years of age, a 2.9 percent increase in the incidence of pediatric melanoma per year from 1973 to 2001 has been noted; the rate of increase was lower (1.4 percent) in young children less than 10 years.[51] Factors conferring risk of adult melanoma, including increasing age, UV exposure, and Caucasian background, were also found to be important in pediatric melanoma. The classic predisposing factors for adult melanoma are likely to be applicable to some proportion of children. In general, pediatric melanomas tend to have a greater proportion of thicker primaries, possibly related to delayed diagnosis compared with adults.

Making a Diagnosis

Early detection is the key to improving prognosis in melanoma. Although melanoma may have a characteristic appearance, there is no single clinical feature that ensures or excludes a diagnosis of melanoma. Even among expert dermatologists, the clinical diagnosis of melanoma can be made in only about 80 percent to 90 percent of cases. The well-known ABCD acronym for melanoma detection was developed in 1985 and continues to be a useful tool for the lay public and physicians.[52] A stands for asymmetry (one half is not identical to the other half); B for border (irregular, notched, scalloped, ragged, or poorly defined borders as opposed to smooth and straight edges); C for color (having varying shades from one area to another); and D for diameter (i.e., greater than 6 mm, approximately the size of a pencil eraser). Lesions having these characteristics may potentially represent melanoma. Studies have found the sensitivity of the ABCD checklist (Box 124-5) to be in the 90 percent to 100 percent range, but the specificity much lower.[53] NM is notable for the frequency it is overlooked using the ABCD rule; it tends to have smooth borders, be evenly colored, and may be small (less than 6 mm) especially in the early stage. Another diagnostic aid that is useful in detecting melanoma is the "ugly duckling" sign.[54] A pigmented lesion that is different from other pigmented lesions on a particular individual should be approached with a high index of suspicion. This is based on the premise that within an individual, nevi should globally share a common appearance or family resemblance. Even in an individual with multiple atypical nevi, the nevi should be morphologically similar.

History is very important in the evaluation of a lesion. The ABCD rule is relatively static and does not account for a critical element of change. For this reason, some have added an E to the ABCD

Box 124-5

ABCD Checklist[a]

- A = Asymmetry
- B = Border
- C = Color
- D = Diameter/Difference
- E = Elevation/Evolving

[a]Does not apply to nodular melanoma.

rule, where E stands for evolving.[55] Others have advocated for the D to stand for "difference" (i.e., a change in appearance or symptomatology over time or difference from the other lesions, similar to the "ugly duckling" sign). Change in color and increase in size (or a new lesion) are the two most common early characteristics noticed by patients that may be useful in discriminating between melanoma and other benign lesions.[56] In addition to change in color, size, or shape/elevation, persistent lesional itching is also an earlier (albeit non-specific) symptom; ulceration, bleeding, and tenderness generally signify a more advanced primary lesion.[57] Therefore, it is important to ask patients if lesions have changed over time, and to pay particular attention to changing or symptomatic lesions. The development of a new pigmented lesion, especially in an individual beyond the age of 40 to 50 years old and on an anatomic site without similar lesions, is also worthy of suspicion.

Physical Examination

The skin examination should be conducted under optimal lighting and encompass the entire skin integument, including the scalp, external ocular/conjunctivae, oral mucosa, genitalia, buttocks, and palms/soles/web spaces. Melanomas in hidden anatomic sites are associated with thicker tumors at diagnosis, often due to later detection.[58] A global assessment of an individual's skin, including number of nevi, both typical- and atypical-appearing, and distribution of nevi should be noted. Other risk factors, such as a family or personal history of melanoma or previously biopsied atypical nevi, should also be noted. Total body and lesional photography may be useful, especially in high-risk patients with numerous nevi.[59] The use of photography to document the appearance of skin lesions (or the absence of a skin lesion) can allow for better and earlier detection of a changing or new lesion. In high-risk patients, a proportion of melanomas are diagnosed with the aid of photographic surveillance rather than being noted by the patient or even the physician.[60] If a lesion suspicious for melanoma is found on skin examination, palpation of the regional lymph nodes should be performed to evaluate for lymphadenopathy.

