Toll-like receptor agonist (TLRa) Ligand for a Toll-like receptor.
Toll-like receptors A set of ten different protein receptors, both cell surface and endolysosomal, expressed by immune cells and some stromal cells, which recognize PAMPs and stimulate the activation of immune defenses.

Abbreviations

APC	Antigen-presenting cell
BALT	Bronchus-associated lymphoid tissue
DAMP	Danger-associated molecular pattern
DC	Dendritic cell
GALT	Gut-associated lymphoid tissue
GI	Gastrointestinal

GM-CSF	Granulocyte/macrophage colony-stimulating factor
GMP	Good manufacturing process
HA	Hyaluronic acid
HMW	High molecular weight
HyAp	Hydroxyapatite
hyppos	Hydrophobic portions/moieties
IL	Interleukin
LPS	Lipopolysaccharide
mAb	Monoclonal antibody
MHC	Major histocompatibility complex
MPLA	Monophosphoryl lipid A
NALP3	Nacht domain, leucine-rich repeat, and pyrin domain-containing protein 3
NALT	Nasal-associated lymphoid tissue
NKT	Natural killer T cell
NLR	NOD-like receptor
OVA	Ovalbumin
PAMP	Pathogen-associated molecular pattern
PCR	Polymerase chain reaction
PE	Polyethylene
PEG	Polyethylene glycol
PEO	Polyethylene oxide
PEVAc	Polyethylene-*co*-vinyl acetate
PLGA	Polylactide-*co*-glycolide
PPO	Polypropylene oxide
PPS	Polypropylene sulfide
RIG	Retinoic acid-inducible gene
TLR	Toll-like receptor
TLRa	Toll-like receptor agonist
TT	Tetanus toxoid

4.419.1. Introduction

Biomaterials designed for drug delivery have had a major clinical impact and are likely to become even more important in a broad range of such applications in the near future. Of particular practical and scientific importance is the application of biomaterials for vaccine delivery and related immunotherapy strategies. Vaccines are often cited as the biomedical advance with the greatest impact on public health ever devised.[1] Vaccines against polio and smallpox have largely eradicated these diseases, and vaccines against seasonal influenza, measles, hepatitis B, and typhus (to name a few) have greatly reduced morbidity and mortality from these infectious agents.[2] However, great challenges remain as vaccines for pathogens that establish persistent chronic infections in unimmunized individuals, which are often highly mutable and fail to elicit protective neutralizing antibody responses, remain an unsolved challenge. Examples of these vaccine challenges include HIV,[3] hepatitis C,[4] tuberculosis,[5] and malaria,[6] which affect millions of people worldwide. In addition to these prophylactic vaccine challenges, therapeutic vaccines against cancer have long been sought but remain in the preclinical and clinical study stage. Here, some of the key challenges include the difficulty in eliciting immune responses against poorly immunogenic tumors that produce a variety of immunosuppressive factors, overcoming tolerance of the immune system against 'self' antigens expressed by tumor cells, and exhaustion of the immune system due to continuous unresolved antigen stimulation over time.[7,8] Finally, vaccines have been pursued as novel therapeutic strategies aimed at redirecting unwanted immune responses triggered by allergens[9] and promoting tolerance against self antigens to reverse autoimmune disease,[10] or as interventions to block pathological processes such as amyloid fiber deposition in Alzheimer's disease.

Vaccines are traditionally viewed as consisting of an antigen, the molecular target against which the immune response must be primed, and an adjuvant, which is generically defined as any component added to the vaccine to enhance the immune response to the antigen. The goal of prophylactic vaccination is to elicit a population of memory lymphocytes (T cells and B cells) capable of (1) maintaining antibodies directed against the antigen(s) in the systemic circulation and/or at mucosal portals of pathogen entry and (2) rapidly responding with new antibody production, regulation of innate immune defense, and killing of infected cells if a pathogen bearing the target antigen(s) enters the host. Therapeutic vaccines have the more challenging goal of eliciting such responses in the face of an ongoing infection/insult. The earliest vaccines were prepared from live attenuated (passaged *in vitro* to generate less virulent forms of the original microbe) or whole-killed (chemically fixed or denatured) pathogens. These approaches elicit extremely potent, often lifelong, immunity as essentially every potential molecular target of the immune response is used in the vaccine (the entire microbe), and the immune system has evolved explicitly for the recognition and elimination of microbes. However, in many cases, live attenuated vaccines are not considered safe (such as HIV), and in some cases, live attenuated/whole-killed vaccines are not feasible due to a lack of viable *in vitro* culture strategies (such as in *vivax* malaria[11]). Further, the whole-killed vaccine approach fails in instances of pathogens that are extremely mutable such as HIV, where a potent immune response raised against a given molecular clone of the virus is not sufficiently cross-reactive to provide protection against the numerous quasispecies circulating in the population. Finally, the cost, time, and complexities involved in producing GMP quality whole pathogens/split pathogen vaccines are a significant issue (e.g., the 6-month-long chicken egg-based production of the seasonal influenza vaccines). These considerations in concert with the molecular biology revolution of the 1970s have led to the pursuit of a broad variety of 'subunit' vaccine strategies – vaccines where a subset of antigens (in some cases, only one) from the pathogen of interest are prepared using recombinant DNA technology and delivered in the form of DNA, recombinant proteins, or safe viral or bacterial vectors.

One of the key drivers in the development of biomaterials for vaccine delivery has been this move toward subunit vaccines, which are generally much less immunogenic than live

attenuated or whole-killed pathogen vaccines. In addition, our expanding understanding of immunology has led to a desire to rationally shape the immune response and the resulting immunological memory elicited by vaccines. For the purposes of this review, we *define biomaterial vaccine adjuvants broadly as any materials combined with antigens to enhance vaccines that are not purely derived from biological components*. Biomaterials can serve several functions in vaccine delivery (**Table 1**): they can promote entry of antigen/adjuvant molecules into mucosal sites that are the critical portals of entry for pathogens, they can promote trafficking of antigen to the lymph nodes and other secondary lymphoid organs where primary immune responses are initiated, they can codeliver inflammatory molecules or directly elicit controlled local inflammation to promote fully functional immune memory, or they can exploit the immune system's evolved capacity to respond efficiently to particulate microbes by delivering antigen/adjuvant signals in a particulate (micron- or submicron-sized) form. A diverse array of biomaterials have been explored as adjuvants for vaccines, including aluminum salt gels (alum), oil-in-water or water-in-oil emulsions, liposomes and solid lipid particles, polymer particles, and antigen-conjugated soluble polymers.[12] These materials may encapsulate/adsorb antigen or alternatively may be mixed and coinjected without significant physical interactions with the antigen, and may codeliver immunostimulatory compounds (e.g., molecular adjuvants such as Toll-like receptor agonists (TLRas)). Despite extensive preclinical and clinical research, only two adjuvant materials are approved for use in the United States, the aluminum salts (alum), and one vaccine employing alum mixed with the TLRa monophosphoryl lipid A (MPLA) (although several additional candidates are in late stage clinical trials). This discrepancy arises due to both the arduous and often empirical nature of vaccine research and the extremely stringent safety requirements for adjuvants used in prophylactic vaccines, especially those used routinely in pediatric populations. Importantly, although safe and often effective, alum is far from ideal as a vaccine adjuvant, as it elicits antibody isotypes largely associated with Th2 immune responses and poor cellular immune responses, poorly adsorbs some vaccine antigens, and is associated with injection site reactions due to the long-lived granulomas formed at the injection site in a fraction of recipients.[13–15]

The field of vaccine delivery is both established and growing, and an exhaustive analysis of the existing knowledge is well outside the scope of any single review. This chapter provides instead a general perspective on our current understanding of how licensed biomaterial adjuvants already in the clinic and new biomaterials in preclinical development work in diverse ways to enhance vaccine delivery, with a particular emphasis on the conceptual and immunological rationale for designing biomaterials for vaccine delivery. In the following two sections, we break this field down broadly into considerations of (i) physical delivery, transporting antigen/adjuvant molecules to target immune cells, and (ii) provision of adjuvant signals, either by the intrinsic composition of biomaterials themselves or via codelivery of adjuvant molecules. Additional excellent reviews are also available overviewing current biomaterials vaccine strategies,[16–20] particle delivery materials for vaccines,[21–23] and the preparation, properties, and historical development of licensed aluminum[13,14,24–26] and oil–water emulsion-based[27] adjuvants.

4.419.2. The Paradigm of Immune Responses in Infection Versus Vaccination

Although vaccinology has its roots in empiricism, modern vaccine design is increasingly motivated and guided by immunology and our growing understanding of the functions of the immune system at a genetic/molecular level. It is no accident that, among the different classes of vaccines, live attenuated vaccines generally give the strongest immune responses. Because the immune system has evolved to deal with infections, vaccines that closely mimic actual infections tend to give the strongest immune responses and subsequent immune memory. The paradigm of how the immune system deals with local infections is thus useful in understanding the goals of vaccination and the design of better vaccines.

In response to infection by viral or bacterial pathogens at a local portal of entry (e.g., skin, mucosa, etc.), infected cells are triggered to release inflammatory cytokines such as interferons and interleukin-1β, which in turn trigger the local release of inflammatory chemoattractants. These attractant signals are displayed on local inflamed endothelium, and promote the entry of early innate immune responders such as neutrophils as well as monocytes and dendritic cells (DCs) from the blood (**Figure 1**). DCs are an important subtype of antigen-presenting cells (APC). DCs are critical initiators of adaptive immune responses,[28] as they sample antigens and dying infected cells at the infection site, become activated, and alter their chemokine receptor expression to permit homing to local lymphatics and from there to the draining secondary lymphoid tissue.[29] Monocytes recruited from blood can enter tissues and differentiate into DCs in response to cues in the inflammatory site as well.[30]

Table 1 Roles for biomaterials in vaccine delivery

Materials characteristic	*(Proposed) function(s) in vaccine delivery*
Penetration of mucosal/skin barriers	Promote antigen/adjuvant deposition at important portals for immune protection
Penetration of tissue/lymphatics	Transport of antigen/adjuvant molecules to secondary lymphoid organs where primary immune responses are initiated
Slow-release depot of antigen	Sustain immune response and development of fully functional memory cells
Elicit local inflammatory signals	Promote fully functional immune memory
Codelivery of antigen with immunostimulatory adjuvant molecules	Promote fully functional immune memory
Particulate presentation of antigen	Drive cross-presentation of antigen to $CD8^+$ T cells and promote B cell response

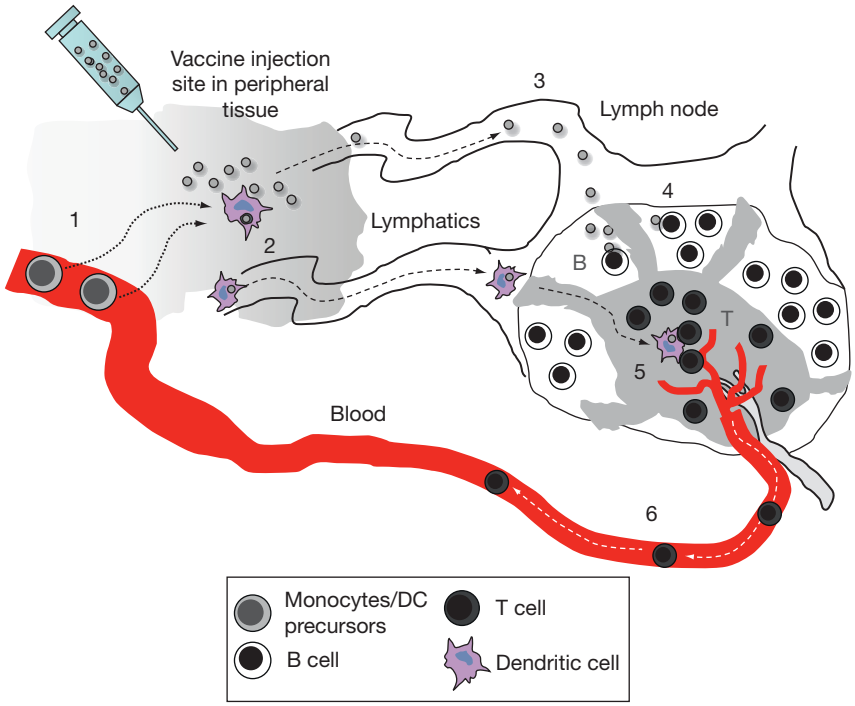

Figure 1 Early steps in the immune response to vaccination or infection. Shown here is a simplified view of the cascade of events that typically accompany immunization or infection: (1) inflammatory cells, including dendritic cell precursors, are recruited to the injection/infection site; (2) encounter with pathogen- or tissue damage-derived 'danger signals' activates recruited dendritic cells, and triggers their migration to lymph nodes. (3) Soluble antigen or small particles can drain directly to lymph nodes, where (4) B cells can be activated in the follicles. (5) Activated dendritic cells acquiring soluble or particle-associated antigen migrate to the T-cell areas of lymph nodes, where antigen-specific $CD4^+$ and $CD8^+$ T-cell activation commences, followed by (6) emigration of activated effector cells to the periphery.

Cell-free pathogens and pathogen debris are also transported by lymph flow to the draining lymph nodes, where B cells and DCs in the LN can acquire and process these antigens directly (Figure 1). Thus, antigen reaches the draining lymph nodes either carried by DCs or transported by lymph.

As they sample antigen at a site of activation of DCs infection or vaccination is critical for the generation of functional memory T and B cell responses. Activation (or maturation) of DCs is mediated by a host of pathogen- and danger-recognition sensors in these sentinel cells, receptors that recognize conserved pathogen-associated molecular patterns (PAMPs) or danger-associated molecular patterns (DAMPs), respectively.[31] PAMPs are molecular motifs evolutionarily conserved in pathogens but absent from host tissue; examples include bacterial cell wall components (lipopolysaccharide (LPS), peptidoglycans), double-stranded RNA (a viral signature), or unmethylated CpG DNA sequences (characteristic of bacterial genomes). DCs recognize PAMPs through cell surface and endolysosomal TLRs and cytosolic nucleic acid sensors such as the retinoic acid-inducible gene (RIG)-I-like receptor family of proteins and NOD-like receptors (NLRs).[32] There are ten identified TLRs to date, which recognize a broad range of PAMP molecules. DAMPS, on the other hand, are molecular signatures of tissue damage, for example, uric acid, ATP, HMGB1 proteins, or hyaluronan fragments. DC activation by DAMPS and PAMPS leads to the production of proinflammatory cytokines such as IL-12 and TNF-α and upregulation of costimulatory receptors required for the activation of naïve T cells (e.g., CD80, CD86, CD40), and triggers a transition in DC antigen processing functions, from 'uptake' to 'presentation,' with internalized antigens being degraded to short peptide fragments that are loaded into the clefts of major histocompatibility complex (MHC) molecules for display at the cell surface. In the absence of these many alterations in DC functional phenotype that accompany maturation, productive T cell and antibody responses are severely compromised. As mentioned above, a last critical change in maturing DCs is the alteration of chemokine receptor expression, which causes the activated cells to begin migrating to draining lymph nodes.

The secondary lymphoid tissues, where naïve T and B lymphocytes reside, are regional control centers for adaptive immune responses, consisting of lymph node-like structures with distinct features depending on the anatomic site. Nasal-associated lymphoid tissue (NALT), bronchus-associated lymphoid tissue (BALT), and gut-associated lymphoid tissue (GALT) are located in the nasal passages, airways, and GI tract, respectively. Regional lymph nodes drain essentially all other peripheral tissue sites, and the spleen acts as a filtration center for immunologic monitoring of the blood. DCs are believed to be the only APCs capable of priming naïve T cells under normal circumstances,[33] and thus are critical controllers of antibody (through regulation of helper T-cell activation, and possibly through direct interactions through B cells[34,35]) and cytotoxic T cell responses. Once in the lymph node, DC-bearing antigen will activate $CD4^+$ helper T cells and

$CD8^+$ cytotoxic T cells, triggering massive proliferation of antigen-specific T cells (Figure 1). B cells, by contrast, are thought to be capable of directly binding antigen transported to lymph nodes;[36,37] cross-linking of cell surface immunoglobulins triggers activation of these cells and the first steps toward antigen-specific antibody production. A fraction of helper T cells may engage antigen-triggered B cells at T cell zone-follicular borders of lymph nodes to promote B-cell proliferation and differentiation toward antibody-producing plasma cells or cells that will enter germinal centers to begin the process of somatic hypermutation/antibody affinity maturation.[38,39] In parallel, activated effector T cells leave the lymph nodes to patrol the peripheral tissues for infected cells (Figure 1). Activated DCs have a short lifespan of only a few days, and as antigen is cleared, stimulation of T cells and B cells wanes, the expanded T-cell population contracts, and a long-lived population of memory T and B cells develops, which can be sustained by homeostatic expansion over many years. Prophylactic vaccines aim at achieving long-lived, highly responsive memory cell populations, while therapeutic vaccines may aim at eliciting a mix of immediate potent effector cells and memory to sustain responses in the long term. All these responses depend on intricate spatial and temporal interactions between immune cells and tissues; thus, the fundamental immune activation scheme outlined here is conventionally termed the 'geographical' view of immunity. Importantly, many of these steps are similar in the response to immunization (Figure 1), as discussed in detail below.

Memory T cells have complex tissue-homing phenotypes that are still under active investigation, defined in part by the specific chemokine and adhesion receptors they express that determine their ability to enter different tissue sites. These memory cells can be roughly compartmentalized into central memory and effector memory cells, based on whether they express CCR7 and CD62L (chemokine and adhesion receptors required for lymph node entry) or lack these receptors (instead expressing homing molecules leading to peripheral tissues).[40] Memory lymphocytes can be 'addressed' to specific sites such as the gut, skin, or bone marrow, and some of these cells may be long-lived and permanently resident within the peripheral tissues,[41] serving as sentries for rapid response upon pathogen challenge at portals of entry. Because provision of rapidly responding effector memory cells directly at sites of entry or sites where pathogen propagation (e.g., the gut in HIV infection[42]) could be important for providing protection against infection, understanding how these tissue-homing phenotypes are established during vaccination is of great interest.

4.419.3. Biomaterials as Delivery Vehicles for Vaccines and Immunomodulators

As in other drug delivery applications, biomaterials can play a key role in the physical delivery of vaccine antigen and adjuvant molecules to the proper organ, tissue, or cell-level locations with appropriate timing to promote immune responses. The biological responses to vaccination follow a geographical/temporal order that closely parallels the immune response to infection outlined above in many cases: (1) antigen/adjuvant is deposited at a peripheral tissue site, (2) antigen is transported to draining lymph nodes, (3) lymphocyte priming commences, (4) effector and, subsequently, memory lymphocytes are generated, and (5) memory cells home to distinct sites throughout the body. We review the challenges and materials strategies for controlling physical delivery aspects following this geographical/temporal order, exploring sequentially the barriers faced by vaccines from their initial entry into the body to the final delivery of molecular cues to immune cells at key tissue sites.

4.419.3.1. Vaccine Delivery Across Mucosal Barriers and Skin

Although the majority of currently licensed vaccines are given via intramuscular or subcutaneous injection, much of the research focus in recent years has been directed toward mucosal delivery. This emphasis is motivated by the finding that the homing of memory lymphocytes can be directed to match the site of origin of an immune response,[43] and the route of immunization can have a dramatic effect on the imprinting of memory homing phenotypes. Thus, oral delivery of vaccines to the GALT preferentially promotes gut IgA antibody responses and T cell homing to the Peyer's patches and mesenteric lymph nodes; skin immunization promotes skin-homing memory T cells; airway immunization promotes memory lymphocytes with airway tropism. In addition to this immunological motivation, skin and mucosal vaccine delivery approaches may offer other advantages. Traditional needle-based vaccine delivery, in addition to contributing to reduced speed, ease, and compliance in administration, has been shown to contribute to reduced overall safety due to needle reuse and needle-based injuries.[44] Although each target mucosal tissue site presents its own unique physiological barriers to vaccine delivery, mucosal vaccine delivery in general faces the challenge of providing transport of antigen/adjuvant molecules through an epithelial barrier to reach the underlying mucosal tissue. A broad range of biomaterials (microparticles, nanoparticles etc.) and delivery strategies (gels, microneedles, etc.) are being developed to overcome these barriers and deposit antigens into tissues, but covering the range of issues unique to each mucosal site is beyond the scope of this review (see also **Chapter 1.115, Calcium Phosphates for Cell Transfection**; **Chapter 4.430, Silica-Based Mesoporous Nanospheres**; **Chapter 4.424, Nanoparticles for Nucleic Acid Delivery**; and **Chapter 4.434, Hybrid Magnetic Nanoparticles for Targeted Delivery**). We refer the interested reader to recent reviews of mucosal and skin vaccine delivery.[22,45–47]

4.419.3.2. Controlling Vaccine Delivery at the Tissue/Organ Level

Once entry into a local tissue site is achieved, via needle injection or transmucosal delivery through one of the routes discussed above, antigen and adjuvant signals must still be transported to draining lymph nodes to initiate primary adaptive immune responses, as naïve T and B lymphocytes recirculate among the secondary lymphoid organs but do not normally enter peripheral tissues. (Direct intra-lymph node injections have been utilized in some cancer vaccine trials guided by ultrasound,[48,49] but would be difficult to translate to mass vaccination settings.) Thus, injection site-to-lymphoid

organ transport becomes the second geographical barrier in vaccination. At least three distinct biomaterial strategies have been explored for vaccine delivery: generation of injection site depots that enable release of soluble antigen over time, strategies to recruit APCs to the site of injection to enhance cell-mediated transport of antigen to lymphoid organs, and direct delivery of antigen to lymph nodes via transport on very small particles that can passively diffuse through the tissue and enter lymphatics.

4.419.3.2.1. Creation of antigen depots

Soluble proteins injected subcutaneously or intramuscularly are rapidly cleared from the tissue by convection and lymph flow, flushing the majority of material through the draining lymph nodes within a few hours.[13,36,50] Thus, the duration of antigen exposure for B cells and DCs to acquire soluble antigen is often very limited. This issue was recognized very early in vaccinology, and the concept of creating 'depots' of antigen that would be released over time to draining lymphoid organs has been explored for many years, particularly in the context of the humoral immune response. The concept of single-shot vaccines that could elicit robust immune responses following a single injection has also been proposed, with the idea that antigen depots or materials releasing staggered bursts of antigen *in vivo* might obviate the need for booster injections.[51–53] Such approaches would be very attractive for vaccines needed in the developing world, where compliance rates with multi-shot vaccination schedules over many months may be poor.

Aluminum-based mineral salts such as aluminum phosphate and aluminum hydroxide – frequently referred to as alum – comprise the oldest and most common class of vaccine adjuvants. First discovered in 1926 as a means of increasing antigen immunogenicity by precipitating diphtheria toxin,[54] alum until very recently was the only clinically approved adjuvant in the United States.[26] Alum was believed to act by reversibly adsorbing/trapping antigen on alum particles, which prolonged their retention at the injection site and provided a slow release of the antigen over time.[55] However, responding B cells are not detected after a few weeks following alum immunization in draining lymph nodes, and excision of the alum injection site 14 days after immunization has no impact on antibody responses.[25,56] Interestingly, alum is resorbed very slowly and generates a granuloma at the injection site; alum particles excised from injection sites after several weeks can be used to successfully immunize naïve animals.[25,57] Together these data suggest that intact antigen is retained for very long periods in alum depots, but release of antigen from the granuloma is very limited after a few days and antigen retained in the peripheral tissue is unable to further promote the antibody response.[58] As discussed in detail below, the importance of long-term depot effects for alum has also been called into question by very recent studies,[24,59] and currently it is recognized that the licensed aluminum hydroxide alum adjuvants have multiple immunostimulatory effects beyond simple antigen retention.[25,60–62]

Notably, oil-in-water emulsions and liposomes, which are the two other most prominent examples of licensed biomaterial vaccine adjuvants, do not necessarily act as long-lived antigen depots either. MF59, composed of nanoscale droplets (~170 nm diameter) of squalene oil stabilized by surfactants, does not alter the tissue clearance of proteins with which it is mixed and coinjected.[27,50] Proteins injected parenterally in saline have the same serum clearance kinetics as that injected in (incomplete) Freund's adjuvant, the classic experimental mineral oil adjuvant.[63] Although liposomes can encapsulate protein antigens in their aqueous core, they are also rapidly destabilized by interactions of high-density lipoprotein particles and other serum components with their lipid bilayer surfaces,[64,65] and thus generally do not have long lifetimes at parenteral injection sites.

Although the slow-release properties of alum and lipid/emulsion adjuvants may be transient, polymer matrix- and microsphere-based delivery systems have convincingly shown an ability to retain and release antigen over periods up to several weeks (see also **Chapter 4.430, Silica-Based Mesoporous Nanospheres**; **Chapter 4.424, Nanoparticles for Nucleic Acid Delivery**; and **Chapter 4.434, Hybrid Magnetic Nanoparticles for Targeted Delivery**). Preis and Langer demonstrated that solid poly(ethylene-*co*-vinyl acetate) (PEVAc) slow-release matrices loaded with protein antigens and implanted s.c. in mice could elicit antibody responses sustained over many weeks and comparable to two injections of the same antigens with complete Freund's adjuvant.[66] PEVAc matrices have also been shown to promote mucosal immunity when used in the form of vaginal rings, releasing antigen in contact with the vaginal epithelium.[67] For safe injectable vaccines, biodegradable poly(lactide-*co*-glycolide) (PLGA) microspheres with encapsulated protein antigens have been shown to elicit sustained retention and slow release of antigen from sites of injection lasting several weeks,[68] and such microsphere delivery agents achieve enhanced antibody titers compared to alum.[69,70] DNA vaccine plasmids encapsulated in PLGA microparticles are detectable by PCR analysis of tissue homogenates from i.m. or s.c. injection sites for up to approximately 60 days, while naked DNA injected at the same sites is undetectable after such long times (see also **Chapter 4.424, Nanoparticles for Nucleic Acid Delivery** and **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**).[71] However, the buildup of an acid environment within PLGA particles as they degrade, and their generally hydrophobic interior, has been shown to lead to protein denaturation and aggregation within particles over time,[72,73] and strategies to overcome this issue have had mixed success.[23,74] Antigen aggregation/denaturation may particularly be a problem for obtaining protective antibody responses against conformational epitopes of proteins. Thus, although PLGA microparticle/nanoparticle technology is well established, PLGA particles with encapsulated antigens have received very limited testing in nonhuman primates[75] and no clinical trials have been run using PLGA-encapsulated vaccines to date.[23] An alternative strategy is to adsorb protein antigens or DNA-encoding vaccine antigens onto the surface of charged biodegradable particles.[76] For example, PLGA particle surfaces modified with the cationic surfactant cetyl trimethylammonium bromide allow electrostatic adsorption of DNA vaccine plasmids or recombinant protein antigens.[77] This approach was pioneered at Chiron Corporation (now Novartis), and avoids antigen damage during encapsulation processes, while eliciting equivalent or superior immune responses. Like other depot strategies, DNA adsorbed on cationic PLGA particles is

retained upto at least 7 days at i.m. injection sites, while naked DNA is undetectable in muscle at this time.[78] Although PLGA is attractive for its long record of safety in humans, alternative bioresorbable polymers that can avoid some of the limitations of PLGA are under development and might offer a viable approach for encapsulated vaccine delivery. Examples include the development of polymers that degrade to uncharged or net neutral products that do not acidify their environment, such as poly(ortho esters)[79] or polyketals.[80,81] However, in relation to all particulate antigen depots, it must be remembered that most tissue sites for vaccination are not static beds of extracellular matrix, but rather contain a dynamic inflammatory infiltrate responding to the injection, and interactions of host cells with foreign particles must be considered to understand the mechanisms of the ensuing immune response. This is examined further in the next section.

4.419.3.2.2. Targeting and 'reverse targeting' of APCs

The particulate nature of microbes is itself a motif used by innate immune cells to recognize foreign material, and monocytes recruited to sites of inflammation internalize particles and carry them to draining lymph nodes.[30] Particles of a size small enough for phagocytosis (~5–10 μm and smaller) but too large for endocytosis by stromal cells are thus 'naturally targeted' to phagocytes (**Figure 1**). However, neutrophils, macrophages, monocytes, and DCs are all phagocytic, and neutrophils and macrophages typically greatly outnumber DCs (or monocytes that might differentiate into DCs *in situ*) early in the host response at injection sites. Flow cytometric analyses of cells infiltrating the peritoneum following PLGA microsphere vaccine injection have found that the vast majority of cells internalizing particles exhibit a macrophage-like phenotype (60–70% at 48 h, vs. 5–8% DCs[82,83]). For particles with mean sizes of a few microns, a small but detectable population of microsphere$^+$ cells can be found in draining lymph nodes 24–48 h after immunization, although these small particle$^+$ populations likely represent a tiny fraction of the total injected dose, which was 1 or more milligrams in these studies.[82,83] Thus, such 'natural targeting' may be inefficient in directing antigen-carrying particles to the DCs most critical for initiating adaptive immune responses. Interestingly, although these studies describe the persistence of fluorescently tagged vaccine particles at injection sites for prolonged periods, no reports have attempted to quantify the fraction of particles that are internalized by phagocytes at the injection site over time – information which could provide significant insight into the ability of released antigen to reach draining lymph nodes. In relation to these issues, recent work exploring the role of particle geometry on macrophage phagocytosis has suggested that it may be possible to engineer phagocytosis-resistant particles purely on the basis of shape considerations, which could be an interesting area for exploration in vaccine delivery.[84]

An alternative to relying on passive processes of phagocytosis is to functionalize particle vaccine carriers with antibodies targeting specific APCs, in order to deliver antigen to APCs via binding of particles to specific receptors. Conjugates of protein antigens with a monoclonal antibody to the DEC-205 lectin receptor expressed by DCs were shown to elicit extremely potent T cell responses following vaccination with minute doses of antigen.[85] Following on this discovery, it was shown that liposome-like plasma membrane vesicles prepared from tumor cells could be targeted to DCs for enhanced internalization by functionalizing the surface of these vesicles with antibody fragments targeting CD11c (a canonical DC surface marker) or DEC-205.[86] Frechet's group demonstrated that anti-DEC-205-functionalized hydrogel microparticles carrying protein antigens triggered enhanced phagocytosis of these particles *in vitro* and an approximately threefold enhanced uptake of particles into DCs following s.c. injection *in vivo*, with a coincident improvement in cytotoxicity and cytokine secretion by antigen-specific T cells.[87] Macrophages and DCs express scavenger receptors, such as the mannose receptor, which promote internalization of pathogens. Thus, in a similar vein, functionalization of DNA vaccine-loaded liposomes with monoclonal antibodies directed against the mannose receptor has been shown to enhance *in vivo* transfection of splenic DCs by ~10-fold following i.p. injection and concomitantly, the generation of cytotoxic T cells.[88]

A final approach for enhancing delivery of antigens into APCs is to use biomaterials for 'reverse targeting'–attracting APCs to antigen depots instead of targeting particulate antigen to cells. Inflammation at sites of infection triggers the release of a host of chemoattractants that recruit monocytes and DCs from the blood;[89,90] these cells can take up antigen and transport it to draining lymph nodes to prime T and B cells.[29] Mimicking this natural response to infection is another strategy to enhance the function of antigen depot vaccine delivery systems. Using PEVAc polymer matrices very similar to that first reported by Langer for vaccine depot generation, Kumamoto prepared implantable rods that released both a protein antigen and a chemoattractant, CCL19 (see also **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**).[91] Notably, CCL19 is an attractant for mature (activated) DCs, not immature (resting/unactivated) DCs, and binds the same receptor (CCR7) as the chemokine CCL21 produced by lymphatic vessels that attracts activated DCs to lymph nodes. By applying a topical inflammatory stimulus over the implant site, these authors were able to activate DCs locally at the implant and then trap them locally for sustained periods, by providing a competing chemoattraction gradient that slowed DC trafficking to CCL21-producing lymphatics. This local trapping provided a greater time window for DCs to accumulate and internalize antigen released from the implanted rods, and thereby enhanced T cell and antitumor responses elicited by the vaccine. In an approach more closely resembling the response to infection, attractants for immature DCs have been encapsulated in PLGA microspheres, allowing the generation of local chemoattraction gradients around collections of microspheres that potently chemoattract resting DCs.[92] Singh *et al.*[93] have shown that *in situ* cross-linkable hydrogels can be loaded with chemoattractants to draw DCs to DNA vaccine depots. One of the most promising antitumor vaccines (presently in clinical trials) is based on the injection of irradiated autologous tumor cells, which are transfected to produce the cytokine granulocyte/macrophage colony-stimulating factor (GM-CSF).[94] GM-CSF is an attractant for DC precursors, and also triggers the differentiation of these cells into potent APCs, which leads to strong immune responses elicited by attracting and differentiating

DCs *in situ*. Recently, Ali *et al.*[95] demonstrated that this process can be mimicked by designing implantable biodegradable PLGA scaffolds carrying GM-CSF and tumor lysates (as a source of antigen), which provides a substantial advantage as no live cells are used in the therapy (see also **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**). Notably, immunostimulatory TLRas could be coreleased from these scaffolds to provide additional 'danger' signals promoting the immune response.

4.419.3.2.3. Lymph node targeting

In the approaches described above, especially those employing implanted matrices or polymer microparticles, most of the 'targeting' of APCs likely occurs in the peripheral tissue injection site, as these materials will have poor, if any, direct access into the lymphatics and downstream lymph nodes. These strategies thus rely on the activation of targeted APCs and the subsequent trafficking of these cells to the lymph nodes to initiate immune responses. Alternatively, vaccines might aim for direct transport to lymph nodes, to allow direct delivery to lymph node-resident DCs and B cells. Although particles draining through lymph were long thought to be largely scavenged by macrophages lining the subcapsular sinus of lymph nodes, recent studies have revealed that viral particles,[96] immune complexes,[97] and synthetic antigen-displaying nanoparticles[98] are transferred through the floor of the lymph node subcapsular sinus by macrophages to B cells scanning for antigen, providing a potential mechanism for B cells to directly acquire particulate antigen. Particles small enough to diffuse through the interstitial matrix at an injection site pass between lymphatic endothelial cell junctions to enter lymphatics, then drain to downstream lymph nodes, and pass through the subcapsular sinus into the lymph node cortex; they could potentially achieve direct delivery to both DCs and B cells. Numerous studies have explored relationships between particle properties and lymph node draining following subcutaneous, intradermal, or intramuscular injection.[99–101] A wide variety of materials have been used in these studies, ranging from lipid-stabilized oil emulsions to solid polymer particles, and potential differences in the stability and elastic properties of these nanoparticles may be relevant to understanding the results obtained in any particular system. However, several general trends emerge: smaller particles, particularly those less than 100 nm in size, are transported more efficiently to lymph nodes from injection sites.[101,102] For rigid polymer particles, sizes under ~50 nm appear to be required for efficient diffusion through tissue matrix in intradermal sites (**Figure 2**),[101] but liposomes of substantially larger diameters are capable of draining to lymph nodes,[100] perhaps reflecting the deformable nature of these elastic vesicles. Attachment of poly(ethylene glycol) (PEG) chains to the surfaces of liposomes or polymer particles reduces interactions of the particles with ECM and adsorption of serum opsonins to the particles,[103] enabling enhanced lymphatic draining.[104,105] Small particles reaching lymph nodes can access

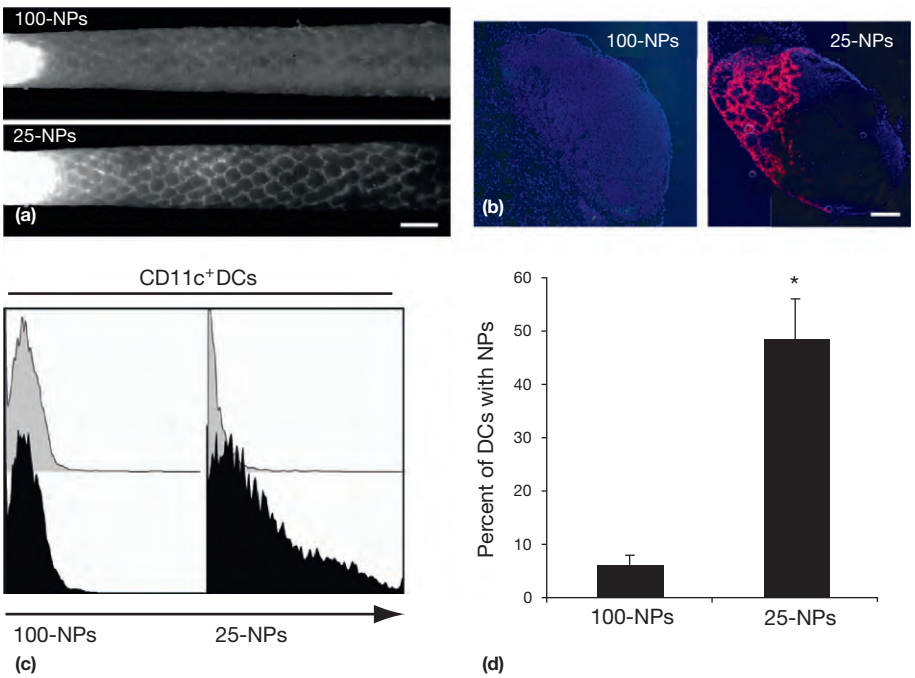

Figure 2 Lymph node-targeting, complement-activating polymer nanoparticles accumulate in lymph nodes after intradermal injection and induce antigen-specific adaptive immune responses in a size-dependent manner. (a) Fluorescence microlymphangiographs demonstrating more efficient draining of fluorescent 25 nm polymer nanoparticles compared with 100 nm nanoparticles through lymphatics in a mouse tail (lymphatic capillaries all drain in one direction), (b) 25 nm, but not 100 nm, nanoparticles are visible in mouse lymph node sections 24 h after injection. (c) Flow cytometry histograms show $CD11c^+$ dendritic cells isolated from draining lymph nodes after intradermal coinjection of fluorescently labeled 100 and 25 nm nanoparticles (black) or phosphate-buffered saline (PBS) control (gray). (d) Quantification of preferential targeting of lymph node DCs by 25 nm nanoparticles compared with 100 nm. Adapted from Reddy, S. T.; van der Vlies, A. J.; Simeoni, E.; *et al*. *Nat. Biotechnol*. **2007**, *25*(10), 1159–1164.

not only macrophages in the subcapsular sinus but also CD11c$^+$ and DEC-205$^+$ DCs in the lymph nodes.[101,106] Lymph node targeting requires not only transport through the lymphatics but also retention in the node, and particles of smaller size and PEGylation can in fact pass through the draining lymph nodes to reach the bloodstream – thus, particles with optimal lymph node accumulation are not necessarily the smallest/most hydrophilic compositions. Functionalization of PEGylated nanoparticles with targeting agents such as antibodies may enhance retention of vaccine particles specifically by DCs.[107]

Only a few studies have directly explored the impact of particle size on lymph node targeting coupled to vaccine responses. Plebanski and colleagues showed that nanoparticle vaccines composed of protein antigen or minimal peptide epitopes covalently linked to monodisperse polystyrene particles were capable of eliciting strong CD8$^+$ T cell and antibody responses.[106,108] Testing a range of particle sizes from 20 nm up to 2 μm, they found that both antibody and CD8$^+$ T cell responses were maximal for particles 40 nm in diameter. In these studies, no specific molecular adjuvant was included, so the nature of the 'danger' signals promoting these responses is not clear, and the clinical translatability of nondegradable polystyrene as a vaccine carrier is uncertain. Reddy *et al.*[101] developed biodegradable nanoparticles based on poly(propylene sulfide), which could similarly display surface-tethered, antigens, and demonstrated that PPS particles of ~25 nm were capable of much more efficient lymph node transport than particles 45 or 100 nm in diameter (**Figure 2**). They further found that display of hydroxyl-terminated PEG at the surface of these particles could be used to activate complement, providing an *in situ* adjuvant signal at the particle surface following injection.[109] These lymph node-targeting and complement-activating particles elicited strong CTL and antibody responses *in vivo* that were comparable to injections of antigen with LPS,[109] a very strong adjuvant in mice that is too toxic to be used safely in humans. Notably, 100 nm particles of the same composition and carrying the same antigen dose gave much weaker immune responses, suggesting that lymph node targeting can substantially amplify the immune response to particulate vaccines.

4.419.3.3. Controlling Vaccine Delivery at the Cellular Level

Vaccine antigens and any associated adjuvant signals must be delivered into tissue sites, transported to either DCs in the tissue or to B cells/DCs in draining lymph nodes, and finally, taken up by individual DCs and B cells. Vaccine materials can play a critical role in modulating this final key step of vaccine delivery. The most studied concept in controlling immune responses at the single-cell level is the use of particulate delivery agents to 'target' antigens to phagocytic APCs (DCs, macrophages, and B cells), which are capable of internalizing particles greater than 1 μm in size with greater efficiency than other cell types. Using alum as the classic example, Mannhalter *et al.*[110] demonstrated that tetanus toxoid (TT) antigen adsorbed to aluminum hydroxide particles induced significant increases in T cell proliferation, mediated by an increase in macrophage/T cell interactions. A more recent report demonstrated that for a model antigen (alpha casein), uptake by DCs *in vitro* was increased fourfold relative to soluble antigen when the protein was adsorbed onto aluminum hydroxide.[111] These findings support the ability of aluminum-based adjuvants to target antigen-presenting DCs by 'particulating' soluble antigens. Similar results have been found for a broad range of particulate biomaterial vaccines, including a range of polymer particles and liposomes.[23] Recent studies have begun to explore additional strategies to exploit such APC-targeted uptake, for example, via the delivery of antigen-loaded polyelectrolyte multilayer-based microcapsules to monocytes and DCs in whole blood.[112] Beyond this simple strategy of preferential internalization by APCs, particulate antigens have been explored for enhancing CD8$^+$ T cell responses and B cell responses by additional mechanisms, as outlined in the following sections.

4.419.3.3.1. Cross-presentation of antigen to CD8$^+$ T cells

Much work has focused on controlling antigen uptake and activation of DCs, due to their central role in regulating naïve CD4$^+$ and CD8$^+$ T cell priming. A key challenge facing subunit vaccines is the elicitation of CD8$^+$ T cell responses, as exogenous antigens internalized by DCs are effectively processed and loaded onto class II MHC molecules for presentation to CD4$^+$ T cells (for induction of Ab responses), but only very inefficiently processed for loading into MHC I molecules for presentation to CD8$^+$ T cells (for generation of cellular immunity). Predominantly, antigen presented on class I MHC derives from proteins processed in the cytosol of DCs (e.g., proteins from a virus that has infected the cell) (see also **Chapter 4.424, Nanoparticles for Nucleic Acid Delivery** and **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**). However, it was shown in the early 1990s that particulate forms of antigen trigger 'cross-presentation,' the loading of exogenous antigens onto class I MHC.[113,114] Although the mechanisms underlying cross-presentation remain controversial,[115] the finding that antigen attached to or encapsulated within particles ranging in size from a few tens of nanometers to several microns is cross-presented with up to 1000-fold greater efficiency has inspired the exploration of a broad range of biodegradable particle carriers for vaccine delivery, including liposomes,[116,117] PLGA particles,[118–120] and hydrogel particles.[121,122] Notably, particle-delivered antigen elicits strong CD4$^+$ T cell responses *in vivo* as well.[118] Although relatively stable materials such as polystyrene or iron oxide particles with surface-attached antigen promote cross-presentation of antigen and subsequent CD8$^+$ T cell responses *in vitro* and *in vivo*,[106,113] another approach that has been explored is the design of particles that disrupt phagosomes/endolysosomes, allowing direct transport of antigen into the cytosol where it can be proteolyzed by the classical MHC I antigen processing pathway. For example, acid-responsive microparticles and nanoparticles that quickly break down in phagosomes[122,123] or swell in response to acidification of these compartments[124] have been used to osmotically disrupt the phagosomal membrane, delivering antigen into the cytosol and eliciting enhanced cross-presentation. DCs are also known to be capable of storing antigen for prolonged periods in their endosomal/phagosomal compartments,[125] and biodegradable particles that slowly release antigen over time in these vesicles or within the cytosol may also be able to prolong antigen presentation.[120] A third strategy to promote CD8$^+$ T cell responses is

to deliver plasmid DNA-encoding antigens directly into DCs so that they produce antigens endogenously, and biodegradable microparticles and nanoparticles capable of endosome/phagosome disruption have been used for such DNA vaccines.[126,127] Although PLGA is not traditionally viewed as an acid-responsive polymer, a few studies have suggested that PLGA particles may also disrupt phagosomes.[120,128] Perhaps employing this mechanism in part, cationic PLGA microparticles with surface-adsorbed antigen-encoding DNA have been shown to enhance $CD8^+$ T cell responses in both mice and nonhuman primates.[77,129,130]

4.419.3.3.2. B cell activation and humoral responses

B cells are triggered by antigen-mediated cross-linking of cell surface Ig receptors. It has long been appreciated that antigen receptor recognition of repetitive surface structural motifs common in microbes efficiently triggers B cell signaling, and such repetitive structures may act intrinsically as danger signals for humoral responses.[131] B cells that bind to organized surface proteins or polysaccharides on viral particles or bacteria are robustly activated.[132] Thus, synthetic vaccine particles displaying many copies of surface-conjugated antigen are efficient triggers of antibody responses.[106,109,133] The most extreme example of the importance of particulate display for humoral responses comes from studies of minimal epitope vaccines: When short peptides are used as defined B cell antigens, display of the peptides on the surface of liposomes triggers robust antibody responses while soluble peptides or peptides encapsulated in liposomes fail to elicit humoral immunity.[133,134] Similar to the case of antigen delivery to DCs, maximal B cell responses might require the codelivery of antigen and accessory danger signals in the same particle.[135]

4.419.4. Biomaterials as Immunostimulators and Carriers of Immunostimulatory Adjuvants for Vaccines

As outlined in Section 4.419.2, antigens must be acquired by the immune system in the context of danger signals to promote the generation of a productive immune response. Biomaterials can thus play a key role not only in vaccine antigen delivery, but also in the codelivery of appropriate danger cues that prime protective immunity to the delivered antigens rather than tolerance. Two strategies for provision of danger signals using biomaterial delivery agents have been explored: (1) biomaterials that intrinsically provide danger signals to responding innate immune cells, and (2) biomaterials as cocarriers of antigens and defined molecular danger signals, such as PAMPs, DAMPs, and cytokines.

4.419.4.1. Intrinsic Adjuvant Activity of Biomaterials

Many biomaterials developed for vaccine delivery have been thought of primarily as passive physical delivery agents, controlling the kinetics and localization of antigen during immunization to promote the immune response. However, our expanding understanding of how the immune system detects danger has led to recent revelations about the complex interaction biomaterials have with the immune system and unexpected danger cues elicited by materials previously viewed as immunologically inert antigen depots. In this context, a discussion of the most established and well-studied adjuvant, alum, and recent discoveries about the role of the inflammasome in mediating biomaterial adjuvant effects is introduced. Then other ways in which danger-sensing pathways may be triggered by biomaterials under development for vaccine delivery are discussed. Together, these recent developments are paving the way for viewing biomaterials themselves as agents for actively shaping immune responses.

4.419.4.1.1. Activation of the inflammasome

As discussed in Section 4.419.4.2.1, alum was traditionally thought to function primarily by providing sustained antigen release from the injection site, but conflicting data existed regarding the actual depot function of alum and its importance in the immune response.[59] In addition, a number of clear biological events occur in response to alum/antigen injections. Coadministration of alum and antigen induces chemokine production and recruitment of monocytes, granulocytes, and macrophages to the injection site.[136,137] Alum also induces secretion of cytokines and the differentiation of monocytes toward a DC phenotype.[62,110,137,138] Alum was also found to trigger antigen-independent proliferation of splenic B cells, which coincides with accumulation of $Gr1^+$ IL-4-producing cells in the spleen, indicating a previously unappreciated role for alum in B cell priming and expansion.[62] Together, these observations suggest a potentially important role for alum in mediating innate immune responses that bridge to adaptive immunity.

Recently, new mechanistic insights have emerged regarding the pathways by which alum triggers this suite of responses *in vivo*, via a danger/pathogen-sensing signaling pathway known as the inflammasome.[60,61,139–141] As highlighted in Section 4.419.2, DCs and other innate immune cells express PAMP and DAMP sensors, which can be cell surface receptors (e.g., TLR2, TLR4 and TLR6) or intracellular proteins (e.g., NLRs). Inflammasomes are cytosolic, multiprotein complexes that play key roles in mediating innate immunity through the induction of inflammatory cytokines in response to bacterial pathogens.[142,143] While several distinct inflammasome complexes have been described, a common downstream event is the production of inflammatory cytokines. For example, activation of the caspase-1 inflammasome leads to production of active caspase-1, which cleaves the inactive precursor forms of two potent proinflammatory cytokines (pro-IL-Iβ and pro-IL-18) to generate active IL-1β and IL-18. IL-1β and IL-18 – along with another inflammasome-inducible cytokine, IL-33 – increase cell migration, induce secretion of interferon-γ, promote differentiation of T_h17 cells, and enhance humoral immune responses (via IL-5 and IL-13). Another inflammasome complex, NALP3 (NAcht domain-, leucine-rich repeat-, and Pyrin domain-containing protein 3), is indicated in sensing and generating proinflammatory responses against bacterial toxins using a similar pathway.[32] *In vitro* studies in mouse and human cells using MyD88-deficient cells (a key adaptor protein required for signaling through TLRs) indicated that alum induces secretion of IL-1β and IL-18 independently of TLR signaling.[140] In mice, IL-1β, IL-18, and IL-33 secretion

by alum was dependent on the NALP3 inflammasome. The mechanism by which alum is capable of triggering the NALP3 inflammasome is still a subject of debate: Alum has been indicated in the induction of uric acid, a known DAMP released from necrotic cells;[139] uric acid crystals can trigger inflammasome activation. An alternative theory suggests the ability of alum to induce phagocytic uptake is critical for inflammasome activation, holding that the danger signal is potassium efflux resulting from rupture of alum-containing endosomes and lysosomes.[60,61] Using alum-containing vaccine formulations administered to NLRP3-deficient mice (mice lacking the NALP3 inflammasome), antigen-specific antibody production was greatly reduced, further supporting the key role of inflammasome activation in alum's adjuvant activity.[60]

These findings regarding the classic adjuvant alum appear to have relevance for a range of vaccine biomaterials, and perhaps for the host response to biomaterials in general. For example, PLGA, one of the most ubiquitous resorbable biomaterials, also activates the NALP3 inflammasome when incubated with immune cells in particulate form. PLGA microparticles have been shown to greatly enhance secretion of IL-1β and IL-18 when incubated with DCs in the presence of LPS, which on its own is a weak inducer of IL-1β.[144,145] This behavior is true for PLGA coadministered with a number of other TLRas that act through intracellular or extracellular TLRs. While PLGA-induced inflammasome activity was found to be dependent on coincubation with TLRas *in vitro*, *in vivo*, inflammasome activation as well as proinflammatory cytokine secretion was induced in the absence of LPS or other TLRas,[145] suggesting that PLGA may serve as, or induce, a second signal for inflammasome activation. IL-1β induction by PLGA particles is NALP3 dependent, and interestingly, inflammasome activation by PLGA is dependent on uptake of particles by DCs, lysosome acidification, and efflux of intracellular potassium ions. Administration of PLGA microparticles with ovalbumin (OVA) leads to increased production of antigen-specific antibodies compared with soluble antigen and this effect persists in NALP3-deficient mice. In contrast, PLGA-induced enhancement of cellular immunity through proliferation of $CD11b^{+}Gr1^{-}$ cells and IL-6 production was absent in NALP3-deficient mice.[145] Thus, PLGA appears to confer adjuvant activity by antigen-independent inflammasome activation, as well as two antigen-dependent mechanisms, namely, enhancement of antibody-specific responses and a yet-to-be-determined route requiring NALP3 inflammasome activation for mediating cellular immunity through induction of $CD11b^{+}Gr1^{-}$ cell populations and upregulation of IL-6. Similarly, particles of chitosan, a biodegradable polysaccharide, have been shown to induce activation of the NALP3 inflammasome and IL-1/IL-18 secretion through a caspase-1-dependent mechanism similar to that of alum.[141] These findings suggest that other nominally nondegradable microparticles (polystyrene, silica) also trigger inflammasomes,[61] and indicate a common route through which particulate biomaterials may confer adjuvant activity.

4.419.4.1.2. Role of TLRs in immune cell response to biomaterials used as vaccine carriers

In addition to inflammasome activation, a variety of biomaterials have recently been implicated in the activation of DCs and PAMP-mediated TLR pathways. Many of these findings have their origins in the study of biopolymers or synthetic polymers for implantable devices and are known to elicit certain anti-inflammatory or inflammatory responses depending on the stability of degradation products postimplantation (see also **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design**; **Chapter 5.502, Engineering Scaffold Mechanical and Mass Transport Properties**; **Chapter 5.520, Bioactive Ceramics and Bioactive Ceramic-Composite-Based Scaffolds**; **Chapter 5.503, Biomaterials and the Microvasculature**; **Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation**; **Chapter 5.506, Effects of Mechanical Stress on Cells**; **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**; **Chapter 5.507, Tissue Engineering and Selection of Cells**; and **Chapter 5.508, Scaffold Materials for hES Cell Culture and Differentiation**).

Naturally occurring polysaccharide biopolymers such as alginate, hyaluronic acid (HA), chitin/chitosan, and heparin have all been recently implicated as triggers of TLRs under certain conditions. HA is a polysaccharide component of the extracellular matrix and widely studied as a component of topical and implantable biomedical materials. *In vivo*, HA is enzymatically degraded by hyaluronidase to oligosaccharides containing glucuronic acid and acetylglucosamine. While high molecular weight (HMW) endogenous HA is essentially inert, low molar mass fragments of HA have recently been shown to activate DCs and macrophages.[146–148] HA degradation products (glycosaminoglycan hyaluronan) produced after lung tissue injury initiate inflammatory responses dependent on both MyD88 and TLR-2/TLR-4 pathways. Interestingly, overexpression of HMW HA was found to be protective against lung injury.[149] Activation is mediated through TLR-4 signaling as indicated by abrogation of these effects in the presence of anti-TLR-4-mAb, or in mice lacking functional TLR-4.[147] Further evidence of the involvement of the TLR-4 pathway is suggested by the upregulation of key TLR-4 signaling components (e.g., p38/p42/44 MAP-kinases) associated with treatment of DCs and macrophages with HA fragments, but not with HMW HA. Similarly, DC activation has also been demonstrated for heparin-containing materials, through activation of NF-κβ and TLR-4.[150–152] An important implication of this work is the demonstration of an endogenous material inert in its native polymeric form, but inflammatory upon specific chemical modification (e.g., breakdown by inflammatory enzymes) – such materials might be very useful as safe, biodegradable vaccine adjuvants. Particles of hydroxyapatite (HyAp), which forms the basis of commercial calcium phosphate vaccine adjuvants, have recently been shown to induce secretion of inflammatory cytokines (e.g., TNF) through activation of the TLR-4 pathway, as well as NF-κβ.[153] Analogous to the case of HA fragments, this response may have evolved as a danger response for damaged bone and other hard tissues, where HyAp particles may be produced.

Polysaccharides derived from pathogens also tend to trigger TLR signaling in a manner that may reflect evolved recognition of multivalent, particulate microbes. For example, the naturally occurring polysaccharide chitin, a component of fungi and parasitic nematodes,[154] elicits size-dependent immune responses in macrophages, stimulating TNF-α production with polymer fragments ranging in size from 2 to 70 μm.[155] Intermediate fragments (40–70 μm) function through the TLR-2, dectin-1,

and NF-κβ pathways, whereas smaller fragments (2–10 μm) were found to mediate immune responses through activation of both TLR-2-dependent and TLR-2-independent dectin-1 pathways involving the mannose receptor and spleen tyrosine kinases. Additionally, only these smaller fragments induced secretion of the anti-inflammatory cytokine, IL-10.[155] Similarly, covalent linking of low molecular weight mannuronic acid polymers (representative of fragments of bacterial alginate polymers) to magnetic particles triggered a robust TNF-α production, whereas soluble forms of these low MW fragments did not.[156] These intriguing findings suggest a plausible mechanism for endogenous immune regulation: large/particulate polysaccharide fragments that are a signature of intact invading pathogens activate *inflammatory* pathways (e.g., TLRs), whereas low MW fragments representative of degraded pathogens activate *anti-inflammatory* cytokines such as IL-10.

In the last few years, a number of synthetic polymers traditionally associated with biomedical devices have also been identified as TLRas, suggesting that even completely nonbiological materials may be capable of modulating immune responses relevant for vaccination. Alkane and alkyl polymers such as polyethylene (PE) are commonly employed as components of biomedical implants. PE in the traditional ultra HMW form used in prosthetic implants is immunologically inert. *In vivo*, however, PE is oxidized such that the concentration of hydroxyl and carboxyl functional groups increases over time.[157] Using oxidized PE purified from implant sites and chemically modified PE with defined levels of hydroxyl and carboxyl groups, Maitra *et al.*[157] recently demonstrated that these materials mediate inflammatory responses by activating TLR-1 and TLR-2 pathways. Polymers induced NF-κβ signaling and activated DCs, leading to secretion of proinflammatory cytokines such as IL-12. Molecular docking experiments indicate that alkane oxidation confers specificity for interactions between oxidized PE and TLR-1/TLR-2 receptors. Clearly, the immune system has not evolved to protect the host from biomedical implants, and this has led to the suggestion that the patterns recognized by the host immune system may in some instances relate to very basic physicochemical properties. One recent theory points out that PAMPs and DAMPs have in common the presence of hydrophobic moieties (hyppos), which might serve as a universal danger signature.[158] For example, HA has already been described as inert – and lacking obvious hyppos – in the polymeric form, but becomes inflammatory upon degradation to oligosaccharide subunits. However, during degradation, hydrophobic portions of HA become exposed,[158] possibly serving as a conformation-specific trigger for TLR activation, similar to that described for PE. Another recent study focused on ionic charge as a core property required for activating T cells and APCs through TLR-mediated pathways.[159] Many zwitterionic bacterial polysaccharides activate T cells and APCs. By introducing cationic charge into naturally occurring anionic polysaccharides through chemical modification, these materials are able to activate monocytes and DCs in a manner similar to wild-type zwitterionic polysaccharides.[159] The ability of natural and synthetic biomaterials to activate TLR pathways through presentation of common physical and chemical properties could provide the foundation for designing new hybrid adjuvants that elicit defined immunological responses. Recently, polyamidoamine dendrimers modified with glucosamine (a prevalent component of exoskeletons, crustacean, and fungi) have been reported.[160] Interestingly, these materials blocked TLR-4 activation by LPS and the production of TNF-α, IL-1β, and IL-6. However, they allowed upregulation of costimulatory molecules including CD25, CD80, CD83, and CD86. Thus, hybrid materials that contain both natural and synthetic components, may allow tailored immunogenic profiles with both pro- and anti-inflammatory character to be elicited *in vivo*.

4.419.4.1.3. Complement-activating biomaterials

The complement pathway is a component of innate immunity that functions to enhance the clearance of antigens by antibodies in the blood stream. Depending on the type of activating signal, complement can be called into action through any of three biochemical pathways (classical, alternative, and lectin), or can be stimulated by the adaptive immune system. When antigen is present in the blood, a biochemical cascade activates a series of precursor proteins – synthesized in the liver and circulating in the blood – to assemble into complement proteins that enhance antigen clearance. These proteins act through several mechanisms, including coating or 'opsonization' of antigens to increase phagocytosis, pore formation on foreign cell membranes to induce lysis, and recruitment of macrophages and neutrophils. Biomedical engineers have long known of the abilities of a range of biomedical polymers to activate inflammatory and complement pathways, but the specific mechanisms by which these materials elicit such responses are only recently being explored at a more basic level.[16,161] Gold surfaces functionalized with defined thiol-containing groups have been investigated, and these studies suggest that mercaptoglycerol- and mercaptoethanol-containing surfaces generate the strongest inflammatory responses.[162] Using complement-depleted animals, this response was found to be generated through a surface-mediated complement activation mechanism. Pluronics, a versatile class of triblock copolymers composed of alternating hydrophilic PE oxide (PEO) blocks and hydrophilic polypropylene oxide (PPO) blocks, have been explored extensively as potential vaccine adjuvants. These block copolymers have recently been implicated in the stimulation of several immune pathways including complement activation through the recognition of terminal hydroxyls, and in the enhancement of CTL and Ab responses.[163–165] Pluronic F108 (PF108) grafted to glass surfaces induces complement activation, whereas PEO homopolymer does not.[163] As with some of the other examples described in this section and previously,[158] this finding suggests that the hydrophobic portion (i.e., PPO repeat units) serves as a distinct chemical functionality involved in activating immune pathways linked to the complement cascade. As discussed in **Section 4.419.3.2.3**, Hubbell and coworkers employed a 25 nm nanoparticles surface modified with pluronic to activate complement *in situ* following parenteral injection.[109] These materials were able to activate DCs, generate danger signals, and, upon conjugation to OVA, mediate cellular and humoral immunity. Thus, new biomaterial adjuvants may find utility in activating TLR and inflammasome pathways as well as by exhibiting intrinsic complement-activating capacity.

4.419.4.1.4. Biomaterial-mediated adjuvant mechanisms not yet elucidated

As described above, the last few years have witnessed a number of exciting discoveries demonstrating the potential of biomaterials to serve as more integral vaccine components. However, many questions still surround the key mechanisms through which the existing biomaterials adjuvants function. Of note, MF59, a widely employed oil-in-water emulsion approved for clinical use in Europe, also shares many of the immunological properties of alum. Both of these adjuvants are able to induce the secretion of multiple cytokines involved in cell migration (CCL2, CCL3, CCL4, CXCL8), enhance monocyte differentiation to DCs, and ultimately facilitate adaptive immune responses by facilitating migration of activated DCs to draining lymph nodes.[137] However, a number of differences exist between the responses elicited by alum and MF59. MF59 has been found to upregulate CD83 and CCR7 on differentiating monocytes compared with the levels observed using alum, and it also appears to act on granulocytes, macrophages, and monocytes, whereas alum acts primarily on only the latter cell populations. This example illustrates characteristic 'immunological profiles' induced by adjuvants, and further studies of MF59 and other new adjuvants will be required to ascertain whether they function through activation of the inflammasome, or through other mechanism(s) distinct from that of alum or PLGA.[166]

Another series of reports describing the ability of biomaterials to induce Th2 helper T cells also raises interesting questions. Scaffold or microparticle forms of PLGA or polystyrene used as adjuvants for immunization with adsorbed OVA enhanced humoral immune responses by supporting Th2 helper T cell development. This effect was sustained for at least 18 weeks, but was not dependent on the specific polymer chemistry (e.g., PLGA composition).[167] Subsequent work has demonstrated that while both scaffold and particle polymer forms generate adjuvant effects, scaffolds induce a higher and more sustained humoral response. Is this finding linked to danger signals resulting from a more invasive implantation of scaffolds that increases tissue damage and necrosis,[168] or is another physical mechanism at play? A range of biomaterials appear to induce differential maturation of DCs depending on the specific composition.[169] When DCs are cultured *in vitro* with PLGA, chitosan, or agarose, the corresponding levels of CD86, CD40, and HLA-DQ (human MHC molecules) increase in a manner similar to that of LPS.[170] In contrast, when DCs are cultured with HA or alginate, these same phenotypes decrease; thus these results suggest chemistry-dependent interactions that exert distinct maturation effects on DCs. How these findings correlate to *in vivo* settings, or the mechanism through which these effects are achieved, is yet to be determined. Recent findings that binding of particulate materials to the membrane of DCs can induce lipid sorting at the cell surface and trigger receptor-independent activation of kinases suggest that much remains to be learned about the pathways by which immune cells can sense materials in their environment.[171] Are there common physical and chemical properties – molecular weight, fragment size, hydrophobicity, physical form, or inflammatory degradation products – that determine the ability of different biomaterials to elicit specific immune responses? Despite these open questions, the intrinsic ability of biomaterials to induce a range of immune responses is a promising feature that holds significant potential in the design of new materials functioning both as carriers and adjuvants.

4.419.4.2. Biomaterials as Carriers of Adjuvant Molecules

As discussed in the previous section, biomaterials are capable of directly activating inflammatory pathways, maturing DCs, and inducing inflammatory cytokine secretion. However, the use of biomaterials as carriers to codeliver defined immunoregulatory molecules (e.g., DAMPs, PAMPs, or regulatory cytokines) together with antigens is a second strategy for providing suitable danger signals during vaccination and regulating the developing immune response. Incorporation of one or multiple adjuvant components, controlled and sustained release, targeting, enhanced uptake, and cargo protection are just some of the performance characteristics biomaterial-based carriers offer for vaccination and immunotherapy.

4.419.4.2.1. Delivery of PAMPs, DAMPs, and related immunostimulatory molecules

Because of their potent ability to drive the development of long-lived, effective immunological memory, the use of molecularly defined PAMPs and DAMPs especially TLRas as adjuvants in vaccines has been of obvious interest. In the simplest setting, mixing antigens delivered by biomaterials adjuvants such as alum, MF59, or PLGA particles with soluble TLRas has been shown to enhance serum antibody levels, T cell proliferation, and interferon-γ production by T cells in response to subunit vaccine antigens.[172,173] Administration of MF59 alone or in the presence of CpG or the TLR4 agonist E6020 has also been reported to elicit similar T cells responses, but addition of the TLRas shifts the antibody isotypes toward a Th1-biased immune response.[174] Thus, simple mixing of TLRas with biomaterials designed to regulate delivery of antigens can enhance vaccine responses. However, coformulation of both antigen and PAMP/DAMP molecules in biomaterials for vaccine delivery has several potential benefits: (i) encapsulated danger signal molecules have been shown to have substantially increased potency, allowing 10–100-fold lower doses of these molecules to be used, potentially reducing side effects;[175–177] (ii) codelivery of antigen and danger signals into the same phagosomal/endosomal compartment within DCs may be important for regulating optimal presentation of antigen to T cells;[178] (iii) particles carrying both antigen and 'helper' ligands to ensure codelivery into antigen-specific cells trigger optimal antibody responses from B cells;[135] and (iv) sustained release of danger signals from controlled-release biomaterials may promote persistent TLR signaling, which has been implicated in breaking tolerance to tumor antigens.[179] Formulation of TLRas by adsorbing or encapsulating these components on or within various biomaterials has been used to enhance immune responses induced by antigens associated with a number of diseases including influenza, meningitis, streptococcus, and HIV, as well as cancer.[176]

Liposome-based vaccines for both cancer and infectious diseases have been explored for many years and provide the earliest examples of codelivering antigen with immunostimulatory molecules via vaccine biomaterials. While only a brief

survey of the work is presented in this chapter, the reader is referred to recent reviews for liposome-mediated TLR delivery.[180,181] Reports from the early 1990s have demonstrated that TLRas incorporated into antigen-carrying liposomes could enhance antibody and T cell responses.[134,182] These studies demonstrated that TLR4 agonist derivatives of LPS incorporated directly into the membrane of liposomes provided strong adjuvant effects, and biased antibody production from IgG1a to more potent IgG2a isotypes. In another strategy, oligonucleotide TLRas such as unmethylated CpG oligos (TLR9 ligands) have been encapsulated in liposomes, providing protection for these compounds from nucleases and prolonging immune responses.[183] Coencapsulation with OVA antigen enhances IFN-γ production and substantially increases IgG responses compared with equivalent antigen and TLRa doses administered in soluble form. In the case of cancer immunotherapy, TLRas – at least in the case of CpG – have also been shown to achieve these effects largely through a potent activation of cytotoxic T lymphocytes.[184,185] Liposomes containing CpG and HER-2/neu-derived peptide – a self tumor antigen – also increased IFN-γ (∼100-fold compared with antigen only); in addition, these materials have been shown to induce significant $CD8^+$ T cell responses.[186] Hepatitis antigen delivered with CpG in liposomes also enhances antibody responses, induces IL-12 production, and drives a Th1-biased immune response compared with the Th2 response observed in control groups immunized with free peptide.[187] Cationic liposomes improve uptake of antigen and CpG oligos into $CD11c^+$ DCs and activate natural killer T (NKT) cells to produce IFN-γ in a TLR-9-dependent manner.[188] This approach has also been recently extended to Leishmania vaccines to increase IgG2a titers.[189]

Although TLR4 and TLR9 agonists have been most widely studied, several additional TLRas have also been explored in the context of liposomal vaccination. Liposomes complexed with CpG or poly(I:C) (double-stranded RNA mimic, TLR3 ligand) and an antigen, trigger cross-priming of $CD8^+$ T cells and also elicit $CD4^+$ T cell responses.[190] In studies involving antigens for melanoma (trp2) or mycobacterium tuberculosis (ESAT-6), these antigen/TLRa complexes controlled tumor growth and offered protective immunity, respectively. Another TLRa, 3M-019 (TLR-7), dramatically improves antibody responses to the model antigen OVA.[191] Coadministration of OVA liposomes and 3M-019 increased levels of IgG2a and IgG2b 625-fold and 3000-fold, respectively, which were further increased when liposomes contained both OVA and 3M-019. A similar trend was observed with cellular immunity, and these observations suggest a potent synergy for codelivery of antigen and TLRas to the same APCs.

PLGA microparticles and nanoparticles have also been extensively studied as carriers for codelivery of antigen and PAMP molecules. One of the early reports of biomaterials as carriers of TLRas described the enhancement of both cellular and humoral immune responses by adsorbing CpG oligonucleotides (ligands for TLR-9) and HIV-associated antigens to separate populations of charged PLGA microparticles, leading to enhanced serum IgG titers and CTL generation.[192] Using PLGA nanoparticles to coencapsulate TT with CpG oligos, Diwan *et al.* demonstrated increased DC activation and enhanced antibody and T cell responses compared to soluble TT/CpG immunizations.[193,194] PLGA microparticles have been used to codeliver hepatitis B core antigen (HBcAg) with the TLR4 agonist MPLA.[195] Particle codelivery enhanced both $CD4^+$ and $CD8^+$ immune responses *in vitro* and *in vivo*.[118,196] *In vitro*, microparticles encapsulating OVA protein along with CpG or the TLR7 agonist imiquimod are phagocytosed by DCs and activate TLR pathways. These materials stimulate proliferation of primary and secondary $CD4^+$ and $CD8^+$ T cells *in vivo*, and elicit levels of cross-priming comparable to those induced by live microbe vectors.[196] An interesting variation of this approach is the addition of a TLR4 agonist (LPS) to the outer surface of PLGA nanoparticles using a double emulsion synthesis technique.[144] In comparison to unmodified nanoparticles, these particles are preferentially internalized and are able to elicit both humoral and cellular immune responses in mice, and were ultimately able to provide protection against West Nile encephalitis. In wild-type mice, IL-1β production is also increased, but this effect was abrogated in the absence of endocytosis and lysosomal fusion, suggesting inflammasome-mediated responses. Additional immune potentiators, including MPLA and RC539, have also been explored using PLGA microparticle-based delivery strategies.[197] In these studies, MPLA and RC539 significantly enhanced antibody-mediated immunity compared with soluble CpG, although the effect on cellular immunity was not described. Together, the observations discussed here suggest that PAMPs carried in biomaterials mediate activation of TLR pathways, and perhaps in many cases, of the inflammasome activation. While codelivery of PAMPs and antigen with biomaterials generally seems to have a positive enhancing effect on immune response, the specific response characteristics vary somewhat among different carrier systems. In the case of anthrax and meningitis studies, for example, PLGA-adsorbed CpG significantly enhanced antibody-mediated immunity and survival compared with soluble CpG.[198,199] In contrast, soluble and surface-adsorbed CpG had similar enhancing effects when administered using PLGA/chitosan microparticles, although encapsulated CpG still produced a marked improvement compared to these formulations.[198] The examples above demonstrate the growing body of literature focused on exploiting the delivery of PAMPs as adjuvants to enhance and direct the immune response, but DAMPs could also provide a complementary approach to enhancing vaccination following similar technical strategies. Because DAMPs function through alternate cell signaling pathways, these materials could serve as complementary adjuvants for new and existing vaccination and immunotherapy studies.

Most of the discussion above has focused on peptide and protein-based antigens, but biomaterials have also been used as a platform for enhancing DNA vaccination, and recently, several approaches have exploited TLRas to increase control over the magnitude and type of immune response associated with these materials.[19,176] As with the case for TLR enhancement of protein-based antigens described above, most of the DNA-based TLR work has also focused on encapsulation or adsorption of TLRas such as CpG on or within polymers and liposomes. Cross-linked polyacrylamide microparticles have been employed to deliver plasmid DNA encoding both a model antigen (β-galactosidase) and CpG immunostimulatory DNA, and these materials were internalized by phagocytic

macrophages, inducing a 40-fold increase in IL-6 secretion.[200] Recently, agonists for TLR-1, TLR2, TLR3, TLR4, TLR6, TLR7, and TLR9 were explored in the context of tumor therapy by injecting tumors with nanoparticles containing both TLRas and plasmid DNA-encoding CD40L.[201] TLR treatments containing CpG and/or poly(I:C) enhanced tumor therapy compared with treatment of plasmid only, activating DCs and inducing an influx of $CD8^+$ T cells. These reports demonstrate the potential for enhancing DNA vaccination through synergistic effects with one or more TLRas, and this is an area that will certainly be further explored in the near future.

In addition to these liposomal and PLGA particle canonical vaccine carriers, several other classes of materials have been employed as carriers of TLRas, including MF59,[173] alum,[202,203] alginate,[204] chitosan,[204,205] and protamine.[206] Each of these materials serves as an additional carrier of PAMPs or DAMPs and the reader is referred to recent reviews for additional background information and references.[16,176] In addition to TLRas, novel molecular danger signals are also being explored as potential adjuvants for biomaterial vaccine delivery. For example, α-galactosylceramide is an NKT cell ligand that has been shown to have potent adjuvant activity for a range of viral, parasitic, protein, and DNA vaccines.[207] This molecule has been formulated in poly(lactic acid) biodegradable nanoparticles for immunotherapy.[177] This and other molecules that act through distinct mechanistic pathways could provide opportunities to address particular immunological gaps, or act synergistically with other antigens and adjuvant molecules.

4.419.4.2.2. Delivery of immunoregulatory cytokines

Cytokines represent an interesting class of molecules that are being explored as adjuvant drug candidates for delivery using a range of biomaterials, providing additional control to shape the nascent immune response beyond the inflammatory signals provided by TLRas and related PAMP/DAMP molecules (see also **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**). Some of the signaling pathways of greatest interest include GM-CSF, which promotes the differentiation of DCs at an immunization site, IL-2, which drives T cell proliferation and effector functions, and IL-12, which promotes cytotoxic T cell differentiation and Th1-biased immunity. For example, influenza antigen (H3N2) can be efficiently loaded into liposomes with IL-2 and/or GM-CSF, and these materials are stable for several months.[208] As with other liposomal vaccines, antibody responses to antigen-encapsulated H3N2 are superior to responses to free antigen, and coadministration of soluble cytokines further enhances this effect. Of particular note, liposomes loaded with antigen and cytokines are even more potent compared with soluble antigen alone, or soluble cytokines administered with antigen-containing liposomes. Antigen- and cytokine-loaded liposomes conferred 100% seroconversion with upto a tenfold reduction in antigen dose, and a marked improvement in protective capacity compared with animals receiving antigen and alum as an adjuvant. GM-CSF has also been used to enhance vaccination using microparticles formed from natural or synthetic materials.[209,210] Albumin-heparin microparticles containing GM-CSF administered along with plasmid DNA-encoding HIV gag induce enhanced Ab, CTL, and T helper responses compared with antigen alone.[210] This result is sustained for at least 1 month, although subsequent boosts do not improve immune response. Interestingly, microparticles encapsulating protein antigen and cytokine serve as effective boost formulations to the DNA/cytokine prime injection, and CTL response can be further enhanced using this regimen. Sustained exposure of DCs *in vitro* to both plasmid-based antigens and GM-CSF has also recently been shown to dramatically increase gene expression using a model antigen *in vitro*.[209] Using PLGA scaffolds loaded with GM-CSF and PEI-condensed plasmid-encoding luciferase, gene expression was increased 20-fold and persisted for 10 days. While this study did not investigate the immunological implications, these findings could be promising for the development of new strategies utilizing biomaterials to concurrently present cytokines and DNA protein antigens, and the use of a scaffold could have some interesting implications for new strategies involving the combination of 'implantable' vaccines that could allow sustained release, reduce the number of injections, and improve patient compliance.

Cytokine-containing liposomes have also been explored in the enhancement of cancer therapies. IFN-γ facilitates tumor immunotherapy when encapsulated in liposomes and administered in conjunction with irradiated B16 cells.[211] Radiolabeling experiments suggest that one of the mechanisms of this enhancement is through an increase in the cytokine residence time *in vivo*, compared with that of soluble IFN-γ. A similar approach has been reported for the codelivery of OVA antigen and recombinant IL-2 by encapsulation of one or both components in liposomes.[212] Compared to formulations containing soluble or liposomal antigen, liposomes containing antigen and IL-2 led to a significant enhancement in antibody and $CD8^+$ T cell responses, as well as increases in protective capacity. Thus, cytokine delivery by biomaterials can lead to enhanced immune responses by coupling increased persistence with physical colocalization of antigen and cytokine signals.

4.419.5. Future Directions

The finding that several natural and synthetic polymers are immunologically inert in one form (polymerized) but active in another – during degradation or at low molecular weights – suggests a new approach for vaccines based on functionally responsive carriers, a topic of great interest more broadly in drug delivery. Perhaps new biomaterial adjuvants can be designed to 'sense' and respond to specific conditions, such as tumor microenvironments, or increases in particular small-molecule concentrations or cell populations. Such materials would thus represent a class of stimuli-responsive formulations that are inert or anti-inflammatory under one set of conditions, but become immunologically active in other conditions or upon receipt of specific environmental cues.

In addition to exploiting native signaling pathways triggered by pathogens, vaccines may also make use of other regulatory strategies to shape immune responses, such as signaling pathway inhibition with small-molecule drugs or via RNA interference. For example, CpG was recently conjugated to siRNA targeting a key immunosuppressive transcription factor active both in tumor cells and immune cell in the tumor environment, STAT-3. Administration of these

materials *in vivo* leads to targeting of specific cells populations (TLR-9$^+$ myeloid cells and B cells), silencing of STAT3, and activation of TLR-mediated antitumor effects.[213] This multifunctional approach illustrates an intriguing idea, based on the simultaneous activation of favorable immune pathways with concurrent silencing, or inactivation of suppressive or negative regulatory pathways. Several recent studies describe promising tumor immunotherapies based on codelivery of tumor antigens and inhibition of stat3 using a synthetic small molecule, JSI-124, and these approaches have employed a variety of polymer micelle, lipid, and particulate biomaterials for delivery.[214,215] Of note, some early variations of this approach have already started to appear that focus on codelivering DNA and anticancer drugs such as doxorubicin.[216–218] One logical expansion is to extend this dual prong approach of enhancing favorable pathways and suppressing 'unfavorable' pathways to other vaccination targets. Another example of interest for vaccination is the recent finding that retinoic acid plays a key role in imprinting particular gut-homing phenotypes to T cells during their activation by DCs.[219,220] Retinoic acid has also been incorporated in nanoparticles formed from synthetic copolymers and this system exhibits many of the basic advantages of biomaterials.[221] While these materials were not studied in the context of vaccination, it appears that the stage is set for an approach in which one activates DCs with an antigen of choice while simultaneously delivering retinoic acid to direct the destination of armed T cells to a particular tissue site – perhaps the site of a budding viral infection. The basic immunology and biological signal literature holds numerous such examples of key pathways involved in mediating particular immunological behavior, such as directing cell migration or constraining an immune response, and one could imagine that any of these pathways could serve as potential future targets for enhancing antigen-induced immune response by simultaneously silencing or inhibiting select pathways. The ability of biomaterials to provide sustained, targeted immune cell delivery of small-molecule regulators that may have poor solubility and very short half-lives may enable many powerful but inexpensive drugs to be considered as adjuvant components in vaccines. Thus, the importance of biomaterials as vaccine delivery agents is likely to grow in the coming years.

4.419.6. Conclusions

Biomaterials have clearly had a major impact on the development of new strategies for vaccination and immunotherapy. Many of the themes discussed in this chapter have highlighted the utility of biomaterials in addressing particular barriers to delivery, at both the organism and cellular level. These materials have also played a key role in facilitating vaccination through classical mechanisms such as sustained delivery and protection of biological cargos. Of particular relevance to vaccination, biomaterials have also recently been exploited for their intrinsic adjuvant activities and served as carriers not only of antigens, but also of a variety of vaccine-enhancing components including PAMPs, DAMPs, and cytokines. The ability of biomaterials, especially biodegradable microparticles and nanoparticles, to shape both humoral and cellular immune responses is providing new and exciting opportunities for the development of safe and effective vaccines/immunotherapies against infectious disease and cancer.

Glossary

Affinity-based delivery system Drug delivery system that employs specific, noncovalent interactions to immobilize and stabilize biomolecules within a matrix to sustain bioactivity and slow diffusion-based release.

Covalent immobilization Method used to incorporate drug delivery system components via covalent linkages (e.g., hydrogels formed via Michael-type additions with thiolated glycosaminoglycans and PEG diacrylate).

Cross-linking Formation of chemical bonds between polymer chains promoting the arrangement of a three-dimensional network (e.g., hydrogel delivery systems formed with heparin and amine PEG-star polymers via EDC/NHS chemistry).

Fibrin Fibrous protein network formed in blood coagulation that is used as a scaffold material for drug delivery systems to achieve controlled release of biomolecules.

Growth factor Proteins capable of promoting cellular growth, cellular differentiation, and regulation of cellular processes (e.g., basic fibroblast growth factor, neurotrophic factor-3, vascular endothelial growth factor).

Heparin Linear polysaccharide used for affinity-based delivery systems that are capable of interacting with proteins via electrostatic interactions, the hydrophobic effect, and hydrogen bonding. They are highly sulfated and also contain carboxylic acids, which contribute to an overall net negative charge.[12] Heparin polymer chains are made up of repeating disaccharides, primarily uronic acid and glucosamine.

Hydrogel Three-dimensional, water-swollen polymeric network capable of promoting controlled release of biomolecules.

Michael-type addition Addition reaction between olefins (alkene containing compounds) and nucleophiles, such as thiols (commonly used with diacrylates to form cross-linked networks).

Microspheres/nanospheres Particulate delivery systems with diameters in the micrometer/nanometer scale that encapsulate biomolecules and promote controlled release.

Neurotrophic factor Protein capable of promoting the growth, differentiation, and survival of neurons in the peripheral and central nervous systems.

Noncovalent immobilization Method used to incorporate components of a drug delivery system via noncovalent linkages (e.g., heparin cross-linked in a fibrin matrix using a bidomain peptide containing a heparin-binding site and factor XIIIa substrate).

Transglutaminase Enzyme that catalyzes covalent cross-linking between glutamine and lysine resides (e.g., factor XIIIa, which cross-links fibrin after noncovalent self-assembly).

Abbreviations

bFGF	Basic fibroblast growth factor
BDNF	Brain-derived neurotrophic factor
BMP2	Bone morphogenetic protein 2
DMA	Dimethacrylate
DTT	Dithiothreitol
EDC	1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide
EGF	Epidermal growth factor
FRET	Förster resonance energy transfer
GAG	Glycosaminoglycan
GDNF	Glial-derived neurotrophic factor
hGH	Human growth hormone
HA	Hyaluronic acid
HIP	Heparin interacting peptide

HSV	Herpes simplex virus
MSC	Mesenchymal stem cell
NGF	Nerve growth factor
NHS	*N*-hydroxysuccinimide
NT-3	Neurotrophin-3
PDGF	Platelet-derived growth factor
PEG	Poly(ethylene glycol)
PF4	Platelet factor 4
PLGA	Poly(lactide-*co*-glycolide)
RGD	Arginine-glycine-aspartic acid
SBA	Succinimidyl butanoic acid
Shh	Sonic hedgehog
tBoc	*Tert*-butoxycarbonyl
TGF	Transforming growth factor
TNF	Tumor necrosis factor
UV	Ultraviolet
VEGF	Vascular endothelial growth factor

4.420.1. Rationale for Using Heparin Conjugates for Drug Delivery

Many types of drug delivery systems benefit different biomedical applications.[1] However, for delivery of protein drugs, such as recombinant growth factors, there are many advantages in using an affinity-based delivery system. Affinity-based delivery systems rely on the use of noncovalent but specific interactions, such as electrostatic interactions, to immobilize and stabilize proteins within a matrix, sustain effective bioactivity, and slow their diffusion-based release. These noncovalent interactions can also protect protein drugs from degradation by proteases and denaturation. In some cases, these interactions may also facilitate the binding of the drug (growth factor) to the cell-surface receptor, as has been observed for basic fibroblast growth factor (bFGF) and heparin.[2] The interactions between protein drugs and affinity-based delivery systems mimic those that commonly occur within the native extracellular matrix between growth factors and cell-surface heparin sulfate proteoglycans, and can provide a repository of drug for controlled release.

Several methods for the direct covalent attachment of growth factors to biomaterials scaffolds have been developed.[3]

> Although intelligent, this approach requires permanent modification of growth factors that may not be desirable due to the potentially decreased protein bioactivity after structural modification and an enhanced immunogenicity once these modified proteins are released *in vivo*.[4]

Further advances in polymeric drugs and inorganic/hybrid controlled release systems are described in **Chapter 4.423, Polymeric Drug Conjugates by Controlled Radical Polymerization**. Additionally, some growth factors may require internalization for complete cell signaling pathway activation, and this is not possible if they are permanently attached to the biomaterial scaffold. Thus, affinity-based drug delivery offers an attractive alternative approach for growth factors, because the growth factor is sequestered in its native form and released by dissociation from the affinity-binding site, followed by diffusion from the biomaterial scaffold. This process can be modulated by using scaffolds that are hydrolytically or enzymatically degradable, providing an additional mechanism for controlling release. In the case of enzymatic degradation, drug release can be controlled by cellular activation of the enzyme (e.g., cellular activation of plasminogen during neurite extension), allowing a cell-mediated mechanism of release.

The most commonly used molecule for the binding site in affinity-based delivery systems is heparin, which has a high degree of similarity to heparan sulfate found in proteoglycans. Because a large number of growth factors bind to heparin with either moderate or high affinity, heparin-binding systems can be used to deliver a broad variety of growth factors for a number of different applications (**Figure 1**).[5] These growth factors include some of the most well-studied heparin-binding growth factors, such as bFGF and vascular endothelial growth factor (VEGF), as well as members of transforming growth factor (TGF, e.g., BMPs), platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and hepatocyte growth factor families.[6–9] Additionally, many morphogens, such as sonic hedgehog (Shh), and pathogens, such as *Bordetella pertussis*, herpes simplex virus (HSV), and *Plasmodium falciparum*, have also been found to bind to heparin.[10,11]

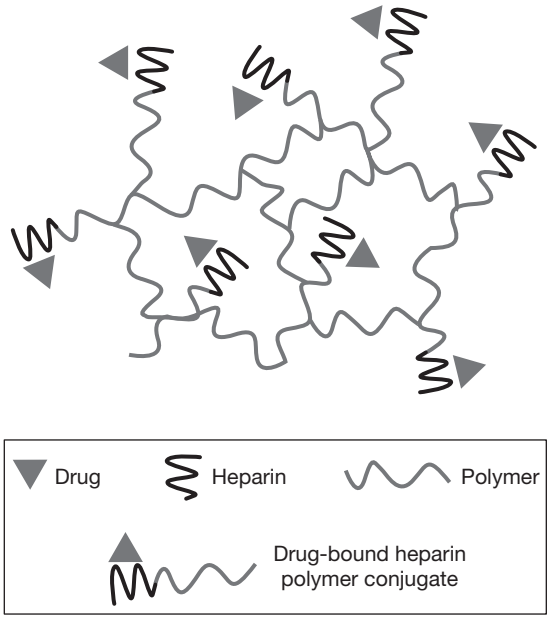

Figure 1 Schematic of heparin conjugate drug delivery system. Heparin is immobilized to a natural or synthetic polymer scaffold by covalent or noncovalent interactions. The heparin serves as a binding site to immobilize heparin-binding proteins (e.g., growth factors) by electrostatic interactions, sequestering them within the scaffold and protecting them from degradation. Drug release can occur by dissociation from the heparin and diffusion from the scaffold or degradation of the polymer scaffold.

Heparin and heparin sulfate are linear polysaccharides. They are highly sulfated and also contain carboxylic acids, which contribute to an overall net negative charge.[12] Heparin polymer chains are made up of repeating disaccharides, primarily uronic acid and glucosamine. While their interactions with proteins are largely electrostatic, there are clear contributions from hydrophobic effects and hydrogen bonding as well, imparting some selectivity and specificity. In addition to binding to growth factors, heparin also binds to a number of enzymes (e.g., antithrombin III), plasma proteins (platelet factor 4), and extracellular matrix protein (e.g., fibronectin, laminin).[13,14] In some cases, specific heparin sulfation codes have been identified that facilitate binding with growth factors (e.g., bFGF) or enzymes (e.g., antithrombin III).[15,16]

Thus, heparin conjugation to biomaterials was originally used as a method to generate nonthrombogenic materials through ionic immobilization in the 1960s[17,18] and covalent coupling in the 1980s.[19] More recently, heparin conjugation has been used for affinity-based delivery of growth factors for roughly three decades. Initially, a lack of flexible methods for heparin incorporation within biomaterial scaffolds limited this approach. However, since 2000, several new methods for heparin conjugation have led to more widespread use of heparin-based drug delivery systems. The next sections will outline the different approaches to heparin immobilization within drug delivery systems. Advancements in carbohydrate polymers and extracellular matrix-inspired biomaterials are described in **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**, respectively.

4.420.2. Methods for Heparin Immobilization

4.420.2.1. Covalent Heparin Immobilization on Beads (Sepharose)

Following the early heparin-immobilization work focused on biomaterial-induced coagulation mitigation, the seminal work demonstrating the utility of heparin-based delivery systems was performed by Edelman and Langer. They used heparin-conjugated Sepharose beads to immobilize bFGF within alginate microspheres. The initial *in vitro* studies demonstrated controlled release of active growth factor for at least 2 weeks, and growth factor activity was greater in the presence of heparin under a variety of environmental conditions than in the absence of heparin.[20] A later *in vivo* study demonstrated that bFGF delivered from heparin–Sepharose beads in alginate microcapsules was biologically active, and stimulated both angiogenesis and neointimal proliferation in a rat carotid artery model.[21] A Phase I clinical trial using this approach demonstrated that bFGF improves revascularization after coronary artery bypass grafts in a small cohort of patients.[22] In a later Phase II trial, improved revascularization was observed with bFGF treatment, with a trend toward improved left ventricular ejection fraction.[23] This work demonstrates that heparin-based delivery systems can be used to provide sustained release of biologically active growth factors in a clinical model.

4.420.2.2. Noncovalent Immobilization of Heparin

Sakiyama-Elbert and Hubbell developed a novel method for immobilization of heparin within biomaterial scaffolds by using noncovalent (primarily electrostatic) interactions rather than covalent immobilization. This three-component delivery system consists of a heparin-binding peptide covalently immobilized on the biomaterial scaffold, heparin, and the heparin-binding growth factor of interest. To demonstrate the feasibility of this approach, they cross-linked a peptide containing a modified version of the heparin-binding domain of antithrombin III into fibrin matrices via the transglutaminase activity of factor XIIIa and demonstrated that bFGF could be released in a controlled manner from this delivery system.[24] They went on to demonstrate that this approach can also be used with growth factors that possess only moderate heparin-binding affinity ($K_D \sim 10^{-6}$) via short basic domains that are accessible on protein surfaces, such as nerve growth factor (NGF), neurotrophin 3 (NT-3), and brain-derived neurotrophic factor (BDNF).[25]

Other studies have shown that this approach can be expanded to other scaffold materials, such as polyethylene glycol (PEG) hydrogels, for the delivery of heparin-binding growth factors. Pratt *et al.*[26] demonstrated that bone morphogenetic protein 2 (BMP2) delivered from plasmin-degradable PEG hydrogels via a heparin-binding peptide–heparin complex could promote improved bone healing in a rat cranial defect model. This approach has also been used for delivery of PDGF-BB to enhance gliding after midsubstance injury in a canine flexor tendon model.[27–29]

In this type of delivery system, three mechanisms control the rate of growth factor release: (1) the concentration of binding sites for the drug, (2) the affinity of the binding sites for the drug, and (3) the rate of degradation of the scaffold/delivery system. Increasing the concentration of binding sites has been found to increase the rate of release up to the limit of incorporation of the binding sites into the delivery system.[30,31] The effect of binding site affinity on the rate of release has also been explored. To identify peptide sequences with a broader range of affinities for heparin, a phage display library was screened to identify sequences with varying affinity for heparin.[32] The role of heparin-binding affinity on peptide-mediated heparin retention was evaluated for electrostatic immobilization of heparin, and increasing heparin-binding affinity has been shown to provide a longer duration of release.[33] For additional work in cell-demanded release of growth factors, refer to **Chapter 4.427, Cell-Demanded Release of Growth Factors**.

This approach for delivery of heparin-binding growth factors has proved useful in a number of applications. Delivery of NGF and glial-derived neurotrophic factor (GDNF) using fibrin scaffolds containing heparin-binding delivery systems has been found to enhance peripheral nerve regeneration in a rat sciatic nerve injury model at both 6 (number of nerve fibers) and 12 weeks (muscle force generation and prevention of muscle atrophy).[34,35] Advancements and recent work in peripheral nerve regeneration and nerve tissue engineering are further described in **Chapter 5.531, Peripheral Nerve Regeneration** and **Chapter 5.532, Nerve Tissue Engineering**, respectively. This approach has also been used for the delivery of NT-3 and was found to promote neural fiber sprouting after acute and subacute (2-week delayed) treatment of rat spinal cord injury.[36,37] More recently, this approach has also been used to deliver NT-3 and PDGF-AA to direct the differentiation and survival of embryonic stem cell-derived neural progenitor cells

in vitro and *in vivo* after spinal cord injury, demonstrating the broad utility of this approach.[38,39]

More recently, novel methods have been developed to assess the interaction of growth factors with affinity-binding peptides in scaffolds. Lin and Anseth used Förster resonance energy transfer (FRET) to assess how the architectures of affinity peptides in cross-linked hydrogels affect their binding to diffusible proteins[4] in thiol–acrylate photopolymerized PEG hydrogels. They incorporated bFGF-binding peptides and used these to control release of bFGF from PEG gels *in vitro*. In **Chapter 1.131, Superporous Hydrogels for Drug Delivery Systems**, additional work involving hydrogels for drug delivery systems is described.

4.420.2.3. Covalent Immobilization of Heparin by EDC/NHS Chemistry

Another early approach to immobilizing heparin within a scaffold was covalently attaching it to a protein, such as albumin or collagen, using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC).[40] Albumin–heparin conjugates were then emulsified to form microspheres and cross-linked with glutaraldehyde.[41] This approach can also be used to cross-link heparin covalently to collagen matrices to provide controlled delivery of bFGF, and this method was found to enhance endothelial cell proliferation *in vitro*.[42,43] Delivery of bFGF from similar matrices also demonstrated increased vascularization for up to 3 weeks *in vivo* in a rat subcutaneous implant model.[44,45]

Other groups utilized this method to couple heparin to other biomaterial scaffolds, such as alginate, decellularized tissue, and PEG. Tanihara *et al.*[46] used heparin-alginate gels to deliver bFGF and demonstrated effects both *in vitro* (fibroblast proliferation) and *in vivo* (increased angiogenesis) in a rat subcutaneous implant model. Conklin *et al.* decellularized pig carotid arteries and reacted the tissue with heparin and EDC to immobilize heparin on the vascular graft surface. The grafts were then coated with bFGF, and this approach was found to increase endothelial cell density and adhesion under perfusion culture conditions for both human microvascular endothelial cells and canine peripheral blood endothelial progenitor cells.[47] Further work in cardiovascular and heart valve tissue engineering is described in **Chapter 5.527, Cardiovascular Tissue Engineering**.