Dermoscopy

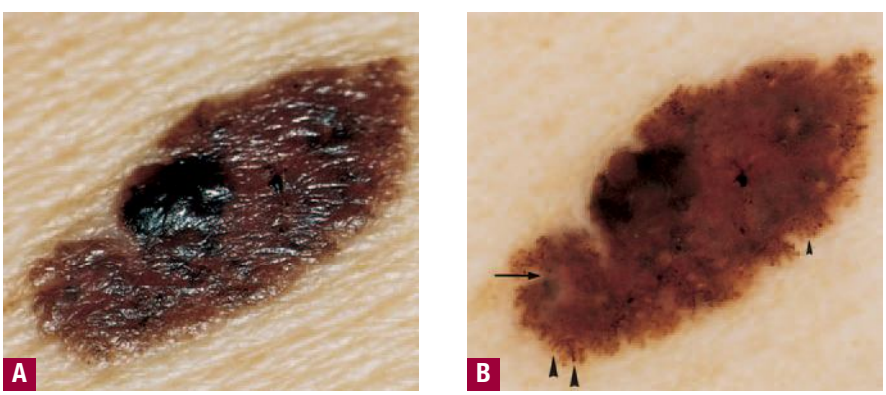
Dermoscopy (also known as *epiluminescence microscopy*, *dermatoscopy*, *incident light microscopy*, and *surface microscopy*) is a simple, non-invasive technique in which a liquid, usually immersion oil, is applied to the lesion, which is then examined with a hand-held lens (magnification usually 10×) or a commercially available device. In experienced hands, it improves both the sensitivity and specificity for the clinical diagnosis of melanoma and other pigmented and non-pigmented lesions, although those without experience and the appropriate training do not realize this benefit. Morphologic features that are otherwise not visible to the naked eye are observed using this technique. Approximately 23 percent of dermatologists in a 2002 report the clinical use of dermoscopy.[61] Its use and popularity as an adjunct to the clinical examination are increasing for both dermatologists and non-dermatologists. Many enthusiastic investigators continue to advance the field of dermoscopy with efforts to improve, refine, and standardize terminology; and simplify the diagnostic categories of pigmented skin lesions.

A new terminology and set of criteria have subsequently been developed for dermoscopy. The *pigment network*, seen as a series of pigmented lines, identifies a pigmented lesion as being melanocytic; it correlates to pigment along rete ridges, both in the basal layer and nests along the dermal-epidermal junction. A typical pigment network pattern has regular delicate lines with gradual thinning at the periphery; whereas an atypical pigment network pattern has irregular, variable, and widened lines that end abruptly at the periphery. *Brown globules* correlate with pigmented nests of melanocytes in the papillary dermis; *black dots* are focal collections of melanocytes and clumps of melanin in the stratum corneum. A *blue-grey veil* represents regression in melanoma. Different diagnostic algorithms using dermoscopic findings have been developed for melanoma, including the ABCD rule, and the 7-point checklist.[62] Pattern analysis, which provides an overall impression of multiple dermoscopic patterns without rigid rules, based primarily on a subjective, simultaneous evaluation of a number of different criteria, is probably the most widely used among experienced experts of dermoscopy. Lists of the important dermoscopy features with clinical pathologic correlations and significance have been widely published and are relatively easily obtainable through courses, societies, and the Internet. Fig. 124-8 summarizes several of these features.

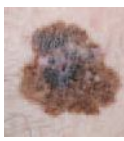
Digital dermoscopy, or digital epiluminescent microscopy, is an advance in non-invasive technology; it permits computerized digital dermoscopic images to be retrieved and examined at a later date so that comparisons can be made and changes detected over time (Fig. 124-9). There are also a number of commercially available automated computer image analysis programs, devices that incorporate image analysis algorithms to digital dermoscopic images, providing objective measurement of changes over time. The use of automated instruments for the diagnosis of melanoma is in an evolving phase. The use of body or lesional photography, professionally obtained or taken by the patient, is also very useful to aid physicians and patients for following lesions, particularly in patients with many nevi.

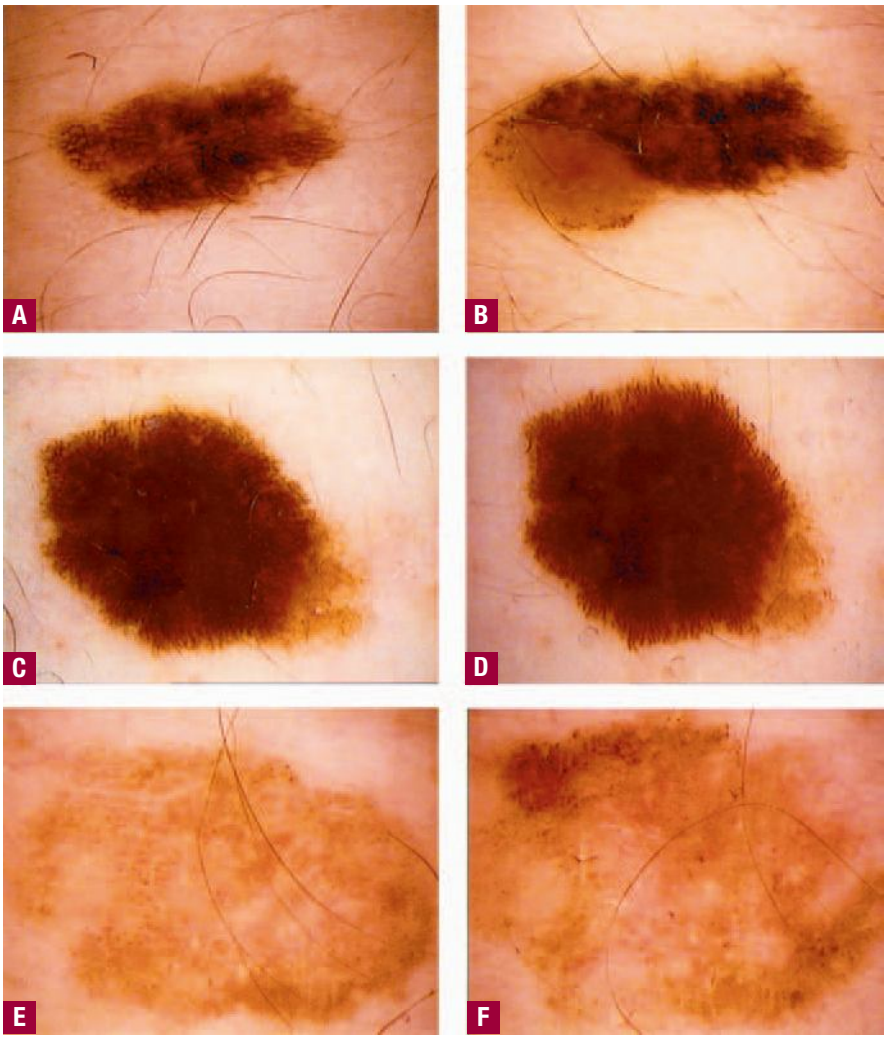
Histopathology

The gold standard for diagnosing melanoma is based on histopathologic evalua-



▲ **FIGURE 124-8** **A.** Superficial spreading melanoma as viewed by close inspection with a hand-held lens or a dermoscope without oil immersion. **B.** With oil immersion, new features become apparent, such as the pigment network, brown globules (*small arrowhead*), pseudopods (*large arrowheads*), and depigmentation, extending irregularly to the periphery of the lesion (*arrow*). (Used with permission from Michael Binder, MD.)





▲ **FIGURE 124-9** Monitoring of atypical nevi (AN) by digital epiluminescence microscopy. All lesions are from patients with multiple atypical nevus syndrome. **A.** Image of AN at time of presentation. The lesion shows features of an AN and, because the patient has multiple such lesions, clinical monitoring at 6-month intervals was scheduled. **B.** Follow-up of the same lesion after 8 months. The lesion has changed. There is asymmetric increase in size and the appearance of a new hypopigmented structure at the periphery on the left. The lesion was excised and histology revealed AN in the right portion of the lesion and superficial spreading melanoma (SSM) < 0.75 mm on the left. **C.** This AN is more difficult to evaluate. Typical AN at baseline (**C**) but after 6 months, (**D**) subtle changes have occurred. There is an increase in size, albeit symmetric, of the lesion, but the pigment network at the upper and lower margin has transformed into a fringe of fine pseudopods suggesting SSM. Histology confirmed SSM < 0.75 mm. **E.** Another AN at baseline. **F.** Follow-up image of the same lesion at 6 months. The most prominent changes are asymmetric increase in size, appearance of a new irregular pigment network, dots, and globules at the upper left margin of the lesion. Histology revealed SSM < 0.75 mm. (Used with permission from Harald Kittler, MD.)

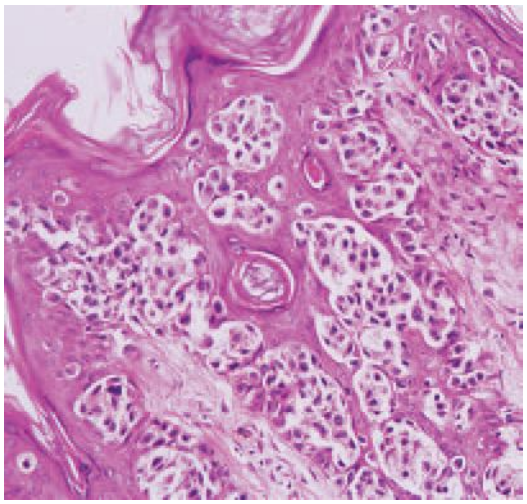
tion of the biopsy specimen, preferably by a dermatopathologist or a pathologist experienced with pigmented lesions. There is some histologic diagnostic discordance in the diagnosis of melanomas and melanocytic lesions, especially with early melanomas, even among experts, but the percentage of cases in which the diagnosis changes from benign to malignant or vice versa, or would result in a major modification in therapy or prognosis, is small.[63–65] The histologic diagnosis of melanoma is based on the assessment of a constellation of findings, including both architectural and cytologic features. No single feature is diagnostic. Cytologic atypia, referring to cellular enlargement, nuclear enlargement, nuclear pleomorphism, hyperchromasia of nuclei, nucleolar variability, and the presence of mitoses especially deep in the dermis, is considered necessary for a diagnosis of melanoma. The major architectural features of melanoma include asymmetry, poor circumscription (i.e., cells at the edge of the lesion tend to be small, single, and scattered), and large size (> 5 to 6 mm). Nests of melanocytes in the lower epidermis and dermis tend to vary a good deal in size and shape, and to become confluent. There is a lack of maturation of nests with descent into the dermis. Pagetoid spread of large solitary epidermal melanocytes, usually considered diagnostic of melanoma, should be assessed cautiously in the context of other findings, as pagetoid spread may be seen in benign lesions including Spitz nevi, spindle cell nevi, vulvar nevi, and acral nevi.