A similar approach was used for immobilization of heparin onto poly(L-lactide-*co*-glycolide) (PLGA)-based materials. Jeon *et al.* developed heparin-conjugated PLGA nanospheres. They synthesized amine-terminated PLGA by reacting PLGA with t-Boc-protected glycine and then deprotected the t-Boc group. Nanospheres of PLGA were formed using an oil–water emulsion and reacted with heparin in the presence of EDC/*N*-hydroxysuccinimide (NHS).[48] They demonstrated controlled release of bFGF over 28 days *in vitro* and increased cell proliferation. In a mouse ischemic limb model, they observed increased capillary density with bFGF and the PLGA nanospheres versus controls. Similar heparin-conjugation methods can also be used with salt-leached porous PLGA scaffolds for delivery of heparin-binding growth factors, such as BMP2. Delivery of BMP2 using this approach was found to increase bone formation in an ectopic bone formation (mouse hind limb muscle) model compared to PLGA scaffolds lacking heparin.[49]

This approach can be expanded to develop scaffolds that consist primarily of heparin through the addition of functional groups that allow polymerization of the heparin. Nakamura *et al.*[50] developed a method for generating photopolymerizable heparin hydrogels cross-linked using UV light. Controlled release of bFGF from these gels was observed *in vitro* and increased capillary number was found *in vivo* with heparin–bFGF gels at 2 weeks in a rat subcutaneous implant model. Additional studies involving biomaterials and the microvasculature are described in **Chapter 5.503, Biomaterials and the Microvasculature**.

This approach can be expanded to heparin along with another polymer as the base material for the scaffold. Freudenberg used amine-terminated PEG-star polymers to form hydrogels for growth factor delivery with heparin using EDC/NHS cross-linking. They also coupled arginine-glycine-aspartic acid (RGD) peptides to the heparin to enhance cell adhesion to the scaffolds. The addition of bFGF and RGD promoted improved cell survival and differentiation of mesencephalic neural stem cells from embryonic day 13.5 mice.[51] This broad body of work demonstrates that this approach is versatile and easy to implement for a variety of biomaterial scaffolds.

4.420.2.4. Covalent Immobilization of Heparin via Generation of Aldehyde Groups

Oxidation of heparin can be used to generate aldehyde groups (e.g., using sodium periodate).[52] The aldehyde groups can then be used to couple heparin to other macromolecules via reductive amination.[19] Liu *et al.*[53] modified hyaluronic acid (HA) to contain amine groups (using periodate and then added amine groups using ethylenediamine in the presence of cyanoborohydride) and then reacted this with heparin-aldehyde via reductive amination. They demonstrated controlled release of bFGF from HA scaffolds via enzymatic degradation of the HA and biological activity of the released bFGF (cell proliferation).

4.420.2.5. Covalent Immobilization of Heparin via Methacrylate Groups

Addition of unsaturated bonds (e.g., polymerized acrylate groups) can also be used to add unique reactive functionality to heparin for incorporation into biomaterial scaffolds. Benoit *et al.* synthesized heparin methacrylate[54] and cross-linked it into PEG dimethacrylate (DMA) hydrogels by photopolymerization. The heparin was used to deliver bFGF, which was found to increase human mesenchymal stem cell (MSC) proliferation and also to sequester proteins for cell adhesion.[55] These gels were also tested in combination with RGD peptides (attached via PEG acrylate) and the greatest differentiation was observed on gels containing both RGD and heparin.[56] Heparin methacrylate has also been photopolymerized with pluronic diacrylate to form hydrogels for bFGF delivery and stimulated neovascularization in a subcutaneous rat implant model.[57] This approach shows a great deal of potential for incorporating heparin-binding growth factors into PEG hydrogels for a broad variety of tissue engineering applications.

4.420.2.6. Covalent Immobilization of Heparin via Thiol Groups

The addition of thiol groups can also be used to give an additional reactive functionality to heparin, which reacts with many existing polymer end groups (e.g., acrylates, vinyl sulfones). The Prestwich lab developed a method for thiolation of glycosaminoglycans (GAGs), such as HA and heparin,[58] by reacting them with EDC and dithiothreitol (DTT). They reacted the thiolated GAGs (HA and heparin) with PEG diacrylate via Michael-type addition to generate PEG–HA–heparin hydrogels.[59] The release of growth factor from these gels was dependent on hyaluronidase for gels containing HA (as part of the GAG component) and bFGF release was sustained for at least 28 days *in vitro*. Delivery of bFGF from these scaffolds was also found to promote neovascularization *in vivo* in a mouse subcutaneous implant model.

Tae *et al.*[60] adapted this approach for use with PEG diacrylate hydrogels in the absence of HA and demonstrated that fibroblasts could be encapsulated within these gels. This approach can also be used for delivery of human growth hormone (hGH) from hydrogels formed from thiolated heparin and PEG diacrylate by Michael-type addition, rather than by photopolymerization.[61] Delivery of osteoprotegerin, a proangiogenic factor from the tumor necrosis factor (TNF) superfamily, from these hydrogels was shown to promote increased vascularization in a subcutaneous mouse implant model.[62] This thiolation method also shows great potential for a broad variety of applications and the thiol chemistry is somewhat more selective because of the relatively low incidence (1–4% frequency) of thiols (cysteines) in protein sequences.[63]

4.420.2.7. Covalent Immobilization of Heparin via Maleimide Groups

Addition of maleimide groups provides another unique functionality to react with polymer end groups and allows conjugation of heparin to biomaterial scaffolds. Heparin-containing PEG hydrogels were made by reacting PEG-tetrathiol with low molecular weight heparin-maleimide. The PEG–heparin conjugates were then reacted with PEG-tetraHIP (heparin-interacting peptide)[64] and these gels were shown to sequester bFGF. This approach can also be modified to react PEG-dithiol with high molecular weight heparin-maleimide and controlled bFGF can be obtained from these gels as well.[65] This approach can be modified to work well with the thiol-based approaches discussed in the previous section.

4.420.2.8. Covalent Immobilization of Heparin Via Hydrazide Groups

Another method for modification of heparin by several groups is the addition of hydrazide groups. The carboxylic acid groups on heparin can be modified to hydrazide groups for covalent attachment to polymers using a method developed by Bulpitt and Aeschlimann.[66] Tae *et al.* used this method to react hydrazide-modified heparin with NHS ester of PEG–bis-butanoic acid (SBA-PEG-SBA) to form hydrogels. They demonstrated sustained VEGF release *in vitro* and increased angiogenesis *in vivo* in a subcutaneous mouse implant model.[67]

4.420.2.9. Covalent Immobilization of Heparin as a Gelation Agent

Others have used the ability of heparin to bind basic peptides and polymer to design materials that self assemble when mixed with heparin. Seal and Panitch demonstrated the ability to form self-assembling PEG hydrogels, by coupling heparin-binding peptides to each arm of PEG tetravinyl sulfone and mixing the PEG with heparin.[68] Zhang *et al.* built upon this approach and used a four-arm PEG modified with either heparin-binding peptides from PF4 or low molecular weight heparin (as described in **Section 4.420.2.7**)[64] to form gels that assemble noncovalently and can deliver bFGF.[69] Rajangam *et al.*[70] used a similar approach to generate self-assembling materials from basic peptide amphiphiles and heparin. They were able to show controlled bFGF release *in vitro* and increase angiogenesis with bFGF delivery *in vivo* in a rat corneal implant model. Some caution must be used with this approach, as the hydrogels formed using this method are generally weak mechanically, but may be useful for applications that require materials to gel after injection in the absence of any cross-linking agent. For further information on growth factor and protein modified surfaces and interfaces, refer to **Chapter 4.416, Growth Factors and Protein-Modified Surfaces and Interfaces**. Additional work involving self-assembling biomaterials is covered in **Chapter 2.205, Self-Assembling Biomaterials**.

4.420.3. Use of Heparin Mimetic Molecules for Delivery of Heparin-Binding Growth Factors

Because of the heterogeneity of heparin, it may be desirable to develop a synthetic analog that can bind to heparin-binding growth factors, but over which there is more selective synthetic control. Toward this goal, Maynard *et al.*[71] used sulfated amino acids and combinatorial chemistry to identify artificial peptide sequences that function as heparin mimetics and are capable of heparin-binding growth factor sequestration. They found a tetrapeptide sequence of sulfated amino acids that can bind to VEGF with micromolar affinity. This approach can be extended for nanopatterning applications using e-beam lithography to provide patterns of heparin-binding growth factors on a surface.[72] This approach holds great potential for developing sequences that are selective for an individual growth factor and that could potentially be resistant to degradation by heparinases.

4.420.4. Summary

In summary, heparin conjugates can be attached to biomaterial scaffolds using the various methods described and have been found to deliver biologically active growth factors in a controlled manner in a number of *in vitro* and *in vivo* models. Thus far, most groups using this approach have delivered model heparin-binding growth factors, such as bFGF and VEGF, often in subcutaneous implant angiogenesis models. However, more recent studies have demonstrated that this approach can be useful in bone, peripheral nerve, spinal

cord, and flexor tendon regeneration models. Because of the large number and wide variety of growth factors that bind to heparin, delivery systems developed using heparin sequestration of growth factors hold great potential for use in many different tissue regeneration applications (Figure 1).

Glossary

Amphiphile Molecule containing a polar hydrophilic group chemically connected to nonpolar hydrophobic group.
Bioavailability The amount of drug or bioactive substance actually absorbed from a given systemic dose.
Critical micelle concentration (CMC) A phase change characterized by the minimum concentration of amphiphilic (surfactant) molecule required to spontaneously aggregate into micelles in solution.
Gel A semisolid matrix incorporating much more swelling solvent than solute, resulting in a material with mechanical properties between liquids and viscous solids.
Gelator A low-molecular-weight or polymeric molecule that induces gel formation in both polar and nonpolar solvents.
Hydrogel A gel formed by solutes in aqueous solution.
Lipid An amphiphilic molecule or surfactant comprising a polar hydrophilic headgroup and one or more nonpolar hydrophobic chains.
Micelle An aggregate of amphiphilic molecules in water with nonpolar parts in the interior and the polar parts forming a corona exposed to water.
Organogel A gel formed by solutes in an organic solvent.
Prodrug A therapeutic agent precursor intrinsically inactive pharmacologically, but capable of being transformed into one or more active metabolites *in vivo* that exhibit therapeutic efficacy.
Surfactant A surface-active molecule, synonymous with an amphiphilic molecule.

Abbreviations

^{1}H-NMR	Proton nuclear magnetic resonance
3D-networks	Three-dimensional networks

USD	United States dollar
UV	Ultraviolet
VRE	Vancomycin-resistant enteroccoci
XRD	X-ray diffraction

4.421.1. Introduction

4.421.1.1. Molecular Versus Polymeric Gelators: Perspectives in Hydrogels

4.421.1.1.1. An introduction to hydrogels

The term 'gel' applies to states of matter between liquids and solids (more viscous than liquids and more elastic than solids): a 'hydrogel' is formed through gelation of a solute in an aqueous solution, while an 'organogel' gelates solutes in an organic solvent. In general, the term 'gelator' depicts a molecule (either polymer or low-molecular-weight molecule) that forms three-dimensional (3D) networks in a given solvent, either through covalent cross-linking or noncovalent intermolecular interactions, resulting in the formation of a gel phase where typically the amount of imbibed solvent exceeds the solid dry mass of the gelator network by up to several hundred percent. Hydrogels consist of elastic networks with interstitial spaces that contain as much as 90–99% (w/w) water.[1,2] Most gels are formed from fibrous nanostructures that entangle or are chemically cross-linked into 3D networks, providing a semiwet environment for molecular-level biological interactions.[3–5] Gels find wide range of applications in cosmetics, drug delivery, sensors, biotechnology separations, wound closure materials, contact lenses, and food processing, to name a few, representing a major part of USD $80 billion drug delivery, contact lens, and wound closure market.

4.421.1.1.2. Polymeric hydrogels

Polymeric hydrogels exhibit the ability to swell in water or various aqueous solutions by forming an enlarged gel phase that, in the case of cross-linked systems, cannot dissolve, regardless of the solvent.[6] There are many different types of hydrogels classified according to their physicochemical properties and their preparation methods.[7] Hydrogels can be generated using either natural polymers (proteins, polysaccharides, and deoxyribonucleotides) or synthetic polymers (from appropriate synthetic monomers). In general, natural polymer-based hydrogels have superior biocompatibility; however, synthetic polymers are well known for inclusion of desired functionality. Thus, logically, a third category could be hybrid hydrogels, generated from the combination of natural polymers (i.e., for desired biocompatibility) and synthetic polymers (i.e., for specific functionality).[8,9]

Primarily, strong interactions between polymeric chains lead to formation of 3D networks that induce gelation. If these networks of chains are connected (i.e., cross-linked) through strong covalent bonds, they are called chemical gels, whereas those connected through noncovalent interpolymeric chain interactions (i.e., physical polymer chain entanglements and self-assembled gels via formation of disordered 3D networks) are called physical gels.[5] With their high water content and ease of modulation of physical and chemical properties through subtle changes in monomer structure and polymer molecular weight, polymeric hydrogels can be both biocompatible and user-friendly.[2,10–14] Biodegradable and biocompatible hydrogels have been designed both based on natural polymers that are susceptible to enzyme degradation and using synthetic polymers that consist of hydrolyzable moieties.[15] For instance, hydrogels using the natural polymer, chitosan, have received a great deal of attention because of their well-documented biocompatibility, low toxicity, and degradability by human enzymes.[16–18] Custom-made hydrogels could be prepared according to need. Bioadhesive properties could be obtained by promoting interchain bridges between the hydrogel polymer's functional groups and mucus glycoproteins.[19,20] Polymers including polyethylene glycol (PEG), polyvinyl alcohol (PVA), poly(2-hydroxyethyl methacrylate) (PHEMA), and polyacrylic acid (PAA) are used in the preparation of hydrogels that have mucoadhesive and bioadhesive properties to enhance drug residence time and tissue permeability.[19,21] Polyvinylpyrrolidone

(PVP) is popular in ophthalmic, drug tablet, and wound healing applications.

4.421.1.1.3. Molecular hydrogels

In addition to conventional polymer gels, low-molecular-weight organogels and hydrogels have been developed that self-assemble into polymer-like fibers, forming the so-called 'self-assembled,' 'supramolecular,' 'low-molecular-weight,' or 'molecular' gels.[22–36] In particular, small molecule hydrogels are promising because of both their compatibility with rational design using nanostructures, and their spontaneous gelation and rapid degradation. Thus, biodegradation of molecular hydrogels might have certain advantages compared to traditional polymeric hydrogels. Importantly, the pool of diverse functional groups benefits the design and synthesis of custom-made molecular gelators according to need. Typically, gelation is a delicate balance between solubility and aggregation; thus, gels are formed by dissolving minute amounts of gelator (~0.1–10%, w/v) in hot solution, while cooling below the gel melting temperature (T_{gel}), the gelator self-assembles into 3D networks that immobilize the complete volume of solvent, supporting their own weight without collapsing the gel structure. A schematic representation of the typical gelation process is illustrated in Figure 1.

The inherent morphology of hydrogels can be characterized using various microscopy techniques, such as polarized optical microscopy (POM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). The stability of a gel can be delineated by analyzing both thermal properties (often with differential scanning calorimetry, DSC),[37–40] and physical state.[37–39,41] In addition, gels can be characterized through various spectroscopic techniques, such as nuclear magnetic resonance (NMR),[38,42,43] ultraviolet (UV),[43,44] circular dichroism (CD),[40,42,45] and fluorescence spectroscopy.[40,45] In addition, the mechanical properties of gels can be investigated through a series of rheology experiments.[46–51] A range of amphiphiles with great structural diversity could be tailored to form nanofibrous 3D networks in aqueous solution, which typically initiates the gelation in water (i.e., hydrogelation). Hydrogelation is readily visually observed as a macroscopic change and acts as a quick and simple test for the formation of a nanofibrous network. Given that such a simple process is required for testing gelation, a large group of molecules (i.e., both low- and high-molecular-weight candidates) could be tested for formation of molecular nanofibers and hydrogels in a relatively short time period.

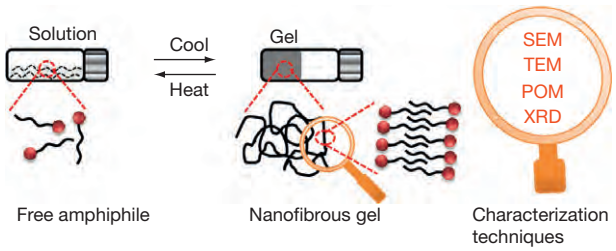

Figure 1 Schematic representation of gelation of solvent through self-assembly of amphiphilic molecules. The majority of self-assembled gels are thermoreversible.

4.421.2. Challenges and Opportunities of Hydrogels in Drug Delivery

4.421.2.1. Delivery of Hydrophobic Drugs

The field of hydrogel-based drug delivery has expanded over the past few decades to significantly improve the bioavailability of water-insoluble drugs, which otherwise exhibit attractive therapeutic potential.[52] Drug discovery efforts within the pharmaceutical industry currently provide a large number of active candidate compounds that could serve as therapeutic agents, yet new drug approval rates have been low (i.e., single-digit) for the better part of the past decade. Most new, potent therapeutic candidates are poorly soluble in aqueous media, limiting possibilities for their formulation and dosing via oral or parenteral administration.[53] In order to overcome this limitation, novel drug delivery systems such as hydrogels, micelles, vesicles, and nanoparticles are continually developed to solubilize and improve drug administration, dosing, and bioavailbility (Figure 2). In general, these nano/micron-sized carriers contain hydrophobic domains to help solubilize poorly water-soluble drugs and stabilize them in dosage forms. Upon administration, they could potentially improve drug therapeutic efficacy through reliable controlled release of the dose while reducing their toxicity profile.

4.421.2.2. Challenges and Opportunities

Although an overwhelming number of hydrogel-based drug delivery formulations and model systems are reported, the field still faces major challenges. Primarily, improvements in both the versatility of clinical usage and drug dosing and release kinetics of such systems for both hydrophobic and hydrophilic drugs remain obstacles.[54] On the front of clinical usage, several factors are at play. First, hydrogels typically have a relatively low tensile strength, making them poorly suited for load-bearing applications. In some cases, this also means that applications of hydrogel-derived medication can be washed away too easily, a problem often solved by subcutaneous injection to form depots.[54] Secondly, although hydrogels are deformable, a property that allows them to conform to the location of their application, they are often not viscous enough so as to allow for simple injection. As a result, methods of *in situ* generated hydrogels have been explored as a possible solution using several strategies. However, photocurable *in situ* gels introduce problems of potential toxicity from methods such as ultraviolet (UV) irradiation or the use of cross-linkers.[54] On the front of release kinetics, hydrogels often produce rapid release of their drug payload because of their large pore size and high water content.[55] Clinical control over dose dumping of hydrophilic drugs or insufficient release of hydrophobic drugs is a problem (see Chapter 4.422, pH-Responsive Polymers for the Intracellular Delivery of Biomolecular Drugs; and Chapter 4.426, Electrospun Fibers for Drug Delivery).

Rewards for overcoming significant challenges in use of hydrogels in drug delivery are substantial. Hydrogel uses with stem cells[56] and developing micro- and nanohydrogels to facilitate faster response[57] are emerging areas. Innovation and creative technical ingenuity are improving capabilities of hydrogels in drug delivery to address some of its most difficult challenges and provide new capabilities.

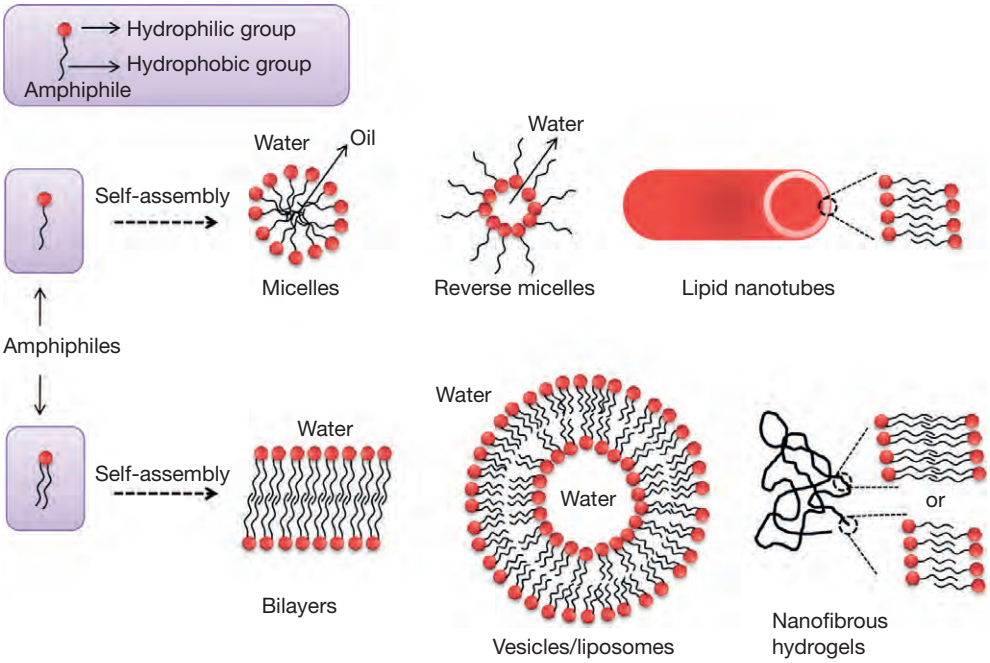

Figure 2 Various self-assembled nanomaterials potentially useful to deliver either lipophobic or lipophilic drugs. Amphiphiles have two distinct regions (hydrophobic/hydrophilic) in their structure, which drives them to self-associate in a given solvent (lyotropic assembly). In general, on the basis of the hydrophilic/hydrophobic ratio, most amphiphiles undergo self-assembly to generate various nanostructures such as micelles, nanofibers, and vesicles.

4.421.3. Self-Assembled Prodrugs

4.421.3.1. Motivation to Design Self-Assembling Prodrugs as Biomedical Gelators

To date, the majority of drug delivery systems load drugs through encapsulation, with inherent limitations such as low drug loading capacity, drug leakage during encapsulation, and inefficient preservation.[58] Another routinely encountered hurdle is the degradation of carriers under *in vivo* conditions before reaching the targeted site. Thus, designing amphiphilic prodrugs to undergo self-assembly to form hierarchical gel nanostructures would eliminate the use of an external gel carrier. It is well established that surfactant-like amphiphiles self-assemble into ordered lyotropic nanomaterial phases, including micelles, vesicles, liquid crystals, hexacosomes, cubosomes, fibers, helices, and nanotubes (Figure 2). Hence, converting known or desired drugs into surfactant-like prodrug structures using synthesis would enable the generation of self-gelling drugs. Such drugs could exhibit diverse formulations and controlled release under either chemical hydrolytic control or phase disassembly control and overcome issues with administration of gels. Herein, we discuss a few key examples of the design and synthesis of self-assembled prodrugs from our and others' research efforts.

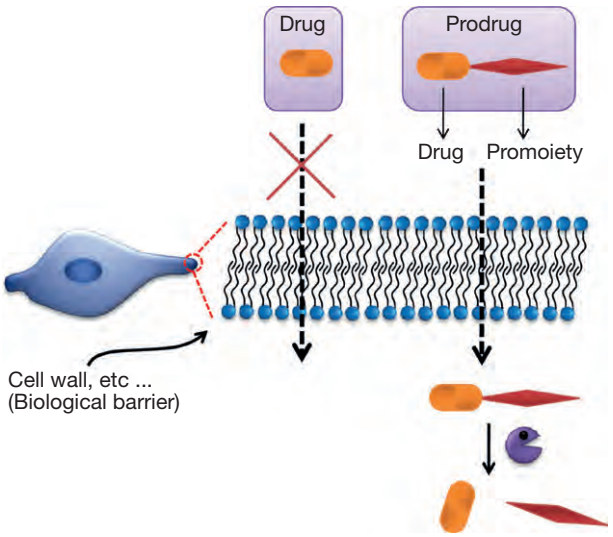

Figure 3 A prodrug is a conjugate of a known drug and a promoiety. In general, a prodrug is an inactive form of the drug; however, its chemistry helps to overcome certain inherent hurdles of the parent therepeutic agent, and could significantly contribute to optimal pharmacokinetics. For instance, a prodrug may facilitate crossing of biological barriers, enhancing distribution in either blood or tissue which otherwise might not be possible with the parent drug.

4.421.3.2. Structure-Based Self-Assembled Prodrugs

Prodrugs are therapeutic agent precursors that may be intrinsically largely inactive, but are transformed within the host into one or more active metabolites *in vivo* that exhibit therapeutic efficacy (Figure 3). The term 'prodrug' was introduced by Albert in 1958[59] to describe molecules that undergo biotransformation prior to exhibiting their pharmacological effects. This transformation usually refers to a chemical change in the prodrug, usually with chemical removal of a specific prodrug component, to yield the active drug form. This can be enzymatically triggered or simply a general hydrolytic event. The use of prodrugs is now the most welcomed strategy for improving the physicochemical and pharmacokinetic

properties of pharmacologically active compounds, increasing the utility of a prospective drug.[60–65] Prodrugs can be categorized on the basis of chemical classes and/or mechanism of activation. Carrier-linked prodrugs, macromolecular prodrugs, labile esters, phosphorylated prodrugs, and antibody–drug conjugates are all examples of chemical classes. In general, most prodrugs are chemical derivatives, synthesized through chemical group transformation, which subsequently require a one- or two-step enzyme-mediated or chemical transformation to produce the potent parent drug. Often, the prodrug approach seems to surmount several hurdles, such as chemical instability, poor water solubility, rapid presystemic metabolism, inadequate absorption, and toxicity.[66] Interestingly, approximately 15% of all new drugs approved in 2001 and 2002 were prodrugs,[62,63] a number expected to increase in the future.

Despite the growth of prodrugs, several inherent problems still exist. For example, once released from an injection site, prodrugs are usually converted into their active drug form rapidly, thus limiting the potential of prodrugs to exhibit extended release. To overcome these challenges, 'self-assembled prodrugs' were designed to achieve (i) maximum drug loading efficiency, and (ii) controlled, prolonged release kinetics (Figure 4). To expand further, avoiding use of an external carrier by turning prodrugs into their own self-deliverable carriers would increase the deliverable dosage fraction of parent drugs per formulation. In addition, the self-assembled (nanovehicular, networked) form of prodrug amphiphiles may undergo much slower degradation (either enzyme- or hydrolysis-mediated) compared to the free (unassembled) molecular prodrug form, enhancing controlled delivery for longer periods of time (sustained/controlled drug delivery).

Self-assembly is an integral part of biological form and function, playing pivotal roles in integrated cellular functions.[67] Intermolecular interactions such as hydrogen bonding, van der Waals interactions, π–π stacking, and strong ionic interactions govern supramolecular chemistry in biology and materials sciences.[68] Prodrug chemistry can be custom tailored to produce drug amphiphiles that assemble into aggregates and become bioactive at different rates.

4.421.3.3. General Strategy to Design Self-Assembled Prodrugs

Despite explosive growth in the development of diverse low-molecular-weight hydrogels, their dependability in drug delivery must address the unknown toxicity of *in situ*-generated metabolites and fragments produced from degradation of the host amphiphilic gelator. Often, the metabolic pathway of those fragments is a 'black box,' and considered one of the major hurdles in low-molecular-weight hydrogel-based drug delivery. This uncertainty can be diminished to some extent by designing amphiphilic prodrugs from clinically approved drugs; thus, the degradation products from the prodrug will be a known drug and a promoiety that could be potentially less toxic. Thus, we have developed a general design approach, that is, selecting the known, clinically approved drugs whose

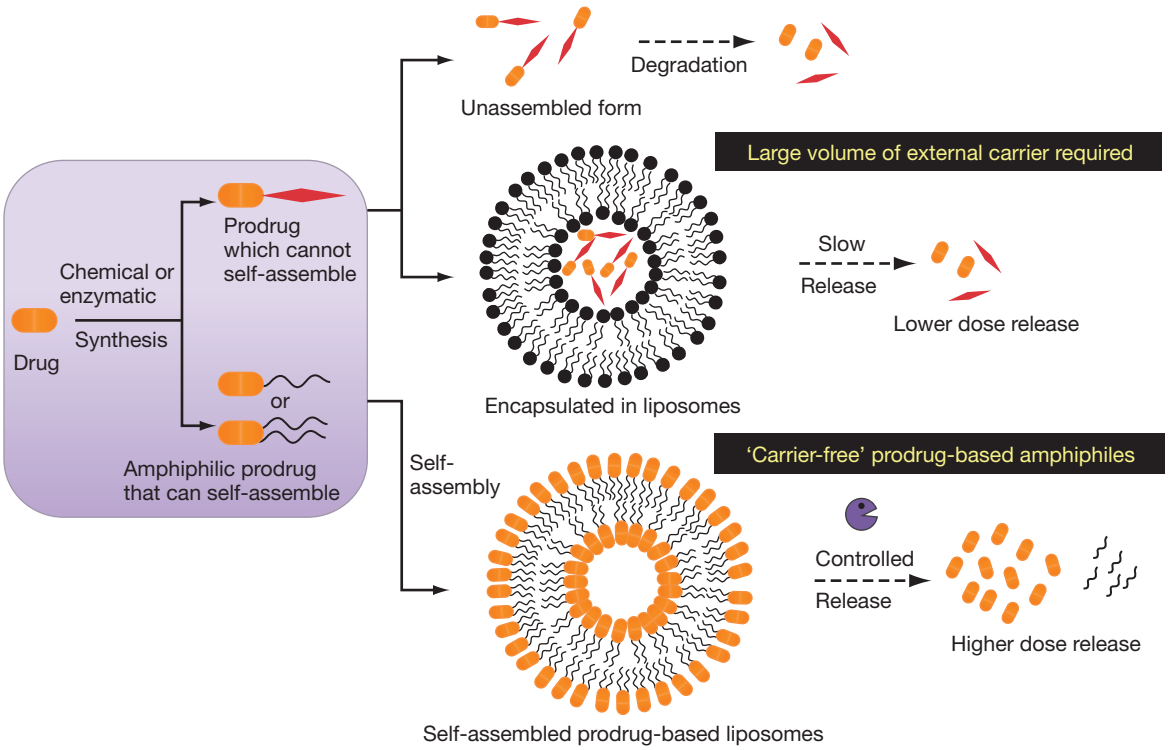

Figure 4 Self-assembled prodrug-based delivery concept. This scheme demonstrates the advantage of self-assembled prodrug-based carriers over traditional encapsulation of drug within an external carrier. In Path 1, either unmodified drug or prodrug that does not self-assemble is encapsulated in an external carrier. However, this approach suffers with low encapsulation ability of additional drugs. Path 2 depicts the superior nature of self-assembled prodrug-based drug delivery. Advantages of this approach are (i) manifold increase in drug loading efficiency, (ii) nonrequirement of external carrier, and (iii) versatile opportunities for controlled release.

metabolic pathways are well documented, followed by attaching a biocompatible promoiety through covalent modification (Figure 5). Consequently, such prodrug amphiphiles could be capable of undergoing self-assembly in aqueous solutions and in a variety of other solvents, and remain susceptible to enzymatic and hydrolytic degradation to produce their active forms. Importantly, self-assembly in water could exploit formation of stable hydrophobic domains, which could be further used to encapsulate other hydrophobic therapeutics. Thus, this approach could enable multiple drugs to be delivered simultaneously (Figure 5) as new combination therapies.

In designing chemical derivatives of known drugs to produce amphiphilic prodrugs, several key factors must be carefully examined, including (i) availability of appropriate functional groups in parent drugs amenable to routine functional-group transformation reactions under mild conditions; (ii) promoiety that ideally should not promote adverse effects, and facilitate stable and reliable prodrug self-assembly in physiological conditions; (iii) linker functional group that should release the parent drug under either enzyme-mediated or hydrolytic degradation; and (iv) degradation by-products that should not generate ancillary bioactivity or toxicity.

4.421.3.3.1. Acetaminophen-based self-assembled prodrugs

To demonstrate this concept keeping the above parameters as a guideline, we have designed and synthesized a series of amphiphilic prodrugs from the clinically approved drug, acetaminophen, *N*-(4-hydroxyphenyl)acetamide, popularly known as paracetamol (Figure 6).[69] Acetaminophen is a common analgesic and antipyretic drug used for the relief of fever and headache. Esters are the most common prodrugs used, and it is estimated that 49% of all marketed prodrugs are activated by enzymatic hydrolysis.[61] Thus, a series of amphiphiles and bolaamphiphiles (**Apn-Prodrugs**) have been synthesized from acetaminophen by appending a biocompatible fatty acid covalently attached through an ester bond susceptible to both esterase-mediated and possible hydrolytic degradation to produce the parent drug (Figure 6). Without an enzyme present, those gels exhibited hydrolytic stability over months.

The amphiphilic acetaminophen prodrugs underwent self-assembly in water to form hydrogels, with minimum gelation concentrations (MGCs) between 0.4 and 1.5% (w/v), and unprecedented thermal and temporal stabilities. As anticipated, acetaminophen prodrug-based amphiphiles formed branched or fibrous/sheet-like networks at the microscopic level, as seen through SEM and TEM (Figure 6). The average thickness of the fibers was in the range of 50–400 nm, with lengths on the order of several microns. Intriguingly, investigation of these hydrogels by X-ray diffraction (XRD) measurements, *ab initio* calculations, and Fourier transform infrared (FT-IR) experiments revealed that lamellar structures were formed by self-assembly of amphiphilic prodrugs (Figure 7). Subsequently, the possibility of single and multiple drug delivery using self-assembled prodrugs has been investigated. The well-studied potential chemotherapeutic drug, curcumin,[70–74] has been utilized as a model hydrophobic drug to encapsulate within self-assembled nanofibers formed by **Apn-Prodrug** amphiphiles. Hydrogels of Apn-Prodrug were found to encapsulate up to 0.5 mM concentration of curcumin, possibly because of efficient localization of hydrophobic curcumin within the hydrophobic nanofibrous prodrug 3D network. Subjected to lipase (an esterase) at 37 °C in phosphate buffer saline (PBS), degradation of the curcumin-encapsulating hydrogel was triggered, and after 48 h the hydrogel was completely degraded to release the parent drug acetaminophen and the encapsulated curcumin (followed using absorbance spectra). On the contrary, in the absence of enzyme, the **Apn-Prodrug** hydrogels showed excellent hydrolytic stability in PBS over the course of a few months. This stability could be due to the presence of tightly self-associated prodrugs, protecting ester bonds in hydrophobic segments and reducing the

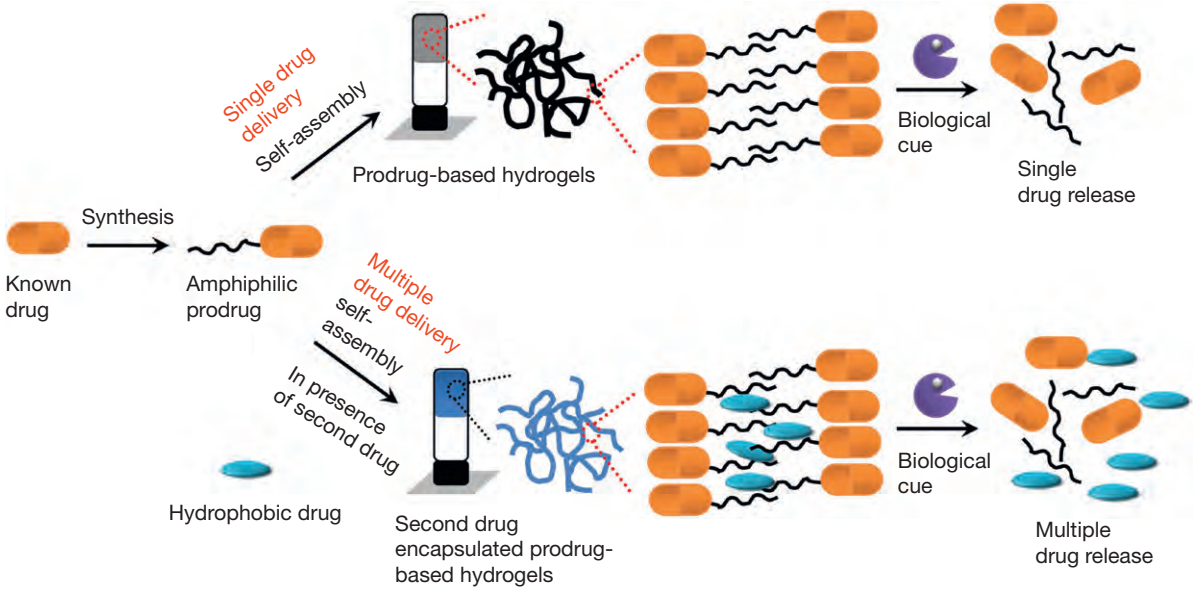

Figure 5 Cartoon presentation of general approach for the synthesis of amphiphilic prodrugs that could self-assemble to form hydrogels. Synthesis and self-assembly of amphiphilic prodrugs, encapsulation of a hydrophobic drug, and triggred multiple drug-delivery are illustrated.

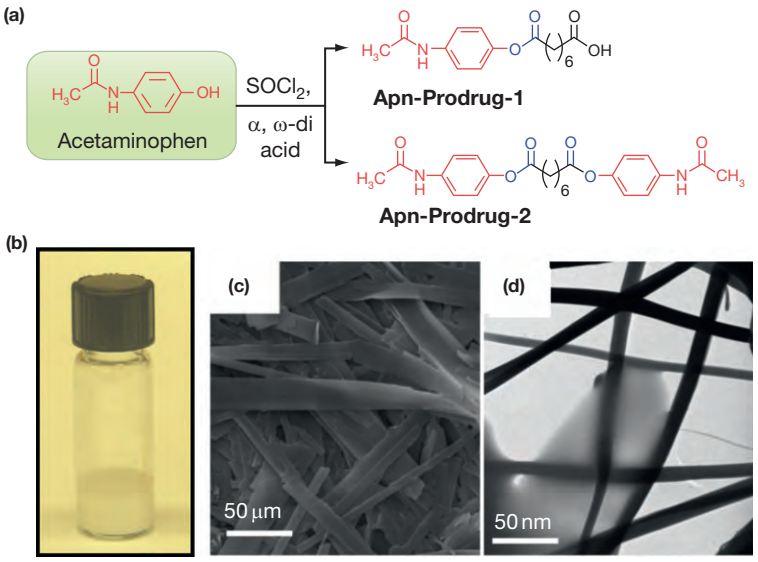

Figure 6 (a) Synthesis of **Apn-Prodrugs** by attaching a fatty acid through an ester link. (b) Image of hydrogel of **Apn-Prodrug-1**, and characterization of the gel through (c) scanning electron microscopy and (d) transmission electron microscopy. Electron microscopy images clearly show the presence of self-assembled fibers.

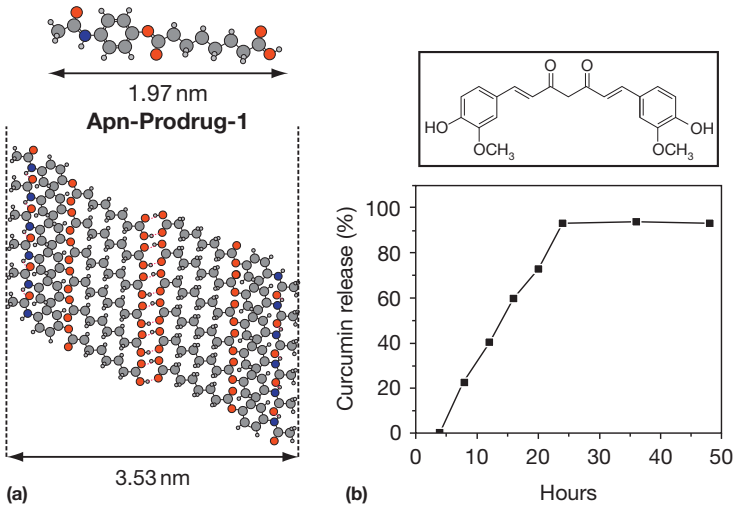

Figure 7 (a) Schematic representation of molecular packing of **Apn-Prodrug-1** into a prodrug hydrogel. (b) Top: curcumin structure; bottom: absorbance maxima of curcumin that was released from hydrogel of **Apn-Prodrug-1** by lipase-mediated gel degradation. Reproduced from Vemula, P. K.; Cruikshank, G. A.; *et al*. *Biomaterials* **2009**, *30*(3), 383–393. Copyright 2009, Elsevier.

accessibility of water molecules compared to the dissolved molecular form. A distinction of the self-assembled prodrug approach is attenuation of the burst release of drug (Figure 7 (b)), a major hurdle in hydrogel-based release of hydrophobic drugs. Another interesting observation was that although the sustained release of the drug occurred over a period of 2 days, the enzyme concentration ($100\,U\,ml^{-1}$) in those experiments was significantly higher than physiological concentrations of esterases (e.g., cholesterol esterase, $7\,U\,ml^{-1}$).[75] Thus, the anticipated release under *in vivo* conditions may provide sustained release for several days, if not months. However, the presence of multiple enzymes, serum, and plasma – the complex biological environment that alters the kinetics of gel degradation *in vivo* – has not been addressed.

4.421.3.3.2. Amygdalin-based self-assembled prodrugs

Amygdalin, an anticancer agent, belongs to cyanogenic glycoside family.[76,77] D-Amygdalin, [*O*-β-glucopyranosyl-(1→6)-β-D-glucopyranosyloxy]benzeneacetonitrile (Figure 8), is a by-product of the processing of apricots, almonds, peaches, and cherries,[78] and its rigid sugar backbone is rich in directional hydroxyl groups. The primary hydroxyl group on amygdalin was selected as a site to generate amphiphilic prodrugs by tethering natural fatty acids with an enzyme-cleavable ester linker.[79] Interestingly, the extremely regioselective esterification ability of lipase has been utilized as a tool to synthesize amygdalin-prodrug amphiphiles (**Amy-Prodrugs**) in quantitative yields (Figure 8). **Amy-Prodrugs** underwent self-assembly to form nanofiber-rich nanoarchitectures in a wide range of

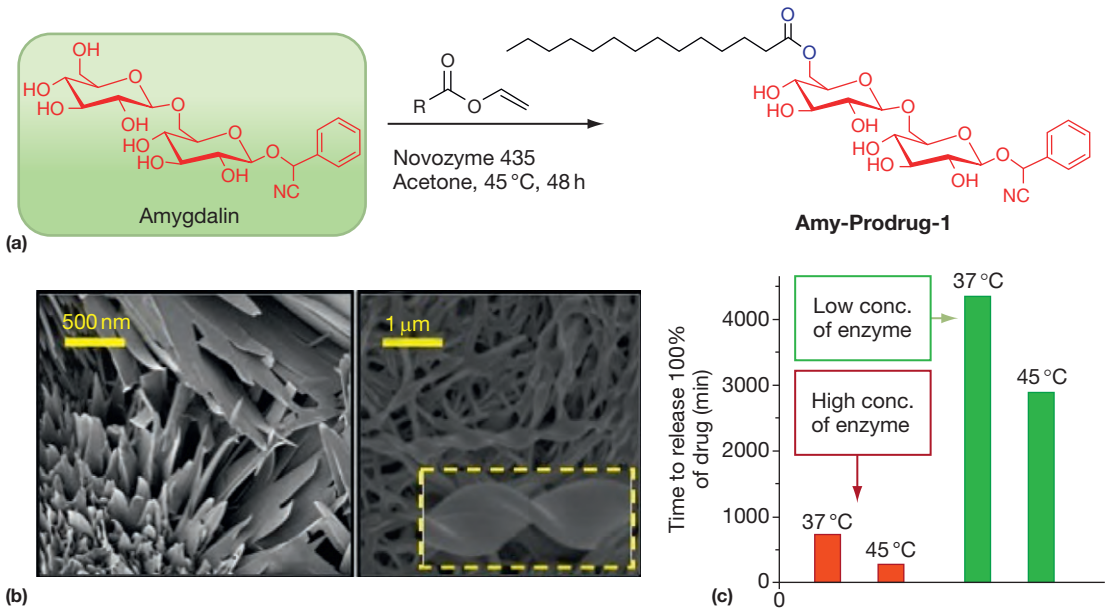

Figure 8 (a) Enzyme-mediated regioselective synthesis of amygdalin-based amphiphilic prodrug, **Amy-Prodrug-1**, which could form both hydro- and organogels at lower concentration. (b) Scanning electron microscopy images of organogel (left) and hydrogel (right), which show sheet-like and helical fibers, respectively. (c) Effect of enzyme concentration (10 and 100 U ml^{-1}) and incubation temperature on gel degradation/encapsulated drug release. By modulating either temperature or enzyme concentration, the drug release kinetics from the networks are modulated. Reproduced from Vemula, P. K.; Li, J.; *et al. J. Am. Chem. Soc.* **2006**, *128*(27), 8932–8938. Copyright 2006, American Chemical Society.

solvents including aqueous solutions, and both polar and nonpolar organic solvents at extremely low MGC values (0.05–0.2%, w/v) revealed the presence of helical fibers and sheet-like structures (Figure 8(b)). Furthermore, to evaluate the ability of **Amy-Prodrug** gels to deliver multiple drugs simultaneously, akin to acetaminophen prodrugs, curcumin has also been encapsulated within the **Amy-Prodrug**-based hydrogels. The ester-based **Amy-Prodrug** amphiphiles were susceptible to lipase, causing an esterase-mediated enzymatic degradation, and therefore, a detailed investigation was carried out to achieve controlled drug delivery. The inherent hydrophobic domains within the self-assembled fibers were utilized for enhanced encapsulation, as in this manner, hydrogels have the potential to increase the bioavailability of water-insoluble drugs. Interestingly, in the absence of esterase enzyme, **Amy-Prodrug**-based hydrogels exhibited unprecedented temporal stability, with no drug leakage occurring under physiological conditions (PBS, pH 7.4, and 37 °C). In addition, we demonstrated controlled gel degradation, allowing drug release through modulation of either enzyme concentration and/or incubation temperature (Figure 8(c)). Interestingly, **Amy-Prodrug**-based hydrogels also did not exhibit any detectable burst release profile, akin to hydrogels made from **Apn-Prodrugs**.

As discussed earlier, it is equally important to understand the by-products formed after enzyme-mediated prodrug-based hydrogel degradation. Conventional thin-layer chromatography (TLC) was performed to characterize the components formed after gel degradation; tetradecanoic acid was shown by ^{1}H NMR spectroscopy. Subsequently, further TLC analysis of the solution demonstrated the presence of amygdalin and curcumin. Taken together, the formation of amygdalin and fatty acid suggests that prodrug degradation occurred as expected at the ester bond of amygdalin prodrugs by lipase (esterase) enzyme.

4.421.3.3.3. Ibuprofen-based self-assembled prodrugs

As a widely used nonsteroidal anti-inflammatory drug (NSAID), ibuprofen is administered as an analgesic and to relieve the symptoms of fever, arthritis, and primary dysmenorrhea.[80] Kim and coworkers incorporated a dipeptide glycine–glycine backbone into (*S*)-(+)-ibuprofen and successfully transformed it into molecular prodrug-based hydrogelator ibuprofen–glycine–glycine (**Ibu-Prodrug**, Figure 9(a)) with an MGC of 0.9% (w/v; 28 mM).[81] To delineate structure–function relationships, ibuprofen was covalently connected to several dipeptides such as glycine–glycine, glycine–alanine, glycine–serine, glycine–phenylalanine, and glycine–histidine (Figure 9(a)); however, only the glycine–glycine derivative could self-assemble to form nanofibrous hydrogels (Figure 9(b)). Extensive spectroscopic studies suggested that hydrogen bonding of amide and carboxylic groups and π–π interactions were the driving forces for efficient self-assembly. This could be efficient peptide motif for gel assembly. Furthermore, on the basis of HPLC retention times, the authors concluded that the hydrolysis product of this hydrogelator was ibuprofen, after incubation with the carboxypeptidase for 24 h. This work is one example of a drug successfully modified into a hydrogelator by a simple peptide motif. The knowledge gained from modification of ibuprofen with simple structures will be insightful and instructive for the modification of more expensive or complicated therapeutic agents.

4.421.3.3.4. Paclitaxel-based self-assembled prodrugs

Paclitaxel, a well-known novel anticancer chemotherapeutic agent originally isolated from the American Pacific yew tree (*Taxus brevifolia*),[82] exhibits an important *in vivo* antitumor activity.[83] However, because of taxol's extreme hydrophobicity,

its poor water solubility ($<5 \times 10^{-6}$ M) still remains as a large hurdle for effective *in vivo* delivery. To overcome this obstacle, various delivery vehicles such as nanoparticles, colloids, and liposomes have been developed.[84–87] In addition, numerous taxol-based prodrugs have been synthesized.[88] Nicolaou *et al.* synthesized the methylpyridinium acetate derivative at the 2′ hydroxyl group of taxol (**Tax-Prodrug-1**, Figure 10),[89] which showed enhanced bioavailability of paclitaxel. Although its water solubility was high, at >20 mM, **Tax-Prodrug-1** underwent self-assembly to form colorless transparent hydrogels.[89] **Tax-Prodrug-1** was found to form several types of assemblies, including regular helices and micelles, depending on the nature of the media. TEM of the hydrogels revealed the presence of fibrillar nanostructures with helices, which exhibited varied lengths around 80 nm, but a consistent diameter of approximately 10 nm. The molecular structure of **Tax-Prodrug-1** is sufficient to promote intermolecular interactions, as it contains a defined polar headgroup, with paclitaxel serving as a hydrophobic chiral backbone, while the hydroxyl and amide groups promote hydrogen bonding.

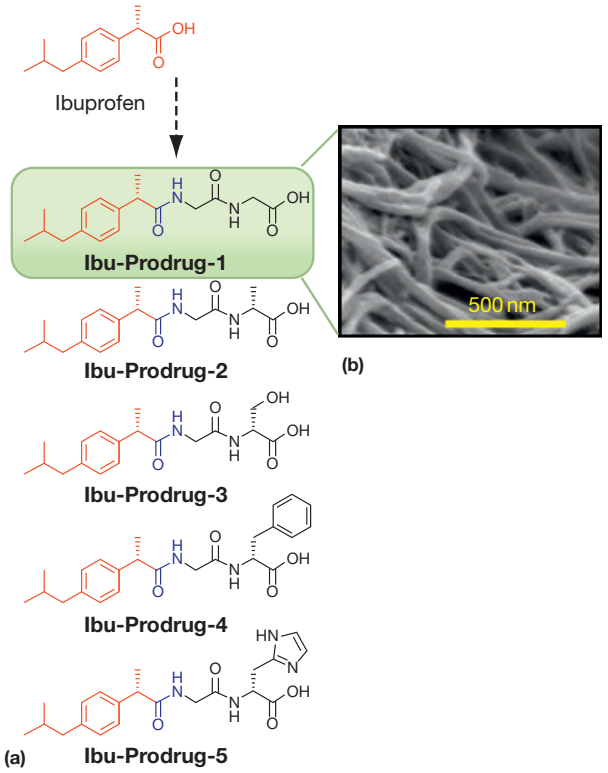

Figure 9 (a) Synthesis of ibuprofen-based self-assembled prodrugs, **Ibu-Prodrugs**. Among various dipeptide-based prodrugs, **Ibu-Prodrug-1** could self-assemble to form nanofibrous hydrogels, (b) scanning electron microscopy image. Reproduced from Bhuniya, S.; Seo, Y. J.; *et al. Tetrahedron Lett.* **2006**, *47*(40), 7153–7156. Copyright 2006, Elsevier.

4.421.3.4. Morphology-Based Self-Assembled Prodrugs

In addition to self-assembled nanofibrous hydrogels, other classes of ordered lyotropic supramolecular phases such as micelles, vesicles, hexacosomes, cubosomes, fibers, helices, and nanotubes were developed by introducing subtle structural modification into known drugs.

4.421.3.4.1. Self-assembled nanoparticles from prodrugs

Acyclovir is a nucleoside antiviral agent against herpes simplex virus (HSV) with low oral bioavailability, typically <20%, and a short circulation half-life, $t_{1/2} = 2.5$ h.[90] Jin *et al.* have synthesized a series of long-chained alkylated derivatives of acyclovir and characterized their ability to self-assemble in aqueous solutions.[91] As it is amphiphilic, the single-chain lipid derivative **Acyclovir-Prodrug-1** (Figure 11(a)) predictably self-assembled at the air–water interface. In general, bulk-phase hydrophobic interactions and hydrogen bonding lead the neutral single alkyl chain derivatives to aggregate layer-by-layer into nanoparticles, while the charged derivatives form self-assembled vesicles based on hydrophobic interactions (Figure 11(b)).[92] The self-assembly behavior of long-chain alkyl derivatives of nucleoside analogs in a given solvent media is determined by the number of alkyl chains and the resulting charged state. Self-assembled nanoparticles formed through **Acyclovir-Prodrug-1** had an average size of 83 nm, with a negatively charged surface.[91] *In vitro* and *in vivo* stability, interaction with cells, pharmacokinetics, and tissue distribution after intravenous (i.v.) administration in animals have been

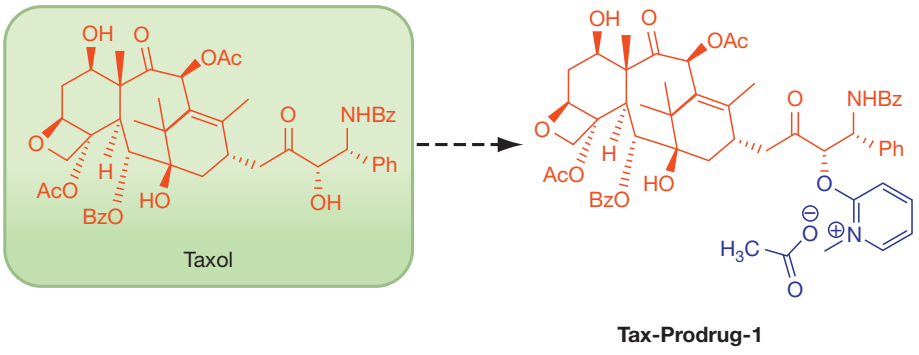

Figure 10 Methylpyridinium salt derivative of taxol (**Tax-Prodrug-1**) forms transparent hydrogels, and under physiological hydrolytic conditions, the parent potent drug, paclitaxel, could be generated. Reproduced from Nicolaou, K. C.; Guy, R. K.; *et al. Angew. Chem. Int. Ed. Engl.* **1994**, *33*(15/16), 1583–1587. Copyright 1994, Wiley-VCH.

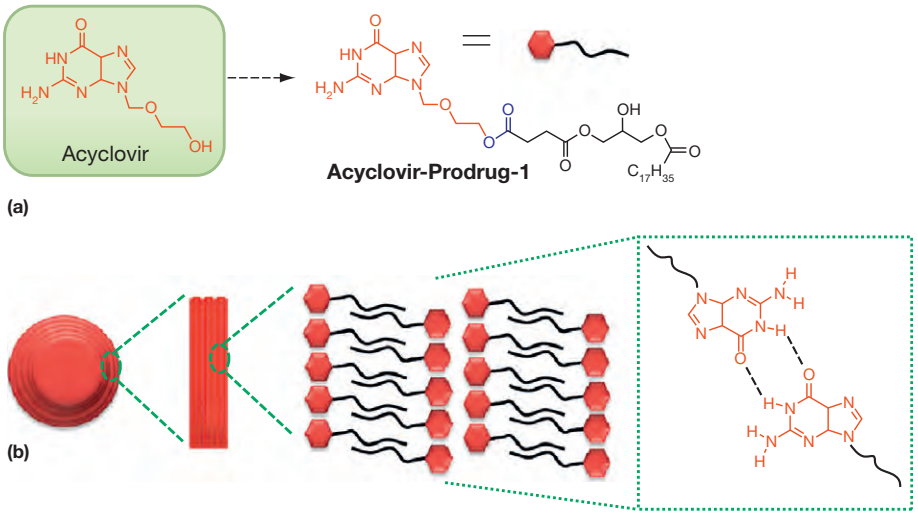

Figure 11 (a) Single-chain amphiphilic prodrugs (**Acyclovir-Prodrug-1**) were prepared from antiviral agent acyclovir. (b) Formation of self-assembled nanoparticles from **Acyclovir-Prodrug-1**. Hydrophobic interactions between lipid chains, and strong hydrogen bonding between nucleobase headgroups stabilize the self-assembled nanoparticles. Reproduced from Jin, Y.; Qiao, Y.; *et al*. *Colloids Surf. B Biointerfaces* **2005**, *42*(1), 45–51. Copyright 2005, Elsevier.

reported.[91] **Acyclovir-Prodrug-1** nanoparticles are degraded by rabbit plasma and pig liver carboxylesterase with half-lives of 25 and 4.5 h, respectively, to release the parent drug, acyclovir.

Clearly self-assembled prodrug-based nanostructures are attractive options for development, yet it is important to consider interactions between nanostructures and organisms/cells before advancing to the clinic. For instance, nanoparticles of **Acyclovir-Prodrug-1** showed slight toxicity to Vero cells with TC_{50} of 1126 μM. On the contrary, acyclovir did not show any toxicity at over 4000 μM. This 'toxicity window' was attributed to the interaction between self-assembled nanoparticles and erythrocytes, with the strong cell-membrane insertion of amphiphilic **Acyclovir-Prodrug-1** a likely primary reason for cell toxicity.

4.421.3.4.2. Self-assembled vesicles from prodrugs

Diverse nucleoside analogs are known to serve as potential anticancer[93] and antiviral[94] therapeutics. Careful inspection of the chemical structure of these agents revealed that derivatization by simple chemical functional group transformation would provide a library of amphiphilic-prodrugs. Antiviral nucleoside analogs have either purine-type (i.e., guanine in **AntiVir-Prodrug-1**, hypoxanthine in **AntiVir-Prodrug-2** and **AntiVir-Prodrug-3**) or pyrimidine-type nucleobase heads (thymine in **AntiVir-Prodrug-4** and **AntiVir-Prodrug-5**), and are conjugated to a steroid-based cholesterol through a dicarboxylic acid (Figure 12) that could promote the formation of self-assembled nanoparticles and vesicles. Jin *et al*. synthesized five cholesterol derivatives of antiviral nucleoside analogues containing representative nucleobase groups, and both their physiochemical properties and their nature of self-assembly have been reported.[95,96]

AntiVir-Prodrug-2 and **AntiVir-Prodrug-3** were synthesized from didanosine, and **AntiVir-Prodrug-4** and **AntiVir-Prodrug-5** were synthesized from zidovudine. In 1991, the FDA approved didanosine as a first-generation anti-HIV agent. Its bioavailability is in the range of 20–40% depending on the formulation used. Various lipid-derivative prodrugs were made from didanosine to improve the bioavailability for direct lymphatic delivery against HIV.[97–99] Didanosine-based vesicles were able to attain longer *in vivo* circulation with twofold enhanced drug bioavilability.[100]

Self-assembly of purine- and pyrimidine-based prodrugs in aqueous solution produced nanosized monodispersed vesicles.[95,96] Schematic representation for self-assembly of **AntiVir-Prodrugs** is illustrated in Figure 13. To initiate vesicle formation, prodrugs were dissolved in tetrahydrofuran, and then added to water, which initiated hydrophobic interactions and intermolecular hydrogen bonding, with promoiety groups and nucleobase headgroups, respectively. The **AntiViral-Prodrugs** self-assembled into bilayers in water, with the polar headgroups outside and the hydrophobic tails inside, to avoid contact with aqueous solution. Furthermore, bending in bilayers (i.e., curvature) resulted in the formation of closed vesicles.

Though self-assembled prodrug-based delivery systems have promising efficiency, there is always room for surprises. For instance, despite producing stable self-assembled nanoparticles, **AntiVir-Prodrug-2** and **AntiVir-Prodrug-3** do not demonstrate effective pharmacokinetics, metabolism, and therapeutic utility.[95] Although **AntiVir-Prodrug-2** and **AntiVir-Prodrug-3** consist of appropriate molecular structures that could promote stable self-assembly, they failed to undergo degradation in physiological media to deliver the parent drug (Figure 13). However, reasons for nondegradability of these prodrugs are unknown. These examples demonstrate that obtaining self-assembly and good stability is not sufficient if active parent drugs are difficult to release via a desired mode in targets. Thus, self-assembled prodrugs should be designed and modified carefully and extensively to accomplish all objectives of self-assembly, stability, and degradation performance.

4.421.3.4.3. Self-assembled micelles from prodrugs

Dynamic colloidal dispersions, micelles, are typically formed through self-assembly of amphiphiles or surface-active molecules

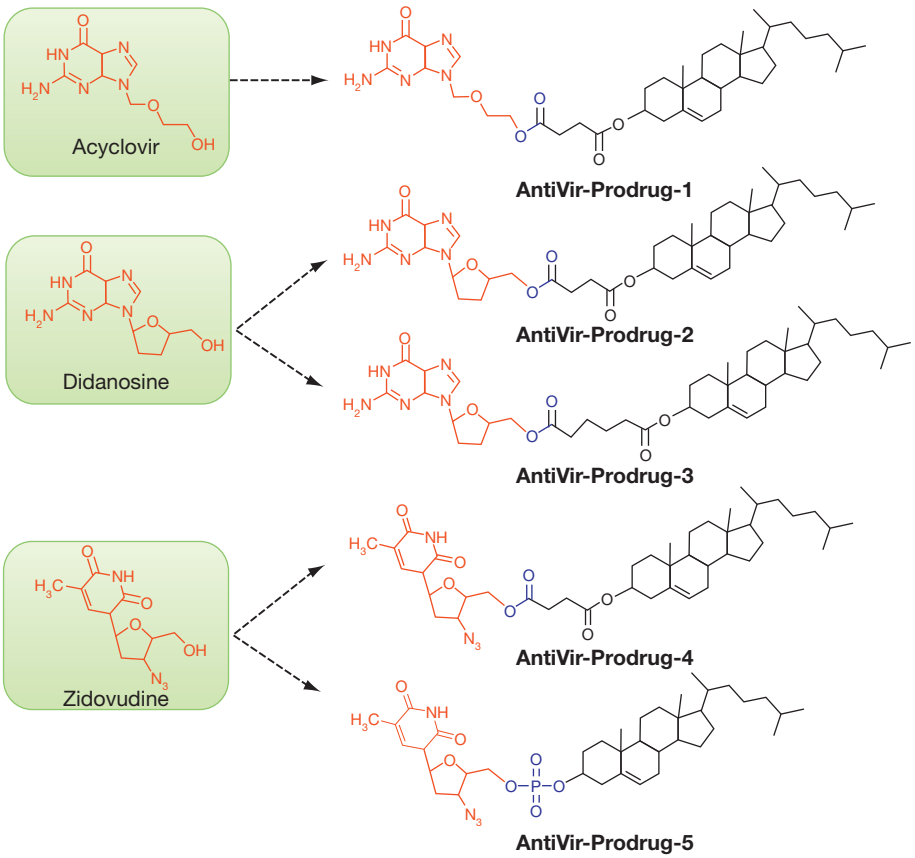

Figure 12 A series of amphiphilic prodrugs prepared from nucleobase-antiviral agents acyclovir, didanosine, and zidovudine. Steroidal cholesterol conjugation has been used to promote strong intermoelcular interactions, while headgroups provide hydrogen bonding. Adapted from Jin, Y.; Xin, R.; *et al*. *Int*. *J*. *Pharm*. **2008**, *350*(1–2), 330–337; Jin, Y.; Ai, P.; *et al*. *Int*. *J*. *Pharm*. **2009**, *368*(1–2), 207–214.

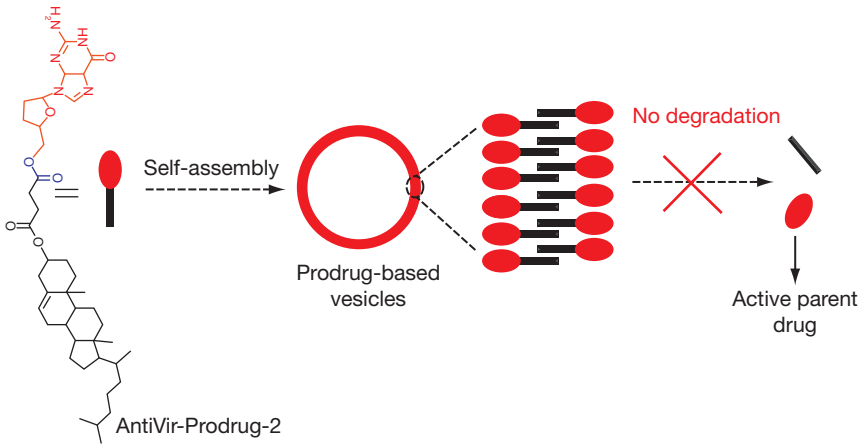

Figure 13 Schematic representation for formation of strong vesicles through self-assembly of **AntiVir-Prodrug-2**. Although efficient self-assembly and impressive stability are observed, they do not undergo degradation (either through biological or chemical cues), and thus fail to regenerate active parent drug. Thus, it is equally important to have a balance between self-assembly, stability, and dispersion characteristics versus degradation to release the parent drug. Reproduced from Jin, Y.; Ai, P.; *et al*. *Int*. *J*. *Pharm*. **2009**, *368*(1–2), 207–214. Copyright 2008, Elsevier.

(surfactants). Below the minimum association concentration, amphiphilic molecules are freely diffusing (unassociated monomers) in a given media; however, as the concentration of amphiphiles increases, self-assembly into molecular aggregates occurs – producing an equilibrium between free prodrug molecules and micelle aggregates at the critical micellar concentration (CMC); however, temperature, pH, and ionic strength influence the CMC and ability to form micelles. Hydrophobic regions of amphiphilic molecules form the core of a micelle, while hydrophilic regions form the micelle's surface/shell.[101]

CS-088, 4-[1-hydroxy-1-ethylmethyl]-2-propyl-1-[4-[2-[tetrazole-5-yl]phenyl]phenyl] methylimidazole-5-carboxylic acid monohydrate (**Figure 14**), is an angiotensin AT1 receptor antagonist known to reduce intraocular pressure (IOP) in rabbits.[102] This IOP reduction is caused by a small increase in uveoscleral outflow, with no changes in aqueous inflow or outflow facility observed when **CS-088** was topically applied to rabbits.[103,104] However, **CS-088** permeability across rabbit corneal membrane decreased at higher concentrations, prompting Kikuchi *et al.* to investigate the self-assembling properties of **CS-088** in aqueous solution.[105] Various characterization techniques such as those based on surface tension and dye encapsulation have been utilized to calculate the CMC of **CS-008**. Above 10 mg ml^{-1} concentration, **CS-088** was found to form micellar aggregates with hydrodynamic radii in the range of 1 nm. The apparent permeability coefficient (P_{app}) of **CS-088** through the corneal membrane was constant in the unassociated state; however, P_{app} significantly decreased as self-assembled structures formed. This demonstrates the importance of thorough characterization of each new self-assembled system for the intended application.

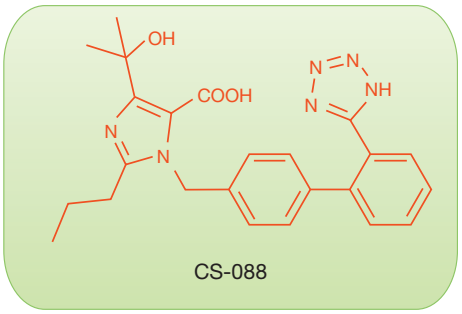

Figure 14 Molecular structure of **CS-088** which could generate micelles. Reproduced from Inoue, T.; Yokoyoma, T.; *et al. Curr. Eye Res.* **2001**, *23*(2), 139–143; Inoue, T.; Yokoyoma, T.; *et al. Curr. Eye Res.* **2001**, *23*(2), 133–138.

In addition, Boury *et al.* demonstrated that a trivial modification of the known drug amiodarone could yield micelles.[106] Amiodarone (**Figure 15(a)**) is an antianginal and antiarrhythmic therapeutic agent widely used in the treatment of heart diseases.[107–109] Amiodarone is poorly water soluble at room temperature; however, low pH produced a cationic amphiphile (**Amid-Prodrug**), with the ability to undergo self-assembly to form micellar aggregates. **Amid-Prodrug** is a nonchiral amphiphilic molecule when protonated at low pH below the pK_a of the amine (but it is reversible with increasing pH). **Amid-Prodrug** is highly lipophilic in its unprotonated form, and has a high partition coefficient (>16500) in the presence of biological membranes such as phospholipid bilayers.[110] Like any surfactant, **Amid-Prodrug** associates at air–water interfaces, with apolar moieties toward the air phase, resulting in surface film (**Figure 15(b)**) that equilibrates with bulk phase spherical micelles (as long as pH is low). In addition, they have also studied the effect of counter ions on micellar self-assembly.

4.421.4. Self-Assembled Irreversible Prodrug-Based Hydrogels

In some of the above discussed examples, selective key steps are (i) converting drug into amphiphilic prodrug by attaching an appropriate promoiety, (ii) generating self-assembled ordered nanocarriers, and subsequently (iii) *generating parent drug* back into the system through cleaving prodrug. On the contrary, we have designed another class of hydrogels: self-assembled irreversible prodrug-based hydrogels. In this approach, initially known drugs could be converted into prodrugs by attaching an appropriate promoiety, and allowing them to undergo self-assembly to form hydrogels. Interestingly, without

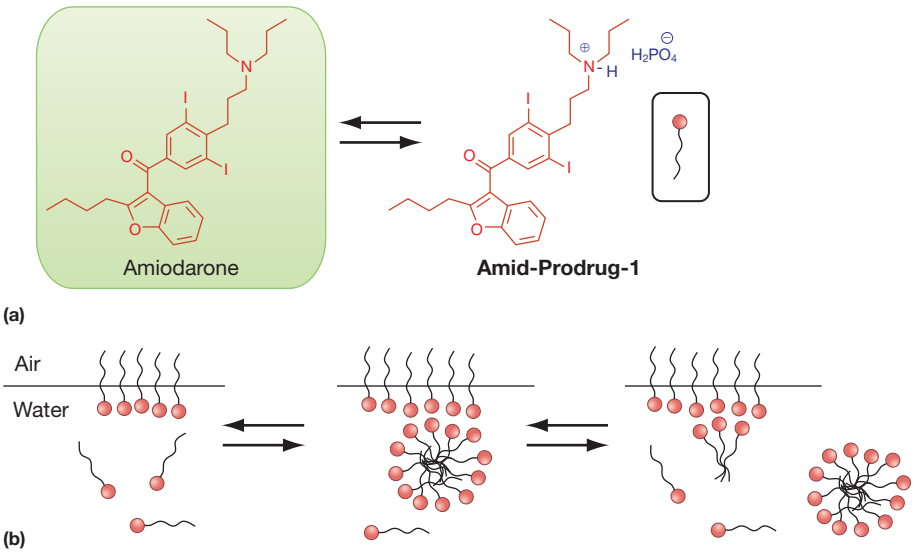

Figure 15 (a) Cationic salts of amiodarone obtain amphiphilic characteristics; thus, (b) at air–water interface **Amiod-Prodrug-1** self-associates to form monolayers at the surface, which subsequently form regular micellar structures. Reproduced from Chatelain, P.; Laruel, R. *J. Pharm. Sci.* **1985**, *74*(7), 783–784. Copyright 1985, Wiley-Liss, Inc.

regenerating the parent drug (absence of prodrug degradation), modified drugs retain their bioactivity in their self-assembled form. For eventual therapeutic use, this mandates development of this fully new molecular entity as a new drug in terms of complete safety and efficacy equivalence testing, and regulatory approval.

4.421.4.1. Paclitaxel-Based Self-Assembled Hydrogels

Recently, modification of paclitaxel with a hydrogelator motif yielded a hydrogel of a paclitaxel derivative with therapeutic bioactivity.[111] In addition, to connect paclitaxel covalently with a motif that tends to self-assemble, while allowing for enzyme cleavage, we have synthesized a drug-based precursor for gelator, **Tax-Prodrug-2** (Figure 16(a)), with enhanced aqueous solubility compared to that of paclitaxel, by attaching a phosphate derivative. Interestingly, the dephosphorylated form (**Tax-Prodrug-3**) could not undergo self-assembly to form a hydrogel directly by changing either temperature or pH, because of its extreme insolubility in water. However, unlike previous examples, an alkaline phosphatase enzyme triggers biotransformation of **Tax-Prodrug-2** into the dephosphorylated form, **Tax-Prodrug-3** *in situ*, triggering self-assembly to form a hydrogel (Figure 16(b)) that consists of nanofibers a few nanometers in width and a few microns in length.[111] A cytotoxicity test (Figure 16(c) and 16(d)) showed a conservation of bioactivity for the paclitaxel-based prodrug. Interestingly, even in its hydrogel form, **Tax-Prodrug-3** exhibited anticancer activity against HeLa cells comparable to that of unmodified paclitaxel. It is possible for fibers endocytosed and dissociated in endosomes/cytoplasm to act as a drug. This demonstrates the possibility of creating nanofibers of therapeutic molecules with a dual role as both the delivery vehicle and drug itself.[112]

4.421.4.2. Vancomycin-Based Self-Assembled Hydrogels

Vancomycin, a broad-spectrum glycopeptidic antibiotic against Gram-positive bacteria, remains one of the most important antibiotics because of its ability to inhibit methicillin-resistant *Staphylococcus aureus* (MRSA),[113] a virulent and highly contagious pathogen spreading in hospitals and communities.[114] Vancomycin has a strong tendency to form multiple hydrogen bonds with itself in aqueous solution, making it an ideal drug in which to introduce a promoiety to generate a prodrug capable of efficient self-assembly to form hydrogels. To validate this

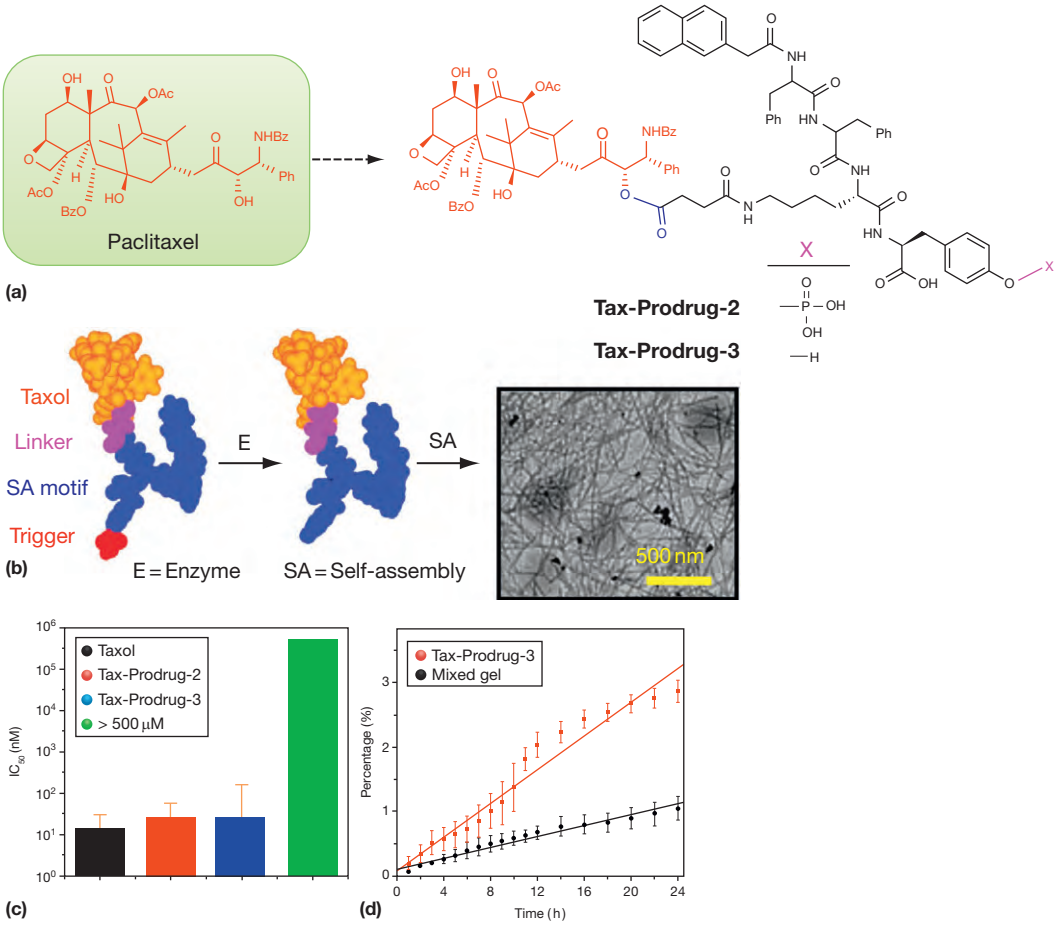

Figure 16 (a) Covalent modification of taxol by attaching peptide-promoiety, to promote self-assembly. (b) Schematic representation of enzyme-triggered hydrogelation of **Tax-Prodrug-3,** and its TEM image. (c) Cytotoxicity (*y*-axis in $\log_{10}$ scale) of taxol, **Tax-Prodrug-2**, **Tax-Prodrug-3**, and the self-assembly motif (green bar) after incubation with HeLa cells for 48 h, and (d) cumulative drug release profile of two types of paclitaxel gels in 100 mM buffer. hypothesis, Xu and coworkers modified vancomycin by introducing a pyrene group to the C-terminal of the backbone of vancomycin, and serendipitously turned vancomycin into the hydrogelator vancomycin-pyrene (**Van-Prodrug-1**), which formed a hydrogel (Figure 17(a)) with an MGC of 0.36% (w/v; 2.2 mM).[115] According to spectroscopic analysis, π–π interactions between pyrenes and the hydrogen bonding between vancomycin moieties drove the self-assembly of **Van-Prodrug-1** in water (Figure 17(b)). Further, TEM study (Figure 17(c)) suggested that **Van-Prodrug-1** self-assembled to afford supramolecular networks that aggregated further into nanofibers as the matrices of the hydrogel. In contrast to most of the structural modifications of commercial drugs that usually cause a loss of activity, **Van-Prodrug-1** exhibited unusual potency, nearly three-orders of magnitude more potent than vancomycin against vancomycin-resistant enteroccoci (VRE).[115] Further investigation indicated that the enhanced efficacy might have resulted from the adsorption of **Van-Prodrug-1** onto surfaces of the bacteria cells.[116] Vancomycin is known to form key H-bonding with D-Ala–D-Ala peptide moieties of bacterial cell wall. Although the generality of this proposed mechanism requires further validation, it is consistent with the work of Tiller and coworkers, in which they showed an excellent example of a molecular hydrogelator that formed a hydrogel on a surface with a concentration 50 times below the MGC.[117] Although the modified vancomycin showed promising potency, the toxicity of this modified drug toward mammalian cells remains to be evaluated. Nevertheless, pyrene is highly toxic itself. Thus, a more attractive design would involve other small molecules such as amino acid analogs that are nontoxic and promote self-assembly.

4.421.4.3. Glucosamine-Based Self-Assembled Hydrogels

D-Glucosamine, one of the most abundant monosaccharides, is used as an oral supplement for the management of mild osteoarthritis with limited efficacy. Glucosamine also plays a role in the process of wound healing, and Shaunak and coworkers have demonstrated that a polyvalent dendrimer of glucosamine conjugates prevented scar tissue formation.[118] Plant *et al.* demonstrated that polymeric hydrogels incorporating glucosamine increased the adhesion with neural tissue of the host, improved vascularization, and enhanced infiltration of nonneural cells of the host.[119] Therefore, glucosamine in/as supramolecular hydrogel may exhibit similar effects and serve as a novel self-assembled drug-based hydrogel. Xu *et al.* proposed that glucosamine-based hydrogel may assist wound healing and prevent the formation of scars.[120] Encouraged by this preliminary work, and based on other low-molecular-weight gelators made from carbohydrates,[121] Xu and coworkers transformed glucosamine into

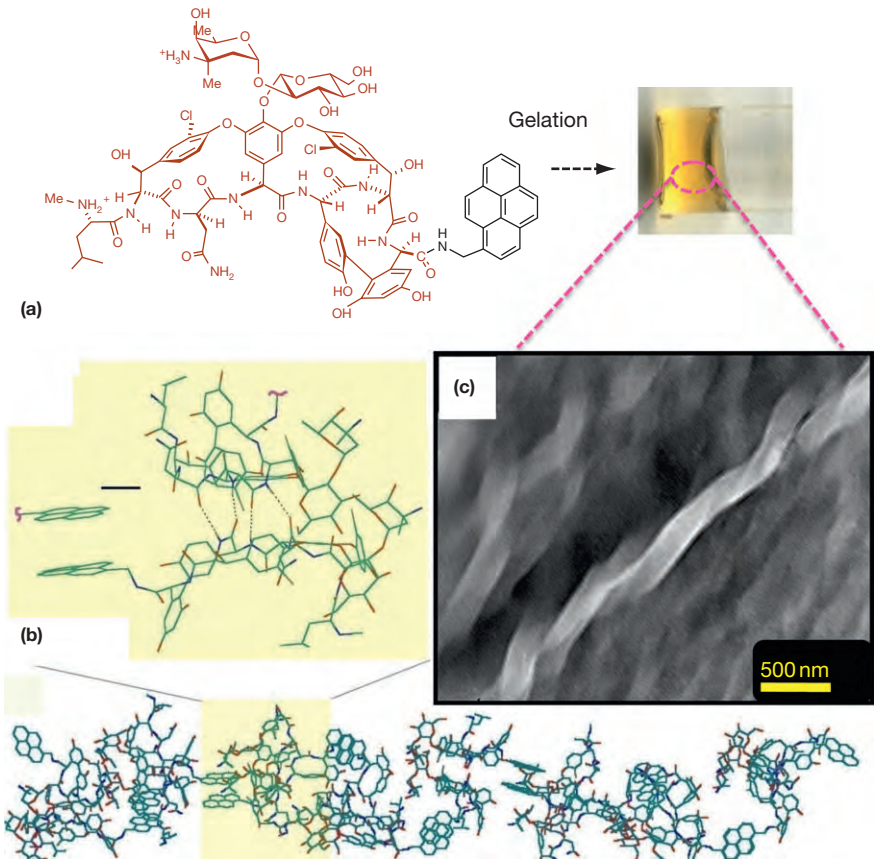

Figure 17 (a) Molecular structure of vancomycin-pyrene (**Van-Prodrug-1**) with the optical image of the hydrogel at 0.36 wt%. (b) The noncovalent interactions involved in the self-assembly of **Van-Prodrug-1**. (c) TEM image of the helical nanofibers of **Van-Prodrug-1**. Reproduced from Xing, B.; Yu, C. W.; *et al. J. Am. molecular gelators, linking either napthyl-L-phenylalanine (**Glu-Prodrug-1**) or napthyl-D-phenylalanine (**Glu-Prodrug-2**, Figure 18).[120] The cell toxicity of these glucosamine prodrugs was thoroughly investigated, and **Glu-Prodrug-2** exhibited better cell tolerance than **Glu-Prodrug-1**. Thus, **Glu-Prodrug-2** was evaluated for its ability to reduce the scar tissue at wound sites on a mice dermal model. The hydrogel of **Glu-Prodrug-2** promoted both significantly faster wound healing and less scarring than was observed in an untreated control group.

4.421.5. Conclusions and Outlook

While prodrugs are routine and significant, self-assembled prodrugs are the 'new kids in the block', and have potential benefits for specific aspects of drug delivery. They are shown to circumvent inherent hurdles routinely encountered in traditional drug delivery methods such as external carrier-based issues. Prodrugs for generating self-deliverable vehicles must have the ability to undergo self-assembly to form stable and hierarchical nanostructures in physiological conditions, and they should be programmed to degrade at the molecular level to release the parent drug at a controllable rate in response to biological cues, preferably at targeted tissue/cells, with acceptable efficacy and toxicity.

During the design process to produce amphiphilic prodrugs, several key factors should be carefully examined, including (i) choice of an appropriate parent drug which has functional groups amenable to routine conjugation reactions under mild conditions; (ii) safety of the promoiety, and its ability to promote self-assembly of resultant prodrugs; (iii) ability of the linker-functional group to undergo reversible defunctionalization to release the parent drug in response to either biological or chemical cues; and (iv) safety of the degradation by-products, and avoidance of the generation of unwanted or toxic moieties *in situ*.

In the early stages of research, most attention is given to both introducing self-assembling ability into the amphiphilic prodrugs and improving stability of the self-assembled nanomaterials. However, the field of drug delivery demands more than the stability of nanomaterials, that is, efficient self-assembly and stability of the materials are insufficient to complete the drug delivery development cycle. These self-assembled prodrugs should have the ability to degrade at targeted locations in response to biological cues to consistently produce the parent potent drug with the desired kinetic rate profile. However, a deep understanding of the mechanism of both drug action and its interaction with the microenvironment and biomolecules such as enzymes and proteins is vital to the ideal design of self-assembled prodrug-based

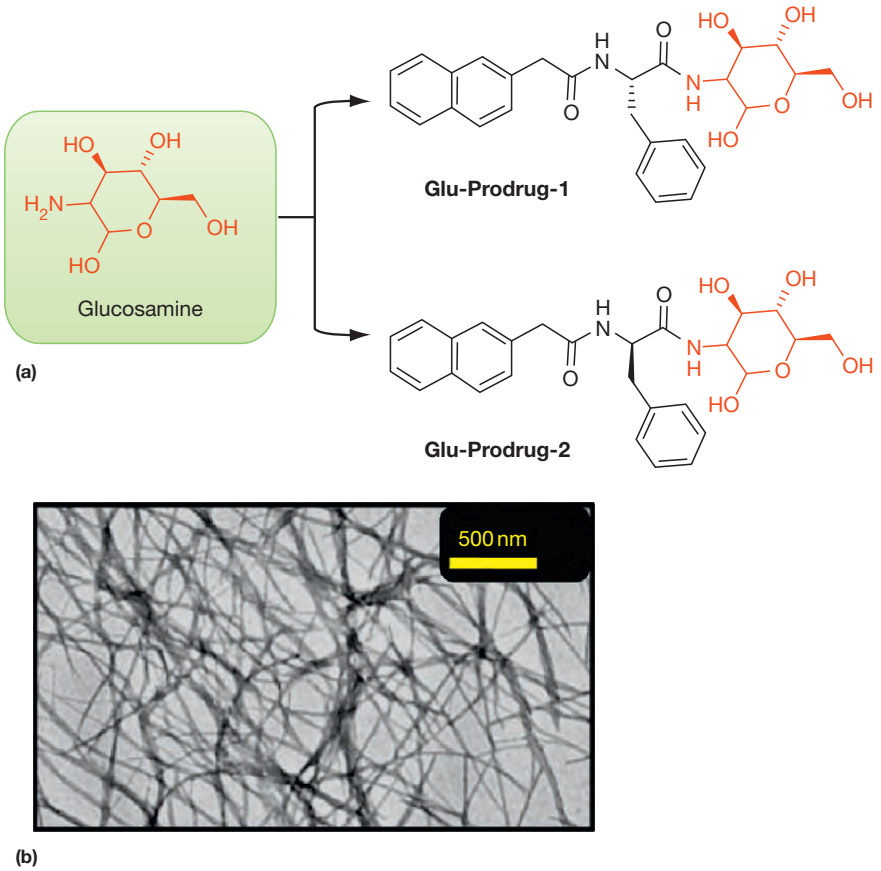

Figure 18 (a) Molecular structures of glucosamine prodrugs, **Glu-Prodrug-1** and **Glu-Prodrug-2,** which have the ability to form hydrogels. (b) TEM image of the nanofibers from the hydrogel of **Glu-Prodrug-2**. Reproduced from Yang, Z.; Liang, G.; *et al. Chem. Commun. (Camb.)* **2007**, *8*, 843–845. biomaterials. Despite the significant advantages of self-assembled nanostructures for achieving controlled drug delivery, the possible adverse effects due to interactions between nanostructures and organelles, cells, enzymes, and proteins must be fully tested, although given the relatively weak mechanical properties, this is not anticipated to present significant issues. Self-assembly, stability, and degradation must simultaneously be considered. Thus, incorporation of multiple disciplines, such as organic chemistry, medicinal chemistry, supramolecular chemistry, nanosciences, pharmaceutics, and clinical science, should accelerate and enhance the design and development of ideal self-assembling drug delivery vehicles. With this awareness, we believe future research will enable the development of such smart systems to benefit certain therapeutic regimes.

Glossary

Amphipathic A molecule that contains both polar (water-soluble, hydrophilic) and nonpolar (not water-soluble, hydrophobic) components in its structure. (synonym to amphiphilic).

Biomacromolecule A polymer consisting of natural monomers (e.g., amino acids or nucleic acids) forming a large molecular weight molecule (e.g., proteins, DNA, carbohydrates).

Block polymer A polymer comprising two or more compositionally distinct subunits linked by covalent bonds. Block polymers with two or three distinct blocks are called diblock polymers and triblock polymers, respectively.

Buffering capacity A measure of the ability of a solution (i.e., containing a pH-responsive polymer) to resist pH change when a small amount of acid or base is added. It can be quantitatively defined as the molarity of strong acid or base that must be added to change pH by one unit, and it is important to recall that buffering capacity is highest when $pH = pK_a$.

Chemoselective The preferential reaction with one functional group (e.g., incorporated onto a polymer terminus) in the presence of others (e.g. pendant groups on the polymer backbone).

Controlled, living radical polymerization A chain growth polymerization that proceeds with negligible termination or chain transfer steps and where the rate of chain initiation is much larger than the rate of propagation. The polymerization proceeds by first order kinetics, and the molecular weight increases linearly with conversion. The degree of polymerization can be predetermined, and the polymers produced are relatively monodispersed. The radical polymerization can be stopped and reinitiated under external control, allowing facile formation of block polymers (see definition above). Chain ends are preserved and can be predefined based on the chemistry of polymer precursors.

Dendrimers Monodispersed, symmetric structures consisting of highly branched architectures that are synthesized through stepwise addition of branched monomers. Each sequentially added layer of branched monomer is known as a dendrimer 'generation'.

Encrypted In this chapter, this refers to a membrane disruptive polymer that is masked by an outer shield consisting of a more inert polymer. The inert polymer is linked to the membrane disruptive polymer by covalent bonds that are broken upon exposure to the more acidic environment in endolysosomes. Removal of the inert polymer shield exposes the core polymer and enables its membrane disruptive activity.

Endocytosis The process by which materials are internalized by a cell without diffusing through the cell

membrane. The material localizes to the cell surface where an invagination is formed that fuses and buds off inside the cell, enclosing the material within an intracellular vesicle. This process can be specific (e.g., receptor-mediated endocytosis) or nonspecific (e.g., pinocytosis or phagocytosis).

Endolysosome The product of the fusion of an endosome and a lysosome during endocytosis.

Endosomolytic Having the capacity to disrupt the integrity of endosomal membranes in response to the acidic pH present inside the endosomal environment.

Enhanced permeation and retention (EPR) The process by which nanoparticles, liposomes, or other macromolecular drugs nonspecifically accumulate in tumors as a result of their leaky vasculature and poor lymphatic drainage.

Lipid A fat, oil, or wax organic compound that is soluble in nonpolar organic solvents (e.g., ether) but not in polar solvents (e.g., water). Many lipids are amphipathic (see definition above), which triggers them to self-assemble into micelles, liposomes, or membranes in polar solvents. The cell membrane and other biological vesicles are composed of self-assembled lipid bilayers, and synthetic lipids can be used to encapsulate drugs into liposomal vesicles for drug delivery.

Proton-sponge effect A process leveraged by pharmaceutical scientists where proton-accepting polymers buffer the microenvironment in endosomes and lead to their eventual disruption. The basic, amine-containing polymers inhibit acidification of the endosomal compartment and lead to continued, abnormal influx of protons and their counter ions. This increases osmotic pressure in the endosome and causes water influx, swelling, and disruption.

Random copolymer A copolymer consisting of more than one monomer heterogeneously incorporated into a polymer with no regular repeating pattern. A random copolymer usually results from the copolymerization of two or more monomers in the presence of a free-radical initiator.

Smart polymers Polymers that respond in a dramatic way to a very slight change in their environment (e.g., pH, temperature, ionic strength, etc.).

4.422.1. Introduction

The underutilized potential of proteins, peptides, DNA, and RNA as therapeutics is widely recognized, and the lack of effective strategies for intracellular delivery of these biologics is the primary barrier hindering their ability to improve therapies for a plethora of human diseases. For example, increased target specificity and disruption of barriers and interfaces currently considered 'undruggable' could be achieved using proteins, antibodies, and peptides as pharmaceutically active inhibitors. Such antagonists could be applied in pathologies where intracellular signaling pathways have gone awry (i.e., cancer). The once 'hot' but now more stagnant field of gene therapy could also benefit from development of efficient nonviral carriers that can escape endolysosomal fates (see **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**). Synthetic systems that can effectively deliver DNA into the cell would likely trigger a dramatic increase in gene therapy clinical activity considering that safety of (highly efficient) viral vector-based approaches is a major concern.[1–3] In addition, short interfering RNA (siRNA) has recently emerged as a class of therapeutics that, if efficiently delivered, may offer a platform technology capable of specific knockdown of any desired protein target.[4,5] Similar to the other classes of biologics, siRNA is hindered by limited endosomal escape because it must access cellular gene silencing machinery and mRNA targets located in the cytoplasm to achieve mRNA degradation. Finally, endosomal escape and cytoplasmic delivery of antigen to dendritic cells constitute a rigorously studied component in vaccine development.[6–29] This is because cytoplasmic delivery to antigen-presenting cells enables processing and presentation through the MHC-I pathway, which leads to activation of cytotoxic T-lymphocytes (CTLs). Importantly, CTLs have the ability to directly identify and destroy foreign cells that express the antigen, making them an important component of a robust, therapeutically effective immune response.

Although the potential pharmaceutical impact is high, there has been minimal clinical translation of intracellular-acting biologic drugs because they have large molecular weights and are hydrophilic and polar compared to small molecule drugs. These properties present a substantial delivery challenge because it is energetically unfavorable for biomacromolecules to diffuse through the nonpolar core of membrane lipid bilayers. Therefore, their internalization must proceed via cell engulfment and internalization processes of various types, generally endocytosis or pinocytosis, producing drug sequestration and degradation in endolysosomes, or exocytosis out of the cell (see **Figure 1**). Thus, even when pharmaceutical strategies are employed for targeting the cell surface and triggering internalization, the endolysosomal escape of biotherapeutics to molecular targets in the cytoplasm presents a formidable challenge.

A key characteristic of intracellular trafficking from the extracellular space through early endosomes, late endosomes, and lysosomes is that the therapeutic is exposed to significant variations in environmental pH ranging from 7.4 in the extracellular space to approximately 5 in the lysosomes (**Figure 1**). This pH gradient provides an environmental stimulus that pharmaceutical scientists have learned to exploit in order to 'activate' carriers, including colloids, lipids, particles, and polymers, to disrupt and escape from endosomal compartments. Specifically, polymers that are membrane-disruptive at acidic pH relevant to endolysosomal trafficking (pH ~5–7) and are inert at pH 7.4 have found numerous applications for intracellular delivery because they have low toxicity and high efficacy. Finely tuned membranolytic activity in this range has been achieved by a variety of anionic and cationic polymers whose pH-dependent protonation states drive physicochemical transitions that trigger this 'switch'. 'Encrypted' membrane-disruptive polymers that are 'unmasked' by acidic conditions have also been developed. The remainder of this chapter reviews the mechanisms of activity of these endosomally disruptive

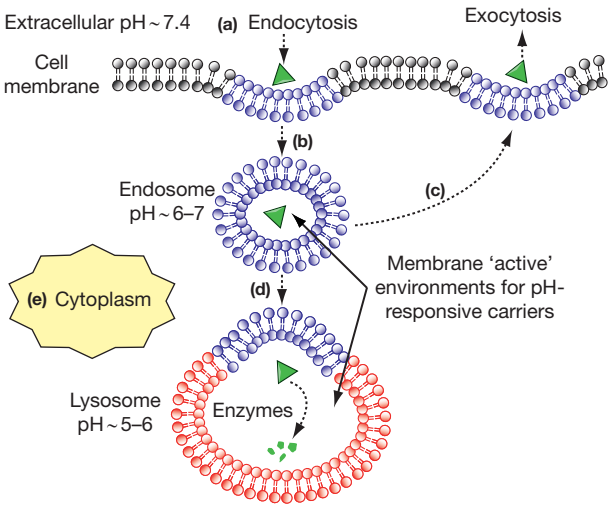

Figure 1 Internalization and trafficking pathways that serve as barriers against biomacromolecular drug intracellular delivery. (a) Biotherapeutics are internalized by endocytosis or pinocytosis into intracellular vesicles (b). Subsequently, the biomolecule is routed toward (c) exocytotic recycling to the extracellular space or (d) trafficking into lysosomes, an environment rich with degradactive enzymes. Endolysosomal membranes maintain localized acidic environments that can be leveraged to activate pH-responsive carriers to enable delivery to the cytoplasm (e) where the biomolecule is able to exert its desired bioactivity.

polymers and discusses some of the most promising advances from each of these classes of pH-responsive drug carriers. It should be noted that potent, pH-responsive lipid-based formulations have a substantial record of development and promise for drug delivery (see Buse and El-Aneed,[30] Jabr-Milane *et al.*,[31] MacEwan *et al.*,[32] Sebiakin Iu and Budanova[33]), but this chapter focuses solely on polymeric delivery systems (see Chapter 4.424, Nanoparticles for Nucleic Acid Delivery).