The different sub-types of melanoma have histopathologic differences as well. SSM is characterized by a population of melanocytes appearing uniformly atypical (Figs. 124-10 and 124-11). LM and LMM are characterized by atypical melanocytes singly and in nests, predominantly confined to the basal layer of the epidermis, which become confluent without pagetoid spread, occurring in the background of photodamage (Figs. 124-12, 124-13, and 124-14). The cells may extend down hair follicles and appendageal structures. The epidermis is thin and atrophic, with loss of rete ridges. There is variable cytologic atypia. The "lentiginous" in ALM is derived from the characteristic lentiginous pattern of most cells being single and located near the dermal-epidermal junction (Fig. 124-15). ALM differs from LM in that there is irregular acanthosis, and the melanoma cells are uniformly malignant and often dendritic. In LM, the cells are highly pleomorphic in an atrophic epidermis. NM demonstrates little tendency for intraepidermal growth; instead, there is a dermal mass of atypical melanocytes (Figs. 124-16 and 124-17). DM is composed of strands of elongated, spindle-shaped cells that often infiltrate deeply. Neurotropic melanoma describes a subset of DMs in which the cells invade perineurally and form patterns resembling nerves.

The typical pathology report useful for management includes creation of a 14-point melanoma profile shown in Box 124-6.

Immunohistochemistry

Immunohistochemistry may be useful for the diagnosis of melanoma, especially in poorly differentiated neoplasms with little or no pigment (i.e., amelanotic melanomas), spindle cell tumors, or tumors with pagetoid spread that are not obviously melanoma. S100 protein is ex-



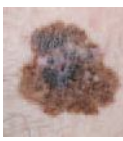
◀ **FIGURE 124-10** Superficial spreading melanoma. This tumor shows intraepidermal growth. In this photomicrograph, the pagetoid distribution is evident in the epidermis. The cells are relatively uniform and have an abundance of dusty, fine pigment. These relatively large melanoma cells are frequently referred to as epithelioid cell type.

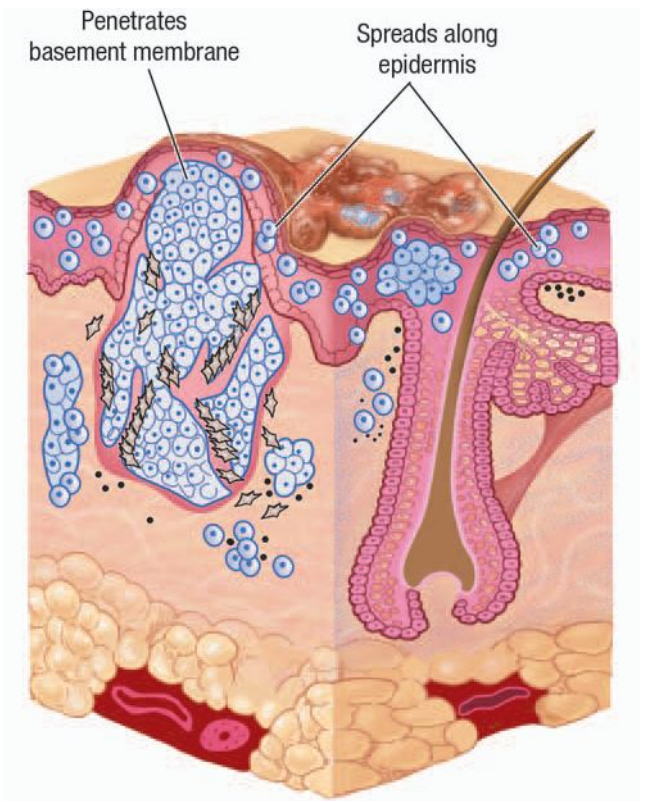
pressed by virtually all melanomas, but also by melanocytic nevi, Langerhans cells, and cutaneous neural tumors. HMB-45 is a monoclonal antibody with high specificity for melanoma cells, although it is frequently negative in DM; DMs commonly exhibit vimentin and S100 positivity. Melan-A and MART-1 (melanoma antigen recognized by T cells) are the names given independently to the same gene encoding a melanocytic differentiation antigen expressed in skin and retina but not other normal tissues. Melan-A is broadly expressed in benign and malignant melanocytic lesions but not in most DMs. It is more sensitive than HMB-45 and more specific than S-100 for melanoma. Search for the microphthalmia-associated transcription factor (Mitf) may be extremely useful, especially in amelanotic melanomas, as it is a marker in the nucleus, whereas all other markers are intracytoplasmic.[66] It stains most melanomas except for DM where staining is usually negative but variable.

PROGNOSIS AND CLINICAL COURSE

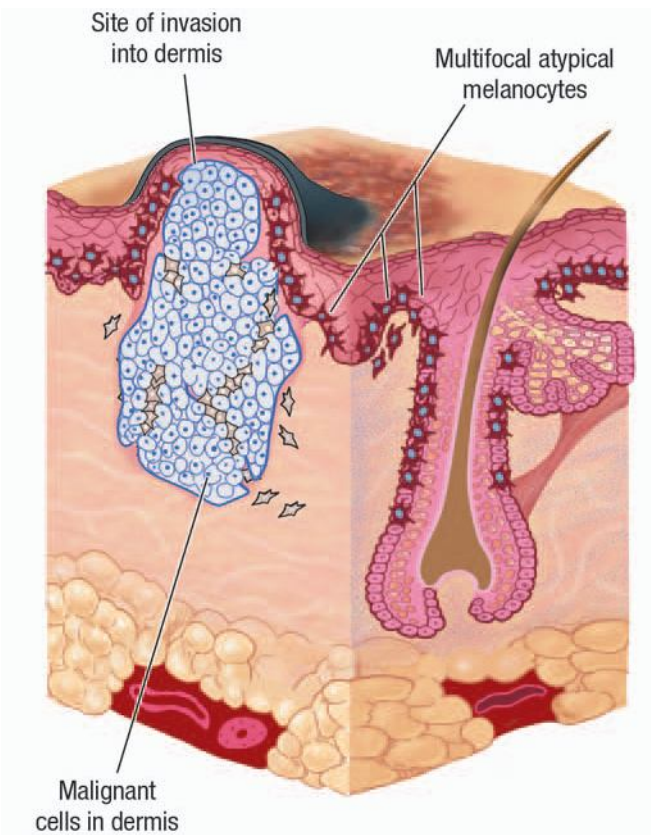
Staging and Prognostic Factors

Accurate staging of melanoma is essential for determining optimal treatment and for assessing prognosis. Accurate staging forms the basis for prognosis and treatment, which is invaluable for the majority of patients in their informed decision-making process. The American Joint Committee on Cancer (AJCC) revised the staging system for melanoma in 2002 with several fundamental changes,[67] which incorporates the most