4.422.2. Acid–Base Equilibria and pH-Responsive Chemistries

The physicochemical behavior of pH-responsive polymers is on the basis of classical acid–base equilibria involving weak acids and bases in buffered physiological systems. All reversible pH-responsive lipid or polymer systems known comprise functional groups that are weakly acidic or basic and respond to local biochemically driven pH changes in physiological systems near pH 7. A weak acid, denoted by 'HA', is capable of acting reversibly as a proton donor (eqn [1]), and its conjugate base (A^-) can serve as a proton acceptor. Both of these actions depend on the local pH and the strength of the acid. Many carboxylic acids (RCOOH) are classical weak acids exhibiting this behavior. These acid groups reside on amino acids (e.g., aspartate), or are products of the Krebs cycle (e.g., malic or succinic acid), phosphates, sulfites, nitrites, and natural metabolites (fatty acids, e.g., oleic acid). Therefore, they are biologically endogenous and their equilibria are common to physiological systems. Additionally, carboxylic acids are common to many water-soluble natural and synthetic polymers of interest as biomaterials (e.g., carboxymethylcellulose, alginate, heparins, nucleic acids, polyacrylic acids, polyamino acids), facilitating their involvement in these host acid–base equilibria processes if introduced appropriately as biomaterials. Matching the pH-responsive polymer's acid–base equilibria to that of the host microenvironment being targeted for delivery is the key to this biomaterial performance.

For a given weak acid dissolved in water, a characteristic equilibrium will be achieved between the concentrations of the acid in its protonated and dissociated forms. The capacity of an acid to dissociate to release protons (i.e., its 'strength') can be quantitatively defined by the acid dissociation constant, K_a (eqn [2]). The logarithmic form (pK_a, eqn [3]) is often used to represent this value as K_a values vary over many orders of magnitude, and the convention is such that strong acids have lower pK_a values than weak acids.

$$[HA] \rightleftharpoons [A^-]\ [H^+] \qquad [1]$$

$$K_a = \frac{[A^-]\ [H^+]}{[HA]} \qquad [2]$$

$$pK_a = -\log K_a = -\log \frac{[A^-]\ [H^+]}{[HA]} \qquad [3]$$

Similar relationships exist for weak bases as common proton acceptors in water. When a base 'B' accepts protons from water, it converts water molecules into hydroxide anions. This equilibrium between the protonated (BH^+) and deprotonated (B) form of the weak base can be described by an analogous set of equations for quantitatively characterizing the degree of basicity with an expression for pK_b (eqn [4]). As with acids, stronger bases have lower values for pK_b. Natural weak bases of physiologic relevance include primary and secondary amines (ammonia, alkylamines) as metabolic by-products, amino acids arginine, lysine, and histidine, and nucleotide bases with pK_b values near pH 7. Chitosan is an important naturally existing basic polymer, and synthetic pH-responsive polymers with weak base chemistry include polyethyleneimine (PEI), poly(lysine), poly(arginine), poly(histidine), poly(amidoamines), and various copolymers. Importantly, water (recall: 55 M concentration in its bulk state) can act either as a weak acid or weak base, depending on the conjugate acid–base chemistry present.

$$pK_b = -\log K_b = -\log \frac{[BH^+]\ [OH^-]}{[B]} \qquad [4]$$

By rearranging eqn [2] to solve for $[H^+]$ and substituting $pH = -\log[H^+]$, the well-known Henderson–Hasselbalch equation is derived (eqn [5a]). An equivalent version of the equation is shown in the base representation (eqn [5b]).

$$pH = pK_a + \log\left\{\frac{[A^-]}{[HA]}\right\} \qquad [5a]$$

$$pOH = pK_b + \log\frac{[BH^+]}{[B]} \qquad [5b]$$

A simplified way to conceptualize the reversible equilibria relationships for weak acids and bases is that, in the case of an acid, when the local pH is equivalent to the pK_a, $\log([A^-]/[HA])$ equals zero (see eqn [5a]). This means that when pH is equal to the pK_a, the ratio $[A^-]/[HA]$ is equal to 1; thus, equivalent concentrations of the protonated (HA) and deprotonated (A^-) forms of the acid coexist. If the local pH is

below the pK_a, the protonated form becomes the dominant species. This central concept is important to this chapter because understanding pH-responsive delivery systems requires correlating the relationship between the local environmental pH and the ionization state(s) of acidic or basic moieties present on larger molecules (e.g., pH-responsive polymers) applied as drug delivery vehicles. This is because many of the pH-responsive polymers discussed in this chapter possess acidic (e.g., –COOH) or basic (e.g., $-NR_2$) moieties that accept or donate protons based upon the pH of their local environment. Significantly, as pH-responsive polymers respond to local physiological pH, these polymer systems increase or decrease the protonation states of their acidic or basic groups, altering their solubility, conformation, size, susceptibility to enzymatic or receptor recognition, target binding, or membrane interactions. These pH-driven, reversible responses from polymer acidic and basic groups produce the effects that can be exploited in their use as biomaterials.

Because protonation/deprotonation is accompanied by requisite changes in ionization, dramatic transformations in the physical properties of the polymer can result from acid–base equilibria. For example, ionization of compounds (e.g., polymers) increases their solubility in water while lack of ionic charges makes molecules more hydrophobic, effectively changing their partition coefficient (as exploited in acidic-gradient chromatography, for example) or their water solubility. Such changes in the polymer hydrophilic–hydrophobic balance can induce conformational changes and phase transitions driven primarily by the association with or repulsion of solvating water. For example, a polymer containing –COOH units donates protons in media with a pH above its pK_a. The resulting ionized $-COO^-$ chemistry increases polymer solubility via solvation with water. With a decrease in local pH, the protonated –COOH form dominates and the more hydrophobic state of this uncharged polymer is unable to solvate sufficiently with water, forcing collapse into a compact polymer globular conformation (partial or complete insolubility). This increased polymer hydrophobicity produces greater lipophilic behavior and increased partitioning into lipid bilayer membranes (e.g., cell membranes, cell organelles). By contrast, polymers containing weakly basic $-NR_2$ moieties accept protons, become ionized (e.g., as $-HN^+R_2$), and are more water soluble in environments with local pH below their pK_b. This means that these basic polymers can absorb acidic proton influx when the pH is near their pK_b, allowing them to buffer the local microenvironment against pH change as they equilibrate. In this regard, it is important to note that such amine-containing weak bases exhibit the strongest buffering capacity at a pH near their pK_b. This property is most relevant to the mechanism of activity for 'proton-sponge' polymers that are discussed subsequently in this chapter. Thus, pH-responsive phase transitions of carboxylated polymers and buffering of environmental pH by polyamines are vital to the membrane activity and endosomal-disruptive mechanisms described herein. The environmental pH at which these activities occur depends on the pK_a or pK_b of the relevant groups, and as discussed, pK_a and pK_b of the acidic/basic groups can often be tuned on the basis of the overall chemistry of the polymer in order to formulate drug delivery systems that are finely tuned to respond in the endosomal environment.

A further important consideration is that biological systems are buffered, and physiological pH is generally buffered between pH 7 and 7.4 in most tissues using two important biological buffer systems based on distinct phosphate and bicarbonate acid–base equilibria. These equilibria can compete with, neutralize, or complicate intended pH-responsive changes in biomaterials. Any pH change in or pH response from introduced agents must respond to these buffers and their pH influence if different from their pK values, or attempt to overwhelm the local physiological buffering capacity to produce sustained pH-responsive dynamics or reversible behavior. Multiple simultaneous polyequilibria, including Donnan effects, metal ion-induced complexation, and solution deviations from the Henderson–Hasselbalch equation, are more complicated, advanced topics beyond the scope of this chapter.

4.422.3. Anionic pH-Responsive Polymers

Anionic, amphiphilic polymers containing a polycarboxylic acid segment are pH-responsive membrane disruptive agents that, because of the protonation of their carboxyl groups and resulting increased hydrophobicity at acidic pH, possess membrane-partitioning behavior. Polymers with these properties can be achieved by synthesizing homopolymers of alkylacrylic acids (i.e., poly(methylacrylic acid) (PMAA), poly(ethylacrylic acid) (PEAA), poly(propylacrylic acid) (PPAA), etc.),[34–37] copolymers of acrylic acid and alkyl acrylates,[37–39] or alkylacrylic acids and other hydrophobic monomers,[40] or alkylamide modification of poly(styrene-*alt*-maleic anhydride)[41,42] (**Figure 2**). Collectively, these polymer families have shown great versatility for intracellular delivery of a multitude of biomacromolecules including peptides, proteins, siRNA, and DNA. In addition, they are amenable toward synthesis via controlled-polymerization techniques, including reversible addition–fragmentation chain transfer (RAFT) (see **Chapter 4.423, Polymeric Drug Conjugates by Controlled Radical Polymerization**).[43] Anionic polymers also enhance drug circulation times and are well-suited for *in vivo* delivery because of their cytocompatibility,[44] but one disadvantage is their inability to complex electrostatically with anionic nucleic acids. Thus, additional components such as cationic polymers/lipids or conjugation sites are needed for packaging/attachment and incorporation of targeting moieties as may be necessary to ensure endocytotic uptake.

Mechanistically, the carboxylate protonation of anionic polymers that occurs in more acidic environments tips their hydrophilic–hydrophobic balance toward an uncharged, net hydrophobic state, triggering the polymer to transition from an extended soluble form into a more compact, less soluble, and globular state that could be membrane disruptive (**Figure 3**). The mechanism of this transition and its role on lipid bilayer disruption have been studied most rigorously for the poly (alkylacrylic acids), and much of this work was pioneered by the Tirrell group with a focus on PEAA disruption of lipid vesicles.[35,36] In 1987, Tirrell *et al.* demonstrated via calorimetry that PEAA transitioned from an ionized, expanded conformation at higher pH into a collapsed, hydrophobic globular coil in acidic conditions with a transition midpoint at approximately pH 6.2,[45] and similar results were later shown with quasielastic light scattering (QELS).[46] This was also analogous

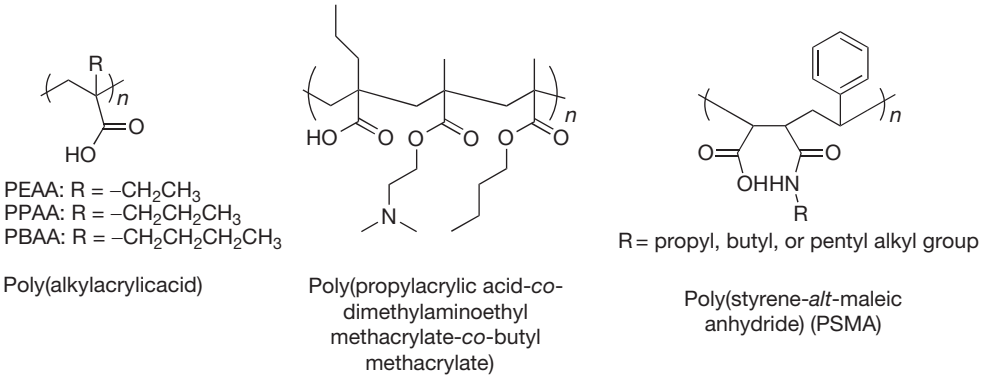

Figure 2 Structures of anionic, pH-responsive polymers useful toward intracellular delivery of biomacromolecules.

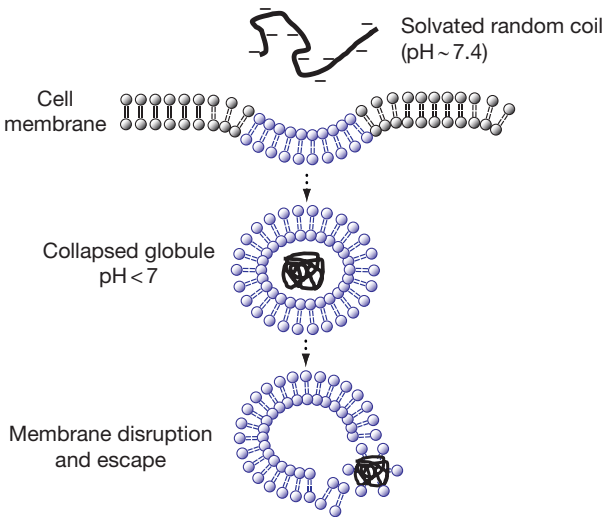

Figure 3 Schematic illustration of pH-driven coil-to-globule transition of poly(alkylacrylic acid) systems used for endosomolytic activity in drug delivery applications.

to behavior previously shown by Chen and Thomas for PMAA, which shows a similar transition at pH < 5.[47] Importantly, this change in polymer morphology correlates with the ability of these polymers to disrupt lipid bilayers. As PEAA and similar polymers are synthetic, polydispersed, and stereoirregular, it is unlikely that the membrane disruptive behavior is dependent on acquisition of any specific (i.e., pore-forming) secondary structure. In fact, Thomas and Tirrell have presented evidence that the membrane disruptive behavior is instead a hydrophobically driven process where the less soluble polymer initially binds to a membrane surface and then disrupts the vesicle bilayer by penetration and formation of mixed polymer/lipid micelles (Figure 3).[36]

Tirrell's studies focused on functionalization of liposomes with PEAA for triggered disruption and release of the contents of these vesicles as opposed to disruption and escape from endolysosomal membranes. Nevertheless, his studies in simplified, well-defined model systems yielded insight into mechanisms of membrane disruption by anionic polymers. The red blood cell (RBC) hemolysis assay has been predominantly used for subsequent studies on more complex biological membranes. This assay provides a relatively simple initial screen, and although its usefulness as an overall predictor for carrier *in vivo* performance may be overstated, past results have indicated that pH-dependent RBC hemolysis correlates with the ability of polymers to disrupt endosomal compartments.[48] Jones and coauthors compared PMAA, PEAA, and PPAA hemolytic profiles, and found that shifts in the pH-dependent hemolytic activity exist that correlate to Tirrell's findings on pH-dependent polymer conformational changes.[34] Their studies found that PPAA created hemolysis just under physiologic pH (7.4), PEAA at pH < 6.2, and PMAA showing no activity in the physiologically relevant range tested. Murthy, Cheung, and coworkers also found that PPAA (Figure 2) was ~15× more membrane disruptive than PEAA and showed maximum membrane disruption at pHs relevant for endosomal trafficking (pH ~6.0).[49–51] The increased activity was attributed to higher pK_a value because of one additional CH_2 group, and this motivated the investigation of poly(butylacrylic acid) (PBAA, Figure 2), where the pK_a was expected to increase yet again. For PBAA, membrane disruption at physiological pH was observed, a characteristic undesirable for ensuring biocompatibility on the basis of the polymer remaining inert in the extracellular environment. In addition to the important balance between pH responsiveness and polymer hydrophobicity, the membranolytic activity of PPAA is dependent upon regularly spaced acid and hydrophobic groups. For example, the membrane-disruptive behavior of PPAA was significantly higher at acidic pHs compared to that of a random copolymer of propyl acrylate (PA) and acrylic acid (AA).[50,52] It was presumed that PPAA can penetrate into the lipid bilayer more efficiently than the random copolymer because of the more regular spacing of the hydrophobic alkyl chains.[50,53] Murthy *et al.* also found that PEAA hemolysis was partially inhibited by addition of osmolytes such as dextran into the buffered solutions, indicating that a colloid osmotic mechanism may contribute to hemolytic activity of these polymers.[37] Colloid osmotic hemolysis results from an osmotic imbalance that occurs when small solutes (i.e., buffer salts) equilibrate across the membrane while larger macromolecules present in the cytoplasm of the RBC are not able to cross transmembrane pores because of size.[54] This creates a net osmotic imbalance, leading to water influx, swelling, and further damage to the lipid bilayer membrane. It is uncertain how much this effect contributes in the endosome, but it is conceivable that the macromolecular

osmotic gradient would be less significant across the endolysosomal membranes relative to this model system. Although the exact mechanism of disruption of these less homogenous biological membranes is not as clearly elucidated, strong evidence remains that the more hydrophobic polymer state at lower pHs leads to partitioning of the polymer into the core of the lipid bilayer, leading to bilayer disruption and solute permeability.

The literature contribution from Jones and coauthors demonstrated one of the most thorough and informative investigations to date on the mechanism of endolysosomal vesicle disruption of poly(2-alkylacrylic acid)s in living cells.[34] Their studies indicated that in human U937 myelomonocytic transformed secondary cells (i.e., cells with a highly phagocytic phenotype), all three 2-alkylacrylic acid polymers tested were able to achieve escape of small molecules and cathepsin B fused with green fluorescent protein from endolysosomal pathways into the cytosol. Furthermore, the pH-driven nature of this activity was validated by experiments showing that agents that inhibit the acidification of endosomes abrogate polymer-mediated endolysosomal release into the cytoplasm. On the basis of experiments using fixed-cell immunocytochemistry and live-cell intracellular stains, the authors found that 2-alkylacrylic acid polymers altered distribution and morphology of late endosomes, but not early endosomes or lysosomes. The polymers may have exerted their effects prior to reaching the lysosomes, or it could be speculated that the lack of change in lysosome morphology may have been related to differences in the compositional integrity of the lysosomal membrane or polymer precipitation (and thus loss of the amphiphilicity required for activity) in this highly acidic environment.

4.422.3.1. Poly(alkylacrylic acid)s

Because PPAA exhibited the optimal pH-responsive membrane destabilization behavior in mechanistic studies, it has been extensively studied for cytosolic delivery of biomolecular drugs. Simple linkage of PPAA to a protein (e.g., streptavidin) did not affect the pH-dependent conformational change of the polymer chains nor its pH-responsive membrane-destabilizing activity.[55] In addition, PPAA conjugation aids in antibody cytosolic delivery, where ~73% of the total antibody was measured cytoplasmically when delivered following PPAA conjugation versus ~0% for free antibody.[55] More recently, PPAA was conjugated to a model antigen, ovalbumin, and used to treat macrophages *in vitro* as a first step toward a polymeric vaccine delivery system. This treatment resulted in increased cellular major histocompatibility complex class 1 presentation and ovalbumin-specific cytotoxic T cell activation, results that require cytosolic delivery and processing of antigen.[56] In a follow-up study using the EG.7-OVA mouse tumor protection model, PPAA was also shown to produce a functionally significant prophylactic effect *in vivo*. In this study, PPAA-based delivery of ovalbumin as a model protein antigen facilitated an 8-fold increase in antigen-specific CTL production and an approximately 3.5-fold increase in the length of tumor-free survival relative to vehicle controls following inoculation with mouse EG.7-OVA thymoma cells.[7]

In addition to these protein delivery applications, PPAA has also proven to be useful in gene therapy approaches. Introduction of PPAA into a mixture dioleoyltrimethylammonium propane (DOTAP), a cationic lipid traditionally used for gene delivery, enhanced plasmid DNA gene expression (20-fold) and serum stability.[49] Further exploration of this delivery system was performed in a murine model of wound healing, showing that when PPAA was added to the formulation, expression of TSP2 was enhanced in TSP2-null mice compared to control formulations.[57] In an analogous ternary system, enhanced gene expression was obtained using a combination of chitosan, DNA, and PPAA in HeLa cells.[58] These studies also showed a lack of colocalization of PPAA and a lysosomal dye, providing mechanistic evidence that PPAA enhanced transfection efficiency by enabling endosomal escape of DNA prior to lysosomal degradation.[57]

Copolymers with diblock architectures that exploit the pH-responsive activity of PAA have also been synthesized and explored for macromolecular intracellular drug delivery. Typically, diblock copolymers have been designed with twofold delivery characteristics in mind – for example, long circulation times or drug complexation and protection, in addition to endosomal escape. One copolymer designed specifically for siRNA delivery is a block copolymer consisting of poly(dimethylaminoethyl methacrylate)-*b*-poly(propylacrylic acid-*co*-butyl methacrylate-*co*-dimethylaminoethyl methacrylate) (pDMAEMA-*b*-p(PAA-*co*-BMA-*co*-DMAEMA)).[59] This diblock copolymer was designed to complex and protect the siRNA, which is negatively charged, and to enable endosomal escape. Therefore, a cationic first block (to condense and protect siRNA) and a terpolymer second block containing PAA (see **Figure 2**) were synthesized (for endosomolysis). Delivery of siRNA using the diblock copolymer resulted in gene product knockdown of up to 30% of untreated cells and resulted in no detectable cytotoxicity,[59] and further optimization through adjusting relative block sizes produced even higher levels of knockdown.[60] Another carrier was developed using the same pH-responsive block but with different delivery requirements. In particular, the polymer poly(*N*-(2-hydroxypropylmethacrylamide))-*b*-poly(propylacrylic acid-*co*-butyl methacrylate-*co*-dimethylaminoethyl methacrylate) (pHPMA-*b*-p(PAA-*co*-BMA-*co*-DMAEMA) was utilized to confer long circulation times (pHPMA block) and endosomal escape (terpolymer block containing PAA, **Figure 2**) to an intracellular-acting proapoptotic peptide.[61] The peptide was conjugated through disulfide exchange using a pyridyl disulfide polymer chain end functionality incorporated through a RAFT-based synthetic procedure. Peptide–polymer conjugates increased HeLa cervical carcinoma cell apoptotic activity over free peptide and resulted in 50% tumor cell death in cultures after 6 h of treatment.[61] Data gathered using these polymer delivery systems indicate that cytosolic delivery is enhanced using PAA functionalities even when incorporated into a diblock copolymer – opening up new and exciting avenues for delivery systems requiring multiple functionalities to overcome diverse delivery hurdles.

4.422.3.2. Poly(styrene-*alt*-maleic anhydride)

Another class of anionic, pH-responsive membrane-destabilizing polymers are copolymers of styrene and maleic anhydride (poly(styrene-*alt*-maleic anhydride), PSMA). Styrene and maleic anhydride are known to produce alternating copolymers[62] that have been used in a variety of applications. Generally, PSMA has many desirable attributes for use as a polymer therapeutic. It enhances drug circulation half-life and lipid solubility, and it

binds noncovalently with albumin during systemic circulation, thereby reducing polymer clearance.[63] The initial use of PSMA was to exploit these properties, and Maeda and coworkers first used low molecular weight PSMA copolymers (<6 kDa) clinically to deliver an antitumor protein, neocarzinostatin (NCS).[64–66] The polymer–protein conjugate (SMANCS)[64–66] significantly improved the pharmacological properties of NCS and has been clinically effective in treating liver cancer. The SMANCS conjugate is also known to accumulate in tumor tissue and the lymphatic system through the proposed enhanced permeation and retention (EPR) effect.[64–66] Additional research by Maeda *et al.* indicated that PSMA enhanced NCS uptake by increasing cell binding. They also speculated that PSMA enhanced translocation of NCS across the endosomal membrane by increasing the interactions between NCS and the membrane at acidic pH.[67] However, in more recent work, PSMA has been thoroughly evaluated as a pH-dependent membrane-destabilizing polymer, and this property is likely the reason for enhanced cytosolic NCS delivery. Specifically, Henry *et al.* found PSMA to be endosomolytic, particularly upon modification of the maleic anhydride with alkyl chains (see **Figure 2**).[68] Results showed that varying the length of alkyl chain used in the modification, the percent modification of PSMA, and the overall molecular weight of PSMA can be utilized to tune the pH-dependent membrane-destabilizing activity of these derivatives.[68] PSMA has also been further developed and optimized for the delivery of siRNA.[69] The pH-responsive complexes were used to deliver siRNA against polo-like kinase 1 (plk1), a gene upregulated in many cancers and responsible for cell cycle progression. Treating cells using the complexes resulted in approximately 50% reduction of plk1 gene expression in NCI/ADR-RES and OVCAR8 ovarian cancer cell lines.[69]

4.422.4. Acid-Degradable Delivery Vehicles

Another class of endosomal-disruptive delivery vehicles has been developed based on the use of acid-degradable chemical linkages. These linkages have been used to fabricate delivery vehicles that hydrolyze at the acidic pH of the endosome and, in turn, generate membrane disruptive molecules that allow escape to the cytoplasm. Two linkages have been extensively used for these applications, the acetal/ketal linkage and the orthoester linkage. The rate of hydrolysis of acetals is first order relative to the concentration of the hydronium ion, and therefore, per unit decrease in pH, the rate of hydrolysis increases by a factor of ten. It is worth noting that the rate of hydrolysis can be tuned according to the structure of the acetal,[70] which can be useful for tuning the point at which hydrolysis occurs during endolysosomal trafficking. Similarly, the rate of hydrolysis of orthoesters also increases with the hydronium ion concentration, but the relationship is not first order and is therefore more difficult to predict. Highly potent disruptive polymers can be 'masked' with more inert carriers using these classes of linkages. One shortcoming is the potential toxicity due to the lack of reversibility relative to an anionic polymer that would revert to a more hydrophilic conformation following endosomal escape.

4.422.4.1. Encrypted Polymers

Murthy *et al.* developed one of the first designs of an endosomal-disruptive polymer drug delivery vehicle based on acid-degradable linkages, termed 'encrypted polymers.'[71,72] In this approach, the polymer contains a membrane-disruptive backbone connected to the other molecular species via acid-labile acetal linkers. A disulfide bond connects the acid-degradable linker to either PEG grafts or a therapeutic molecule. A targeting ligand for endocytosis can be attached to the PEG chains (**Figure 4**). In cases where the drug is not conjugated via a disulfide bond, ionic groups can be incorporated at the PEG terminus to complex with charged drugs (i.e., nucleic acids). In the intact polymeric configuration, PEG chains 'mask' the membrane disruptive potential of the backbone. However, once the pH of the maturing endosome drops, hydrolysis of the acid-degradable linker 'unmasks'

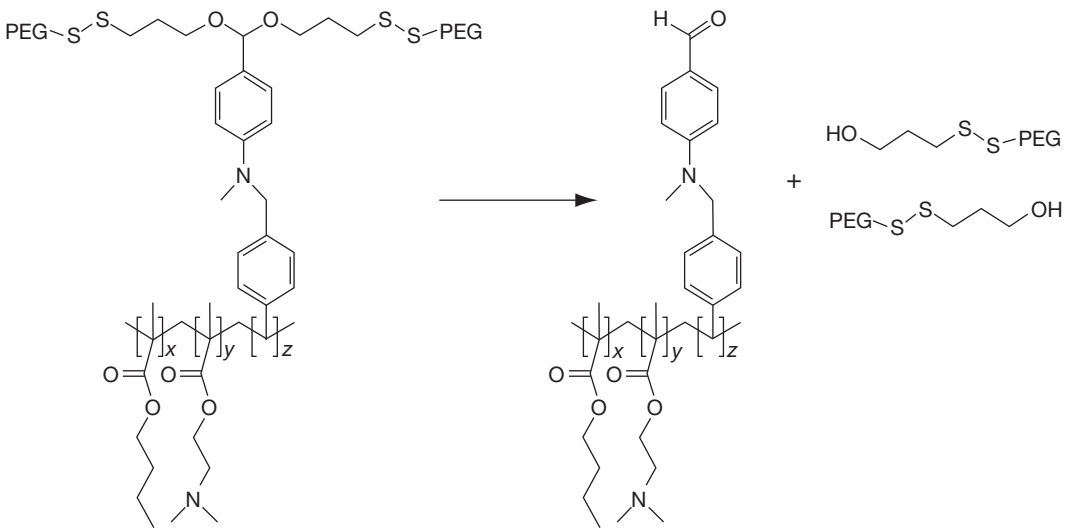

Figure 4 Chemical structure of encrypted polymers. Before hydrolysis, the membrane-disruptive backbone is 'masked' by PEG grafts through an acid-labile acetal linkage. As the pH drops, hydrolysis of the acetal 'unmasks' the backbone, leading to disruption of the endosome.

the backbone which disrupts the endosome and allows the drug to diffuse into the cytoplasm. Importantly, this design enables the development of polymers that are significantly more effective at membrane disruption compared to anionic pH-responsive polymers, because of the greater hydrophobicity and cationic content that can be incorporated into the polymer backbone. However, the synthesis of polymers containing acetal linkages is fairly challenging and limits the type of molecules that can be generated with the encrypted polymer strategy.

4.422.4.2. Buchwald Coupling-Based Vehicles

Knorr *et al.* developed an elegant strategy for generating endosomal-disruptive drug delivery vehicles, composed of polyethyleneimine (PEI) polyplexes, on the basis of the Buchwald coupling reaction.[73] Polyplexes of PEI with negatively charged DNA have been widely used because of their ability to shield DNA from serum degradation, stimulate endocytosis, and create the 'proton-sponge' effect to trigger endosomal escape (discussed in detail below). However, in order to achieve high gene transfer activity, an excess of cationic PEI is needed, which leads to toxicity. Knorr *et al.* were able to alleviate these side effects by neutralizing the polyplex surface using PEG chains incorporated into the formulation through acid-degradable acetal linkages. Similar to the previous encrypted polymers, the acetal link between the PEG and the PEI allows for removal of PEG units from the polyplexes as the pH drops, facilitating efficient endosomal disruption. The synthesis of the key intermediate needed to generate these complexes is shown in Figure 5 and uses the Buchwald–Hartig coupling reaction to substitute a PEGylated aromatic bromine with a protected piperazine. This key step also generates an aniline type acetal, which has rapid hydrolysis kinetics at acidic pHs.[70]

4.422.4.3. Acid-Cleavable Lipid Drug Delivery Vehicles

Natural lipids known as the plasmalogens contain vinyl ether linkages in their alkyl regions that are hydrolyzable at acidic pH. Plasmalogens can be utilized to achieve triggered release of liposomal contents at endosomal pH, and have been explored for over a decade for applications in drug and gene delivery.[74–76] Several newer synthetic types of lipids have also been developed that incorporate acid-degradable linkages. These lipids are designed to be stable at pH 7.4 but decompose at the acidic pH of the endosome to generate products that are membrane disruptive. For example, Guo *et al.* synthesized a PEGylated lipid that contains an orthoester linkage, via the route shown in Figure 6.[77] This lipid is stable in pH 7.4 buffer at 37 °C, but degrades at pH 5 within one hour, generating a lipid byproduct that is membrane disruptive. At pH 5.5, liposomes containing 10 mol% of this lipid released most of their contents within 30 min.[77]

4.422.5. Osmotically Disruptive Cationic Polymers

Another approach to achieve intracellular delivery has been the use of cationic, amine-containing polymers thought to facilitate endosomal release through osmotic disruption (e.g., the hypothesized 'proton-sponge' effect[78–82] first proposed by Behr and coworkers[78,79]). During normal endosomal trafficking, endolysosomes are acidified by the action of an ATPase-driven proton pump in the vesicle membrane (see Figure 7). If present within the vesicle, proton-accepting polymers buffer the acidic microenvironment and inhibit the normal drop in pH. This leads to a continued, abnormal influx of protons and their counter ions. The higher ion concentration increases osmotic pressure inside the vesicle, leading to water influx, swelling and disruption of the endosome, and release of its contents into the cytoplasm (see Figure 7). Although it is efficient for gaining cytosolic entry for therapeutics, proton-sponge-mediated endosomolysis has the potential to induce cytotoxicity because of release of endolysosomal enzymes along with therapeutic. Thus, there is a poorly understood, but critical balance that must be achieved between efficient therapeutic escape and the potential negative side effects of endolysosomal disruption (e.g., more escape may not always be 'better'). Nonetheless, a distinct requirement for endosomal disruption via the proton-sponge effect is buffering capacity of

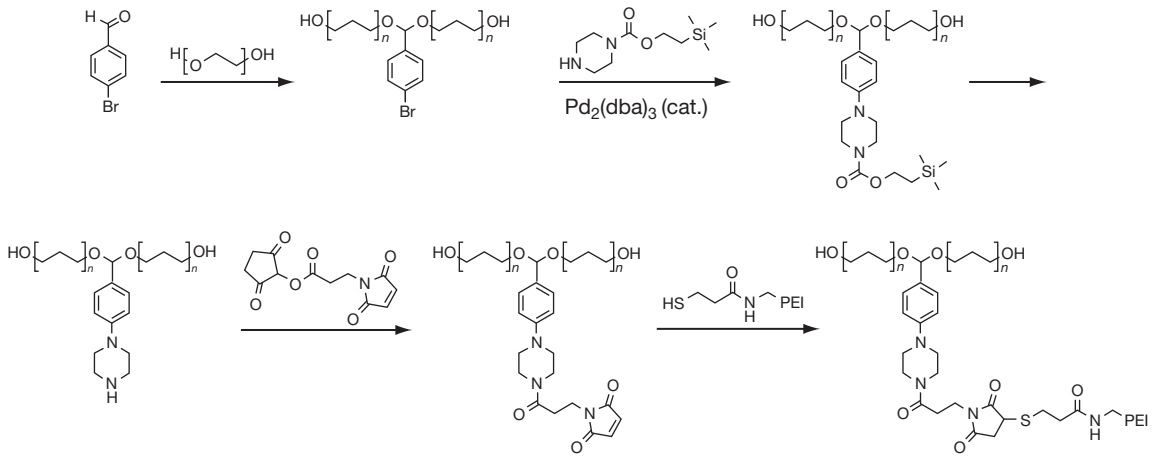

Figure 5 Buchwald–Hartig coupling for synthesis of an acid-cleavable PEI polyplex.

the polymer that matches the range of pH values present during endolysosomal trafficking (e.g., pH 7.4 to 5.0). Therefore, secondary, tertiary, and some quaternary amines are capable of mediating 'proton-sponge' endosomolysis. Primary amines (e.g., of poly(L-lysine) and PEI) are not considered to be active via this mechanism ($pK_a > 8.0$), but modifications to the architecture of these polymers can performed to lower the pK_a of the amines and render them endosomolytic.[83]

Cationic polymers whose mechanism is on the basis of the 'proton-sponge effect' have demonstrated efficient intracellular delivery of nucleic acid drugs[84–86] and proteins.[87–90] Somewhat serendipitously, these polymers were initially investigated as they were available commercially and able to complex negatively charged nucleic acids into readily internalized particles. These particles are overall positively charged and associate electrostatically with negatively charged plasma proteins, platelet and erythrocyte membranes, and glycosaminoglycans located on cell surfaces to permit nonspecific cell endocytosis.[91] However, the major drawbacks limiting therapeutic development of cationic polymers are their intrinsic cytotoxicity and serum instability *in vivo*. Therefore, current advances in cationic polymer development include development of chemical compositions that reduce or eliminate cytotoxic side effects while enhancing *in vivo* stability.

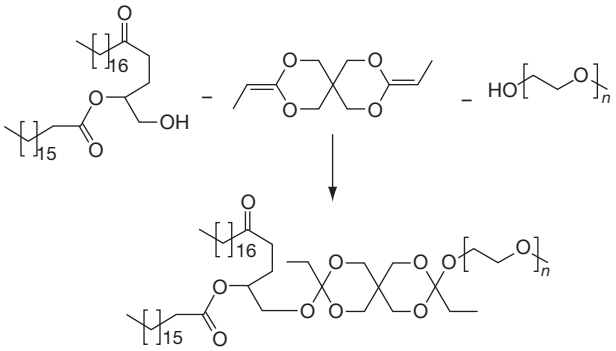

Figure 6 Synthetic scheme used by Guo *et al.*[77] for preparation of a lipid containing an acid-cleavable orthoester linkage.

4.422.5.1. Poly(L-lysine)

One of the first cationic polymers used for DNA delivery was poly(L-lysine).[92] Although poly(L-lysine) is able to complex DNA, its transfection activity is very low, requiring addition of endosomolytic agents such as chloroquine to modulate gene expression (see **Figure 8(a)**). Therefore, poly(L-lysine) has been relegated to use in mechanistic studies. However, these mechanistic studies have led to noteworthy contributions to the understanding of DNA/polymer complex formation,[92] targeting strategies,[93–105] and endolysosomal escape.[92,94]

4.422.5.2. Polyethyleneimine

PEI is the current gold standard cationic polymer for intracellular DNA delivery because of its proven efficacy. A variety of different polymers and copolymers of linear and branched architectures of PEI (see **Figure 8(b)** and **8(c)**) have been synthesized and utilized for biotherapeutic delivery. Branched PEI (bPEI) is highly endosomolytic because of its high density of primary, secondary, and tertiary amines, of which only 15–20% are protonated at physiological pH[106,107] (primary amine $pK_a \sim 9.0$, secondary amine $pK_a \sim 8.0$, and tertiary amine $pK_a \sim 6–7$), making it a buffering agent to weak acids and powerful proton sponge. However, linear PEI (lPEI) contains mostly secondary amines and is 90% protonated at physiological pH, limiting its ability to mediate 'proton-sponge' endosomolysis. Literature covering the use of PEI as a delivery agent is vast (see Lungwitz *et al.*,[84] Morille *et al.*,[108] Park *et al.*[109]); recent advances (published within the past ~10 years) are summarized herein.

PEI polymers have been used to effectively deliver oligonucleotides,[106,110] plasmid DNA (pDNA),[107,111,112] and Epstein-Barr virus-based plasmid vectors[113–117] as well as RNA, siRNA,[118,119] and intact ribozymes.[120] Not only has PEI had great success for *in vitro* macromolecular drug delivery, but it has also been utilized *in vivo* to deliver DNA to a variety of tissues, including the central nervous system,[121,122] kidney,[123] lung,[122,124] and tumors.[125] As detailed above, the amine-rich structure of PEI generates its endosomolytic activity. However,

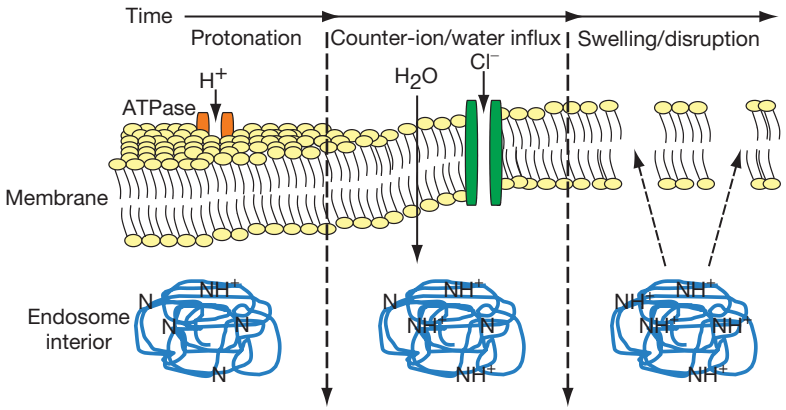

Figure 7 The 'proton sponge' effect. Upon endosomal uptake, ATPases pump protons (H^+) in to acidify the compartments, but secondary and tertiary amines on the proton-sponge polymers prevent acidification, leading to continued ion import. Concomitant counter-ion (Cl^- and others) influx into the endolysosomal vesicle creates an osmotic gradient, triggering water influx, vesicle swelling, and membrane rupture, releasing the polymer and drug cargo into the cytosol.

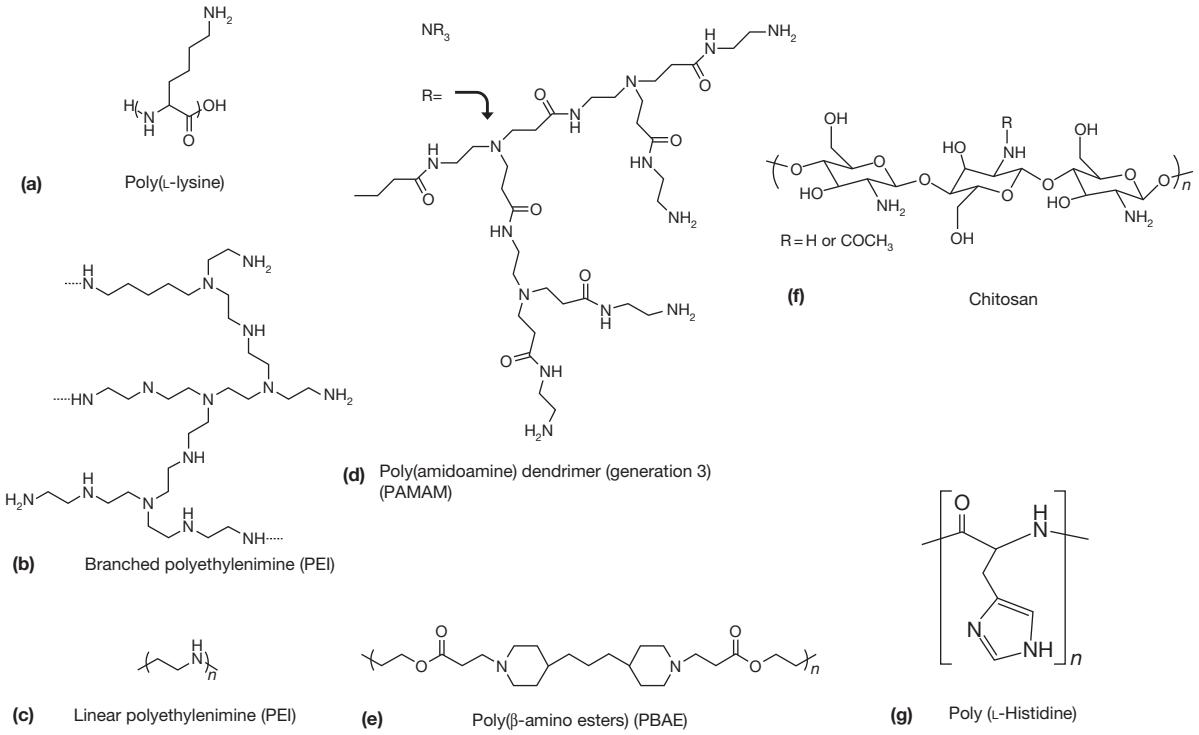

Figure 8 Structures of amine-containing, 'proton-sponge' polymers useful toward intracellular delivery of biomacromolecules.

the amines of PEI are also exploited for electrostatically condensing drug cargo (nucleic acids or anionic proteins) and to enhance uptake. More recent work has also exploited PEI's primary amines to conjugate macromolecular drugs[126] and/or other molecules that enhance endosomal escape or enable tissue-specific targeting.[28,98,127–130]

Linear PEI, as described above, contains mostly secondary amines that are protonated at extracellular pH and do not buffer the pH range present in endocytosis pathways. On the basis of this observation, one would hypothesize that bPEI would outperform lPEI for cytosolic delivery because it is a much better 'proton sponge' in the relevant pH range. However, gene delivery studies utilizing lPEI (MW = 22 kDa) showed greater transfection efficiencies and lower cytotoxicity compared to bPEI (MW = 25 kDa).[131,132] The greater efficiency of lPEI is hypothesized to be due to inherent kinetic instability of lPEI complexes under physiological salt conditions.[133] Efficient gene therapy using lPEI (MW = 22 kDa) has also been verified *in vivo* by a study showing significant and long-lasting (15 days or longer) expression of a reporter gene following injection directly into solid tumors using micropumps.[125]

Although remarkably potent with respect to intracellular drug delivery both *in vitro* and *in vivo*, PEI suffers from high levels of cytotoxicity, which has limited its translation into clinical use. Cytotoxicity associated with PEI is primarily attributed to necrosis and mitochondrial apoptosis activation.[134] In addition, *in vivo* experiments have revealed that free and bPEI/DNA complexes activate genes in the Th1/Th2 immune response and adaptive immune response.[135] Moreover, systemic administration of unshielded bPEI (800 kDa) was lethal in animal models.[136] Therefore, much of the recent developments in the arena of PEI polymer therapeutics are focused on abrogating cytotoxicity. For example, cytotoxicity can be moderated through the use of low molecular weight PEIs (5–48 kDa),[137–139] but increased overall polymer concentrations are needed to achieve comparable efficacy. Importantly, the lower molecular weight PEIs (~25 kDa) used at greater concentrations also improved serum stability relative to higher molecular PEIs, increasing their probability for success for *in vivo* therapeutic delivery.[138] Alternatively, many studies have explored conjugation of low molecular weight PEIs with degradable linkages such as amides, acetals, esters, and disulfides. This approach produces a polymer with lower toxicity and relatively high gene transfection efficiency, as well as long-term safety.[140–143] Others have altered the amines to contain other molecules, such as poly(ethylene glycol), imidazole, or peptides to reduce toxicity of PEI while maintaining effective intracellular delivery.[82,118,144,145]

4.422.5.3. Poly(amidoamine) Dendrimers and Polymers

Dendrimers are synthetic, spherical, highly branched macromolecules of nanometer dimensions (see **Figure 8(d)**). The size and the charge of these polymers are controlled by varying the number of generations or branches in the polymer synthesis.[146] Because of the large number of secondary and tertiary amines on the polymer, poly(amidoamine) (PAMAM) dendrimers, in particular, are potent weak bases and proton sponges. Haensler and Szoka originally reported the use of PAMAM dendrimers for gene delivery.[147] They found that the sixth generation dendrimer was better at gene delivery than higher and lower generations by 10-fold. Because of their relatively high gene delivery efficiency, PAMAM dendrimers have recently been used in several *in vivo* gene delivery

studies.[148–151] However, there are conflicting reports regarding their biological safety.[152,153] The cytotoxicity of PAMAM dendrimers is similar to PEI: necrosis and mitochondrial apoptosis activation. To reduce these unintended side effects, Wang *et al.* decorated PAMAM with poly(ethylene glycol) (PEG) chains, resulting in 12–105-fold increases in the IC50 values with PEG versus undecorated PAMAM.[154] The level of cytotoxicity was inversely related to the molecular weight of the PEG conjugated to the dendrimers, but longer PEG had a negative effect on cellular uptake. For example, greater than 90% of the cells internalized dendrimers functionalized with 2 kDa PEG compared to only ~60% when 5 kDa PEG was used. This finding again highlights the critical balance between activity and cytotoxicity of cationic macromolecular carriers and serves further motivation to pursue systems actively targeted for receptor-mediated endocytosis. In addition, PAMAM dendrimers have been partially degraded at their amide bonds and found to be more effective DNA delivery polymers (> 50-fold enhancement of transfection activity)[155] compared to intact dendrimers. PAMAM dendrimers have also been modified with 3.5 kDa PEG containing a mannose or galactose unit for cell surface receptor targeting.[156] These hybrid polymers self-assembled with DNA and presented the targeting moiety on the outer shell, which enabled improved transfection over PEI. Although the authors did not posit a reason for enhanced activity, the hybrid, multifunctional nature of the dendrimers provided facile means to tune carrier properties to optimize blood stability, cellular targeting, DNA binding, and endosomal buffering capacity.

4.422.5.4. Poly(β-amino esters)

Poly(β-amino esters) (PBAEs) are very recent additions to the growing list of pH-responsive polymers. PBAE are structurally similar to the PAMAM polymers discussed above and have been formulated into hyperbranched dendrimer structures as well.[157] Formulations of PBAE polymers have been used for intracellular delivery of nucleic acids, including siRNA[158] and DNA.[159–172] PBAE have very interesting and unique properties that make them favorable toward drug delivery. PBAE are insoluble at physiological pH and can be formulated into micron-sized particles for drug delivery. On the basis of their size, PBAE particles accumulate in the tumor microenvironment through either vascular filtration or extravasated via the EPR effect. Although PBAEs are not soluble at physiological pH, they rapidly dissolve upon exposure to a slightly acidic pH of 6.5, and once solubilized, PBAEs (shown in **Figure 8(e)**) have tertiary amines that serve as powerful proton sponges. PBAEs are also desirable because they decompose into cytocompatible, low molecular weight degradation products, diols and bis(β-amino acids), and, therefore, are significantly less toxic than PEI and poly(L-lysine).[81] A library of PBAE polymers has been screened to find molecular parameters that support efficient transfection.[159–161] Although effective compositions were identified, no clear design criteria were identified, and the role of some key factors (i.e., molecular weight and charge density) were not comprehensively investigated. For example, the top 5% most effective carriers of the 486 compositions examined for delivery of a luciferase reporter gene to COS-7 cells ranged in molecular weight from ~5 to ~50 kDa. All of these carriers condensed DNA into sub-150 nm particles with positive surface charges. Moreover, the top nine performers had very similar structures, providing a framework with which PBAE carriers can be further modified to fulfill other design criteria required for *in vivo* delivery of nucleic acid drugs (circulation time, targeting, dosing).[173]

4.422.5.5. Chitosan

Chitosan, a naturally derived polysaccharide obtained by deacetylation of chitin, is composed of two subunits, D-glucosamine and *N*-acetyl-D-glucosamine, linked by a 1-4 glycosidic linkage (see **Figure 8(f)**). Chitosan is a nontoxic, biodegradable, and renewable polymer with a long history of use in drug delivery for the entrapment of enzymes[174,175] and controlled release of proteins.[176–179] In addition, because of its disaccharide composition, chitosan contains several primary and secondary amines capable of endosomolysis via the 'proton-sponge' effect. Therefore, chitosan has been examined as a pH-responsive drug delivery polymer,[180–185] mostly for nucleic acid-based therapeutics. In particular, low molecular weight chitosan (LMWC) has been most extensively explored because high molecular weight chitosan polymers are insoluble in aqueous solutions at physiological pH. LMWC interacts with DNA to form complexes that efficiently protect it from degradation by DNase I. Chitosan also exhibits greater gene delivery efficiency and lower cytotoxicity than PLL.[109] However, even LMWC suffers from relatively poor solubility in physiological buffers and lower endosomolytic activity compared with PEI. To augment its drug delivery activity, modification of chitosan with a variety of chemical moieties has been a recent area of interest to provide better endosomal escape and solubility. For example, PEI has been conjugated to chitosan to enhance endosomal escape properties, enabling 10–100-fold increases in transfection efficiency in a variety of cell lines.[186] Chitosan has also been modified with lactose through reductive amidation to target drug uptake through the asialoglycoprotein receptor of hepatocytes. However, lactosylated chitosan failed to enhance transfection of a hepatocyte cell line, which was attributed to insufficient cell membrane interaction needed for ligand–receptor binding because of reduced surface charge of the modified carrier.[187] Imidazole-functionalized chitosan (MW = 130 kDa) resulted in a more potent pDNA and siRNA carrier, largely attributed to increased solubility at physiological pH and 'proton-sponge' capability due to introduction of additional secondary and tertiary amines within the polymer backbone.[188] Imidazole-functionalized chitosan was further modified with PEG to inhibit serum-induced aggregation *in vivo*.[189] The PEGylated imidazole-chitosan was found to be highly efficient in delivering bioactive siRNA in a mouse model, resulting in up to 50% gene silencing in lung and 40% gene silencing in liver. Importantly, this carrier exhibited minimal cytotoxicity or other adverse side effects *in vivo*, indicating great promise for further development into a clinically relevant nucleic acid delivery system.

4.422.6. Histidine- and Imidazole-Containing Copolymers

Histidine (His) is an amino acid with an imidazole side chain containing a secondary amine that makes His a weak base

(Figure 8(g)). Protonation of this amine on poly(His) or synthetic imidazole-containing polymers in acidic environments provides membrane fusogenic properties with negatively charged liposomes[190] and makes it useful as a biocompatible drug delivery tool because of its 'proton-sponge' activity.[191] Like the other proton-sponge polymers, poly(His) was initially sought for its ability to enhance cytoplasmic access of pDNA for gene therapy. With the aim of achieving biocompatible systems made of natural amino acids, lysine (Lys) and His have been utilized in numerous successful combinations because the high pK_b of the primary amines on Lys makes it cationic and efficient at condensing nucleic acids at physiologic pH, while the lower pK_b of His provides endosomal buffering.

Midoux, Monsigny, and coauthors made some of the earliest advances toward improving poly(Lys)–DNA complex transfection efficiencies using a histidine-rich peptide[192] or by delivery using a poly(L-lysine) (degree of polymerization = 190) partially substituted with histidine residues.[193] In the later study, substitution with 72 ± 9 histidyl residues (38% substitution of the Lys primary amines) was found to produce the best transfection, and these carriers were also found to maintain their activity in the presence of up to 20% serum. Approximately 1.5 times better transfection efficiency and significantly higher biocompatibility (~90% versus ~40% viability) have also been achieved in 293 T cells using poly(His) grafted to poly(Lys) relative to poly(Lys) alone (20:1 polymer:DNA weight ratio for both). However, chloroquine increased transfection efficiency for both polymers, indicating that even grafting of His polymers did not produce optimal endosomal escape.[194] Langer and coauthors have also explored imidazole-containing systems for gene delivery. One approach incorporated glycosylated poly(His) (glycosylation was performed to increase water solubility at physiologic pH) into ternary complexes with DNA and transferrin-functionalized poly(Lys) used for complexation and receptor-mediated uptake.[195] They also synthesized both poly(His)–PEG block polymers and polymer combs of PEG grafted to a poly(His) backbone.[196] Although they did show promise, none of these carriers resulted in transfection efficiencies equivalent to control formulations using 25 kDa PEI. However, in another study similar to the earlier approach by Midoux *et al.*, 73.5, 82.5, and 86.5 mol% imidazole substitution of the primary amines was performed on a 34 kDa poly(Lys). This same approach was utilized to optimize the balance between cationic content and endosomal escape functionality, and the most substituted polymers (86.5 mol% imidazole content) produced similar protein expression as PEI in several cell lines *in vitro* with significantly less cytotoxicity (e.g., ~100% viability for modified polymer versus <25% viability for PEI for the median polymer concentration tested using an MTT viability assay).[197] Mixson and coauthors have also explored a variety of histidine–lysine (HK) copolymers with varying branching and H/K ratio, and they have found that optimal polymer architecture (linear vs. branched) may vary based on cell type because of differences in the pH of endocytotic vesicles.[198,199] Mixson's group more recently derived highly branched HK polymers that were efficient siRNA carriers,[200] and effective siRNA delivery has also been shown in hepatocytes using a His-containing reducible polycation designed to effectively unpackage the siRNA in the reducing environment of the cytoplasm.[201] Histidine has also been used to modify chitosan through reducible disulfide bonds[202] and covalent amide linkages[203] to enhance endosomal escape and increase transfection efficiency.

Use of poly(His) to facilitate delivery of small molecule drugs is a relatively unique application compared to other proton-sponge polymers. In a chemotherapeutic drug delivery application, paclitaxel was successfully delivered intracellularly using *N*-acetyl histidine-conjugated chitosan self-assembled nanoparticles.[204] Histidines have also been extensively used in micelle carriers, and Bae's group has prolifically contributed to poly(His) applications in this context. Their initial effort was aimed at micelles that release their payload in the slightly acidic extracellular environment common to hypoxic solid tumors. In this application, a 5 kDa poly(His) was coupled to a 2 kDa PEG to form a diblock polymer. This polymer was found to produce stable micelles at pH 8 that were destabilized below 7.4 as the imidazoles in the micelle core became increasingly protonated and hydrophilic.[205] A follow-up study focused on intracellular delivery of chemotherapeutics using a mixed micelle carrier composed of a diblock polymer with 5 kDa poly(His) and 2 kDa PEG and a diblock polymer with 3 kDa poly(L-lactic acid) (PLLA) and 2 kDa PEG.[206] The poly(PEG-*b*-PLLA) was employed in conjunction with poly(PEG-*b*-His) to increase the hydrophobicity of the micelle core, and the PEG end of the poly(PEG-*b*-PLLA) was conjugated to folate to target the micelles for receptor-mediated endocytosis in cancer cells that overexpress the folate receptor. It was determined that the mixed micelles with 25 wt% poly(PEG-*b*-PLLA) and 75 wt% poly(PEG-*b*-His) had optimal pH-responsive properties. This formulation shifted the pK_b of the His imidazole to be better tuned to respond in the lower pH of the endosomes while also increasing micelle stability at pH 7.4, which is key for *in vivo* systemic delivery applications. Further physicochemical characterization verified that progressive protonation in acidic environments increases hydrophilicity and electrostatic repulsion of imidazole rings, which overwhelms the hydrophobic interactions in the core of the micelle.[207] Scale-up and clinical applicability of this micelle system were also shown to be feasible on the basis of the stability and activity of reconstituted particles lyophilized in the presence of 33 wt% Pluronic F127 copolymer as an excipient.[208]

The folate-targeted mixed micelle was subsequently applied in numerous studies aimed at chemotherapeutic delivery to multidrug resistant (MDR) cancer cells. These cells overexpress drug efflux pumps, and targeted uptake of drugs via endocytosis (i.e., the folate receptor pathway) is believed to circumvent this delivery challenge. Thus, the combination of folate targeting with poly(His) proton-sponge activity was the key approach for efficient intracellular delivery. In an initial application, this strategy produced more than 90% cytotoxicity in doxorubicin resistant MCF-7 cells at 10 μg ml^{-1}, while free doxorubicin had no effect on viability of MCF7s at this dose. In an *in vivo* tumor inhibition study, the folate-targeted pH-responsive mixed micelles produced 2.7-times smaller tumors than free doxorubicin and 1.9-times smaller than non-pH-responsive poly(PEG-*b*-PLLA) control micelles. The targeted micelles produced 20-times greater doxorubicin accumulation in the tumor relative to free doxorubicin and also

decreased body weight loss relative to free drug, indicating decreased systemic toxicity.[209] In a subsequent mechanistic study examining drug retention, MDR cells pulsed with the pH-responsive doxorubicin micelles for 30 min *in vitro* retained 80% of the drug after 24 h while control micelles without the pH-responsive component retained only 40% of the drug.[210] Subsequent studies verified the ability of the folate-targeted, pH-sensitive mixed micelles to inhibit MDR ovarian A2780/DOX^R xenograft tumors, which were fivefold smaller than free doxorubicin controls after 27 days.[211]

Bae and coauthors recently developed a second generation mixed micelle carrier composed of poly(PEG-*b*-(His-*co*-phenylalanine (Phe))) and poly(folate-PEG-*b*-PLLA). Relative block sizes were the same as in the first generation system, but further control over the pH buffering range of the histidine was achieved through varying the ratio of His and Phe in the copolymer block. In this study, it was found that a copolymer with 16 mol% Phe buffered the pH range from 7.6 to 4.7 and produced optimal *in vitro* results.[212] In an *in vivo* study, mixed micelles with 80 wt% poly((His-*co*-Phe)-*b*-PEG) (5 kDa His-*co*-Phe and 3 kDa PEG) and 20 wt% poly(folate-PEG-*b*-PLLA) (2 kDa PEG and 3 kDa PLLA) were tested in an MDR ovarian tumor xenograft model. Three IV injections of 10 mg kg^{-1} doxorubicin were given at 3-day intervals, and the mice delivered this dose using the pH-responsive micelles (loaded at 20 wt% doxorubicin) had an average tumor size of 300 mm^3 at day 50. The free doxorubicin controls, on the other hand, were euthanized on day 27 because tumor sizes had reached approximately 3000 mm^3.[213] Finally, other authors have recently developed histidine-containing mixed micelle systems that achieve pH-sensitive drug release and proton-sponge activities.[214–216] Tsai and coauthors developed one of the most noteworthy, comparable systems using mixed micelles composed of poly(HEMA-*co*-histidine)-*g*-PLA and the diblock copolymer PEG–PLA. In an *in vivo* study, an equivalent dose of 5 mg kg^{-1} doxorubicin was given three times at 5 day intervals using these micelles with folate targeting. This treatment inhibited tumor volume by up to 80% relative to untreated controls at day 25 while free doxorubicin inhibited tumor growth by only 40%.[216]

4.422.7. Fusogenic Peptides

Naturally occurring peptide sequences derived from bacterial toxins and viruses and synthetic analogues of these peptides have also been rigorously exploited as pH-responsive, endosomal-disruptive agents. Design cues from natural systems are logical to follow because, although intracellular biomolecular drug delivery has proven to be an immense challenge for pharmaceutical scientists, microorganisms have evolved over millennia to possess efficient mechanisms for transport of peptide toxins and genetic material into eukaryotic cells. One example is the diphtheria toxin produced by *Corynebacterium diphtheria*, which possesses a pH-responsive fragment that forms transmembrane pores in endosomes that enable entry of a disulfide-linked toxin fragment into the cytosol.[217–225] Other examples include the melittin peptide derived from bee venom[226] and the influenza viral protein hemagglutinin, which can mediate pH-dependent fusion of the virus with the endosomal membrane to enable delivery of the viral genetic material into the cytoplasm.[227–233] A multitude of other fusogenic proteins have also been tested, including synthetic hemagglutinin derivatives, model amphipathic peptides (MAPs), β-amyloid transmembrane protein derivatives, and a family of fusion-associated small transmembrane (FAST) proteins (i.e., the p10 avian reovirus, the p14 reptilian reovirus, and the p15 baboon reovirus).[48,234–238]

Another class of peptides called cell-penetrating peptides (CPPs) has some overlap with the pH-responsive, fusogenic category. The initial discovery that the trans-activating transcriptional factor (TAT) of HIV-1 can penetrate cell membranes[239,240] was followed shortly thereafter by the description of the *Drosophilia*-derived antennapedia (also known as penetratin)[241] that triggered the development of a new research field focused on development of CPPs for intracellular drug delivery. The fact that CPPs can cross biological membranes at physiologic pH has motivated exploration of their ability to transport cargo such as pDNA, siRNA, antisense oligonucleotides, proteins, antibodies, peptides, small molecule drugs, nanoparticles, and contrast agents into cells (see recent CPP reviews[242,243]). CPPs are composed of a diversity of peptide sequences, some of which are highly cationic while others are amphipathic structures, and their precise mechanism of internalization is controversial. Strong evidence suggests that there are, in fact, multiple modes of uptake including membrane fusion and translocation directly into the cytosol in addition to vesicular pathways such as endocytosis or macropinocytosis, which can lead to entrapment in endosomes.[243,244] In this vein, it has been demonstrated that low levels of cytosolic activity of drug cargo are achievable using CPPs alone. However, bioactivity suffers from vesicular sequestration, which is supported by evidence that endosome-releasing polymers and peptides can increase cytosolic delivery of CPP conjugates and fusion proteins.[61,245–249] Alternatively, Lundberg and coauthors have shown that it is possible to directly increase the endosomal escape potential of the CPP itself in order to circumvent the need for additional drug components. Using this promising strategy, they made a synthetic analogue of penetratin called EB1 that was strategically substituted with His amino acids to achieve pH-responsive endosomolysis. This synthetic variant was found to significantly improve the therapeutic efficacy of siRNA compared to other CPPs tested.[250]

4.422.7.1. GALA

Because the peptide GALA is one of the most extensively characterized synthetically engineered fusogenic peptides,[251] a more in-depth discussion will be dedicated to this model peptide. The thorough mechanistic understanding of the pH-responsive membrane activity of GALA can be used as a model to lend insight into the biophysical properties of other less well-characterized fusogenic peptides. GALA is a 30-amino acid (AA) sequence (WEAALAEALAEALAEHLAEALAEALEALAA) possessing repeats of glutamic acid-alanine-leucine-alanine (Glu-Ala-Leu-Ala or EALA). The Glu-Ala-Leu-Ala repeating structure was innovatively engineered by Szoka *et al.* to possess a combination of charged/acidic (Glu), spacer (Ala), and hydrophobic (Leu) AAs that impart pH-dependent structure–function properties that mimic fusogenic viral proteins to form pores in

membranes under acidic conditions.[252–254] Near neutral pH, Glu residues exist predominantly in an ionized state, making GALA hydrophilic and creating intramolecular charge repulsion that causes the peptide to adopt an extended state. When exposed to the slightly acidic endosomal environment, Glu residues ($pK_a \sim 6$) are protonated, which transforms GALA into a more hydrophobic state with decreased anionic charge density and triggers the peptide to adopt an amphipathic α-helical structure[254] (**Figure 9**). Within this helix, the Glu residues form a hydrophilic α-helical face, and the Leu residues localize to the opposing, nonpolar face.[252] This amphipathic helix is able to interact with lipid bilayers in an orientation parallel to the membrane, and it subsequently self-aggregates and reorients into a pore perpendicular to the membrane surface once a critical number of approximately 10 peptide chains have oligomerized.[255–257] These pores, which generate pH-dependent lipid vesicle leakage, are lined on the interior with hydrophilic Glu residues while the more hydrophobic amino acids associate with the alkyl chains that constitute the interior of the lipid bilayer.[252,253,255] One potential limitation of GALA is that cholesterol content and some phospholid compositions can reduce pore formation.[258,259] However, more recently, new derivatives of GALA have been created that are activated earlier in the endosomal pathway at a higher pH (i.e., pH 6–7 versus pH < 6 for GALA), and these variants have also improved performance in cholesterol-containing membranes.[260]

GALA has been predominantly applied as a constituent of nonviral vectors for nucleic acid delivery, and Haensler and Szoka were the first to apply GALA for pDNA delivery.[147] GALA was conjugated to cationic PAMAM dendrimers (10–13 GALA per dendrimer used in a 1:1 ratio with unmodified dendrimer) to enhance endosomal escape of plasmids electrostatically complexed with PAMAM. Using a luciferase plasmid as a reporter system, the authors found that inclusion of GALA on the dendrimers improved transfection for all seven cell types tested. For some cells (i.e., fibroblast (CV-1), leukemia (K562), and hepatocyte (HepG2) cell lines), luciferase activity increased by four orders of magnitude in GALA-containing dendrimers relative to unmodified PAMAM. Subsequently, Simoes and coauthors used cationic liposomes to electrostatically complex GALA (anionic due to Glu residues) into ternary (lipid/GALA/DNA) and quaternary (lipid/GALA/DNA/transferrin) systems.[261–263] They initially developed a ternary system formed by cationic lipids complexed with GALA followed by plasmid condensation to form a net negatively charged carrier, and it was found that this approach produced a fourfold increase in luciferase production relative to controls.[261] A follow-up, mechanistic study found that GALA enhancement of transfection was inhibited by bafilomycin, a drug that inhibits endosomal acidification, verifying the key contribution of pH-dependent GALA activity.[262] Subsequently, a quaternary system that also included the targeting ligand transferrin was developed and shown to successfully transfect human macrophages, a particularly difficult target for nonviral gene therapy due to their potent lysosomal degradative activity.[263] The quaternary complex performed better than two control ternary systems (lipid/DNA/transferrin and lipid/GALA/DNA) and better than an alternative quaternary complex containing the influenza-derived fusogenic peptide, HA-2, as an alternate to GALA. However, a primary shortcoming of using multiple, electrostatically complexed components was exemplified by the significant falloff in activity observed in the presence of serum.

The Harishima laboratory has produced the most recent advances in the use of GALA in liposomal drug delivery.[264–269] An early application involved mixing GALA with commercially available cationic liposomes. This resulted in as much as a fivefold increase in transfection efficiency in some conditions tested, further illustrating the efficacy of GALA for enhancing cytoplasmic delivery.[265] In other studies, GALA was derivatized with cholesterol (chol-GALA) in order to anchor GALA to the surface of the liposome. Chol-GALA efficiently mediated diffusion of the model molecule rhodamine from the liposomal carrier into the cytosol of treated cells (while GALA encapsulated within the liposomal aqueous interior did not).[264] In subsequent iterations of this carrier, transferrin was covalently linked to the liposome surface to target the liposomes for cell uptake. This targeted system effectively delivered nucleic acids (plasmid and siRNA) and the antitumor peptide, mastoparan.[267–269] Enhanced *in vivo* circulation time and production of smaller, more homogeneous particles were also achievable through carrier surface PEGylation. Not surprisingly, it was found that attachment of PEG chains to the liposomal surface inhibited activity of GALA anchored in

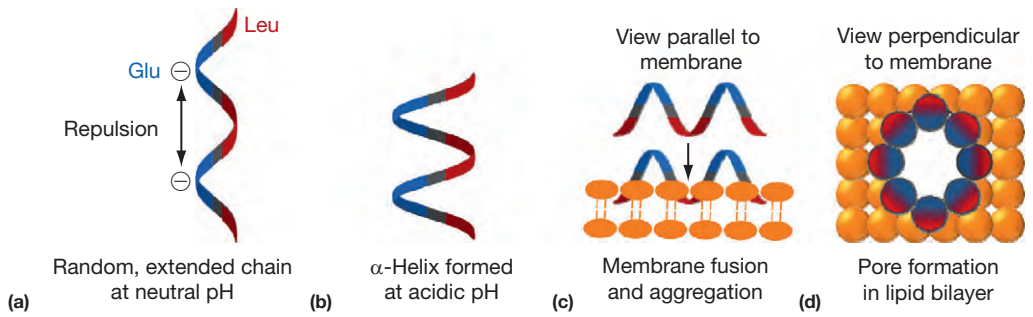

Figure 9 Schematic illustration of GALA pH-dependent activation. (a) The Glu residues in GALA extend the peptide backbone at neutral pH but are protonated at acidic pH, triggering the peptide to adopt an alpha helix structure (b). The GALA alpha helix is amphipathic in nature and (c) initially interacts and aggregates parallel to the lipid bilayer. (d) When a critical number of peptides aggregate (estimated to be 10), they self-assemble into a transmembrane channel with polar Glu residues lining an aqueous pore that allows biomacromolecule diffusion across the bilayer.

the membrane.[267] However, activity could be restored when GALA functionalization was present both on the lipid membrane and on the free PEG chain ends[267] or by using reversible PEG attachments removed in matrix metalloproteinase-rich environments.[268]

GALA peptides have also been utilized for delivery of therapeutic proteins. One of the first applications was by Anderson and coworkers who covalently conjugated GALA to the Fab fragments of an antitumor antibody with the goal of enhancing cell–surface interactions, tumor retention time, and therapeutic functionality.[270] Although their application did not exploit the pH-responsive properties of GALA for cytoplasmic delivery, it did prolong cell-surface antibody retention of the protein in human melanoma cells (although this effect was not as apparent in a similar colon carcinoma application). More recently, Kuehne and Murphy conjugated GALA to OKT9, an antibody against the transferrin receptor, with the ultimate goal of targeted, intracellular delivery of cancer-killing immunotoxins.[271] Optimal performance was achieved with 2–3 GALA peptides per therapeutic antibody, although a sevenfold greater concentration of GALA in the OKT9 conjugate form was required to cause 50% leakage compared to free GALA. Inclusion of a flexible PEG spacer between GALA and OKT9 did not rescue pH-dependent activity, although the potential negative effect of the hydrophilic linker on membrane interactions was not addressed. In a recent study, Kobayashi *et al.* tested the ability of biotinylated GALA to achieve cytoplasmic delivery of avidin (serving here as a model protein) and quantum dots (QDs) surface functionalized with streptavidin.[272] Cellular uptake for these systems was enhanced by electrostatic formulation with a commercially available cationic liposome transfection agent. Four GALA peptides per avidin improved cytosolic delivery of the model protein, and GALA functionalization of the QDs decreased their colocalization with lysosomes. However, QD staining remained punctate, and it was not apparent whether decreased presence in lysosomes was due to altered intracellular trafficking or the inability of QDs to escape through small GALA-formed pores in the endolysosomal membranes. Thus, additional work will be needed to further elucidate and develop GALA-induced cytosolic delivery of QD imaging probes.

The most recent developments incorporating GALA functionality have involved its incorporation into genetically engineered proteins. Wang and coauthors recently engineered a biomimetic protein consisting of GALA, a DNA-condensing set of histone H2A repeats, a cathepsin cleavable motif (that separates the targeting ligand and its potential steric hindrances once the full construct reaches the cathepsin-containing endosomes), and a HER2 receptor cancer cell surface targeting motif.[273] This novel application showed the importance of GALA activity in achieving gene transfer using this approach and serves as a starting point for development of future biosynthetic vectors with perfectly defined, monodispersed compositions and architectures that may prove to be advantageous to the chemosynthetic approaches utilized previously. Another recent, novel approach employed GALA as a component in an engineered protein designed to produce pH-sensitive 'nanocages' that, after further development, may serve as a new type of acid-induced molecular switch.[274]

4.422.8. Future Perspectives

Significant promise exists for expanding the number of pharmaceutically druggable targets using peptide-, protein-, and nucleic acid-based macromolecular therapeutics to overcome classic delivery challenges presented by small molecule drugs. However, application of these high molecular weight and polar molecules is precluded by substantial delivery hurdles. As we have reviewed in this chapter, primary delivery goals include providing mechanisms for cellular uptake and endosomal escape. Although pharmaceutical scientists have developed innovative pH-responsive polymers that can overcome these hurdles, numerous other design criteria must be optimized before these technologies can be translated into the clinic. Major limitations to the clinical translation of pH-responsive polymers include low transfection efficiency, toxicity, lack of stability and desirable pharmacokinetics *in vivo*, and difficulty with scaling up the complex synthesis and purification procedures required for incorporating drug, pH-responsive polymer, and targeting agents.

Because delivery efficiency of polymer systems still remains very low compared to that of viruses, endosomolytic carriers must be developed that are exquisitely potent in achieving biomolecule cytoplasmic delivery. For example, if one assumes that a single drug carrier is internalized into a spherical endosome of 200 nm diameter,[275] the pH-responsive agent would need to be activated by a modest environmental change of approximately 2 pH units to produce endosomal disruption at a concentration of less than 400 nM. This 'thought exercise' only accentuates one of the primary challenges in these applications; pH-responsive carriers must be sufficiently potent to robustly and reliably produce activity under these conditions while avoiding carrier-induced toxicity, immunogenicity, serum instability, and steric hindrance of biomolecule activity.

Multiple carriers have approached virus-like potency, but there is often a correlation between their activity and toxicity. PEI is a good example that has encountered great difficulties in balancing the trade-off between toxicity and transfection efficiency. Recently, a zwitterionic, biodegradable delivery system has been developed that exhibits similar activity to PEI, but this carrier hydrolytically degrades into completely nontoxic byproducts.[276] This approach and others are generating new promise that potent, nontoxic synthetic delivery systems are achievable for delivery of nucleic acids.

The complex but necessary chemistry involved in assembling endosomal-disruptive agents with the targeting agent and drug involves either assembling a micelle or nanoparticle that contains all components or performing sequential conjugation reactions between three independent macromolecules. Both approaches are technically challenging and can have difficulty in characterizing and purifying, making the production of well-defined, monodispersed formulations one of the major challenges in pharmaceutical development. Fortunately, controlled radical polymerization techniques such as a RAFT[43] and atom transfer radical polymerization (ATRP)[277,278] have enhanced the ability of polymer chemists to achieve precise molecular weight control, monodispersity, well-defined (i.e., block and other) architectures, and incorporation of site-specific, chemoselective conjugation chemistries. Furthermore,

there are a number of new, selective, orthogonal chemistries, that is, site-specific 'click' chemistries[279–282] that enable rapid and precise conjugation of constituent parts of the polymer therapeutic with high efficiency. These tightly controlled and highly efficient approaches can improve quality of the final product and decrease the number of synthetic steps required, making mass production more feasible.

Finally, although pH-responsive carriers address intracellular delivery of therapeutics *in vitro*, they often do not account for the multitude of new challenges that are present *in vivo*. Delivery systems must be equipped to perform in the harsh *in vivo* environment, which is more chemically complex and biologically diverse than *in vitro* cultures. For systemic intravenous delivery, drugs must be equipped to effectively modulate their interactions with thousands of different blood proteins. For example, binding of serum proteins 'marks' drug carriers for removal from the body through the macrophages of the reticuloendothelial system (i.e., liver).[283,284] PEG functionalization is the primary method used to reduce protein adsorption and subsequent carrier clearance. In a promising new approach, Huang *et al.* recently found that optimally sized (~100 nm), stable liposomes could be generated using PEG functionalization and that high density but 'sheddable' surface PEGylation may be key to improving tumor accumulation. In these studies, a previously unprecedented 70–80% injected dose per gram of tissue biodistributed to xenograft tumors, and effective silencing of tumor genes was achieved at impressively low (i.e., $<1\ mg\ kg^{-1}$) siRNA doses.[285–287] Although the generalized applicability is clearly limited, another approach has been to design systems that promote interactions with serum proteins (i.e., apolipoprotein E) in order to use them as endogenous targeting ligands to improve targeting and uptake in the liver.[288] In addition to opsonization in the blood, electrostatically complexed drugs (e.g., nucleic acids) can also be quickly replaced with other anionic molecules (heparin, glycosaminoglycans, etc.) in the extracellular environment. These competing interactions can destroy the integrity of the formulation and produce 'naked' drug delivery that leads to very little therapeutic efficacy, thus making the microenvironment within the targeted tissue another important consideration.[289]

The complexity of diverse *in vivo* delivery barriers further underscores the importance of controlled-polymerization strategies to provide novel synthesis of well-defined chemoselective conjugation chemistries that might better address challenges. Because these chemistry techniques enable synthesis of highly reproducible and controlled (e.g., monodispersed) polymer therapeutics, they are expected to lead to more reliable and predictable structure–function relationships that may enhance the probability of improved performance both *in vitro* and *in vivo*. As synthetic advancements continue to emerge in this area, it will also be vital that great emphasis is placed on assembling interdisciplinary teams (e.g., pathologists, medicinal chemists, polymer chemists, oncologists, clinicians, etc.) well equipped to identify and solve the diversity of drug delivery challenges. With this more comprehensive approach, a complete set of design criteria can be carefully identified and incorporated into carriers during the initial development stages. This will lead to biomacromolecular drugs better optimized for specific medical applications and will aid in the continued evolution of pH-responsive polymer therapeutics toward clinical reality.

4.423.1. Introduction

Synthetic polymers have been utilized broadly in biomedicine, including temporary assisting materials such as sutures, dressing grafts, tissue regeneration scaffolds, permanent implants, and drug delivery vehicles. Polymeric materials used in such applications share common properties, for example, biocompatibility, low immunogenicity, renal clearance without causing kidney failure, and stability in physiologic conditions.[1–5] Ever since Ringsdorf established the concept of polymers as pharmacologically active drug carriers,[6] many have focused on designing macromolecules as drug delivery matrices. Colloidal encapsulants (liposomes, microspheres, nanospheres, micelles), polymeric complexes, polymer–drug conjugates, and polymers as prodrugs are classes of matrices already reported (**Figure 1**). These polymers improve the drug-loading efficiency, solubility, specificity, and constancy of serum concentration of drugs, as well as the circulation time of biomolecular drugs (i.e., protein/peptides, DNA, and RNA) (see **Chapter 4.403, The Innate Response to Biomaterials**).

The first polymer–drug conjugate was reported by Jatzkewits in 1955, in which he demonstrated a sustained release of mescaline from a copolymer of *N*-vinylpyrrolidone and peptamine, opening a new era of polymer conjugate research.[6–8] In many cases, the presence of a polymer can solubilize hydrophobic drugs (many market-available anticancer drugs such as doxorubicin (DOX) and paclitaxel are hydrophobic,[9–11]) aiding in their formulation and lowering their toxicity. The pharmacokinetics of drug substances can be modified by attaching high molecular weight polymers to elongate the blood circulation time. In addition, polymers help target tumors by the enhanced permeability and retention (EPR) effect[12] due to their large size.

Ever since Abuchowski and coworkers introduced the pharmaceutical advantage of poly(ethylene glycol) (PEG) conjugation to a protein, that is, lowered immunogenicity,[13] a great deal of work has also been reported on improving the therapeutic effect of protein drugs via polymer conjugation.[14–18] It has consequently been shown that PEG increases the circulation time of protein and peptide drugs by preventing protease degradation, and reducing immunogenicity and antigenicity by hindering antigenic determinants.[16,19–21] The nonreactive chemical property of the PEG minimizes unwanted reaction and chemical interference with functional drugs when used as a drug delivery platform. Synergistically combining the properties of drugs with those of synthetic polymers has become a well-accepted strategy to improve the pharmacological and biological effects of the therapeutic agents.

Much effort has also been focused on exploiting functional synthetic polymers for delivering drugs in a target-directed or stimuli-responsive manner (Figure 2).[3,22–24] The release rate of drugs and/or degradation of polymer matrices can be tuned by introducing hydrolytically or enzymatically degradable chemical linkages.[8] The polymer–drug conjugate can facilitate endocytotic cellular entry in select cases, for instance, by masking adverse interactions of highly charged drugs with cell membranes.[25] Thermosensitive conjugates, which exhibit a lower critical solution temperature (LCST), enable entrapment of drugs, followed by penetration through biological barriers after undergoing a phase transition.[26,27] Polymer conjugates with tumor-specific antibodies or ligands can be used as homing devices for targeted delivery of anticancer

(a) Polymer conjugates with side chains that release drugs via hydrolysis, change in pH, or enzyme action; (b) masking of highly charged drugs (such as DNA) with polymers; (c) stimuli-responsive (such as temperature, pH, light, current, and mechanical stimuli) encapsulation of drugs; (d) target-directed therapy via polymeric conjugates with a specific homing molecule (such as antibodies).

drugs or contrast agents, enabling visualization of tumor sites (see **Chapter 4.421, Self-Assembled Prodrugs**; **Chapter 4.422, pH-Responsive Polymers for the Intracellular Delivery of Biomolecular Drugs**; **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**; **Chapter 5.510, Engineered Bioactive Molecules**; and **Chapter 1.123, Degradable Polymers**).[8,24,28]

Although polymeric conjugates by and large have the many advantages mentioned earlier, challenges still remain: only a few polymer conjugates have been tested for clinical use. Heterogeneity with respect to polymer molecular weight, composition, or structure can be problematic, as it often causes batch-to-batch and/or lab-to-lab variations. This can lead to unpredictable pharmacokinetic and pharmacodynamic behavior, reduction in bioactivity, or unreliable release kinetics. Polymerization techniques that provide well-defined polymer chains with reactive moieties for site-specific conjugation can overcome these limitations. Controlled radical polymerizations (CRPs) meet these requirements, and this chapter will focus on synthetic strategies by CRP to prepare polymer–drug conjugates.

4.423.2. Overview of Controlled Radical Polymerization

Polymers with predetermined molecular weights, complex architectures, and functional end groups are attainable with CRPs. Reversible addition–fragmentation chain transfer (RAFT) polymerization,[29] atom transfer radical polymerization (ATRP),[30] and nitroxide-mediated polymerization (NMP)[31] are widely used CRP techniques. Different from living cationic and anionic polymerizations, CRPs have high tolerance to many functional groups such as alcohols, esters, amides, and carboxylates; yet similar to these approaches, the molecular weight distributions are narrow.[32] The strategies can be used to form block,[33,34] branched,[35–37] star,[38–43] comb/graft[40] copolymers, as well as architectures desired for polymer–drug conjugations (see **Chapter 1.121, Polymer Fundamentals: Polymer Synthesis**).

4.423.2.1. Reversible Addition-Fragmentation Chain Transfer Polymerization

RAFT polymerization, invented by Rizzardo, Moad, and Thang, is a facile and versatile CRP technique that is compatible with a wide range of monomers (acrylates, methacrylates, acrylamide, methacrylamide, styrene, and vinyl acetate).[44,45] Moreover, controlled polymerization of cationic,[46] anionic,[47,48] and zwitterionic[49] monomers are made possible in aqueous media via RAFT polymerization. RAFT polymerization takes advantage of a reversible chain transfer agent (CTA) to produce low polydispersity index (PDI) polymers. A number of thiocarbonylthio-based CTAs, including dithioesters,[29] trithiocarbonates,[50] dithiocarbamates,[51,52] and xanthates,[53,54] have been studied. The mechanism of RAFT polymerization first proposed by its inventors at the Commonwealth Scientific and Industrial Research Organization (CISRO)[29] and studied by others,[55–57] is depicted in **Figure 3**. An important feature is reversible addition of the growing polymer radical to the reactive C=S of the CTA, followed by rapid fragmentation to form the stable radical R•. Selection of an appropriate R group is important to achieve controlled polymerization for a specific set of specific monomers because the chosen R group must be stable enough to be

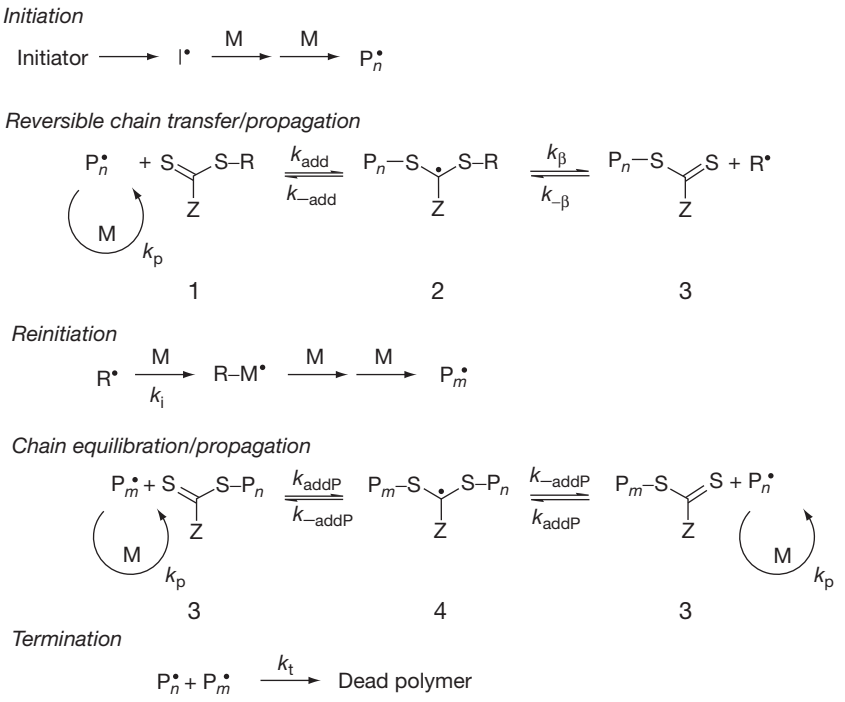

Figure 3 Generally accepted mechanism for reversible addition–fragmentation chain transfer polymerization. Reprinted with permission from Moad, G.; Rizzardo, E.; Thang, S. H. *Aust. J. Chem.* **2006**, *59*, 24. © 2006 CSIRO Publishing.

fragmented as a radical, yet reactive enough to reinitiate the polymerization. The equilibrium between the propagating polymeric radical and dormant RAFT agent–polymer adduct results in uniform chain growth and low PDI for the resultant polymer.

4.423.2.2. Atom Transfer Radical Polymerization

ATRP, also termed transition metal-mediated living polymerization or transition metal-catalyzed living free-radical polymerization, is another popular CRP technique that was first reported by Matyjaszewski[30,58–60] and Sawamoto.[61] Like RAFT polymerization, ATRP is tolerant to many functional groups, allowing a broad range of monomer choices, including styrenyls, alkyl (meth)acrylates, acrylonitrile, and (meth)acrylamides. Control is gained in the ATRP process by a reversible termination reaction, shown in Figure 4.[60] The radicals are generated through a reversible redox process (±1 change in oxidation state of the metal), catalyzed by a transition metal (such as copper, ruthenium, iron, or nickel) complex. The equilibrium between activation (k_{act}) and deactivation (k_{deact}) is important. Owing to fast initiation and reversible deactivation, ATRP results in a uniform chain growth, and thus well-controlled molecular weight.

4.423.2.3. Nitroxide-Mediated Polymerization

Nitroxide-mediated living free-radical polymerization (NMP) is another well-studied CRP technique that involves using reversible termination of the growing polymer chain to reduce the overall concentration of the propagating radical chain end.[31] Stabilized nitroxides, such as 2,2,6,6-tetramethylpiperidinyloxy (TEMPO), are introduced to trap carbon-centered free radicals generated from the addition of initiator to vinyl monomers. Solomon, Rizzardo, and Moad first reported the concept of NMP, in which a standard free-radical polymerization of methyl acrylate or styrene monomers in the presence of TEMPO produced low molecular weight polymers.[63–65] Georges *et al.* reported a bulk polymerization of styrene with a bimolecular initiation process at high temperature (130 °C) in a molar ratio of benzoyl peroxide:styrene:TEMPO of 1:3:1 to result in a linear

conversion with PDIs between 1.2 and 1.3.[66] Unimolecular initiators for NMP, developed by Hawker and coworkers, allowed better control over molecular weight and architecture.[67,68] A representative NMP reaction is shown in Figure 5. Upon heating, the alkoxyamine derivative initiator heterolytically cleaves to form a methylbenzyl radical that initiates the polymerization of styrene, as well as the mediating nitroxide radical, in a 1:1 stoichiometry.

Synthetic polymers produced by CRP have increasingly been employed in materials for biotechnology, biomedical, nanotechnology, and pharmaceutical use.[2,69,70] In the following sections, polymer conjugates of synthetic drugs and biomolecules (proteins and peptides) prepared using CRP techniques are discussed. Because biomedical applications of polymers synthesized via CRPs have been extensively reviewed,[23,62,71–73] the following sections are not comprehensive but rather provide an overview of the field.

4.423.3. Examples of Polymer Conjugates Synthesized by Controlled Radical Polymerization

4.423.3.1. Polymer–Small Molecule Drug Conjugates

As already discussed, polymer conjugation often improves drug efficacy by aiding solubility and suppressing toxicity. Drugs can be conjugated to the ends of the polymer chain or to the side chains (Figure 6). The latter allows the drug loading to be regulated by varying the conjugation density along the polymer backbone, either via postpolymerization side-chain modification or copolymerization of monomers with different dangling side chains. This feature may be suitable for small molecule drug conjugation, while the chain-end conjugation is typically more appropriate for larger molecules such as proteins and peptides. Certain drugs must be released to function; in such cases, the release rate can be finely tuned by introducing a cleavable linkage between the drug and the polymer backbone. As a result, the polymer–drug conjugation technique has been extensively utilized for drug delivery and tissue-engineering applications. Some have already been investigated in clinical trials, including anticancer drugs such as DOX and paclitaxel (Taxol) conjugated to poly(*N*-(2-hydroxypropyl)methacrylamide) (pHPMA) or poly(L-glutamic acid).[74–76] Historically, polymer–drug conjugates have been prepared by conventional radical polymerization. Implementation of CRP provides better control over the production of polymer–drug conjugates. Polymers with desired molecular weight and narrow polydispersity can be achieved reliably and reproducibly. Polymer architecture can be manipulated at the molecular level, which offers the design of higher-order macromolecular assemblies.[77]

Godwin *et al.* introduced the use of CRP to produce a polymer with activated ester side chains and narrow polydispersity indices for potential application in polymer–drug conjugates.[78] They polymerized *N*-hydroxysuccinimide (NHS) methacrylate via copper-mediated ATRP in the presence of 2,2′-bipyridine to give various molecular weights with PDIs <1.20. They conjugated *p*-nitroanilide as a model drug in various ratios to demonstrate the potential to produce polymer–drug conjugates in a well-controlled manner. In subsequent studies, the synthesis of polymers with a wide range of side-chain functional groups have been reported via ATRP, including NHS ester,[79,80]

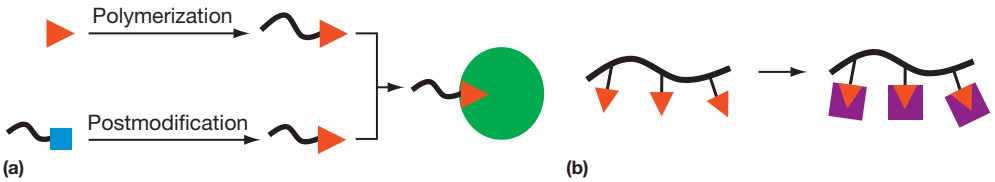

Figure 6 Polymer conjugate architectures. (a) Chain-end conjugation by chemoselective initiator/chain transfer agent (upper route) or by postmodification of polymer chain-end (lower route). (b) Conjugation via reactive functional groups along the polymer side chain.

2,4,5-trichlorophenol ester,[81] and *p*-nitrophenyl ester.[82] Activated polyesters can react with primary amines under mild conditions (pH and temperature) resulting in stable amide bonds in relatively high yield. While the activated esters are most commonly used for polymer–drug conjugate synthesis, polymers with other side-chain functional groups have also been reported. These include epoxides,[83,84] oxazolones,[85] and acetal[86] functional groups. Click chemistry has drawn much attention in recent years because it results in high reaction yields in the presence of other functional groups without side reactions, making it suitable for many biologically active drugs.[87] Polymers with the click reaction partners, either azides[88] or alkynes,[89] have been prepared. RAFT polymerization has also been utilized to produce polymers with narrow PDI that are functionalized with reactive side chains such as activated esters,[90–95] disulfides,[96,97] protected alkynes,[98–100] and acetals/aldehydes.[90,101] Polymers with reactive side chains that are prepared via NMP have also been reported, including alkynes,[102,103] oxazolones,[104] and epoxides.[105,106] The reactive side chains of polymers that could be potentially used for polymer–drug conjugation are summarized in Figure 7.

Anticancer drugs have been particularly targeted by researchers for polymer conjugation, because large molecules passively target some solid tumors via the EPR effect. While the direct use of CRP techniques in anticancer drug conjugation is still in the initial stages, recent efforts have been promising. Rickert *et al.* was the first to report polymer conjugation of tamoxifen, a breast cancer drug (Figure 8(a)).[107] They prepared a polyester by polymerizing NHS methacrylate via CuBr-mediated ATRP in the presence of 2,2′-bipyridine (polymer molecular weight 12 500 Da and PDI 1.07) and conjugated a 4-hydroxytamoxifen derivative with 50% substitution. Antagonistic activity to the estrogen receptor (ER) was improved compared to protein-based conjugates as indicated by IC_{50} values obtained from a radiolabeled estradiol competition assay. Chen *et al.* demonstrated camptothecin (CPT)–polymer conjugates in two different architectures: CPT-terminated polymer and CPT as side-chain pendant groups (shown in Figure 8(b)).[108] They polymerized biocompatible poly(methacryloyloxyethyl phosphorylcholine) (polyMPC) either by using a CPT-modified ATRP initiator to make CPT-terminated polyMPC or by copolymerizing MPC and trimethylsilyl propargyl methacrylate with azidyl CPT via ATRP in one-pot to make polyMPC-*graft*-CPT. Hydrolytically degradable ester linkages were introduced and the *in vitro* cytotoxicity was tested on three different cancer cell lines: human breast (MCF7), ovarian (OVCAR-3), and colon (COLO 205) adenocarcinoma cells. The conjugates were potent as anticancer drugs, although the IC_{50} values were higher than CPT due to the slow release of CPT from the polymers. This study demonstrated feasibility of controlling the drug loading and

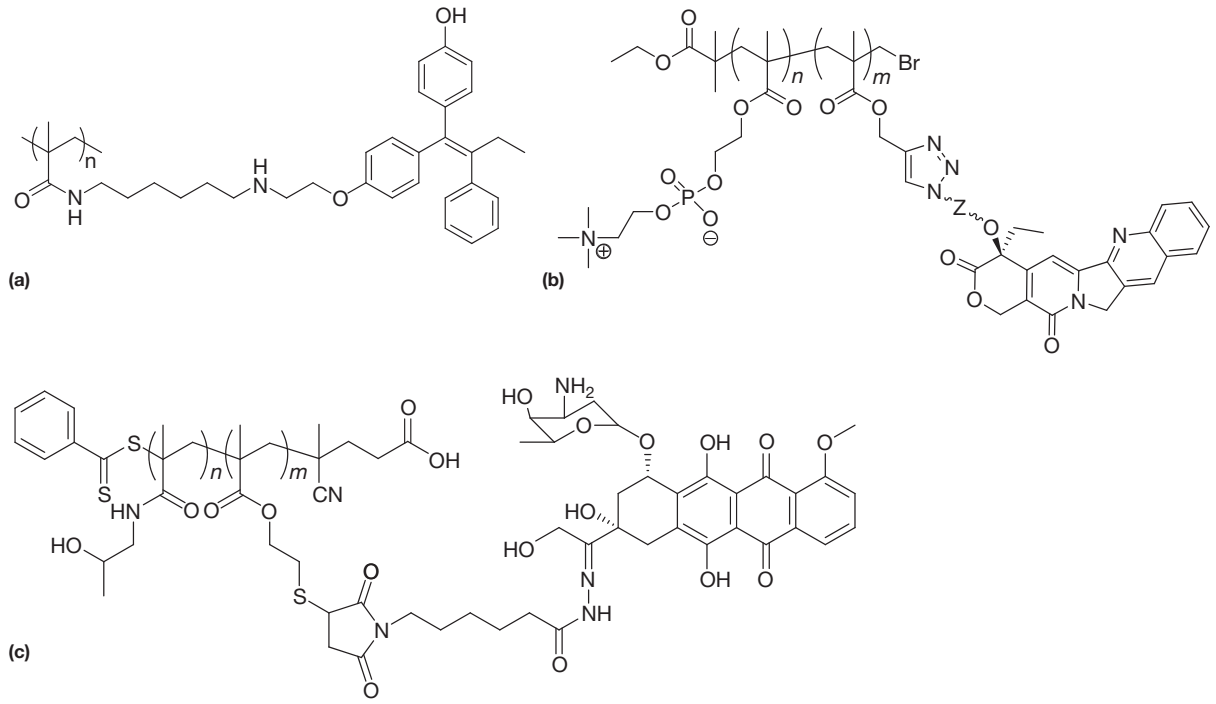

Figure 8 Structure of polymer conjugates of (a) tamoxifen,[107] (b) camptothecin,[108] and (c) doxorubicin.[109]

release rate in polymers with precisely designed molecular weights and narrow molecular distribution, as well as variable choice of degradable linker arms. Jia *et al.* reported conjugation of Dox to an amphiphilic block copolymer of HPMA and a thiol-reactive monomer 2-(2-pyridyl disulfide)ethyl methacrylate (PDSM) synthesized via RAFT polymerization using 4-(cyanopentanoic acid)-4-dithiobenzoate as the CTA (**Figure 8(c)**).[109] Maleimide hydrazone-modified Dox was then conjugated to the pyridyl disulfide pendant group at 32% substitution. The remaining reduced thiol groups were oxidized to disulfides to form cross-linked miscellular particles. Study of the pH-dependent release of Dox via cleavage of the acid-susceptible hydrazone linkage showed 3.6-fold faster liberation of Dox at lower pH (pH 5.0) than the physiological pH. These results are promising for targeting acidic tumors.