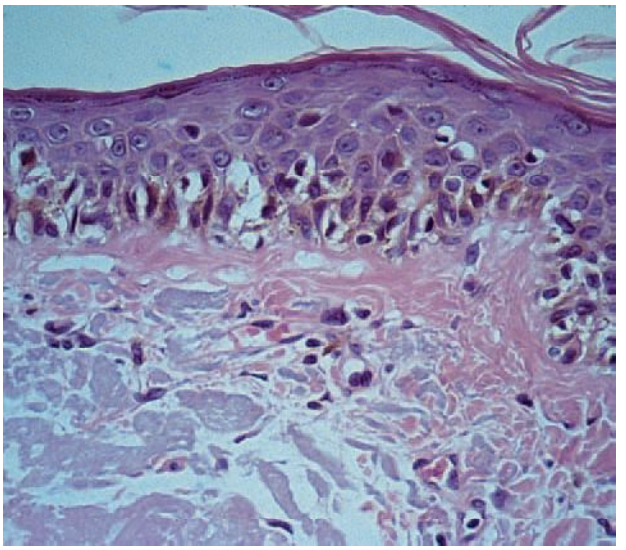




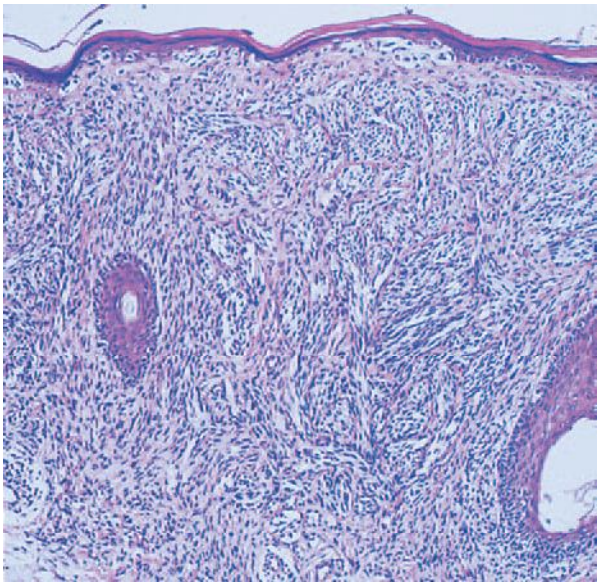
▲ **FIGURE 124-11** Superficial spreading melanoma. The border is irregular, and the lesion is elevated throughout its entirety. Biopsy of the area surrounding the large nodule shows a "pagetoid" distribution of large melanocytes that are occurring singly or in nests, and uniformly atypical. On the left is a large nodule, and scattered throughout the surrounding portion of the nodule are smaller popular and nodular areas. The nodule on the left shows malignant melanocytes that are very large, have an abundance of cytoplasm, and often have regularly dispersed fine particles of melanin. The nodules may also show spindle cells or small malignant melanocytes as in lentigo maligna melanoma and nodular melanoma.



▲ **FIGURE 124-12** Lentigo maligna melanoma. Illustrated on the right is a large, variegated, freckle-like macule (not elevated above the plane of skin) with irregular borders; the tan areas show increased numbers of melanocytes, usually atypical and bizarre, and are distributed single file along the basal layer; at certain places in the dermis, malignant melanocytes have invaded and formed prominent nests. At the left is a large nodule that is composed of epithelioid cells in this illustration; the nodules of all four main subtypes of melanoma are indistinguishable from each other.



▲ **FIGURE 124-13** Lentigo maligna. This is a proliferation of pleomorphic melanocytes in the basal layer of an atrophic epidermis in sun-damaged skin.



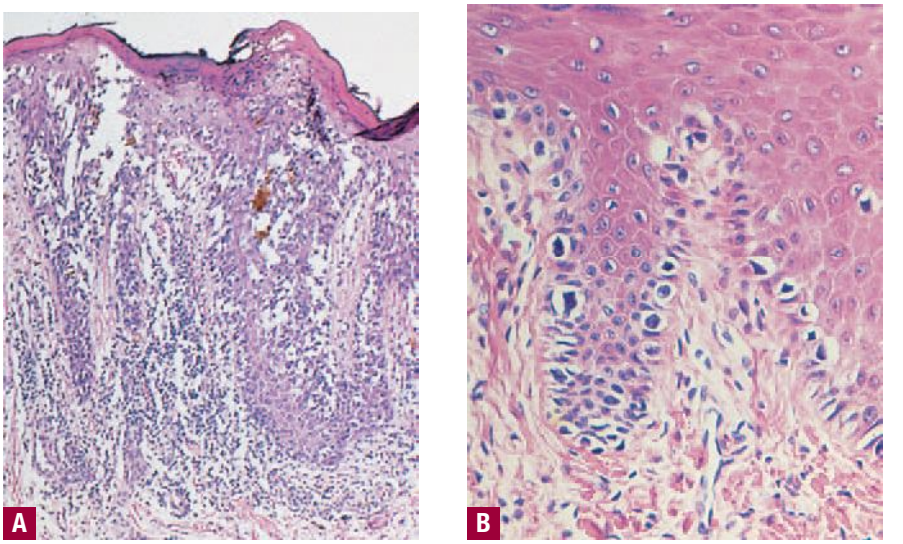
▲ **FIGURE 124-14** Lentigo maligna melanoma. Extending from the epidermis into the dermis are numerous elongated melanocytes. In lentigo maligna melanoma, these cells are frequently spindle-shaped.

important prognostic factors, such as microstaging and nodal status, and translates them into reported survival rates. It is well recognized that the current staging classification system is not perfect, and plans for the next revision are anticipated in 2009. In spite of some drawbacks, the current staging system is clinically valuable and should be used, particularly in clinical trials, reports, and studies to make data comparable. Multicenter retrospective data from 17,600 patients with melanoma were used to determine the significant prognostic variables in the current AJCC classification system.[68] T describes the extent or thickness of the primary tumor, N the extent of lymph node metastases, and M the extent of distant metastases. Table 124-2 presents the TNM categories (*t*umor size, *n*ode status, *m*etasasis classification), and Table 124-3 lists the stage groupings. There are five stages based on prognosis: stage 0 (in situ disease), stages I and II (localized disease), stage III (regional disease), and stage IV (distant metastatic disease). In general, prognosis and survival rates worsen with increasing stage (Table 124-4). At initial presentation, approximately 85 percent of patients have localized disease (stages I and II), 10 percent have regional metastatic disease, and 5 percent have distant metastatic disease.[67]

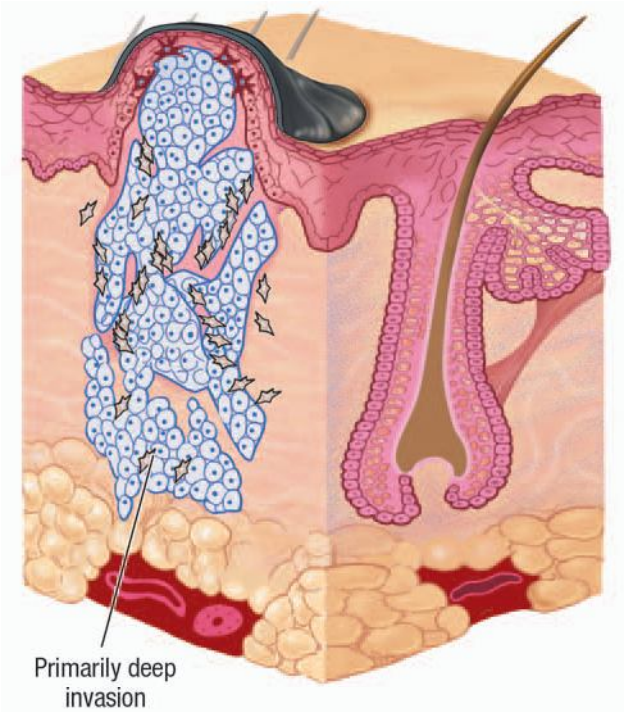
Prognostic Factors in Microstaging (See Table 124-4)

TUMOR THICKNESS The single most important prognostic factor for survival and clinical management in localized stage I and II cutaneous melanoma is tumor thickness.[68] As originally described by Breslow, thickness is measured from the top of the granular layer of the epidermis to the greatest depth of tumor invasion using an ocular micrometer and measured in millimeters (see eFig. 124-17.1 in online edition). Survival decreases with increasing Breslow depth. Clark level is an alternate, less accurate method of depicting tumor thickness by the anatomic level of invasion and is less important in current microstaging. Historically described by Clark, melanoma is confined to the epidermis in level I, extends into the papillary dermis in level II, accumulates in and expands in the papillary dermis in level III, extends into the reticular dermis in level IV, and invades the subcutaneous fat in level V (see eFig. 124-17.1 in on-line edition). Clark level of invasion may have an impact on survival for thin melanomas < 1 mm, when a Clark level of IV or V upstages a melanoma from T1a to T1b. However, other data suggest that, compared to Breslow depth, Clark level is a weaker prognostic indicator for survival.[69]

ULCERATION Ulceration also currently represents an independent prognostic



▲ **FIGURE 124-15** Acral lentiginous melanoma. **A.** Photomicrograph showing hyperkeratosis associated with plantar location of this melanoma. Fibrosis and patchy host response are noted in the dermis. **B.** High-powered photomicrograph showing lentiginous proliferation of abnormal melanocytes along the dermal-epidermal junction.



▲ **FIGURE 124-16** Nodular melanoma. This tumor arises at the dermal-epidermal junction and extends vertically into the dermis; intraepidermal growth is present only in a small group of tumor cells that conjointly are also invading the underlying dermis. The epidermis lateral to the areas of this invasion does not demonstrate atypical melanocytes. As with lentigo maligna melanoma and superficial spreading melanoma, the tumor may show large epithelioid cells, spindle cells, small malignant melanocytes, or mixtures of all three.

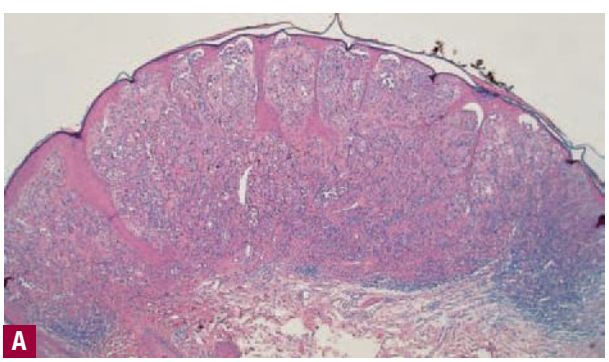
factor for localized melanoma in the AJCC study and was highly correlated with survival.[68] The presence of ulceration in the primary confers a higher risk of developing advanced disease and lower survival rate. The presence of ulceration upstages all patients with localized as well as regional disease [i.e., stages I to III (see Table 124-2)]. Ulceration correlates with tumor thickness; it occurs infrequently in thin melanomas (6 percent for melanomas < 1 mm) and frequently in thick melanomas (63 percent for melanomas > 4 mm). Conversely, multivariate analysis of data from the German Central Malignant Melanoma Registry demonstrated ulceration to have a significant negative impact on the prognosis for patients with T2 and T3 lesions, but not for T1 and T4. For stage III regional disease, the impact of ulceration on overall survival was significant in bivariate but not multivariate analysis. In spite of these drawbacks, the new staging classification should be used, particularly in clinical trials, to make data internationally comparable.[70] One potential shortcoming of ulceration as a variable is that ulceration is not always a homogeneous phenomenon and may result from trauma, which is prognostically insignificant. For this reason, ulceration should only be reported when there is evidence of host response at the site, including fibrin and nuclear debris. Their presence indicates a preoperative event not possibly associated with artifactual causes due to surgery or processing.