4.423.3.2. Polymer–Protein Drug Conjugates

The global protein drug market, which includes growth hormones, insulin, cytokines, plasma proteins, vaccines, and monoclonal antibodies, is rapidly increasing. However, delivering protein-based pharmaceutics is challenging because of their short circulation times and lack of stability in media, as well as enzymatic and cellular (i.e., endothelial) barriers *in vivo*. As discussed previously, polymeric conjugation to such protein drugs mitigates these issues, vastly improving clinic usability. With polymer chains attached, protein drugs need to be administered (injected) less often, increasing patient compliance.

PEGylation is the most implemented method for delivering protein therapeutics, since the nontoxic and low-immunogenic PEGs have been shown to enhance efficacy by protecting proteins from environmental and enzymatic degradation. Use of linear PEG, either PEG-diol or monomethoxy PEG (mPEG), in protein conjugation poses potential problems owing to the heterogeneous products that result.[18,110] An end-group-functionalized linear PEG can be straightforwardly conjugated to the amine side chain of lysine residues, the N-terminus, or the thiol side chain of cysteines. However, an electrophilically modified PEG can react with multiple residues on proteins, resulting in mixtures of PEG isomers per protein. This heterogeneity is problematic for drug manufacturing processes, regulatory approvals, and clinical use. Another possible problem of conventional linear PEGylation is that the residual diol-PEG in mPEG may cause cross-linking of conjugate products, lowering the overall yield.[16] Moreover, recently increasing evidence has been reported on PEG's immunogenicity, contrarily to the conventional assumption, which may impact clinical application of PEGylated therapeutics.[111]

CRP techniques provide a route to polymers for conjugation to proteins that circumvent some of the issues associated with PEGylation, in that monofunctionalized polymers that are well defined are readily synthesized. Other polymers, besides those that are PEGylated, are readily accessed, allowing a greater functionality space to be explored. In addition, hydrophobic polymer protein conjugates can be synthesized. This leads to materials that self-assemble such as miscelles for potential drug delivery applications.[112] Polymers synthesized by CRP that target natural and unnatural amino acids have been reviewed.[62,71–73] Some examples of polymers that target amine or thiol residues are given below.

The Haddleton and Maynard groups independently reported a way to utilize CRP to generate in one step end-functionalized polymers that react with proteins.[113,114] The general approach is to utilize a protein-reactive ATRP initiator or RAFT CTA in the controlled polymerization (**Figure 9**). Haddleton polymerized poly(ethylene glycol) methyl ether methacrylate (mPEGMA)

monomers using *N*-succinimidyl-2-bromo-2-methylpropionate as an initiator in the presence of Cu(I)Br/*N*-(ethyl)-2-pyridylmethanimine catalyst to yield a monofunctionalized brush PEG polymer with a narrow PDI (<1.15).[113] They showed that a complete conjugation was achievable by using the polymer prepared by initiation with N-succinimidyl 2-bromopropionate, in their lysozyme model system. An average 6–7 polymer molecules were observed, which were in good agreement with the number of free amine residues in the lysozyme. In another report, they also studied an α-aldehyde-terminated PEGMA by using acetal-functionalized ATRP initiator.[115] The acetal group was deprotected to give an aldehyde and conjugated to amine groups of lysozyme via reductive amination (**Figure 10**). Use of PEGMA with well-controlled molecular weight and functional groups provides an alternative PEGylation method that may allow further protection from proteolysis compared to that of linear PEG.[116] Maynard reported a cysteine-targeting polymer by utilizing a pyridyl disulfide-functionalized 2-bromo-2-methylpropionate ATRP initiator to polymerize 2-hydroxyethyl methacrylate (HEMA). The obtained polymers with various molecular weights had PDIs <1.25 and retained 85–91% of the end group. Conjugation to bovine serum albumin (BSA), which contains 45–50% free Cys34 residue, was demonstrated, and the sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis showed a band shift to higher molecular weight in conjugates. Other studies employing cysteine-reactive maleimide[89] and pyridyl disulfide[117] ATRP initiators were reported. RAFT polymerization was also used to produce reactive end groups

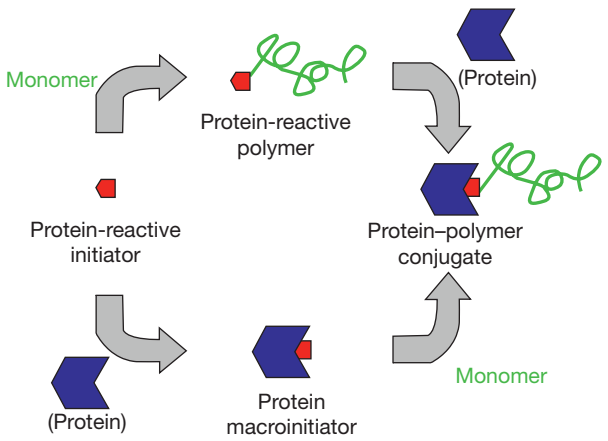

Figure 9 Routes to protein–polymer conjugates. Reprinted with permission from Heredia, K. L.; Maynard, H. D. *Org. Biomol. Chem.* **2007**, *5*(1), 45–53. © 2007 RSC Publishing.

for protein conjugation, such as pyridyl disulfide,[41,109,118–120] maleimide,[121,122] vinyl sulfone,[123,124] and thiozolidine.[125] In some cases, the functional group was incorporated directly into the CTA. In other cases, postpolymerization modification, such as aminolysis/reduction of thiocarbonylthio or heating with a protein-reactive azo initiator, was carried out to give thiol-reactive polymers.

The Maynard group first reported a novel approach to prepare protein–polymer conjugates that involves using the protein as a macroinitiator for polymerization, as illustrated in **Figure 9**.[126] Streptavidin (SAv) was activated with a biotinylated 2-bromoisobutyrate ATRP initiator, and *N*-isopropylacrylamide (NIPAAM) was polymerized in the presence of CuBr/2,2′-bipyridine catalyst at room temperature.[126] The result demonstrated a new method of site-specific polymer conjugation to protein; furthermore, the protein retained its bioactivity. In this route, the removal of unconjugated polymer is not necessary. On subsequent study, the *in situ* polymeric conjugation of BSA and T4 lysozyme by using the proteins as active ATRP initiators was described (**Figure 11**).[127] The free Cys residue of proteins was activated by using thiol-reactive, either a 2-pyridyl disulfidyl or a maleimidyl 2-bromoisobutyrate ATRP initiator and subsequently, NIPAAM was polymerized. Both conjugates showed higher molecular weight shifts by SDS PAGE. The enzymatic activity of lysozyme–pNIPAAM conjugate was the same as unmodified lysozyme. This study confirmed the versatility of the 'grafting-from' polymer conjugation method. Others have also reported the synthesis of protein–polymer conjugates utilizing 'grafting-from' ATRP. These include BSA–polystyrene giant amphiphiles[128] and chymotrypsin–p(MPEG-methacrylate)s.[129] Recently, several researchers have utilized this 'grafting-from' approach to prepare PEGylated proteins with improved therapeutic effects. Caliceti *et al.* demonstrated *in situ* PEGylation human growth hormone[130] and Chilkoti of myoglobin.[131] For the latter, the resulting myoglobin-polymer conjugate showed 40 times improved pharmacokinetic property compared to the unmodified version ($t_{1/2\alpha}$= 2 h compared to $t_{1/2\alpha}$ = 3 min). In a subsequent study, the same group also utilized ATRP to polymerize OEGMA from a modified C-terminus of green fluorescent protein (GFP).[132] The conjugate demonstrated 20 times improved pharmacokinetic property (i.e., from $t_{1/2\alpha}$ = 0.1 h to $t_{1/2\alpha}$ = 4 h) and 50 times greater tumor accumulation than did unmodified GFP. These latest results demonstrate the applicability of using the 'grafting-from' approach to generate conjugates for use *in vivo*.

Protein-mediated RAFT polymerizations were also reported.[133,134] The Centre for Advanced Macromolecular

Design (CAMD) group modified the free cysteine of BSA using a pyridyl disulfide-functionalized trithiocarbonate CTA and polymerized NIPAAM in a phosphate buffer at 25 °C in the presence of azobisisobutyronitrile (AIBN).[133] They attained high molecular weight BSA–pNIPAAM conjugates (up to M_n~200 000) with increasing monomer conversion and were able to retain narrow PDIs (<1.20) below 50% monomer conversion (M_n~100 000). Sumerlin also reported a BSA-*grafted*-pNIPAAM conjugate by modifying BSA with a maleimide-functionalized trithiocarbonate.[134]

Exploitation of external stimuli-responsive materials, those that respond to temperature, pH, enzyme, and magnetic field, is at the forefront of biomaterials. Incorporation of these smart polymers into protein–polymer conjugate systems provides tools for making conjugates with tailored therapeutic properties and actuation. For example, pNIPAAM has been widely studied in drug delivery since it exhibits a thermoresponsive phase transition behavior (LCST); the polymer goes through a hydrophobic transition and becomes less soluble above the LCST.[135] This feature can be used for facilitating the localization of anticancer drugs or surface modifiers for control of cellular adhesion.[136] Various applications of protein-pNIPAAM, such as control of biorecognition, triggered release, and actuation, have been demonstrated.[136–139] Recently, Maynard and coworkers,[43,122,126,140–143] and Sumerlin and coworkers[134,144] have described a series of synthetic methods to produce BSA– or SAv–pNIPAAM conjugates via controlled radical polymerization. It is anticipated that stimuli-responsive polymeric conjugates with a well-defined structure will be increasingly used in biomedical research.

In summary, protein–polymer conjugates synthesized using CRPs, by either the 'graft-to' or 'grafting-from' approach, are promising as therapeutics. A homogeneous product may lead to increased therapeutic efficacy, and easy routes to these materials are provided via CRP techniques. Conjugates synthesized using ATRP or RAFT polymerization may find use in a myriad of applications, including as-targeted delivery of anticancer drugs by using tumor-specific antibodies,[145] immunodiagnostics,[146] and signal enhancement of immunoassays.[147] It is possible that this fast-developing field will soon be applied to clinical use.

4.423.3.3. Polymer–Peptide Drug Conjugates

Functional peptides that mimic the specific secondary structures and biological roles of their native proteins are applied as cell-permeation agents,[148–150] antimicrobials,[151] bioadhesives,[152] and molecular imaging tools.[153] Polymer conjugation may further stabilize and solubilize peptides and improve their efficiency.[154] Thus, well-defined functional peptide–polymer conjugate materials have enormous potential in biomedicine.

Different routes for preparing peptide–polymer conjugates have been reported. Polymers that are synthesized via CRPs with reactive initiators/CTAs[155] or side chains[90] can be conjugated to a specific amino acid of peptides in a postpolymerization approach. Peptide–polymer conjugates have also been produced by utilizing peptidyl monomers[78,156] or peptide-modified ATRP initiators.[157] Solid-phase peptide synthesis (SPPS) methodology offers facile production of oligopeptides in high purity, yield, and reproducibility.[158] Taking advantage of SPPS, peptide–polymer conjugates have also been prepared on solid phase by activating the resin-bound peptides with ATRP (**Figure 12**) and NMP initiators[151,159] or RAFT agents.[160]

Peptides that interact with cell surface receptors are exploited in tissue-engineering scaffolds. One such peptide, Agr-Gly-Asp (RGD), is the most investigated peptide for cell adhesion; the sequence derives from many extracellular matrix (ECM) proteins, including fibronectin. Mei *et al.* reported a solid-phase synthesis of peptide–polymer hybrid GRGDS-pHEMA using ATRP.[161] The GRGDS peptide was synthesized via standard fluorenylmethyloxycarbonyl (Fmoc) solid-phase synthesis using a Wang resin.[158] The peptidyl initiator was prepared by adding 2-bromopropionyl bromide; the initiator was used to polymerize HEMA in the presence of copper(I) chloride. The peptide–polymer conjugate was then liberated from the solid resin to give a polymer with a PDI of 1.47. Hentschel *et al.* reported another method for preparation of an RGD–polymer conjugate.[160] The GGRGDS sequence was synthesized by standard Fmoc solid-phase synthesis on a 2-chlorotrityl chloride resin, and a trithiocarbonate RAFT CTA was introduced. The peptide–CTA conjugate was then cleaved and used for polymerization of *n*-butyl acrylate (*n*BA), NIPAAM, and oligo(ethylene glycol) acrylate (OEGA) to yield PDIs between 1.1 and 1.2. Both studies showed that cells adhere specifically to the RGD–polymer materials, demonstrating a versatile methodology to produce well-defined peptide–polymer materials. Maynard reported a polymer with RGD as a pendant group.[90] Poly(diethoxypropyl methacrylate) (pDEPMA) was polymerized via RAFT using cumyl dithiobenzoate (CDB) as the CTA in the presence of AIBN (M_n 14 400 and PDI 1.26). The protected side chain was then

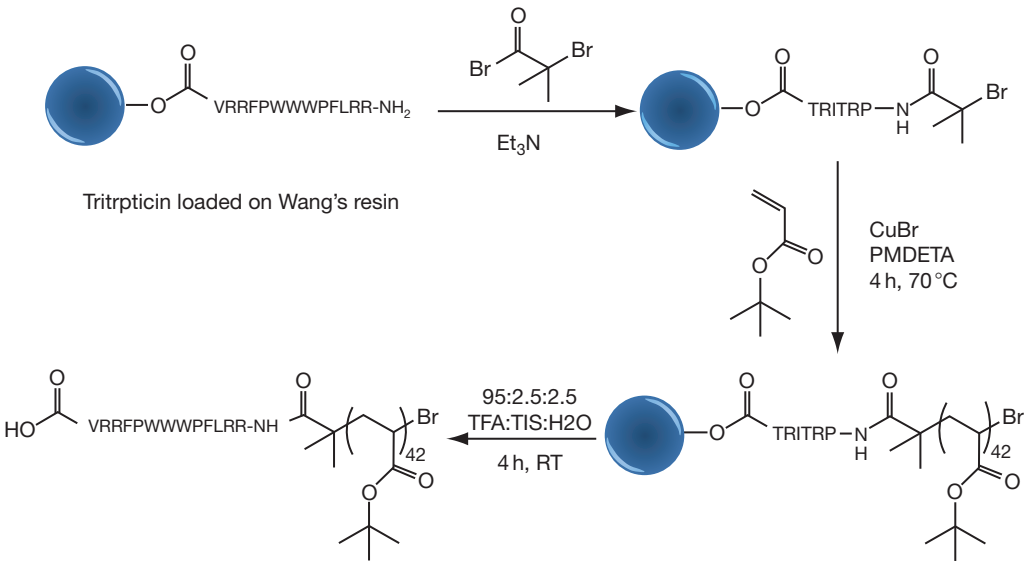

Figure 12 Synthetic strategy for peptide–polymer conjugate via solid-phase atom-transfer radical polymerization. Reproduced with permission from Becker, M. L.; Liu, J.; Wooley, K. L. *Biomacromolecules* **2004**, *6*(1), 220–228. © 2005 American Chemical Society.

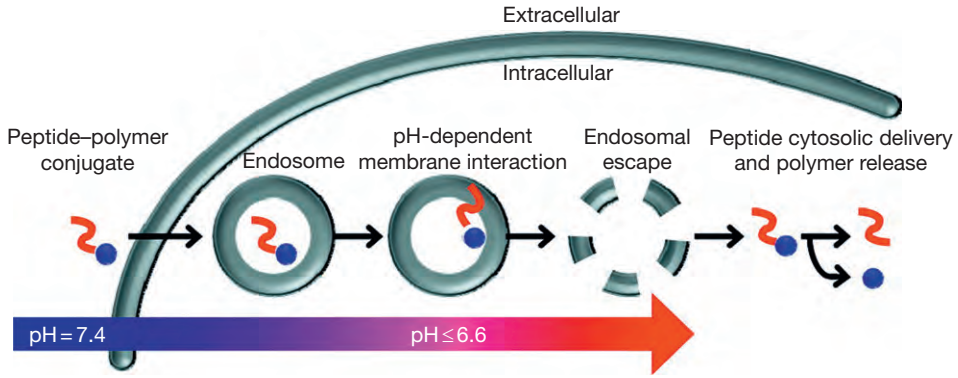

Figure 13 Intracellular delivery of a proapoptotic peptide via conjugation to a reversible addition–fragmentation chain transfer synthesized endosomolytic polymer. Reprinted with permission from Duvall, C. L.; Convertine, A. J.; Benoit, D. S. W.; Hoffman, A. S.; Stayton, P. S. *Mol. Pharmacol.* **2010**, *7*(2), 468–476. © 2010 American Chemical Society.

deprotected in a 1:1 mixture of trifluoroacetic acid:H_2O to give an aldehyde side chain. Aminooxy-functionalized RGD was conjugated to this polymer via oxime chemistry with a targeted 15% substitution.

Similar to nonbiologic drug conjugates described earlier, the peptide density along the polymer backbone can be finely tuned. This feature is advantageous in biomedical applications where multivalency is required. For example, a copolymer of poly(HPMA-*co*-*N*-methacryloyloxysuccinimide), prepared via RAFT, has been reported: the polymer was subsequently conjugated with a bioactive oligopeptide, HTSTYWWLDGAPK.[162] It was demonstrated that this polyvalent peptide conjugate improved, by three orders of magnitude, inhibition of anthrax toxin, compared to monovalent peptide.

A polymeric conjugate with a proapoptotic peptide derived from homology domain BH3 of B cell lymphoma 2 was recently reported by Hoffman and Stayton.[155] A Cys-terminated fusion peptide of BH3 with a cell-permeating peptide Antp[163] was prepared and conjugated to a pyridyl disulfide-functionalized RAFT polymer. The polymer was composed of two modules: pHPMA to increase solubility and circulation time and a copolymer of dimethylaminoethyl methacrylate (DMAEMA), butyl methacrylate (BMA), and propylacrylic acid (PAA) to trigger pH-dependent cytosolic release of the therapeutic peptide. A pyridyl disulfide-functionalized trithiocarbonyl CTA was used to polymerize HPMA, and the polymer was, in turn, employed as a macro-CTA to construct the second block of poly(PAA-*co*-BMA-*co*-DMAEA). The result showed that the pH-dependent block assisted the homogeneous endosomal distribution of internalized peptide, and the peptide–polymer conjugate exhibited apoptotic functionality (**Figure 13**).

4.423.4. Prospects and Challenges

Synthetic polymeric materials offer tremendous opportunities to improve drug efficacy. It has been proved that polymers enhance the performance of biological drugs, such as therapeutic proteins and peptides, by protecting them from degradation, increasing circulation time, and facilitating cell

internalization. Numerous polymeric materials have been investigated for medicinal purposes, and some of them have made it to the clinic. However, problems inherent in the heterogeneity of the polymer and conjugation site need to be circumvented. Recent progress in controlled radical polymerization has enabled remarkable improvement in controlling molecular weights, polydispersities, architectural structures, and placement of functional groups in polymers for these applications.

There are some important considerations that should be taken into account when designing polymeric conjugates. The polymeric component (chain ends, functional pendant groups, and degradation products) should have minimal interaction with the host (i.e., no toxicity or minimal immunogenicity). The polymer should be excreted from the body in a timely manner without accumulating in any organs. If a degradable site is introduced to achieve this, the degradation should occur in a predictable manner with controlled kinetics, and the by-products should be inert to the body. CRP conjugation products often contain unwanted impurities such as copper catalyst from ATRP or released 2-pyridyl thione from pyridyl disulfide-functionalized polymers. These should be completely removed prior to administration.[164]

Advancement in the rapidly emerging interdisciplinary study of system biology, materials characterization, and imaging technologies promises a better understanding of pharmacokinetics and pharmacodynamics, as well as host responses, of administered polymeric conjugates. One can design an optimized polymeric conjugate that provides both medical effects and requirements as biomaterials, and expect minimized undesirable side effects and maximized therapeutic effects. Controlled radical polymerizations will certainly play an increasing role in designing small molecule, protein, and peptide–drug polymer conjugates of this description in the future.

4.424.1. Introduction

Gene therapy employs nucleic acids to treat or prevent disease. The nucleic acids may be entire genes, partial genes, oligonucleotides, and synthetic analogs of DNA and RNA such as morpholino-oligonucleotides and peptide nucleic acids. There is great clinical interest in using gene therapy for treating a wide range of diseases, including single gene disorders, such as cystic fibrosis and Duchenne muscular dystrophy, and complex, multifactorial diseases such as neurodegeneration and cancers. At present, over 2000 trials in gene therapy are recruiting, in progress, or completed (clinicaltrials.gov), yet only two treatments have received worldwide approval: gendicine,[1] an adenovirus engineered to express p53 for the treatment of head and neck carcinoma, has been approved in China and Vitravene (Fomivirsen), a synthetic oligonucleotide, has FDA approval for the treatment of cytomegalovirus retinitis in human immunodeficiency virus (HIV)/AIDS patients but has been removed from the market by its manufacturer.[2] There are many factors that have limited the translation of gene therapy from the bench to the bedside, not least the relative youth of the field and the complex nature of the therapeutics compared to traditional small molecules. One particularly important problem that has hampered clinical acceptance is the inherent difficulty in delivering nucleic acids specifically to a target site, at a therapeutic dose and with a practical administration regime. The human body is a hostile place for unknown nucleic acids with multiple barriers to delivery and the requirements for an efficient delivery vehicle; protection from degradation, delivery into cells, and subsequent release of the delivered material into the cytosol are challenging. If effective methodologies for the delivery of nucleic acids can be achieved, then gene therapy may finally live up to the promise it has offered.

This chapter focuses on nanoparticles (NPs) for delivering nucleic acids, a field that has attracted an ever-increasing interest in the last 20 years. The challenges for biomaterials to deliver DNA, RNA effectively and reliably , and related therapeutics remain significant, but the therapeutic opportunities are enormous.

4.424.1.1. Therapeutic Opportunities for Nucleic Acids

Gene therapies may be loosely divided into two classes: gene addition/replacement and gene silencing. Gene addition/replacement is the best known of these and involves the replacement of a gene that is mutated, resulting in lost or incorrect function, by delivery of a normal allele. Hemophilia B, for example, is a hereditary disorder characterized by a mutation in the gene that encodes for the protein factor IX which is, in part, responsible for blood coagulation. In severe cases, where circulatory levels of factor IX are <1% of normal, this leads to episodes of spontaneous bleeding which can prove fatal. Gene replacement therapy for hemophilia B involves the introduction of a normal gene for factor IX resulting in restoration of blood coagulation activity.[3] Genes that do not normally exist in the target cells may also be introduced, a strategy that is often used in potential cancer treatments by introduction of a viral genome; once introduced, virus is produced in the cell resulting in its destruction. Gene silencing therapies, typified by antisense methodologies, allow for the removal of a gene that is upregulated as part of disease pathology. For example, the antiapoptopic protein Bcl-2 is upregulated in many multi-drug-resistant cancers;[4,5] silencing the gene that encodes for Bcl-2 may result in improved tumor susceptibility to apoptosis-inducing chemotherapeutics such as doxorubicin.

4.424.1.1.1. DNA therapies

DNA therapies are used for gene addition/replacement. Those under development include treatments for hereditary genetic disorders, such as hemophilia B, cystic fibrosis, and the retinal disorder Leber's congenital amaurosis (LCA), that are caused by single mutated genes, as well as multifactorial diseases such as cancer. The replacement of malformed factor IX in hemophilia B has been demonstrated in a canine model using a recombinant adeno-associated viral (rAAV) vector to deliver the normal gene. Therapeutic levels of factor IX were achieved and sustained for long periods (>2 years) postadministration, but expression was limited to weeks when assessed at clinical trial.[3] LCA is a degenerative disorder of the retina that begins in childhood and results in complete blindness by adulthood. Mutation of any one of a number of genes can result in LCA, with research to date focusing on mutation in the gene RPE65. Phase I clinical trials for the treatment of LCA with rAAV vectors delivering normal RPE65 have demonstrated some restoration of sight in patients.[6,7] A later trial found that younger patients, with less degeneration prior to treatment, could regain sufficient sight to negotiate a maze in low light conditions.[8] Gene replacement is also the basis of action for gendicine in the treatment of cancers with a mutation of the tumor suppressor gene TP53 that encodes the tumor suppressor protein p53. The introduction of antiangiogenic genes, that inhibit the production of tumor vasculature and consequent blood supply, allows tumors to be starved of nutrients and also prevents removal of waste products from the tumor, resulting in necrosis. Additional genes have been added to improve the spread through tumors. Alleles encoding for fusogenic membrane proteins, proteins that cause cells to fuse into a large multinuclear *syncytia*, allow a single infected cell to fuse with many neighboring cells; as these syncytia grow, they become nonviable and die via necrosis.[9]

4.424.1.1.2. Antisense and small-interfering RNA therapies

Antisense oligonucleotides are a family of short (<50 bp), noncoding oligonucleotides that bind to RNA via Watson–Crick base pair matching, resulting in modulation of RNA function.[10] Although RNA function may be affected by several mechanisms, for therapeutics, two of the most heavily studied are RNA interference (RNAi) and RNase H-mediated degradation.[10,11] RNAi is a cellular gene regulatory process that involves the binding of oligonucleotides, for example, small-interfering RNA (siRNA) and microRNA (miRNA), to posttranscriptional messenger RNA (mRNA) as part of an RNA-induced silencing complex (RISC).[12] When siRNA base pair matching is complete, the mRNA is then cleaved by RISC, resulting in the silencing of the target gene. For miRNA, where some mismatching is typical, mRNA translation is disrupted, resulting in downregulation of the target gene. The ability to silence genes has made siRNA-induced RNAi an invaluable tool in

determining gene function. RNase H-mediated cleavage is a nuclear process that is responsible for removal of the RNA primer during DNA replication.[13] Its degradation can be induced by introducing an antisense oligonucleotide for the RNA target.

Several therapeutic targets exploiting these mechanisms have been identified and several therapies are in various phases of clinical trial.[10,14,15] Antisense phase III trials currently include oblimersen (in conjunction with fludarabine and rituximab), which targets the antiapoptotic Bcl-2 protein, for the treatment of various cancers, including non-Hodgkin's lymphoma;[16] Aganirsen, which targets insulin receptor substrate-1 reducing angiogenesis, for the prevention of corneal graft rejection;[17] and Bevasiranib, which targets vascular endothelial growth factor, for the treatment of age-related macular degeneration/diabetic macular edema.[18] Fomivirsen (Vitravene) binds to mRNA responsible for the production of protein IE2 which is essential for replication of cytomegalovirus.[2]

4.424.1.2. Formulation Issues for Nucleic Acid Therapeutics

A number of formulation constraints for nucleic acid drugs are common to those of all controlled drug delivery systems. For any drug that is especially potent, or unstable under certain conditions, delivery systems are needed that can control the rate of drug release such that steady plasma levels are obtained. In addition, there is the desire for a low dosage volume, a need to avoid toxicity, and an ability to target the drug to the disease sites. Accurate and efficient dosing leads to improved patient compliance and enhanced therapeutic outcome – this is particularly important for cancer therapies where the aim is to selectively kill the cancer cells while leaving healthy cells intact. Many controlled drug delivery systems have accordingly been developed, and in a variety of formats, including emulsions, micelles, micro- and nanocapsules, micro- and nanospheres, and molecular complexes/conjugates.

However, in contrast to more common small molecule drugs, biopolymer drugs such as DNA and RNA have further requirements in terms of formulation and delivery on account of their much higher molecular weights. Although some mechanical delivery routes, such as microneedle injections, gene guns, electroporation, and hydrodynamic techniques, have been developed for direct introduction of unprotected nucleic acids, these have had limited success. Being large molecules, ranging from 13 kDa for a siRNA duplex to several million Dalton for a typical DNA plasmid, they are subject to physical shear forces, which are often important in an encapsulation process. In addition, owing to their biological origin, they are susceptible to *in situ* degradation by enzymes, capture (opsonization), and eventual destruction by the immune system. Delivery systems are thus required not only to protect DNA and RNA therapeutics from chemical and physical degradation before reaching their target site, but also to effect release once they have reached the target site. Again, the polymeric and charged nature of the nucleic acids renders the release and (intra) cellular uptake processes more problematic than for small lipophilic drugs. An outline description of the hurdles to gene delivery is given in the next section, followed by the evaluation of the classes of NP delivery systems developed to protect, transport, and release nucleic acids. More detailed considerations of key biological barriers en route to the desired therapeutic outcome are included for specific NP systems as these can vary with the type and function of each delivery system.

4.424.1.2.1. Barriers to nucleic acid delivery

For any drug to exert a therapeutic effect, it must reach its physiological target, which is in the nucleus or mitochondria for DNA and in the cytoplasm for RNA. Adequate adsorption and access to the target sites are important attributes of nanoparticulate nucleic acid delivery systems, as are prevention of nonspecific distribution in the body, premature metabolism, and premature excretion. The efficiency of naked DNA delivery is significantly hampered because of the existence of many extracellular and intracellular barriers. However, long-term gene expression is possible if the target cell is muscle (postmitotic) or hepatocytes (slowly mitotic). Therefore, to improve the delivery efficacy, nucleic acid therapeutics must be condensed to a small size and protected from serum and intracellular nucleases. The nucleic acid must be delivered to the target cell, cross the external cell membranes passively or actively, leave any subcellular organelles (such as endosomal compartments), avoid degradative enzymes, and then must escape traffic to the digesting lysosomes. Furthermore, if the biopolymer is DNA, it must cross into the nucleus ready for transcription. NP carriers must thus protect the nucleic acids and help transport them across all these cell barriers, yet ensure release at the correct time. In addition, for an injectable delivery formulation, the carriers with encapsulated/complexed nucleic acids must be capable of extended circulation in the bloodstream in order to have a chance to reach their cellular target (**Figure 1**).

NPs are inherently of the correct size range to gain access to tissues and cells (<250 nm in diameter is preferable), and can be stabilized to enhance circulation time by charge or by coating with a hydrophilic polymer such as poly(ethyleneglycol) (PEG). For commercial development, it is also desirable for a nucleic acid carrier to have adaptable functionality, so that one 'platform carrier' can be adapted for application across a wide range of disease targets with reliable chemical and formulation properties. Above all, the NPs must be safe, that is, nontoxic, nonimmunogenic, and fully cleared from the body after drug delivery.

4.424.2. General Classes of Nucleic Acid Delivery Systems

A variety of nucleic acid delivery systems (often termed 'vectors') are being developed. In general, these are in the submicron size range and hence fit broadly into the accepted definitions of NPs. It should be noted, however, that for pulmonary delivery of nucleic acids, particles in the 1–5 μm size range may be used for the initial delivery to the desired physiological site, and implantable biodegradable matrices of much larger size ranges are also under consideration for controlled release applications. Nevertheless, most DNA delivery vectors have been designed to accomplish the function of protecting their delicate biopolymer cargo through condensing and compacting the DNA into particles smaller than 1 μm in diameter.

For this chapter, we consider NPs to be colloidal species with submicron diameters among which the most widely

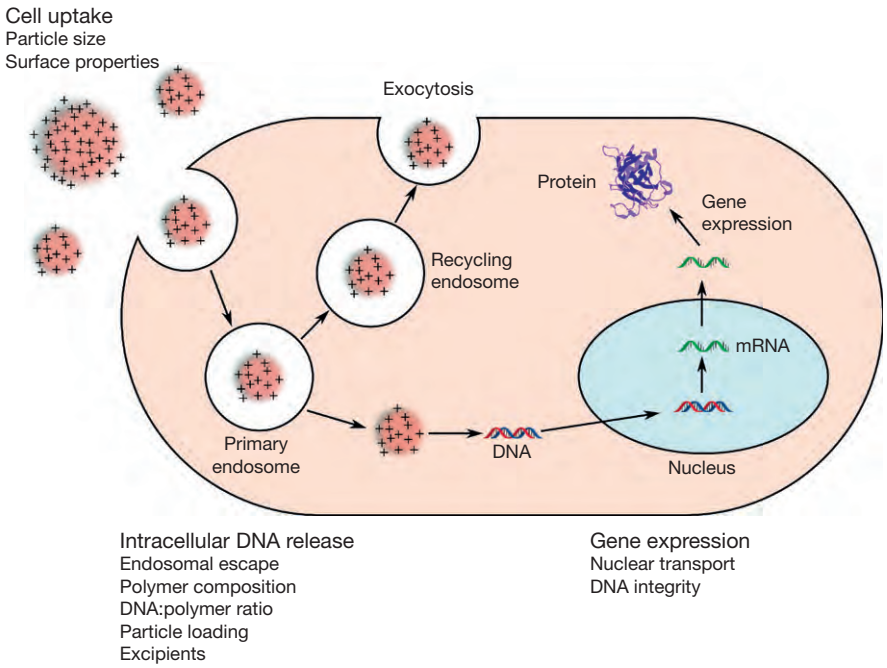

Figure 1 Formulation factors affecting the delivery of nucleic acids.

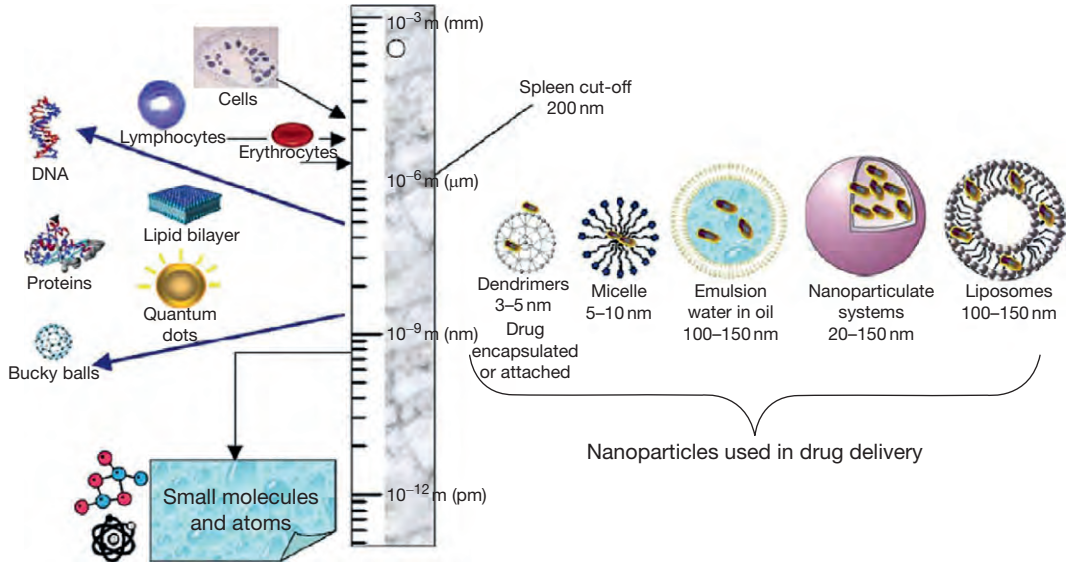

Figure 2 Classes of nanoparticles and carriers for drug delivery applications. Reprinted from Arruebo, M.; Fernández-Pacheco, R.; Ibarra, M. R.; Santamaría, *J. Nanotoday* **2007**, *2*, 22–32.

explored for biomedical applications are those between 10 and 500 nm in diameter. This class of materials is being investigated as carriers both for conventional drugs and biopolymer therapeutics, such as peptides, proteins, and enzymes, as well as nucleic acids.[19] They can be prepared from biodegradable or nonbiodegradable, inorganic, organic, and biological materials. Many components ranging from lipids, natural polymers such as albumin, gelatine, and derivates of alginate, through to a host of synthetic polymers have been evaluated (Figure 2).[20,21]

As noted previously, DNA and RNA are large, negatively charged, hydrophilic macromolecules that do not cross biological membranes efficiently. Compaction and protection inside a nanoscale carrier is a means by which the transport of nucleic acids can be enhanced, as particles in this size range can be taken up into biological tissue and subcellular organelles by a variety of processes. Classes of NP vectors for gene delivery fall broadly into two types: viral and nonviral, but irrespective of their classification, an ideal gene delivery vector needs to meet the following requirements:

- Ability to transport nucleic acids of varying sizes
- Ability to transduce cells

- Ability to target a specific cell type and/or subcellular organelle
- Controlled release of nucleic acid at target site
- Low toxicity and immunogenicity.

In addition, nucleic acid vectors need to be able to cross biological barriers without adverse interaction with other cells, blood components, or the reticuloendothelial system (RES).[22]

4.424.2.1. Viral Vectors for Nucleic Acid Delivery

Nature has solved the problem of nucleic acid delivery with its own nanoscale vehicles: viruses. Viruses are prototypical gene therapy agents that have evolved to fulfill many of the roles required of a gene therapy vector (see **Chapter 2.202, Engineering Viruses For Gene Therapy**). It is, therefore, unsurprising that much research has focused on the production of viruses as gene therapy vectors, several of which have been extensively reviewed recently and to which the reader is referred for a more detailed coverage of the topic.[23–26] Viral vectors have several advantages over their nonviral counterparts, including established mechanisms for cell entry, nucleic acid release and nuclear transport, and long-term gene expression through sustained replication (e.g., adeno-associated virus) or gene integration into the host genome (e.g., retroviruses). Despite their prevalence, more than two-thirds of gene therapy clinical trials to date have used viral vectors (http://www.wiley.co.uk/genmed/clinical), there are still outstanding barriers to the widespread use of viral vectors. First and foremost are safety concerns regarding the immunogenicity, toxicity, and mutagenicity of viral vectors. Adenovirus serotype 5 (Ad5), the most widely used vector in clinical trials, has been linked to severe immune response resulting in a patient fatality.[27,28] Gene integration has also been linked to leukemia-like disease in children treated with murine leukemia virus for severe combined immunodeficiency disorder.[29] These problems have been alleviated to some extent through modification of viral vectors to remove the gene(s) responsible for pathogenicity or improve target selectivity. The other disadvantages of viral vectors may be summarized as a lack of versatility and the resulting cost of development, regulatory clearing, and manufacture. No virus is universally applicable to gene therapy due to the aforementioned safety concerns, packaging capacity (the size of a genome that can be contained within a virus), and their compatibility with the desired administration route. Continuing the Ad5 example, stability has been demonstrated to be sensitive to both increases and decreases in genome length, limiting the size of genes that may be added or removed as required. Additionally, systemic (intravenous) delivery is complicated by Ad sequestration by erythrocytes[30] and commonality of anti-Ad neutralizing antibodies.[31,32] The genetic modifications required to tailor a viral vector to a disease and the resulting procedures to demonstrate its regulatory safety and subsequent manufacture make viral gene therapy financially very costly. Synthetic nonviral NPs offer a simpler, cheaper method of nucleic acid delivery that may be applicable to a wider range of diseases.

4.424.2.2. Nonviral Vectors for Nucleic Acid Delivery

Nonviral vectors are potentially advantageous compared to viral vectors due to the possibilities of enhanced stability, ease of modification, low acute toxicity, low cost, standardized production, better (bio)safety profile, and higher flexibility. Although nonviral vectors can be derived from inorganic materials, synthetic or natural lipids and polymers, dendrimers, and combinations of these, for this chapter, we concentrate on organic and polymeric materials, as inorganic vectors have been the subject of a number of recent reviews.[33–35] The resultant vectors can be in the form of liposomes, micelles, vesicles, or polyelectrolyte complexes, but nearly all are generated as NPs with various degrees of structural rigidity. The association of many of these carriers with DNA or RNA is via charge–charge interaction, utilizing cations in a lipid or polymer to form polyelectrolyte complexes with the polyanionic nucleic acid. Complexes of nucleic acids with cationic lipids are often described as lipoplexes, while those with polymers are generally referred to as polyplexes.[22,36–39] Other NP delivery systems encapsulate DNA or RNA without charge interactions by kinetically trapping the nucleic acid in a polymeric matrix or reservoir, for example, inside the hydrophilic core of a vesicle or polymersome. In general, nonviral vectors are less immunogenic than viral systems and can therefore be administered repeatedly to the patient without leading to severe immune responses.[40,41] Another major advantage is greater flexibility regarding the size of the delivered transgenes compared to viral delivery. For example, the titers of recombinant adenoviruses are heavily reduced when the genome is either too short or too long.[42] However, it should be noted that to date, nonviral vectors have shown low overall transfection efficiency, and the resultant gene expression has often been of short duration. Some nonviral vectors have also been shown to be toxic.

4.424.3. Classes of Nonviral Vectors

4.424.3.1. Cationic Lipids and Liposomes

Cationic lipids are amphiphilic molecules in which the water-soluble group is positively charged. Generally, they may be considered to be composed of three sections: a hydrophobic lipid group, or anchor, which may be either one or two fatty acid or alkyl moieties or a cholesterol moiety, a hydrophilic amino head group, and a linker that connects these moieties. Lipid anchors have typically been chosen for their ability to facilitate lipoplex fusion with the cell membrane and to aid in destabilization of intracellular barriers such as endosomal compartments[43] while the amino moieties bind the nucleic acid electrostatically serving to condense it.[44,45] The electrostatic interaction between lipids in cationic liposomes and anionic biopolymers results in a polyelectrolyte interaction as the self-assembled cationic lipids behave, in effect, as a polycation. The resulting materials are able to associate into a range of different structures with nucleic acids, including DNA/RNA adsorbed onto the surface of cationic liposomes, encapsulated within the interior of the liposome itself or the nucleic acid absorbed between the lamellae of multilamellar structures.[46,47]

Focused methodical research into lipid-mediated DNA delivery *in vitro* can be considered to have started in 1987, with the discovery that high transfection levels could be obtained with DNA complexed to dioleyloxypropyl trimethylammonium chloride:dioleoylphosphatidylethanolamine (DOTMA:DOPE) liposomes in the JZ-1 cell line.[48] (A 1:1 mixture

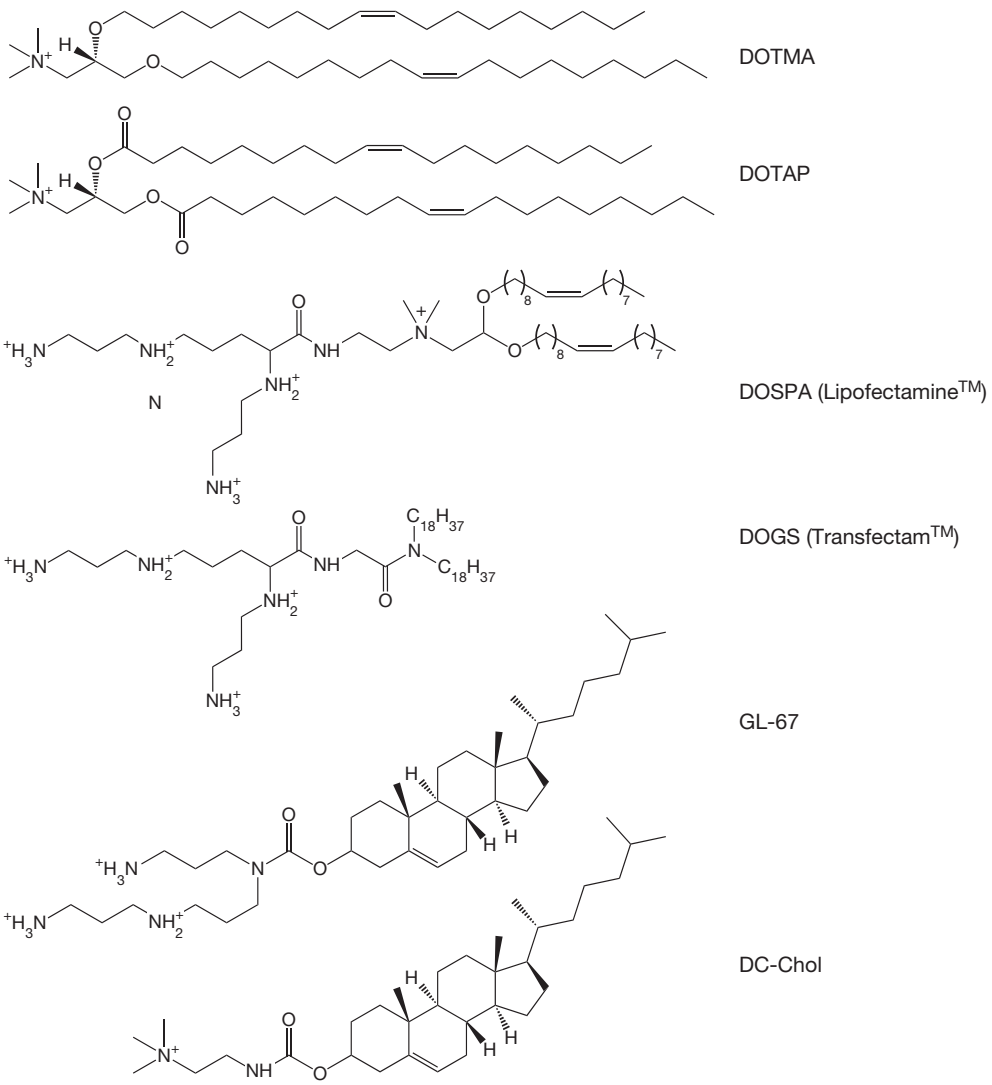

Figure 3 Example structures of cationic lipids. *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA). 1,2-bis(oleoyloxy)-3-(timethylammonio)propane (DOTAP). DOSPA, dioctadecyl amino glycyl spermine (DOGS). *N*-4-spermine cholesteryl carbamate (GL-67). 3-β-[*N*-(*N*′,*N*′-dimethylaminoethane)-carbamoyl] cholesterol (DC-Chol).

of DOTMA:DOPE has since been commercialized as Lipofectin (GIBCO-BRL).) In this example, DNA was simply mixed with the cationic lipids as opposed to the encapsulation of DNA into the liposome. Since this groundbreaking work, many other cationic lipids have been extensively studied as nonviral gene carriers.[48] In addition to DOTMA and DOPE, common examples include 1,2-bis(oleoyloxy)-3-(trimethylammonio)propane (DOTAP),[49] dioctadecylamidospermine (DOGS, Transfectam™),[50] 3-β-[*N*-(*N*′,*N*′-dimethylaminoethane)-carbamoyl] cholesterol (DC-Chol),[51] and GL-67[52] (see **Figure 3** for structures). In general, these have been used in the form of liposomal systems, as these have been demonstrated to reduce extracellular degradation by DNase, resulting in increased transfection efficiency.[53]

Structure–activity relationship studies have demonstrated that even subtle differences in the head group structure, such as a change from alanine to its isomer β-alanine, can cause significant differences in transfection efficiencies of certain cell lines.[54] Postmitotic cells are considered to be more difficult to transfect than dividing cells, as many transfection reagents rely on the breakdown of the nuclear envelope in order to take up the therapeutic DNA (usually in the form of a plasmid, or pDNA). Lipofectamine 2000, a widely used commercially available vector, has been found to be efficient in the transfection of postmitotic neuronal cells (rat embryonic cortical and hippocampal tissues)[55] and is able to facilitate the delivery of DNA through intact nuclear membranes.[56] Lipoplexes formulated with a high positive charge have shown charge-related toxicity and therefore, *in vivo* applications of these gene delivery agents require them to be administered as close to the target site as possible.[57] This administration preference has recently been demonstrated in several *in vivo* studies. Experiments conducted by Saada *et al.* involved the instillation of a transfection solution of bis-guanidinium-tren-cholesterol/dioleoylphosphatidylethanolamine (BGTC/DOPE) cationic liposomes into sheep fetus airways, combined with tracheal occlusion, to treat lung hypoplasia associated with congenital diaphragmatic

hernia (CDH). The gene therapy strategy required dosing of keratinocyte growth factor to the airways to improve the development of type II alveolar cells, which are found to be of reduced abundance in CDH cases treated purely with tracheal occlusion. The tracheal occlusion maintained the transfection reagent in contact with the target region, and the liposomes used were found to mediate efficient transfection into the sheep airways.[58] A preliminary study involving a single patient involved treatment of hereditary inclusion body myopathy by intramuscular injection of 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) and cholesterol liposomes carrying the therapeutic gene. An improvement in muscle function was observed in some of the muscle groups treated, and limited toxicity was noted.[59]

Lipids featuring polycationic spermine head groups, such as DOGS, and GL-67, have been demonstrated to form lipoplexes with better defined, more compact (50–100 nm), structures compared to other cationic lipids and promote more efficient escape from endosomal compartments.[60] GL-67:DOPE liposomes have been demonstrated to yield a 1000-fold increase in transfection compared to naked DNA and 100-fold compared to other cationic lipids in a murine model via nasal delivery to lungs.[52]

Careful design of formulation has enabled lipoplexes to be produced using anionic lipids, in which ternary complexes of endogenous-occurring nontoxic anionic lipids (e.g., DOPG/DOPE mixtures), combined with Ca^{2+} ions (to provide cation content), and nucleic acids were found to impart high transfection efficiency and low toxicity.[61–63] It has been proposed that excess Ca^{2+} ions associated with the lipoplex surface could be responsible for its interaction with the cell surface, thus facilitating cellular uptake.[61]

4.424.3.1.1. Cytocompatibility of cationic lipids and liposomes

Despite their widespread use in lab-based studies, there are still some concerns for liposomal delivery vectors. As with many other nonviral vectors, cell toxicity, poor nucleic acid loading, instability, and inefficient entry to the cell (and for DNA to the nucleus) still represent major hurdles to their intended application.[46,64–67] It has also been found that DNA lipoplexes can display increased cytotoxicity compared to the cationic lipid alone, resulting in cellular apoptosis.[68] In an attempt to overcome these hurdles, other groups that target the lipoplexes to specific cells or subcellular compartments may be coupled with cationic lipid surfaces. The transactivating transcriptional (TAT) activator peptide from HIV has been reported to enhance cell entry by a nonendocytotic pathway.[69] TAT peptide–liposome–DNA complexes have been shown to possess both improved efficiency of gene delivery and reduced toxicity as compared to cationic lipids alone.[70] Antibody-recognizing cell surface molecules and tissue-specific ligands such as asialoglycoprotein and transferrin (Tf) have also been attached to the surface of liposomes. Accordingly, it is possible that enhanced targeted liposomal formulations may yet prove advantageous in practical nucleic acid delivery. In addition, it is worth considering that specific modalities in nucleic acid delivery can be more or less important for classes of cationic lipids and other vectors dependent on the particular application. Thus, transfection by cationic lipids is widely used for *in vitro* cell culture experiments, where toxicity is less of a problem, whereas for *in vivo* therapies or *ex vivo* transfection and reinfusion, cation-induced toxicity is much more problematic.

4.424.3.2. Synthetic Peptides

Peptides and novel polypeptides are an important class of nucleic acid vectors. Some polypeptides are inherently favorable for delivery in the cytosol as they possess specific amino acid sequences that can destabilize cellular and subcellular membranes.[71,72] Several peptide sequences have been shown to have pH-selective endosomolytic effects,[73] while peptides rich in basic residues, such as lysine and/or arginine, exhibit the ability to efficiently condense large nucleic acids into small, compact particles.[74,75] Additionally, there are cargo proteins containing nuclear localization signals (NLS), which can be recognized by import carriers (such as importin-β), in the cytoplasm that have been found to be essential for nuclear translocation capability.[76,77] In recent years, the design of polypeptides capable of responding to environmental changes or stimuli (e.g., the redox potential gradient) by alteration of their properties and behavior has begun to be exploited for improving the efficacy of the delivery process. Redox-sensitive polyplexes based on such cationic peptides represent a promising option because of the possibility of combining DNA condensation capability with an inherent biological activity of the peptides.[78,79] Various basic amino acids have been utilized in the manufacture of synthetic peptide vectors, primarily lysine, arginine, and histidine (pK_a values of ~10.5, 12.5, and 6, respectively), often combined with the thiol-functional amino acid cysteine.

4.424.3.2.1. Lysine-containing peptides

Lysine has a well-documented efficacy in polyplex formation due to the efficient anion-binding capability of its positive side chains, which are fully protonated at physiological pH (pK_a ~10.5). This in turn increases extracellular stability of polyplexes and their cellular uptake via endocytosis due to the electrostatic binding to proteoglycans on cell surfaces. Lysine has generally been converted to the homopolymer, poly-L-lysine (PLL), which is the most commonly used polypeptidic gene delivery vector. PLL is a biodegradable material that can mediate gene delivery both *in vitro* and *in vivo*.[80,81] PLL is commercially available in various molecular weights ranging from approximately 1 to 300 kDa. Its pK_a value is ~10 which is relatively high compared to other polypeptidic vectors. This property enables it to package nucleic acids into nanoparticulate complexes, masking the negative charge of DNA and RNA and shielding against enzymatic and hydrolytic degradation. High-molecular-weight PLL has a greater net positive charge and therefore forms tighter, smaller, and more stable complexes than the low-molecular-weight PLL[82,83]; however, high-molecular-weight PLL has shown high levels of cytotoxicity.[74] In general, PLL has been regarded as quite inefficient in terms of endosomal escape and transfection efficiencies,[46] and is less potent than poly(ethyleneimine) (PEI).[84] The poor gene expression observed *in vitro* when PLL was used alone necessitated the concomitant addition of endosomolytic reagents such as chloroquine or a fusogenic peptide.[81,85,86] PLL has been enhanced as a vector by direct modification, such as the

incorporation of cleavable bonds in the backbone or side chains, to reduce *in vivo* toxicity and to enhance transfection efficiency due to facilitated release of nucleic acid. It has also been possible to attach targeting ligands, such as sugars, folic acid derivatives, antibodies, and proteins (e.g., Tf), allowing receptor-mediated gene delivery to be achieved.[87] Transfection efficacy of PLL has also been improved by conjugation to other peptides such as fusogenic or cell-penetrating peptides (CPPs) or modification with histidine to enhance endosomal escape.[88]

4.424.3.2.2. Arginine-containing peptides (CPPs)

Arginine-containing peptides are highly cationic and hydrophilic, and have been shown to be promising biological transport systems. This has been attributed to the arginine residues causing translocation of vectors to the cell membrane, allowing access to the cellular interior and leading to efficient internalization of cargo.[89] Certain specific arginine-based systems are strongly membrane-permeabilizing and have come to be referred to as protein transduction domains (PTDs) or CPPs. Examples of these peptides are TAT, the transcription activating factor of the HIV,[69,90] and the drosophila homeodomain protein-derived penetration.[91] The TAT peptide has been the most frequently investigated protein-derived CPP, and its translocation efficiency seems to be due to a small cluster of basic amino acids (GRKKRRQRRR) containing mainly arginines and lysines[90,92]; cell surface binding of TAT residues is not dependent on specific receptors.[93,94] TAT has been widely exploited for the intracellular uptake of different size cargoes in different cell types both *in vitro* and *in vivo*[95,96]; studies have also reported facilitated delivery of TAT-conjugated protein into live mice tissue following intraperitoneal injection.[97–99]

4.424.3.2.3. Histidine-containing peptides (endosomal escape peptides)

Histidine-based peptides have also been explored for gene delivery studies due to their biocompatibility and lack of toxicity.[100] The imidazole side chain of histidine has a pK_a of ~6.0[81,101] and thus becomes cationic in a slightly acidic medium. These histidine-rich peptides are able to buffer effectively at endosomal pH, resulting in an influx of counterions into the endosomal compartments (the proton sponge hypothesis[102]) as well as form strong electrostatic interactions with the subcellular membranes when protonated, allowing the endosomal escape of DNA.[103]

A peptide containing several histidines, H5WYG (GLFHAIAHFIHGGWHGLIHGWYG), was designed by Midoux and coworkers and was shown to efficiently permeabilize cell membranes at pH 6.4. H5WYG also increased the expression of genes transferred to cells and was resistant to protein adsorption due to its neutral charge at physiological pH.[103,104] Polyhistidine, containing a high density of imidazole groups, has been investigated as a gene vector but, due to its insolubility at physiological pH (at pH > 6.0), it has required covalent conjugation to more water-soluble components, such as to gluconic acid (glycosylated polyhistidine), for formation of complexes with nucleic acids.[105] Polylysine conjugated to the Tf has been added to DNA/poly-L-histidine polyplexes to achieve DNA condensation and to provide targeting for receptor-mediated endocytosis. The resultant complexes were shown to have desirable physicochemical properties for gene delivery and were essentially nontoxic.[100]

Benns and colleagues synthesized *N*-Ac-poly(L-histidine)-graft-poly(L-lysine) (PLH-*g*-PLL) by grafting poly(L-histidine) to PLL in order to make use of the dual properties of both polymers for efficient gene transfer (extracellular DNA binding and endosomal escape).[106] Similarly, Pichon and coworkers designed histidylated polylysine molecules that yielded a transfection of 3–4.5 orders of magnitude higher than polylysine alone.[107]

4.424.3.2.4. Cysteine-containing peptides

Cysteine, possessing side-chain sulfhydryl (thiol) groups, has been exploited as a useful tool for the introduction of disulfide bridges between cationic polymer chains to form thiopolycations.[74] The disulfide bond (–S–S–) between cysteine side chains forms readily upon oxidation in biological conditions. Furthermore, two advantageous characteristics render this bond attractive in the context of gene delivery vectors. These are (i) the reversibility of thiol-disulfide conversion within the cell and (ii) the relative stability of disulfide links in plasma.[108] Disulfide bonds have been investigated extensively in the design of (bio)reducible polycations (RPCs), by utilizing the presence of a high redox potential difference between the oxidizing extracellular space and the reducing intracellular space.[109] RPCs can form stable complexes with nucleic acids in the extracellular oxidative environment, while allowing for triggered DNA or RNA release intracellularly via cleavage of the disulfide bonds by glutathione (GSH), which is located in both cytoplasmic and nuclear compartments; consequently, gene expression is enhanced and cytotoxicity is significantly reduced.[71,74,109] Oupický and colleagues developed a synthetic vector based on an RPC prepared by oxidative polycondensation of the peptide Cys–Lys_{10}–Cys, enabling reduced toxicity and efficient DNA release.[110] Addition of DOTAP to these RPCs yielded up to a 187-fold higher level of gene expression compared with nonreducible PLL.[111]

4.424.3.3. Chitosan and Derivatives

Chitosan is a heteropolysaccharide, derived from the natural product chitin, consisting of 2-acetamido-2-deoxy-*N*-D-glucose (*N*-acetylglucosamine) and 2-amino-2-deoxy-*N*-D-glucose (glucosamine) linked by β-1→4-glycosidic bonds, and arranged in a random manner.[112] The pK_a of the glucosamine amino groups has been reported to be ~6.5.[113,114] Chitosan is prepared by alkaline N-deacetylation of chitin, which is mainly derived from crustacean shells.[112,115] Owing to low immunogenicity, minimal toxicity, biocompatibility, and biodegradability, chitosan has been considered as a suitable candidate for nonviral gene delivery.[116] However, some chitosans have shown cytotoxicity, which was dependent on their molecular weight, degree of deacetylation, and salt form.[117] Chitosan cell compatibility has been enhanced by separating and purifying low-molecular-weight fractions.[118] The degree of deacetylation has also been found to be important in terms of transfection efficiency, as it affects zeta potential, cellular uptake, and *in vitro* and *in vivo* transfection of its complexes.[119]

The strength by which chitosan can complex nucleic acids can be controlled by changing the fraction of positively charged monomer (i.e., by changing the degree of chitin

deacetylation). The degree of acetylation must not exceed 35% to obtain stable chitosan polyplexes.[120] Transfection efficiency is unaffected by chitosan molecular weight in the 20–200 kDa range,[121,122] but high molecular weights lead to low solubility at physiological pH[123] and high viscosity.[120] However, complexes between small multivalent cations, including chitosan oligomers, and DNA are not stable under physiological conditions.[60,124] Hence, chitosan fractions have been chosen specifically to have backbones long enough to form stable polyplexes, but sufficiently short to be soluble at neutral pH with minimal viscosity modification, as well as forming complexes that are easily dissociated and less prone to aggregation.[105,124] Moreover, shorter polycations have displayed reduced toxicity, including decreased complement activation and platelet aggregation, compared to their high molecular weight counterparts.[125,126] Chitosan–DNA complexes were found to be less compact than other polyelectrolyte complexes due to the rigidity and low cation density of the chitosan backbone; this may result in DNA degradation due to increased exposure to extracellular nucleases.[127]

Chemical modification of chitosan has been utilized to improve these properties. Solubility at physiological pH has been increased while reducing viscosity by conjugation of a lactobionic acid, to yield galactosylated chitosan.[128] Modification with histidine[129] or deoxycholic acid has resulted in amphiphilic chitosan that self-associates into 100–300 nm aggregates depending on molecular weight and on the level of incorporation of the hydrophobic moiety. Deoxycholic acid-modified chitosan polyplexes were shown to transfect COS-1 cells *in vitro*, but no comparison to a commercial transfection reagent or unmodified chitosan was shown (**Figure 4**).[130]

4.424.3.4. Synthetic Polymer/Polyplex Carriers

In addition to the biomimetic and naturally derived polymers described earlier, many synthetic polymers have been investigated (see **Chapter 1.121, Polymer Fundamentals: Polymer Synthesis**; **Chapter 1.130, Electroactive Polymeric Biomaterials**; **Chapter 1.131, Superporous Hydrogels for Drug Delivery Systems**; **Chapter 4.422, pH-Responsive Polymers for the Intracellular Delivery of Biomolecular Drugs**; **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**; and **Chapter 1.123, Degradable Polymers**). Synthetic polymers are advantageous compared to peptides and polysaccharides as they may be synthesized with relative ease and in large quantities. Properties such as molecular weight and side-chain functionality may also be finely tuned to the desired application. Synthetic polymeric NPs for nucleic acid delivery can be split into three broad subtypes: those that condense DNA or RNA into NPs via polyelectrolyte interactions, those that encapsulate the nucleic acid into the core of a capsule or matrix, and those that complex with DNA or RNA on a surface of a preformed NP (**Figure 5**).

Important parameters for all polymeric nucleic acid delivery systems are the molar mass of polymer, composition, viscosity,

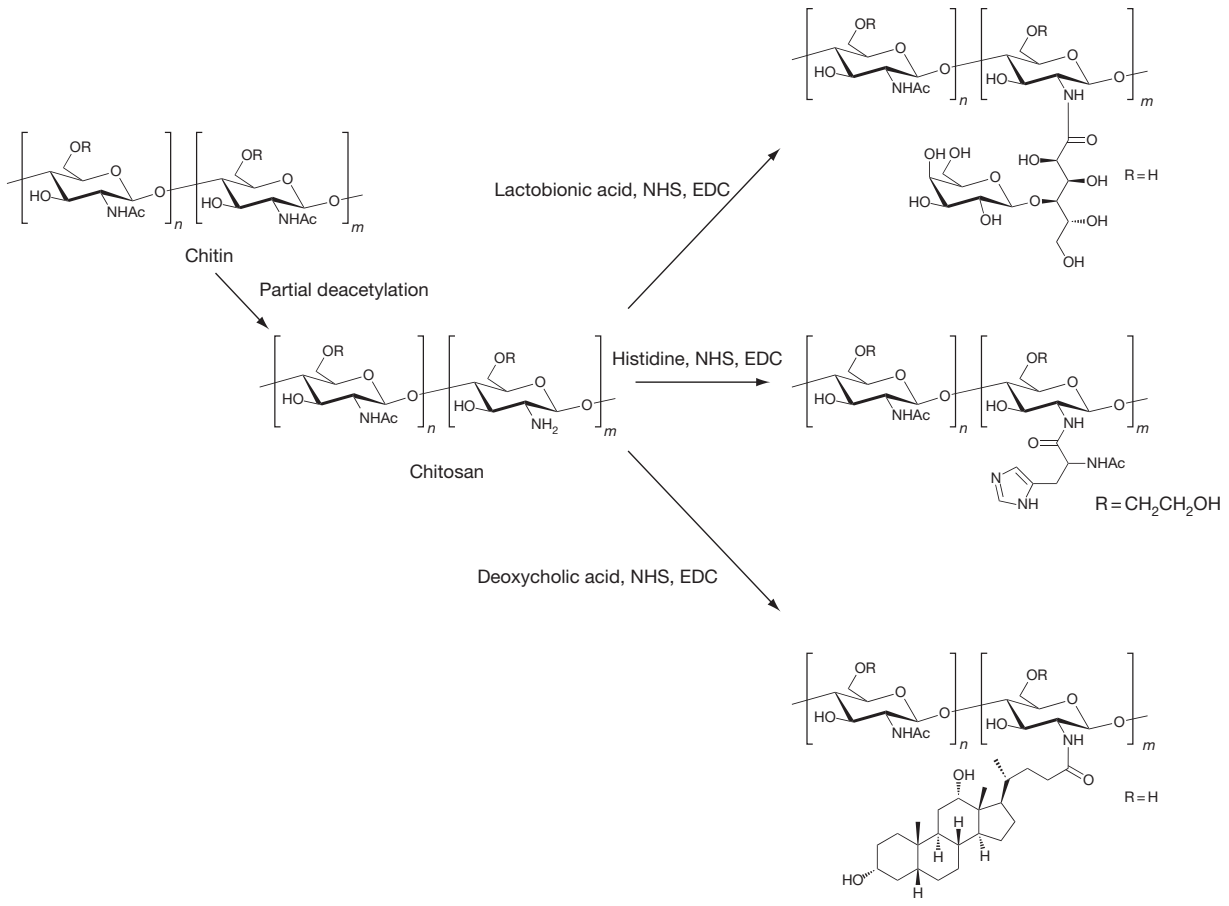

Figure 4 Chitosan derivatives for nucleic acid delivery (polyplex carriers).

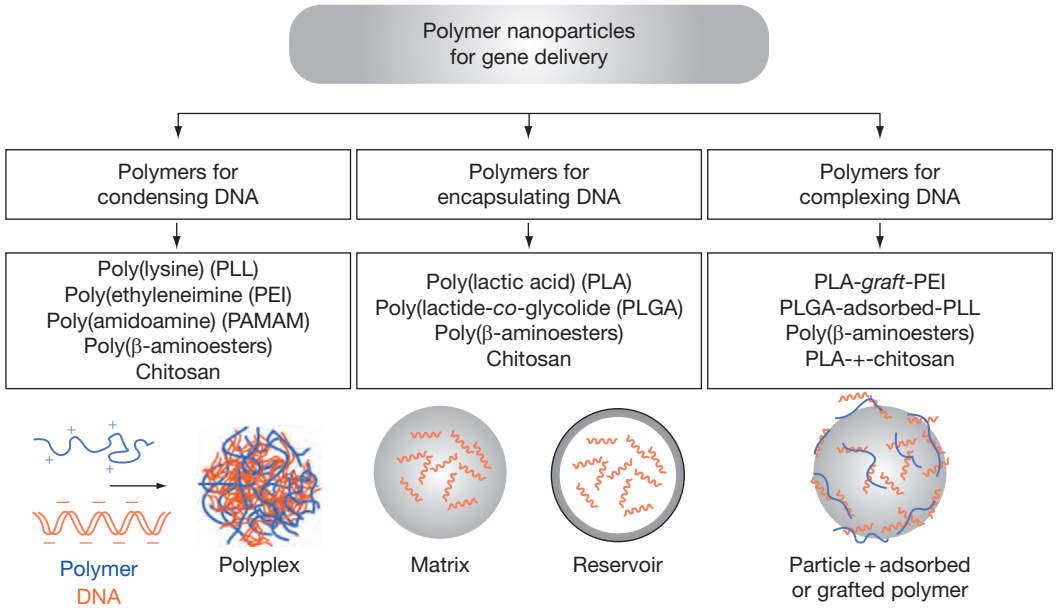

Figure 5 Categories of polymeric nanoparticles used for gene delivery.

and biocompatibility or degradability. Other factors such as emulsifying capabilities and charge of the polymer can affect interactions with, or loading of, nucleic acids, as well as change other properties such as the overall size of the NP, its surface functionality, cellular uptake, and release of cargo.

4.424.3.4.1. Polycations for condensing nucleic acids

The field of polymeric cationic nucleic acid delivery vectors is an intensively researched and highly competitive area. Many natural and synthetic polycations have been used for delivery of nucleic acids, with the focus mostly on DNA delivery until the potential of siRNA became apparent. These include histones (H1, H3, or H4), polylysine, histidylated polylysine, polyornithine, polyarginine, high-mobility group protein (HMG) 1 and 17, modified chitosans, cationized human serum albumin, PEI, polypropyleneimine (PPI), cationic dendrimers, poly(2-(dimethylamino) ethyl methacrylate) (PDMAEMA), polyallylamine derivatives, diethylaminoethyl (DEAE)-dextran, and poly(*N*-alkyl-4-vinylpyridinium) salts.[131–138] Efficiency of gene delivery can be improved by chemical modification as well as adding targeting ligands and nuclear localizing sequences to these polycations.[22,84,139,140] One almost universal feature of these delivery agents is the ability of the vector to condense large nucleic acids such as plasmid DNA into particles that are in the 50–250 nm size range. This size, akin to that of virus particles, enables endocytosis of the particle to overcome the cellular membrane barrier. The condensed structure also provides protection of the nucleic acid from *in vivo* enzymatic degradation. Condensation of the polyanion is achieved through electrostatic interactions and subsequent loss of charge–charge repulsion as the negatively charged phosphate groups of the nucleic acid backbone interact and are neutralized by the cations of the polymer carrier. Polymeric DNA delivery, although far less efficient than viral DNA delivery, offers advantages in terms of size of DNA that can be delivered, improved safety profiles, and ease of production.

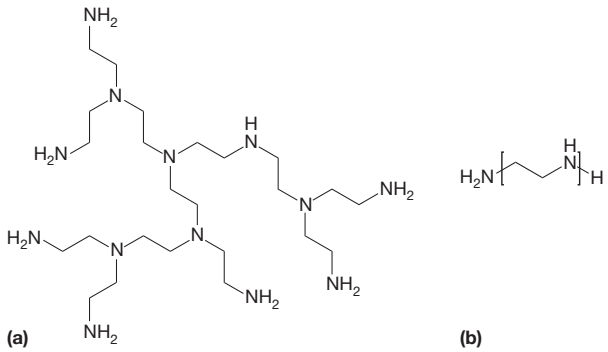

Figure 6 Polyethyleneimine (PEI) structures: (a) branched PEI and (b) linear PEI.

4.424.3.4.1.1. DEAE–dextran

DEAE–dextran was one of the first polycations to be used in gene delivery studies. In 1965, Vaheri *et al.* used DEAE–dextran for *in vitro* delivery of infectious viral nucleic acids and in 1984, Lopata *et al.* performed transfection studies with DEAE–dextran. However, compared to other polymers, DEAE–dextran has been found to be toxic and nonbiodegradable, and its transfection efficiency is low. These properties have limited its usage as a gene carrier system.[141,142]

4.424.3.4.1.2. Polyethyleneimine

PEI is a linear or branched cationic polymer (Figure 6), available in different molecular weights (e.g., 700 Da, 2, 25, 50, 70, 800 kDa), that condenses DNA by electrostatic interactions and displays high transfection efficiency *in vitro* and *in vivo*. Every third atom of PEI is an amine group, and protonation can increase from ~20% at pH 7 to ~45% at pH 5.[143] This in turn facilitates its interaction with negatively charged cell membranes via heparan sulfate proteoglycans, resulting in improved cellular uptake.[144]

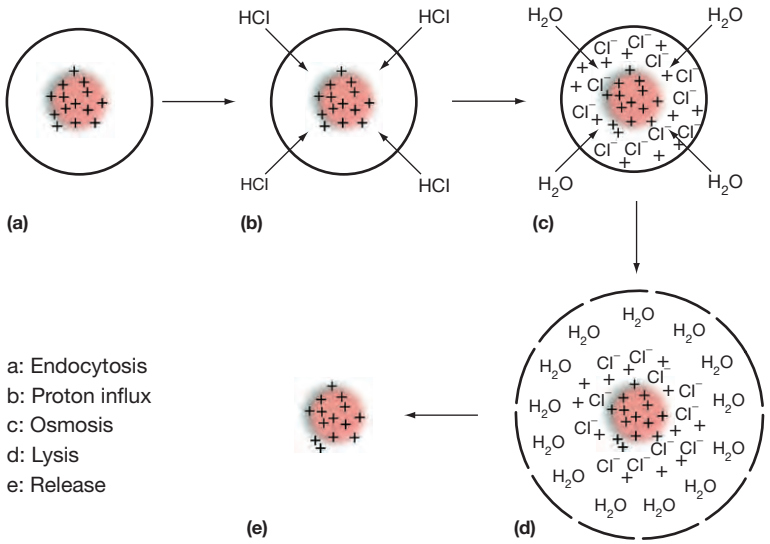

Figure 7 The proposed proton sponge mechanism of endosomal escape: (a) polyplexes enclosed in an endosome after endocytosis (b) due to the pH buffering in the endosome, the protons are continued to pump in the vesicle resulting in Cl^- influx and increase in the osmolarity inside the endosomal vesicle. (c) Because of the osmolarity increase, water passes into the endosomal vesicle. (d) The increase in water volume results in the swelling of the endosomal compartment until it ruptures to (e) release the polyplex into the cytoplasm which leads to nuclear uptake of DNA.

Use of PEI as a DNA delivery vector was initially proposed in 1995 by Boussif *et al.*[131] Promising results were obtained *in vitro* and since then the polymer has been extensively studied in attempts to improve the efficiency and reduce its toxicity. PEI is regarded as a prototypical vector material on account of its high density of amine groups and its potential to buffer endosomes aiding escape of the DNA from degradation in the lysosome. The high buffering capacity of PEI contributes significantly to its high transfection efficiency specifically via the proton sponge effect (**Figure 7**).[60,131,145,146] After cellular uptake of PEI polyplexes, via endocytosis, acidification of the endosome begins, and PEI induces very high accumulation of protons, leading to the passive influx of chloride ions accompanied by water. The increase in osmotic pressure results in swelling and eventually rupture of the endosomal vesicle and efficient DNA release.[131,147]

Akinc *et al.* explored in detail the effect of PEI as a proton sponge and the resulting enhanced release of PEI/pDNA complexes. When endosomal acidity was reduced using a proton pump inhibitor (bafilomycin), transfection was reduced by two orders of magnitude. A similar reduction in transfection efficiency was seen when the ability of PEI to become increasingly protonated was removed through N-quaternization. Both these results suggested that the effectiveness of PEI resulted, in part, from its ability to confer escape of polymer–DNA complexes from endosomes and thus avoid degradation of DNA in subsequent digesting lysosomes.[102]

PEI polyplexes have the advantage of being less toxic and more efficient than lipoplexes *in vitro*[148] and *in vivo*.[131,149] They are also more efficient than PLL and do not require endosomal escape agents (e.g., chloroquine).[150] The DNA condensing ability of PEI has been found to be critical for transfection efficiency.[84] For example, 2 kDa PEI, which condensed pDNA into large aggregates (2 μm in size), yielded poorer transgene expression than 25 kDa PEI that formed small compact particles (80–100 nm).[151,152]

Despite being very efficient in transfecting cells, the main disadvantage of PEI is its high cationic charge density and nonbiodegradability. This has resulted in some toxicity compared to otherwise similar but biodegradable polycations.[135,153–156] Lower molecular weight PEI (800 Da) shows less toxicity but also a reduction in transfection efficiency.[143,157] Therefore, much research has been focused upon polymerizing the lower molecular weight species using degradable linkages to enable higher transfection efficiency with reduced toxicity.[157–159]

4.424.3.4.1.3. Amino-functionalized methacrylates and methacrylamides

(Meth)acrylate and (meth)acrylamide polymers have attracted attention as gene delivery vectors due to their biocompatibility, relative ease of synthesis, and availability of functional monomers with different positive charge-bearing moieties. Cationized polymers previously tested as gene delivery include poly[2-(dimethylamino)-ethyl methacrylate] (p[DMAEMA]); poly[3-(dimethylamino)-propyl methacrylate] (poly[DMAPMA]); poly[2-(dimethylamino)-ethyl methacrylamide] (p[DMAEMAm]); poly[3-(dimethylamino) propyl methacrylamide] (p[DMAPMAm]); poly[2-(trimethylamino) ethyl methacrylate chloride] (p[TMAEMA]); poly[2-(diethylamino)ethyl methacrylate], (p[DEAEMA]); and poly[2-(dimethylamino)ethyl acrylate], (p[DMAEA]). Of these, p[DMAEMA] has been shown to have the best transfection efficiency.[160] p[DMAEMA] is a water-soluble synthetic polycation that can strongly bind nucleic acids through electrostatic interactions forming small and compact particles. However, p[DMAEMA]/DNA ratio was found to determine both the size and charge of the condensed polyplexes. Moreover, the weakly basic secondary amines in the p[DMAEMA] side chains are partly (~50%) protonated at physiological pH (pK_a ~7.5), hence are expected to confer some endosomal escape properties through buffering and osmolysis of acidic endosomal vesicles. However, p[DMAEMA] has demonstrated cytotoxic effects, which

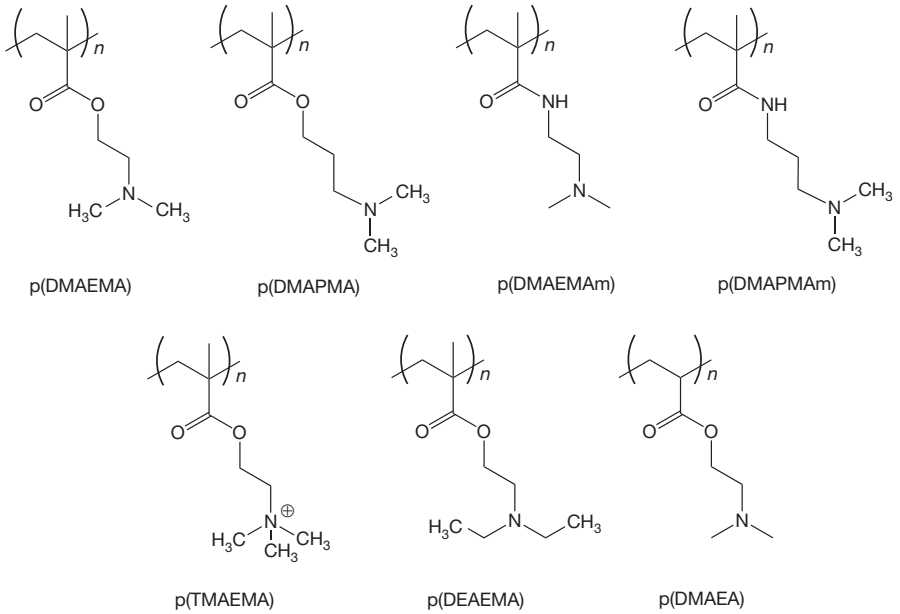

Figure 8 Structures of (meth)acrylate and (meth)acrylamide polymers tested as nucleic acid delivery vectors.

are thought to be due to late endosome or lysosome bursting, leading to undesired enzymatic activity in the cytosol. The observed p[DMAEMA] cytotoxicity and nonbiodegradability have limited its usage in gene delivery, irrespective of its efficiency to transfect cells (Figure 8).[160–162]

4.424.3.4.1.4. Dendrimers

Dendrimers are highly branched, spheroidal, cascade polymer molecules that are synthesized either by divergent or convergent methodologies, forming tree-like architectures.[163] Polyamidoamine (PAMAM) (Starburst) dendrimers, synthesized from an ammonia or ethylenediamine core by successive addition of methyl acrylate and ethylenediamine, have been evaluated extensively as gene delivery vectors.[164–168] PAMAM dendrimers showed high buffering capacity[169] and significantly higher transfection efficiency than PEI for a variety of cell lines.[170,171] Such dendrimers have multiple terminal primary amines with pK_a of approximately 9 (i.e., protonated at physiological pH) and interior tertiary amines with pK_a of 5.5.[166,172] For these systems, it is considered that nucleic acids interact with primary amines on the dendrimer surface while the internal tertiary amines act as buffers exploiting the proton sponge mechanism of endosomal escape. Once endocytosed, the internal tertiary nitrogens of the PAMAM–nucleic acid complexes are protonated in the acidic endosome causing swelling and eventual lysis of the endosome with subsequent release of the polynucleotide into the cytoplasm.[173,174] However, certain cationic dendrimers have been found to be hemolytic and cytotoxic depending on their molecular weight (or generation, see Figure 9) and the number of surface amine groups.[175]

Transfection efficiency of PAMAM dendrimers has been enhanced by adding endosomolytic agents, and also by preparing partially degraded or fractured dendrimers. The improved gene transfer properties of the latter have been partially attributed to their higher aqueous solubility and resistance to aggregation.[22]

Many other dendrimer-based systems have been prepared, with promising recent data on the *in vivo* efficacy of

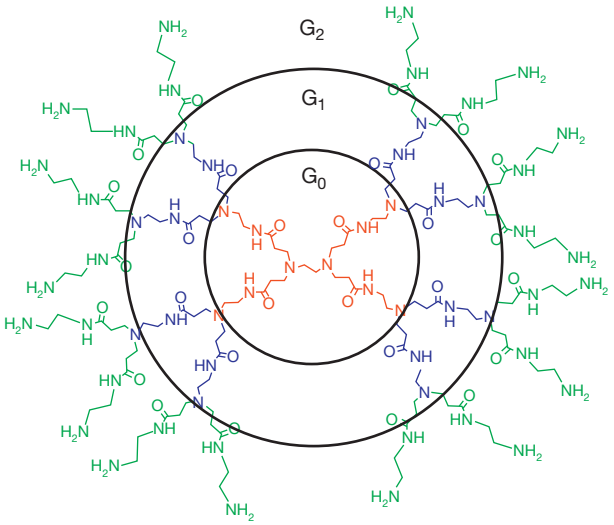

Figure 9 Structure of polyamidoamine (PAMAM) dendrimer. (The core is shown in red (G0). Primary (G1) and secondary (G2) generations are shown in blue and green, respectively.)

poly(propyleneimine) (PPI) dendrimers. Lower-generation (e.g., G2) PPI dendrimers have been found to be the most effective gene carriers compared to higher generation analogs, and these vectors have also been used for efficient delivery of oligodeoxynucleotides (ODNs).[139]

4.424.3.4.2. Polymers for nucleic acid encapsulation

A second class of polymeric gene delivery system utilizes polymers in matrix or encapsulant form. Nanospheres or nanocapsules are obtained according to the preparation method. Nanocapsules are vesicular systems in which the drug is entrapped in the core, whereas nanospheres are usually regarded as matrix systems in which the drug is dispersed.[21]

4.424.3.4.2.1. Micro- and nanoparticle-based gene delivery

Polymer-based micro- and nanoparticles provide several advantages for the delivery of macromolecules such as DNA and RNA. Polymeric delivery systems provide protection against nuclease degradation by encapsulation of the drug and macromolecules in the polymeric matrix.[176] Control over the release of biopolymer into a particular tissue or organ can be achieved via careful tailoring and choice of the polymers and by adjusting parameters such as nucleic acid:polymer ratio, polymer molecular weight, porosity, and functionality. Incorporation of plasmid DNA and oligonucleotides into a matrix of either polymer microparticles or NPs has been investigated widely. Various natural and synthetic polymers can be formulated as matrices and microspheres.[177,178] The structures of some polymers that have been used in microparticle formation for DNA delivery are shown in **Figure 10**.

Poly(lactic acid-*co*-glycolid acid) (PLGA)-based polymers have been widely used in developing microparticles/NPs for encapsulating therapeutic molecules for controlled release applications due to their inherent advantage over conventional devices, including extended release rates from days to months.[179–182] Macromolecules such as proteins, peptides, plasmid DNA, and human growth hormone factor have been successfully incorporated into PLGA-based microparticles/NPs.[183–185] Microparticles with diameters larger than 1 μm are internalized mainly through phagocytosis preferentially by antigen-presenting cells (such as macrophages and dendritic cells), but not by other cells. As a consequence, biodegradable microparticles have been especially investigated for (DNA) vaccination purposes against viruses and tumors, as antigen-presenting cells play a pivotal role in initiation of immune responses. Conversely, submicron-sized particles offer important advantages over microparticles as their cellular uptakes are relatively higher; studies have shown that NPs of 100-nm diameter have 2.5-fold greater cellular uptake when compared to 1 μm and sixfold greater when compared to 10-μm microparticles in Caco-2 cell lines.[186] Similar results were also obtained in a rat *in situ* intestinal loop model; efficiency of uptake of 100-nm-size particles was 15–250-fold greater than larger-sized (1 and 10 μm) microparticles.[187]

4.424.3.4.2.2. Fabrication of nucleic acid-loaded PLGA NPs: challenges and opportunities

A number of approaches are described for encapsulating plasmid DNA or RNA within PLGA-based NPs, including spray drying, phase separation methods, and double emulsion techniques.[188–191] Initially, these approaches were used for encapsulation of peptide and proteins within the PLGA particles but have now been extended to incorporate nucleic acids. The double emulsion technique refers to a process where the aqueous cargo is dispersed in the organic phase to make a water-in-oil emulsion using homogenization or sonication. In the phase separation method, the particles are produced by extracting the organic solvent or adding nonsolvent to induce coacervation, while in spray-drying techniques, particle formulation is achieved by atomizing the emulsion through a stream of hot air to induce rapid solvent evaporation. In addition to the approaches mentioned previously, plasmid DNA can also be coated on the surface of PLGA particles.

4.424.3.4.2.3. Double emulsion techniques for matrix NP nucleic acid delivery

Double emulsions of nucleic acids have typically been formed by mixing or dispersing of an aqueous solution of DNA or RNA with a solution of PLGA dissolved in an organic solvent. The dispersion of the nucleic acid solution is usually performed by using sonication or homogenization techniques. This results in the formation of a first, or primary emulsion in which the aqueous droplets containing nucleic acid are suspended in the organic phase. The size of the droplet formed by sonication or homogenization can be optimized by adjusting the amount of shear force used during the dispersion process. The primary emulsion is then mixed with a second aqueous solution that contains surfactants to prevent the aggregation of water-in-oil droplets (coalescence). The addition of primary emulsion with the solution of surfactant results in precipitation of polymer around the aqueous droplets and finally, the evaporation of the organic solvents leads to the formation of solid particles in which the nucleic acid is embedded and trapped in the polymeric matrix of the particles. PLGA-based particles are sensitive to moisture and undergo hydrolysis upon contact with water; therefore, it is important to keep the final particles free of moisture. Drying of the particles can usually be done by lyophilization for long-term storage. Cryoprotective sugar, usually sucrose or glucose, may be added to the formulation to preserve the tertiary structure (e.g., DNA supercoiling) during the drying process.[192]

One drawback of the double emulsion technique is the shear force used to disperse the aqueous solution of nucleic acid in the organic phase. The energy input through shear force can damage the biopolymer reducing its integrity and, eventually, biological activity. Additionally, contact of nucleic acid with the organic phase can adversely affect the tertiary structure. There are some methods that have been used to minimize nucleic acid damage during the dispersion process. Condensation of DNA with cationic polymers such as PLL has been carried out as described earlier to reduce the size of the DNA and make it less exposed to shear force while preserving

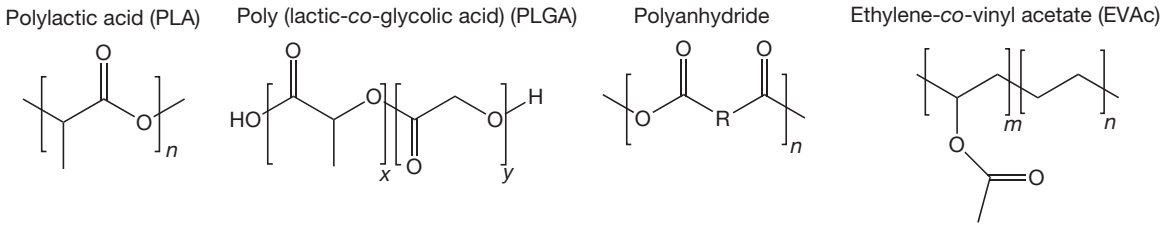

Figure 10 Structure of selected polymeric materials used for gene delivery in nanoparticles.

supercoiling and retaining its biological activity.[193,194] Another technique that has been adopted to reduce the damage by shear force has been to conduct the dispersion of the DNA solution in organic phase of PLGA at reduced temperature. This generated a more viscous solution that was less affected by shear force during the dispersion process.[192] One remaining issue for double emulsion techniques has been low-reported encapsulation efficiencies of the therapeutic biopolymer in the particles. The key problem is that of dose as sufficient therapeutic needs to be incorporated for efficacy. Even for potent biopolymers, such as siRNA, encapsulation of the nucleic acid has often been reported to be inefficient. For example, encapsulation efficiencies of less than 50% have been described for siRNA in PLGA NPs prepared by the double emulsion route, equating to $\sim 3\,\mu g\,mg^{-1}$ loadings on the delivery system.[195]

4.424.3.4.2.4. Spray-drying techniques for matrix NP nucleic acid delivery

Nucleic acid-loaded particles have been produced by combining emulsification steps with spraying via an atomizer through a steam of hot air. Initially, the nucleic acid solution is mixed with a solution of polymer, for example, PLGA in organic solvents using shear force to form droplets of DNA or RNA in the bulk (organic/polymer) phase. Finally, the particles are formed by spraying the suspension of nucleic acid droplets in PLGA solution through an atomizer in the presence of hot air. During spraying of the suspension through the hot air, the organic solvent and water evaporate, resulting in the formation of dried solid particles loaded with nucleic acid. Spray-drying techniques have enabled control of nucleic acid carrier particle size by factors such as the flow rate through the atomizer, temperature of the air, and size of the nucleic acid aqueous droplets.[196] The advantage of this process over the double emulsion technique has been that the addition of primary emulsion into a second aqueous phase is absent, thus reducing nucleic acid loss. However, the mechanical and thermal stresses have not been eliminated from spray-drying techniques, affecting DNA supercoiling.

4.424.3.4.2.5. Adsorption of nucleic acids on PLGA particle surfaces

In this technique, particles have been made by double emulsion techniques in the absence of nucleic acids to produce empty PLGA particles, and in the second aqueous phase stage, the particles have been suspended in solutions of cationic agents which coat the outer surface. Examples have been reported of nucleic acid binding to the external surface through electrostatic interaction, although for this type of procedure, usually the loading efficiency of the biopolymer has been limited to 1% (w/w).[197]

4.424.3.4.2.6. Challenges associated with matrix particles as nonviral gene delivery systems

Generally, nonviral gene delivery systems have been significantly less efficient in comparison to viral vectors. For matrix particles to be considered for practical gene delivery systems in future, they will need to be able to carry a higher amount of the therapeutic biopolymer than has been achieved to date. Secondly, as has been mentioned earlier, the integrity of the nucleic acid such as the supercoiled structure of DNA needs to be preserved during matrix particle formulation, that is, all the detrimental conditions of high shear forces and thermal stress should be avoided or reduced.[198] Considering the *in vivo* transfection efficiency, matrix particles based on PLGA have demonstrated protection of DNA from extracellular nucleases, but have also shown undesirable 'burst release' profiles, as adsorbed DNA has been prematurely lost from the surface of the particles. Another problem particularly associated with PLGA NPs has been the effect of hydrolysis of the PLGA backbone during biodegradation. The hydrolysis process generates lactic and glycolic acid units and may lead to substantial reduction in pH in the PLGA matrix where nucleic acids have been embedded. This in turn has been reported to cause degradation of DNA, compromising its therapeutic effect.[191,199] For RNA therapeutics, similar problems of stability can occur, but with the further complication of rapid degradation of RNA via RNAses. In addition, the short, rigid siRNA chains are difficult to condense compared to large DNA plasmids. This may seem counterintuitive, but in fact better condensation of siRNA into particles has been obtained by linking several siRNA molecules via short flexible linkers, such that multipolymer complexes with polycations are formed. This is most likely a result of connected siRNA 'rods' folding back on each other bridged by polycations, forming a tightly packed complex overall, whereas unconnected siRNA units adopt a more loose arrangement when complexed with the same polycations.[200]

4.424.3.4.3. Polymer micelles and vesicles as NP nucleic acid delivery systems

Polymeric micelles and vesicles form another important class of delivery agent, with some features similar to the nucleic acid condensing vectors, and other properties resembling those of the matrix NP systems. Block copolymers with a cationic segment and a noncharged hydrophilic block have been widely investigated for their ability to self-assemble with polyanionic DNA or RNA to form core–shell structures with high stability and reduced interaction with blood components (**Figure 11**).[201]

Polymeric micelles have a number of other advantages for application in gene delivery.[202] Assembly may be controlled by variation in polymer block length, functionality, and external stimuli, while the chemistry of the external block may be varied to increase steric shielding or add targeting ligands. The general principles behind the use of polymeric micelles are similar to those for other polymer systems used in gene delivery, that is, a cationic segment is often used to condense the nucleic acid, while PEG and other hydrophilic polymers are used to confer protection against nucleases as well as extend residence time in the bloodstream to allow passive targeting. There are now a number of excellent reviews that cover the detailed and more specialist aspects of polymer micelles for nucleic acid delivery.[203–205] Disadvantages of these systems include low drug payload, poor stability in serum in some cases, and potential issues with cost and scale-up.

4.424.3.4.3.1. Stimuli-responsive polymersomes

Polymersomes are vesicular structures, analogous to liposomes, formed by the self-assembly of amphiphilic block copolymers in solution. Due to their higher stability and tuneable size compared to liposomes, they have garnered great interest as potential drug delivery vehicles.[206] In particular,

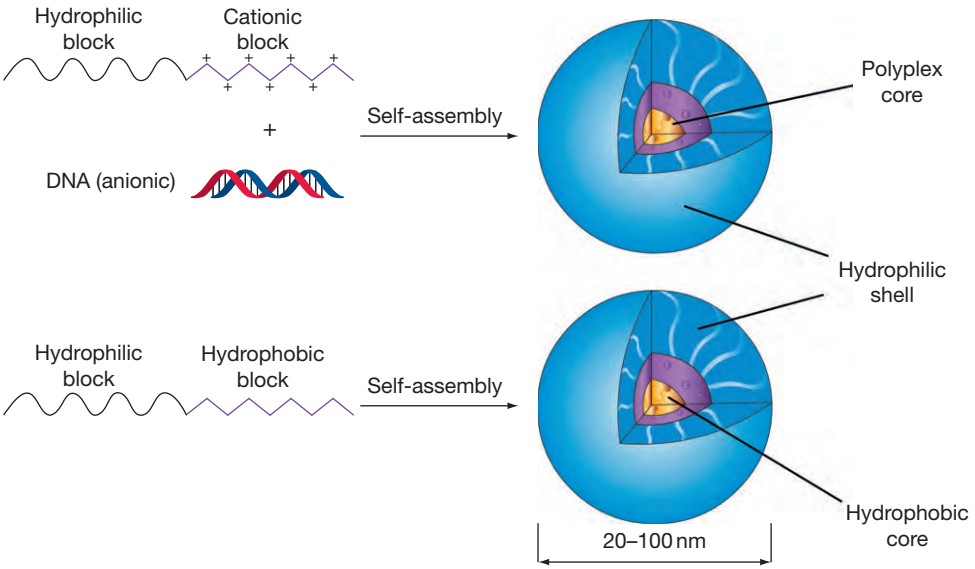

Figure 11 Formation of polymeric micelles.

polymersomes have the ability to trap nucleic acids inside their core (in the 'waterpool'), or in charged components in their membranes. In addition, through control of polymer–polymer interactions, this class of vesicles can reversibly self-associate. This versatility enables further control of nucleic acid binding and release, and several exciting examples of polymersomal gene delivery agents have been reported in recent years. Block copolymers of hydrophilic 2-(methacryloyloxy)ethyl phosphorylcholineMPC (MPC) and pH-responsive 2-(diisopropylamino)ethyl methacrylate (DPA) have been demonstrated to reversibly form polymersomes with a transition at pH ≈ 6.[54,207,208] Dissolution of the polymer with plasmid DNA at pH 6, followed by an increase to pH 7.5, resulted in polymersomes containing DNA with an encapsulation efficiency of ~20%. *In vitro* cell viability and transfection efficiency were assayed in comparison to Lipofectamine TD and $CaCl_2$; poly [MPC-*block*-DPA] polymersomes were found to have high transfection efficiency with reduced toxicity compared to controls.[209] Further study also determined the absence of any proinflammatory/immunogenic response to the polymersomes *in vitro*.[210]

4.424.4. Opportunities and Challenges in NP Therapeutics: Biological Barriers to Nucleic Acid Delivery

Although NP systems have been shown to be effective for many gene delivery experiments in cell culture, the extension to *in vivo* efficacy remains problematic. This is because circulation and uptake of NPs varies in different parts of the body and with healthy compared to diseased tissue. In healthy tissues, distribution of NPs through the body and their removal is size-dependent as shown in **Table 1**.

However, in some cases, selective removal of NPs can be advantageous, as it results in accumulation at a site that may be a therapeutic target. Passive targeting of NPs can occur in cancerous regions, because the microvasculature is highly permeable and leaky in these sites, while efflux mechanisms can be less efficient. The accumulation of polymers and NPs in the cancer tissues or cells is known as the enhanced permeation and retention (EPR) effect.[211] In addition, because of the sizes of the capillaries, passive targeting is possible to the mononuclear phagocyte system (MPS) organs (liver, spleen, and bone marrow). For delivering NPs and their cargo to other organs, active targeting (e.g., via a cell surface affinity ligand) is necessary.

In active targeting, functional groups that recognize the specific cell epitopes or receptors are attached to the carrier systems. These may be low molecular weight ligands (folic acid, thiamine, sugars), peptides (RGD, LHRD), or higher molecular mass weight moieties such as proteins (transferrin, antibodies, lectins) and polysaccharides (hyaluronic acid). In addition, active targeting can be achieved by introducing functionality on the carrier that will evoke a change of structure, conformation, or nucleic acid binding/release in response to an external stimulus, such as temperature, pH, electric charge, light, sound, and magnetism, or to a biological trigger such as reducing potential or pH.[20,212]

4.424.4.1. Systemic Barriers

Even with active targeting systems, a number of other factors must be considered. For the therapeutic nucleic acid to reach its site of action within the cell nucleus, it must negotiate a plethora of biological barriers, which vary with the administration route and desired target.[213] If the intended route of administration is intravenous, into the systemic circulation, then one of the first challenges presented is that of the blood. Typically, synthetic DNA delivery vectors are cationic and, when used in excess to DNA to form stable particles, the overall complex assumes a positive charge. Therefore, these DNA complexes bind to the cell surface via charge–charge interactions with the negatively charged proteoglycans of the cell membrane. This in turn facilitates their internalization by different

Table 1 Relevant sizes regarding particle distribution through and removal from the capillaries of the human vascular system.

		Size	*System/organ*
Particle removal[a]	Tight-junction capillaries	<1 nm	Central nervous system, blood–brain barrier
	Continuous capillaries	~6 nm	Tissues such as muscle, skin, and lung
	Fenestrated capillaries	~50–60 nm	Kidney, intestine, and some endocrine and exocrine glands
	Sinusoidal capillaries	~100–1000 nm	Liver, spleen, and bone marrow
Particle delivery	Arteriole radius	0.005–0.07 mm	Circulatory system. Particles supplied by intravenous administration. Elimination involves opsonization and removal by monocytes in the blood
	Artery radius	0.08–7.5 mm	
	Venule radius	8–100 μm

[a]In this table, only the morphological pores contributing to diffusive permeability are listed. Actual transcapillary exchanges can be modified by active transport mechanisms, which are able to internalize particles with sizes from 20 to 200 nm.

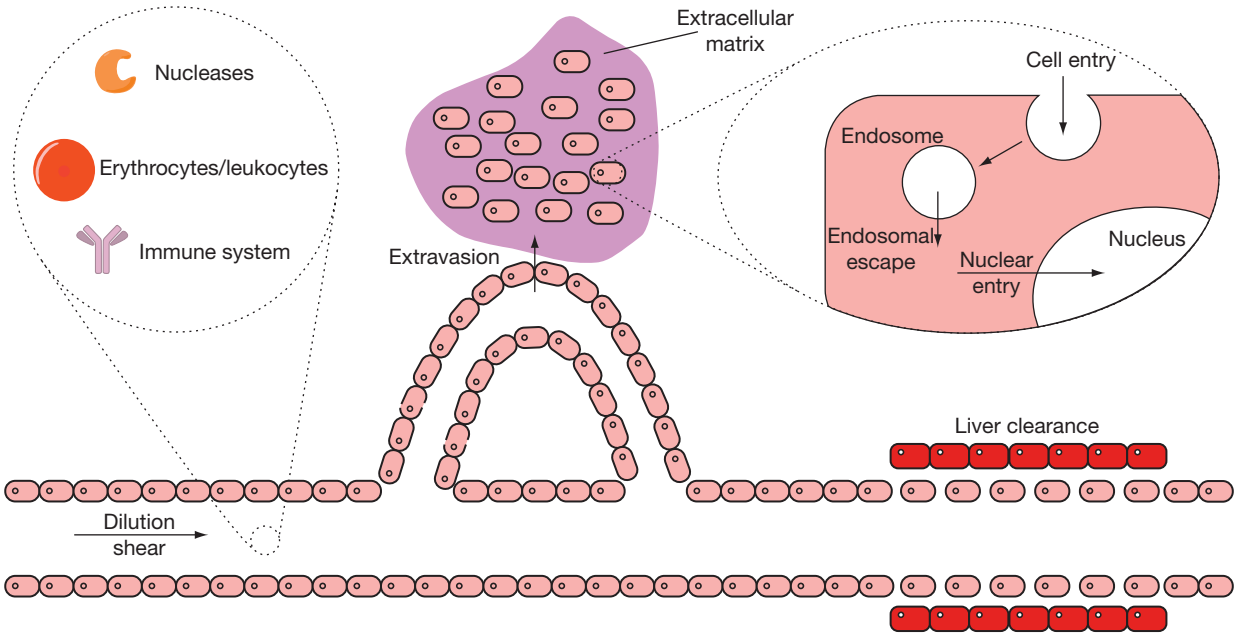

Figure 12 Biological barriers to DNA delivery, both extracellular and intracellular.

endocytic mechanisms.[214,215] However, while vector–DNA complexes with an overall positive charge are known to be suitable for transfecting cells *in vitro*, this effect does not necessarily translate *in vivo*. The condensation of DNA into colloidal polyplexes that can be taken up by cells through endocytosis in cell culture cannot guarantee their passage through different barriers *in vivo* and subsequently, the transfection efficiencies vary between different types of systems.[216]

The net positive charge makes the lipo-/polyplex delivery systems susceptible to interactions with negatively charged proteins present in plasma.[217] Complexes between DNA and the polycation poly(ethylenimine) (PEI) have been shown to interact with immunoglobulin M, fibrinogen, fibronectin, and complement C3. Interactions with these proteins (opsonization) can lead to activation of the complement system and removal of complexes out of the bloodstream via the RES.[218] Organs of the RES, including the liver, spleen, adrenal gland, and bone marrow, have discontinuous capillaries with pores enabling uptake of particles ~50 nm in diameter.[213] It has been found that coating vector/DNA complexes with neutral hydrophilic polymers such as PEG can minimize interactions with proteins in the plasma,[217] thus reducing opsonization and prolonging circulation time. However, it should be noted that RES filtration efficiencies often approach 95% of the administered dose.

Another area that can hinder NP-associated nucleic acids reaching their target site is the capillary bed in the lungs; aggregated polyplexes or lipoplexes can become trapped in the fine capillaries of the lung. Several polymeric gene delivery vectors have been found to localize initially within the lung, sometimes aggregated with erythrocytes, which has resulted in enhanced transfection of this organ.[143,219] Shielding of positively charged complexes between DNA and PEI by covalently attaching the cell-binding ligand Tf has been shown to decrease nonspecific interactions between the complex and the erythrocytes, alongside reducing gene expression in the lungs and directing gene expression to subcutaneous Neuro2a tumors (**Figure 12**).[220]

4.424.4.2. Cellular Barriers to Uptake of Nucleic Acids

If the delivery vector overcomes the hurdles encountered in the bloodstream and reaches its target tissue (<5% of dose,

typically), it must then negotiate the cellular membrane to gain entry into the cell. As noted earlier, nucleic acids are large negatively charged molecules which cannot passively transport across the hydrophobic interior of the cell membrane. Delivery vectors that can condense the nucleic acids to nanometer-sized particles can exploit the uptake pathways of endocytosis. Broadly speaking, the process of endocytosis may be defined as the means by which material can be taken into the cell and includes phagocytosis and pinocytosis. Many different types of endocytic mechanisms have been characterized, including both those involving clathrin-coated pits, which involve some of the most widely adopted receptor-mediated endocytosis pathways, and those that are clathrin-independent, such as the caveolae route.[221–223]

Many nucleic acid delivery systems have employed targeting ligands to direct the therapeutic to a particular tissue type, for example, Tf targeting to tumor cells[220] and galactose ligands targeting to liver cells.[224] These ligands ensure the uptake of the nucleic acid–vector complex using receptor-mediated endocytosis, which has been found to result in higher transfection efficiencies than ligand-free complexes.[217] Following endocytosis, the nucleic acid–vector complexes become enclosed within endosomes. Some endosomes are classified as sorting endosomes that are responsible for recycling receptors back to the membrane surface. When a receptor–ligand complex is taken up into the cell, the acidity within the endosome can release the ligand from the receptor. Materials that are not recycled back to the cell surface become susceptible to degradation within the late endosome where the pH is lowered to pH 5–6. The late endosome eventually fuses with the lysosome where hydrolase enzymes further digest the introduced materials. Consequently, NP delivery vectors require mechanisms to escape the endosomal environment in order to avoid degradation of their delicate biopolymer cargo. Polymers exhibiting buffering between pH 7 and 5, such as PEI and PAMAMs, have been proposed and proceed to intracellular targets to enable endosomal escape through the 'proton sponge mechanism' as described previously. Increased chloride ion accumulation in buffered endosomes was found to occur prior to swelling and lysis of the endosomes.[225] Non-buffering poly(amines), such as poly(lysine), did not show as much chloride ion accumulation and were less likely to escape the endosomal compartments. This has been suggested to account for the lower transfection efficiency of poly(lysine) compared to PEI vectors. Indeed, grafting of imidazole groups (pK_a 6.5) to poly(lysine) increased its transfection efficiency, indicating that the imidazole units acted as endosomal escape moieties. DNA delivery systems that lack endosomal escape mechanisms have shown improved transfection efficiency when applied with a separate endosomal buffering agent such as chloroquine.[102,135,213]

Once released into the cytoplasm, DNA delivery systems must find a way to transport DNA and gain entry into the nucleus through the nuclear envelope. A proportion of complexes between PEI and DNA, in a similar way to adenoviruses, have been seen to migrate through the cell under active transport mechanisms along microtubules, either as free complexes or within endosomal compartments. This motor protein-driven transport localized the complexes to the perinuclear region of the cell. Transport of the complexes was hypothesized to take place along the microtubules to the microtubule organizing center of the cell, which resides close to the nucleus.[226] Entry of macromolecules into the cell nucleus is regulated, with the nuclear pore complex limiting access to materials greater than 40 kDa. Species of larger size require a nuclear localization signal in order to be actively transported into the nucleus. Nuclear localization signals generally comprise a peptide of four cationic residues. Researchers have explored the attachment of these signals to complexes and DNA in order to improve uptake into the nucleus.[227]

4.424.4.3. Overcoming Systemic and Local Biological Barriers: Surface Coating of NPs with Hydrophilic Polymers and Targeting Agents

Although cationic lipids and polymers can condense nucleic acids efficiently to form NPs, the presence of a high overall positive charge can result in nonspecific interactions with body components and/or toxicity (see **Chapter 3.319, Characterization of Nanoparticles in Biological Environments**). Coating or functionalizing the surfaces of NPs has been reported by many groups, using a number of methods:

1. *PEG shielding of polyplexes*. The most popular shielding agent is PEG, which can form an extended swollen hydrated layer, thus effectively masking the positive charge of polycation/DNA complex NPs. The overall positive zeta potentials of the complexes have been reduced by this method, leading to decreased interactions with other body components, lower toxicity of the complexes, and increased circulation time.[228]
2. *Poly[N-(2-hydroxypropyl)methacrylamide] (pHPMA) shielding*. Like shielding with PEG, toxicity of the complex and interaction with other body components has been reduced by attachment of this hydrophilic polymer.[229]
3. *Ligand attachment*. Ligands such as Tf have been covalently attached to polycations, leading to a decreased zeta potential, as well as active uptake. In this way, nonspecific interactions have been lessened and toxicity has been reduced.[22]

4.424.4.3.1. Sterically stabilized PEGylated polyplexes

As described previously, the positively charged surface of the polyplexes can lead to undesired nonspecific interactions with blood components,[230,231] rapid elimination by the RES, aggregation,[232] and serum complement system activation.[218] This results in reduced circulation times and can cause significant toxicity and/or poor transfection efficiency.[233] PEG has been used to shield cationic DNA polyplexes, where the polycation has been PEI,[234–236] PLL,[83] and PAMAM,[237] incorporated either by condensing DNA with PEG-polycation copolymers (pre-PEGylation) or by coupling a PEG layer onto the surface of preformed polyplexes (post-PEGylation). Surface neutralization by PEGylation has formed sterically stabilized polyplexes with increased solubility, enhanced stability, reduced toxicity, and prolonged circulation times. Ogris and coworkers prepared PEGylated PEI/DNA complexes that exhibited improved plasma circulation and reduced *in vivo* toxicity, and resulted in high-level gene expression in tumors after systemic administration into tumor-bearing mice.[217]

Although PEG shields have improved the characteristics of polycation/DNA complex NPs in the extracellular compartment and increased their systemic delivery to target cells, overstabilization of this shield (stable and irreversible) has negatively affected the subsequent desired intracellular steps of polyplex internalization into the cell and endosomal release, thus reducing overall transfection efficiency.[238–240] This overstabilization by the shielding PEG layer has been overcome by forming pH-sensitive PEG coatings for polyplexes: these systems have exhibited enhanced transfection efficiency,[241–243] with up to 100-fold higher gene transfer activity reported for pH-sensitive PEGylated DNA complexes compared to stable PEG-shielded polyplexes.[243]

4.424.4.3.2. Overcoming local biological barriers: surface modification of NPs with targeting ligands

Target cell specificity of polyplexes has been achieved by the incorporation of cell-binding ligands into the surfaces of nanoparticulate vectors, most notable for polymer–DNA complexes. A variety of targeting ligands have been attached covalently or noncovalently to polycations such as Tf, epithelial growth factor (EGF), folate, galactose-containing ligands, low-density lipoprotein (LDL), basic fibroblast growth factor (bFGF), and antibodies.[224,244–251]

Tf, an iron-binding glycoprotein, is a common ligand that is recognized by and binds to Tf receptors on cell surfaces. Tf has been used as a tumor-targeting ligand for several drug delivery systems, and Tf-based gene delivery has been termed 'transferrinfection.'[250] For example, Tf–PLL–DNA conjugates were designed and revealed efficient delivery systems for gene transfer into many cell lines.[252,253] Also, there have been numerous reports on tumor-selective gene transfection by Tf–PEI–DNA complexes.[230,254–256] After their intravenous injection, gene expression in the tumors was approximately 100-fold higher than in other tissues.

Combining the two surface modification strategies by attaching both ligand (e.g., Tf and EGF) and hydrophilic polymers (e.g., PEG and HPMA) was found to have beneficial outcome on the *in vivo* use of polyplexes. It was found that the attachment of both PEG and Tf to modify the surface of PEI/DNA complexes either before or after complex formation not only decreased polyplex toxicity and increased its solubility and stability to freeze drying but also increased polyplex circulation time.[217,257] Moreover, intravenous injection of a shielded PEG–PEI–Tf system containing DNA encoding for tumor necrosis factor-α(TNF-α) was shown to inhibit tumor growth in murine tumor models.[257] Tf targeting of both PEG-coated and noncoated PEI/DNA complexes enabled gene delivery into distant subcutaneous neuroblastoma tumors of syngeneic A/J mice.[217,220,257] In a similar study, it was also found that EGF–PEG-coated PEI/DNA polyplexes efficiently targeted human hepatocellular carcinoma xenografts in SCID mice showing 10–100-fold higher localization in the xenografts compared to other organ tissues.[258]

4.424.4.3.3. Chimeric/hybrid NPs for overcoming systemic barriers gene delivery

An innovative approach to highly targeted gene delivery has been the development of chimeric vectors, which are hybrid combinations of viral and nonviral gene carriers. One study employed DNA-loaded liposomes fused with ultraviolet (UV)-inactivated HVJ (hemagglutinating virus of Japan; Sendai virus) to obtain fusogenic viral liposomes. These carriers were reported to be able to protect DNA from endosomal and lysosomal degradation[37,259] (**Figure 13**).

Similar approaches have involved solubilization of influenza virus A with detergent followed by mixing with a cationic lipid (dioleoyldimethylamonium chloride:DODAC) to form cationic virosomes capable of complexation with DNA. The HIV envelope proteins, gp120 and gp41, have been attached

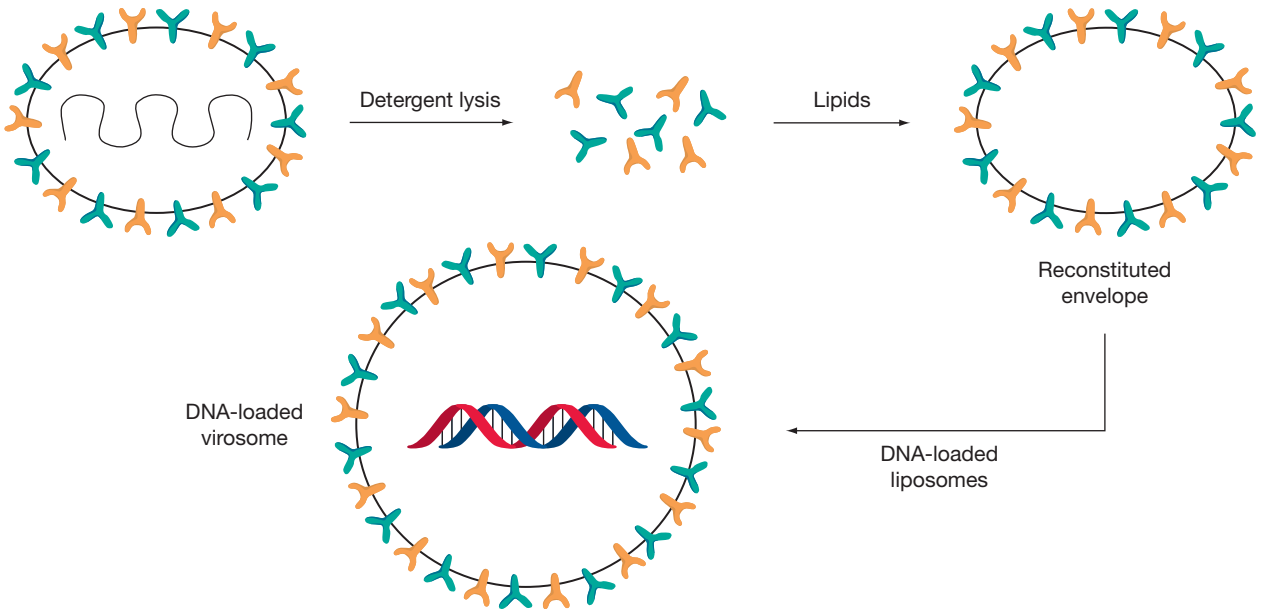

Figure 13 Virosome formation. Envelope viruses are lysed by detergent and then mixed with lipids to form a reconstituted envelope presenting viral proteins. Addition of a DNA-loaded liposome results in fusion to yield a DNA-loaded virosome.

to liposomes to form gene carriers with similar cell recognition and entry properties to HIV but without pathogenicity. In addition, HVJ–liposomes have been prepared using both cationic and anionic lipids. Studies showed that HVJ–anionic liposomes achieved greater penetration and wider distribution compared to cationic ones; however, transfection efficiencies were lower. The authors thus suggested that anionic HVJ–liposomes should be used for gene transfer across a range of tissues, while cationic ones should be used for restricted regions or surface areas.[259] These data are analogous with those for cationic and anionic liposomes, and indicate the balance between systemic and local effects, and potency and side effects.

4.424.4.4. Formulation Issues for Nucleic Acid Therapeutics – Binding Between Vector and Nucleic Acid: A Balancing Act

Although NP systems have been shown to be very effective in protecting nucleic acids from biodegradation, a balance needs to be achieved between sufficient protection while allowing adequate release such that the vector can release the nucleic acid.[133] Several studies have revealed that vector unpackaging presents a significant barrier for DNA delivery. Schaffer *et al.* conducted a detailed study into the ability of a variety of different lengths of poly(lysine) to mediate DNA delivery. It was found that the larger polymers led to less efficient delivery due to a reduced tendency to dissociate from the DNA within the nucleus. Lower molecular weight polymers showed enhanced transgene expression, which was correlated to a reduced inhibition of transcription in the nucleus. A similar effect was seen with PEI (25 kDa) where the larger polycation inhibited transcription of the transgene to a greater extent than the 2 kDa sized polymer.[105] Glover *et al.*[260] showed that although PEI showed higher amounts of plasmid DNA–polymer complex uptake into cell nuclei, higher levels of transgene were achieved by fewer plasmids delivered by lipofectamine as it dissociates from the DNA before entering the nucleus.

Attempts to strike the most effective balance in binding between polymer and DNA have been made by several groups. Kurisawa *et al.*[261] explored the incorporation of hydrophobic butyl methacrylate (10%) into poly[*N*-isopropyl acrylamide-*co*-DMAEMA] copolymers using lower amounts of the cationic DMAEMA (20%) and found the transfection efficiency to be twofold higher than that of the p[DMAEMA] homopolymer. Similarly, Park and Healy[134] investigated the effect of polycation content in polymers of poly[lysine-*graft*-poly(lactide-*block*-ethylene glycol)] in order to achieve enhanced DNA release from the controlled release formulation.

Many stimuli- or environmentally responsive polymers and NPs have been investigated for nucleic acid delivery, and this field has been very extensively reviewed in recent years. However, the common concept in all of these studies is a change in NP behavior or properties, which enable targeting and/or release of the nucleic acid cargo. These changes in the delivery system can be a conformational switch, exposure of a binding group, cleavage of a side chain linked to a binding group, such that the affinity of the carrier NP with the nucleic acid changes. Even with the stimuli-responsive systems, to date no single gene vector fulfills all the desirable characteristics of protection, targeting, and delivery of the nucleic acid, and each has its own advantages and limitations. The optimization of a vector system, thus, has to be individualized according to each clinical setting, leaving both challenges and opportunities for researchers in the gene delivery field.

4.424.5. Conclusions

Large numbers of nanoparticulate nucleic acid delivery systems have now been evaluated in the laboratory, and several drugs have progressed to clinical trials. However, in addition to therapeutic efficacy, a major question that needs to be answered is the *in vivo* fate of NPs, whether of natural or synthetic origin. Any material introduced into the body must either degrade to harmless fragments or be excreted unchanged once it has fulfilled its therapeutic use. This is one reason why only a relatively small number of gene delivery vectors have been used in the clinic and, in turn, is due to difficulty, time, and expense of conducting full toxicological studies of biological and synthetic materials, to determine the ultimate fate of all vector, and vector-derived fragments in the body.

There also remain many challenges for the biomaterials scientist in developing better materials for biomedical applications. True precision in the engineering and modification of viruses or in the generation of synthetic architectures, placement of functionality, and ease of conjugation or complexation with a nucleic acid are all necessary for optimum biomaterial formulations. In addition, 'intelligent,' controlled behavior is likely to be required in these materials in order that an injected, inhaled, or even ingested NP can carry the nucleic acid to a disease site or repair a defective gene.

Finally, it is important to recognize that the trade-off between what is achievable in a research context and what is affordable as a medicine, and for nucleic acid delivery in particular, many hurdles are still to be overcome. The challenge for biomaterials scientists is to devise materials that best combine nucleic acid binding and release in a format that can readily be manufactured, administered, and monitored to produce a safe, effective human therapeutic. If this can be done in a cost-effective and safe manner, the long-promised benefits of gene therapy might be realized.

Glossary

Endocytosis The cellular uptake of macromolecules and solutes into membrane-bound vesicles derived by the invagination and pinching-off of pieces of the plasma membrane.

Enhanced permeability and retention (EPR) effect A theory used to explain how long-circulating macromolecules, including PEGylated liposomes and colloids 200 nm in diameter and below, can passively accumulate in tumor tissue and sites of inflammation after systemic administration. Such particle accumulation is attributed to changes in tissue capillary vascular permeability in inflammatory sites, including discontinuous or absent basement membranes, lack of an effective lymphatic drainage system, and altered fenestrations and tight junctions.

Lipoplexes Complexes formed between DNA and cationic lipids, which are used mainly in the form of cationic liposomes.

Liposome A spherical vesicle with a membrane composed of a phospholipids bilayer used to deliver drugs or genetic materials into a cell.

Micelles A collection of amphiphilic surfactant molecules that spontaneously aggregate in water into a spherical vesicle. The center of the micelle is hydrophobic and therefore can sequester hydrophobic drugs.
Octaarginine (R8) A peptide that consists of eight arginine residues and possesses membrane translocation activity.
Polyethyleneimine (PEI) A cationic polymer that can condense DNA and possess a buffering capacity (proton sponge mechanism) to allow cytosolic release.
Polyplexes Complexes formed spontaneously when a cationic polymer is mixed with DNA.
Reticulo-endothelial system (RES) The reticuloendothelial system (RES), part of the immune system, consists of phagocytic cells, primarily monocytes and macrophages, that are located in reticular connective tissue. These cells accumulate in lymph nodes and the spleen. The Kupffer cells of the liver and tissue histiocytes are also part of the RES system.
RNA-induced silencing complex (RISC) A multiprotein complex that incorporates one strand of an siRNA. RISC uses the siRNA as a template for recognizing complementary mRNA. When it finds a complementary strand, it activates RNase and cleaves the RNA.
Small fragment homologous replacement (SFHR) A method for gene therapy. The method involves the introduction of small fragments of exogenous DNA into regions of endogenous genomic DNA, which is virtually homologous to the exogenous DNA. The exogenous DNA fragments contain sequence modifications that correct mutations in the endogenous DNA or introduce mutations that alter a cellular or an infecting pathogen phenotype.

Abbreviations

AAV	Adeno-associated virus
AKI	Acute kidney injury
ApoB	Apolipoprotein B
ASGPr	Asialoglycoprotein receptor
asODN	Antisense synthetic ODN
BBB	Blood–brain barrier
BMD	Becker muscular dystrophy
Bmpr1a	Bone morphogenetic protein receptor type 1 A
BSA	Bovine serum albumin
caALK6	Constitutively active activin receptor-like kinase 6
CFTR	Cystic fibrosis transmembrane conductance regulator
CHEMS	Cholesteryl hemisuccinate
CNS	Central nervous system
CMV	Cytomegalovirus
DGF	Delayed graft function
DMD	Duchenne muscular dystrophy
DME	Diabetic macular edema
DOPC	1,2-Dioleoyl-*sn*-glycero-3-phosphocholine
DOPE	1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine
DOTAP	1,2-dioleoyl-3-trimethylammonium-propane
DOTMA	*N*-[1-(2,3,-dioleyoxy)propyl]-*N*,*N*,*N*-trimethylammonium
DOX	Doxorubicin
DTS	DNA nuclear targeting sequence
EPR	Enhanced permeability and retention
EPO	Erythropoietin
FACS	Fluorescence-activated cell sorter
FGF	Fibroblast growth factor
FH	Familial hypercholesterolemia
FRET	Fluorescence resonance energy transfer
GalNac	*N*-acetylgalctosamine
GFP	Green fluorescent protein
HGF	Hepatocyte growth factor
HIV	Human immunodeficiency virus
His-PLL	Histidylated PLL
HPV	Human papillomavirus
HSPGs	Heparan sulfate proteoglycans
HSV	Herpes simplex virus
HVJ	Hemagglutinating virus of Japan
IL	Interleukin
JNK-1/-2	c-Jun *N*-terminal kinase-1/-2
LDL	Low-density lipoprotein
LPD	Liposome–polycation–DNA
LPLL	Lipo-PLL
MEND	Multifunctional envelope type nanodevice
miRNAs	MicroRNAs
MMP	Matrix metalloproteinase
MTOC	Microtubule-organizing center
MPS	Mononuclear phagocytic system
MRI	Magnetic resonance imaging
MVD	Microvessel density
NLS	Nuclear localization signal
N/P	Nitrogen to phosphorus
NPC	Nuclear pore complex
ODN	Oligodeoxyribonucleotides
PAsp	Poly(aspartate)
PCR	Polymerase chain reaction
PEG	Poly(ethylene glycol)
PEG-PAsp	PEG-*b*-poly(aspartate)
PEG-PAsp(DET)	PEG–polyaspartamide with an ethylenediamine unit as a side chain
PEG-Plys	PEG–poly(lysine)
PEI	Polyethylenimine
PIV	Parainfluenza virus
PK	Pharmacokinetics
PLL	Poly-(L-lysine)
PMPA	Poly[(3-morpholinopropyl) aspartamide]
PPD	PEG-peptide-DOPE
R8	Octaarginine

RES	Reticuloendothelial system	**SPLP**	Stabilized plasmind–lipid particle
RISC	RNA-induced silencing complex	**STR-R8**	Stearylated octaarginine
RNAi	RNA interference	**TAT**	Transcriptional transactivator
Runx2	Runt-related transcription factor 2	**TLR**	Toll-like receptor
RSV	Respiratory virus	**Tf**	Transferrin
siRNA	Small interfering RNA	**TNFs**	Tumor necrosis factors
SCAD	Short-chain acyl-CoA dehydrogenase	**TRAIL**	TNFrelated apoptosis-inducing ligand
α-SMA	α-smooth muscle actin	**VEGF**	Vascular endothelial growth factor
S/MAR	Scaffold matrix attachment region	**Wet-AMD**	Wet-age-related macular degeneration
SNALP	Stable nucleic acid lipid particle		

4.425.1. Introduction

Gene therapy has long been proposed as a new therapeutic strategy for directly treating diseases at the level of genes. In this therapy, nucleic acids themselves play an important role as a drug and they need to be delivered safely to a site of action, such as the cytosol and nucleus. Therefore, it is essential for these molecules to be able to pass through the plasma and nuclear membranes to efficiently reach the target sites. As the plasma membrane is composed of a lipid bilayer, only low-molecular-weight and lipophilic compounds are able to pass through via diffusion. As nucleic acids are high-molecular-weight, negatively charged molecules, a safe and efficient gene delivery system is needed for them to reach their target.[1] Both viral or nonviral gene delivery systems are used to circumvent these problems. Viral vectors are the ultimate gene delivery system, especially from the view point of efficiency. However, nonviral vectors have advantages over viral vectors particularly from the viewpoints of safety and commercial production. Therefore, much effort has been expended to improve the performance of nonviral vectors, and we will discuss the major carrier systems that have been developed to date for use as gene therapy. These systems generally involve the use of cationic liposomes or cationic polymers to control DNA/RNA intracellular trafficking as well as pharmacokinetics (PK) after their systemic administration.[2] We also describe a newly developed multifunctional envelope-type nanodevice (MEND) based on the concept of programmed packaging, in which multifunctional devices are integrated into a nanocarrier system according to the program designed to overcome all of the barriers during the course of biodistribution as well as intracellular trafficking.[3]

Once in the blood circulation after systemic administration, carrier systems should be sufficiently stable in the blood circulation and be able to avoid immunological recognition to reach a target tissue. The EPR (enhanced permeability and retention) effect, a key concept in passive drug targeting, is introduced, especially for tumor targeting. The concept of active targeting for the selective delivery of nucleic acids to a target cells via receptor-mediated endocytosis, which leads to controlled intracellular trafficking, is also discussed. Vascular endothelial cells are absolute barriers to the passage of nanoparticles from circulation to targets. A breakthrough technology designed to overcome endothelial barriers will also be introduced.

In most cases, both viral and nonviral vectors enter cells via a type of endocytosis, which is a common cell system for macromolecular uptake.[4] Once in endosomes after endocytosis, gene delivery systems must then escape from endosomes to reach the cytosol. Otherwise, they will be degraded by fusion with lysosomes. The cytosol is a major site of action in terms of controlling the function of mRNA, but plasmid DNA (pDNA) must be delivered to the nucleus for transcription. Therefore, the nuclear membrane is a major barrier for high-molecular-weight pDNA. Functional devices need to be introduced to overcome these intracellular barriers such as the endosomal and nuclear membranes. The appropriate design of a nonviral gene vector requires an in-depth understanding of both the characteristics of the vectors themselves as well as mechanisms by which they interact with cellular components.[5]

In this chapter, a nonviral gene delivery system is discussed from several important view points, including the packaging concept, PK, intracellular trafficking, and *in vivo* applications.

4.425.2. Packaging Concept

4.425.2.1. Nucleic Acids

Gene therapy is an attractive approach for treating causes of disease rather than the symptoms.[6] There are many types of candidate nucleic acids for gene therapy (**Table 1**).

Table 1 Summary of candidate nucleic acids for gene therapy

Candidates	*Structure*	*Function*	*Target site*
pDNA	dsDNA	Gene expression	Nucleus
ODN	ssDNA	Gene silencing by antisense technology	Cytosol
		Gene correction	Nucleus
siRNA	dsRNA	Gene silencing by RNA interference	Cytosol
miRNA	ssRNA	Gene silencing by RNA interference	Cytosol

ds, double stranded; ss, single stranded.

For example, pDNA is a candidate for gene-complement therapy. In this strategy, pDNA needs to be delivered to the nucleus for cellular expression of a therapeutic protein. In the case of oligodeoxyribonucleotides (ODN), they must be delivered to the cytosol or nucleus depending on their intended therapeutic use. Gene silencing using antisense synthetic ODN (asODN) can be applied to the suppression of specific genes for tumor growth and virus replication.[7–15] This strategy can be achieved by the cytosolic delivery of asODN to target cells, because asODN inhibits target mRNA in the cytosol for gene silencing. On the other hand, gene-correction therapy requires the delivery of therapeutic ODN to the interior of the nucleus, where the sequence of a disease-causing gene is converted to the normal sequence by the ODN. Strategies for silencing human diseases using RNA interference (RNAi) have attracted attention as an innovative gene therapy. RNAi-mediated gene silencing requires the cytosolic delivery of small RNAs, which include small interfering RNA (siRNAs) and microRNAs (miRNAs).

The main requirement for successful gene therapy is that the therapeutic nucleic acids must pass through the plasma membrane and reach their intracellular targets. The DNA (or RNA) molecule, which is a basic element of a therapeutic nucleic acid, is a hydrophilic, negatively charged, high-molecular-weight molecule. The addition of naked DNA molecules to cells is not likely to result in significant internalization because the DNA cannot pass through the lipophilic plasma membrane. Therefore, a gene vector is needed to carry the DNA to the target site.[4] Vectors can be divided into viral and nonviral vector categories. They differ primarily in the process used for their assembly. A viral vector is assembled in a cellular production system,[16] whereas a nonviral vector is constructed in a test tube.[2,3,17–20]

To achieve efficient gene delivery using a nonviral vector, it is first necessary to efficiently package the nucleic acid cargo into the vector. Second, the vectors must be efficiently targeted and internalized by specific cell types. Finally, sophisticated regulation of intracellular trafficking is needed to release the vector from the endosome and deliver it to its final destination (Figure 1). For example, siRNA should be delivered to the cytosol, where siRNA digests the target mRNA for gene silencing, whereas pDNA should be delivered to the nucleus for gene expression. Thus, the final destination is dependent on each cargo, and vectors must be designed with the specific target site appropriate to the cargo in mind. Here, we describe target sites and therapeutic effects of nucleic acid candidates in detail, as this information can be helpful in the development of nonviral vectors.

4.425.2.1.1. Plasmid DNA

For gene-complement therapy, the gene sequence encoding the therapeutic protein should be delivered to the nucleus for gene expression. pDNA, which is a closed circular DNA molecule containing sequences that allow the gene to be grown in bacteria, is one candidate for realizing gene-complement therapy. pDNA usually carries only one or a few genes representing the genetic therapeutic instructions for the host and has a single origin of replication. The molecular weight is >1 MDa and the hydrodynamic diameter in aqueous suspension is >100 nm. pDNA is very convenient as a material for gene therapy because it can be easily prepared in large quantities using bacterial production system and harvest. Examples of some candidate diseases for gene-complement therapy are described below.

Inherited diseases are typically caused by a single gene mutation or deletion. Therefore, pDNA containing a particular normal gene for a deficient protein could be used if reliably delivered for therapeutic replacement. Examples of candidate-inherited diseases for gene therapy are summarized in Table 2.[21–26] For example, familial hypercholesterolemia (FH) is a genetic disorder caused by the lack of a receptor for

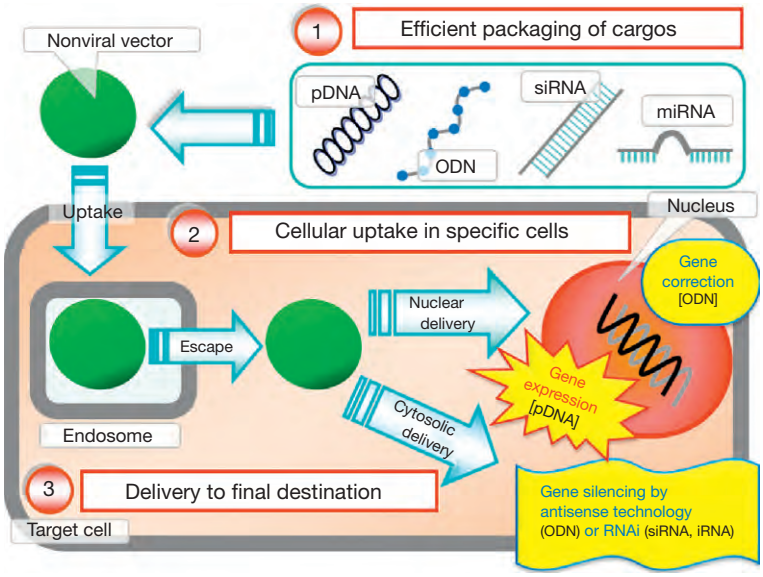

Figure 1 Schematic diagram of gene delivery using nonviral vector. To achieve efficient gene delivery by nonviral vectors, efficient packaging of cargos into the vectors must first be achieved (1). Second, the vectors must be efficiently targeted and internalized by specific cell types (2). Finally, the vector should be delivered to the final destination of each cargo (3).

Table 2 Candidate diseases for gene therapy

Disease	*Defect*	*Target*
A. Inherited diseases		
SOID	AD	T cells
CF	CFTR	Lung
Gaucher's disease	Glucocerebrosidase	Liver
Hernoglobinopathies	Globins	RBC precursors
Hemophilia	Clotting factors VIII and IX	Liver and muscle
Familial hypercholesterolemia	LDL receptor	Liver
Muscular dystrophy	Dystrophin	Muscles
B. Acquired diseases		
Cancer	Defect in tumor supressors and/or presence of oncogenic factors	Variable
Neurological diseases	Defect in doparnine synthesis	CNS
Cardiovascular diseases	Defect in blood vessels	Arteries
Infectious diseases	Suppressed immune system (HIV) or liver destruction (HBV)	T cells, liver, macrophages

SCID, severe combined immunodeficiency; AD, adenosine deaminase; CF, cystic fibrosis; CFTR, cystic fibrosis transmembrane conductance regulator; RBC, red blood cell; LDL, low-density lipoprotein; CNS, central nervous system; HIV, human immunodeficiency virus; HBV, hepatitis B virus.

low-density lipoprotein (LDL), resulting in circulation of LDL particles in the bloodstream, a condition referred to as hypercholesterolemia.[24] Cholesterol contributes to the accelerated formation of atherosclerotic plaques in blood vessel walls. The transfection of patient liver cells with a gene for the LDL receptor represents a strategy for eliminating this condition.

Acquired diseases can also be amenable to treatment by gene-complement therapy. Although no single gene can be identified as the only cause of the disease in acquired diseases, the expression of a single gene in target cells can potentially lead to the elimination of the disease state. Examples of acquired diseases amenable to gene therapy are summarized in Table 2.[27–35]

For these therapies to be successful, vectors are needed to deliver pDNA to the nucleus of target cells. Nonviral vectors are quite attractive for this because of their excellent safety profile, even though their transgene expression efficiency is low in comparison to viral vectors. It is obvious that the intracellular DNA trafficking, particularly nuclear entry in nondividing cells, is a very important issue for high transgene expression. Moreover, the controlled intranuclear disposition of the delivered DNA is also an important issue in terms of achieving practical gene therapy. For example, transgene expression with nonviral vectors is generally transient and of short duration. To overcome these problems, efficient and practical gene therapy using nonviral vectors is required.

4.425.2.1.2. Oligodeoxyribonucleotide

ODNs are predicted to be useful tools for gene therapy mediated by gene silencing and gene correction. In the case of pDNA, its final destination is only the nucleus for gene expression, whereas ODNs must be delivered to the cytosol or nucleus, depending on the therapeutic strategy. In antisense technology, the use of an antisense sequence can inhibit gene expression (gene silencing). In this strategy, asODN must be delivered to the cytosol in target cells, because asODN inhibits target mRNA in the cytosol. On the other hand, gene correction requires the delivery of therapeutic ODN to the nucleus in target cells, because gene correction by ODN occurs in the nucleus. The details of these strategies are described below.

Gene silencing mediated by cytosolic asODN delivery has various advantages, such as technical simplicity, high stability, and temporal effects. This strategy has already been applied to the suppression of specific genes for growth of tumor and virus replication.[7–15] The concept underlying antisense technology involves the use of a sequence that is complementary to a specific host mRNA, which inhibits this mRNA expression thereby inducing a blockade in the transfer of genetic information from DNA to protein. Translation is inhibited by blocking the attachment of mRNA to a ribosome, inhibition of mRNA splicing, or RNase-mediated cleavage of the target mRNA with a DNA/RNA heteroduplex.[31,36] Many antisense sequences showed beneficial therapeutic effects in reducing tumor growth. These include antisense against the human papillomavirus (HPV) E7 protein, fibroblast growth factor-2 (FGF-2),[37] and c-Jun *N*-terminal kinase-1/-2 (JNK-1/-2).[38]

Gene correction (nucleotide sequence conversion) using therapeutic ODN is also an attractive strategy for gene therapy and biotechnology.[39–47] Conversion of the mutations to the normal sequence (gene correction) and disruption (knockout) of disease-related genes would be achieved when the therapeutic ODN is delivered to the nucleus. Single-stranded oligonucleotides, chimeric 2′-*O*-methyl-RNA/DNA oligonucleotides, and triplex-forming oligonucleotides have been examined as chemically synthesized nucleic acids for gene correction. Heat-denatured 400−800 bp double-stranded polymerase chain reaction (PCR) fragments containing the normal sequences have also been examined for their gene correction abilities by the small-fragment homologous replacement method. It has recently been reported that gene correction efficiency with a single-stranded DNA fragment, prepared by the digestion of single-stranded phagemid DNA with a restriction enzyme, is higher than that with a conventional PCR fragment.[48–50]

4.425.2.1.3. Small interfering RNA and microRNAs

During recent decades, RNAi is found to be a natural mechanism for reducing the production of a specified protein via cleavage of mRNA.[51,52] The key therapeutic advantage of using RNAi lies in its ability to specifically and potently

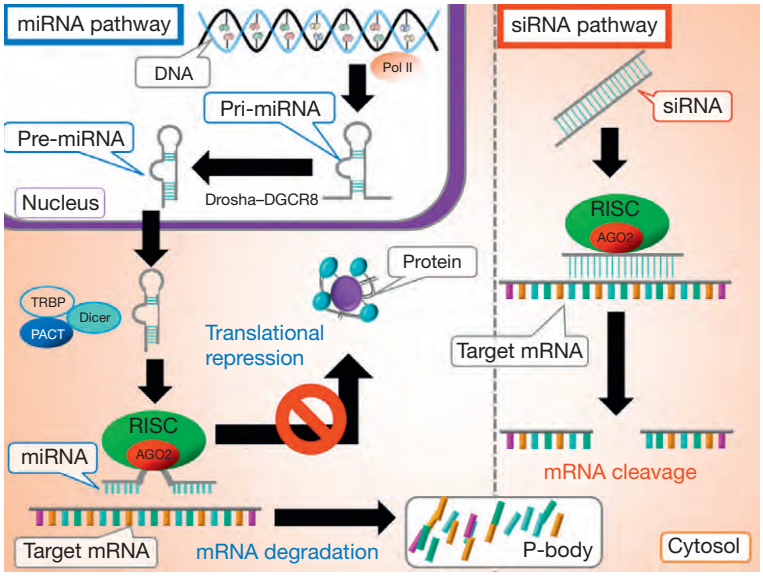

Figure 2 Different mechanisms of RNA interference for siRNA and miRNA. As shown in the pathway on the right, siRNAs are loaded into Argonaute 2 (AGO2) and the RNA-induced silencing complex (RISC). The siRNA guide strand recognizes target sites to direct mRNA cleavage, which is carried out by the catalytic domain of AGO2. As shown in the pathway on the left, endogenously encoded primary microRNA transcripts (pri-miRNAs) are transcribed by RNA polymerase II (Pol II) and initially processed by Drosha–DGCR8 (DiGeorge syndrome critical region gene 8) to generate precursor miRNAs (pre-miRNAs). These precursors are exported to the cytoplasm and subsequently bind to the Dicer–TRBP–PACT complex, which processes the pre-miRNA for loading into AGO2 and RISC. The mature miRNA recognizes target sites in the 3′ untranslated region (3′ UTR) of mRNAs to direct translational inhibition and mRNA degradation in processing (P)-bodies that contain the decapping enzymes.

knock down the expression of disease-causing genes. Gene silencing mediated by an RNAi requires the cytosolic delivery of small therapeutic RNAs including siRNAs and miRNAs. The major role played by small noncoding RNAs in regulating gene expression has recently been recognized.[53–55] siRNAs are produced from long double-stranded RNA that is exogenously introduced artificially by either nonviral or viral transfection. It is thought that the function of siRNAs is to defend cells against unwelcome genetic elements, such as viruses, as shown in Figure 2.

In contrast, miRNAs are encoded by genomes and are evolutionarily conserved among species. miRNAs are intended to act as key regulators of cellular processes as diverse as developmental timing, cell proliferation, cell death, apoptosis, fat metabolism, morphogenesis, and cell differentiation. Both siRNAs and miRNAs act by means of a protein–small RNA complex, the RNA-induced silencing complex (RISC) that silences target gene expression. Via the RISC, siRNAs can direct the cleavage of an mRNA at any single binding site to which they are highly complementary, whereas miRNAs usually act as translational repressors by binding to partially complementary binding sites of their target mRNAs.

4.425.2.2. Carrier Systems

4.425.2.2.1. Liposomes

Liposomes are self-closed colloidal particles in which bilayer membranes composed from self-aggregated lipid molecules encapsulate a fraction of the medium in which they are suspended into their interior.[56–58] Liposomes are formed spontaneously when phospholipids are dispersed in aqueous media, giving rise to a population of vesicles ranging from 10 nm to 10 μm in diameter. They are highly promising as a carrier or sustained release system for the encapsulated molecules. Liposomes have several other advantages such as their biocompatibility, biodegradability, low toxicity, and immunogenicity. In addition, they can incorporate various molecules at high concentrations, and the lipid bilayer can protect the biologically active molecules from damage by chemicals or enzymes. The surface of liposomes can be easily modified with various functional devices such as targeting ligands or other specific devices for optimization.

Conventional liposomes that are not modified with any specific entities were first used as delivery systems to deliver DNA into cells mainly because of their ability to enhance intracellular accumulation of these large and charged molecules across cell membranes. However, the procedure was not efficient as conventional liposomes do not highly bind to cell surfaces and, as a result, they are not highly internalized.[58] Improvements were achieved by using pH-sensitive liposomes,[59] but the use of liposomes in transfection in gene therapy was revived mainly with the emergence of cationic liposome–nucleic acid complexes (lipoplexes). Cationic liposomes can condense and compact DNA. Such complexes can be several orders of magnitude more efficient in transfection than other approaches.[60,61] Gene transfer using cationic liposomes can also be achieved *in vivo* using localized or systemic administration (especially in the lung endothelial cells).[62] Cationic liposomes used for gene delivery are normally formed from cationic lipids along with a neutral lipid such as dioleoylphosphatidylethanolamine (DOPE) or cholesterol. DOPE is frequently used because of its ability to fuse with other lipids when exposed to a low pH, such as in endosomes, which aids in the release of associated DNA into the cytosol.[63,64]

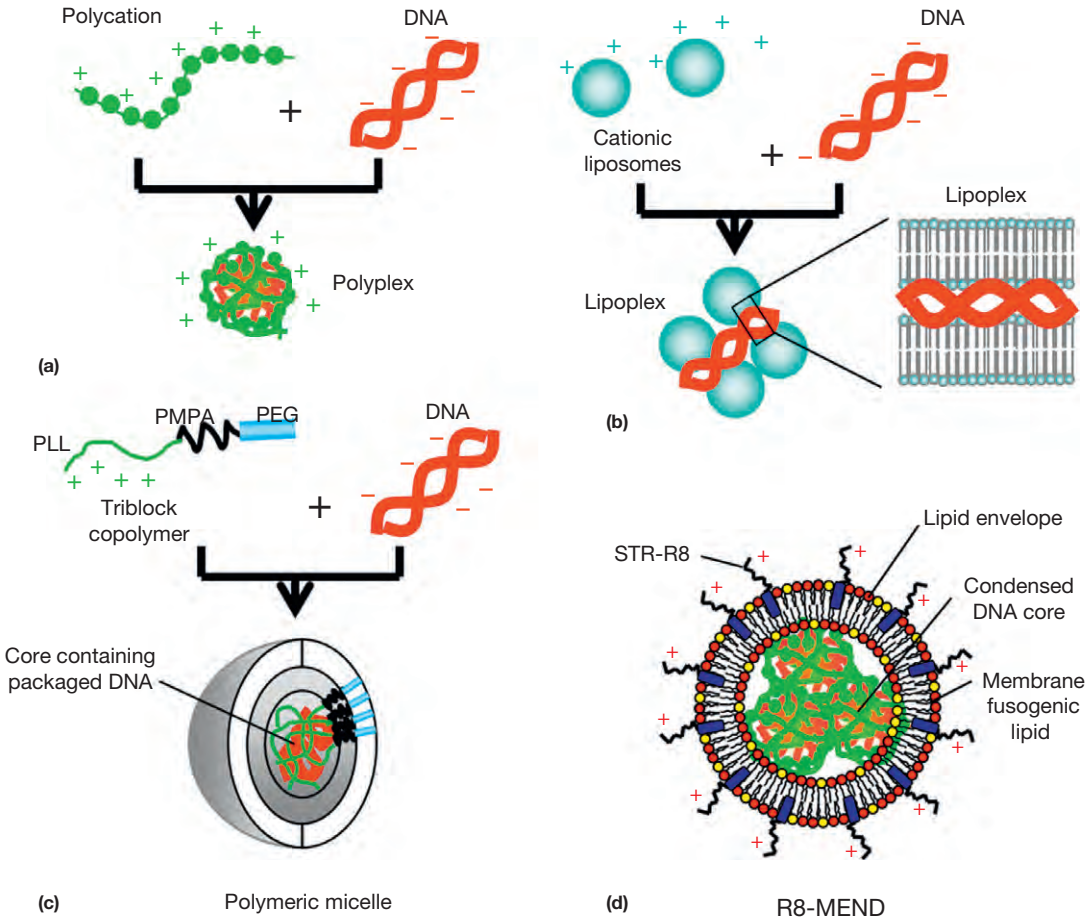

Figure 3 Schematic diagram of different gene carriers. (a) Polyplexes are formed spontaneously by mixing a polycation and DNA. (b) Lipoplexes are complexes formed between DNA and cationic liposomes. The formation of lipoplexes is generally difficult to control and different structures are produced. The interaction involves the formation of multilamellar structures consisting of DNA sandwiched between lipid bilayers. (c) An example of polymeric micelle formed between DNA and a triblock copolymer. This copolymer consists of: a PEG segment for biocompatibility, a PMPA segment to enhance endosomal escape and a PLL segment for DNA binding. (d) Octaarginine-modified multifunctional envelope-type nanodevice (R8-MEND) for gene delivery. It consists of a condensed DNA core covered with a lipid envelope that contains fusogenic lipids and the surface is modified with stearylated R8 for enhancing cellular uptake as well as endosomal escape.

Cholesterol provides structural stability and protection, and there is evidence that it can influence targeting *in vivo* via scavenger receptors.[65,66]

Lipoplexes are typically formed by direct mixing between cationic lipids and DNA solutions. Positively charged lipids bind to negatively charged phosphate molecules on the DNA backbone through electrostatic interactions as shown in Figure 3. Generally, complexes are formed with an excess positive charge to permit the interaction with the negatively charged cell surface. The ratio between the cationic charge of the liposome and the negative charge of the DNA usually are factors that control the lipoplex size.[67] At high positive or negative charge ratios, relatively small complexes are formed, while, larger aggregates are usually formed when the net charge is close to neutrality.[67,68] Cationic liposomes used are typically small (around 100 nm) before adding to DNA; however, complexes formed with DNA exhibit diameters that range from as small as 200 nm to structures as large as 2 μm.[69] Formation of lipoplexes is generally difficult to control, and different structures are produced in the same lipoplex preparation. The proposed model for describing the interaction between cationic liposomes and DNA involves a compaction of DNA and charge neutralization followed by aggregation and formation of heterogeneous multilamellar structures of different shapes consisting of DNA sandwiched between lipid bilayers. Finally, it is proposed that DNA affects the liposomes, inducing lipid mixing and rearrangement resulting in the fusion of the multilamellar structures to form large DNA/lipid complexes.[70]

Usually, positively charged lipoplexes lead to more efficient gene expression by virtue of ionic interactions with the negative cell surface constituents.[71] In addition to the compaction and neutralization of DNA, cationic liposomes provide a protective role against cellular nucleases. This can be attributed to the compaction and covering of DNA by the lipid bilayers.[68] However, the positive charge of lipoplexes makes them susceptible to interaction with the negative components in blood circulation, including hundreds of plasma proteins, platelets, and blood cells, after *in vivo* administration.[18,72,73] Although

smaller-sized lipoplexes would be expected to be more efficiently internalized via endocytosis, larger lipoplexes have been reported to improve transfection efficiency.[74] This may be due to the greater ability of the larger particles to sediment onto the cell surface. However, the *in vivo* transfection ability of larger complexes is weak, mainly due to their inability to reach the target cells because of their large size, which also renders them more susceptible to interaction with extracellular components.

Unless a specific targeting ligand is incorporated in the system, the binding of lipoplexes to cell surfaces is the result of random, nonspecific ionic interactions between cationic complexes and anionic cell surfaces and biopolymers. Negatively charged cell surface constituents, such as heparan sulfate proteoglycans (HSPGs) and integrins, play an important role in the cellular binding of positively charged lipoplexes.[75] For example, in proteoglycan-deficient mutant cells, the cellular binding of lipoplexes and polyplexes is reduced.[75] The presence of soluble heparin and heparan sulfate in the medium competitively inhibits the binding. At this point, the HSPGs may act as nonspecific receptors for cationic macromolecules, but their exact role in mediating cellular uptake is not clear. There is some evidence to show that the transmembrane proteins, syndecans, may cluster to form focal points at the plasma membrane during binding to cationic particles and this clustering induces their interaction with the actin cytoskeleton, probably resulting in the formation of tension fibers. This tension provides the energy required to engulf the particles.[76]

The main disadvantage of lipoplexes as gene delivery systems is their nonspecificity.[72] They can bind to all cell types, as well as hundreds of plasma proteins and biopolymers, owing to nonspecific electrostatic interactions with negative components. An alternative is specific liposomes, which carry surface-attached targeting ligands or antibodies and have the capability to interact specifically with tissues and cells based on the ligand attached to the surface. For example, hepatocytes exclusively express large numbers of high-affinity cell-surface receptors that bind to and subsequently internalize asialoglycoproteins.[77] Introducing a galactose moiety into a gene delivery system can achieve liver-parenchymal-cell-specific gene transfection. Mannose-receptor-mediated gene transfection is another approach for targeting macrophages, which overexpress mannose receptors on their surface.[78] Transferrin (Tf), an iron-binding glycoprotein, has been used as a tumor-targeting ligand for gene delivery systems.[79,80] Tf receptors are overexpressed in rapidly dividing cells because of the increased cellular need for iron. The folate receptor is another example of receptors overexpressed in tumor cells and it can be used for tumor targeting.[81,82] Despite the potential of targeted liposomes as specific gene delivery systems, most of the currently used ligands are internalized by clathrin-mediated endocytosis, and the poor intracellular trafficking associated with this pathway significantly limits the transfection activities of the systems.[83–85] Therefore, functional devices that increase the cytosolic delivery of genes are needed. For example, the intracellular fate of Tf liposomes was largely improved by adding GALA (glutamic acid-analine-leucine-alanine), a pH-sensitive fusiogenic peptide, which enhances the endosomal escape in response to the low pH in endosomes.[79,86,87]

Cationic liposomes, with their high fraction of cationic lipids, can produce cell toxicity. A recent approach to decrease this known cell toxicity includes replacing cationic lipids with a cationic peptide such as arginine-rich peptides. Torchilin *et al.* reported liposome modification with a peptide derived from the transcriptional transactivator (TAT) protein of human immunodeficiency virus (HIV-1).[88] TAT-modified liposomes were rapidly and efficiently internalized into cells. These liposomes were able to bind to DNA and internalize them efficiently with lower cytotoxicity compared to liposomes containing cationic lipids.[89] Other reports showed efficient internalization of TAT-, penetratin-, and octaarginine-modified liposomes.[90–94] We have previously shown a rapid and efficient internalization of liposomes modified with both low- or high-density octaarginine (R8).[95] We used a simple and versatile strategy to attach R8 to liposomes, using the stearylation of R8. Stearylated R8 (STR-R8) was mixed with other lipids during the formation of liposomes, exploiting stearyl groups to be anchored into the lipid bilayer thus leaving the R8 freely attached at the surface. The prepared R8-modified liposomes were around 100–150 nm in diameter and were positively charged.[95] The liposomes are rapidly and efficiently internalized into different cell lines as judged by flow cytometry and confocal microscopy. Both hydrophilic and lipophilic model drugs were efficiently internalized when encapsulated in R8-liposomes without any remarkable cytotoxicity. When double-labeled liposomes were added to cells, high intracellular fluorescence could be detected inside cells and both labels were highly localized, indicating that the liposomes are internalized as intact vesicles.[95,96] These results showed that R8-liposomes are highly promising drug delivery systems with little or no cytotoxicity, which prompted us to investigate the applicability of R8-liposomes in gene delivery, as will be explained later.

4.425.2.2.2. Polymers

One main class of nonviral gene delivery vectors extensively investigated comprise complexes of cationic polymers and DNA, termed polyplexes.[97,98] Cationic polymers without hydrophobic moieties can condense DNA more efficiently, resulting in smaller DNA condensed particles as shown in **Figure 3**. Among the many cationic polymers available, those most frequently used in gene delivery are poly-L-lysine (PLL) and polyethylenimine (PEI). Upon mixing with DNA, electrostatic interactions occur between the polymer cations and DNA anions, forming particles as small as 20–40 nm in some cases.[99–102] Polyplexes form spontaneously by mixing aqueous solutions of DNA and cationic polymers at appropriate nitrogen/phosphorous (N/P) ratios. Polyplex size and charge depend to a greater extent on the ratio between the cationic polymer and DNA than on the polymer properties.[99]

DNA compaction with cationic polymers provides several advantages including size reduction, charge neutralization, and DNA protection against nucleases and other enzymes. However, polyplexes formed with PLL are generally less efficient than cationic lipids, and a ligand is usually attached to PLL polyplexes to increase their cell internalization.[103] Furthermore, these polyplexes have low ability to escape from intracellular endocytic compartments. The more recently introduced PEI polymer produces more efficient cell DNA internalization and endosomal escape.[101] The latter ability is attributed to a theorized proton sponge effect that causes swelling and disruption of

endosomes under vesicle acidification. Polyplexes formed between PEI and plasmid DNA at the proper NP ratio produce highly efficient gene expression *in vitro*. However, both branched and linear PEI used for gene delivery generally produce toxicity. Linear PEI is generally preferred for *in vivo* applications because of its lower toxicity. However, branched PEI is more suitable for modification due to the presence of a higher percentage of primary amines. Examples of modifications include incorporation of targeting ligands to increase specificity, labeling the polymer with fluorophore for intracellular trafficking, or the addition of poly(ethylene glycol) (PEG) to increase polyplex stability. Incorporation of PEG reduces interaction with blood components, resulting in decreased uptake by the organ-based reticuloendothelial system, and resulting in prolonged circulation times for PEGylated polyplexes. However, PEGylation also reduces cellular uptake by cells, which in turn reduces the transfection efficiency.

Short, positively charged peptides such as TAT and oligoarginines also have the ability to condense DNA.[104–107] TAT peptide was shown to be able to compact and stabilize DNA, and the complexes were superior to PEI.[107] In addition, PLL-linked TAT was efficient as a transfection reagent.[105] Octaarginine (R8) was shown to have the ability to condense DNA and the complexes were as efficient as PLL polyplexes.[104] In addition, the *N*-terminal stearylation of R8 greatly improved its transfection ability.[108] This was attributed to the improved condensation of DNA by R8 by both the hydrophobic stearyl group and cationic peptide, producing both ionic and hydrophobic binding with the DNA. Stearylated R8 polyplexes showed improved cellular binding and internalization, resulting in transfection activities as efficient as the commercially available cationic lipid transfection reagent lipofectamine.[104,108]

Similar to lipoplexes, cationic polymer–DNA complexes bind to cell surfaces through ionic interactions with negatively charged cell surface constituents. Cellular binding of polyplexes to proteoglycan-deficient mutant cells is highly reduced.[75] In the addition, the presence of soluble heparin or heparan sulfate also prevented cellular binding and uptake of polyplexes. Uptake of PEI polyplexes was proposed to occur through actin-mediated phagocytosis mechanisms as a result of the adhesion of polyplexes to syndecan molecules followed by their clustering in lipid rafts.[109] The exact role of negative cell surface constituents in mediating cellular uptake of polyplexes remains unclear.

The term 'lipopolyplex' has been introduced recently and involves the condensation of DNA using a polycation followed by entrapping the polyplexes within anionic or neutral liposomes.[110–112] The charge ratio between DNA and cationic polymers can be controlled to produce negatively charged complexes that can be further complexed or entrapped in cationic liposomes.[110] Lipoplyplexes are generally more efficient in cell transfection than lipoplexes or polyplexes.[113] This method combines the high compaction of polyplexes and the facilitated endosomal escape of lipoplexes. In addition, it provides more protection to DNA, and the complex surface can be easily modified with functional ligands for targeting or for long circulation.

4.425.2.2.3. Polymeric micelles

A micelle is generally defined as a collection of amphiphilic surfactant molecules that spontaneously aggregate in water in a concentration-dependent manner to produce a metastable aggregate. The core of the micelle is hydrophobic and therefore can sequester hydrophobic drugs. Conventional micelles are formed from small surface-active molecules that have a polar head group and a hydrophobic tail (amphiphiles). However, micelles can also be formed from large amphiphilic block copolymers. In aqueous media, amphiphilic block copolymers, which have a large solubility difference between hydrophilic and hydrophobic segments, spontaneously form polymeric micelles with a core–shell structure in which a hydrophobic inner core is surrounded by a hydrophilic shell or corona.[114] In contrast to micelles from small surfactant molecules, polymeric micelles are generally more stable and can retain the loaded drug for a prolonged period.[115,116] Biocompatible PEG is often used as the hydrophilic segment to improve water solubility and to provide a 'stealth' corona to decrease nonspecific interactions, leading to increased blood circulation time.[117–119] Such polymeric micelles are usually large enough to escape renal excretion (15–30 nm). However, their size is controlled below 100 nm to allow extravasation and tumor accumulation, even though drug loading efficiencies at this size are generally low. These characteristics facilitate tumor accumulation by the EPR effect.[120]

One example of polymeric micelles used in drug delivery is the anticancer drug doxorubicin (Dox). Dox-conjugated PEG-*b*-poly(aspartate) (PEG–PAsp) block copolymers spontaneously form polymeric micelles in aqueous media.[121–123] Dox was covalently conjugated to the side chains of the poly(aspartate) (PAsp) segment. This conjugation provided sufficient hydrophobicity in the PAsp segment due to Dox's hydrophobicity, thus forming a stable inner core of polymeric micelles. A Dox molecule can be physically entrapped in the micellar core by hydrophobic interactions. This physically entrapped Dox exerts the major cytotoxic function, while the conjugated Dox works mainly to increase micelle stability.[124] The PEG–PAsp(Dox) micelle showed prolonged blood circulation times and effective accumulation into a subcutaneous ectopic solid tumor (murine colon adenocarcinoma (C-26)).[125,126]

Following the same concept, polymeric micelles were used for gene delivery. A polymeric micelle containing nucleic acids is formed by complexation between DNA or RNA and a block copolymer having a hydrophilic segment and a cationic segment. Complexation of plasmid DNA with PEG–poly(lysine) (PEG–PLys) occurs spontaneously.[127,128] The PEG shell promotes extended systemic circulation and thus tumor accumulation by the alleged EPR effect. Polyplex micelles containing pDNA indeed exhibited efficient gene introduction in cultured cells, achieving prolonged blood circulation.[129] These results demonstrate that polymeric micelles might also serve as promising gene carriers in gene therapy.

Polymeric micelles can be regarded as a first-generation system, as they are mostly monofunctional.[130] Supramolecular multifunctional nanodevices prepared with smart multifunctional polymeric micelles designed with stimuli-responsive properties may provide promising systems with increased targeting ability and reduced toxicity.[130] For example, active targeting using specific ligands can increase gene delivery efficiency and reduce side effects. Antibodies and their fragments, transferrin, folate, sugars, and peptides are commonly used to achieve active tumor site targeting.[131] One example of

such targeted smart nanocarriers is the polymeric micelle encapsulating pDNA targeted to hepatocytes bearing abundant ASGP receptors bind lactose moieties.[132] The transfection of these micelles in HepG2 cells showed that lactose-bearing micelles were significantly more efficient at transfection than micelles lacking lactose.[133] Another example involves targeting vascular cells near tumors to inhibit formation of new blood vessels, thus cutting off the nutritional supply to cancer cells. The cyclic RGD peptide (c(RGDfK)), which specifically target integrin receptors on vascular cells, was conjugated to PEG–PLys block copolymers,[134] showing increased transfection efficiency *in vitro* compared to ligand-free polyplex micelles.

A second approach to prepare smart multifunctional polymeric micelles involves the use of stimuli-responsive biodegradable micelles. Nanocarriers must be sufficiently stable to resist extracellular degradation and dissociation. However, they must also release their nucleic acid payload near their intended site of action. One class relies on acid-dependent degradation of polymeric micelles. Nanocarriers internalized through endocytosis experience a pH drop in endosomes. Thus, drug carriers with pH-sensitive linkages based on hydrazone, *cis*-aconityl, or acetal groups that degrade at low pH can be prepared. Such carriers are stable at physiologic pH but degrade under acidic conditions inside cells. As an example of acid-sensitive micelles, a triblock copolymer was designed for micelle formation by two cationic segments in a single polymer strand.[135] In this triblock copolymer, each segment has its own distinctive role: a PEG segment for biocompatibility, a second segment composed of low pK_a amines (poly[(3-morpholinopropyl) aspartamide] (PMPA)) for buffering capacity to enhance endosomal escape, and a third segment composed of high pK_a amines (PLys segment) for DNA payload binding. The transfection activity of the triblock system exhibited one order of magnitude higher transfection compared with the PEG–PLys block copolymer with similar PLys unit length. This transfection efficiency is comparable with that of the well-known PEI/pDNA polyplex, but with a remarkably lower cytotoxicity.

To find a suitable cationic segment, PEG block copolymers with a series of cationic side chains were synthesized. A polymer library was prepared, from which it was found that PEG–polyaspartamide with an ethylenediamine unit as a side chain (PEG–PAsp(DET)) had high transfection efficiency as well as low cytotoxicity.[136] This polymeric micelle provided gene expression in primary cells as well as in *in vivo* disease models with low toxicity. The polyplex micelle prepared with PEG–PAsp(DET) and pDNA was also applied to vascular lesions with good results.[137] The micelle was instilled intravascularly into rabbit carotid arteries with neointima, exhibiting appreciable reporter gene transfer into vascular lesions without any vessel occlusion by thrombus. The PEG–PAsp(DET) polyplex system was also applied for *in vivo* gene transfer in a bone-defect model of mouse skull bone.[138] The polyplex micelle was mixed with a calcium phosphate cement scaffold and installed into the bone defect. Sustained release of PEG–PAsp (DET) from the scaffold and transfection of surrounding cells were observed. Transfection of constitutively active activin receptor-like kinase 6 (caALK6) and runt-related transcription factor 2 (Runx2) induced osteogenic differentiation in mouse calvarial cells with no signs of inflammation.

In a similar way, stimuli-responsive smart nanocarriers can be prepared with a disulfide bond, which is known to be stable in the extracellular environment yet readily cleaved inside the cell due to the increased concentrations of glutathione. In this regard, bioresponsive smart polymeric micelles that dissociate inside cells in response to chemical stimuli were designed. The inner core of the micelle was cross-linked through disulfide bonds for cleavage inside the cell, increasing the stability of the micelle. At the same time, the efficient release of packaged pDNA was demonstrated in response to reducing reagent (dithiothreitol), mimicking the intracellular environment.[139] Gene transfection was higher by an order of magnitude than that of the non-cross-linked system, with the cross-linked micelle exhibited appreciable gene expression in parenchymal cells of the mouse liver through intravenous injection.[140] The disulfide cross-linking micelle maintained the original transfection capacity even after freeze–thaw treatment without the use of any protective reagents, while the non-cross-linked micelles showed significantly lower transfection efficiency after the same treatment.

4.425.2.2.4. Multifunctional envelope-type nanodevice

Recently, we developed a multifunctional envelope-type nanodevice (MEND) as a novel nonviral gene delivery system based on a new packaging concept termed 'programmed packaging'.[110] Programmed packaging was proposed to develop a rational nonviral gene delivery system equipped with various functional devices, including ligands for specific receptors, pH-sensitive fusogenic peptides for endosomal escape, and a nuclear localization signal (NLS) for enhanced nuclear delivery, to overcome several barriers in the process of gene delivery to the nucleus of target cells.[141] Simple mixing of these functional devices is not sufficient to have each function exerted at the appropriate time and correct place, and therefore an innovated nanotechnology is required to assemble these multiple components. The concept of programmed packaging consists of three components: (1) a program to overcome all barriers; (2) designs of several functional devices to overcome different barriers; and (3) technology to assemble all the pieces into a nanosize single structure.[3]

The MEND system mimics an envelope-type virus. It consists of a condensed DNA core covered with a lipid envelope. DNA is condensed with a polycation to control size for facilitated lipid coating and to protect DNA from degradation. The lipid envelope is equipped with various functional devices to avoid various extracellular and intracellular barriers. The MEND was constructed using a lipid film hydration method.[110] This method is based on packaging in three consecutive steps: (i) DNA condensation with polycations to form positive or negative polyplexes; (ii) hydration of the lipid film, which carries an opposite charge for electrostatic binding of condensed DNA; and (iii) sonication to self-assemble liposomes or lipid envelopes and packing the condensed DNA within the envelope. A typical MEND was prepared by using PLL/DNA positive polyplexes of ~100 nm in size. The lipid film contained a negatively charged lipid such as cholesteryl hemisuccinate (CHEMS) and hydrated with an aqueous solution containing positive DNA/PLL particles. Packaging of the PLL/DNA particles into a lipid bilayer was achieved by sonication in a bath-type

sonicator. The diameter and ζ-potential of the MEND were around 300 nm and −40 mV, respectively. DNA encapsulation efficiency was greater than 70%.[110]

As we had previously shown that R8 had a great potential for enhancing cellular uptake of liposomes,[4,95,96] we investigated the applicability of the R8 peptide to MEND internalization. We found that the cell internalization and transfection efficiency of MEND was greatly improved by R8 modification.[110,141] The internalization of MEND via nonclassical pathways, which can avoid lysosomal degradation, probably plays an important role in the R8-mediated improvement.[95] The R8-MEND consisting of EPC/Chol showed higher transfection activities than PLL/DNA complexes.[141] Substitution of EPC with the fusogenic lipid DOPE increased the transfection activities by more than 4 orders of magnitude compared to negatively charged PLL/DNA particles. Furthermore, the transfection activity was increased further by replacing cholesterol with the negatively charged fusogenic lipid CHEMS.[141] DOPE and CHEMS may enhance the cell internalization efficiency into the cytoplasmic space by their fusogenic properties, thus facilitating nuclear delivery of DNA. Thus, the transgene delivery ability of R8-MEND could be improved by about 2 orders of magnitude by optimization of the lipid envelope.

Moreover, the R8-MEND was examined for its ability to deliver siRNA expression plasmids.[142] The pDNA encoding anti-luciferase siRNA was condensed by PLL and packaged into the R8-MEND. The silencing effect of the R8-MEND(PLL) exhibited a 96% level of inhibition of luciferase activities in the co-transfection study without any detectable toxicities. The silencing effect was maintained at more than 60% even under conditions of a 100-fold dilution. In luciferase-transformed cells, however, the R8-MEND(PLL) did not show the same high silencing effect (only 10%), suggesting heterogeneity in the transfection by the R8-MEND(PLL).[142] To solve this problem, the DNA condensing agents were optimized by comparing PLL, STR-R8, and the spermatozoal peptide protamine. While there was no difference in the silencing effect among these R8-MENDs in the co-transfection study, the R8-MEND (protamine) showed a 70% silencing effect in the transformed cells. Thus, the transgene ability of R8-MEND was further improved by optimization of the DNA condensing agent.[142]

The transfection activity of the optimized R8-MEND was further compared with that of an adenovirus, one of the most potent viral vectors, in human cervical cancer HeLa cells, and in a human lung epithelial carcinoma cell line A549.[141] These cells display receptors for adenovirus serotype 5, such as coxsackie and adenovirus receptor (CAR) and integrin receptors. In both cell lines, the transfection activities of the adenovirus increased with increasing dose up to 1×10^5 particles per cell, above which toxicity appeared and the transfection activities then decreased. The transfection activities of R8-MEND were as high as those of the adenovirus using 1×10^5 particles per cell. As judged from the protein content in cell lysates after transfection, the R8-MEND showed no significant cytotoxicity, while higher doses of the adenovirus produced significant cytotoxicity (~50% loss of protein content).[141] The optimized R8-MEND did not contain cationic lipids, and this may explain its low cytotoxicity. The transfection activity of R8-MEND was strongly inhibited by amiloride (~95%). This indicates that macropinocytosis is the major pathway mediating the efficient transgene delivery of R8-MEND. As will be explained in a later section, the uptake by macropinocytosis involves the formation of large and heterogeneous macropinosomes (>1 μm), which appear to be leaky and fuse with lysosomes to a lesser extent. As macropinosomes are large, macropinocytosis readily explains the efficient internalization of the relatively large R8-MEND (>300 nm), which is somewhat larger than clathrin-coated vesicles (~150 nm) and caveolae (~50 nm).

The R8-MEND was particularly useful for *in vivo* gene delivery into hair follicles after topical application to the skin of a 4-week-old ICR mouse.[141] Gene expression was observed in the hair shafts and follicle cells treated with R8-MEND encapsulating LacZ- or green fluorescent protein (GFP)-encoding plasmid DNA. The gene transfer efficiency of R8-MEND was significantly higher than that of lipoplexes made of the commercially available reagent Lipofectamine and DNA. In a further experiment, R8-MEND containing DNA encoding bone morphogenetic protein receptor type 1 A (Bmpr1a), which is involved in the hair growth cycle, was applied to the mouse skin. The R8-MEND formulated Bmpr1a gene was able to extend the hair growth period.[141]

Further applications of R8-MEND include successful delivery of antisense ODNs, which can inhibit the function of mRNA in the cytosolic space. For delivery of ODN, ODN-encapsulated R8-MEND (ODN-MEND) packaged using protamine as a condenser showed a 90% antisense effect 8 h after transfection, and a persistent antisense effect of over 75% for up to 48 h, which was much more effective than that of LipofectAmine2000 (LA2000).[142,143] These results suggest that R8-MENDs are able to deliver encapsulated nucleic acids to the cytosol as well as to the nucleus, and that protamine can also function as an efficient decondenser not only in the nucleus but in the cytosol as well.

The R8-MEND was also expected to be an efficient and safe delivery system of siRNA. However, it was unclear whether the siRNA could be packaged well into the MEND, because the structure and physicochemical characteristics (i.e., persistence length) of double-stranded RNA (siRNA) differ from those of plasmid DNA and ODN. Thus, a polycation able to compact siRNA as a nanoparticle was screened by measuring the size and ζ-potential of complexes formed between siRNA and polycations PLL, STR-R8, and protamine.[144] Only STR-R8 was able to compact siRNA to form nanosized particles (<100 nm), whereas all three polycations were able to condense pDNA or ODN. The hydrophobic stearyl moiety, which is not contained in PLL or protamine, may be critical in aiding compaction of siRNA into small particles. The silencing effect of siRNA-encapsulated R8-MEND (siRNA-MEND) was compared with that of LA2000. The siRNA-MEND inhibited luciferase activity by more than 80% in HeLa cells stably expressing luciferase. In contrast, an absolute silencing effect could not be obtained for LA2000, possibly due to nonspecific enhancement of gene expression by LA2000 treatment. In addition, the R8-MEND-encapsulated siRNA showed no cytotoxicity.[144]

In vitro gene delivery assays, mostly delivery to culture cell monolayers on solid supports (either cell culture plates or 3D scaffolds), often employ serum-free media to prove concept. This condition in the absence of serum proteins is practically irrelevant for all but the most carefully concocted *ex vivo* cell transfections. However, vector transfection performance in

serum-containing media is substantially reduced (i.e., often only 1–10% of cells). Analogously, for effective *in vivo* application of synthetic, nonviral, especially cationically based, gene vectors, a primary drawback is the lowered transfection activity in the presence of plasma, with its many proteins and cells. This is also the case for the vector R8-MEND. Efforts to overcome the very demanding serum protein transfection challenges include optimization of vector charge density, optimization of lipid composition, and grafting of corona polymers that effectively resist plasma component complexation and extend circulation. Our current trials toward improving synthetic vector *in vivo* application and efficacy in trasngene delivery are described in Section 4.425.3.2.1.

4.425.3. Pharmacokinetics

4.425.3.1. Factors Governing the PK of a Carrier System

After a carrier system is administered, its fate in the body is often unknown and difficult to track. Numerous biological barriers exist to protect the human body from invasion by foreign molecules and particles, as shown in Figure 4. These barriers hinder drug delivery and must be overcome in order to effectively deliver the carrier to a target organ. Cationic compounds such as cationic lipids, including DOTAM,[60,61] DOTAP,[145] and natural polymer,[146] or a synthetic polymer including PLL, PEI, and dendrimer are commonly employed as carrier systems, defining lipoplexes and polyplexes. The physicochemical properties of their nucleic acid complexes, such the N/P ratio, surface charge, size and structure of the cationic compounds, have a strong effect on their biodistribution. In addition, the destination of a carrier system in the body would be significantly altered by the route used for its administration. From the viewpoint of practical use, systemic administration would be desired because of the ease of operation. Immediately upon i.v. injection, a carrier system faces a myriad of different biological components in the systemic circulation (e.g., blood proteins, RNAses, DNAses, cells, platelets). For successful gene delivery to a target organ, the carrier needs to avoid nonspecific interactions with this biological milieu. The carrier system also should not be eliminated from the blood circulation by kidney glomerular filtration, lung capillaries, and uptake by the liver and spleen (the reticuloendothelial system (RES)), and should subsequently be delivered to the target organ at sufficient doses to reliably produce therapy. Therefore, in this section, the factors governing the PK of a carrier system are discussed from the viewpoint of the properties of the carrier system such as charge and size after systemic administration.

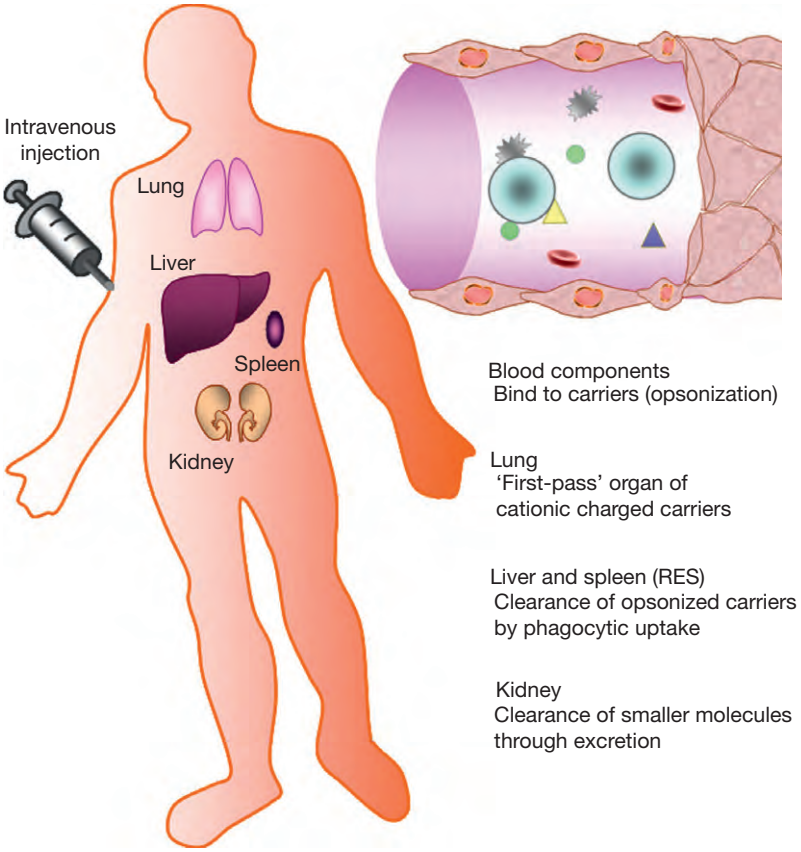

Figure 4 Biological barriers in the human body. Macromolecules with molecular weight smaller than the renal excretion threshold (typically molecular weight <50 kDa, and diameter <10 nm) are eliminated from blood circulation through glomerular filtration in the kidney. After systemic administration, cationic carriers aggregate with blood components (opsonins), which allows accumulation in the lung capillary. The opsonized carriers are finally taken up by liver and spleen, collectively known as the reticuloendothelial system (RES).

4.425.3.1.1. Carrier charge

The surface charge of carrier complexes plays an important role in determining the final destination of the complexes. It is known that the higher cationic charged complexes of DNA with polymers or lipids exhibit a gene expression in the lung that is 10–100-fold higher than in the liver, spleen, or kidney as early as 2 h after intravenous administration.[147,148] The maximum level of expression was maintained in the lung over the first 24 h, followed by a rapid decrease. The remarkably rapid and efficient transgene expression in the lung raises the question of what happens following the systemic administration of positively charged gene carriers. After entering the blood stream, the cationic charged surface immediately interacts with anionic serum proteins and cells in the blood, resulting in the formation of aggregates with sizes of more than 1 μm[149–152] Based on biodistribution analyses, a large fraction of the carrier dose (60–80%) of lipoplexes or polyplexes is found mainly in the lung at early phases within minutes after systemic administration. This is because aggregated complexes are trapped in the small capillaries in the lung due to the fact that pulmonary vasculature is the first capillary bed encountered, the so-called first-pass effect.[150,153] However, as early as 1–2 h post injection, this amount drops to less than half, with increasing amounts shifted to the liver. This phenomenon suggests that binding of serum proteins to complexes might be reversible, which is explained by the displacement of serum proteins from complexes by extracellular proteoglycans, allowing their shift from lung to liver.[154]

Histochemical analyses indicate that cells expressing genes were found in both endothelial cells and pneumocytes.[149] It is possible that vascular endothelial cells are transfected as the result of the direct association of complexes in blood, whereas the mechanism of the translocation of complexes in pulmonary cells through endothelial cells remains unclear. The efficiency and pattern of gene expression in the lung and other organs by the complexes are greatly influenced by the properties of the complexes. For example, in a lipoplex, DOTMA containing an ether linkage exhibits a more efficient gene expression in the lung than DOTAP containing an ester linkage.[148] In general, a higher N/P ratio of complexes tends to lead to a higher transgene activity. As mentioned above, cationic charged complexes are capable of introducing transgene expression in lungs after systemic administration, whereas side effects such as acute cytotoxicity-related liver necrosis and death resulting from a high cationic charge remain to be solved.[155] On the other hand, distinct from lung, the amount of DNA in the liver increases with time up to 24 h post i.v. injection. Even though a large amount of DNA accumulation ultimately occurs in the liver, gene expression in the liver was significantly lower than that in the lung.[148] Why do gene carriers represent less 'lipofectable' results in liver than in lung after systemic administration? To address the underlying mechanism, the features of the liver as a major clearance organ of nanocarriers must be better understood, with an insight into carrier properties, principally size, that carriers should satisfy.

4.425.3.1.2. Carrier size

How does the size of a carrier influence its biodistribution and fate in the body? In general, this depends on its route of administration. But, macromolecules with a lower molecular weight than the renal excretion threshold (typically, molecular weight <50 kDa and diameter <10 nm) are eliminated from circulation through kidney glomerular filtration.[156] Because the complexes considered herein are tens to hundreds of nanometers in diameter, they are not removed through renal excretion. Opsonized complexes are found in lung, and subsequently in liver and spleen, due to uptake by cells of the mononuclear phagocytic system (MPS), including macrophages located in liver and spleen (originally and also still known as the RES), which function as an important host defense mechanism.[157] Therefore, the liver and spleen are the major clearance organs of complexes after intravenous injection. One of the reasons for why the liver is less 'lipofectable' could be the uptake and the degradation of lipoplexes by nonparenchymal Kupffer cells. Additionally, another important role of carrier size should be considered in terms of delivery to parechymal hepatocytes in the Disse space through endothelial capillaries. Blood vessels are responsible for supplying molecules, nutrients, and oxygen and, of course, delivering the systemically administered carriers to organs. On the basis of morphological features of the endothelium, blood vessels have been classified as continuous, fenestrated, or discontinuous.[158] The liver lacks a continuous basement membrane, liver blood vessels contain fenestrae that are 100 nm in diameter on average,[159] and Kupffer cells, the resident liver macrophages, are located in the sinusoidal space,[160] as shown in **Figure 5**.

For successful gene delivery to liver parenchymal cells, the behavior of carrier systems should be controlled, considering the characteristics of liver blood vessels organized by nonparenchymal fenestrated endothelial cells and Kupffer cells. In other words, a diameter of less than 100 nm and escape from Kupffer cell recognition would allow carriers to gain access from the sinusoidal space to hepatocytes thorough the liver fenestrae. Hashida and coworkers reported that delivery of higher amounts of pDNA to parenchymal cells than nonparenchymal cells was achieved using cationic liposomes in which Gal-C4-Chol had been incorporated, because hepatocytes express an abundance of asialoglycoprotein receptors (ASGPr) that selectively recognize galactose and *N*-acetylgalctosamine (GalNac) residues.[161] However, this behavior may not be sufficient for transfection in distant sites (e.g., tumors). In the next section, properties of nanoparticles relevant to evade macrophages to facilitate long circulation in the blood and delivery of a carrier system to a tumor are discussed.

4.425.3.2. Passive Carrier Targeting

In the case of anionically charged complexes, opsonization also occurs, followed by rapid disappearance from the blood circulation by scavenger receptors on macrophages known to be involved in the uptake of a variety of polyanionic molecules or macromolecular complexes.[162] For complexes with a neutral surface, carrier opsonization by thousands of plasma proteins takes place in the blood circulation.[163] To overcome nonspecific interactions of complexes with blood components and nontarget cells, the most common strategy is to shield the surface of complexes with hydrophilic, uncharged polymers such as PEG. In the early 1990s, it was reported that

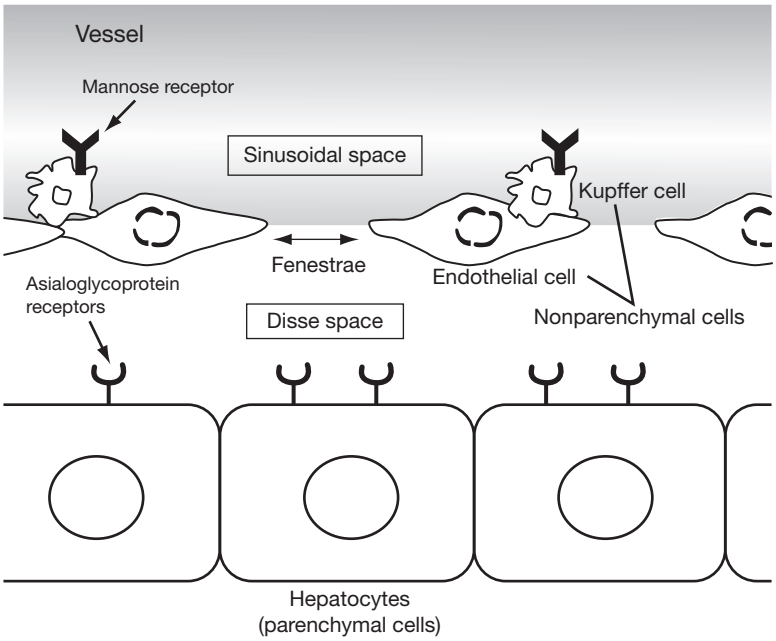

Figure 5 Sinusoidal barriers in liver. Liver blood vessels are organized by nonparenchymal fenestrated endothelial cells containing 100 nm diameter pores and Kupffer cells, lacking a continuous basement membrane. Opsonized carriers are taken up and degraded by the Kupffer cells, reducing transfection efficiency for gene carriers. Therefore, sizes below 100 nm in diameter and with capability to avoid Kupffer cell recognition would allow the carriers to gain liver access from the sinusoidal space to hepatocytes thorough the vascular fenestrae.

modification with PEG allows liposomes to circulate for hours in blood circulation after intravenous administration.[164–166] The PEG moiety forms an aqueous grafted brush layer on the surface of liposomes and provides lipid bilayer stabilization and steric hindrance, which results in inhibition of the plasma protein opsonization.

Cullis and coworkers developed stabilized plasmid–lipid particles (SPLP) composed of a cationic lipid, DOPE, and PEG-CerC20 encapsulating pDNA, which exhibited a long half-life in the systemic circulation.[167] It is well known that long-circulating liposomes (e.g., half-life >6 h) with an average diameter of 100–200 nm accumulate efficiently in tumor tissues.[168] Matsumura *et al.* found that high-molecular-weight (40 kDa or higher), long-circulating macromolecules as well as various long-circulating nanoparticulate pharmaceutical carriers are capable of spontaneously accumulating in solid tumors and inflammation areas via the proposed EPR effect.[169] This effect is based on the empirical observation that the pathological neovasculature of tumor tissue, with its discontinuous or absent basement membrane unlike normal tissues, is 'leaky,' allowing for some molecule extravasation and accumulation in the interstitial tumor space passively if long circulating, as shown in Figure 6. Such carrier accumulation is additionally facilitated by the lack of a lymphatic system, which is normally responsible for the drainage of macromolecules from tissues. This effect is not universal to all tumors but is also common to some inflammatory diseases where vasculature barriers break down.

Advances in the development of long-circulating liposomes that can find tumors via the EPR effect permit an improved use in tumor chemotherapy, such as DOXIL (CAELYX). However,

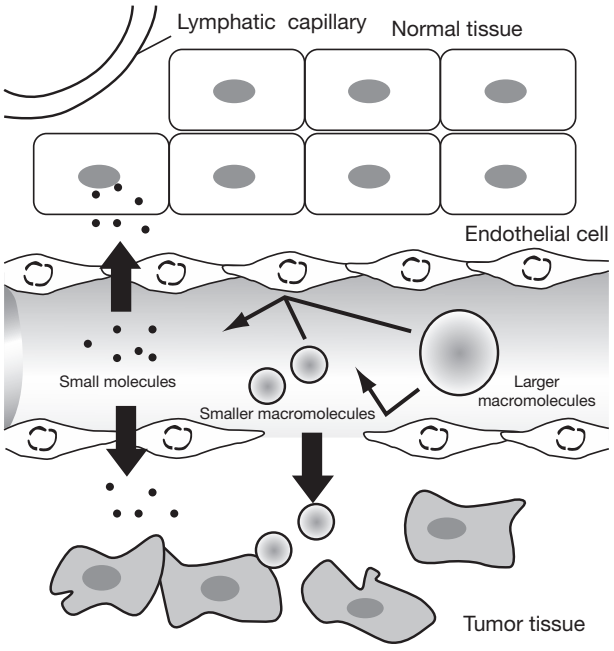

Figure 6 Unique microvasculature of tumor tissue and the EPR effect. Long-circulating nanoparticulate pharmaceutical carriers with <200 nm in diameter are capable of spontaneous accumulations in solid tumors and inflammation areas via the EPR effect. Unlike normal tissue, pathological neovasculature in tumor tissues, such as discontinuous or absent basement membrane, allows for their extravasation and accumulation in an interstitial tumor space passively. The lack of lymphatic system, responsible for the drainage of macromolecules from tissues, also facilitates the carrier accumulation.

the issue of PEGylation is a drawback in *in vivo* applications of such complexes as gene carriers directed to tumors and other organs. PEGylation reduces specific interactions with target tumor cells and results in minimal cellular uptake and poor endosomal escape, yielding a significant loss of bioactivity.[170,171] These issues are currently referred to as the 'PEG dilemma.'