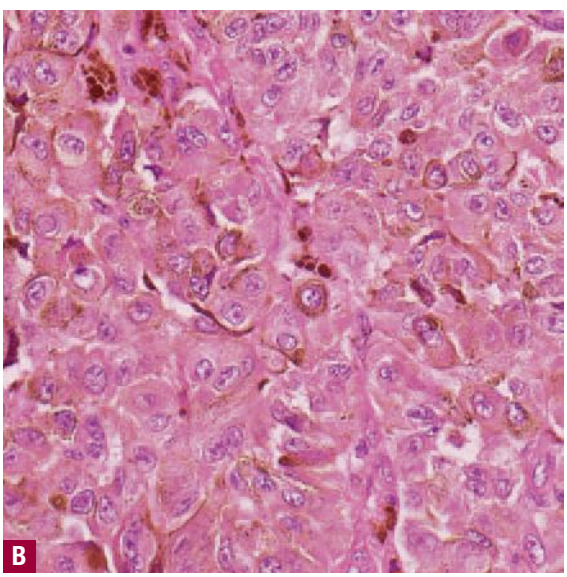
Box 124-6

Melanoma Pathology Checklist

- Body site
- Histologic pattern sub-type
- Breslow depth
- Clark level
- Mitotic rate
- Vertical vs. radial growth phase
- Ulceration
- Regression
- Satellitosis
- Angiolymphoid spread
- Neurotropism
- Tumor-infiltrating lymphocytes
- Co-existing nevus
- Margins

MITOTIC RATE There is a growing body of literature and studies to strongly support a significant independent relationship between tumor mitotic rate and prognosis in melanoma. Mitotic rate, measured as the number of mitoses per square millimeter, is usually counted as





▲ **FIGURE 124-17** Nodular melanoma. **A.** Low-powered photomicrograph demonstrating a dome-shaped expansile tumor located in the upper dermis. **B.** High-powered photomicrograph reveals nests of anaplastic epithelioid cells in the tumor.

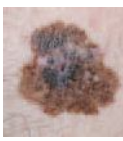


TABLE 124-2
Melanoma TNM Classifications[a]

T Classification	Thickness (mm)	Ulceration Status
T1	≤ 1.0	a: without ulceration and level II/III b: with ulceration or level IV/V T2
T2	1.01–2.0	a: without ulceration b: with ulceration
T3	2.01–4.0	a: without ulceration b: with ulceration
T4	> 4.0	a: without ulceration b: with ulceration
N Classification	**Number of Metastatic Nodes**	**Nodal Metastatic Mass**
N1	1	a: micrometastasis[b] b: macrometastasis[c]
N2	2–3	a: micrometastasis[b] b: macrometastasis[c] c: in-transit met(s)/satellite(s) without metastatic nodes
N3	4 or more nodes, or matted nodes, or in-transit met(s)/satellite(s) with metastatic node(s)	
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

TNM = tumor size, node status, metastasis classification.
[a]Six major changes are included in the 2002 version of American Joint Committee on Cancer melanoma staging system:
1. Anatomic level is used only in the staging of thin tumors. Thickness and ulceration are primarily used in the T category. The anatomic level of invasion (Clark levels) is currently understood to be an independent prognostic feature only for thin melanomas. As a result, Clark levels are incorporated only into staging of thin melanomas (< 1.0 mm or category T1).
2. Ulceration of the tumor has been added to the staging system. Ulceration is an independent risk factor and portends a higher risk of developing advanced disease. The presence of ulceration "upstages" all patients with stages I to III disease. In a given T grouping, the new system subclassifies patients as "a" for tumors without ulceration, and "b" for tumors with ulceration.
3. The number of metastatic nodes, rather than the size of nodes, is used as a primary criterion in the N staging.
4. The system incorporates a new convention for categorizing patients both clinically and pathologically. This system incorporates date from lymphatic mapping and sentinel node biopsy.
5. In-transit and satellite metastases have been grouped in the same subclassification (N2c). Patients with intralymphatic metastases but no nodal metastases are recognized as having a similar prognosis and are thus grouped together.
6. Distant metastatic melanoma is classified by site(s) of metastases and levels of lactic dehydrogenase detected in serum.

[b]Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
[c]Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.