4.425.3.2.1. Strategy for addressing the PEG dilemma

4.425.3.2.1.1. Targeting by specific ligands

One strategy for overcoming the PEG problem is to display affinity ligands on the PEGylated carriers for receptors on targeted cells, which would be expected to improve their selectivity, binding, and uptake of the carriers to targeted cells. Transferrin (Tf) and certain antibodies have been widely investigated as target ligands for gene delivery in targeting to Tf-receptor overexpressed tumor cells.[172,173] Wagner and coworkers developed Tf-linked PEG–PEI for tumor-selective gene delivery.[173] The surface charge of the complexes was shielded by either PEG or a higher density of linked Tf, which was intended to block undesired nonspecific interactions with blood components, followed by selective targeting to tumor cells. One well-characterized target is integrin, a heterodimeric cell-adhesion membrane receptor family, composed of α and β subunits.[174] The arginine-glycine-aspartic acid (RGD) motif has often been used for the targeted delivery of drugs and genes because of its ability to recognize integrins expressed on both tumor cells and tumor endothelial cells,[175] but not expressed on normal cells. Other active targeting to either tumor cells or new blood vessels can be achieved via the use of overexpressed molecules such as the folate receptor.[176–182] Despite their utility in cell monocultures *in vitro*, as tumors *in vivo* are very heterogeneous with multiple cell types with multiple phenotypes, one ligand targeting one cell feature may not be sufficient to produce therapy.

4.425.3.2.1.2. Facilitating endosomal escape

Endosomal release of a cargo such as pDNA or siRNA into the cytoplasm is a critical step in achieving successful gene delivery. Endosomal escape is caused by membrane fusion or the disruption of endosomes.[183] PEGylation, however, confers steric stability to complexes and inhibits their disruption and fusion with the inner endosomal membrane after their uptake. Therefore, valid approaches involve timely removal of the PEG moiety from complexes in the target site in response to the local environment. This would be expected to improve the cellular uptake and subsequent endosomal escape of carriers. The low pH of the endosomal environment is exploited as a trigger for PEG cleavage. Szoka and colleagues constructed pH-sensitive PEG lipids containing an orthoester linkage, and transfection experiments showed a greater luciferase expression of the pH-sensitive lipoplexes as compared to stable PEGylated carriers.[184] Other linkages such as hydrazone linkages, β-thiopropionate, vinyl ester, orthoester, or acetals were also investigated as pH-sensitive PEG system in lipoplexes or polyplexes.[185–189]

Besides the pH gradient, the intracellular reducing environment is considered an alternative stimulating trigger. A PEG-lipid containing disulfide bonds developed by Zalipsky and colleagues accelerated the rate of release of cargo from liposomes compared to a noncleavable PEG-lipid-modified liposome.[190] Hatakeyama *et al.* synthesized an enzymatically cleavable PEG-lipid (PPD) containing a peptide substrate for a matrix metalloproteinase (MMP) present in the extracellular space of tumor tissues.[178,179] Ambegia *et al.* proposed a novel strategy involving the use of exchangeable PEG-lipids, which provides serum stability, long circulation lifetimes, and efficient transgene expression in tumors by using SPLP.[191]

Alternative methods for increasing the endosomal escape of PEGylated carriers are the acceleration of either membrane fusion or deliberate disruption of the endosomal membrane. The pH-sensitive fusogenic membrane peptide GALA was developed on the basis of the endosomal escape mechanism of the influenza virus.[86] GALA undergoes a structural change to an α-helix under acidic conditions. Harashima and colleagues recently demonstrated that a combination of GALA with a PEGylated liposomal formulation containing ether pDNA or siRNA facilitated endosomal release of the cargo and efficient gene expression or knockdown.[192–194] Melittin-PEI-containing carriers showed enhanced gene expression due to their high lytic activity at acidic pH to trigger enhanced membrane destabilization in endosomes.[195] Other peptide derivatives, such as INF7, have also been used.[196] The manipulation of cellular uptake and the endosomal escape of PEGylated carriers using bioreponsive systems should be valuable strategy for overcoming these obstacles and to achieve successful tumor gene delivery.

4.425.3.3. Endothelial Barriers

The continuous vascular capillary is the most ubiquitous type found in the body other than those naturally fenestrated in liver and porous in some tumor tissues, and the resulting transport of molecules and nutrients is strictly regulated by tight junctions and transporters.[158] Therefore, gene delivery to parenchyma over the continuous endothelium is considered to be an ultimate challenge. Because the central nervous system (CNS) beyond the blood–brain barrier (BBB) is connected with related disorders such as Parkinson's disease and Alzheimer's disease, gene therapy for the brain is a highly desirable goal. Pardridge and colleagues demonstrated the liposomal delivery of pDNA and siRNA using particles modified with monoclonal antibodies against insulin or transferrin receptors on the BBB via receptor-mediated endocytosis.[197,198] Kumar *et al.* demonstrated brain delivery of siRNA using RVG, a rabies viral glycoprotein, and an oligoarginine conjugate (RVG-9R).[199] RVG-9R enabled transvascular siRNA delivery to the brain via acetylcholine receptors and the targeted gene knockdown was achieved. However, the efficient delivery of a carrier system through the continuous vascular endothelium is still under development. Despite the remarkable progress made on the development of delivery systems, optimization of target-specific, safe, and efficient carrier systems of nucleic acids remains an ongoing challenge. These barriers will have to be overcome to advance gene and nucleic acid therapeutics to the clinical study stage for crucial diseases.

4.425.4. Intracellular Trafficking

4.425.4.1. Routes of Cell Uptake

The sites of action of gene-based therapeutics are mainly inside cells, either in the cytosol or in the nucleus. Therefore, the

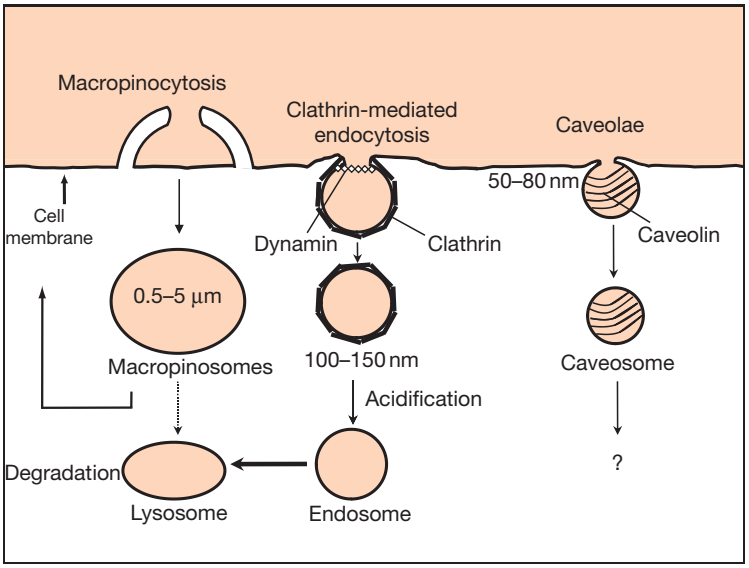

Figure 7 Different endocytic pathways involved in gene delivery. Clathrin-mediated endocytosis is the common and most characterized cell entry pathway. The clathrin coat is removed, and vesicles mature to late endosomes and eventually fuse with lysosomes for degradation. Caveolae are flask-shaped invaginations of the plasma membrane. Caveolae result in the formation of caveosomes. This pathway is generally nonacidic and nondigestive. Macropinocytosis involves the formation of large and heterogeneous macropinosomes that mostly recycle their contents back to the cell surface.

reliable internalization of genes and gene vectors into cells is a prerequisite to efficient transfection. Gene vectors and macromolecules, in general, use different cell internalization pathways for traversing cellular membranes as shown in **Figure 7**. Identifying the specific internalization pathway for a gene vector is critical to effectively optimize the system for efficient transfection. This is due to the fact that the internalization pathway is closely related to the intracellular trafficking and the fate of the internalized molecules. Many distinct pathways and internal endpoints are possible depending on carrier properties, cell type, tissue type, cell cycle, and activation. Selecting these pathways for a particular carrier is currently difficult. Some internalization pathways may favor high lysosomal degradation and endosomal escape is difficult, while other pathways may less efficiently lead to lysosomal degradation and cytosolic delivery is easier.[200] For example, the internalization through clathrin-mediated endocytosis is generally believed to lead to extensive acidic and lysosomal degradation.[201,202] Meanwhile, caveolar endocytosis leads to entrapment of internalized molecules in caveosomes that are not highly acidified and do not fuse with lysosomes.[84,203] Similarly, the internalization through macropincoytosis leads to the entrapment of internalized molecules in large macropinosomes that are generally recycling to the cell surface with low fusion with lysosomes.[204,205]

Actually, while identifying the internalization mechanism is important, directing a certain gene vector into a certain internalization pathway using specific functional device is probably more important as a promising strategy for avoiding lysosomal degradation. Combining internalization through a cell uptake pathway that avoids lysosomal degradation with effective methods to escape endocytic vesicles is expected to lead to high levels of cell transgene expression. For example, we have previously shown that the uptake of lipid vesicles encapsulating different nucleic acids can be directed to macropinocytosis through the proper use of octaarginine peptide.[95,141] Topology control and the density of the attached peptide were shown to be important factors in targeting internalization through macropinocytosis.[95,108] Proper attachment of the peptide to the lipid envelope in a way that the peptide remains free for interaction with cellular membranes was shown to be important for determining the uptake mechanism.[108] In addition, only liposomes modified with a high density of octaarginine were internalized mainly through macropinocytosis, while those modified with a low density of octaarginine were internalized mainly through clathrin-mediated endocytosis.[95] Therefore, these factors, along with others, should be carefully considered while designing a nonviral gene vector. Internalization through macropinocytosis still requires an efficient system for escaping vesicular entrapment. When the system was combined with a highly fusogenic lipid envelope or with a fusogenic peptide, effective cytosolic delivery was achieved as was evident from confocal laser scanning studies. As a result, the R8-MEND system that was described earlier produced highly efficient gene expression and its application extends to oligonucleotide and siRNA delivery.[3]

Regarding the internalization mechanism of lipoplexes in general, available studies show contradicting results. This suggests that complex factors affect the internalization mechanism, including the diameter, charge, composition of the lipoplexes, as well as the physiology of a certain cell type. Early reports of lipoplex internalization suggested that fusion between the lipids and the plasma membrane is responsible for delivering DNA directly to the cytosol.[60,61,206] It was suggested that the interaction between the liposomes and DNA or the cell membrane destabilizes the liposomes, thus facilitating their fusion with each other and with other membranes. However, most of the following experimental evidence supports the involvement of endocytosis as a main cell entrance route. For example, use

of endocytosis inhibitors significantly reduces transgene expression. Furthermore, interference of the endocytic pathway with lysosomotropic reagents such as chloroquine was found to enhance gene expression.[103] The strongest evidence comes from electron microscopy imaging of gold-labeled DNA formulated in lipoplexes, which clearly shows the presence of DNA in intracellular vesicles, typically entering via endocytosis.[207,208] In general, it is currently believed that membrane fusion is important for transfection but that most of the uptake occurs through endocytosis. Membrane fusion occurs as a result of endosome acidification and is responsible for releasing the endosome contents to the cytosol.

The available data regarding the contribution of a certain endocytic pathway in the overall internalization show diverse results. Rejman *et al*. reported that uptake of lipoplexes formed between the cationic lipid DOTAP and DNA is inhibited by chloropromazine and potassium depletion but is unaffected by filipin and genestein, suggesting that the uptake occurs solely by clathrin-mediated endocytosis.[209] Furthermore, they have shown that particles internalized by this pathway are eventually degraded in lysosomes. Earlier, Zhou *et al*. suggested that the uptake of lipo-PLL (LPLL) lipoplexes occurs through clathrin-mediated endocytosis as the presence of the actin-depolymerizing reagent cytochalsin B increased transfection activities.[210] They suggested that clathrin-mediated endocytosis is the most productive pathway for internalization. Zuhorn *et al*. have shown that lipoplex-mediated transfection occurs through cholesterol-dependent clathrin-mediated endocytosis.[211] Cholesterol depletion with methyl-α-cyclodextrin decreased the activities of SAINT-2/DOPE lipoplexes. This is largely indicative of non-clathrin endocytosis. However, inhibitors of caveolae-like filipin and cytochalasin D had only a slight effect on cell internalization. Co-localization with Tf and the inhibition by potassium depletion further confirmed the involvement of clathrin-dependent endocytosis. Matsui *et al*. suggested that the uptake of LipofectACE lipoplexes occurs through phagocytosis in poorly differentiated airway epithelial cells.[212] Similar to the uptake of large (2 μm) microspheres used as markers for phagocytosis, they found that the uptake of lipoplexes was inhibited by cytochalasin B as well as by potassium depletion.

The uptake of polyplexes also occurs through endocytosis, but without fusion with the cell membrane, and similarly shows some diverse results regarding specific uptake pathways. In general, it is believed that the uptake of PLL and PEI complexes occurs through clathrin-mediated endocytosis. Goncalves *et al*. have shown that the uptake of histidylated PLL (His-PLL) occurs through both clathrin-dependent and clathrin-independent pathways, the latter mostly macropinocytosis as it was inhibited by amiloride and stimulated by phorbol esters.[213] Furthermore, they found that macropinocytosis of the polyplexes and the recycling of DNA impaired transfection and concluded that clathrin-mediated endocytosis is the most productive pathway. Rejman *et al*. also suggested that the uptake of PEI-polyplexes occurs through both clathrin-dependent and clathrin-independent pathways. However, they suggested that the latter mechanism involves the caveolae as it was inhibited by filipin and genestein.[209] Another difference arises from the finding that clathrin-mediated endocytosis is less productive as caveolar internalization escapes lysosomes, thus leading to efficient transfection.

Finally, it is worth mentioning that cellular uptake may or may not be a rate-limiting step in transfection with cationic lipoplexes. For example, the binding and cellular uptake in differentiated primary cell cultures were shown to be rate-limiting steps to efficient transfection. These steps were not rate-limiting in some transformed cell lines such as HeLa cells.[214]

4.425.4.2. Endosomal Escape

After internalization via the several possible mechanisms described above, the internalized molecules exist in different types of endocytic vesicles. The contents of these vesicles are considered still outside the cells as they have no direct access to the cytosol or the nucleus. These vesicles either fuse with lysosomes for degradation or recycle their contents back to the cell surface. Therefore, escape from endocytic vesicles is essential for efficient transfection. Actually, entrapment in endocytic vesicles and lysosomal degradation should be regarded as two different barriers to efficient transfection. This is because some endocytic vesicles do not fuse with lysosomes and the contents are not subject to lysosomal degradation. However, they are still distant from their site of action, being entrapped in closed vesicles. In other words, escaping lysosomal degradation does not necessarily lead to efficient cell transfection. Escaping vesicular compartment or enhancing cytosolic delivery is probably the more useful term, which directly reflects improved transfection.

Different gene vectors use different mechanisms to escape from endosomes. The most common mechanism involves the fusion between lipids in lipoplexes with lipids in endosomal membranes under acidic conditions leading to membrane destabilization as shown in **Figure 8**. Lipoplexes containing the pH-sensitive fusogenic lipid DOPE can release the associated DNA into the cytosol.[64] DOPE forms a stable lipid bilayer at physiological pH ~7. However, at an acidic pH 5–6, DOPE undergoes a transition from a bilayer to an inverted hexagonal structure, which is highly unstable and rapidly fuses with and destabilizes the endosomal membrane, releasing the associated DNA to the cytosol.[63] Evidence shows that fusion with the endosomal membrane is essential for DOPE-containing lipoplexes.[215] DOPE seems to cause this pH-dependent membrane fusion as a similar neutral lipid DOPC does not lead to endosomal escape.[210] Another explanation of membrane fusion involves flip of anionic lipids of endosomal membranes from cytoplasmic side to endosomal luminal side.[216] The positive charge of cationic lipids increases under acidic conditions, causing flipping of anionic lipids from the cytoplasmic side to face the endosomal lumen. Interaction between cationic lipids of the lipoplexes and anionic lipids from endosomal membrane leads to the formation of neutral ion pairs, which destabilizes the endosomal membrane. This lipid mixing displaces DNA from cationic lipoplexes and allows its release into the cytoplasm. It is possible that only DNA or the lipoplexes as a whole will be released to the cytosol after fusion. If lipoplexes are released, the dissociation of DNA must occur in the cytosol or even at the nuclear membrane to achieve transfection.

The second mechanism of endosomal escape involves endosome disruption, which is evident with the polycation

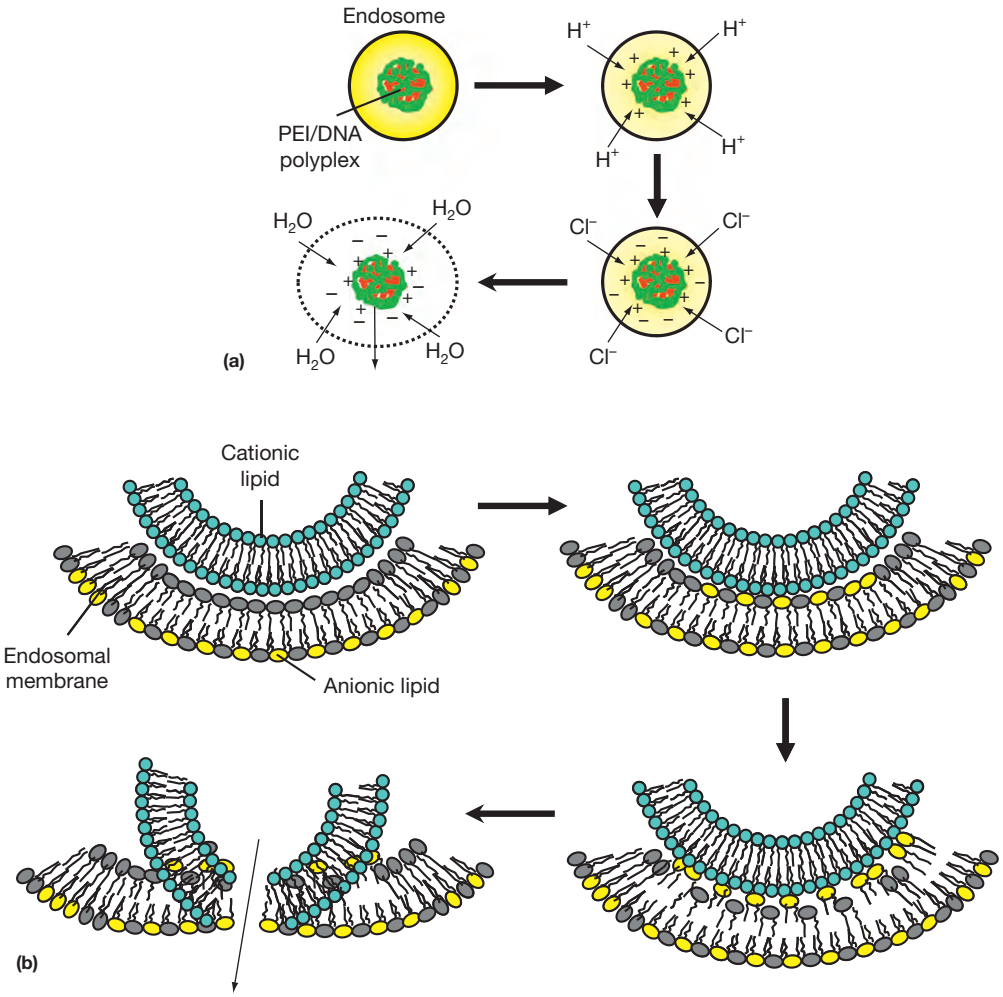

Figure 8 Mechanisms of endosomal escape. (a) Proton sponge mechanism. PEI becomes more protonated at low pH as in endosomes. This protonation triggers an influx of Cl^- ions with protons, leading to a water influx and finally, the swelling and rupturing of the endosomes. (b) The positive charge of cationic lipids increases under acidic conditions, causing flipping of anionic lipids from the cytoplasmic side to face the endosomal lumen. Interaction between cationic lipids of the lipoplexes and anionic lipids from endosomal membrane leads to the formation of neutral ion pairs, which destabilizes the endosomal membrane.

PEI. Transfection with PEI-polyplexes is not improved by fusogenic peptides or chloroquine.[217] The 'proton sponge hypothesis' proposed by Behr *et al*. is frequently used to explain this phenomenon.[97] This hypothesis suggests that PEI becomes more protonated at low pH, as in endosomes, when they actively acidify. PEI acts as a localized buffer within these vesicles, inducing excessive proton pumping into the vesicle. This protonation triggers a co-influx of Cl^- ions with the protons, leading to an osmotically driven water influx and finally the swelling and rupturing of the endosomes.

Pore formation is an additional mechanism of endosomal escape. Certain peptides have the ability to induce membrane pore formation, which facilitates DNA release into the cytosol. These peptides are either derived from viruses, such as the peptide derived from the *N*-terminal sequence of the influenza virus hemagglutinin subunit HA-2, or prepared synthetically such as GALA (WEAALAEALAEALAEHLAEALAEALEALAA) or KALA (WEAKLAKALAKALAKHLAKALAKALKA).[80,218] These peptides undergo conformational changes at low pH in endosomes to interact with and perturb the endosomal membrane. Incorporation of the influenza HA-2 subunit augmented Tf-PLL-mediated gene transfer.[219] Presence of the cholesterol-GALA peptide on the liposomal membrane effectively enhanced the endosomal release of the liposome contents.[79]

Another approach for increasing endosomal escape is the use of lysosomotropic reagents such as chloroquine. It is the weak hydrophobic base that enters the lysosomes and becomes protonated in its acidic environment. As with the proton sponge hypothesis, this presence and buffering capacity triggers a localized swelling of lysosomes and destabilization of their membranes. Chloroquine also inhibits the acidification and maturation of endosomes, thus retarding the lysosomal degradation of genes.[220] Addition of chloroquine to the transfection medium usually favors transfection. This may be due to the destabilization of the endosomal/lysosomal membranes and/or to a slow down in the translocation of DNA to the lysosomes. However, depending on

the system used, chloroquine may also decrease transfection, such as with PEI-polyplexes, by inhibiting endosome acidification required for the release of DNA from endosomes. It is worth mentioning that use of chloroquine and similar lysosomotropic reagents is usually associated with toxicity, which limits their use in actual therapeutic applications.

4.425.4.3. Cytoplasmic Transport

Once released into the cytosol, cytoplasmic transport is also a crucial barrier for macromolecules. Due to the cytoplasmic viscosity, the translation diffusion of dextrans or Ficolls in cytoplasm is 3–4-fold slower than in water.[221] Diffusion of large-sized DNA (>250 bp) is greatly impeded and is dependent on the size of the molecule.[222] This is most likely due to restrictions by actin cytoskeletal filaments.[223] Viruses (i.e., adenoviruses[224,225] and HSV[222,226,227]) have developed a sophisticated machinery for overcoming these biological barriers and are able to successfully deliver their genomes to the nucleus. It is now generally accepted that adenovirus particles are taken up via endocytosis,[204] and then released to the cytosol by disruption of the endosomal membrane via the action of capsid protein VI, which is released from virus particles in response to an acidic pH environment.[228] Adenovirus particles then undergo microtubule-dependent transport to the periphery of the nucleus or to the microtubule-organizing center (MTOC) with the aid of dynein, a microtubule-associated motor protein.[224,229–235] Real-time particle tracking provides new insights into the dynamic transport mechanism of particles in cytoplasm. A detailed particle tracking analysis revealed that the apparent nuclear accumulation of adenovirus results from a dynamic equilibrium involving the more frequent minus end-directed transport toward the nucleus and less frequent plus end-directed transport.[235]

In contrast to viruses, the issue of whether artificial nanoparticles are subject to microtubule-dependent cytoplasmic transport is less well understood. The dynamic transport of PEI-based nanocarriers has been studied.[236–239] An EGF-tagged PEI polyplex[237] showed three-phase dynamics for cytoplasmic transport: (Phase I) a slow directional motion caused by retrograde actin flow; (Phase II) random motion with instantaneous velocity; and (Phase III) directional motion along microtubules. However, the most significant difference between adenovirus and PEI-based carriers is that the directional transport of a PEI-based vector occurs in conjunction with vesicular transport, while adenovirus directly binds to motor proteins.

Another concern is the dissociation of plasmid DNA from the gene carrier. It has been shown that the direct cytoplasmic injection of the lipoplex exhibited a much lower transgene expression compared with the injection of naked DNA.[73,240] In addition, Itaka *et al.* demonstrated that in various types of PEI-mediated transfection the level of transgene expression is correlated with the extent of DNA decondensation in the cytoplasm.[241] Moreover, cytoplasmic translocation of pDNA may be driven by the insertion of specific sequences such as the SV40 enhancer region.[242,243] This region includes consensus sequences for various transcription factors (i.e., AP-1, AP-2, and NF-κB). Therefore, a transcription factor, when bound to the specific sequence of pDNA, may accelerate nuclear delivery. As this accumulation was inhibited by the disruption of microtubules and by the co-injection of anti-dynein antibodies, it is plausible that pDNA accumulates in the nucleus via dynein-mediated transport.[244]

In contrast, data from several studies suggest that the cytoplasmic decondensation of DNA is disadvantageous for transgene expression. Naked DNA is easily degraded by nucleases in the cytoplasm with a half-life of dozens of minutes.[240,245] Furthermore, the diffusion of naked DNA in the cytoplasm is severely limited because of the viscosity of the cytoplasm; the diffusion coefficient of naked DNA > 2000 bp in the cytoplasm is less than 1% of that in water.[222] In fact, pDNA released into the cytosol cannot enter the nucleus and, therefore, has no appreciable transfection activity.[246] Transgene expression was reported to be severely diminished in cell-cycle-arrested (synchronized) cells, suggesting that release of pDNA into the cytoplasm may not facilitate pDNA delivery to the nucleus in nondividing cells.[247] Early release in the cytosol may not be adequate for gene expression. The timing and location (cytosol or nucleus) for the DNA decondensation may be important factors for efficient transgene expression.

4.425.4.4. Nuclear Delivery

In mitotic cells, it is generally thought that pDNA primarily enters the nucleus when the nuclear membrane structure breaks down during the M-phase.[248–251] However, in nondividing cells, the nuclear membrane structure remains intact. Therefore, the nuclear membrane is the ultimate barrier to be overcome for successful nuclear delivery in nondividing cells. The mutual transport of various types of molecules between the cytosol and nucleus occurs via the nuclear pore complex (NPC), which allows the passive transport of gold nanoparticles with sizes of <9 nm.[252] The mechanism for the nuclear localization signal (NLS)-dependent nuclear import of proteins is well characterized.[253] One of the most well-defined NLS signals is the peptide (**PKKKRKV**) derived from the SV40 T-antigen (NLS_{SV40}). Endogenous or chemically modified NLSs bind to importin α and is subsequently recognized by importin β, which facilitates nuclear import of cargo via its efficient interaction with hydrophobic phenylalanine-glycine (FG) rich domains inside of the nuclear pore.[254] One of the most important characteristics of NLS-dependent transport is that the threshold size of the NPC expands to >39 nm in size.[255,256]

Wolff and coworkers investigated the effect of pDNA size on nuclear transport activity using digitonin-permeabilized cells.[257,258] Short DNA (<200 bp) fragments were effectively imported into the nucleus, whereas nuclear import decreased when the size of the pDNA increased and was negligible at a size of >1500 bp. The typical plasmid DNA used (>5 kbp) is too large to pass through the cell's nuclear pore complexes. In fact, microinjection studies demonstrated that more than 100-fold larger amount of pDNA is required to achieve a transgene expression by cytoplasmic microinjection compared to that by nuclear microinjection. This suggests that less than 1% of the cytoplasm-microinjected plasmid DNA reaches the nucleus.[240] Therefore, efficient systems for the nuclear delivery of pDNA would be highly desirable in developing an efficient gene delivery system.

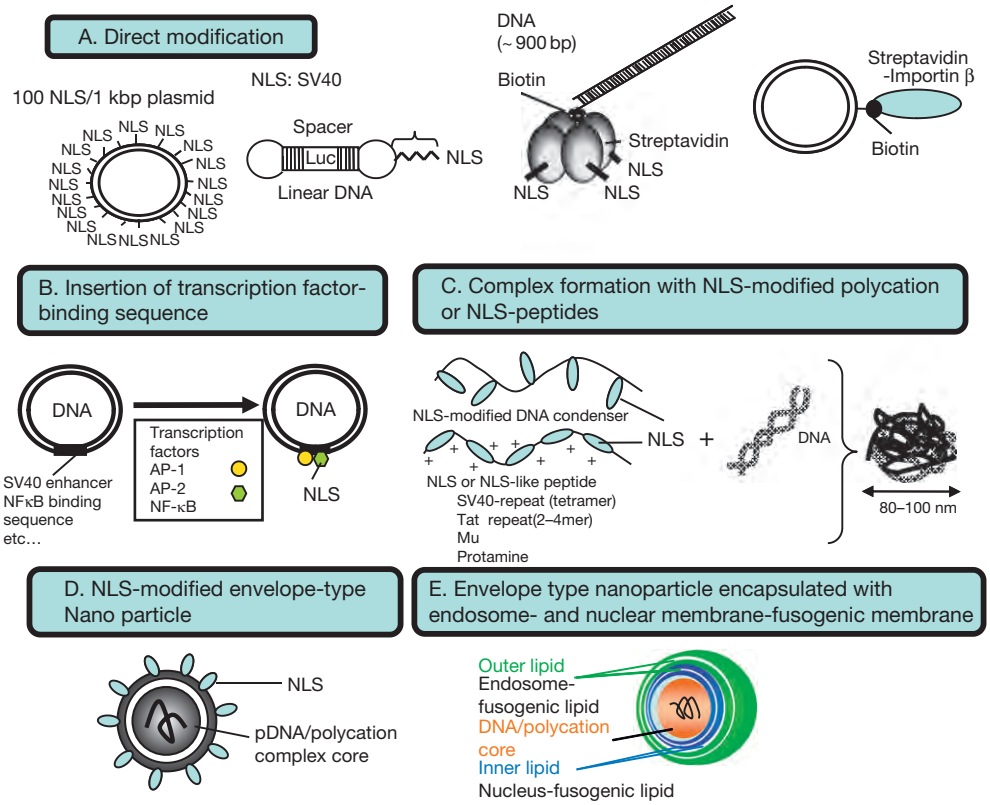

Figure 9 Strategies to overcome a nuclear member barrier. (a) Direct modification of NLS peptides and/or nucleus-targeting proteins to pDNA by chemical linkage or avidin–biotin interaction. (b) Insertion of nuclear-transcription factor-binding sequences (i.e., NF-κB) in the pDNA. (c) Condensation of pDNA with NLS itself or NLS-modified polymers. (d) Surface modification of NLS on the surface of lipid-based particle. (e) Encapsulation of pDNA in NLS-fusogenic lipid envelope.

In the light of these findings, many trials were designed to improve nuclear delivery processes (summarized in Figure 9). First, NLS were chemically linked to the plasmid DNA itself.[259] However, in this strategy, >100 NLS peptides/1 kbp are required to induce the nuclear delivery of pDNA, where transcription is severely inhibited. Similarly, several groups conjugated NLSs on the edge of linearized pDNA. However, microinjection studies[260,261] failed to demonstrate the utility of this strategy. As it uses highly cationic NLS_{SV40}, electrostatic interactions between NLS_{SV40} and DNA may prevent it if being recognized by importins. One excellent strategy for overcoming this issue is to modify the pDNA with an NLS-possessing protein or importin β via avidin–biotin interactions.[258,262] Alternatively, specific DNA sequences can be introduced into the plasmid DNA (i.e., NF-κB binding sequence,[263–266] SV40 enhancer[242,243] and smooth muscle gamma actin promotors,[267] and the oriP sequence derived from the Epstein-Barr virus[268]), which allows the binding of nuclear transcription factors in the cytosol and supports nuclear import. This strategy is advantageous in controlling nuclear import in a signal-dependent and cell-type-dependent manner. Proteomic analysis identified core histone H2B and NM23-H2, a ubiquitous c-Myc transcription-activating nucleotide diphosphate kinase, as a cytoplasmic determinant for nuclear import of a pDNA-containing fragment of the SV40 promoter and enhancer region (*D*NA nuclear *t*argeting sequence, DTS). Insertion of these protein-related sequences (NM23-H2 and Chx10) significantly enhanced gene expression.[269] Moreover, DTS-specific interactions with cytoplasmic cofactors (i.e., importin β1, importin 7, and the small guanosine triphosphatase, Ran) were demonstrated.[270]

A second approach is to condense pDNA with an NLS-modified polycation. One example is an NLS_{SV40}-modified PLL. Condensation of pDNA with this polycation resulted in a slight enhancement in transgene expression compared with nonmodified PLL.[271,272] To avoid electrostatic interactions between NLS and DNA, a novel NLS derived from heterogeneous nuclear ribonucleoprotein-A1 (M9) was conjugated to a cationic peptide (scattered SV40 NLS). Complexes, formed with M9-modified polycations exhibited enhanced transfection activity by lipofection.[235] An alternative approach is to condense pDNA with the NLS peptide itself or NLS-like peptides. Currently, various NLS variants, such as tetramers of SV40 NLS,[273] TAT oligomers,[107] Mu peptide derived from the adenoviral core,[274,275] and protamine,[276,277] are under investigation. DNA condensation with these peptides enhances transgene expression. Of note, cytoplasmic microinjection showed that the transgene expression of pDNA was enhanced by condensation depending on the N/P charge ratio (+/−) when it was condensed with protamine, a peptide containing four possible NLS-like regions consisting of basic amino acid and proline or serine residues.[276] At a low charge ratio, the basic

amino acids of protamine may be largely occupied in the condensation of pDNA, and, as a result, NLS-like function would be limited. By increasing the charge ratio, the protamine displayed on the surface of particles functions as an NLS, allowing the particles to be recognized by nuclear transport-associating proteins. However, it is difficult to control the density of surface-displayed NLS, as it would likely vary with condensation status.

One strategy for controlling topology is to use nuclear transport molecules that are noncationic and water soluble, such as sugars. Sugars as NLS were first reported by Duverger *et al.*[278] They reported that large amounts of sugar-conjugated bovine serum albumin (BSA) accumulated in the cell nucleus. In recent decades, the function of sugar molecules as a nuclear transport signal[279–281] and its mechanism[280,282–285] have been partially clarified. According to these reports, sugar-dependent nuclear transport is mediated by its receptors (i.e., lectins) and occurs in an energy-dependent manner via the NPC. Glycosylated polymers, such as lactosylated polylysine and lactosylated polyethyleneimine, have recently been reported.[286–289] It was recently reported that surface modification of fluorescent nanoparticles (quantum dots) with maltotriose enhanced their nuclear accumulation.[290] Another strategy is to modify the NLS on a pDNA-encapsulating liposome by inserting a lipid derivative of a NLS. The NLS is spontaneously oriented outward from the particles, and results in the effective transfection of nondividing cells (i.e., primary dendritic cell cultures).[291]

The modification of lipid derivatives of sugars on the surface of lipid envelope-type nanoparticles also enhanced gene expression by 10–100-fold in synchronized HeLa cells.[247] In the case of adenovirus (Ad), it first docks to the NPC. Then, the proximity of the Ad capsid to the NPC allows hexon binding to histone H1. The hexon–histone H1 complex is then transported to the nucleus by histone H1 import factors (i.e., importin 7 and importin β). This triggers the nuclear transfer of Ad genomic DNA in conjunction with the disruption of the viral capsid.[292] While the mechanism for nuclear delivery with NLS-modified particles is currently unknown, NLS-modified lipid nanoparticles may mimic this mechanism; the particles first dock to the NPC via the surface-modified NLS, and are subsequently disassembled on the NPC. Meanwhile, a NPC-independent nuclear transport approach has recently been proposed. In this strategy, intracellular membrane barriers are overcome using stepwise membrane fusion. The critical structural elements of the particle are a DNA–polycation condensed core coated with two nuclear membrane–fusogenic inner envelopes and endosome–fusogenic outer envelopes, which are shed in a stepwise fashion as the core is trafficked through the cell.[293]

4.425.4.5. Intranuclear Disposition

It is generally accepted that the most significant obstacle to the clinical use of nonviral vectors is their low transfection activity. Viruses have evolved sophisticated mechanisms to overcome intracellular barriers. Dose–response data for transgene expression showed that, Lipofectamine PLUS (LFN), a lipoplex-based nonviral vector, required 3–4 orders of magnitude more gene copies than the adenovirus to achieve a comparable transgene expression.[294] Therefore, it is important to clarify which intracellular process is responsible for such a large difference in transfection activity. A quantitative comparison of intracellular trafficking between LFN and adenovirus clarified that the nuclear transport efficiency of adenovirus was only twofold greater than that of LFN. Thus, the large difference in transfection efficiency cannot be explained by intracellular trafficking. A comparison of the nuclear delivery of DNA revealed that 3–4 orders of magnitude more gene copies were required when LFN was used to obtain a transfection activity comparable to that of adenovirus. Transcription efficiency was calculated as expression divided by gene copies in the nucleus. As a result, adenovirus was found to be 8100-fold more efficient at nuclear transcription than LFN.[294] This result indicates that a post-nuclear delivery process is critical to the difference in transfection efficiency between LFN and adenovirus. Less efficient nuclear transcription compared to adenovirus was also demonstrated in the case of a PEI-based polyplex.[295]

Transgene expression of nucleus-delivered DNA is limited by both transcription and translation. Transcription efficiency was calculated as mRNA expression divided by nuclear DNA. Similarly, translation efficiency was calculated as transgene expression divided by mRNA expression. Measurements of mRNA products showed that the translation efficiency of adenovirus was approximately 16-fold higher than that of LFN. Collectively, the translation efficiency of adenovirus was 460-fold higher than LFN. Therefore, the 3 orders of magnitude difference in the postnuclear delivery process was attributed to the 1 order of magnitude difference in transcription efficiency and the 2 orders of magnitude difference in translation efficiency.[296]

Imaging of intranuclear DNA using *in situ* hybridization showed that adenoviral DNA was specifically located in the euchromatin region, where transcription activity is relatively high. Moreover, decondensation efficiency was dramatically lower in the case of LFN. Collectively, these results suggest that poor decondensation and poor targeting activity of DNA to the euchromatin region are responsible for the less efficient nuclear transcription with LFN. *In vitro* translation activity was drastically inhibited in the presence of LFN, whereas only a slight inhibition was observed in the case of adenovirus. These data indicate that electrostatic interactions between LFN and mRNA are significant contributors to the difference in translation efficiency between LFN and adenovirus.[296]

4.425.4.6. Heterogeneity in Transfection

Another drawback to the use of the current nonviral gene vectors is heterogeneous transgene expression. As gene expression is achieved when cells pass through the mitosis phase,[248–251] nuclear delivery is considered to be a key process that limits transduction in nonexpressing cells. However, recent imaging studies showed that intranuclear disposition is also a rate-limiting factor for heterogeneous gene expression. Simultaneous visualization of the nuclear delivery of pDNA and transgene expression in an individual cell clarified that nuclear delivery was achieved only in 22.5% of the cells. Moreover, marker gene expression was detected in a portion of the nuclear pDNA-positive cells only, suggesting that the postnuclear delivery process is also a determinant of heterogeneity.[297] This is also supported by results showing a relationship between the amount of nuclear pDNA and marker gene expression. Transfected cells

were separated into three fractions depending on marker gene expression using a fluorescence-activated cell sorter (FACS), and thereafter the nuclear accumulation of DNA was determined. As marker gene expression is related to the nuclear delivery of pDNA, nuclear delivery is one of the determinants for the heterogeneity of gene expression. However, it is noteworthy that a large number of pDNA (700–800 copies) are delivered to the nucleus, even in cells with a low expression.[298] Therefore these data also support the conclusion that intranuclear disposition is important for efficient gene expression. For an examination of the relationship between decondensation and gene expression in living cells, imaging of fluorescence resonance energy transfer (FRET) among donors and acceptors labeled on pDNA is a useful technique.[299] Especially in polyplexes, pDNA decondensation in the nucleus is the major determinant of gene expression.

4.425.5. *In Vivo* Applications

Worldwide trends and status of gene therapy clinical trials were reviewed in 2007 in the *Journal of Gene Medicine*.[300] From the first human gene therapy trial in 1989,[301] the number of clinical trials increased rapidly and peaked in 1999. After the report on the unfortunate fatal adverse effects associated with the use of the adenovirus vector[302] and retrovirus vector-induced oncogeneity,[303] the number of trials decreased in 2003. However, the number is now slowly recovering from 2004 to 2006. Up to 2007, 1340 gene therapy studies have been completed, with viral vectors used in two-thirds of the total 1304 trials, whereas nonviral approaches are becoming increasingly more common. Table 3 summarizes some candidate genes for curing diseases. It is noteworthy that not only in clinical studies but also in animal studies viral vectors are used in most of the trials. The most serious bottleneck for the current use of a nonviral gene carrier appears to be their low transfection efficiency in the presence of plasma proteins and cell media. Upgrading transgene expression efficiency is, therefore, essential if the use of nonviral vectors is to be expanded.

4.425.5.1. *In Vivo* Delivery of pDNA

4.425.5.1.1. Cancer

Gene therapy is a promising strategy for treating some cancers. Strategies for cancer gene therapy include (i) manipulation of the cell cycle and apoptosis, (ii) activation of the immune system, and (iii) inhibition of angiogenesis. Concerning the first approach, tumor suppressor genes such as p53[384–386] and proapoptotic genes bax,[387] caspase 9,[388] and toxins (i.e., diphtheria toxin A[389]) inhibit tumor growth when overexpressed in cancer cells. Tumor necrosis factors (TNFs) such as the TNF-related apoptosis-inducing ligand (TRAIL) is a potent inducer of apoptosis in tumor cells but not in normal cells and tissues.[390,391] Genetic prodrug-activation therapy or suicide gene therapy is an alternative approach to modulate tumor cells to acquire sensitivity to prodrugs (i.e., ganciclovir). The example includes the gene transfer of DNA encoding thymidine kinase combined with a ganciclovir prodrug[392,393] and cytosine deaminase which converts fluocytosine into 5-fluorouracil.[394]

Stimulation of cancer immunotherapy is a second approach. Activation of the immunoresponse against a tumor can be achieved by the topical expression of cytokines such as interleukin 2 (IL-2),[395] interleukin 12 (IL-12),[396,397] and granulocyte-macrophage colony stimulating factors.[398] When a lipoplex is systemically administered, high levels of IL-12 and INF-γ are produced, most probably due to the inflammatory effect of the lipoplex itself, and the innate and adaptive immuneresponses appear, irrespective of the gene expression form of pDNA.[399,400] This side effect of the lipoplex itself may aid in combating pulmonary metastasis.

Finally, inhibition of angiogenesis is a novel approach for limiting tumor growth. The most widely demonstrated approach is the use of soluble vascular endothelial growth factor (VEGF) receptor (soluble FLT1), which antagonizes the binding of VEGF to VEGF receptors, a key player in angiogenesis.[401,402] In the nonviral approach, cationic liposomes modified with inactivated hemagglutinating virus of Japan (HVJ) target gastric cancer. By expressing soluble FLT1, the microvessel density (MVD) is decreased, resulting in a significantly longer survival compared to control mice.[403] Another gene is endostatin, a broad-spectrum angiogenesis inhibitor that may interfere with the pro-angiogenic action of growth factors such as basic fibroblast growth factor (bFGF/FGF-2) and VEGF.[404] Herpes simplex virus encoding endostatin inhibits angiogenesis in colon carcinomas in model mice.[405] A combination of two adenovirus vectors that encode the fusion protein of endostatin/angiostatin, as well as the soluble form of the endothelial cell-specific TEK tyrosine kinase (TIE-2) receptor, a receptor of angiopoetin1, synergistically inhibited tumor growth in a PC-3 prostate xenograft tumor mouse model.[406]

4.425.5.1.2. Liver

The liver plays an important role in the synthesis (i.e., carbohydrates and lipids), filtration, degradation, and storage of various substances, and is a critical sentinel of healthy blood biochemistry. At the same time, the liver protects the whole body from xenobiotics via its strong metabolic bioactivity. Therefore, a loss of liver function leads to the development of a variety of severe pathologies.

Generally, access of nanoparticles from blood to the parenchymal cells is blocked by the continuous endothelium. However, the liver is comprised of a unique thin-walled endothelium (sinusoids) containing small pores called fenestrations. In addition, Kupffer cells (stellate macrophages) are distributed throughout the endothelial cells that line the sinusoids. As a result, the liver is a major clearance organ for nanoparticles as nanosized particles can gain access to hepatocytes, or alternatively can be trapped by Kupffer cells. The liver is a promising organ as a target of viral (adenovirus, lentivirus, and adeno-associated virus; AAV) and nonviral gene delivery carriers via i.v. administration. Avoiding accumulation in the liver of non-liver-targeted vectors is often a critical challenge in systemic administration. Of note, the hydrodynamic i.v. injection of naked DNA resulted in a high transgene expression predominantly in the liver.[407,408] The image-guided insertion of a balloon catheter into the hepatic vein of the selected lobe, followed by an injection of plasmid DNA using a computer-controlled injection device, enables lobe-specific hydrodynamic gene delivery to the liver.[409]

A wide variety of animal models are used in gene delivery studies of liver-derived monogenic disorders.[45]

Table 3 Genes for the cure of disorders

Organ	*Target disease*	*Gene*	*Animals*	*Vector/method*	*Reference*
Liver	Cirrhosis (chronic administration of dimetylnitrosamine)	Hepatocyte growth factor (HGF)	Rat	Electroporation	304
	Growth hormone deficiency (hypophysectomized mouse)	Human growth hormone (hGH)	Mouse	Hydrodynamic	305
	Hemophilia	Factor IX	Mouse	Hydrodynamic	306
			Human	AAV	307
	Wilson disease	ATP7B	Rat	Lentivirus	308
	Cirrhosis (chronic administration of carbon tetrachloride)	Urokinase-type plasmisnogen activator (uPA)	Rat	Adenovirus	309
	Cirrhosis (chronic administration of carbon tetrachloride and bile duct ligation)	Matrix metalloprotease 8	Rat	Adenovirus	310
	Glycogen storage disease type Ia (GSD-Ia)	Glucose-6-phosphatase-α	Mouse	Adeno-associated virus (AAV)	311
	Glycogen storage disease type Ib (GSD-Ib)	Glucose-6-phosphate transporter	Mouse	Adenovirus	312
	Mucopolysaccharidosis type-I (MPS I)	α-L-Iduronidase (IDUA)	Mouse	Lentivirus	313
	Mucopolysaccharidosis type-I (MPS IIIb)	α-*N*-Acetylglucosaminidase (NAGLU)	Mouse	Lentivirus	314
	Mucopolysaccharidosis type-VII (MPS VII)	Canine β-glucuronidase (cGUSB).	Dog	Retroviral vector	315
	Glycogen storage disease type II	α-Glucosidase (GAA; acid maltase)	Mouse	AAV	316
	Hepatic fibrosis (chronic administration of dimetylnitrosamine)	Heme oxygenase-1	Rat	AAV	317
Kidney	Unilateral ureteral obstruction	Smad7	Rat	Ultrasound-microbubble	318
		Egr-1	Rat	Electroporation	319
	Renal fibrosis in a remnant kidney	Smad7	Rat	Ultrasound-microbubble	320
	Chronic renal disease induced by unilateral ureteral obstruction	HGF	Mouse	Hydrodynamic	321,322
Lung	Transplanted lung	Endothelial nitric oxide synthase (ecNOS)	Rat	Adenovirus	323,324
	Hemophilia	Erythropioetin	Mouse	AAV	325
		Factor IX	Mouse	AAV	325
	Transplanted lung	TGF-β	Rat	Lipoplex	326
	Irradiation damage	Manganese superoxide dismutase (MnSOD)	Mouse	Lipoplex	327
	Pulmonary emphysema	α1-Antitrypsin	Cotton rat	Adenovirus	328
			Rabbit	Lipoplex	329
			Human	Lipoplex	330
			Human	Lipoplex	331
	Cystic fibrosis (CF)	Fibrosis transmembrane conductance regulator (CFTR)	Mouse	Adenovirus	332
			Human	Adenovirus	333–336
			Mouse	Lentivirus	337
			Rabbit	AAV2	338
			Nonhuman primate	AAV2	339
			Human	AAV2	340–345
			Mouse	AAV5	346
			Nonhuman primate	AAV5	347
			Mouse	Lipoplex	348,349
			Human	Lipoplex	350–355
			Human	Lipoplex (GL-67)	356,357
			Human	Polyethylene glycol-substituted 30-mer lysine peptides	358

(*Continued*)

Table 3 (Continued)

Organ	*Target disease*	*Gene*	*Animals*	*Vector/method*	*Reference*
	Allergic bronchopulmonary aspergillosis (ABPA) concomitant with CFTR deficiency	CFTR	Mouse	AAV	359
	Allergy in Cftr deficient mouse	IL-10	Mouse	AAV	360
Muscle	Pulmonary emphysema (genetic disorder)	α1-Antitrypsin	Mouse	AAV	361
			Nonhuman primate	AAV	361
	Hemophilia	Factor IX	Human	AAV	362,363
	Fibrosis induced by glomerulonephritis	Decorin	Rat	Naked pDNA	364
	δ-Sarcoglycan (δ-SG)	Muscular dystrophy	Hamsters	AAV	365
	Short-chain acyl-CoA dehydrogenase (SCAD)-deficiency	Short-chain acyl-CoA dehydrogenase (SCAD)	Mouse	AAV	366
	Cardiomyopathy	HGF	Mouse	Adenovirus	367
	Diabetic nephropathy	HGF	mouse	Adenovirus	368
	Duchenne muscular dystrophy (DMD)	Dystrophin	Mouse	Electroporation	369
				Naked pDNA	370
			Human	Naked pDNA	371
	Diabetic hind limb ischemia	Hepatocyte growth factor (HGF)	Rat	Hemagglutinating virus of Japan (HVJ)-liposome	372
Heart	Ischemic heart disease	VEGF	Porcine	Direct myocardial DNA injection	373,374
			Porcine	Adenovirus	375
			Human	Direct DNA injection	376,377
			Rabbit	Water-soluble lipopolymer (WSLP)	378
		VEGF2	Human	Direct DNA injection	379
		FGF-2	Porcine	Direct DNA injection	373
		HGF	Porcine	Direct DNA injection	380
		HGF	Rat	HVJ liposome	381
		Sonic hedgehog	Mouse/rat	Direct myocardial DNA injection	382
		Netrin-1	Rabbit	Water-soluble lipopolymer (WSLP)	383
	Congestive heart failure	δ-SG	Hamsters	AAV	365
	Glycogen storage disease type II	α-Glucosidase (GAA; acid maltase)	Mouse	AAV	316

Some trials are summarized in Table 3. Transduced genes play important roles in hepatocytes for metabolism and transport. Examples include (i) Long–Evans cinnamon rats, a model for Wilson disease, in which copper-transporting ATPase 2 (ATP7B) is hereditarily lacking and (ii) the Gunn rat, a model of Crigler–Najjar syndrome type I, deficient in UDP-glucuronyltransferase. Another category is gene products excreted from liver to circulating blood, which then act in different organs or in the liver itself. Examples include hemophilia,[306,307] α1-antitrypsin deficiency glycogen storage diseases,[311,312,316] and mucopolysaccharidosis.[313–315]

Concerning liver gene therapy, the rapid decrease in transgene expression is an obstacle to be overcome. As the half-life of gene expression is shorter than that of the remaining amount of pDNA, intranuclear inactivation and degradation of pDNA are key factors in the overall decrease in gene expression.[410] Optimized selection of the gene expression cassette is essential for efficient and sustained transgene expression. In liver, a combination of chicken β-actin and cytomegalovirus (CMV) enhancer is one promising candidate for liver gene expression.[411] Moreover, Wooddell *et al.* reported that the optimal expression cassette consists of an albumin promoter combined with an alpha-fetoprotein MERII enhancer, the 5′ intron from the factor IX gene, and the 3′UTR from the albumin gene including intron 14.[412] Addition or removal of specific sequence elements in pDNA is an alternative or supporting strategy for prolonging hepatic gene expression. The scaffold matrix attachment region (S/MAR) is an AT-rich sequence locating in close proximity to promoters, replication origins, and multiple nuclear processes, such as recombination and breakpoint sites, to attach chromosomal DNA to the nuclear scaffold/matrix.[413] The hydrodynamic injection of S/MAR-inserted pDNA showed long-lasting gene expression after the hydrodynamic injection when gene expression was controlled by a liver-specific α1-antitrypsin promoter.[414] Another strategy involves removing plasmid backbones consisting of an antibiotic resistance gene, an origin of replication, and inflammatory sequences that are intrinsic to bacterial DNA (minicircle system; reviewed in Mayrhofer *et al.*[415]). Genomic integration of expression cassette by means of phage phiC31 integrase-mediated recombination is an alternative candidate for achieving long-term gene expression.[416] Improved DNA construction is a factor for future studies directed toward clinical applications.

4.425.5.1.3. Lung

The lung is an important target for gene therapy for curing α1-antitrypsin deficiency and cystic fibrosis. α1-Antitrypsin deficiency is an inherited metabolic disorder in which mutations in the coding sequence of α1-antitrypsin prevent its export from hepatocytes. It results in the loss of circulating α1-antitrypsin, predisposing to early-onset panlobular emphysema. In addition, it causes an abnormal accumulation of the glycoprotein in hepatocytes, resulting in programmed cell death, hepatic inflammation, fibrosis, and cirrhosis (reviewed in Fairbanks and Tavill[417]). Gene therapy related to α1-antitrypsin deficiency has been extensively reviewed.[418]

The cystic fibrosis transmembrane conductance regulator (CFTR) is an anion channel regulated by cAMP-dependent phosphorylation, which is expressed in epithelial cells of a wide variety of tissues including the reproductive tract. In the lung, CFTR plays an important role in ion transport in the conducting pulmonary airways and exocrine glands. Mutations in the gene encoding CFTR causes cystic fibrosis (CF), a common genetic disease in the Caucasian population. Gene delivery for CF has also been reviewed.[419] Nonviral gene therapy for CF has been more extensively reviewed in Pringle *et al.*[420]

Similar to the liver, the short duration of gene expression is also an obstacle in lung-targeted gene therapy. The human polyubiquitin C (UbC) promoter is a promising choice for sustained gene expression in lungs when delivered by electroporation.[421] Moreover, it is likely that the silencing of lung gene expression is closely related to the host immunoreaction in response to gene carriers. The most plausible determinant is an unmethylated CpG sequence in pDNA, a ligand for Toll-like receptor 9 (TLR9) in endosomes.[422,423] The action is enhanced when pDNA is complexed with cationic liposomes.[356,357,424] In the lung, a wide variety of cytokines are produced, including IL12, INFγ, and TNFα.[425] As commonly used viral promoters, such as the CMV immediate/early promoter, are attenuated in response to cytokines (i.e., TNFα and IFNγ) by a transcription-related mechanism,[426,427] inflammatory cytokines produced from macrophages in response to the gene carrier may paracrine-regulate the gene expression in target cells.[428] The complete deletion of CpG motifs from pDNA results in a dramatic reduction in cytokine production, even in the case of lipoplex-based gene carriers, and in sustained gene expression,[429] indicating that CpG-free pDNA is highly beneficial for gene delivery for the lung, and most probably for other tissues.

4.425.5.1.4. Kidney

The simplest method of gene delivery to the kidney is through hydrodynamic injection of plasmid DNA (pDNA). Dai *et al.* injected human pDNA encoding hepatocyte growth factor (hHGF) with a large volume of saline via the tail vein of mice over a span of 5–10 s. The hydrodynamic technique was originally developed for targeting gene delivery to the liver. However, this technique is also promising when the kidney is obstructed, such as during chronic renal fibrosis caused by unilateral ureteral obstruction (UUO).[321] As a result of the injection of pDNA encoding hHGF, hHGF was expressed in >90% of glomeruli, whereas no transgene expression was observed in the tubular compartment.[430] hHGF expression suppresses the renal expression of TGF-β and of the TGF-β receptor, thereby ameliorating renal failure.[321] Similarly, hHGF expression also protects renal epithelial cells from necrosis and apoptosis by inducing the expression of the anti-apoptotic Bcl-xL protein.[430] Another effective route for the administration of naked DNA is retrograde renal vein injection. The injection of erythropoietin (EPO) encoding DNA, increased serum EPO concentrations to a level sufficient for erythropoiesis.[431]

The ultrasound-microbubble system is a promising method for widely distributing DNA to various compartments. Under optimal conditions, FITC-labeled ODN accumulated in all glomerular cells (>95%), vascular and perivascular cells (>90%), and medullary tubular and interstitial cells (70–80%) after ultrasound treatment.[318] In the UUO mouse, endogenous smad 7 expression is reduced in conjunction with Smad 2 and 3 activation, resulting in tubulointerstitial fibrosis. The transfection of pDNA encoding Smad 7 into UUO mice results in Smad 7 expression in as high as 95% of the glomerular cells, all of the capillary endothelial cells, and all of the interstitial fibroblastes/myoblasts, thereby preventing tubulointerstitial fibrosis.[318]

Electroporation is a widely used technique for the transfection of DNA into muscle, skin, liver, and cancer cells. Interstitial cells were targeted by slowly injecting DNA into the ureter while clamping the left renal vein, followed by the delivery of square-wave electric pulses. In UUO rats, the early growth response gene 1 (Egr-1), which increases α-smooth muscle actin (α-SMA) levels, was increased in interstitial cells. The introduction of DNAzyme against Egr-1 blocked the expression of the corresponding gene, with a concomitant reduction in TGF-β, α-SMA, and type I collagen, thereby inhibiting interstitial fibroblasts.[319]

4.425.5.1.5. Muscle

Skeletal muscle is an attractive target not only for viral vectors but also for nonviral vectors. Importantly, in skeletal muscle, plasmid DNA can be administered and used without any special delivery system and persist for long in an extrachromosomal form.[432] Viral vectors such as adenovirus and AAV are also applicable.[433]

Gene delivery to the skeletal muscle is a promising strategy for the production of topically functional proteins, such as dystrophin,[371] as a therapeutic protein for Duchenne muscular dystrophy (DMD) or Becker muscular dystrophy (BMD) patients.[371] HGF is also a highly promising factor for the cure of ischemic diseases, because of its strong angiogenesis activity.[434] Meanwhile, muscle gene delivery is a convenient strategy for supplying various types of proteins that are useful for the total body (i.e., factor IX for hemophilia[362,363]) or other disease-associated organs. Conlon *et al.* demonstrated that intramuscular administration of AAV encoding short-chain acyl-CoA dehydrogenase (SCAD) systemically corrected fatty acid oxidation disorders in SCAD-deficient mouse.[366] Similarly, decorin[364] and HGF[368] expressed in muscles by naked DNA and adenovirus, respectively, are secreted into the bloodstream, and systemically function for the kidney diseases.

For the case of cardiac muscle, the direct injection of pDNA is a major tool for gene transduction. To date, curing ischemic diseases is a major goal of gene delivery. Expert reviews with operative examples are available.[383]

4.425.5.2. *In Vivo* Delivery of siRNA

The field of RNA interference (RNAi) has expanded at a remarkable rate since the discovery in 1998 by Fire, Mello, and colleagues of the ability of double-stranded RNA to silence gene expression in *Caenorhabditis elegans*.[435] Tuschl *et al.* demonstrated that small synthetic interfering RNA (siRNA) consisting of 21–25 nucleotides with a 3′ overhang can achieve sequence-specific gene knockdown in a mammalian cell line.[436,437] RNAi has been widely applied in gene functional analysis and has become a powerful tool for drug target discovery. The first successful use of siRNA for *in vivo* gene silencing in mice was achieved in the liver via rapid injection of a large volume of physiological saline solution containing naked siRNA, so-called hydrodynamic injections, for a hepatitis C virus into the tail vein of mice.[438] Since that report, siRNA-mediated marker gene knockdown in postnatal mice by hydrodynamic injections has been observed by Lewis *et al.*,[439] and Lieberman and colleagues subsequently demonstrated that *Fas* knockdown in the liver by siRNA hydrodynamic injections protects mice from fulminate hepatitis.[440] Given their specific potent RNAi triggering activity, siRNA is considered as a new generation of biopharmaceutical drugs. Gene product inhibition mechanism is triggered by introduction of siRNA into the cytoplasm, where the guide strand of siRNA (usually antisense strand) loaded into RISC binds to its target mRNA and the expression of the target gene is blocked. After normal intravenous injection (not hydrodynamically), siRNA is rapidly eliminated from blood circulation through renal excretion to the urine due to its molecular weight (−13 kDa).[441] On the other hand, from the view point of cellular uptake, its molecular weight as well as polyanionic and hydrophilic nature interrupts the free transport of siRNA across the cell membrane. Furthermore, naked siRNA is subject to degradation by serum RNases within a short period in the body. Therefore, for the *in vivo* use of siRNA, chemical modification can be used to increase their half-life for *in vivo* stability and targetability for specific organs, and cells should be installed by conjugation or the delivery system. In this section, *in vivo* siRNA delivery and its clinical use are discussed.

4.425.5.2.1. *Chemical modification, bioconjugation and targeted* in vivo *siRNA delivery*

Chemical modification of siRNA has been investigated in attempts to prolong its half-life without destroying its biological activity. Stability against nuclease degradation has been achieved by introducing a phosphorothioate (P=S) backbone linkage at the 3′ end for exonuclease resistance and 2′-sugar modification (such as 2′-*O*-methyl or 2′-fluoro) to provide endonuclease resistance.[442] The strategy for improving the therapeutic efficacy of siRNA involves the bioconjugation of functional peptides, lipophilic molecules, or aptamers to one or both strands of the siRNAs. Cholesterol, when covalently conjugated to siRNA, induces significant silencing of the apolipoprotein B (apoB) gene in the liver and jejunum after intravenous administration in mice ($50\,mg\,kg^{-1}$), which resulted in decreased plasma apoB protein levels and the total level of cholesterol, because cholesterol conjugation increases the hydrophobicity and cellular association of the complex.[443] Song *et al.* demonstrated that an antibody-protamine fusion protein is capable of delivering siRNA (80 μg×3) to HIV-infected tumor cells and silencing target genes via either direct or intravenous injection in tumor-bearing mice.[444] Kumar *et al.* demonstrated the brain delivery of siRNA using RVG, a rabies viral glycoprotein, and sn oligoarginine conjugate (RVG-9R) (50 μg × 3).[199] Aptamer–siRNA conjugates showed efficacy in cell-specific knockdown via intraperitoneal administration in tumor xenograft mice (1 nmol × 10).[445] The direct conjugation of vitamin E (α-tocopherol) to siRNA resulted in the efficient delivery of siRNA to the liver and the knockdown of apoB when administrated i.v. in mice ($32\,mg\,kg^{-1}$).[446] As mentioned above, bioconjugation approaches resulted in the tissue- and cell-specific delivery of siRNA and exhibited an *in vivo* therapeutic potential.

4.425.5.2.2. *Lipid-based* in vivo *siRNA delivery*

Various lipid-based delivery systems have been developed for *in vivo* applications of siRNA for diseases of the liver, infectious diseases, or cancer. Stable nucleic acid lipid particle (SNALP) formulations composed of a cationic lipid such DLinDMA and a PEG-lipid derivative have been used for the siRNA-mediated targeting of the Ebola-virus-specific gene in guinea pigs (i.p.; $1\,mg\,kg^{-1}$) or ApoB (i.v.; 1 or $2.5\,mg\,kg^{-1}$) in livers of cynomologus monkeys.[447,448] Systemic administration of SNALP has been demonstrated for siRNA-mediated cancer therapeutics in an intrahepatic tumor model in mice ($2\,mg\,kg^{-1} \times 6$).[449] Vitamin A-coupled liposomes were used in the delivery of siRNA and the resolution of liver fibrosis because of the specific uptake via vitamin A ($0.75\,mg\,kg^{-1} \times 12$).[450] Hashida and colleagues reported that galactosylated cationic liposomes could induce a silencing effect in the liver via targeting parenchymal cells mediated by galactose ($0.18\,nmol\,g^{-1}$).[451] Huang and colleagues developed ligand-targeted liposome–polycation–DNA (LPD) nanoparticles for siRNA delivery.[452] LPD modified with anisamide targeting sigma-receptor-expressing tumor cells showed siRNA-mediated therapeutic efficacy on tumor growth after i.v. injection into tumor-bearing mice ($0.6\,mg\,kg^{-1} \times 3$). Yagi *et al.* developed Wrapsome, which contains siRNA-binding cationic liposomes, as a core completely covered with a PEGylated neutral lipid bilayer.[453] After systemic administration, Wrapsome induced gene silencing in tumor cells of a xenograft mice model, resulting in the inhibition of tumor growth (50 μg × 7). Santel *et al.* designed a vasculature endothelium-targeted liposomal delivery system for siRNA, AtuPLEX, which exhibited knockdown of endothelium markers such as CD31 in a xenograft tumor ($1.88\,mg\,kg^{-1} \times 9$).[454] Antibodies against β_7 integrin-modified liposomes induced siRNA-mediated silencing in leukocytes *in vivo* ($2.5\,mg\,kg^{-1} \times 4$).[455] Natural lipid analogs of cardiolipin have been successful in systemically delivering siRNA to cancer xenografts.[456] Incorporation of siRNA into a neutral liposome instead of a cationic liposome has been investigated based on DOPC.[457] Commercially available cationic liposome reagents have been also used for siRNA delivery via local administration. The vaginal insertion of the Oligofectamine (Invitrogen)/siRNA complex targeting herpes simplex virus (HSV)-2 led to uptake by the epithelial and lamina propria cells in the vagina in mice and protected the mice from lethal infection for periods of up to 9 days (500 pmol).[458] Pretreatment with siRNA (70 μg) using TransIT TKO (Mirus) via intranasal treatment

Table 4 Examples of siRNA delivery for treatment of diseases

Formulation/delivery system	*Target site*	*Target gene*	*Route*	*Dose*	*Reference*
Conjugation or peptide complex					
Cholesterol–siRNA	Liver	ApoB	i.v.	50 mg kg^{-1}	443
Aptamer–siRNA	Tumor/s.c.	Swap	i.p.	1 nmol × 10	445
RVG-R9/siRNA	Viral encephalitis/brain	FvE^{J}	i.v.	50 μg × 3	199
Antibody-protamine/siRNA	Tumor/s.c.	c-Myc, MDM2, VEGF	i.v.	80 μg × 3	444
Antibody-protamine/siRNA	Tumor/lung metastasis	–	i.v.	6 nmol	455
Vitamin E-siRNA	Liver	ApoB	i.v.	2 mg ml^{-1}	446
Cholesterol-R9	Tumor/s.c.	VEGF	i.t.	3.5 μg×6	180
Dynamic PolyConjugates	Liver	ApoB	i.v.	50 μg	460
Liposomes/lipoplexes					
SNALP	Liver	ApoB	i.v.	1.2.5 mg kg^{-1}	448
Galactosylated liposome	Liver	Ubc13	i.v.	0.18 nmol g^{-1}	451
Vitamin A-liposome	Cirrhosis liver	gp46	i.v.	0.75 mg kg^{-1} × 12	450
SNALP	Tumor/intrahepatic	PLK1	i.v.	2 mg kg^{-1} × 6	449
Anisamide-LPD	Tumor/s.c.	EGFR	i.v.	0.6 mg kg^{-1} × 3	452
Wrapsome	Tumor/s.c.	KLF5	i.v.	50 μg×7	453
PEGylated LIC liposome	Tumor/s.c.	B043	i.v.	10 mg kg^{-1} × 10	461
Cardiolipin liposome	Tumor/s.c.	c-raf	i.v.	7.5 mg kg^{-1} × 10	456
AtuPLEX	Tumor endothelium/s.c.	CD31	i.v.	7.88 mg kg^{-1} × 9	454
Neutral liposome (DOPC)	Tumor/peritoneal metastasis	EphaA2	i.v.	150 μg kg^{-1} × 8	457
Immunoliposme	Leukocyte	Cyd1	i.v.	2.5 mg kg^{-1} × 4	455
SNALP	Ebola virus	Polymerase L	i.p.	1 mg kg^{-1}	447
Oligofectamine	HSV-2/vagina	UL27/29	local	500 pmol	458
TransIT TKO	RSV, PIV/lung	P protein	i.n.	70 μg	459
Polymer/polyplexes					
RGD-PEG-PEI	Tumor/s.c.	VEGFR2	i.v.	40 μg×3	175
PEI	Tumor/s.c.	Her2	i.p.	0.6 nmol	462
His-Lys polymer	Tumor/s.c.	Raf-1	i.v.	50 μg×7	463
Tf-OEI-HD	Tumor/s.c.	Ran	i.v.	2.5 mg kg^{-1} × 3	464
iNOPs	Liver	ApoB	i.v.	5 mg kg^{-1}	465
Cyclodextrin-containing polycation	Tumor/s.c.	EWS-FLI1	i.v.	2.5 mg kg^{-1} × 8	172
Others					
Atelocollagen	Tumor/s.c.	VEGF	i.t.	10 μM×4	466
Atelocollagen	Tumor/metastasis	EZH2/p1 10-α	i.v.	50 μg×3	146
Chitosan nanoparticle	Lung	EGFP	i.n.	30 μg×5	467
Chitosan nanoparticle	Tumor/s.c.	RhoA	i.v.	1.5 mg kg^{-1} × 10	468
siRNA-MRI probe	Tumor/s.c.	Survivin	i.v.	440 nmol kg^{-1} × 4	469

protected from respiratory syncytial virus (RSV) and respiratory syncytial virus (PIV) pulmonary infection.[459] Other lipid-based delivery systems are listed in Table 4.

4.425.5.2.3. *Polymer-mediated* in vivo *siRNA delivery*

Cationic polymers have also been investigated for use as siRNA delivery vehicles as well as lipid-based carriers. Of the many cationic polymers used for gene delivery, PEI has also been widely studied for siRNA delivery. Schiffelers *et al.* complexed siRNA with PEGylated PEI, of which the RGD motif was attached to the distal PEG end, known as ICS-283, and is currently undergoing preclinical study.[175] Systemically delivered siRNA for the VEGF receptor 2 (VEGFR2) mediated by RGD-PEG-PEI inhibited protein expression within the tumor, and suppressed both angiogenesis and tumor growth due to RGD recognition of integrin-overexpressed tumor cells and tumor endothelial cells (40 μ × 3). A histidine-lysine rich polymer was shown to systemically deliver siRNA (50 μg × 7) to MDA-MB-435 tumor xenografts and silence Raf-1, followed by the inhibition of tumor growth.[463] Wagner and coworkers demonstrated that transferrin-shielded siRNA OEI-HD polyplexes induced the siRNA-mediated silencing of Ran in an s.c. xenograft neuroblastoma after i.v. injection (2.5 mg kg^{-1} × 3).[464] Hu-Lieskovan *et al.* developed cyclodextrin polymers as siRNA delivery agents.[172] Tumor growth in mice of metastatic Ewing's sarcoma was inhibited by the systemic administration of polycationic cyclodextrin with adamantine-PEG for stabilization and Tf for specific targeting (2.5 mg kg^{-1} × 8). Moreover, cyclodextrin-containing polycation nanoparticles showed promising safety profiles in a nonhuman primate study.[470] A listing of polymer-based siRNA delivery is shown in Table 4.

4.425.5.2.4. *Other delivery systems*

In addition to lipids and polymers, several other delivery systems have been examined. Atellocolagen is a very large protein (300 kDa) derived from pepsin-treated type I collagen from calf dermis and has been used to administer siRNA both locally and systemically in tumor models.[146,466] Medarova *et al.* developed dual-purpose probes for *in vivo* siRNA delivery and the

simultaneous imaging of its accumulation in tumors by means of a magnetic resonance imaging (MRI) probe, in which siRNA was immobilized on the surface.[469] The systemically injected siRNA-MRI probe could be monitored by MRI and the level of targeted human survivin expression was suppressed to below 15% compared to a saline-treated control (440 nmol $kg^{-1} \times 4$). As mentioned above, substantial advances have been made in the field of *in vivo* siRNA delivery. However, numerous challenges and obstacles remain to be solved. The dose-based relationship between the PK of any siRNA delivery system and its pharmacodynamics has not been well defined in most studies. Safety profiles of the delivery systems should be investigated, including off-target effects and immune stimulation. With the further remarkable advancements in siRNA delivery, the potential use of RNAi molecules as therapeutic agents holds great promise.

4.425.5.2.5. Clinical trials of siRNA therapeutics

siRNA therapeutics are currently in progress in clinical trials (Table 5). Most trials rely on forms of localized delivery such as intravitreal or intranasal administration, while trials involving the systemic administration of either siRNA or with delivery agents are now under way. Cand5 or Bevasirnabin, which targets VEGF mRNA by intravitreal injection, developed by Acuity Pharmaceticals (now re-named as Opko Health) became the first ever RNAi therapeutic indicated to treat wet age-related macular degeneration (wet-AMD) to enter into human clinical trials in October 2004. Wet-AMD is caused by the oversecretion pf VEGF, which induces angiogenesis and increases vascular permeability and inflammation, all of which are thought to contribute to the progression of the disease. Phase I and II trials investigating the safety and efficacy of the compound gave satisfactory results. As of early 2006, Cand3 is also being evaluated in a separate phase II trial for efficacy in the treatment of diabetic macular edema (DME). However, it was reported that the silencing of target VEGF by Cand5 in wet-AMD was caused by nonspecific immunostimulation of the TLR3 pathway.[471] This fact led them to terminate the Phase III study of Bevasiranib. In November 2004, immediately after the beginning of Cand5, Sirna Therapeutics (now owned by Merck) initiated a Phase I study of their candidate Sirna-027, a chemically modified siRNA targeting VEGF receptor mRNA and administered by intravitreal injection. Phase I and II dose–escalation trials suggested that Sirna-027 was efficacious. A further Phase II trial was commenced with Allergan (Sirna-027 was renamed AGN211745), but this compound failed to show efficacy. Therefore, Allergan made the decision to terminate this clinical study in May 2009. These issues suggest that further research needs to address the important challenges related to a more effective design, enhanced biological stability, and efficient targeted delivery *in vivo*. Alnylam Pharmaceuticals, a leading company in the siRNA field, has developed several siRNA candidates. ALN-RSV01, a siRNA targeting the virus nucleocapsid N gene, is in a Phase II clinical trial for treatment of respiratory virus (RSV) infections via intranasal inhalation using a nebulizer. In 2009, they conducted a Phase I trial of ALN-VSP, a liposomal formulation of siRNA, in collaboration with Tekmir for the treatment of liver cancer via systemic administration. The first ever siRNA drug candidate to be delivered systemically in humans was Quark's QPI-1002 (formerly AKIi-5) which is in Phase I clinical trials since 2007 for the treatment of either acute kidney injury or delayed graft function. Calando Pharmaceuticals' CCLAA-01 is a cyclodextrin-based polymeric nanoparticle containing siRNA against the M2 subunit of ribonucleotide reductase with Tf targetability for treating a variety of tumors. CCLAA-01 has entered phase I trials in March 2008, and is the first clinical trial using a targeted and systemic siRNA delivery system for cancer treatment. A number of important lessons can be learned from *in vivo* studies with siRNA (Table 4). The RNAi revolution has fundamentally changed our understanding of how gene expression is regulated, and has provided powerful new tools for therapeutic targeting, biological research, and drug discovery. As we learn more about the *in vivo* action of siRNA delivery systems, including their biodistribution, precise

Table 5 siRNA therapeutics currently in clinical trials

Company	*Product*	*Formulation*	*Disease*	*Target gene*	*Route*	*Status*
Opko Health (formerly Acuity Pharmaceticals)	Bevasirnanib (Cand5)	Unmodified siRNA	Wet-AMD	VEGF	Intravitreal	Phase III[a]
			DME	VEGF	Intravitreal	Phase II
Allergan (Sirna Therapeutics/Merck)	AGN211745 (Sirna-027)	Modified siRNA	wet-AMD	VEGFR	Intravitreal	Phase II[a]
Quark/Pfizer	PF-04523655 (RTP801i-14)	Modified siRNA (AtuRNAi)	wet-AMD	PTR801	Intravitreal	Phase II
			DME	PTR801	Intravitreal	Phase II
Qurak	QPI-1002 (Akli-5/15NP)	Modified siRNA (AtuRNAi)	AKI	p53	Intravenous	Phase I
			DGF	p53	Intravenous	Phase I
Alnylam Pharmaceuticals	ALN-RSV01	Modified siRNA	RSV	Nucleocapsid	Intranasal	Phase II
Alnylam Pharmaceuticals/Tekmir	ALN-VSP	Liposomal formulation	Liver cancer	KSP/VEGF	Intravenous	Phase I
Calando Pharmaceuticals	CALAA-01	Cyclodextrin-containing polymer formulation	Solid tumor	M2 subunit	Intravenous	Phase I

Wet-AMD, wet age-related macular degeneration; DME, diabetic macular edema; AKI, acute kidney injury, DGF, delayed graft function; RSV, respiratory virus; TLR3, Toll-like receptor3.

[a]Clinical studies have been called off because medicinal effect is not due to specific gene silencing, but nonspecific immune stimulation via TLR3.

mechanisms, and toxicogenomics, it will be possible to refine delivery strategies for improved efficacy and safety, which will open the way for new types of therapeutics.

Acknowledgments

This work was supported by Grants-in-Aid for Scientific Research (S) from the Ministry of Education, Culture, Sports, Science and Technology of Japan and by grants from the Special Education and Research Expenses of the Ministry of Education, Culture, Sports, Science and Technology of Japan. We would like to thank Dr. Milton Feather for his helpful advice in editing the manuscript.

Glossary

Amphiphilic Physical property of a molecule or material that is both hydrophilic and hydrophobic.
Blooming A surface condition where an element of a fiber is exposed after other components are eroded away.
Denaturation Disruption of the natural configuration of a protein.
Electrospinning The electrostatic drawing of fibers.
Glycosaminoglycan A long unbranched polysaccharide that is found extracellularly.
Integrin A major class of adhesion receptors found on the cell membrane.
Ligands A chemical functional group that can be bioactive.
Lysozyme An enzyme that digests and breaks down bacterial cell walls.
Mandrel A collection substrate such as a rod that can be rotated to collect electrospun fibers.
Myoblast A cell that can become a myocyte (also known as a muscle cell).
Nanoscale A material with a dimension below 100 nm in one of the axes.

Neurite A cellular process that projects away from the cell body of a neuron and may transmit electrical signals.
Osteoblast A cell found in bone tissue that is responsible for bone formation.
Spinneret The orifice through which a polymer melt is pushed; often a flat-tipped needle in electrospinning.
Transfection The process of introducing nucleic acids into cells.

Abbreviations

BMP	Bone morphogenetic protein
BSA	Bovine serum albumin
DNA	Deoxyribonucleic acid
FDM	Fused deposition modelling
FITC	Fluoroscein isothiocyanate
HFIP	1,1,1,3,3,3-hexafluoro-2-propanol
MMP	Matrix metalloproteinase
O/W	Oil-in-water
PCL	Poly(ε-caprolactone)
PDLLA	Poly(DL-lactic acid)
PE	Polyelectrolyte
PEG	Poly(ethylene glycol)
PEI	Poly(ethylene imine)
PEO	Poly(ethylene oxide)
PLCL	Poly(L-lactide-*co*-ε-caprolactone)
PLLA	Poly(L-lactic acid)
PVA	Poly(vinyl alcohol)
RGD	Arginine-glycine-aspartic acid
TE	Tissue engineering
UV	Ultraviolet
VEGF	Vascular endothelial growth factor
W/O	Water-in-oil

4.426.1. Introduction

New drug delivery concepts have focused on nanoscale delivery over the past decade to improve release control, levels of dosing, and local delivery for drugs to reduce undesired side effects from systemic delivery.[1,2] As reviewed here, there are numerous manufacturing routes for nanostructured fibers, with electrospinning being one dominant approach used for tissue engineering (TE).[3–5] What distinguishes electrospun TE materials from other controlled release drug systems is that the fiber is also the scaffold/matrix for cells. The traditional concept of drug delivery is also different here – immobilized bioactive molecules are also considered a component of a drug delivery system. Many immobilized bioactive molecules such as growth factors and/or integrin-binding ligands are provided to cells via contact with their nanofiber substrates and are currently exploited in TE.

The term 'nanofiber' has been used widely and should first be defined. Widespread use of the term 'nano' in recent electrospun fiber research is encouraged by focused attention on nanotechnology in general. In a great number of research papers, the term nanofiber is applied to any fiber with diameters below 1000 nm; however, this description is misleading. There have been numerous discussions on 'what is nanotechnology' with widespread agreement within the materials science community – the dominant core of nanotechnology research[6] – that the upper limit for nanotechnology is 100 nm.[7–9] The key point for defining this boundary is the quantum effects and material behavior observed below 100 nm.[10] In contrast, the majority of 'nanofibers' electrospun for TE applications are above this 100-nm boundary.

However, this should not devalue the importance of the scale range of interest for TE applications. Cellular entities do not embrace the SI unit system, and do not prefer fibers that are only below 100 or even 1000 nm! Living tissues require a multitude of conditions for survival and vary from cell type and organ of interest. In relation to the intense focus on electrospinning 'nano' materials, the manufacture of fibers in the dimensions between 1 and 15 μm is not well described in the literature. However, these fibers are the diameters required to achieve the minimum interconnectivity for cellular penetration, which is usually 2 to 3 μm and above. These interconnecting pores facilitate cellular penetration into the scaffold and mass transport for metabolism, while a high surface area is still maintained. Because of their importance in TE, this chapter will focus on electrospun fibers up to 15 μm in scale, but define them on a basis accepted by Reneker, where a fiber with a diameter below 10 μm is termed an 'ultrafine fiber,' while a 'nanofiber' is below 100 nm.[9]

4.426.1.1. Historical Perspective

Electrospinning is now widely used within the TE community where the majority of research articles are available and has attracted significant interest over the last 20 years. Such a rapid rise in development reflects the simplicity, speed, and cost-effectiveness of the process. However, it is important to have a historical perspective on the technology as it can still be regarded as in its infancy. As such, the electrospinning literature is very dynamic: current shortfalls and limitations with the technique could quickly be overcome in a few years and replaced with a new set of challenges. With future developments in surface modification, electrospinning configurations, and writing technologies, electrospinning will be at a different stage in another decade. It is therefore useful to understand the origins of electrospinning to appreciate where we stand regarding electrospun drug delivery systems and applications in TE.

Even though most of the electrospinning literature is recent, solution electrospinning was first demonstrated at the turn of the twentieth century.[11,12] While the technique was primarily

the focus of patents until the mid-twentieth century,[13–15] solution electrospinning was competing with other methods of manufacturing fibers, and issues of scale-up, and with little requirement for making ultrafine fibers in this period, it was overshadowed by mechanical extrusion techniques. During the 1990s, however, Reneker and coworkers showed that solution electrospinning could be used for nanotechnology research – it is inexpensive and simple to perform in the laboratory.[16] The next 15 years generated the vast majority of our knowledge with this technique, with now literally hundreds of different polymers electrospun into nano- and ultrafine fibers. Following a similar path, melt electrospinning was first described in a 1936 patent[14] and in a 1981 series of papers[17–19] before Reneker published a 2001 meeting abstract that involved melt electrospinning polypropylene in vacuum.[20] While there were periods in the twentieth century with no electrospinning reported in the literature, there was significant work performed on electrostatic drawing of fluids. In particular, the understanding how certain fluids break up (due to Raleigh instabilities) and modeling of stable jets were most famously studied by Taylor in the late 1960s.[21] Table 1 shows the number of full-length articles, proceedings papers, and reviews published from 1994 until 2009, and reflects this rapid growth and interest in electrospinning. The challenge for electrospinning within TE through the next decade is to live up to the hype surrounding the process and be used in a clinical setting.

4.426.1.2. Scope of Electrospun Fiber Use

Normally, electrospun fibers drug delivery systems for TE also form the scaffold/matrix upon which cells survive (Figure 1). Therefore, both a high surface area and pores large enough for cell invasion and metabolism transport are crucial properties for a successful TE scaffold. Electrospun fiber meshes have been investigated in most of the different tissues in the body, including vascular grafts, bone, nerve, and cartilage. The straightforward principles and the low cost of setting up electrospinning devices in the laboratory have allowed many laboratories to readily make ultrafine fibers. In turn, these materials have been investigated *in vitro* to determine their biocompatibility with various cells. There is an increasing interest in using electrospun fiber-based systems as substrates for three-dimensional cell culture, where experiments on fundamental cell biology, drug delivery, and cancer research are performed. A range of review articles for different TE organs and tissues are shown in Table 2.

Biological signals are an important component of TE constructs, and both surface-bound and soluble factors are incorporated within the design as drug delivery systems. Mediation of various biological signals can be performed either through signaling molecules (e.g., growth factors, nitric oxide) or compounds that induce a change in biological behavior (e.g., anti-inflammatory steroids). Drugs can be delivered via release systems from the electrospun fibers, or by making these agents available on the surface of the fiber, either free or carried within other nanostructures (Figure 1). In this perspective, electrospun fibers can play a multifunctional role in TE. Firstly, the fiber behaves as a mechanical support for the cell as a substrate, scaffold, or matrix, and even influences cell differentiation. Figure 1 also shows that the flexibility of the material can influence the cell phenotype.[35] Matrix remodeling is also a component of any TE construct, and fiber properties play a role

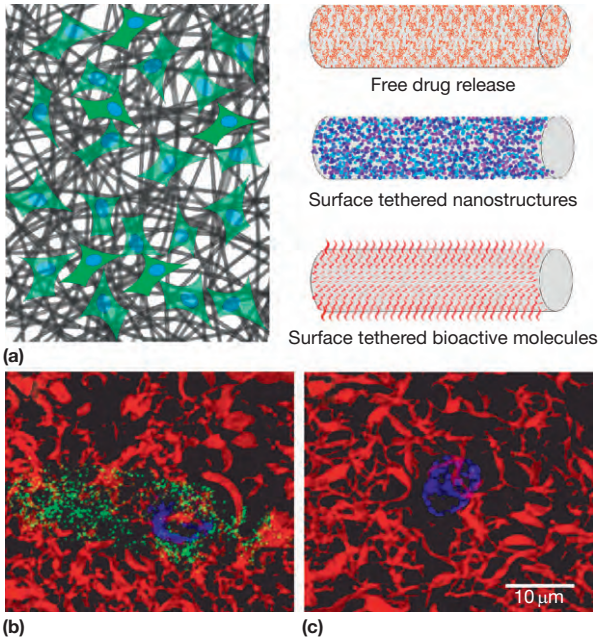

Figure 1 (a) Schematic of a fibrous scaffold for cell support in tissue engineering. Drugs can be released free, via nanostructures or provided on the surface of the fiber. (b, c) Confocal microscope images of human dermal fibroblasts within a collagen scaffold. The different mechanical moduli of the scaffolds affect the alpha-smooth muscle actin in the cell, indicating (c) a shift to a proto-myofibroblast phenotype. (b, c) Reproduced from Ayres, C. in how this develops. The surface properties of the electrospun fiber can also be modified to provide cell-anchoring or differentiation signals. Finally, the release of a soluble factor from the fiber, to provide a therapeutic level of drug to cells, is the final challenge of drug delivery. One component of this challenge is to provide a therapeutic level of the drug over the period of time that is biologically relevant. This therapeutic window, well described elsewhere,[36] is a level of dosage that is neither too low nor too high in the context of a specific therapy, and is provided over the timescale of interest.

One of the more significant limitations of electrospinning for TE is that in a majority of studies, the collected material is not a scaffold, but a thin sheet (e.g., a mat) of ultrafine fibers that is not cell invasive. When looking at the collection of the electrospun fibers, this is not surprising – since the fibers are usually below 1 μm in diameter, and when they stack upon one another, the pore sizes between the fibers are also below this value. Furthermore, the electrospun fibers tend to insulate the collector after a certain collection period and therefore, uniform electrospun meshes and mats typically never become thicker than 100 μm in the *z*-direction. Low volumes and cell invasiveness are two clear challenges for electrospun fibers in the future, and research groups are already devising methods to overcome this limitation.

4.426.2. Principles of Electrospinning

Electrospinning was a term coined with the recent interest in nano- and ultrafine fiber fabrication and refers to 'electrostatic spinning,' where an electric field draws a fiber out from a polymer solution or melt. It is a very simple and inexpensive technique to use in the laboratory, and allows researchers to perform 'nanotechnology' studies, although as previously mentioned, applying the term nanofiber to electrospun materials may not be fully correct.

The description of the electrospinning technique is reviewed well elsewhere.[37,38] In particular, the review by Reneker and Yarin provides a good overview of electrostatic jet formation (**Figure 2**).[39] Electrospinning is particularly useful for drug delivery, as soluble release systems can be incorporated by simply adding the drug to the solvent that is electrospun. The drug is incorporated within the fiber during processing, and then later released, according to the structure of the fiber and the nature of the polymer(s). Electrospinning can occur from both polymer solutions and polymer melts; however, as there is little literature for polymer melts, this review will emphasize fiber drug delivery from solution electrospinning (see **Chapter 1.127, Electrospinning and Polymer Nanofibers: Process Fundamentals**).

4.426.2.1. Polymers used in Electrospinning

The number of different polymers electrospun is literally in the hundreds. While it is not necessary to discuss all of them here, extensive lists of electrospun polymers can be found in other articles.[28,40] **Table 3** provides a selected list of electrospun polymers – these are selected since they are often investigated by different groups. By no means comprehensive, this table provides a good place to start for electrospinning with a range of different polymers.

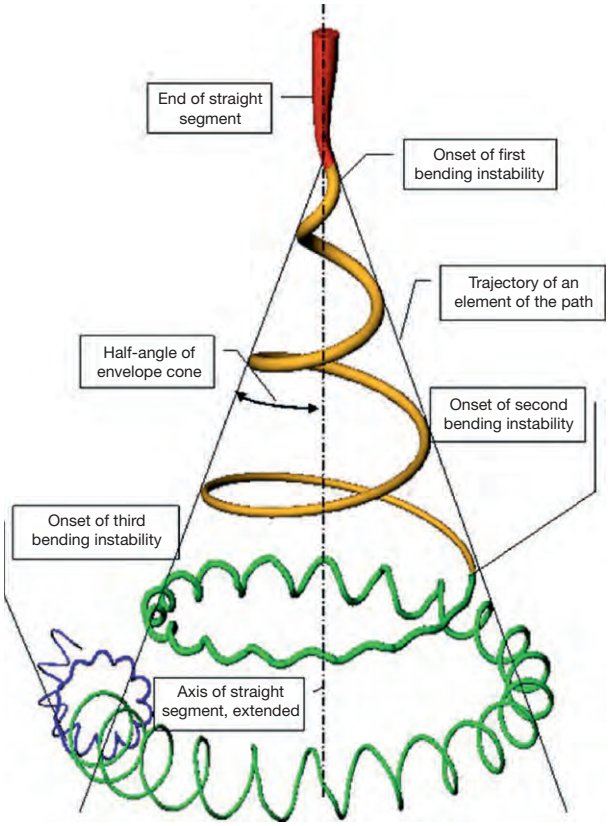

Figure 2 Trajectory of an electrostatically drawn polymer jet, demonstrating the various bending instabilities. Reproduced from Reneker, D. H.; Yarin, A. L. *Polymer* **2008**, *49*, 2387–2425, with permission from Elsevier.

Biologically derived polymers have the advantage of providing biological signals to cells; however, the nature of the actual fiber should be confirmed, since this can be altered by the electrospinning process. For example, collagen can be denatured to gelatin during electrospinning, due to both the solvent used (often 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP)) and the high voltage applied.[46] Silk fibroin is another biologically derived polymer often electrospun; however, it requires some treatment to dissolve the polymer or render it insoluble after electrospinning.[55–57] This is true for many polymers electrospun from aqueous solution – a degree of posttreatment is needed after generating the fiber so that is does not redissolve upon placement in aqueous media. In this way, non-water-soluble polymers have an advantage of incorporating drugs as posttreatment, and an extra step is not necessary.

4.426.2.2. Electrospinning Parameters Used to Alter Fiber Morphology

While the polymer and its properties are an important facet of electrospinning, the conditions used to deliver the solution are also relevant. Most importantly, this includes the applied electrical potential difference between the spinneret and the collector and also the flow rate to the spinneret. In addition, the spinneret–collector distance and the spinneret diameter all

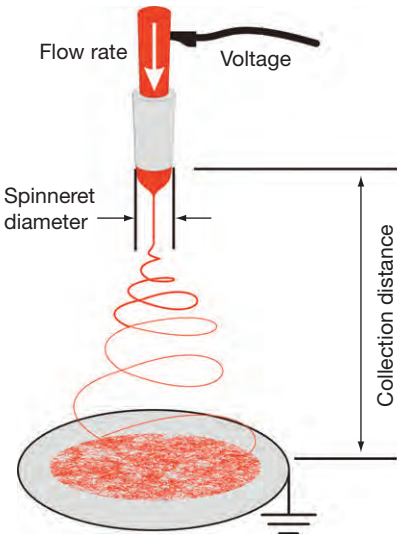

Figure 3 Various instrument parameters that influence the types of fibers collected.

influence the ultimate diameter of the fiber and consequently, the morphology. These parameters are schematically demonstrated in Figure 3 and are well reviewed elsewhere.[37,38,58–60] Many researchers showed that the fiber diameter and the structured morphology depended on processing parameters such as solution viscosity (e.g., concentration and polymer molecular weight), applied electric field strength, solution feeding rate, ionic salt addition, and solvent.[61–64] Although significant work has been done to characterize the properties of fibers as a function of process and material parameters, most of the investigations are not systematic and describe the electrospinning process without quantitative accuracy. Orthogonal experimental methods were used to investigate qualitative and quantitative correlations between fiber characteristics (diameters and morphologies) and the processing and materials parameters by Cui *et al.*[65] Their results showed that both the molecular weight of the polymer and solution concentration significantly influenced the fiber diameters and morphologies, while regression analysis revealed quantitative relations between fiber properties (diameters and beads percent) and electrospinning parameters (polymer molecular weight and solution concentration).

While investigating the various parameters for electrospinning, Son *et al.* found that electrospun poly(ethylene oxide) (PEO) fibers could be obtained, and the average diameters of PEO fibers ranged from 0.36 to 1.96 μm with increasing PEO solution concentration from 3, 4, 7, and 7 wt%. The higher the solvent dielectric constant, the thinner the PEO fiber was.[44] Heikkilä *et al.* investigated the importance of different solution and process parameters on evaluating multinozzle electrospinning of polyamide-6, and the chosen solution parameters were polymer grade, viscosity of solution, salt content and solvent grade and process parameters, voltage, distance, nozzle size and feeding pressure of solution. They found that the viscosity of the solution was the main parameter determining the fiber diameter, and also the salt content and the strength of the electric field had a strong effect on it.[66]

4.426.2.3. Permutations of the Electrospinning Process

Beyond polymeric constitution and instrument parameters, there are numerous configurations of the electrospinning apparatus that result in distinctly different types of fiber morphology. Many of these permutations involve the nature of the collector (Figure 4). While a static single collector is the most widely adopted, this has limitations when used for certain aspects of TE (see Section 4.426.2.4). While the collector is often grounded, this is not necessary and opposing voltages on the spinneret and collector have been employed to generate the potential difference necessary to electrostatically draw the fibers.

4.426.2.3.1. Rotating collectors

The collector has often been configured so that it rotates either rapidly to align the collected fibers or slowly so that a random network of fibers is formed – the latter is also combined with electrospraying or freezing to induce a porous morphology within the electrospun material (see Section 4.426.2.4). If the angular momentum is great enough, fibers will align themselves along an axis, although the efficiency of the alignment does not appear to be at the same level as when using dual collectors (Figure 4). Larger sheets of electrospun fibers can be manufactured this way, and a hollow rotating collector filled with solid carbon dioxide can grow ice crystals off the surface to generate porosity in the electrospun mesh (see Figure 9). When fibers are oriented on a rotating collector, then cells tend to align their actin filaments in the direction of the fibers.[51]

One benefit of using rotating collectors is the ability to incorporate gels and/or cells within the fibrous construct. This was nicely demonstrated by Stankus *et al.*, where two spinnerets were used for a single rotating collector.[67] Gelatin and cells were electrosprayed from one spinneret, while a polymer dissolved in dimethyl sulfoxide was used to electrospin the fiber. Another role for rotating collectors is to fabricate a tubular structure, which is of interest for vascular and applications in the nervous

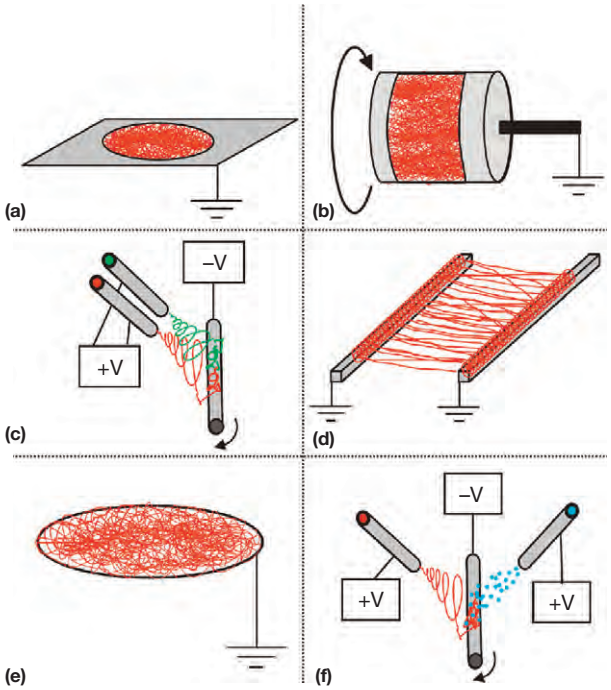

Figure 4 Various collector types for electrospinning. (a) single collector, (b) rotating collector, (c) coelectrospinning onto a rotating collector, (d) dual collectors, (e) ring collector, and (f) simultaneous electrospinning and electrospraying onto a rotating collector.

system in particular. Using different polymers, laminated tubes that consist of collagen and polyurethane have been fabricated.[68] Furthermore, nerve guides made from electrospun fibers have also been manufactured.[69]

4.426.2.3.2. Ring collectors

If there are geometrical gaps within the conductive collector, then the electrospun fibers can bridge this gap and be suspended in the air. This was demonstrated by Vacanti and colleagues,[41,70] where a ring of wire was used to suspend a thin membrane of electrospun material. Cardiomyocytes were seeded on this membrane and then cultured, to create a cell sheet that could be investigated further. The wire ring behaved as a mechanical support for the fragile electrospun mesh and was incorporated within the *in vitro* experiments. However, there are limits with this approach in that above certain air gaps, fibers do not bridge and suspend in the air.

4.426.2.3.3. Dual collectors

Similar to that described in Section 4.426.2.3.2, when the collectors are completely separated by a gap, the fibers are suspended in the air.[42,76] This approach has been used numerous times for making aligned fibers. The significant difference between this approach to align fibers and that of a rotating collector is that the oriented fiber is typically single and suspended without contact with other fibers. This is useful for applications where a dilute concentration of fibers is required on a surface. For example, a series of aligned fibers collected onto a rotating mandrel have morphological similarities to that of a grooved surface. Individual fibers made using dual collectors can be taken out and mechanically tested individually, or placed *in vitro* where single cell–single fiber interactions are observed. One problem with dual collectors is that it is not currently a continuous process, and the fibers start becoming nonuniform as the deposited fibers begin to insulate the collector. Sun *et al*. combined a dual collector with a rotating mandrel and manufactured an oriented sheet with various distances between the fibers. This allowed *in vitro* experiments to determine the diameter and how far apart suspended electrospun fibers need to be before cells can adhere to them.[77]

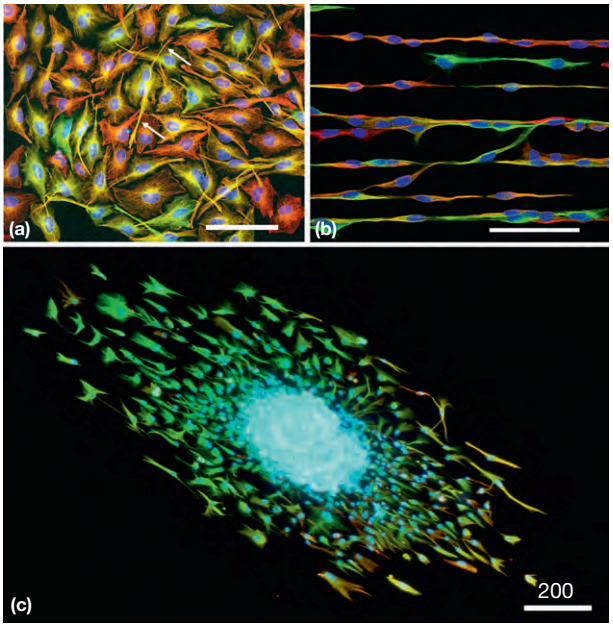

Figure 5 *In vitro* culture of astrocytes on (a) polylysine treated cell culture well and (b, c) aligned electrospun fibers deposited on chemically reactive substrates. The substrates adhere to the fibers and then continue to react with water, resulting in a nonadhesive surface for cells. The only location for cell attachment is on the electrospun fiber. (b) An image of an astrocyte cell line while a pellet of primary astrocytes is placed on the oriented electrospun material (c). Adapted from Gerardo-Nava, J.; Fuhrmann, T.; Klinkhammer, K.; *et al*. *Nanomedicine Uk* **2009**, *4*, 11–30, with permission from Future Medicine Ltd.

4.426.2.3.4. Adhesive collectors

One technical issue with the *in vitro* analysis of ultrafine fibers is that media exchanges can lift off fibers from a substrate. While glues and adhesives can be used, this causes complications with the analysis and may not be very effective. Therefore, electrospinning has been performed on collectors that bind and hold the fibers to a frame, which can then be removed. Similarly, collectors with a parallel gap have been used to create a series of oriented fibers, upon which cells can be seeded and visualized. Parameters such as fiber spacing can then be determined for a range of different cell types and diameters.

Recently, a chemically reactive and nanolayered hydrogel was used to coat glass cover slips, and adhered electrospun fibers, but also continued to react with water to form a protein-resistant surface between the fibers (Figure 5). This allows 'dilute' quantities of fibers to be deposited while providing a neighboring flat surface that is nonadherent to cells.[78,79] Fibers can either be

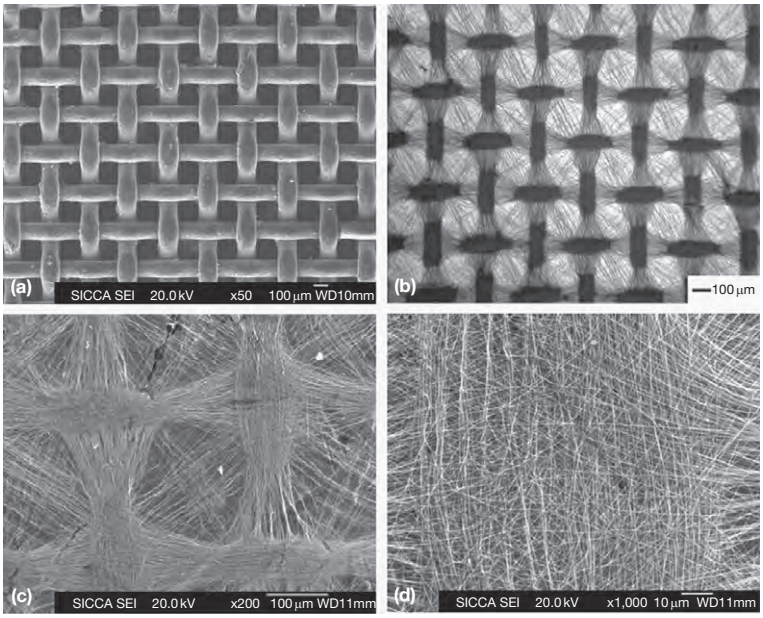

Figure 6 (a) A scanning electron microscopic (SEM) image of a patterned collector and (b) an optical image of an electrospun mesh collected on (a). (c, d) SEM images of electrospun fibers collected on (a). Reproduced from Zhang, D. M.; Chang, J. *Adv. Mater.* **2007**, *19*, 3664–3367, with permission from Copyright Wiley-VCH Verlag GmbH & Co., KGaA.

electrospun directly onto this chemically reactive surface, or collected and then transferred to this substrate. Adhesion and migration assays on RGD (arginine-glycine-aspartic acid)-modified or collagen-blended electrospun fibers have been demonstrated so far.[78] While these hydrogel collectors are not used for TE, they allow confirmation of surface modification and the binding of bioactive peptides to the surface of the electrospun fiber, including qualitative testing of the fibers for protein adsorption.

4.426.2.3.5. Patterned collectors

Ordered microstructures and patterned materials can have specific functions in biomedical applications, and therefore, ordered and structured patterns of electrospun fibers are of interest. As far back as 1966, different patterned electrospun fibers could be obtained by Simons,[80] using a fabric to deposit and collect them. With the development of electrospinning, more collector systems were used to control architectures and patterns, including electroconductive templates, magnetic fields, and dielectric materials. One interesting aspect of patterned collectors is that pore size of the resulting meshes can be altered and increased for cellular penetration.

Zhang *et al.* used electroconductive templates for the patterning of electrospun fibers, and found that the shapes of the collector could greatly affect the structures of the electrospun mats (Figure 6).[81] Neves *et al.* also fabricated patterned electrospun fibers using various shaped collectors with specific dimensions and designs, and they further evaluated the structures of fibers for biomedical applications. The blending polymers of PEO and poly(ε-caprolactone) (PCL) resulted in patterned electrospun fibrous mats, and mechanical properties of fibrous mats depended on the degree of fibers alignment (which could be strained up to 200%), and osteoblasts preferred cell adhesion within certain areas of the patterns.[82]

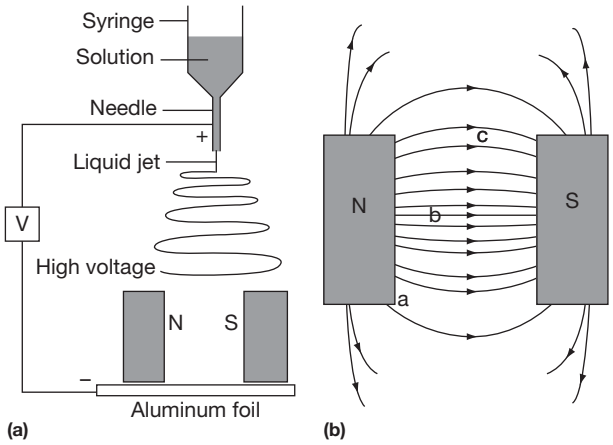

Figure 7 (a) Illustration of the apparatus for magnetic electrospinning to generate aligned fibers. (b) Calculated magnetic field strength vectors in the region between the two magnets. The arrows denote the direction of the magnetic field lines. Reproduced from Yang, D. Y.; Lu, B.; Zhao, Y.; Jiang, X. Y. *Adv. Mater.* **2007**, *19*, 3702–3705, with permission from Copyright Wiley-VCH Verlag GmbH & Co., KGaA.

Wang *et al.* also found that electrospun fabrics with tailored architectures and patterns have potential for TE applications through inducing an ordered cellular organization.[83]

Yang *et al.* used a different approach – magnetic electrospinning – to generate an electrospun pattern (Figure 7) for fabricating well-aligned arrays and multilayer grids fibers.[84] Through prepared magnetized electrospinning solutions and magnetized collectors, the magnetic field caused the magnetized electrospun fibers to align in a parallel fashion along the magnetic field lines. Yan *et al.* collected aligned electrospun ultrafine fibers using dielectric materials, and they studied the relationship between collector relative permittivity

and fibers alignment. They found that well-aligned electrospun fibers could be obtained by manipulating the electric field profile with various dielectric materials as collectors.[85]

4.426.2.3.6. Electrospinning writing

There have been numerous attempts to control the deposition of the electrospun fibers to prevent chaotic deposition.[45] While this is challenging work, some approaches are quite simple. A process called 'near-field electrospinning' was developed, which involves lower voltages (600 V) and smaller collection distances (0.5 mm).[86] This prevents the polymer jet from undergoing significant whipping instabilities, and the fiber can be 'drawn' by moving an *x*–*y* stage or spinneret (Figure 8). Interestingly, the jet can be deposited as a straight fiber above a certain speed – below this, the forces associated with a visco-elastic jet hitting the collector surface results in coiled fiber morphology. One permutation on this concept is to generate a charged drop without a Taylor cone and then mechanically pierce the drop, so that the surface is disrupted and a polymer jet is also drawn out into an electrospun fiber.[87]

Writing of the polymeric jet is also where polymer melts are interesting. Since polymer melts are nonconductive materials, whipping instabilities can occur near the collector surface, or not at all (Figure 8). In a similar manner to near-field electrospinning (but with higher voltages and larger gaps), an *x*–*y* stage can be used to 'write' with the electrospun fiber. Discrete lines of coiled electrospun fibers can be written with melt-electrospun PCL/poly(ethylene glycol-*block*-PCL) blends (Figure 8), and is a promising method for applying electrospun fibers directly onto cells or tissues.[88] Compared to patterning techniques such as fused deposition modelling (FDM) and direct writing, these electrospinning writing techniques are in their infancy.

There are also approaches to control the deposition of electrospun fibers without any movement of the collector. Deitzel *et al*. showed that a metallic ring surrounding the jet, and with a potential difference between that of the spinneret and the collector, was able to 'focus' the deposition area of the fibers.[45] Building on this, Craighead and colleagues devised an 'electrostatic lens,' with four independent electrodes, that formed a ring around the polymer jet.[89] While unable to fully control each deposited fiber, the approach is unique and will undoubtedly be expanded upon in the future.

4.426.2.4. Three-Dimensional Scaffolds of Electrospun Fibers

As previously mentioned, the lack of freely accessible volume or cell invasiveness of electrospun materials has impeded their efficacy as a TE scaffold (Table 4). The low pore size of electrospun meshes is a fundamental issue with the layering of fibers

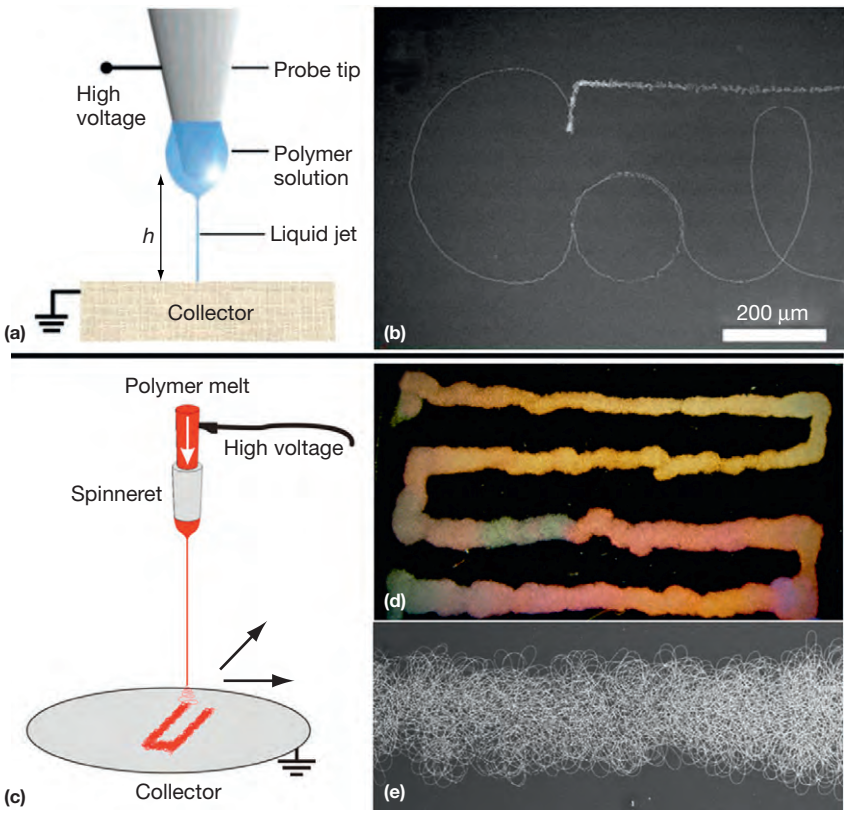

Figure 8 Electrospinning writing onto a substrate. Near-field electrospinning (a) involves close spinneret to collector distances with polymeric solutions and results in writing of the fiber. Electrospinning with a nonconductive material such as a polymer melt (c) results in instabilities just above the collector, allowing writing (d, e) with a moving *x*–*y* stage. (a, b) Reproduced from Sun, D. H.; Chang, C.; Li, S.; Lin, L. W. *Nano Lett*. **2006**, *6*, 839–842, with permission from American Chemical Society. (c, d) Reproduced from Dalton, P. PCL/starch	Fiber-bonded PCL/starch microfibers	73
PCL	Electrospun PCL microfibers	74
PLGA	Melt-electrospun PLGA	75

with diameters below 1 μm. Some mechanism is therefore needed to introduce porosity into and between the fibers. However, there are approaches that respond to this challenge and there are different effective approaches to achieve this, shown in Figure 9. These are electrospinning onto ice crystals, hydrospinning, coelectrospinning/electrospraying, and electrospinning microfibers.

4.426.2.4.1. Electrospinning onto ice crystals

One interesting approach is to electrospin onto ice crystals, as they grow off a surface (Figure 9). This has been done by using a hollow rotating drum filled with solid CO_2, which grows

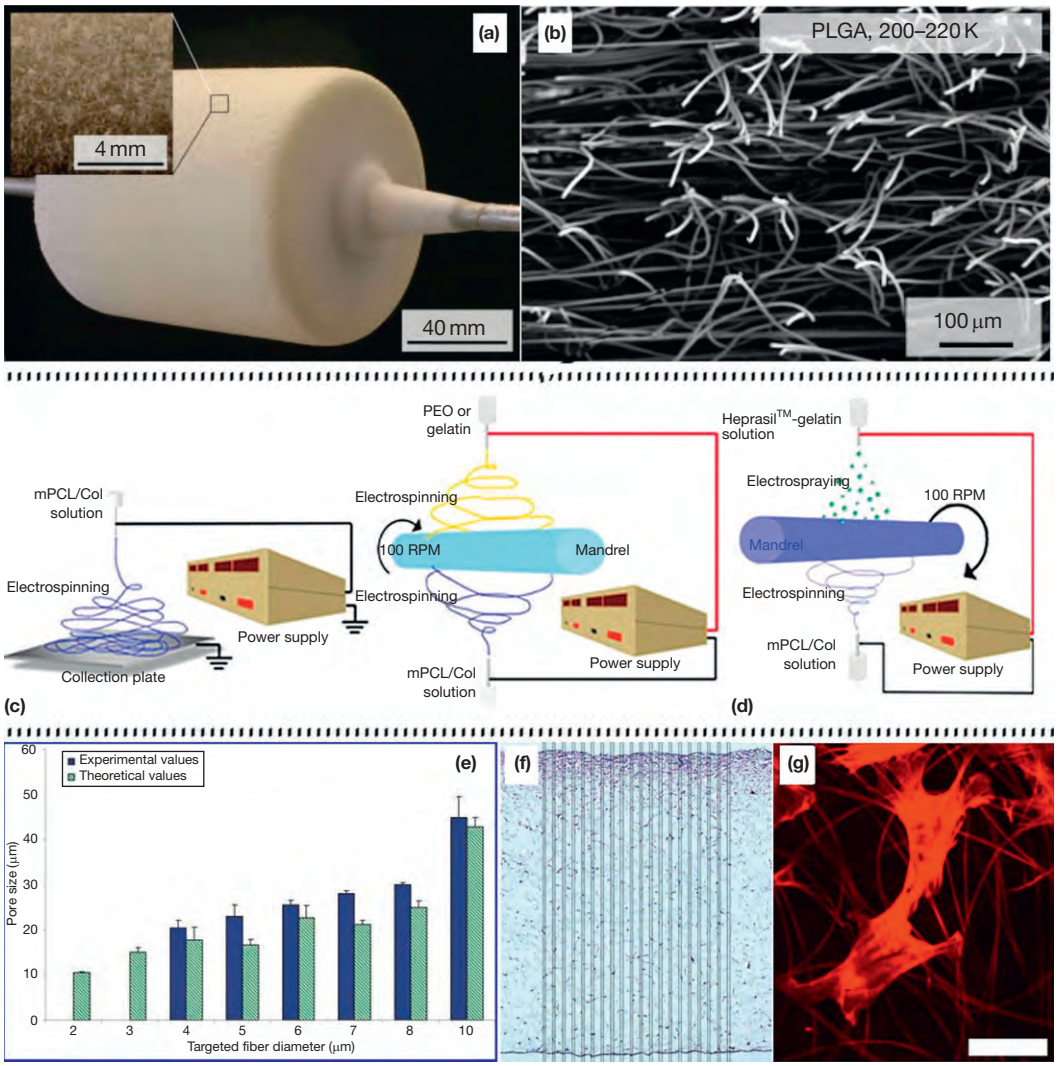

Figure 9 Various approaches to manufacture cell-invasive electrospun fibers. (a) Electrospinning onto ice crystals and the resulting fibers (b) provide a highly porous material. (c) and electrospinning/electrospraying (d) are also methods to improve porosity. The fiber diameter is also important, as shown in (e) where fibers below 2 μm do not provide enough interconnecting porosity for cell penetration (f). Melt-electrospun fibers of this diameter allow cell penetration (g). (a, b) Reproduced from Simonet, M.; Schneider, O. D.; Neuenschwander, P.; Stark, W. *J. Polym. Eng. water crystals off the collector while depositing the fibers.[90] The electrospun fibers are embedded within the ice, which is sublimed away via lyophilization. The consequence is increasing the interconnective pores. Furthermore, the porous fibers can be mechanically pulled and transformed into a material with a consistency of cotton wool.[91]

4.426.2.4.2. Hydrospinning

In this method, electrospun fibers are collected upon water as a film and then transferred to a microscope slide.[92] By repeating this process, multiple layers are generated, and the water is then removed with a vacuum. The resulting scaffolds have considerable volume and are highly porous and cell invasive. Alternatively, the process can be modified to incorporate cells into the process at any stage, which results in a unique method to incorporate cells within a TE scaffold. In the study reported by Levenberg and colleagues, myoblasts were successfully cultured with an equal density throughout the electrospun scaffold.

4.426.2.4.3. Simultaneous electrospinning/electrospraying

Another approach to decrease the fiber density is to simultaneously electrospray and electrospin. In an excellent research Wagner and colleagues electrospun polyurethane while electrospraying a mixture of smooth muscle cells and gelatin.[67] The resulting construct has higher cell survival when cultured in a bioreactor compared to a static culture. In addition, Hutmacher and colleagues electrospun PCL/collagen while electrospraying a thiolated hyaluronic acid solution.[93] The resulting mixed electrospun fibers and gel was infiltrated with human fetal osteoblasts up to 200 μm into the scaffold. In both instances, a rotating collector was used and the spinnerets were positioned at 90° apart from each other. This approach is interesting, as the pore size of the scaffolds is increased and at the same time, a cellular component can be introduced into the material (via electrospraying).

4.426.2.4.4. Electrospinning microfibers

When electrospun fibers are produced with diameters of 2 or 3 μm, the pore size of the resulting scaffold is 10.5±0.1 μm and 14.9±1.0 μm, respectively, and large enough for cellular penetration.[74] This latter point is interesting, as there are only a handful of studies on cellular interactions with fibers with diameters between 2 and 10 μm. With numerous studies investigating submicron-diameter fibers and with lower limits to the diameters of mechanically drawn fibers, this is a notably underinvestigated fiber diameter range. Such micron-diameter fibers were investigated as scaffolds, with mesenchymal stem cells penetrating up to 1200 μm into the scaffold under flow conditions and 300 μm under static. Furthermore, an electrospun mesh was deposited on top of the microporous electrospun material, creating a bimodal scaffold that consisted of 600-nm ultrafine fibers deposited onto a 5-μm PCL mesh. Melt electrospinning, which can readily produce micron-diameter fibers,[94] has been used for this purpose in producing cell-invasive scaffolds in combination with solution electrospinning. Outlined by Kim *et al.*, the same source of PLGA was simultaneously solution- and melt-electrospun onto a rotating mandrel, resulting in a thick cell-invasive mesh.[75] This mesh was 'bimodal,' in that it contained a mixture of ultrafine solution-electrospun fibers with a diameter of 530±240 nm and melt-electrospun microfibers with a diameter of 28.0±2.6 μm. The bimodal scaffold was able to seed a greater number of cells than did a melt-electrospun scaffold alone.

4.426.2.4.5. Electrospinning onto scaffold carriers

Electrospun fibers have also been deposited onto scaffolds typically used for TE, with the larger pores filled with electrospun fibers. Conventional fibers can also be mixed with electrospun fibers, creating a scaffold where the ultrafine electrospun fibers are mechanically supported by the larger structures. This is achieved in one instance by melt-spinning poly(L-lactide-*co*-ε-caprolactone) (PLCL) into a cylindrical structure for vascular TE and then electrospinning onto this.

Notably, an automated scaffold assembly system has been used to construct the scaffold carrier in one study.[72] FDM has become widely used in different TE applications and in this instance, the process was interrupted between each layer to deposit an electrospun PCL/collagen fiber mesh (Figure 10).[72]

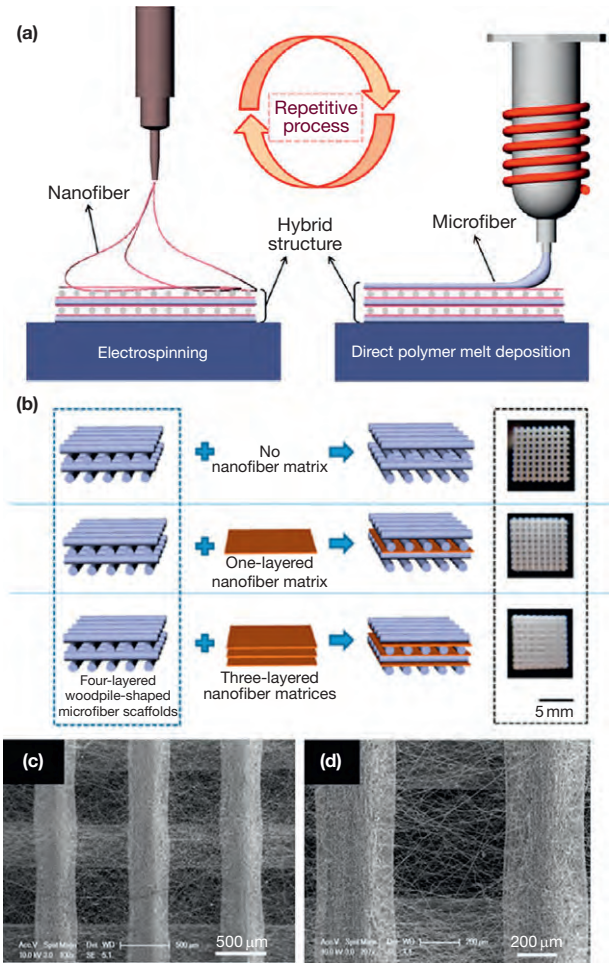

Figure 10 Combining electrospinning with a melt-printing technique to create an electrospun carrier. Reproduced from Park S. H.; Kim, T. G.; Kim, H. C.; Yang, D. Y.; Park, T. G. *Acta Biomater.* **2008**, *4*, 1198–1207, with permission from Elsevier.

The resultant construct had large pores, while the electrospun fibers were structures upon which cells could adhere to. This effectively increases the surface area available for penetrating cells to attach.

4.426.3. Drug Delivery from Electrospun Fibers

The ideal interaction between cellular and fibrous components in a TE construct should initially be controlled. This is why drug delivery should not just be considered as the release of soluble molecules from a degrading biomaterial, but also the availability of bioactive molecules on a scaffolds surface that initiate and perpetuate certain cellular functions. The latter is a complex effort, with protein adsorption potentially fouling the surface to prevent specific cellular signaling. There are excellent and pertinent reviews elsewhere on the subject of protein adsorption on flat surfaces and monolayers (see **Chapter 4.406, Protein Interactions with Biomaterials**);[95–97] however, the inclusion of electrospun fibers in this research is an important translation of fundamental surface chemistry research. Whether a drug is bound or released from a fiber, the drug must be available to the cells or tissue at a suitable concentration for an appropriate length of time for the specific outcome. Drug release from electrospun fibers is therefore a complex component of electrospinning research. However, incorporation of the nonbound drug into electrospun fibers is relatively straightforward – they are simply blended into the solution to be electrospun. As described later, there are issues with this approach such as nonideal mixing, protein denaturation, and blooming of the drug to the fiber surface. Expansion of the range of drugs that can be directly encapsulated within the fibers involves their appropriate dispersal within the electrospinning solution.

Drug release from electrospun fibers could be controlled by various fabrication conditions, for example, the polymer types, fibers diameters, blending of different content, fiber surface coating, drug dispersion, electrospinning models, and so on.[98] However, most biodegradable electrospun fibers directly entrapping drugs exhibited high burst effects with poor controlled release patterns, probably due to incompatibility of drug/polymer/solvent system and slow degradation of biodegradable polymer.[98–100] Therefore, additives to fiber materials that increase both drug solubility and compatibility in the polymer solution have influenced drug release profiles by altering the drug dispersion inside the electrospun fibers.

4.426.3.1. Drug Inclusion within the Polymeric Solution

Simply adding the drug to the electrospinning solution is a rapid method to produce an electrospin-controlled release system. This blends the drugs into the polymeric jet, and evaporation of the solvent results in drug-loaded ultrafine fibers; however, this approach is only suitable for limited drugs with suitable stability and solubility in the solvent. An example of a successful approach is the incorporation of heparin into PCL electrospun fibers.[43] Using a chloroform/methanol solvent mixture, both the PCL and heparin are dissolved and electrospun. The heparin is homogenously dispersed within the electrospun fibers. After an initial burst release, heparin diffuses from the electrospun fibers for 14 days and retains biological activity (**Figure 11**).

By adding drugs to electrospun fibers, an initial burst release is common. Incorporated drugs locate on the fiber surface because of the rapid solvent evaporation and resulting high ionic strength (due to drug phase separation to fiber surface) and polymer in solution. Therefore, fibrous mats prepared by blending drugs into the electrospinning solution will result in a burst effect during the initial stage of drug release (see **Chapter 4.417, Tethered Antibiotics**).[99,101] This could be useful for antibacterial approaches, where the initial burst release is used to eliminate intruding bacteria before they begin to proliferate.[102] For water-soluble, -insoluble, and -microsoluble drugs, the electrospinning solvent is particularly important for fabricating the fibers. For water-soluble drug systems, triethyl benzyl ammonium chloride and poly(L-lactic acid) (PLLA) are dissolved into a solvent of a 2:1 (in volume) mixture of chloroform and acetone.[101] Drugs are capsulated inside the fibers, and drug release in the presence of proteinase K follows nearly zero-order kinetics due to PLLA fiber degradation. Cui *et al*. dissolved water-soluble paracetamol into acetone solution containing PDLLA and found that electrospun fibers with larger diameter exhibited longer periods of nearly zero-order release, and higher drug encapsulation resulted in a more significant burst release.[103] For water-microsoluble drugs, Brewster *et al*. investigated poorly water-soluble drugs (itraconazole and ketanserin) loaded in a water-insoluble, nonbiodegradable polymer.[52] Electrospinning solutions were made by dissolving drug and polymer in dimethylformamide (for itraconazole) and in dimethylacetamide (for ketanserin). The collected nonwoven fabrics were shown to release drugs at various rates and profiles based on the ultrafine fiber morphology and drug content.

Another way of incorporating drugs into electrospun fibers is via emulsion electrospinning, in which two miscible or immiscible components can be conveniently electrospun into a composite fiber with a core layer encapsulated inside a shell. In this way, drugs or their mixture can be enclosed within the polymer outer shell to form a core–shell-type drug delivery device.[104,105] Core–shell electrospun fibers are described in greater detail in **Section 4.426.3.4**.

4.426.3.2. Bioavailability of Drugs at the Fiber Surface

While much drug delivery research with electrospun fibers focuses on mixing the drug before electrospinning, making the drugs available at the surface of the fiber is important for some specific applications such as prevention of bacterial infection.[106] Therefore, postinclusion of drugs has been adopted to coat the electrospun fibers using bioactive molecules, drug and cell recognizable ligands after electrospinning. There are four main approaches for drug loading onto surfaces of electrospun fibers for drug delivery through physical technology, and they are (1) chemical binding, (2) drug adsorption, (3) nanoparticle formation, and (4) multilayer assembly.[3,107] Furthermore, there is recent research into making bioactive electrospun fiber surfaces using surface segregation.

4.426.3.2.1. Chemical binding

Bioactive molecules and drugs can be incorporated after electrospinning using a posttreatment with chemical coupling agents to surface bind the drug of interest. Yao *et al.* developed a novel antibacterial material of electrospun polyurethane fibrous membranes; they modified the fibers with plasma pretreatment, followed by UV-induced graft copolymerization of 4-vinylpyridine and the quaternization of the grafted pyridine groups with hexylbromide.[108] They found that these fibrous membranes possessed effective antibacterial properties. In another example of electrospun fiber chemical modification, Ma *et al.* grafted methacrylic acid onto polysulfone fibers through radical initiation to introduce polymer carboxyl groups, and Cibacron blue F3GA and bovine serum albumin (BSA) were covalently attached on the fiber by using carbodiimide as a coupling agent. They found that the functionalized polysulfone electrospun membranes had a capturing capacity of 22 mg g^{-1} for BSA.[109] Kim *et al.* fabricated amine-functionalized block copolymers (PCL-*block*-PEG-NH_2) (poly(ethylene glycol), PEG), electrospun fibers, and chemically conjugated linear poly(ethylene imine) (PEI) to the fibers surface using matrix metalloproteinase (MMP)-cleavable peptides, and then DNA was electrostatically incorporated onto electrospun fibers (**Figure 12**).[110] They found that DNA and PEI were rapidly released in the presence of MMPs, and the transfection efficiency of the release fractions was influenced by the ratios of the released DNA and PEI.

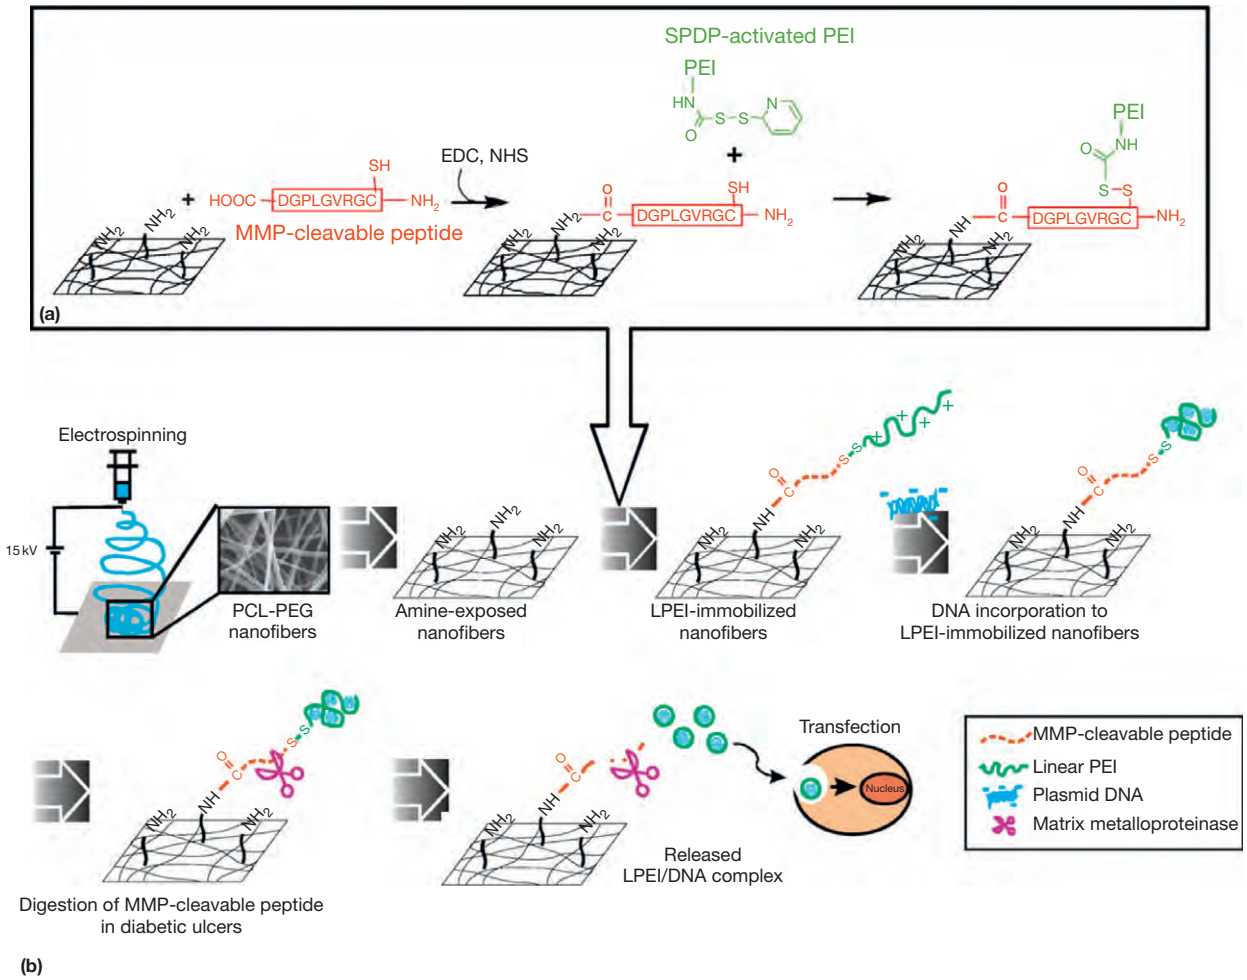

Figure 12 (a) Synthetic scheme of LPEI immobilization on the surface of an electrospun fibrous matrix via a MMP-cleavable linkage. Release* **2010**, *145*(3), 264–271, with permission from Elsevier.

4.426.3.2.2. Drug adsorption

Some drugs adsorb onto electrospun fibers through simple physical adsorption, using electrostatic interactions, hydrogen bonding, and hydrophobic interactions.[3,111] Patel *et al*. developed aligned and bioactive electrospun scaffolds by immobilizing extracellular matrix protein and growth factor onto ultrafine fibers, which simulated the physical and biochemical properties of native matrix fibrils. Carboxylic groups on the PLLA ultrafine fibers could be obtained through briefly treating the electrospun fibers with a base, with di-NH_2-PEG, and then heparin covalently attached to the carboxylic groups on the PLLA electrospun fibers using cross-linkers 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride and *N*-hydroxysulfosuccinimide. Heparin, a highly sulfated glycosaminoglycan, exhibits strong binding affinity with various growth factors such as fibroblast growth factor, vascular endothelial growth factor (VEGF), heparin-binding epidermal growth factor, and transforming growth factor-β. They found that the immobilized biochemical factors (as efficient as soluble factors) synergized with aligned ultrafine fibers to promote highly efficient neurite outgrowth but had less effect on skin cell migration.[112] Proteins can also adsorb onto hydrophobic surfaces. Ramakrishna *et al*. adsorbed laminin onto electrospun fibers for investigations with neural tissue. Laminin-adsorbed fibers, however, had modest neurite outgrowth compared to laminin/PL-adsorbed glass surfaces. When laminin was included within the electrospinning solution, neurite growth of PC-12 cells was significantly higher compared to electrospun fibers with adsorbed laminin.[113]

4.426.3.2.3. Nanoparticle formation

Therapeutic or biocompatible nanoparticles such as hydroxyapatite and silver (Ag) nanoparticles have been combined with the nanostructured electrospun fibers to functionalize the materials.[3,114,115] Rujitanaroj *et al*. prepared gelatin electrospun fibers containing Ag for wound dressing pads through a gelatin solution containing $AgNO_3$ (Figure 13). They found that cumulative release of Ag^+ ions from fibers *in vitro* occurred rapidly during the first 60 min before leveling off in a typical burst-release profile. Cui *et al*. prepared poly(DL-lactic acid) (PDLLA) electrospun fibers with calcium nitrate entrapment and then incubated in phosphate solution to form *in situ* calcium phosphate nanoparticles on the polymer fibers matrix.[116] They then further grafted gelatin or chitosan on the PDLLA electrospun fibers through an optimized aminolysis process, and the hydroxyapatite nanoparticles could nucleate and grow on these PDLLA electrospun fibers in simulated body fluid.[117] The hydroxyapatite nanoparticles could also be induced to nucleate and grow onto electrospun fibers surface through functional surface groups of electrospun fibers.[118]

4.426.3.2.4. Multilayer assembly

Layer-by-layer polyelectrolyte (PE) multilayer assembly is an important and versatile surface modification method exploiting electrostatic forces on charged substrates.[119] Muller *et al*. reported layer-by-layer surface functionalization of high-aspect-ratio polystyrene electrospun fibers of various diameters with PEs, deoxyribonucleic acid (DNA) oligonucleotides, and PE/gold nanoparticle composite layers.[120] In this study, PEs were introduced onto polystyrene electrospun fibers through sequential immersion into an aqueous solution of fluorescein isothiocyanate (FITC)-labeled poly(allylamine hydrochloride) and poly-(styrene sulfonate) for 20 min. The DNA was deposited in two steps – firstly, the fibers were treated with sulfuric acid to impart an initial positive charge to the surface, followed by the adsorption of DNA. The PE/Au nanoparticle-coated fibers were prepared by adding a 4-(dimethylamino)-pyridine-stabilized gold nanoparticles dispersion to the PE-coated polystyrene electrospun fibers for 1 day. This study demonstrates that electrospun fibers can be readily modified with various agents by the layer-by-layer assembly approach.

4.426.3.2.5. Surface-segregated chemistry for functionalization

Thermodynamically driven surface segregation is an approach that provides a single-step approach to functionalization of electrospun fibers. Charged amino acid species have been included within the electrospun solution and are concentrated on the surface of the fiber after electrospinning.[121] Studies also show that electrospun fibers can be rendered both protein-resistant and functionalized with a biologically active compound by using amphiphilic polymers. When a PEG-*block*-PCL copolymer is predominantly hydrophilic, and solvent mixtures are used, the resulting fibers are hydrophilic.[122] Furthermore, when end-modified PEG-*block*-PCL is used (e.g., RGD-PEG-*block*-PCL or biotin-PEG-*block*-PCL), the fibers are protein-resistant, hydrophilic, and functionalized. Using a more simplified approach, an amphiphilic and isocyanate star-shaped macromer is used as a reactive additive to a PCL or PLGA solution, creating both a biofunctionalized and hydrophilic fiber.[123,124] Protein-resistant fibers are produced using solutions containing only 7% star-shaped macromer, relative to the PLGA or PCL. Functionalization is through adding a bioactive peptide to the macromer/polymer solution prior to electrospinning with RGDS and RDES-modified electrospun substrates exhibiting distinct differences with cell adhesion.

4.426.3.3. Release Rates and Bioactivity of Incorporated Drugs

Drug release rates and bioactivity from electrospun fibers have been found to depend on a variety of parameters such as the mode of encapsulation, the properties of the encapsulating material, the concentration of the drug encapsulated, and the fibers matrix architecture. This provides sufficient flexibility to control the rate of drug release and maintain drug bioactivity to achieve therapeutically effective doses for the required time period.

In creating electrospun fibers that are drug carriers, Kim *et al*. dissolved model protein lysozyme and polymer into organic solvents for blending fibrous mats, and they observed a high initial burst (45%) with a low controlled release profile, attributed to the presence of lysozyme particles on the fiber surface.[98] The major disadvantages of this type of electrospinning are the severe burst-release phenomenon and the limited effective lifetime of the delivery. To delay the drug release rate, BSA was incubated into PCL electrospun fibers via coaxial electrospinning by Zhang *et al.*, and they found that over 50% of the protein release was observed for fibers with only 0.2% of BSA entrapment.[125] Qi *et al.* encapsulated protein-loaded Ca-alginate microspheres into polymer fibers generating beads-on-string morphologies. The polymer shells around the beads were too thin to modulate protein release, and over 40% of the protein doses were released from the fibers during the initial 12 h.[126] Yang *et al.* incubated lysozyme into PDLLA electrospun fibers prepared by emulsion electrospinning process for core–shell structures, and they found that around 27% of the burst release was detected from fibers with a 1.0% of lysozyme loading, followed by sustained release for 2 weeks.[127]

Another important factor is the maintenance of both structure and bioactivity of the incorporated proteins, which is difficult due to both the complex physical and chemical instabilities inherent in proteins because of the processes of electrospinning, storage, and release. Li *et al.* studied silk fibroin fibers containing bone morphogenetic protein 2 (BMP-2) prepared via electrospinning as a bone TE scaffold. The results suggested that BMP-2 in the electrospun fiber led to higher calcium deposition and upregulation of BMP-2 transcript levels when compared with the control group.[128] Zeng *et al.* obtained electrospun composite fibers through incubating luciferase into poly(vinyl alcohol) (PVA) and poly(*p*-xylylene) (also known as parylene) ultrafine fibers prepared by chemical vapor deposition. Luciferase retained its enzymatic activity after electrospinning and release.[129] However, even though electrospun fiber-based protein delivery systems are in early stages of development, protein structural stability and bioactivity and their controlled release profiles from the fibers require substantial improvements.

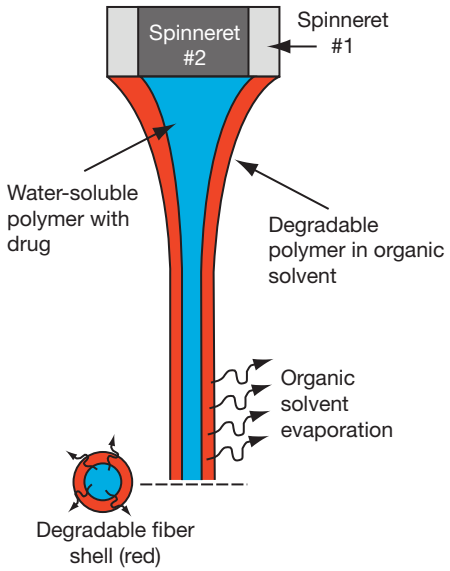

Figure 14 Schematic of coaxial electrospinning showing the core–shell structure of the resulting fiber.

4.426.3.4. Coaxial Electrospinning

One important variation of the electrospinning technique is coaxial electrospinning. This involves using two spinnerets – one inside of another, delivering two polymer solutions that are immiscible with each other (Figure 14). The result of this configuration is that the internal fluid is drawn within the outer fluid in the same Taylor cone, and a two-phase fiber is created with a core and a shell. This fiber can be treated so that the second core phase can be removed to generate a hollow tube – this process provides remarkable continuity in the core–shell structure. Undoubtedly, reiterations in what can be delivered within the polymeric core will influence future drug delivery system designs involving electrospinning.

Zhang *et al.* obtained core–shell-structured electrospun fibers using coaxial electrospinning (Figure 15), with FITC-conjugated

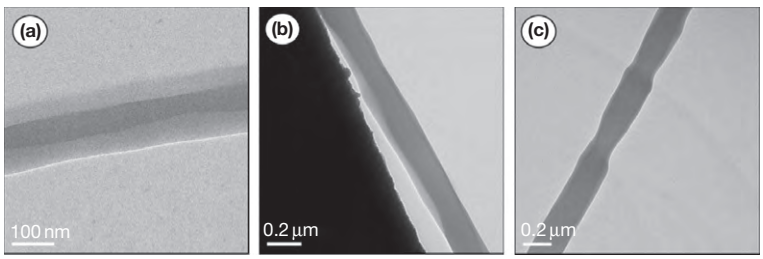

Figure 15 Typical TEM images of coaxially electrospun PCL-r-fitc-BSA/PEG ultrafine fibers produced from varying inner flow rates of 0.2–0.6 ml h^{-1} and with outer flow rate of 1.8 ml h^{-1}. (a) Core component properly located in the center, (b) irregular movement of the core component, and (c) fluctuated fiber shape. Reproduced from Zhang, Y. Z.; Wang, X.; Feng, Y.; Li, J.; Lim, C. T.; Ramakrishna, S. *Biomacromolecules* **2006**, *7*, 1049–1057, with permission from American Chemical Society.

BSA (FITC-BSA) as the core and PCL as the shell. They found that BSA protein in the core–shell-structured electrospun fibers could be released continuously over more than 5 months.[125] Two model proteins – BSA and lysozyme – were incorporated into PCL fibers via coaxial electrospinning by Jiang *et al.*[130] They found that the core thickness could be increased by increasing the feed rate of the inner core material, with more rapid release of core contents. Core–shell electrospun fibers of cationized gelatin-coated PCL were prepared by coaxial electrospinning by Lu *et al.*, and the gelatin was used for immobilizing diverse macromolecular model bioactive agents (FITC-labeled BSA (FITC-BSA), FITC-heparin, or VEGF) to the fibers for release. Sustained release of VEGF could be controlled from heparin-adsorbed electrospun fibers, and the released VEGF maintained its bioactivity.[131] Using coaxial electrospinning, Ahmad *et al.* developed a device with three coaxially arranged needles to obtain multilayer encapsulated fibers (**Figure 16**) for drug delivery.[132] In this regard, coaxial electrospinning is a versatile method for altering how the contents could be released steadily from the multilayered structure.

4.426.3.5. Emulsion Electrospinning

Electrospinning with water-in-oil (W/O) or oil-in-water (O/W) emulsions can yield core–shell fibers.[126] Modified core–shell electrospinning techniques (such as emulsion and coaxial electrospinning) are important to expand the utility of the process. Xu *et al.* electrospun a W/O emulsion containing a PEO solution in water and an oily phase of an amphiphilic poly (ethylene glycol)–poly(L-lactic acid) (PEG-*block*-PLA) di-block copolymer dissolved in chloroform (**Figure 17**).[133] They found that the fiber size and diameter of core and shell could also be changed through adjusting solvent and proportions. Xu *et al.* also prepared core–shell electrospun fibers through W/O emulsion electrospinning, and a water-soluble anticancer agent (doxorubicin hydrochloride) was included into amphiphilic poly(ethylene glycol)-poly(L-lactic acid) (PEG-PLLA) di-block copolymer.[105] They found that drug release in core–shell structure fibers became slower and slower and the accumulated release percentage became steady (**Figure 18**). Yang *et al.*[134] obtained core–shell-structured ultrafine fibers of BSA and PDLLA through emulsion electrospinning as carriers for therapeutic proteins. Release data suggested that emulsion electrospinning can provide a useful core–sheath structure for effective release and protection of bioactive proteins. Yang *et al.* further investigated the structural integrity, bioactivity, and release patterns of lysozyme encapsulated within the core–shell-structured ultrafine fibers prepared by emulsion electrospinning. They found that emulsion electrospinning successfully produced core–shell-structured ultrafine fibers that could significantly delay initial burst release, prolong the release period depending on the protein loading amount, and protect the structural integrity and bioactivity of encapsulated lysozyme during incubation in release medium.[127]

Research performed with emulsion electrospinning has demonstrated that the characteristics of the drug (e.g., solubility and compatibility) are not the defining properties for

Figure 16 Thread encapsulation. electrospinning technology, and that flexible drug formulations within electrospun fibers could be designed and obtained.

4.426.3.6. Morphological Variations Affecting Drug Delivery

One common observation with electrospinning is the formation of 'beads' along the fiber length, long been considered an undesirable phenomenon.[135] However, beads along the fiber could be used as reservoirs for drug or cell inclusion, and could have distinct degradation properties from the fibers. The optimization of bead percent was also necessary to extend such fiber applications in biomedical, biotechnological, and other industrial fields.[65] The possible effects of fiber beads on cellular proliferation, growth, and adhesion are not known. On the positive side, understanding reasons for development of beads provides another parameter for scaffold design.

4.426.3.7. Additives to Modify Electrospinning Materials

Release of pharmaceutical agents can be altered to be immediate, delayed, or pulsed depending on the polymer carriers used and other included additives. Some studies report correlations of additives and drug distribution in the polymer to release profiles and degradation.[136] The addition of additives to electrospinning solutions is an important parameter influencing the fiber morphology because of changes to polymer solution physicochemical properties including the surface tension.[103] Yang *et al*. fabricated core–shell-structured composite electrospun fibers (lysozyme/methyl cellulose/PDLLA) with lysozyme as a model protein, encapsulated into the PDLLA fibers along with methyl cellulose (MC additive).[127] They also obtained BSA and MC in PDLLA core–sheath ultrafine fibers by emulsion electrospinning.[134] The MC additive benefited core–shell electrospun fiber formation and showed no effect on the Amide I FTIR band for both lysozyme and BSA. The protein-specific activity retention of secondary structure through Fourier transform infrared analyses was significantly higher for lysozyme and BSA encapsulated within composite fibers containing additives than free lysozyme and BSA incubated with fibers. The MC additive could quicken protein release. With the additives released from composites leading

to more pores in the fibers, water penetrated into the fiber and promoted faster hydrolysis of the polymer backbone, so that the mass loss of the fiber matrix and molecular weight loss for PDLLA were much more rapid than that of pure PDLLA.

4.426.4. Conclusions and Future Directions

There is an increasing demand for engineered nanostructured polymeric materials and surfaces to improve interfaces in biomedicine, biology, materials science, and nanotechnology. Electrospinning has, in particular, been widely used within laboratories due to its inexpensive convenience and simplicity, and its capacity to deliver bioactive molecules to cells or tissues. Many current forms of fibers, however, are not very cell-conducive for TE use. Controlled drug delivery via these fibers is one component of this growing and burgeoning part of TE. Drugs can be incorporated by simply adding them directly to the electrospinning polymer solution, or bound to the fiber surface using postelectrospinning treatments or single-step processes. While many polymers were electrospun over the past decade, controlling the specific chemistry of the electrospun fiber surface remains a challenge. Ongoing advancements with different electrospun fiber morphologies using different device configurations will fabricate different fiber designs. Various approaches to collect electrospun fiber in distinct solid morphologies are evolving. Relatively little is known about 'microscale' electrospun fibers – those with 2–15-μm diameter range that might yield different porous scaffolds useful for TE.

Glossary

Angiogenesis Formation of blood vessels from preexisting ones.
Angiogenic switch Switch of a tumor from an avascular to a vascular state because of the disturbed balance of pro and antiangiogenic signals.
Arteriogenesis The formation of larger arteries from arterioles.
Cell-mediated Activities which are restricted to the cell surface, resulting in a localized effect (here extracellular matrix remodeling).
Haptotaxis The recruitment of cells toward an immobilized signal.
Heparan sulfate A linear charged polysaccharide that is bound to proteins.
Morphogenesis Processes that control the formation of functional shapes and tissues.
Proteoglycan Proteins with a substantial glycosylation.
Transglutaminase An enzyme that catalyzes the reaction between a γ-carboxamid (glutamine) and amine (lysine) groups.
Ulcer An open lesion, for example, in skin or mucosa often maintained by an inflammation and/or an infection.
Vasculogenesis The *de novo* formation of capillaries from angoiblasts.

Abbreviations

2D	Two-dimensional
Ang-1	Angiopoietin-1
bFGF	Basic fibroblast growth factor
BMP-2	Bone morphogenetic protein-2
CAM	Chick chorioallantoic membrane
EC	Endothelial cell
ECM	Extracellular matrix
FXIII	Factor XIII
HA	Hyaluronic acid
HUVEC	Human umbilical cord vein endothelial cell
KGF	Keratinocyte growth factor
L1Ig6	Sixth Ig-like domain of the cell adhesion molecule L1
MMP	Matrix metalloproteinase
NGF	Nerve growth factor
NT-3	Neurotrophin-3
PDGF-BB	Platelet-derived growth factor-BB
PEG	Poly(ethylene glycol)
PTH	Parathyroid hormone
SDF-1α	Stromal cell-derived factor-1 alpha
TGF-β2	Transforming growth factor beta-2
VEGF	Vascular endothelial growth factor
α_2PI_{1-8}	*N*-terminal amino acid sequence (NQEQVSPL) of α2-plasmin inhibitor
α_2PI_{1-8}-Pla-VEGF	α_2PI_{1-8} fused via a plasmin linker to VEGF
α_2PI_{1-8}VEGF	α_2PI_{1-8} fused to VEGF

4.427.1. Introduction

4.427.1.1. Medical Motivation

Polypeptide growth factors and cytokines are key players in normal tissue morphogenesis as well as tissue regeneration in the diseased adult. Intense basic research has led to a great deal of knowledge about the biological characteristics and potency of these factors in triggering specific cellular responses.[1–3] However, the translation of this scientific understanding of growth factor function into pharmacological enhancement of tissue repair in clinical therapies has been rather unsuccessful.[4] For example, one of the more relevant and therefore well-studied needs has been the treatment of chronic wounds, such as diabetic ulcer, pressure ulcer, or venous static ulcer, that are caused by deficient vascular supply. Scores of trials with ulcer patients using growth factors or cytokines have produced disappointing results.[5–7] One likely reason for the poor clinical outcomes with recombinant growth factor therapeutics in the past has been the modes of growth factor delivery, that is, their topical application or injection in soluble form.[8] Without embedment, the soluble factors are very rapidly cleared from the target site by diffusion, or never reach the target in sufficient quantities, or reach it only at extreme dose.[9] To overcome this problem, relatively simple delivery systems such as creams or sprays were tested for sustained release of growth factors or cytokines, but in this context they were inefficient.[5,10] In recent years, research was done to find a biomaterial environment that preserves growth factor activity, entraps growth factors, and permits their controlled, local release into the surrounding tissue.[11,12] This strategy was expected to prevent the rapid clearance from the pharmacological site of application which is often observed. Key questions that need to be addressed for pharmacological intervention with growth factors are the following:

- how do we prevent rapid clearance of a growth factor signal?
- how do we preserve its activity?
- how can we translate a supranormal dose of exogenous growth factor signal into a local, physiological, tiny dose of active factor?
- which dose is optimal for which treatment site?
- how can we achieve this optimal dose?
- how can we maintain it over a prolonged period of time?

The aim of this chapter is to describe materials that are either of biological origin or are fully synthetic and are engineered to address the criterions listed above. Of the myriad of possible materials, promising candidate materials for growth factor delivery strategies would be hydrogels, as they are three-dimensional (3D) cross-linked polymers that are swollen by and typically comprise more than 95% water.[13] They have comparable mechanical properties to the naturally occurring extracellular matrix (ECM), allow the diffusion of nutrition, proteins, and respiratory gases, and can thus be considered good ECM mimetics (see **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**; **Chapter 2.211, Polymers of Biological Origin**; and **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**).[14,15]

To explain the principles of cell-demanded growth factor presentation, we focus on hydrogel-forming materials that have been extensively studied in the context of engineering growth factor release. Design principles that could potentially be used as 3D matrices, but so far have only been tested in 2D conditions, are not considered. We begin by describing the development of biologically derived and synthetic hydrogel platforms which might be used in different growth factor delivery strategies. Then, the benefit of these release schemes are exemplified in the context of treatment strategies for the induction of new blood vessel formation (angiogenesis).

4.427.1.2. Technological Motivation for Development of Biomaterial Mimetics of Natural ECM

Materials that are degradable by hydrolytic or proteolytic means and therefore only temporarily occupy space, subsequently giving way to in-growing cells, allow the formation of new tissue and mitigate problems with chronic foreign body responses. The use of such implant materials to incorporate bioactive molecules, followed by implanting them at the site of desired administration, is an attractive strategy for localized growth factor delivery. To become effective, this approach demands biomaterial schemes for growth factor administration that emulate biological principles of growth factor function and the cell biological basis that is necessary to produce functional tissue. Alongside their base function to protect the embedded factor from clearance and proteolytic inactivation, these biomaterial delivery vehicles must mimic the *in vivo* release mechanisms and profiles (**Figure 1(a)**).

Initially, clinically approved biomaterials such as α-hydroxy-ester-based polymers or alginates have been adapted for localized growth factor delivery (the reader is referred to other reviews[16,17] and references therein; **Figure 1(b)**). Release of growth factors from such polymer depots is either driven by passive diffusion, or coupled to the material degradation rate via ester hydrolysis, which occurs independently of ongoing biological activity and thus can be out of tune with the actual healing process. Such materials offer to adjust the release kinetics by varying the amount of growth factor admixed to the matrix or by altering the material degradation rate via material composition or structure. However, these measures for dosing often proved insufficient to synchronize growth factor levels with cellular demands at the healing site.[16] Moreover, these polymer preparations provide neither sites for biologically specific molecular interaction with the growth factor molecules embedded in the polymer, nor sites for specific interaction with cells at the target tissue. Thus, growth factor release kinetics and cell–material interactions are often poorly controllable.

In order to match the needs of the treatment site, a reciprocal signal exchange between the material and the recruited cells is desirable. Such a molecular 'dialogue' may be achieved by incorporating into the material biological, active moieties that can directly interact with cells or interpret cell-derived signals, for example, proteolytic activity at the target site.[18,19]

In the last decade, the design of new materials for drug delivery and tissue repair has been inspired by functionalities of natural ECM that provides a tissue repository for storage, protection, and cell-regulated release of growth factors. In essence, the natural ECM is a cell-secreted, protein- and glycosaminoglycan-rich scaffold that not only provides

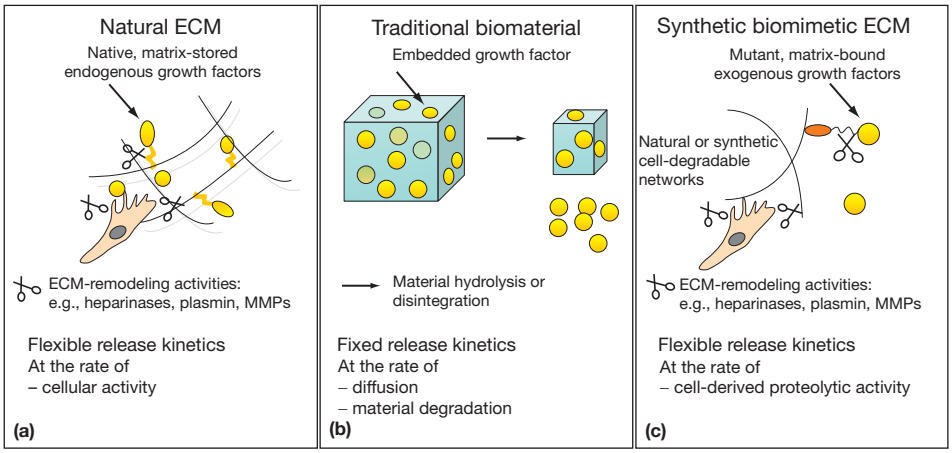

Figure 1 Biomaterials schemes for growth factor administration. (a) Many growth factors in the natural extracellular matrix (ECM) are matrix immobilized and released by local cellular activity. (b) In traditional biomaterials, growth factors are entrapped and released by diffusion and matrix degradation. (c) Matrix and growth factor engineering to control the distribution and release kinetics of growth factors.

mechanical stability but also plays a highly functionalized role in presentation and storage of biological signals, which contributes to tissue homeostasis, remodeling, and regeneration in case of injury. Our current view is that most endogenous polypeptide growth factors are not freely diffusible in tissues but are tightly associated with ECM components, such as heparan sulfate proteoglycans or fibronectin.[20] These assemblies between growth factors and matrix components are critical to stabilize the factors' active conformations, and serve as a depot of growth factors. Degradation of the matrix components by cellular enzymes such as heparinases or proteases then leads to the release of the growth factors in soluble form.[21] The preparation of both natural and completely synthetic materials with biological characteristics of the ECM has become central to tissue engineering approaches that aim to deliver growth factors in a therapeutically efficient mode and by more natural ECM-based mechanisms (**Figure 1(c)**).

4.427.2. Enabling Polymer Hydrogels for Cell-Demanded Release

As stated by Randy Pauch in his famous booklet *'The Last Lecture'* – engineering is not about the perfect solution but about the perfect solution with limited resources.[22] For a long time, the surgical material arsenal for potentially realizing cell-demanded release of growth factors from material implants was indeed very limited. In fact, growth factors were admixed to the bulk of materials or adsorbed onto the surface of scaffolds and were thus released in a largely uncontrolled fashion. For over a decade now, engineering of natural matrices and growth factors has enabled improved cell-instructive, biomimetic matrices.[23]

4.427.2.1. Collagen Engineering

Collagen matrices derived from tissue extracellular matrices have been successfully used in many tissue engineering applications, including improved endothelialization after coating vascular grafts with collagen matrices loaded and heparinized with basic fibroblast growth factor[24] (**Figure 2(a)**). Type I collagen forms highly porous networks with good adhesion and migration properties but exhibits poor binding capability for growth factors (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**). However, one of the major limitations of naturally derived matrices like collagen in engineering applications is their inherent biological properties such as susceptibility toward proteolytic enzymes that has hindered their use in clinical settings. In order to prevent rapid degradation of collagen matrices, they are cross-linked by *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide and *N*-hydroxysuccinimide. The resulting matrices were shown to be noncytotoxic *in vitro*[25] as well as *in vivo*.[26,27] Thrombogenicity of collagen in vascular graft coatings was even shown to be reduced after this cross-linking step.[28] Taking advantage of heparin's anticoagulation activity, protocols for its immobilization during the chemical cross-linking of the matrix were established (see **Chapter 2.216, Collagen–GAG Materials** and **Chapter 4.420, Drug Delivery via Heparin Conjugates**).[29,30] These engineered matrices prevented platelet adhesion and blood coagulation in response to collagen. They were additionally shown to recapitulate some of the retention and presentation properties of the naturally occurring ECMs toward growth factors. These biomimetic matrices have been employed to deliver basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) by controlled diffusion and matrix degradation, and in consequence to induce angiogenesis (**Table 1** and references therein). As preparation of these matrices relies on chemical cross-linking of heparin to the collagen fibers, their usage will be restricted to implant materials which are fabricated prior to application.

4.427.2.2. Fibrin Engineering

Fibrin is a natural polymer that forms by polymerization of activated fibrinogen during blood coagulation and plays an important role as provisional matrix in homeostasis and wound healing (see **Chapter 2.217, Fibrin**). In the wound, fibrin serves as a provisional platform for the infiltration of cells from neighboring tissues during the repair process. Fibrin is nontoxic, and various biomedical-grade 'fibrin glues' are

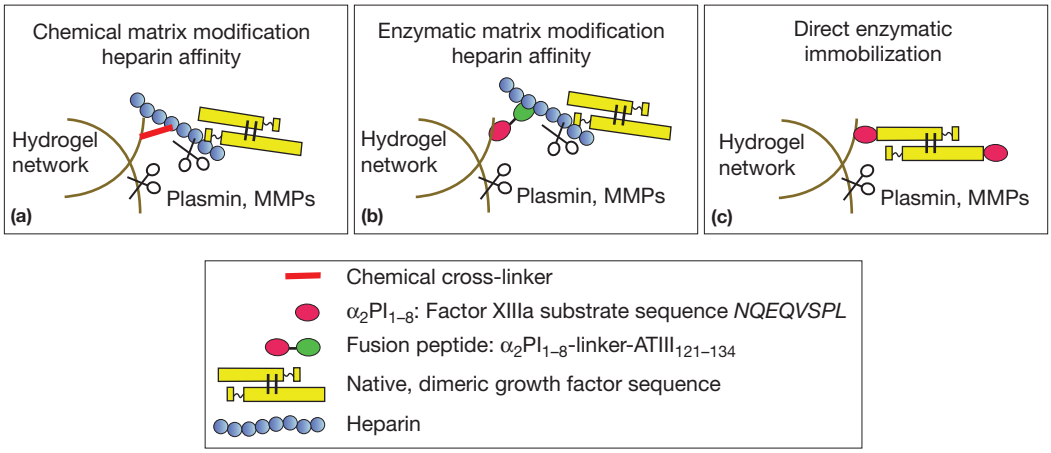

Figure 2 Engineering of biologically derived polymers. Heparin is retained within the matrix (a) by chemical cross-linking or (b) by matrix-bound heparin-binding peptides. (c) Engineered growth factors are covalently tethered to the matrix.

accepted for clinical application.[39] Fibrin can be applied clinically as an injectable matrix, which can be readily formed by mixing solutions containing fibrinogen, thrombin, and the transglutaminase factor XIII (FXIII) directly at the site of therapeutical need. First, a physically linked gel is formed through thrombin-mediated conversion of soluble fibrinogen to fiber-forming fibrin, which is subsequently stabilized by FXIII-mediated cross-link formation between fibrin fibers. Under physiological conditions, the transglutaminase FXIII is also responsible for tethering of α2-plasmin inhibitor to the fibrin network. While fibrin provides many qualities desired for healing, in its natural form it provides no or low binding affinity for growth factor proteins. Thus, initial success to use fibrin as a matrix to deliver growth factors has been limited to physical growth factor entrapment and release.

In 1999, a new technology was reported that permits cell-demanded release of exogenous bioactive (polypeptide) factors, including growth factors, in the context of the biological matrix fibrin[40–44] (**Figure 2(b)** and **2(c)**). Exogenous peptides or proteins that are produced as fusion peptides or proteins with the specific eight-amino acid substrate sequence NQEQVSPL, derived from α2-plasmin inhibitor (α_2PI_{1-8}), at their N-terminus can be covalently attached to fibrin during the coagulation process through transglutamination by factor XIIIa (FXIIIa) enzymatic action.[43] Fibrin matrices containing these tailored immobilized proteins can then serve as depots, be proteolytically remodeled by invading cells, and thus represent excellent candidate vehicles for the delivery of biologically active proteins prompted by cell invasion and associated enzymatic activity.

The two principally distinct schemes for growth factor incorporation into fibrin are summarized in **Table 2**: the linkage of the heparin-binding growth factors to modified fibrin decorated with heparin (**Figure 2(b)**) and the covalent incorporation of the otherwise diffusible growth factors (**Figure 2(c)**) modified with NQEQVSPL sequence.

The first principle mimics the growth factors' natural presentation modality through heparan sulfate proteoglycans in the ECM (see **Chapter 4.420, Drug Delivery via Heparin Conjugates**). It is on the basis of the affinity-based interaction of heparin (**Figure 2(b)**) with a modified fibrin matrix and an electrostatic interaction of growth factors with natural affinities for heparin.[46,55] To accomplish the heparin immobilization, a synthetic bidomain peptide consisting of a heparin-binding peptide derived from both antithrombin III and the α_2PI_{1-8} domain is covalently incorporated into fibrin during the coagulation process.[41] When heparin is added simultaneously into the mixture before coagulation, a matrix rich in heparin is created. A growth factor entrapped within this matrix would then interact with the incorporated heparin molecules and be

retained within the matrix.[46,55] The release of heparin-bound proteins from such engineered fibrin matrices is based on enzymatic matrix degradation by fibrinolysis, heparin degradation by heparinases as well as dissociation from heparin, and subsequent diffusion of the growth factor out of the gel. Using the protein's intrinsic affinity for heparin is an elegant strategy, which however is limited by the highly variable binding efficiency among different growth factors. This strategy has also been employed with other naturally derived polymers, such as gelatine and chitosan,[72] and has been recently extended also to semisynthetic and fully synthetic materials platforms.[73,74]

In the second design, the engineered growth factor molecules are directly linked to the fibrin backbone by the enzymatic activity of FXIII.[40,44] The tethered growth factors are presented to invading, fibrin-remodeling cells and are eventually liberated by bulk matrix degradation (**Figure 3(a)**). The rate of release is dependent on the activity of locally recruited cells, which on their surface secrete and activate fibrinolytic enzymes such as matrix metalloproteinases (MMPs) or plasmin. This mode of growth factor presentation, which relies on the disintegration of the fibrin matrix, can thus be considered a slow and cell-dependent one. Through the introduction of a plasmin-susceptible linker domain between the tether and the growth factor domain, protein release may be achieved not only by the cleavage of the matrix network itself but also by cleavage of the fibrin-coupling domain. As the release will be faster because of two simultaneous mechanisms, it can be considered an accelerated cell-demanded mechanism[51] (**Figure 3(a)**). This differential susceptibility to local proteolysis as a consequence can be applied in materials with different programmable and predictable growth factor release rates, which might be desired for controlled delivery of growth factors in experimental or clinical settings. The direct tethering of growth factors to fibrin, although an appealing and feasible approach, suffers the major limitation that growth factors that are employed to confer the biomaterial with biological activity must use time and labor-intensive procedures to genetically engineer and recombinantly express their modified forms.

4.427.2.3. Polysaccharide-Based Semisynthetic Materials

Polysaccharides, such as hyaluronic acid (HA), heparin, and alginate, are largely nontoxic materials with good biocompatibility that are present in living organisms and used in many different biomaterials design concepts.

Besides fibrous proteins, HA represents a major component of the ECM. HA consists of repeating units of glucuronic acid with *N*-acetyl-D-glucosamine with an average molecular weight between 100 and 5000 kDa[75] and is well known as a highly biocompatible polymer (see **Chapter 2.214, Hyaluronic Acid**). HA by itself has no known functionalities that facilitate the chemical binding and presentation of therapeutic growth

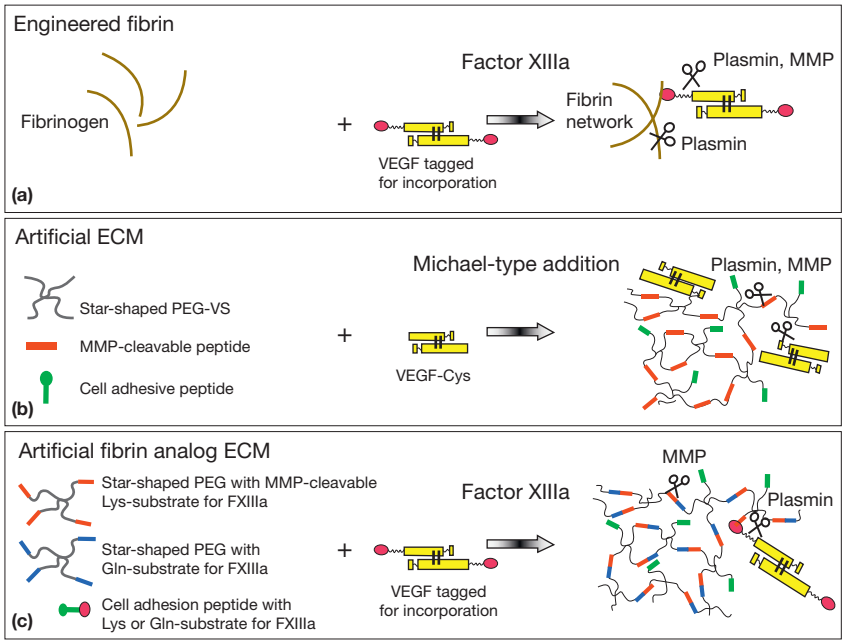

Figure 3 Engineering of synthetic biomaterials. (a) Tethering of engineered growth factors by FXIIIa enzymatic reaction to fibrin. (b) Free cystein (Cys) containing growth factors are chemically immobilized during Michael-type reaction-controlled PEG–hydrogel formation. (c) Artificial fibrin analog, PEG-based matrices are formed by FXIIIa. Engineered growth factors are simultaneously tethered to the matrix.

factors. Introducing known binding functionalities for growth factors would make these sugar-based materials more versatile biomaterials. Many attempts have been made to functionalize HA with chemical groups to modify it with synthetic polymers or bioactive signals (for review see Yadav *et al.*[76]). For example, HA modifications with thiol residues to enable cross-linking with PEG via Michael-type reactions have been described.[77] The same reaction was simultaneously used to decorate the forming HA-PEG hydrogel with biologically active components such as heparin and gelatin in a thiol-specific fashion.[77,78] Trace amounts of heparin were demonstrated to confer the HA-PEG materials with reasonable binding properties for heparin-binding growth factors.[78]

Protein-free scaffolds based on PEG and a noncovalent assembly of peptides with heparin have been used to study the delivery of growth factors. Such materials were formed by blends of heparin-functionalized and ATIII-peptide-functionalized four-arm star PEG polymers.[74,79–81] As these injectable materials form via affinity interactions, they are reversible and might mediate not only the retention but also the activity of growth factor molecules. The advantage of using the heparin affinity to control growth factor delivery is that naturally occurring molecules can be readily employed and time- and cost-intensive protein engineering can be avoided. However, such a system relies on the protein's affinity for heparin which might be limited and highly variable among different growth factors. Semisynthetic release systems relying on heparin binding affinity of growth factors are summarized in **Table 3**.

4.427.2.4. Fully Synthetic ECM Mimetic Hydrogels

As biologically derived polymers are difficult to engineer and bear the risk of disease transmission or induce immunological reactions, they are frequently substituted with fully synthetic materials for tissue engineering. Ideally, such materials are biocompatible and can be engineered toward specific applications, for example, by varying the building block composition. Initially, synthetic materials that interacted only moderately with cells in culture or in the living tissue were employed. A major stride has been made by introducing peptide building blocks or even recombinant proteins into synthetic hydrogels.[86–89] This allowed not only to control the physical and chemical properties of man-made materials but also to instill biological function into them. Introduced functions include integrin binding sites[90,91] and sequences susceptible toward cell surface-localized proteases.[18,19,92] That these materials can recapitulate some properties of the cell-derived polymeric ECM was demonstrated by 3D cell culture experiments. Cell spreading, migration, and proliferation in these fully synthetic matrices relied on the presence of the prototypic integrin binding peptide RGD and also MMP-sensitive linker peptides, proving that cell adhesion and matrix degradation were achieved.[18] The provisional character of the matrix was further demonstrated by its complete remodeling and replacement with native ECM in the context of bone regeneration.[19,93]

Attempts to control growth factor delivery from synthetic, ECM-mimicking materials are summarized in **Table 4**. Initial approaches relied on the incorporation of free cysteine-containing growth factors using thiol-specific Michael-type reactions, which also drive cross-linking of the matrix, to form cell-instructive matrices[98] (see **Figure 3 (b)**). Release of covalently bound growth factors in this system is coupled to the material degradation rate, tuned properly to the local cellular activity and thus considered as cell controlled.

4.427.2.5. Fully Synthetic Fibrin Mimetic Hydrogels

Formation of matrices and incorporation of growth factors by chemical means might compromise the bioactivity of cell surface molecules and more importantly the protein cargo. Recently, a scheme has been established that relies on cross-linking of synthetic hydrogel matrices under physiological conditions by a FXIIIa-catalyzed enzymatic reaction[100–104] (**Figure 3(c)**). In one example, the material is composed of equimolar blends of star-shaped poly(ethylene glycol) (PEG) precursors that are functionalized with either the FXIIIa-specific substrate Lys (AcFKG)[101] or Gln (NQEQVSPL) sequence.[43] On addition of the enzyme, the matrix is formed, and simultaneously any protein or peptide carrying a FXIIIa-specific sequence can be immobilized within the matrix.[99] This design principle now allows the site-specific tethering of growth factors to the fully defined synthetic matrix as described above for the clinically relevant fibrin. By this scheme not only is the bioactivity of growth factors preserved but the release properties can also be flexibly and reproducibly controlled, namely, by (i) controlling the matrix cross-link density, (ii) engineering the matrix susceptibility toward proteolytic remodeling, and (iii) using different immobilization strategies. As release profiles can thus be tuned almost independently of the physical, chemical, and other biological properties, this new material might be interesting for future clinical applications.

4.427.3. Preclinical Evaluation in Angiogenesis

It is becoming increasingly evident that not only do appropriate biological signals need to be presented, but also that their spatiotemporal mode of presentation and combinations of several signals are necessary for proper induction of new and functional tissues.[15,105] Novel biomaterials concepts, developed to match some of these demands, will have to confirm the beneficial outcome in clinically relevant situations. One demanding application that is at the same time optimal for the rigorous evaluation of controlled growth factor delivery systems is the need to control angiogenesis. As outlined below, disturbed or insufficient angiogenic functions are involved in many diseases and await improved intervention modalities. In most of the sites requiring angiogenesis, the presence of body fluid will contribute to dilution, diffusion,

and eventually proteolytic inactivation of the therapeutically administered growth factor using conventional treatments.

4.427.3.1. Clinical Need for Angiogenic Therapy

Impaired vessel function, disrupting normal blood supply (ischemia), and consequently producing deficient functions of the heart or limbs, as well as hindering chronic wound healing, remains a major medical problems in societies with Western lifestyles and demographic shifts to longer life span. While improved surgical and minimally invasive interventional procedures (e.g., percutaneous transluminal balloon angioplasty or stent application, or the restoration of tissue perfusion pathways, e.g., by coronary artery bypass surgery) to restore blood supply in underperfused regions of the heart or leg have helped to decrease the mortality rates, the prevalence of ischemia has increased.[106] In many patients with tissue ischemia, for example, in the lower extremities in peripheral vascular disease, or in coronary artery disease, the intrinsic capacities for spontaneous tissue repair appear to be severely compromised, for reasons that are not understood at present. Multiple deficits may be responsible for inadequate regeneration of functional vasculature in ischemic patients, including (i) insufficient levels of endogenous angiogenic growth factors; (ii) disease- or age-related changes in cell metabolism, and an imbalanced production of angiogenic growth factors that have complementary functions in the initiation of vessels and their subsequent maturation into a stable vasculature; or (iii) an inability of cells to rebuild an extracellular microenvironment that fulfills its natural function as a site of growth factor-mediated cell signaling. As these causes may be coupled, the ischemic and chronic wound conditions present complex challenges for healing therapies. Therefore, prevention and treatment of ischemia represents an important goal. Tissue engineering has emerged as a significant potential alternative to conventional therapies of tissue or organ failure by surgical repair, transplantation, or mechanical devices.

4.427.3.2. Lessons from Embryonic Development and Early Therapeutic Angiogenesis Research

The establishment of a vascular supply is an important process not only during embryonic development but also in the adult, for wound healing or female reproductive functions.[107,108] Blood vessel formation in development is initiated by an assembly of endothelial progenitor cells (EPCs) into a primitive vascular network (vasculogenesis), which is expanded by sprouting or intussusceptive angiogenesis and finally remodeled by flow-driven mechanisms (arteriogenesis) that are not well understood at this point. These processes are regulated by various families of growth factor ligands that act through paracrine signaling by activating tyrosine kinase receptors, expressed on endothelial cells and supporting vessel wall cells. The most prominent growth factors tested in therapeutic angiogenesis regimens are VEGF-A, placental growth factor (PlGF), angiopoietin 1 (Ang 1), platelet-derived growth factor B (PDGF-B), FGF, and ligands of the ephrin family.

VEGF, initially regarded as the most promising entity, was shown to mediate blood vessel formation by chemotactic recruitment of EPCs or endothelial cells to the sites of neovascularization.[109] It promotes the differentiation of EPCs as well as the proliferation of endothelial cells. In tumors, the secretion of superphysiological levels of VEGF among other proangiogenic factors, in a phenomenon called angiogenic switch, attracts new blood vessels.[110,111] In common with tumors, the administration of superphysiological doses of exogenous VEGF induces the formation of supernumerary vessels. These vessels tend to be malformed and leaky, which in consequence cause edema and compromise the function of the tissue. Recent findings demonstrate a clear relationship between the morphology of newly formed vessels and the rate of VEGF release.[112] Additionally, neovessels are absolutely dependent on continuous long-term VEGF presentation to become patent and lasting.[113,114] On the basis of this knowledge, VEGF seemed to be an ideal candidate to prove the efficiency and functionality of the cell-controlled growth factor delivery.

4.427.3.3. Cell-Demanded Release in Vascularization

Synthetic and fibrin-based implants supplied with angiogenesis-stimulating growth factor signals were explored to promote regeneration of vascular-deficient tissue *in situ*.[115] Such provisional tissue replacement materials, formed directly at the site of therapeutic need, deliver biological signals to stimulate the body's own repair mechanisms to grow its cells into functional tissue, and might be valuable tools for a therapeutic treatment in regenerative medicine known as *in situ* tissue engineering.[116]

To this end, engineered growth factor variants were created with the eight-amino acid N-terminal domain (α_2PI_{1-8}) fused either directly (α_2PI_{1-8}–$VEGF_{121}$)[44,49] or in front of a plasmin-sensitive sequence linker (α_2PI_{1-8}–Pla–$VEGF_{121}$)[51] to the N-terminus of native variant $VEGF_{121}$ (**Figure 4(a)–4(c)**). These modified growth factors were readily incorporated into fibrin or synthetic fibrin analogs, whereas the native protein was unbound and therefore washed out rapidly in an aqueous environment. Biochemical analyses of the $VEGF_{121}$-modified cell-instructive the fibrin matrices, combined with mathematical modeling, confirmed that the release rate is controlled by plasmin susceptibility of the fibrin matrix and the linker peptide.[51] Thus, matrices with predictable and differential $VEGF_{121}$ release profiles could be generated by the use of (i) native $VEGF_{121}$ (burst diffusion-controlled release) (**Figure 4(a)**), (ii) α_2PI_{1-8}–Pla–$VEGF_{121}$ (accelerated, cell-demanded release) (**Figure 4(b)**), or (iii) α_2PI_{1-8}–$VEGF_{121}$ (slow, cell-demanded release) (**Figure 4(c)**). Cell culture and chick chorioallantoic membrane (CAM) experiments demonstrated that neither the method of matrix incorporation nor the plasmin-mediated liberation compromised the growth factor's activity.[49] More importantly, however, the kinetics of VEGF presentation to the CAM resulted in newly formed vascular networks that were (i) tumor like and of chaotic nature, in the case of fast VEGF release, (ii) largely disturbed in the case of intermediate release, and (iii) mostly well formed and with good integrity of the vascular basement membrane when VEGF was presented in a sustained, slow fashion. Subcutaneous murine implants confirmed that the balanced and prolonged presentation of the VEGF protein induced the formation of more mature and leakage-resistant blood vessels compared to the rapidly released factor.[49] This

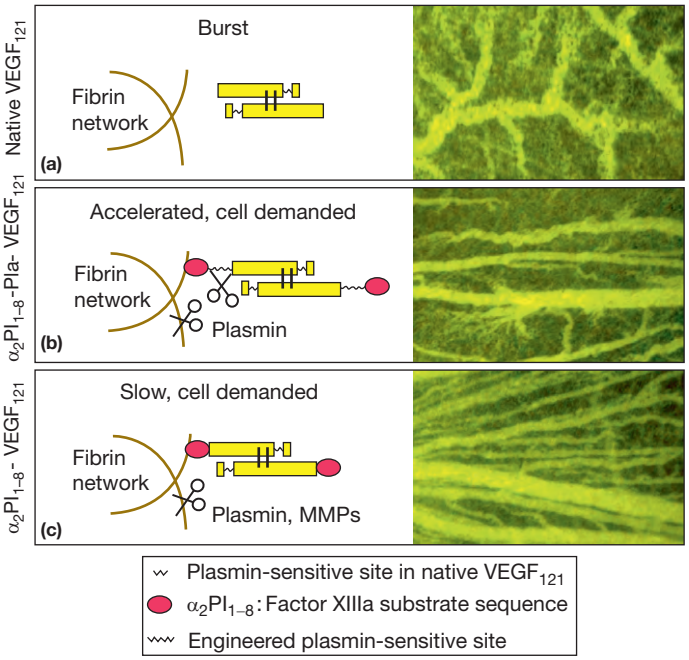

Figure 4 Therapeutic angiogenesis assay on the chick chorioallantoic membrane comparing fibrin scaffolds with different release regimen. (a) Native $VEGF_{121}$ entrapped in fibrin matrices is released by diffusion and induces malformed new vessels. (b) Cell-demanded accelerated release of $VEGF_{121}$ by matrix and linker cleavage results in vessels of better quality. (c) Slow, cell-demanded release of $VEGF_{121}$ by matrix degradation results in higher vessel number of 'good quality.'

observation is most likely because of the more balanced expression and activation of the differentially signaling VEGF receptors VEGFR1(Flt) and VEGFR2 (KDR). In experiments exceeding 3 weeks, slowly delivered VEGF proved to be more efficient in inducing blood vessels that were also more mature.[50] Yet, the newly formed vessels, independently of their stabilization, regressed at later time points, most likely because of a lack of metabolic need. In these experiments, exhaustion of the exogenous VEGF signal cannot be excluded. Thus, materials with a longer lifetime, which provide more rigorous control over VEGF over time, need to be evaluated in therapeutically relevant preclinical settings.

In conclusion, materials that provide sustained low-level presentation of VEGF might be employed to stimulate new blood vessel formation and induce the formation of stable and patent vessels. As their *in vivo* stability might largely influence the biological outcome, systems with a larger freedom to engineer the materials properties with respect to *in vivo* lifetime and growth factor release rate might be desirable.

4.427.4. Conclusion and Future Directions

The release of single growth factors by a relatively simple delivery regimen has been shown to enhance regional revascularization in preclinical and, to some extent, clinical trials. In clinical trials, the only marginal improvement in response to treatment could partially be explained by the nonideal delivery modalities of growth factors. As the biological demand might only be insufficiently matched regarding duration, amount, and activity of the presented growth factor, improved delivery devices and modalities were explored. Besides the elaboration of materials that can be loaded with defined quantities of protein and their release in a diffusion- and material-degradation controlled manner, protein engineering strategies were followed to generate novel classes of materials containing naturally derived and/or synthetic components.

One appealing way to control the release profile of growth factors is the immobilization of growth factors within hydrogel materials by covalent or high-affinity interactions. Such materials platforms have growth factor storage and presentation characteristics comparable to those of the natural ECM. In this context, the immobilization of locally produced factors and their slow but continuous exposure to neighboring cells under homeostatic conditions or in response to tissue remodeling are important. Many of the now-available materials schemes rely on the high-affinity interactions between growth factors and heparin. Through tethering of heparin molecules to the backbone of a matrix, hydrogels are obtained that readily bind several growth factors albeit with different efficiencies. A more reproducible way of immobilizing growth factors in a hydrogel matrix, but at the expense of labor-intensive recombinant protein production, is the covalent tethering of bifunctional factors to the material. Release of the growth factors from such matrices was shown to be controlled by site-directed, cell-mediated proteolysis. Initial studies exploring cell-mediated delivery of angiogenic, neurogenic, and osteogenic growth factors proved that these factors are delivered in a balanced and active manner. In the case of angiogenesis using this regimen, even singular VEGF therapy successfully induced morphologically integer vessels, whereas conventional delivery induced vessels that were malformed and leaky. These findings indicate that

cell-mediated protein delivery might not only improve efficiency but also safety of growth factors treatments, and in the future could be useful for therapeutic applications.

Delivery strategies at this stage are established only for a limited number of growth factors. The binding affinities of many growth factors and cytokines to heparin are not yet known and the fraction of proteins binding with high affinity cannot be estimated. The covalent tethering of growth factors relies on cloning, expression, and purification of every individual protein. For these reasons, it would be valuable to have a more versatile and broadly reliable release regimen available. Materials platforms should be developed, which can be applied to immobilize and present a large spectrum of proteins. Ideally, such platforms would allow the use of commercially available proteins. As biological events are tightly regulated by time and spatially controlled expression of different growth factors, engineering strategies should aim at mimicking such staged or simultaneous release. In order to make protein-presenting hydrogels relevant tools to study fundamental biological questions such as haptotaxis, and composition and function of tissue-specific niches, sequential or even trigger inducible release of factors would be desirable (see **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**). Furthermore, strategies developed for protein delivery might best be combined with those for gene delivery, or even common shared platforms might be of interest. Because of their high flexibility in design, fully synthetic matrices could be an ideal basis to create both protein and gene delivery platforms to control growth factor and cytokine distribution in time and space.

Acknowledgments

We would like to thank Prof. M.P. Lutolf for fruitful discussions and critically reviewing the manuscript. This work was supported by grants from the Swiss National Science Foundation (No. CR3213-125426/1) and the European Community's Angioscaff Program contract No. 214402.

Glossary

BET analysis An analysis based on the theory proposed by Brunauer, Emmett, and Teller in 1938 to determine the specific surface area of a material.

Biocompatibility The ability of a material to perform its desired function without eliciting any undesirable local or systemic effects.

Burst release A rapid release of more than 50% of drug within 24 h.

Isoelectric point The pH at which a particular molecule or surface carries no net electrical charge.
Mesoporous materials Materials containing pores with diameters between 2 and 50 nm.
Microporous materials Materials containing pores with diameters smaller than 2 nm.
Xerogel A gel dried at a temperature close to room temperature and under atmospheric pressure.

Abbreviations

APTES	Aminopropyl(triethoxy)silane
BSA	Bovine serum albumin
DMDES	Dimethyl(diethoxy)silane
ETES	Ethyl(triethoxy)silane
HLB	Hydrophile–lipophile balance
MTES	Methyl(triethoxy)silane
NMR	Nuclear magnetic resonance
PCL	Poly(caprolactone)
PDMS	Poly(dimethylsiloxane)
PEG	Poly(ethylene glycol)
PEI	Poly(ethyleneimine)
PNIPAAm	Poly(*N*-isopropyl acrylamide)
PTES	Propyl(triethoxy)silane
PVI	Poly(vinylimidazole)
TEOS	Tetraethoxysilane
TGF-β1	Transforming growth factor-β1
TMOS	Tetramethoxysilane

Symbols

C_{max} Maximum safe concentration
C_{min} Minimum effective concentration

4.428.1. Introduction

Therapeutic drugs, once administered, should be present in a concentration between the minimum effective concentration (C_{min}) and the maximum safe concentration (C_{max}) in blood, lest full efficacy is not achieved or side effects may occur. Typical systemic drug administration procedures, such as direct injection, inhalation, or ingestion, usually result in an inefficient bolus delivery and may need multiple administrations to avoid toxic plasma concentrations. Oral delivery and injection, which are the typical routes for drug administration, do not easily allow to control the rate of drug adsorption or do not enable to easily reach the target tissue of therapeutic interest, and are often associated with an immediate and rapid drug concentration spike. Consequently, the initial concentration of the drug in the body peaks above the level of toxicity and then gradually diminishes over time to an ineffective level. The duration of therapeutic efficacy then becomes dependent on the frequency of administration and the half-life of the drug. High dosages of drugs are often administered to achieve an effective blood concentration.

Controlled release systems can maintain the levels of therapeutic agents within the effective range, can reduce spread to undesirable sites, can avoid toxic side effects, and can enable more optimized drug dosage by virtue of increasing bioavailability and therapeutic index of the drug molecule. With these systems, drug levels in blood can follow 'constant' profiles between C_{min} and C_{max} for extended periods of time. Depending on the formulation and the application, this duration can vary from 24 h to 1 month to 5 years (in case of certain implants). This unique aspect of controlled release systems helps reduce the number of drug administrations required during a specific treatment.

One of the first principles underlying controlled drug delivery was to provide for a desirable near constant safe drug concentration at the site of action for prolonged durations. In addition, controlled release also offers numerous other advantages over systemic drug administration, such as protection of fragile drugs and increased patient compliance and convenience. It is also worth mentioning that controlled release systems can be utilized to target the release of the drug to the precise site of action within the body. For example, a drug molecule that acts on a receptor in the brain will not be effective if it is distributed by the patient's blood system without being able to cross the blood–brain barrier. Suitable controlled release materials loaded with such drug molecules and implanted inside the brain will allow drug molecules to be released at site of action.

An ideal drug delivery system must be biocompatible with human tissue, capable of achieving high drug loading, free from accidental leakage, and easy to fabricate. Many biocompatible materials including liposomes,[1] polymers,[2,3] and sol–gels[4,5] have been proposed as controlled release systems. Among these controlled release systems, the sol–gel processed oxides are biodegradable and biocompatible materials. They can also be made in a bioactive form. Unlike polymeric drug carriers, the sol–gel silica only elicits a minimal inflammatory response.[6,7] Also by nature of its simple processing conditions, various therapeutic agents can be homogenously incorporated in the nanoporous sol–gel silica.[7–12]

The nanostructure of sol–gel silica can be extensively and reproducibly varied by careful alteration of various processing related parameters. The variation in structure of sol–gel materials affects the release kinetics of the incorporated drug molecules, which in turn provides excellent control of the release profile.

Since the mid-1980s, when Avnir showed that the sol–gel process could be used to entrap dye molecules, the sol–gel process was first considered as no other than as expensive, fancy

glass making technique, useful to functionalize glass with organic molecules.[13] The same investigators continued to pursue the entrapment or immobilization concept with sol– gel materials. Thus, enzymes were entrapped in the sol–gels, and high retention of activity was reported in the early 1990s.[14–16] When entrapped in the sol–gel material, the enzymes were intended to function as biocatalysts within the sol–gel matrix. The entrapment of living organisms such as cells or bacteria was explored later using the same rationale.[17–20]

The use of sol–gel for the controlled release of incorporated molecules, a conceptually diametrically opposed idea for keeping molecules entrapped, did not emerge until the mid-to-late 1990s.[8,9,21–26] The demand for controlled, prolonged release of therapeutic agents started to pick up in pharmaceutical industry, and the quest for better matrix materials has brought sol–gel materials to the controlled release arena.

Many biocompatible oxides have been synthesized with the sol–gel method and used as controlled release systems. Sol–gel processed titanium dioxide (TiO_2) with porous structure was used to incorporate drug molecules inside the pores first, followed by controlled release thereafter.[27–30] Sol–gel processed TiO_2 containing an anticonvulsant drug (valproic acid) has been tested for the control of epileptic seizures in the temporal lobe of the brain.[29] Also a composite comprising sol–gel-derived TiO_2 and poly(ε-caprolactone) (PCL) was used for controlled drug delivery.[31] Sol–gel processed hydroxyapatite can also be used as a controlled delivery material.[32] Hydroxyapatite can further be coated with sol–gel silica to provide better control on the release of incorporated molecules. A hydroxyapatite/sol–gel silica composite was used to impregnate drug[33,34] and compared with hydroxyapatite and sol–gel silica materials alone. It was found that the composite material prevented rapid release and showed a prolonged release profile.[33] Among many sol–gel processed oxides that have been studied for their potential use as a controlled release carrier, sol–gel processed silica has been most thoroughly explored for applications as a controlled release material.

Herein, we focus extensively on sol–gel processed silica to illustrate the benefits and to elucidate the structure–property–processing relationships of sol–gel oxides as controlled release system. In this chapter, we discuss the general sol–gel process and the biocompatibility of the sol–gel oxides. As a control release system, the release kinetics of the incorporated molecules is discussed. Following the discussion regarding the effect of physical and chemical processing parameters of sol–gel-derived oxides on drug release kinetics, we review the applications potential of these materials in the controlled release arena. In the last section, we also summarize various applications that are being pursued with sol–gel oxides as controlled release system for pharmaceutics and biological molecules.

4.428.2. Sol–Gel Process

4.428.2.1. Overview

Although other sol–gel materials such as titanium oxide or hydroxyapatite have been tried for controlled release application,[35] silica sol–gel has been studied most extensively as a controlled release material in no small reason because it can be processed uniquely at room temperature. While traditional sol–gel processed materials will invariably include a sintering step intended to densify the material and achieve higher strength, the sintering step is conceptually deleterious when sol–gel processed silica would be used for controlled release. In fact, most therapeutically active molecules are unstable at higher temperature. Although mechanical properties are less critical in this application, the very fundamental inclusion of sintering in the classical processing of sol–gels rendered this departure of omitting sintering a nonobvious and failure prone approach.

The sol–gel process has been extensively studied during the 1980s–1990s. In this section, we briefly introduce the sol–gel process for silica used to synthesize controlled release sol–gels. Readers who are interested in more detail about the sol–gel process at large are referred to *Sol–Gel Science* by Brinker and Scherer, which deals with the general physical and chemical principles of sol–gel processing.[36]

In a typical sol–gel process, silica precursors (organosilanes), such as tetramethoxysilane (TMOS, $Si(OCH_3)_4$) or tetraethoxysilane (TEOS, $Si(OC_2H_5)_4$), are subjected to a hydrolysis–condensation reaction to form a colloidal suspension of silica particles, subsequent to which the particles condense in a new gel phase. The hydrolysis reaction, which can be either acid or base catalyzed, replaces alkoxide groups of organosilane with hydroxyl groups. Siloxane bonds (Si–O–Si) are formed during the subsequent condensation reaction. Alcohol and water are byproducts of the condensation reaction and evaporate during drying. In general, drugs are added to the liquid sol after hydrolysis. During condensation, the drugs are homogenously incorporated within the silica xerogel (a xerogel is a sol–gel processed material not or not yet subjected to sintering).

Different reaction rates of hydrolysis and condensation, especially the relative rates of hydrolysis and condensation, influence the silica particle formation. The nanostructure of sol–gel silica can be extensively varied in a controlled manner by selecting different processing parameters, including the pH of the sol and the water/alkoxide molar ratio, and by selecting various additives.[36,37] For example, the silica matrix has a microporous structure with a pore size smaller than 2 nm in case of hydrolysis under acidic conditions, while a mesoporous structure with a pore size range from 2 to 20 nm can be obtained under alkaline catalysis conditions. It is a logical concept to consider that the release kinetics of the drug molecules can be influenced by the variation in nanostructure of silica xerogel thus achieved by varying the processing.[38]

4.428.2.2. Hydrolysis

The hydrolysis occurs by the nucleophilic attack of the oxygen contained in water on the silicon atom of the organosilane. The hydrolysis is most rapid and complete when catalysts are employed. Many researchers have reported that mineral acids are more effective catalysts than an equivalent concentration of base.

Under acidic conditions, the alkoxide group (OR) is protonated, which makes the silicon more electrophilic and susceptible to attack by water. All strong acids behave in a similar way as the hydrolysis is a first-order reaction, while weak acids

require a longer time for the hydrolyzation. In acid-catalyzed reactions, the hydrolysis rate is increased by alkyl groups with less steric hindrance around silicon (i.e., hydrolysis of TMOS is much faster than TEOS).

Under basic conditions it is likely that water dissociates to produce nucleophilic hydroxyl anions in a rapid first step. The hydroxyl anion then attacks the silicon atom and liberates the alcohol. Similar as acid-catalyzed hydrolysis, the steric factor also affect the hydrolysis rate and the base-catalyzed hydrolysis reaction is also dependent on catalyst concentration.

Sonolysis is an alternative method to promote hydrolysis without acid or base catalysts. By subjecting the silica precursor and water mixture to ultrasonic vibration, active radical species are formed. Such active radical species, derived from silica precursors ($(OR)_n(OH)_mSiO^{\bullet}$ and $(OR)_n(OH)_mSi^{\bullet}$ $(m+n=3)$) reacts with an active radical species from water ($H^{\bullet}$ and $^{\bullet}OH$) to form a $Si(OR)_n(OH)_m$ $(m+n=3)$ such as hydrolyzation pruduct.[39] Sol–gels prepared through sonolysis are commonly referred as sonogels. Sonogels have been tested for their feasibility as pharmaceutical delivery systems.[40] However, concern that the ultrasonic irradiation, which is necessary for producing the radical species, may damage the incorporated sensitive drug molecules has limited the pursuit of this processing method to produce controlled release materials.

No matter what condition, the overall hydrolysis reaction is given by the reaction:

$$Si(OR)_4 + 4H_2O \rightarrow Si(OH)_4 + 4ROH \qquad [I]$$

4.428.2.3. Condensation

Condensation is the polymerization process that creates siloxane bonds.

The condensation reaction is as below:

$$Si(OH)_4 \rightarrow SiO_2 + 2H_2O \qquad [II]$$

Under acidic condition, the condensation involves protonated silanol species. The protonation of silanol makes the silicon more electrophilic and thus more susceptible to nucleophilic attack. Under basic condition, the condensation reaction involves the attack of nucleophilic deprotonated silanol on a neutral silicate species.

The condensation rate is highly affected by the pH condition. The maximized condensation rate can be achieved around pH 7.0 where both protonated and deprotonated silanols are highest in concentration, while the minimum condensation rate is found around the isoelectric point (pH ~2.0).

The overall sol–gel process is as follows:

$$nSi(OR)_4 + 2nH_2O \rightarrow nSiO_2 + 4nROH \qquad [III]$$

Condensation reactions (eqn [II]) involving the silanol groups (Si–OH) produce siloxane bonds (Si–O–Si) plus the by-products water or alcohol. Under most conditions, condensation commences before hydrolysis is complete. However, conditions such as, pH, H_2O/Si molar ratio (R), and catalyst can force completion of hydrolysis before condensation begins. Additionally, because water and alkoxides are immiscible, a mutual solvent such as an alcohol is utilized. With the presence of this homogenizing agent, alcohol, hydrolysis is facilitated due to the miscibility of the alkoxide and water. As the number of siloxane bonds increases, the individual molecules are bridged and jointly aggregate in the sol. When the sol particles aggregate, or inter-knit into a network, a gel is formed. Under acidic conditions, the most basic silanol species are most likely to be protonated. Therefore, condensation reaction may occur preferentially between neutral species and protonated silanols situated on the end groups of chains. As the result, the final gel is mostly an extended, weakly branched structure. Under alkaline condition, as most acidic (deprotonated) silanols resides in the middle of the chains, the condensation is directed toward the middles rather the end of the chains, leading to more compact higher branched structures.

The condensation in gels continues long after gelation, due to large amount of unreacted silanol groups. Aging is an extension of the gelation step in which the gel network is reinforced through further condensation. The gel matrix shrinks due to the expulsion of solvent, called syneresis, and this takes place during drying.

Depending on the condensation conditions, the final sol–gels have different structures. Sol–gels that condensed in acidic conditions generally acquire low-porosity microporous (smaller than 2 nm) pore structures and the sol–gels that condensed under basic condition have mesoporous pore structures.

During the hydrolysis of TEOS or TMOS, a significant amount of alcohol is liberated, which may denature the incorporated protein molecules. This problem can be overcome by using aqueous precursors of silica such as sodium silicate, silicic acid, or glycerated silanes.[41,42] This procedure mimics the biogenic silica formation (biosilicification) in aqueous environment with the dilute silicic acidic $Si(OH)_4$ solutions. In such a way, living organisms such as cell and bacteria can be safely encapsulated in the silica matrix.[43]

4.428.2.4. Physicochemical State of Sol–Gels and Incorporated Drugs

4.428.2.4.1. Sol–gel

During the sol–gel process, hydrolysis and condensation reactions determine the states and numbers of Si–O–Si linkages in the sol–gel oxide structure. Ideally, a four-functional metal alkoxide such as TEOS reacts to completion, forming a tetrahedrally bonded glass network. If either the hydrolysis or condensation reactions are incomplete, the tetrahedrally bonded SiO_2 network is not fully formed. The silicon connectivity can be categorized with five degrees: Q^0 denotes a silicon with no Si–O–Si linkages, Q^1 denotes a silicon with one Si–O–Si linkage, Q^2 denotes a silicon with two Si–O–Si linkage, Q^3 denotes a silicon with three Si–O–Si linkage, and Q^4 denotes a silicon with four Si–O–Si linkages.[44] The degree of condensation, defined by Viitala,[45] is $Q^4/(Q^2+Q^3)$. Obviously, the higher degree of condensation, the more silicons have four Si–O–Si linkages. The degree of condensation can be obtained by using solid-state ^{29}Si magic-angle-spinning nuclear magnetic resonance (NMR) measurement.

4.428.2.4.2. Incorporated drugs

Drugs with low volatility (low vapor pressure) will remain inside the silica gel structure during the water and alcohol evaporation. If the drug added in the sol is not as volatile as

water or ethanol, theoretically, the final drug retention within the sol–gel should be 100%. Indeed, many studies have evidenced a close to unit drug retention.

Sol–gel materials are attractive for the delivery of poorly water soluble drugs. It is a major therapeutic challenge to deliver water insoluble drug due to low bioavailability and insufficient dissolution during the gastrointestinal absorption. Hydrophobic drugs with low water solubility, dissolved in organic solvents, can easily be mixed with a hydrolyzed sol. After removal of the organic solvents and byproducts (water and ethanol) through evaporation, drugs are stored inside the sol–gel matrix and ready for delivery. Both the sol–gel process and silica inorganic matrix are robust enough to tolerate many organic solvents.

Further studies also revealed that drugs incorporated in the sol–gel silica pores are in the amorphous state.[46–48] In general, the amorphous form of drugs has a faster dissolution rate and a higher solubility when compared to its crystalline form.[49] This particular phenomenon is very beneficial for the delivery of poorly water soluble drugs.[46,50,51] Both *in vitro* and *in vivo* studies confirmed that drugs with low water solubility are released faster when incorporated in mesoporous silica. In addition, more drugs can be released, thereby increasing the bioavailability.[46]

4.428.2.5. Ordered Mesoporous Silica

Ordered mesoporous silica materials with pore sizes in the range from 2 to 30 nm represent a variant of sol–gel oxides used for controlled drug delivery. Mesoporous silica was first studied by the researchers of Mobil Oil Corporation in 1992.[52] The synthesis methods of mesoporous silica such as MCM (mobile composition of matter) and SBA (Santa Barbara Amorphous) are similar to the regular sol–gel process. The reaction also involves the hydrolysis (eqn [I]) and subsequent condensation (eqn [II]) of silica precursors (organosilanes) such as tetraethoxysilane (TEOS). In this case, a mixture of ethanol, water, aqueous ammonia, and surfactants in basic (pH 10–12) environment is used. The surfactants first self-assemble into a micelle structure when the surfactant concentration reaches the critical micellar concentration. The shape and size of the micelle structure depends on factors, such as chemical and physical properties of the surfactant, surfactant concentration, pH, and temperature. During hydrolysis and condensation, the silica forms at the surface of the surfactants micelle through strong electrostatic interactions. After removing the surfactant either by solvent extraction or calcinations at high temperature, the porous structure remains in the silica material. The surface area and pore size of the mesoporous silica materials can be adjusted by choosing different surfactants and pH values.[53] The drug is incorporated by soaking the mesoporous silica in a highly concentrated drug solution and subsequent drying. Mesoporous silica have unique features such as a stable structure, open pores, and a controlled pore size with narrow pore size distribution. These materials are also promising materials for controlled release.[54] Different drug release kinetics can be achieved by either adjusting the structural properties or modifying the mesoporous silica walls with organic moieties.[55–57] In **Chapter 4.429, Ordered Mesoporous Silica Materials**, the mesoporous silica is discussed in great detail.

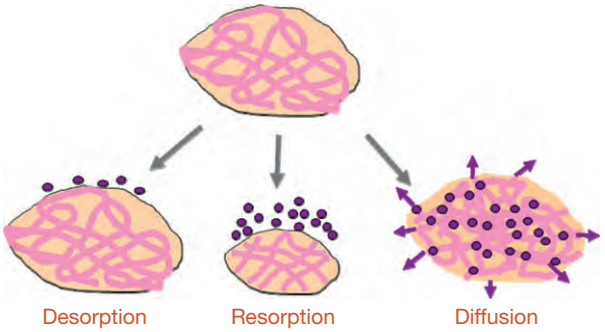

Figure 1 Schematic representation of the drug release mechanisms.

4.428.3. Drug Release Mechanisms

Drugs can generally be released from a matrix in three different ways. **Figure 1** is a schematic representation of the drug release mechanisms. Among the three mechanisms, desorption release accounts for the release of molecules that are superficially absorbed on the surface of the materials. This mechanism is hard to control, but it contributes negligibly to the total drug release. Therefore, the majority of drug released from sol–gel silica is controlled by the diffusion rate of drug molecules from the pores within the silica by the degradation of the silica matrix itself, or by both.

4.428.3.1. Diffusion-Controlled Release

The diffusion-controlled release is the leaching of drug molecules encapsulated in the pores of the silica when liquid penetrates the porous matrix, dissolves the drugs and diffuses into the exterior liquid due to concentration gradient. The drug release is governed by Fick's law of diffusion. One of the most important controlled release equations to describe the release kinetics of molecules in a diffusion-controlled process is called the 'Higuchi equation.' The Higuchi equation has helped define the mathematical perspective of controlled release drug delivery systems since the era of development of sustained release dosage forms.[58] This equation has been applied for diffusion-controlled release from a porous matrix, from which a drug is leached by the bathing fluid that penetrates the matrix through pores and capillaries:

$$Q = \sqrt{\frac{D\varepsilon(2A - \varepsilon C)Ct}{\tau}} \qquad [1]$$

with Q, amount of drug released after time t; D, diffusivity of the drug in the permeating fluid; τ, the tortuosity factor of the capillary system. The tortuosity indicates that the tortuous path of transport of a drug through porous structure. The tortuosity accounts for the complexity of pore geometry; A, the total amount of the drug present in the matrix; C, the solubility of the drug in the permeating fluid; and ε, the porosity of the matrix. The porosity is the fraction of pores in the system that open to the surface.

The above eqn [I] can be expressed in more simple form as:

$$Q = k\sqrt{t} \qquad [2]$$

where k is known as Higuchi dissolution constant. Thus, the cumulative release of drug released is proportional to the square root of time.

Today, the Higuchi equation is one of the most widely used and the most well-known controlled release equations. According to this equation, and as stated, the cumulative release of released drug is proportional to the square root of time. The rate of release can be increased by increasing the drug's solubility (C) in the host matrix, or the inverse, can be decreased by decreasing the solubility.

It is important to note that a few assumptions are made in this Higuchi model. They include (i) the initial drug concentration in the system is much higher than the matrix solubility, (ii) perfect sink conditions are maintained, (iii) the diffusivity of the drug is constant, and (iv) the swelling of the matrix is negligible. The sink conditions are achieved by ensuring the concentration of the released drug in the release medium never reaches more than 10% of its saturation solubility.

It can be seen from the Higuchi equation that the nanostructure structures of sol–gel, such as the pore volume, the specific surface area, and the pore diameter have a major influence on the release phenomena. The pore surface chemistry also can affect the drug molecular release through drug sol–gel interaction.

In addition to the commonly used Higuchi model, other release kinetic models have been proposed to describe the drug release behavior from sol–gel processed xerogels.[59,60] The Higuchi model only considers the drug released from planar/tabular matrix. In reality, the sol–gel oxides can be prepared into various shapes, such as coatings, fibers, and particles. Among these various shapes, sol–gel oxide particles, or powders attracted more attention by virtue of its simple preparation process and easy application. Therefore, studies have been devoted to analyze release kinetics from spherical matrix. Baker and Lonsdale[59,60] developed a model from the Higuchi model and described the drug release from spherical matrices according to the equation:

$$\frac{3}{2}\left[1-\left(1-\frac{M_t}{M_\infty}\right)^{2/3}\right]-\frac{M_t}{M_\infty}=kt \qquad [3]$$

where M_t/M_∞ is the fractional drug released at time t; k, the constant depending on the structural and geometrical characteristics.

To study the release kinetics, data obtained from *in vitro* drug release studies were plotted as $d[(M_t/M_\infty)]/dt$ with respect to the root of time inverse.

In diffusion-controlled release, the pores are large enough to be thought of as 'channels' for diffusion (pore diameter greater than drug molecular), diffusion occurs predominantly through these water-filled pores. However, if the pores are smaller than drug molecules, then the diffusion-controlled mechanism may not be able to account for the kinetics of drug release.

4.428.3.2. Degradation-Controlled Release

When implanted in to body, silica sol–gels gradually degrade over time. The dissolved sol–gel silica is harmlessly excreted in soluble form through the urine, as described below. The sol–gel silica degradation rate is mostly depended on silica's structure. In a normal conditioned body (pH around 7.4 and temperature around 37 °C), the solubility of amorphous silica is around 120–150 ppm while the crystalline silica is ten times less soluble.[61,62] Not only is the solubility, but also the dissolution rate is dependent on the structure. There are two major parameters that one can focus on to vary the sol–gel silica degradation rate: degree of condensation and specific surface area.

Compared with Si–O–Si linkage, the silanol (Si–O–H) group is easier to break through a hydrolysis process. Therefore, the amount of silanol groups is related to the degradation rate. The degradation rate is higher when more silanol groups are present in the silica. When the degree of condensation is low, there are much more free silanol groups in the silica surface.[45,61]

A well-hydrolyzed sol of alkoxides gelled to a low degree of condensation can result in a high number of free silanol groups per surface area. As an example, in a typical silica sol–gel process, a sol with low water-to-TEOS ratios and low pH (pH around 2) near gel point, for example, to $t_{gel}=0.90$–0.98 (0 corresponds to sol preparation, 1.00 to the gel point) can be spun to form fibers. Sol–gel fibers are spun immediately before the condensation process, leaving no time for condensation reactions. The resulting silica fiber having a very low degree of condensation usually degrades within less than a day.[45] Other fast form-giving processes can also form silica with a low degree of condensation, such as freeze drying and spray drying. On the other hand, the regular slow spontaneous gelation process of the same sol gives rise to fully condensed silanol groups. Thus, spontaneously formed silica monoliths dissolve at a much slower rate.

The specific surface area also affects the degradation rate. The higher the specific surface area, the more silanol groups are accessible, such as to be liberated from the surface into the dissolution medium. Therefore, a high surface area makes the silica to degrade faster.[62] Typically, silica hydrogels contain a very high water content, about >90% (w/w) of water and <8% of silica.[63–65] The sols for these hydrogels are generally prepared at high water-to-alkoxide ratios (>50). Silica hydrogels dissolve completely within 2–3 days *in vitro* using sink dissolution conditions.

The mathematical model developed by Hopfenberg describes the idealized kinetics of drug release from a matrix by any erosion/relaxation process regardless of mechanism, and it is assumed that the relaxations are not confounded by diffusion processes.[66] In this model, all mass transfer processes involved in controlling drug release are assumed to add up to a single zero-order process (characterized by a rate constant, k_0) confined to the surface area of the system. This zero-order process can correspond to a single physical or chemical phenomenon, but it can also result from the superposition of several processes, such as dissolution, swelling, and matrix chain cleavage. Good examples for systems where Hopfenberg's model can be applied are surface eroding polymers or sol–gel silica matrices where a zero-order surface detachment of the drug is the rate limiting release step. Hopfenberg derived the following, general equation, which is valid for spheres, cylinders, and slabs:

$$\frac{M_t}{M_\infty}=1-\left(1-\frac{k_0 t}{c_0 a}\right)^n \qquad [4]$$

M_t and M_∞ are the cumulative amounts of drug released at time t and at infinite time, respectively; c_0 denotes the uniform initial drug concentration within the system; a is the radius of a cylinder or sphere or the half-thickness of a slab; n is a 'shape factor' representing spherical ($n=3$), cylindrical ($n=2$), or slab geometry ($n=1$). For sol–gel silica system, the above equation can be approximated (for $n=1$) to:

$$\frac{M_t}{M_\infty} = kt \quad [5]$$

4.428.3.3. Mixed Release Kinetics

From the above discussion, it is evident that the release kinetics controlled by diffusion can be described by Higuchi model. The Higuchi model can be rewritten as:

$$\frac{M_t}{M_\infty} = kt^{0.5} \quad [6]$$

where M_t/M_∞ is the fractional drug released at time t; k, the constant depending on the structural and geometrical characteristics.

Similarly, the release kinetics controlled by degradation can be expressed as:

$$\frac{M_t}{M_\infty} = kt \quad [5]$$

where M_t/M_∞ is the fractional drug released at time t; k, the constant depending on the structural and geometrical characteristics.

Based on Fick's second law of diffusion and assuming that the release experiment proceeds in perfect sink condition and that the drug distribution is homogeneous, Peppas introduced the following simple exponential relationship to describe drug release under mixed release kinetics conditions, including both degradation and diffusion.[67,68]

$$\frac{M_t}{M_\infty} = kt^n \quad [7]$$

where M_t/M_∞ is the fractional drug released at time t; k, the constant depending on the structural and geometrical characteristics; n, the indicator of the mechanism of drug release.

This equation can be used until 60% of the drug has been released. It is shown that exponent values $n<0.5$ are indicative of diffusion-controlled release. $n=1.0$ indicates actually zero-order drug release kinetics, which can be achieved also with degradation-controlled release. The n values between 0.5 and 1.0 are indicative of anomalous transport behavior including both diffusion and degradation. Although the power law has its limitations, it is considered to be more useful in the comparative studies providing explanations for the diffusion-controlled release with consideration of the matrix degradation effect on the release kinetics.

4.428.3.4. Difference Between *In Vitro* and *In Vivo* Kinetics

Considering that one can vary sol–gel processing conditions, that the range of the size of drug molecules is large, and that drug molecules may interact with the silica, drug release from sol–gel silica can be diffusion-controlled, degradation-controlled or both. With such unique property for sol–gel materials, the drug release profile can be readily adjusted for various applications.

Although many models have been proposed to fit *in vitro* drug release behavior, one has to carefully apply the *in vitro* release profiles for the *in vivo* situation, as in fact *in vitro* release profiles often do not completely correlate to the *in vivo* profiles. The *in vivo* degradation rate of silica structures is much slower than *in vitro* degradation rates. For example, it has been found that the *in vitro* degradation rate is about eight to ten times higher than *in vivo* degradation rate for sol–gel silica. Such results indicated the longer degradation period and longer drug release duration *in vivo*.[61,69]

The difference in the behavior between *in vitro* and *in vivo* data likely stem from two origins: difference in fluid flow *in vitro* and *in vivo*, and tissue – sol–gel carrier interaction. When implanted, the fibrous capsule around the drug carrier may reduce the fluid flow around the drug-controlled release material and slow down drug diffusion from the carrier material into the surrounding tissues.[6,69] In case of a situation where there is tissue – sol–gel carrier interaction present, research has shown that serum proteins absorbed on the silica sol–gel result in a 20–30% reduction in dissolution, suggesting a slower degradation *in vivo*.[62]

4.428.4. Control of Release Kinetics

One of the unique properties of sol–gel oxides as drug carriers for controlled release is that the drug release kinetics can be optimized through either physical or chemical alterations of the silica. The silica xerogel structure can be extensively varied in a controlled manner by selecting different processing parameters, such as the pH of the sol, the water/alkoxide molar ratio, and the use of various additives. In addition, chemically modified silica sol–gels can interact with an incorporated drug, and thereby alter the drug diffusion rate. Molecules sensitive to external stimuli such as temperature, light, or pH attached within the pores can further be used to regulate the drug release kinetics.

4.428.4.1. Effect of pH of the Sol

During hydrolysis, all strong acids (e.g., hydrochloride acid, nitric acid, and sulfuric acid) behave similarly as the hydrolysis is a first-order reaction, while weak acids such as acetic acid require a longer time for hydrolysis. Thus, the time to achieve a homogeneous state of hydrolysis is longer for catalysis with weak than strong acids. The size and shape of the silica colloid in the hydrolyzed sol are also different. Therefore by selecting either a strong or a weak acid (which would catalyze the sol at different pH values), it is easy to alter the final structure of gel. Under different pHs, sol–gel silica structures are developed with different porosity.[70,71] During the condensation, the silica colloids in the sol (3–10 nm) will pack differently to yield various xerogel structures ranging from microporous (pore size <2nm) to mesoporous (pore size 2–50 nm) at different synthesis conditions.[36,72] The pH of the colloidal silica particles has a major impact on the packing properties. Therefore,

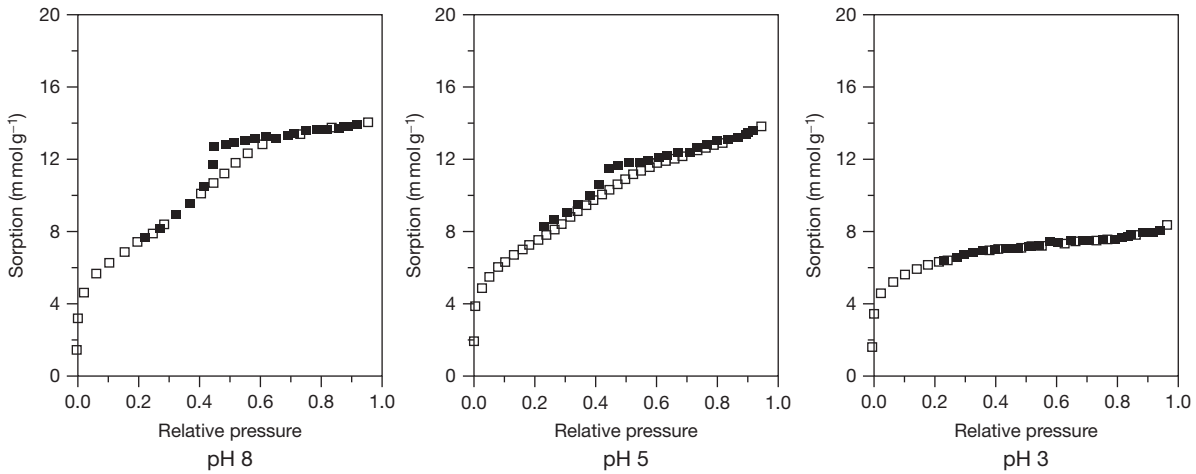

Figure 2 Effect of gelation pH on the microstructure of silica gels. The pore volume of silica increases and the silica clusters become more and more loosely packed as pH increases from low to high. Reproduced from Chu, L.; Tejedor-Tejedor, M. I.; Anderson, M. A. *Microporous Mater.* **1997**, *8*(5–6), 207–213, with permission from Elsevier.

the microstructure of the resulting gels will be different.[70] When sol is prepared at the isoelectric point of the hydrolyzed silica precursor, the silica colloids aggregate easily due to lesser electric compulsive forces. As a result, silica colloids can easily form a densely packed structure and silica sol–gels have the most condensed structure at pH values around the isoelectric point. Above the isoelectric point, the gel results in a more porous structure.

Nitrogen adsorption–desorption isotherms were used to analyze the nanostructure of silica xerogels. It was found that the gelation of sol with same sized silica colloids (~6 nm) at different pH resulted in gels with different pore volumes. Figure 2 shows that when the gelation was carried under pH close to isoelectric point (pH = 3), the resulting gel showed a type I isotherm, and a pore volume of about 30%. When the pH was raised to 5 or higher (pH = 8), the gels formed showed a type 2 isotherm and a pore volume up to 50%.[73] With less pores, release of the drug dexmedetomidine shows a slower diffusion rate from the silica sol–gel prepared near the isoelectric point of the silica than when the sol–gel is prepared at either low (pH = 1) or high pH (pH = 5) (Figure 3).[70]

A procedure known as a 'two-step acid–base catalyzed process' requires less time for the hydrolysis process and gives more freedom on pH selection during the condensation reaction. In fact, when the sol is prepared at low pH (strong acid) the hydrolysis process is very fast. But once homogenous hydrolysis is achieved, the pH of the sol can be adjusted for the condensation reaction. One can add a strong alkaline solution such as NaOH. By doing so, the sol is catalyzed and condensed within a totally different environment. The two-step acid–base-catalyzed sol–gel materials exhibit hierarchical structures that are otherwise difficult to achieve using single step acid-catalyzed or base-catalyzed gels.

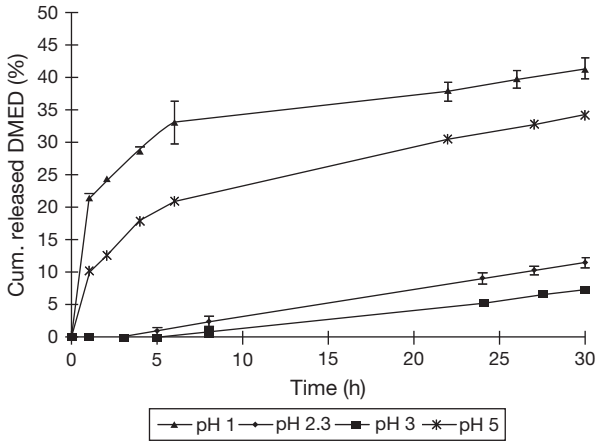

Figure 3 Effect of processing pH on the release rate of dexmedetomidine from silica gel microparticles prepared with water/TEOS ratio 14. The drug (dexmedetomidine) release shows slower rate from the silica sol–gel prepared near the isoelectric point (pH = 2.3–3) of the silica compared to the silica sol–gel prepared at low (pH = 1) or high pH (pH = 5) values. Reproduced from Kortesuo, P.; Ahola, M.; Kangas, M.; *et al*. *Biomaterials* **2002**, *23*(13), 2795–2801, with permission from Elsevier.

4.428.4.2. Effect of Water/Alkoxide Molar Ratio

The water/alkoxide molar ratio (R) in the sol can also affect the xerogel nanostructure. As the water/alkoxide molar ratio increases, pore volume and specific surface area of xerogels increase without a concomitant change in pore size.[11] Higher water/alkoxide ratios are associated with higher surface area and larger pore volume.[38] The corollary of the higher pore volume is that larger amounts of water can penetrate into the sol–gel pores and that diffusional drug release increases. Actually, differences in pore volumes lead to major changes in release kinetics. For example, the release kinetics of vancomycin from xerogels synthesized with the water/TEOS molar ratio $R = 10$ shows a much faster release compared to that from sol–gels prepared at $R = 4$ (Figure 4). It was found that about 90% of the incorporated vancomycin was released from xerogels synthesized with $R = 10$ and

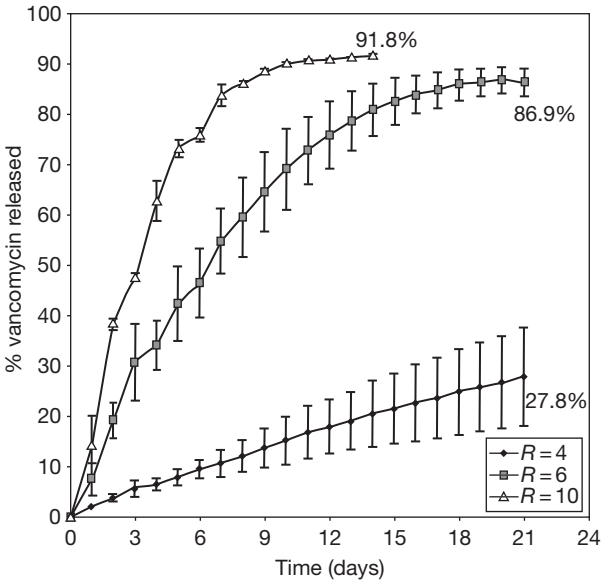

Figure 4 Percent of incorporated vancomycin released from disks of load 20 mg g^{-1} as a function of time and water/TMOS molar ratio (R) ($n = 3$, errors bars represent ± 1 standard deviation). Average total vancomycin amount in water/TMOS molar ratio four disks of load 20 mg g^{-1} was 8.5 mg per disk. Percentage cumulative release of vancomycin from xerogel increases as water/alkoxide molar ratio (R) increases. Reproduced from Aughenbaugh, W.; Radin, S.; Ducheyne, P. *J. Biomed. Mater. Res.* **2001**, *57*(3), 321–326, with permission from Wiley.

$R = 6$ by 14 and 21 days, respectively. In contrast, only 28% of vancomycin was released from xerogels prepared with $R = 4$ after 21 days of immersion.[38]

4.428.4.3. Effect of Drying Conditions

During the drying step, solvents are removed from the silica matrix, thereby giving rise to empty pores in the matrix. When conventional drying or ambient drying in air is used, the gel shrinks due to capillary forces. The final product is called xerogel; it typically has pores with size less than 1.5 nm. When the solvent is removed by freeze drying, the resulting solid material is called cryogel. An aerogel is formed when solvent in the gel is removed by extraction using supercritical drying. Freeze drying and supercritical drying preempts capillary effects, and thereby protects the gel structure from collapse. For cryogels and aerogels, the gel volume remains unchanged and large pores are obtained. It has been demonstrated that after a sol turns into the gel state, and the drying is a supercritical drying using CO_2 at 40 °C, the dried aerogels have a large pore size ranging from 10 to 30 nm. As a result, the drug release rate from aerogels is much faster than from conventionally dried xerogels.[74–76]

In addition to effects resulting from pore structure, the chemical state of the sol–gel surface also controls the drug release rate from aerogels and cryogels. For aerogels and cryogels, the condensation reaction is hindered due to difficulty in silanol movement. A lesser degree of condensation means more unreacted silanol (Si–O–H) groups on the surface. These silanol groups can easily break due to hydrolysis when the sol–gels are present in a physiological milieu. Therefore, a higher amount of residual silanol groups results in a higher rate of degradation. Many researchers have observed that xerogels prepared by a quick drying method such as freeze drying or spray drying have fast release kinetics duo to this higher rate of degradation.[45,61,77,78]

Recently, it has also been found that the drying temperature affects the drug release rate.[71] The reasoning was offered that the decrease of the drug release rate is caused by the decrease in pore size and pore volume of the xerogels. It was concluded that higher drying temperatures cause a faster evaporation rate and results in a higher capillary pressure which results in a denser gel. However, other research found that the drying temperature did not affect the release rate.[79] Such difference suggests that more detailed work is needed to elucidate the effect of drying temperature.

4.428.4.4. Effect of Additives

4.428.4.4.1. Polymers

Controlled amounts of polymers or biopolymers, such as poly(ethylene glycol) (PEG), poly(vinylimidazole) (PVI), poly(ethyleneimine) (PEI), or chitosan, can be added to silica xerogels during the sol–gel process without disturbing the silica formation. When small amounts of soft polymer are added, the polymer additives can reduce the shrinkage of the material by functioning as a 'pore filling' material, and the resulting silica composites have a smaller specific surface area and less pores.[80,81] Due to the lesser number of pores and the 'pore filling' property of the polymers, drug releases becomes slower.[79,82] By adding chitosan to sol–gels, it has been possible to remarkably reduce an initial burst release.[81] Another effect associated with the addition of polymers is the change in mechanical properties of the silica. When chitosan is added to sol–gel silica, the strength, strain to failure, and fracture strength of silica are significantly enhanced.[81]

There are adverse effects associated with adding large amounts of polymers to sol–gels. The silica network formation during the condensation reaction can be severely disturbed. As a result, a weaker silica structure with large pores is formed.[79,83] Swelling of polymer in the sol causes the expansion of silica sol–gel matrix and creates large pores in the sol–gel. Thus, diffusion-controlled drug release would be dominant in such systems. However, the sol–gel matrix degrades faster due to a low degree of condensation caused by polymer interference.[83] As a result of this, it is very difficult to control the drug release kinetics from these materials. Studies have shown that drug release rate were much faster when 8.6–27.4 wt% PEG or 23.7 wt% poly(dimethylsiloxane) (PDMS) were added in the sol–gel during the sol–gel process.[83,84]

Drug release kinetics can also be changed by embedding the silica sol–gel particles in a polymeric matrix.[85] Drug containing silica sol–gels or mesoporous silica particles have been mixed with a polymer matrix for the subtle control of the release kinetics. When silica is surrounded by the polymer matrix, the polymer acts as a barrier to water influx that is necessary to release the drug from the silica sol–gels and thereby reduces the release rate. The polymer–drug interaction through hydrogen bonding or electrostatic interaction also reduces the drug

release rate. Studies with silica sol–gel/tyrosine-poly(ethylene glycol)-derived (ether carbonate) polymer composites revealed that a prolonged drug release profile can be achieved comparable to silica sol–gel alone.[85] Other polymer reactions, namely swelling and bulk erosion can also be effective parameters to adjust drug release kinetics in composite polymer–sol–gel systems.[86,87]

4.428.4.4.2. Organically modified alkoxy silanes

Organically modified alkoxides, such as $RSi(OEt)_3$ $R_2Si(OEt)_2$ (e.g., R=CH_3 or CH_2CH_3) or PDMS ($[Si(CH_3)_2O]_n$), which are derived by the addition of organically modified silanes to TEOS or TMOS-based sol–gels can be used to adjust the drug release kinetics. Many researchers have succeeded in partially substituting TEOS or TMOS with organically modified alkoxy silanes such as dimethyl(diethoxy)silane (DMDES), methyl (triethoxy)silane (MTES), ethyl(triethoxy)silane (ETES), or propyl(triethoxy)silane (PTES) in sol–gel process. It was found that the condensation rate of the alkyl-substituted alkoxysilanes decreases with increasing length of the alkyl chain[36] and the drug release rate from this type of sol–gel silica is slower compared to that from conventional ones. The decrease in the release rate may be due to the hydrophobic nature of the stable CH_3 or CH_3CH_2 groups present in the silica network. These alkyl-groups act in two possible ways: they either prevent the hydrophilic molecules to diffuse out or they prevent water molecules to penetrate into the silica network.[24,37,88–91]

Organically modified silanes using an amide moiety were also synthesized with the goal of controlling the drug release kinetics by taking advantage of electrostatic interactions between protonated aminopropyl groups and carboxylate groups present in the drugs. It was shown that the release rate of ibuprofen could be considerably reduced when the aminopropyl-triethoxysilane was used to functionalize the silica materials.[92]

4.428.4.4.3. Surface modification

Sol–gel oxide to drug interaction can be a useful tool to adjust the drug release kinetics. Various surface modifications have been explored to change this interaction. By way of example, the surface of mesoporous silica particles was coated with magnesium oxide (MgO) using a hydrothermal method. This rendered basic properties to the surface of the silica particles. Such surface characteristics are useful for the controlled release of drug substances with acidic groups such as ibuprofen.[93] In fact, it was observed that the release rate of ibuprofen was considerably reduced in such systems. The extent of rate reduction increased with the amount of MgO coated onto the internal surfaces.[93]

Sol–gel silica itself can also be used to coat mesoporous silica particles for additional control of their release rates. Drug release rates decrease with the increase in the number of coatings. With a judicial organosilane selection and an optimal number of coatings deposited, an initial burst release can be attenuated.[94]

4.428.4.4.4. Stimuli-responsive delivery

Molecules with moveable elements attached to the pore can be used to regulate the drug release through pores. These moving parts respond to external stimuli such as temperature,[95] light,[96–98] pH,[99] and chemical agents.[100] When the right stimuli are present, the movable parts that block the pore on the surface of the silica particle move away from the pore thus allow the drug diffusion through the pores. Thus, the release can also be controlled by external stimuli.

4.428.5. Biocompatibility and Resorption

4.428.5.1. Biocompatibility

Silica glass materials have a favorable tissue response when implanted subcutaneously or in bone.

When implanted subcutaneously, tissue irritation was not observed at the site of implantation and the acute inflammation subsided within a 7-day span, a typical duration for any wound healing. A fibrous capsule was present from around 14 days.[7,70] The xerogels gradually resorbed over time and bulk material breakdown or sol–gel related tissue necrosis was not observed.

In our laboratory, we have extensively studied the tissue response to various xerogels in the subacute implantation phase (up to 4 weeks of implantation). When implanted in bone (iliac crest of New Zealand white rabbit), the implanted silica xerogel showed a minimal inflammatory response and a gradual resorption over time. At 2 weeks of implantation, there was also extensive trabecular bone ingrowth around the silica xerogel. There was no statistical difference in amount of bone formed in empty defects (controls) and bone defects filled with silica granules (**Figure 5**). The size of all granules gradually decreased with implantation time, revealing gradual resorption.[6]

4.428.5.2. Systemic Biocompatibility of Resorbable Silica-Based Glasses

Silicon, next to oxygen, is the most prevalent element on Earth (26%) and crystalline silica in the form of quartz is the most abundant mineral in the Earth's crust. Although silica is a major component in our environment, it is not a major component of our tissues. Mammals, including humans, have evolved mechanisms over time to remove silicon from their bodies in order to maintain trace concentrations of silicon. In animals, silicon is most abundant in connective tissue, hair, feathers, skin, tendons, muscle, and bone. Silicon is a constituent of certain glycosaminoglycans and polyuronides, where it occurs firmly bound to the polysaccharide matrix.[101] In most tissues, silicon concentrations in humans range from 0.6 ppm for serum, to 41 ppm for muscle, and to a high of 57 ppm for lung tissue. In other animals, the silicon concentrations are similar to humans, <1 ppm in serum and 25 ppm in femora of both rats and monkeys.[102–104]

In our laboratory, we performed *in vivo* studies with granules of silica-based glass using rabbits. The granules were implanted in two separate studies. The implantation was either in the tibiae[105] or in the paraspinal muscle[101] of rabbits.

We traced the silicon release from silica glasses and the silicon excretion from the body. In addition, we examined a variety of tissues for silicon accumulation using chemical and histopathological analyses. We also evaluated the kidney function of the rabbits, and to this end, we measured urinary

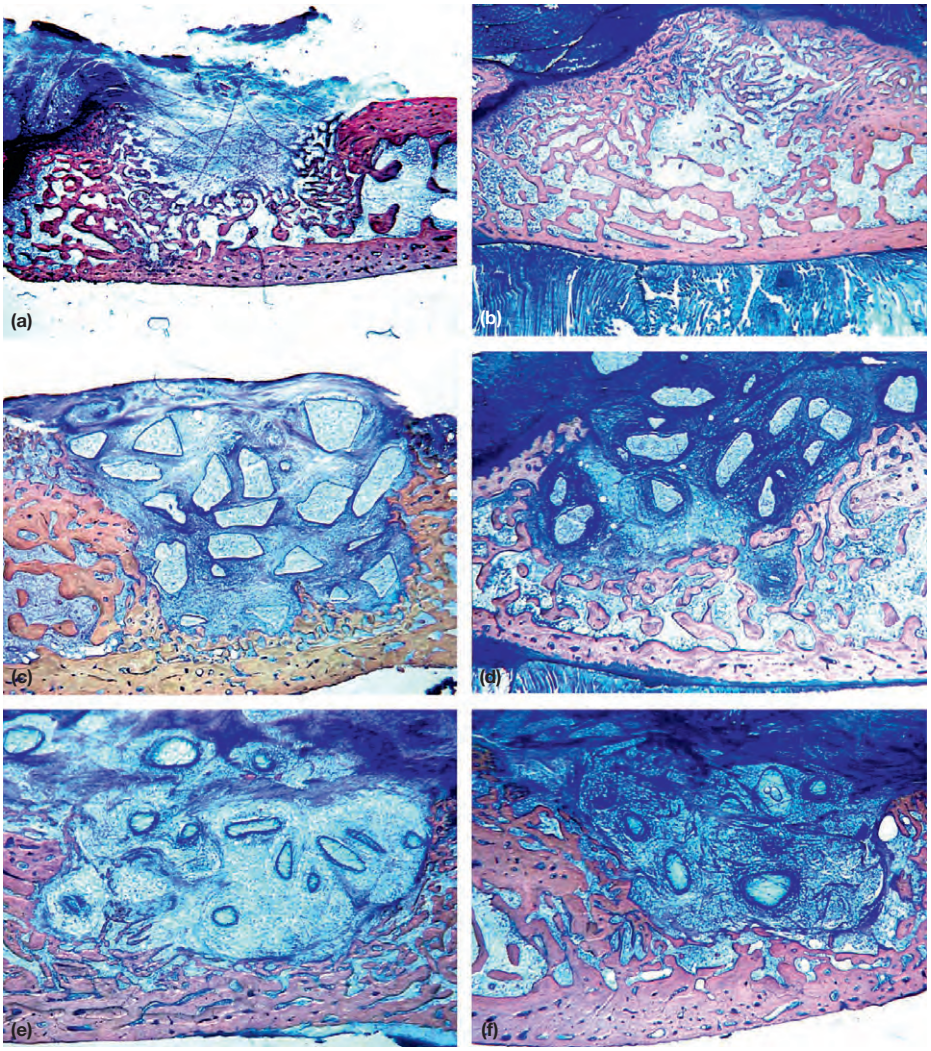

Figure 5 Light micrographs of rabbit bone tissue response to (a, b) control, (c, d) S100, and (e, f) S90V granules without apatite surface layer after implantation into the iliac crest defects: for 2 (a, c, e) and 4 (b, d, f) weeks (phase II of the experiment). Original magnification: 12× (a, e, f) and 10× (b–d). Progressing healing of the defect via trabecular bone growth was observed for both the control and the implant groups. Extensive trabecular bone growth occurred at the opening and the borders of the defects at 2 weeks of implantation. After 4 weeks, the amount and the density of the trabaculae increased for all the experimental groups. S100: pure silica xerogel; S90: xerogel composition 90% SiO_2–5% CaO–5% P_2O_5. Reproduced from Radin, S.; El-Bassyouni, G.; Vresilovic, E. J.; Schepers, E.; Ducheyne, P. *Biomaterials* **2005**, *26*(9), 1043–1052, with permission from Elsevier.

creatinine. Creatinine is a natural metabolite found in the urine that is proportional to the body's muscle mass. Its excretion rate reflects kidney function, with a decreased rate reflecting impairment. We found that the creatinine excretion rates were relatively constant and stable over three different treatment groups sampled at several time points during the experiment. Since creatinine excretion rates were similar for all rabbits, we concluded that the surgical procedure and the increased silicon excretion did not adversely affect kidney function.

For silica implanted in the tibiae, the silicon release was measured in 24-h urine and blood samples for up to 7 months after implantation. Surrounding bone and muscle tissue as well as kidney, liver, lung, lymph nodes, and spleen were resected for chemical and histopathological analyses. The urinary silicon of both implanted groups was significantly higher than in the control group (Figure 6). The calculated average excretion rate was approximately 1.8 mg day^{-1}, and as such, the amount of implanted silicon was excreted within statistical bounds in 24 weeks. Increased concentrations of silicon were not found in any of the organs and the histological appearance of all organs was normal. Since no significant increase in silicon was found in any of the organs including the kidney, the increased silicon excretion rate was within the physiological capacity of rabbits.

In the study with silica implantation in the paraspinal muscle, silicon was traced and the release quantified by obtaining 24-h urine and blood samples for up to 6 months after implantation. In addition, local muscle tissue as well as the same organs as in the previous study were resected for chemical and histopathological analyses. The urinary silicon of the

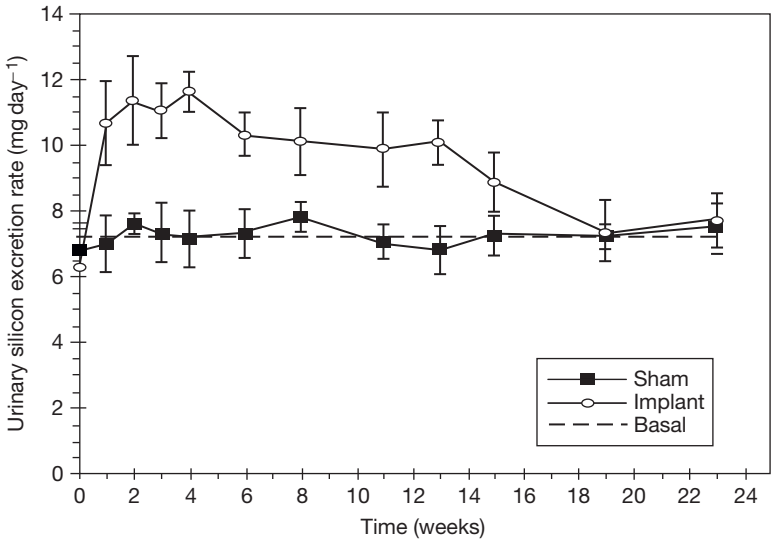

Figure 6 Urinary silicon excretion rates for the long-term study with 'long' implants. Total silicon excreted by the implant rabbits after 19 weeks = 318 mg (100%). $n = 7$ for both sham and implant groups. Basal excretion rate is the average of all sham data points. Week 0 was sampled before surgery and Week 1 was sampled immediately after surgery. Reproduced from Lai, W.; Garino, J.; Flaitz, C.; Ducheyne, P. *J. Biomed. Mater. Res. A* **2005**, *75A*(2), 398–407, with permission from Wiley.

group with implanted granules was significantly higher than in the sham-operated, control group. The average excretion rate was 2.4 mg day^{-1}, and as such, 100% (within statistical bounds) of the implanted silicon was excreted in 19 weeks. No elevated concentrations of silicon were found at the implant sites or in the other organs at sacrifice, that is, 24 weeks. The histological appearance of all organs was normal throughout. The concentrations of silicon measured in the urine were well below saturation and since no significant increase in silicon was found in any organ, including kidney, the increased silicon excretion rate was within the physiological capacity of rabbits.

In both studies, systemic measurable levels of Si were only found in the urine. The Si-release product in the blood must be relatively small in order to pass through kidney filtration. In humans, the size of molecules passing through filtration is approximately 18 Å.[106] The increased urinary Si measured in these studies supports the hypothesis that the silica gel from the reacted silica glass granules is dissolved into the blood stream and removed by the kidney.

Silicic acid, $Si(OH)_4$, in food and beverages has been reported to be readily absorbed across the intestinal wall and rapidly excreted in the urine.[107,108] In plasma and red cells, Baumann found that the concentration of silica was the same (0.4–0.5 ppm) and was present as a monomer. When 50 mg of soluble silica was given to humans in drinking water, it was all excreted in the urine within 10 h; the concentration in urine ranged from 200 to 600 ppm at its peak, depending on urine volume, and it was still all monomeric. The elimination rate was constant when measured as micrograms per minute, regardless of urine volume and the rate was proportional to the amount not yet excreted (first-order rate constant). The concentration in blood reached 2–3 ppm, and if 300 mg of soluble silica was given, it reached 6 ppm. Baumann also showed that monomeric $Si(OH)_4$ penetrates all body liquids and tissues at concentrations less than its solubility (1.7 ppm which is 1% of Si solubility in water). However, Policard *et al.*[109] suggested that polymeric molecules of silicic acid containing up to four to five silicon–oxygen units characterize the transport form of silicic acid in blood.

With a clinically relevant dose, a slow silicon dissolution rate from silica glass and subsequent diffusion into the blood was observed. Under these conditions, the critical concentration at which silicon polymerizes (180 ppm) was never reached.[110] Meanwhile the kidney's ability to excrete the Si resorption product continued and no accumulation of silicon took place.

The systemic accumulation of silicon from Si-containing bioactive ceramics depends on the rate of dissolved silica that diffuses into the tissue and into the blood. Furthermore, the rate of dissolution is dependent on dose, site of implantation, effective surface area, and chemical composition of the silica. Given silicon biology, the rate of dissolution is typically smaller than the rate of excretion. As seen in both studies, the silicon release rates from the silica glass granules were well within physiological tolerances.

When massive amounts of silica-containing bioceramics powder were injected intraperitoneally into rats and mice (5000 mg kg^{-1} body weight), the animals died by nephrosis. Silica deposition in renal tubules was observed, indicating that a large quality of silicon eluted from the powder and accumulated and repolymerized within renal tubules.[111–113] Although a large amount of dissolved silica can be toxic, the adverse effect results from a combination of extreme conditions: ultra high powder load (5000 mg kg^{-1} body weight), fast silica dissolution rate, and abundant blood circulation (peritoneal injection). These conditions are far removed from those in the applications being pursued with sol–gel-controlled release materials.

With knowledge of trace silicon chemistry in the body and the aforementioned bioactive silica glass resorption

studies,[101,105] these studies suggest that the removal pathway of silicon from silica glass *in vivo* can be described as follows: (1) the bioactive silica is constantly reacting with its surroundings, and the silica gel is removed by a combination of silicon dissolution into the circulating interstitial fluid and active degradation by phagocytic action of macrophages contacting the silica matrix surface; (2) the silicon-containing resorption product diffuses into the local tissue and then enters the bloodstream or lymph to be distributed to other parts of the body in soluble form;[107,109,114] (3) since there are no known physiological processes specific for the absorption and metabolism of soluble silicon, the silicon will finally be filtered out of the blood by the kidney;[109,115–117] during this resorption, the silicon concentration in the organs and body fluids remains within physiologically safe ranges.

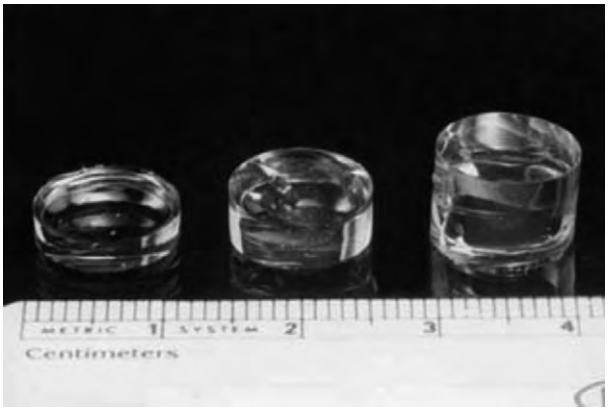

Figure 7 Silica xerogel monoliths. The samples are glassy, transparent, and crack-free. The thickness of samples varies with the amount cast. Reproduced from Radin, S.; Ducheyne, P.; Kamplain, T.; Tan, B. H. *J. Biomed. Mater. Res.* **2001**, *57*(2), 313–320, with permission from Wiley.

4.428.6. Applications

4.428.6.1. Sol–Gel Application Forms

Sol–gel materials can be prepared in a variety of different physical forms, including monoliths, crushed particles, microspheres, nanospheres, fibers, hydrogels, thin films, and composites. Silica sol–gel monoliths or crushed particles were used as implantable or injectable materials.[21,22,24] Spray-drying and emulsification methods were used to prepare silica xerogel microspheres and nanospheres with a narrow particle size range with the goal of excellent control of the release kinetics of various incorporated molecules.[59,118,119] Hydrolyzed silica sols containing drugs were either directly sprayed and dried in air, or mixed and separated by nonpolar organic solvents, in order to form microspheres or nanospheres. Drug-loaded sol–gel films have been produced by applying a solution of liquid sol with drugs onto implant surfaces with the goal of releasing therapeutic agents at the implantation site of devices.[120,121] Silica hydrogels (water content ~90 wt%), which provide, in principle, a viable aqueous environment essential for living organisms, enable the delivery of viruses for gene therapy.[65]

4.428.6.1.1. Monoliths

In case of room temperature synthesis of acid-catalyzed sol–gel-derived silica, the sol starts to gel after hydrolysis. Time to gelation can vary from a few hours to tens of days. The gelation time is determined by synthesis parameters including pH, water/alkoxide ratio, etc. (as described above). After aging in sealed vials for several days, the gels are dried until the gel weight became constant. A major weight loss (75–78%) is typically observed and shrinkage during drying does not lead to cracking of the resulting disks.[11] Figure 7 shows typical sol–gel xerogel monoliths. Monoliths can be processed further, by crushing them into granules or fine powders with a size range upward from 10 μm.

4.428.6.1.2. Particle

4.428.6.1.2.1. Microparticles

4.428.6.1.2.1.1. Emulsion sol–gel process A sol–gel solution is prepared by combining tetramethylorthosilicate (TEOS), an aqueous solution of the active molecule and methanol at the desired pH. The resulting solution is stirred for 30 min at 300 rpm and left to age for 1 day at ambient temperature. In parallel, a surfactant (e.g., sorbitan monoleate) is dissolved in a nonpolar solvent (e.g., cyclohexane) followed by homogenization to form a clear surfactant/solvent solution. The sol–gel solution is then added to the surfactant/solvent solution and the resulting emulsion vigorously stirred. A suspension of microspheres forms and is filtered, washed, and dried.

The condensation and gelation occur inside the water pool and the silica particles form inside this water pool. The size of sol–gel droplets, which eventually become particles, is controlled by the interfacial tension between the water and oil phases. The higher interfacial tension leads to a smaller size of sol–gel droplets and the formation of small silica particles. The nature of surfactant and solvent can be exploited to control the size of sol–gel particles.[119] Figure 8 shows the variation in the size of silica particles obtained by changing the polarity of the organic solvent used as the oil phase, or by changing the nature of the surfactant.

4.428.6.1.2.1.2. Spray-drying sol–gel process In this method, when the acid-catalyzed hydrolysis of the silica precursor has gone to completion, the condensation of the silica sol is stopped before the onset of gelation. The 'close-to-gel' silica sol can be sprayed with a spray dryer to form silica microparticles. The scanning electron microscopy image of Figure 9 shows that spray-dried silica microspheres have a smooth surface and are formed in an aggregated cluster of spheres. Nitrogen adsorption measurements show that spray-dried silica particles have a very low surface area of less than $2\,m^2\,g^{-1}$, indicative of materials that exhibit no or only very small open porosity. The *Q*-values that have been reported ($Q^2 = 19–20\%$, $Q^3 = 39–42\%$, and $Q^4 = 38–42\%$) indicate a low degree of condensation for spray-dried silica. In these materials, the drug release kinetics is predominantly mediated by degradation of the silica matrix.[12]

4.428.6.1.2.2. Nanoparticles

The process of preparing nanosized silica particles with a sol–gel technique is slightly different from that mentioned above for synthesizing micro-sized particles with an emulsion sol–gel

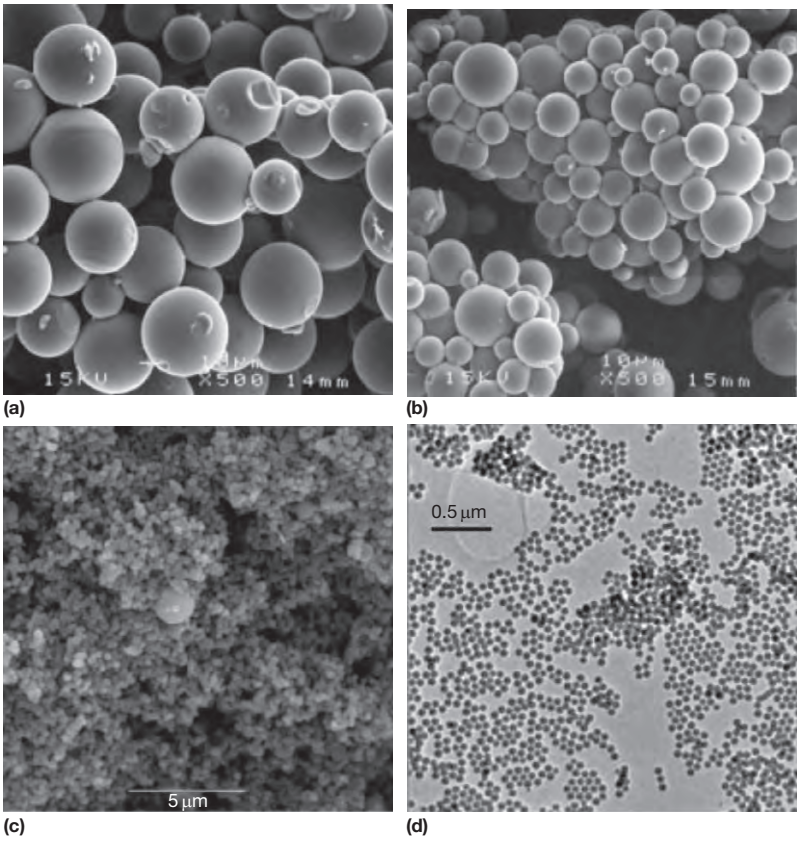

Figure 8 Electron micrographs of silica particles synthesized using (a) SPAN80/kerosene, (b) SPAN80/cyclohexane, (c) AOT/cyclohexane, and (d) NP9/cyclohexane. Both an increase in the polarity of the solvent and a decrease in the surfactant hydrophile–lipophile balance lead to a smaller water droplets and thus, the production of smaller sol–gel particles. Reproduced from Barbe, C.; Bartlett, J.; Kong, L.; *et al*. *Adv*. *Mater*. **2004**, *16*(21), 1959–1966. Copyright Wiley-VCH Verlag GmbH & co. KGaA.

process.[122] In the present case, the silica precursor is introduced in a surfactant/oil solution and slowly diffuses through the surfactant wall into the water droplets, where it is hydrolyzed and condensed. By virtue of this, silica precursor forms the emulsion prior to the gelation. As a result, the hydrolysis and condensation occur simultaneously and a smaller size particle is formed. With respect to the emulsion properties, surfactants with a mid-range HLB (hydrophilic–lipophilic balance) value (between 10 and 15) are suitable for nanoparticle synthesis.

4.428.6.1.3. Fibers

Conventionally, glass fibers are obtained by drawing or blowing a high temperature oxide melt through a small orifice. High temperature processes, however, cannot be used when the goal is to synthesize fibers loaded with drugs. In order to overcome this problem, sol–gel technique including only steps at room temperature has been used to synthesize silica fibers. Specifically, fibrous gels can be drawn from spinnable sols at room temperate and then converted into fibers, again at room temperature.[123]

In this method, the silica sols are prepared from TEOS, water, ethanol, and acid. After hydrolysis, the sols are poured into test tubes and sealed. At this stage drugs can be added to the sol. The test tubes are placed into a water bath and the temperature kept constant at 40 °C. After vigorously stirring for 2 min, the sol is then immediately put back into the water bath. Some ethanol evaporates, which accelerates the reaction kinetics in the sol. After evaporation of ethanol, the sols are cooled to either 20 or 0 °C. The spinning is started when the viscosity of the sol reached a value in the range 2–100 Pa s. To avoid breaking of sol–gel filaments air bubbles have to be removed from the spinning solution under partial vacuum and dry spinning is employed to prepare sol–gel fibers.[124–126] After spinning, the fibers can be dried either in air (or an oven, but this is not desirable given the addition of drugs). **Figure 10** is the representative SEM image of silica fibers prepared by sol–gel technique.

Silica fibers prepared using this process have a very high degree of condensation. The BET surface area of silica fibers prepared by sol–gel is less than 1 $m^2 g^{-1}$, indicating a dense surface of the fibers. Except for a very brief release stage with diffusion control (<1%), the drug release from the fibers is governed by silica degradation.

4.428.6.1.4. Thin films

Dip-coating or spin-coating techniques are commonly used for the deposition of sol–gel thin films onto a variety of substrates. For dip coating, the substrate is dipped and withdrawn at a controlled speed from sol using a dipping device. On the other

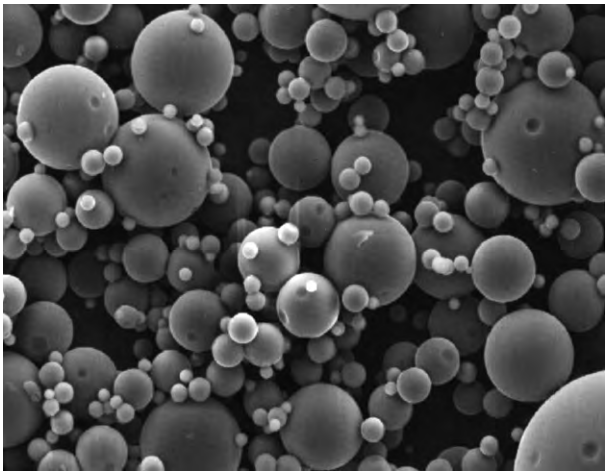

Figure 9 Scanning electron micrograph of sol–gel silica microparticles prepared by spray-drying method. Original magnification ×2500. Reproduced from Kortesuo, P.; Ahola, M.; Kangas, M.; Kangasniemi, I.; Yli-Urpo, A.; Kiesvaara, J. *Int. J Pharm.* **2000**, *200*(2), 223–229, with permission from Elsevier.

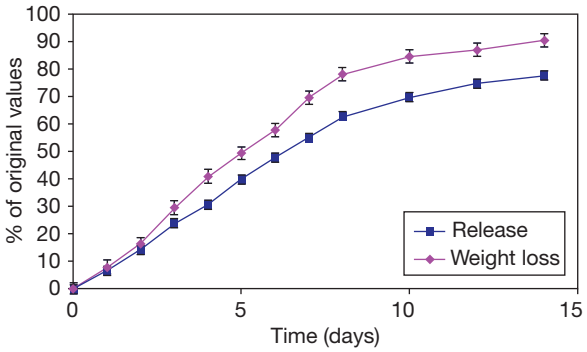

Figure 11 Sol–gel/vancomycin film with release and stability extended up to 14 days: mean cumulative vancomycin release (expressed as % of the original load) and degradation (weight loss, %) as a function of immersion time in PBS. The film was composed of three layers and contained 10% vancomycin. The calculated load in the various films varied from 20 to 22 mg cm^{-2}. The error bars represent the standard deviation ($n = 3$). Reproduced from Radin, S.; Ducheyne, P. *Biomaterials* **2007**, *28*(9), 1721–1729, with permission from Elsevier.

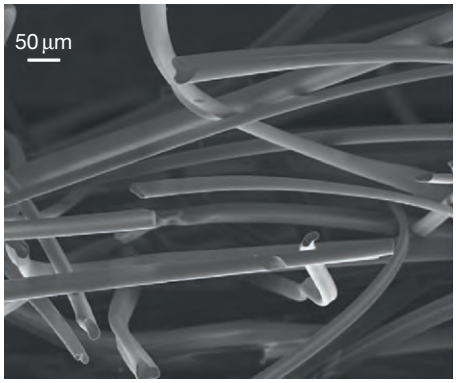

Figure 10 Scanning electron micrograph image of drug (dexmedetomidine hydrochloride) containing silica fiber spun at a sol viscosity of 33–100 Pa s. Reproduced from Czuryszkiewicz, T.; Ahvenlammi, J.; Kortesuo, P.; *et al. J. Non-Cryst. Solids* **2002**, *306*(1), 1–10, with permission from Elsevier.

hand for spin coating, excess amount of sol is dropped on the substrate, which is then rotated at high speed to spread the sol on the substrate by centrifugal force. The thin film coatings are typically air-dried. In order to produce thin film composed of several layers, the dipping or spinning and drying procedures are repeated several times.

During the drying, there is little time for the condensation reaction, resulting in silica coatings with a low degree of condensation. This low degree of condensation, together with a resultant low porosity, the drug release kinetics are primarily controlled by silica degradation and a zero-order release is predominant.[120] Figure 11 shows that the zero-order release profiles of sol–gel dipped coatings that contain vancomycin is associated with a similar degradation rate of the sol–gel films.

4.428.6.1.5. Hydrogels

After hydrolysis and condensation, the sol gradually turns into a gel. There are applications for use of the material in this condition. Thus, unlike when used in monolith form, silica hydrogels are not dried before use. The silica gel, in its gel phase is used as controlled release system. Because of the high water content at this stage (>75 wt%), such silica gel is also called a hydrogel.

The applications with silica hydrogel can be traced back to 1997 when Pope *et al.* encapsulated mouse islet cells into silica hydrogel in order to achieve an *in vivo* secretion of insulin.[17] This research inspired many others for using silica hydrogels in the encapsulation of cells. These gels with cells then served as building blocks for artificial organs and transplants. A prime consideration in these studies was preventing immune response and transplant rejection by walling off the cells in these materials with nanosized pores.[127]

Recently, silica hydrogel was also used for the controlled delivery of virus. The sol–gel process was modified so that the adenoviruses could be added to the liquid sol. After the gel formation, the adenoviruses became encapsulated inside the solid gel structure. Infectivity of the virus was sustained for more than 855 days when stored at 4 °C. Observed linear virus release kinetics correlated to silica dissolution rate suggests that the release mechanism is degradation controlled.[65]

4.428.6.1.6. Mixed oxide sol–gels

Calcium and phosphate containing xerogel composites have been synthesized through a sol–gel procedure by adding calcium precursor (such as calcium methoxyethoxide or calcium chloride) and phosphate precursor (such as triethylphosphate) into the sol.[22] The addition of Ca- and P-oxides affected the physical properties of xerogels, decreasing the surface area and increasing the pore size. When these materials were exposed to physiological fluids, a calcium phosphate

layer quickly formed on their surface. The newly formed calcium phosphate layer was beneficial for new bone formation and provided an excellent surface to stimulate the osteoblastic differentiation of stromal marrow cells.[72] This calcium phosphate layer could dramatically reduce the dissolution rate of xerogel composites and can be used to regulate the degradation-controlled drug release rate from the xerogel.

Calcium only containing xerogel was explored for hemorrhage control. Such an idea stems from the understanding that the Ca ions released from xerogel can induce an accelerated coagulation response.[128]

Owing to the significant antimicrobial properties of copper and silver, sol–gel silica comprising these metal ions have been explored in order to provide for a controlled delivery of copper and silver ions. Mesoporous silica was synthesized through a one-step based catalyzed self-assembly process with cetyltrimethylammonium bromide (CTAB). Silver ions were loaded by soaking silica particles in the silver nitrate solution. Copper-containing xerogels were prepared by adding copper sulfate solution in the sol solution during the one step acid-catalyzed hydrolysis process. After drying, the copper ions were incorporated inside the xerogel. It has been reported that Cu or Ag ions released from xerogels exert a bactericidal action and can be used to aid in wound healing.[129,130]

4.428.6.1.7. Composites

Polymers of synthetic or biological origin can be mixed with sol–gels to form polymer–sol–gel composites. The matrix of the composite can be either the polymer or the sol–gels. Regardless of the matrix, the release kinetics as well as the mechanical properties of the composites can be readily adjusted. Details on polymer–sol–gel composites have been extensive discussed in **Section 4.428.4.4.1**.

4.428.6.2. Therapeutic Agents of Various Size

Because of their controllable structure, sol–gel materials show an efficient and exquisitely tunable delivery of drugs varying in size. Molecules ranging from small (molecular weight of a few hundred Dalton) to large, such as protein molecules (with molecular weight exceeding 50 kDa) can be released at a controlled rate. Recently, very large therapeutic agents such as DNA or virus have been incorporated and released from sol–gel silica in a controlled manner.[65] Cells, which are much larger than viruses, can be delivered with sol–gel system as well. **Chapter 4.431, Encapsulation of Cells (Cellular Delivery) Using Sol–Gel Systems** describes this extensively.

4.428.6.2.1. Small therapeutic agents

Many small drugs, such as dexmedetomidine (MW 200),[37,70,131] steroids (progesterone, estradiol, estrone, and hydrocortisone, MW range 271–362),[26] ibuprofen (MW 206),[132] lidocaine (MW 234),[89] bupivacaine (MW 288),[59] biphosphonates (MW 303),[12] toremifene citrate (MW 598),[7,69,79] and vancomycin (MW 1449)[9,11,133] have been successfully loaded in silica sol–gel oxides using a sol–gel method.

With a size smaller than the pore size of the silica xerogel, the release kinetics of these drugs is mostly diffusion-controlled. The interaction between any drug and the silica sol–gel affects the diffusion rate, though. It has been shown that drugs with fewer hydroxyl and carbonyl groups have a faster diffusion rate, due to less hydrogen bond formation with the silanol groups present in the silica surface.[26] A study on the incorporation of the local anesthetic lidocaine in silica sol–gels suggested that the release of lidocaine can be easily controlled by partially substituting TEOS with organically modified alkoxides (MTES or PTES) or nonionic surfactant.[89]

4.428.6.2.2. Intermediate sized therapeutic agents (proteins or growth factors)

Various proteins and growth factors with molecular weight over several kiloDalton, such as heparin (MW 2–16 kDa), transforming growth factor-β1 (TGF-β1) (MW 25 kDa),[21] trypsin inhibitor (MW 21 kDa),[8] bone morphogenetic protein-2 (BMP-2) (MW 30–32 kDa),[22] bovine serum albumin (BSA) (MW 68 kDa),[45,78] have been incorporated into silica sol–gel and the release kinetics determined *in vitro* and *in vivo*. It was shown that the incorporated proteins maintained their original conformation and were resistant to protease degradation.[63] Depending on the size of protein molecules and pore size of the silica xerogel, the release was diffusion-controlled or degradation-controlled. When pores in the silica sol–gel matrix were not large enough for diffusion of the molecules, the drug release rate was determined by the silica dissolution rate. For example, it has been reported that BSA (MW 66 kDa) was not released in SiO_2-saturated buffer, indicating that the release of large molecule is controlled by SiO_2 matrix dissolution.[45,78]

Heparin is an anticoagulant that is used to overcome the propensity for blood to clot, for instance when it contacts damaged endothelium in a surgical wound. Silica sol–gels have been successfully employed for controlled delivery of heparin to prevent thrombus formation at the site of trauma. Heparin incorporated in sol–gel retains its biological activity before the release.[10] It has been reported that heparin of small molecular weight showed diffusion-controlled release kinetics (<8 kDa), while large size heparins (13–16 kDa) has zero-order release profiles indicative of a dissolution-controlled mechanism.[10,88]

The first report showing the delivery of a biological growth factor from sol–gel based silica was performed in our laboratory and published in 1997.[21] TGF-β1, a 25 kDa homodimeric polypeptide growth factors, which can modulate osteoblast cell activity, including adhesion, proliferation, differentiation, and maturation were incorporated into silica sol–gel oxides. The sol–gel procedure was carried out in acidic condition, as TGF-β1 is highly stable under such conditions. The *in vitro* study demonstrated that sol–gel can provide a sustained release of biologically active TGF-β1 over a 7-day period in a degradation-controlled manner. The released TGF-β1 from silica sol–gel still kept its inhibitory effect on the proliferation of lung epithelial cells, a cell line which is arrested by TGF-β1 in the G1 phase of the cell cycle. On the basis of published TGF-β1 potency, the released amount is capable of eliciting bone tissue reactivity. These findings suggest that the sol–gel oxide loaded with growth factors has potential to serve as an effective bone graft material for the repair of osseous tissue defects.

4.428.6.2.3. Large therapeutic agents (DNA or virus)

Typically, DNA is incorporated into biodegradable polymers for controlled delivery of genes.[134–137] The concept of sol–gel silica mediated gene delivery has not been tested until recently. It was reported that DNA in a silica sol–gel matrix showed good resistance to nuclease and that the DNA release rate could be adjusted chemically by adding linking agent such as aminopropyl(triethoxy)silane (APTES) to the sol–gel precursor.[138] Because of their large size, only small DNA molecule can be released from silica xerogel through diffusion. Pierre *et al*. found that DNA molecules are bonded to the silica network through the P–O–Si link during the encapsulation process. For this reason and by virtue of constraints arising from the small pore size, they found that large DNA molecules remain trapped inside the xerogel and only small DNA molecules (<50 bp or ~17 kDa) can be released from silica xerogel through diffusion mechanism.[139]

Recently, scientists in Finland have demonstrated that recombinant adenoviruses coding for beta-galactosidase (lacZ) can be encapsulated in silica hydrogel for gene delivery[65] (adenovirus genome is double stranded DNA with a size larger than 26 kbp).

They prepared the silica hydrogels at room temperature from TEOS and water. Nitric acid was used as a catalyst. Before virus addition, the pH was adjusted to 6.6 by adding NaOH, The recombinant adenoviruses were added while vigorously mixing. The sols turned into gels within 5–10 min. Water content of the resulting silica gel was 90 ± 3 wt% and silica with adenovirus degraded within 10 days *in vitro*. During the degradation of the silica sol–gels in Tris–HCl buffer, the amount of the virus released from the silica gel increased over time. Viral release kinetics was in accordance with silica hydrogel degradation. Linear release kinetics of the virus suggests that the mechanism is dependent on silica dissolution.[65] Figure 12 shows the degradation, release kinetics from silica hydrogel and its infectivity.

The encapsulated recombinant adenoviruses stayed infective for months at 4 °C. *In vitro* study showed that adenoviruses released from silica gel were able to infect fibroblasts longer than 28 days. It was also reported that this virus incorporated in the silica hydrogel was completely absorbed after 21 days *in vivo*.[64] Furthermore, *in vivo* investigations revealed that antibody induction for silica-adenovirus-implanted mice was slower than for mice treated with virus alone suggesting that the silica matrix provided immuno protection until the virus was released. In needle-injected mice, the highest amount of virus in tumor and liver was seen on day 2, whereas in silica-implanted mice, the amount of virus increased continuously for 2 weeks. This study of antitumor efficacy of oncolytic adenovirus incorporated in silica showed that virus incorporated in silica improved the median survival of mice from 57 to 91 days.[65]

4.428.6.3. Clinical Applications

Because of their excellent biocompatibility and tunable delivery properties, the sol–gel materials have been investigated for treating various clinical conditions, including pain management, bacterial infection control, osteoporosis prevention and bone repair, cancer therapy, hypertension treatment, anticoagulation, and gene therapy (Table 1).

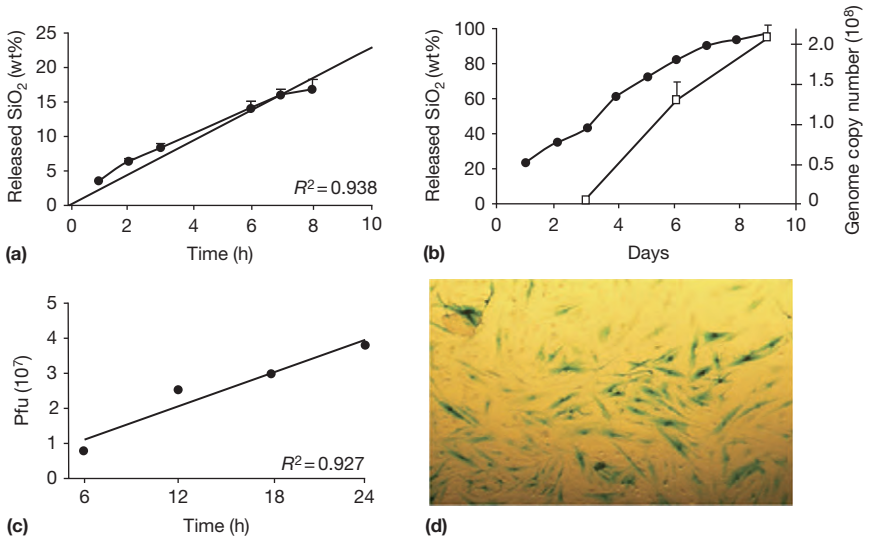

Figure 12 (a) Degradation of the silica gel in 250 ml of 0.05 M Tris–Cl buffer (pH 7.4) at +37 °C and released Si. Release was extrapolated by linear regression ($n = 3$). (b) Silica gel degradation (●) relative to release of adenovirus (□). Gel was dissolved in 250 ml of Tris–Cl buffer, and Si content was measured daily ($n = 4$). The buffer was changed every third day. The release of replication-deficient adenovirus was measured with quantitative PCR. (c) *In vitro* release and infectivity of silica-embedded oncolytic adenovirus Ad5-D24RGD. Silica gels were dialyzed at +37 °C and 106 r.p.m. in 200 ml of growth medium. TCID50 test was performed to quantify the release of functional oncolytic virus/implant. (d) Viability of silica-embedded LacZ-coding adenovirus cultured 3 days on HSF cells after incubating for 229 days at +4 °C. Error bars (a and b) indicate SE HSF, human skin fibroblast. Table 1 Overview of clinical uses of sol-gel materials. Among the uses, several areas stand out, including pain management, bacterial infection control, and cancer therapy

Application fields	*Therapeutic agent*	*Size*	*Physical forms of the sol–gels used in the studies*	*References*
Pain management	Dexmedetomidine	MW 200	Monolith, microparticle, fiber	37,70,125,131
	Diclofenac	MW 296	Monolith	71
	Ibuprofen	MW 206	Monolith, microparticle	34,132
	Lidocaine	MW 234	Monolith	89
	Bupivacaine	MW 288	Microparticle, granule, composite	59,85
	Mepivacaine	MW 246	Composite	85
Bacterial infection control	Vancomycin	MW 1449	Coating, monolith, micoparticle	9,11,133
	Gentamicin	MW 448	Granule, composite	86,140
	Tobramycin	MW 468	Composites	141
	Cu^{2+}	MW 64	Granule	129
	Ag^{+}	MW 108	Microparticle	130
	Nitric oxide	MW 30	Coating	142,143
Cancer therapy	Toremifene citrate	MW 598	Monolith, microparticle	7,69,79
	Cisplatin	MW 300	Granule	83,84,144
	Doxorubicin	MW 543	Granule, microparticle, nanoparticle	62,77,91,119,122,145
Osteoporosis prevention/bone reunion	Biphosphonates	MW 303	Microparticle	12
	BMP-2	MW 32 kDa	Granules	8,22
Hypertension treatment	Nifedipine	MW 346	Micoparticles	24
Anticoagulant	Heparin	MW 2–16 kDa	Monolith, granule	10,88
Hemorrhage control	Ca^{2+}	MW 40	Microparticle, composite	128,146
Growth factors	TGF-β1	MW 25 kDa	Monolith	21
Gene therapy	Recombinant adenoviruses	MW >26 kbp	Hydrogel	65

4.428.6.3.1. Pain management

Sol–gel silica materials containing local anesthetics such as bupivacaine or mepivacaine have been synthesized and their effect to treat pain *in vivo* demonstrated. Before, sustained, controlled release of bupivacaine and mepivacaine from polymer–xerogel composites was shown *in vitro*.[59,85,147]

Dexmedetomidine, an alpha-2-agonists, is widely used in veterinary anesthesia. Dexmedetomidine contained in sol–gel monoliths (rod in shape) was subcutaneously administrated to dogs in a bioavailability study. This *in vivo* study showed that the mean maximum safe concentration of dexmedetomidine (C_{max}) in serum extended over 5 h, much longer than in the control arm with a bolus injection (1 h).[37] After injection, the concentration of dexmedetomidine in serum declined rapidly and was undetectable after 6 h. In contrast, measurable dexmedetomidine concentrations were still found in serum samples taken after 48 h when silica xerogel rods with dexmedetomidine were implanted. This study proved that anesthetic drugs (dexmedetomidine) incorporated in silica xerogel can be released in a sustained way *in vivo*.[37]

Other than the aforementioned drugs, ibuprofen, diclofenac, and lidocaine have also been incorporated in sol-gels.[34,89,132]

4.428.6.3.2. Bacterial infection control

The controlled release of bactericidal drugs from sol–gel materials have been studied. Among them, vancomycin is the typical antibiotic used for treating refractive bone infections caused by Gram-positive bacteria such as *Staphylococci* and *Streptococci*.[32] Room temperature processed sol–gel silica loaded with vancomycin showed a controlled release for up to 4 weeks. A first-order release was observed, suggesting a diffusion-controlled process. By varying sol–gel synthesis parameters, such as water/alkoxide molar ratio and vancomycin concentration, the vancomycin release kinetics were tailored to meet specific therapeutic goals.[11,133] Room temperature processed vancomycin-containing sol–gel silica thin films on titanium implant surfaces were investigated for the treatment of osteomyelitis. The sol–gel/vancomycin thin film showed a long-term sustained release of vancomycin. The bactericidal efficacy of the released vancomycin was retained *in vitro* and *in vivo*.[11,120,121] **Figure 13** shows that vancomycin-containing sol–gel-coated Ti rods exhibit controlled antibiotic release *in vitro* and an effective treatment of virulent infection *in vivo*.

4.428.6.3.3. Cancer therapy

The controlled delivery of antitumor drugs, either directly to the tumor site or via the blood circulation, is a widely studied concept in cancer therapy. Doxorubicin is one of the most potent antitumor agents used in the general treatment of cancer. The continuous release of doxorubicin from xerogel materials has been pursued by implanting xerogel inside the tumor. Prokopowicz proceeded as follows: he synthesized doxorubicin-containing xerogel monoliths, which he then crushed to obtain granules for easy implantation. He found that that this xerogel powder can continuously release the doxorubicin for more than 2 days. He also determined that the release kinetics was diffusion controlled.[91,145]

Another approach for cancer drug delivery is to use silica nanoparticles. Nanoparticles, when administered intravenously,

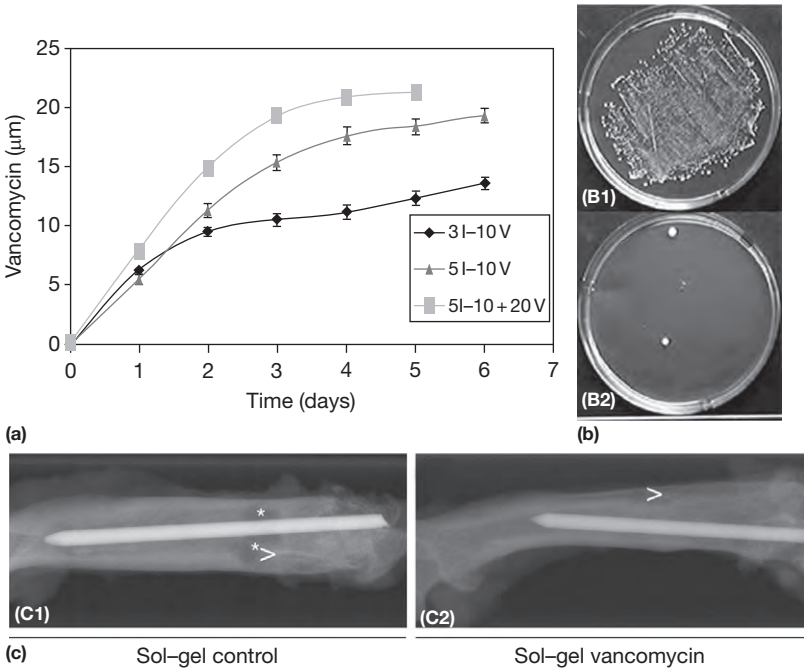

Figure 13 Vancomycin-containing sol–gel-coated Ti rods exhibit controlled antibiotic release and effective microbicidal activity. (a) vancomycin release into PBS for more than 5 days, (b) vancomycin-containing sol–gel-coated Ti rods minimize bacterial adherence *in vivo* for 7 days (B1: sol–gel silica coating alone, B2: vancomycin-containing sol–gel silica coating). Many bacteria were visualized on the control plates (B1), very few colonies were recovered from the vancomycin-containing sol–gel silica-coating rods at 7 days (B2). (c) Radiographic analysis indicates that vancomycin-containing sol–gel-coated Ti rods prevent osteomyelitis. (Control sol–gel (C1) and vancomycin-containing sol–gel (C2) coated Ti rods were implanted into infected rat femora.) The femora were harvested at 28 days. Note that while the sol–gel-coating rods show unmistakable signs of bone infection (periosteal elevation, enlargement of the medullary canal [>], as well as focal cysts [*]), there are minimal changes in the bones treated with vancomycin-containing sol–gel silica-coating rods. Reproduced from Adams, C. S.; Antoci, V. A., Jr; Harrison, G.; *et al. J. Orthop. Res.* **2009**, *27*(6), 701-709, with permission from Wiley.

can travel through the blood circulation and can deliver the antitumor drug to specific target sites. Barbé *et al.* demonstrated that xerogel nanoparticles with doxorubicin incorporated can release this drug in a controlled fashion over several weeks.[119,122]

4.428.7. Summary

The excellent bioresorbable and biocompatible behavior of sol–gel oxides have been well documented *in vivo*. The *in vitro* and *in vivo* drug release rates from sol–gels have also been extensively studied. Kinetics can be easily adjusted by varying sol–gel processing parameters, as well as by modifying their chemical compositions. Not only can the sol–gel process be adjusted for different release kinetics of a particular drug, it is also possible to adjust the sol–gel process for various drugs. Sol–gel oxides have proven to be useful in pharmaceutics industry for the controlled delivery of small drug molecules. What is even more attractive with sol–gel oxides is their potential in biotechnology for the sustained, controlled delivery of large molecules such as proteins, DNA, or virus. Highly sensitive proteins, growth factors, polypeptides, and even virus can be easily encapsulated in the sol–gel oxides. Incorporated biomolecules retain their original conformation and are stable to protease degradation *in vivo* before released. Undoubtedly, sol–gel oxides represent a very promising controlled release carrier material for the next generation of controlled delivery systems.

Glossary

Bioactive agent Bioactive agents are those substances able to induce an effect on or to stimulate a response in a living tissue.

Biomimetism Reproducing artificially essential properties of one or several biological systems. It finalizes products and processes as they are used in Nature.

Functionalization Functionalization is the addition of functional groups onto the surface of a material by chemical synthesis methods. The functional group added can be subjected to ordinary synthesis methods to attach virtually any kind of organic compound onto the surface.

Local controlled delivery Release of an agent at a controlled rate for an extended time in a specific place to localize agent action.

Macropores Macropores are those pores with diameter larger than 50 nm according to IUPAC pores classification. Biomaterials scientific community traditionally considers macropores as those pores with diameter above 100 μm.

Mesopores Mesopores are those pores with diameter in the range 2–50 nm according to IUPAC pores classification.

Mesoporous bioactive glasses Mesoporous bioactive glasses are materials with chemical compositions similar to those of conventional bioactive sol–gel glasses (SiO_2–CaO–P_2O_5) and the textural properties and ordered mesopore arrangement of ordered mesoporous materials.

Micropores Micropores are those pores with diameter smaller than 2 nm according to IUPAC pores classification. Biomaterials scientific community traditionally considers micropores as those pores with diameter below 10 μm.

Nanoscale The nanoscale has been defined as being of the order of 100 nm or less.

Ordered mesoporous materials A mesoporous material is a material containing pores with diameters between 2 and 50 nm forming ordered arrangements of pore networks. They have high surface areas, great pore volumes, and narrow pore size distributions. These materials are excellent matrices to host different molecules, which make them suitable for numerous applications in catalysis, separation, biomedical field, etc.

Rapid prototyping Rapid prototyping is the name given to a host of related technologies that are used to fabricate physical objects directly from computer-assisted design (CAD) data sources. These methods are unique in that they add and bond materials in layers to form objects. Such systems are also known by the general names solid freeform fabrication and layered manufacturing and offer advantages in many applications compared to classical subtractive fabrication methods such as milling or turning.

Surfactant Short for 'SURFace ACTive AgeNT,' it is a molecule that lowers surface tension. Such molecules contain both hydrophobic and hydrophilic components and are thus semisoluble in both organic and aqueous solvents.

Abbreviations

AL	Alendronate
ACP	Amorphous calcium phosphate
AMS	Anionic surfactant templated mesoporous silica
BSA	Bovine serum albumin
C_8	Octyl chains
C_8TAB	Octyltrimethylammonium bromide surfactant
C_{10}TAB	Decyltrimethylammonium bromide surfactant
C_{12}TAB	Dodecyltrimethylammonium bromide surfactant
C_{16}TAB	Hexadecyltrimethylammonium bromide surfactant
C_{18}	Octadecyl chains
CHA	Carbonate hydroxyapatite
CLCT	Cooperative liquid-crystal template mechanism
cmc	Critical micelar concentration
CTAB	Cetyltrimethylammonium bromide surfactant
DMS	Dimethylsilyl groups
ED	Electron diffraction
EDS	Energy dispersive scattering
FDU	FuDan University
F127	Pluronic® F127 block copolymer surfactant containing poly(ethylene glycol)-block-poly(propylene glycol)-block-poly(ethylene glycol) units ($EO_{100}PO_{65}EO_{100}$)
FSM	Folded sheet materials
FTIR	Fourier transmission infrared spectroscopy
HPLC	High-performance liquid chromatography
KIT	Korean Advanced Institute of Science and Technology
LCT	Liquid-crystal templating mechanism
MBG	Mesoporous bioactive glass
MCF	Mesostructured cellular foam
MCF-NH_2	Mesostructured cellular foam material functionalized with aminopropyl groups
MCM	Mobil composition of matter
MCM-41-DMS	MCM-41 mesoporous material functionalized with dimethylsilyl groups
MCM-41-MS	MCM-41 mesoporous material functionalized with methylsilyl groups
MCM-41-NH_2	MCM-41 mesoporous material functionalized with aminopropyl groups
MCM-41-SH	MCM-41 mesoporous material functionalized with mercaptopropyl groups
MCM-41-TMS	MCM-41 mesoporous material functionalized with trimethylsilyl groups
MS	Methylsilyl groups
MSU	Michigan State University
NMR	Nuclear magnetic resonance
OCP	Octacalcium phosphate
P123	Pluronic® P123 block copolymer surfactant containing poly(ethylene glycol)-block-poly(propylene glycol)-block-poly(ethylene glycol) units ($EO_{20}PO_{70}EO_{20}$)
PTHrP	Parathyroid hormone-related protein
PUF	Polyurethane foam
PVP	Poly(vinylpyrrolidone)
SBA	Santa BArbara
SBA-15-$C_3N^+Me_3$	SBA-15 functionalized with *N*-trimethoxysilylpropyl-*N*,*N*,*N*-trimethyl ammonium chloride
SBA-15-$C_3N^+Me_2C_{18}$	SBA-15 functionalized with octadecyldimethyl (3-trimethoxysilyl-propyl) ammonium chloride

4.429.1. Introduction

Since their discovery in 1990s, silica-based ordered mesoporous materials (SMMs) have received much attention from the scientific community because of their outstanding textural and structural properties. During the last few years, SMMs have found many applications in catalysis, sensors, separation, etc.[1,2] Recently, the biomedical research field has shown a growing interest toward these ordered mesoporous materials. These matrices exhibit two principal features: they can act as controlled delivery systems and they have bone-bonding capability through the development of nanoapatites similar to the

biological ones onto their surfaces when in contact with physiological fluids.

It was in 2001 when MCM-41 was proposed for the first time as a controlled delivery system, using ibuprofen as the model drug.[3] Their stable mesoporous structures and well-defined surface properties make SMMs good matrices to host a wide variety of drugs and biologically active species for local controlled delivery applications.[4–13] The structural and textural properties of mesoporous matrices can be tailored depending on the targeted guest molecule. Moreover, there are a number of silanol groups covering the mesoporous silica walls susceptible of undergoing chemical functionalization with organic functions. The different approaches developed up to date to achieve better control over drug loading and release kinetics are tackled in this chapter.

The *in vitro* bioactive behavior of SMMs has been also demonstrated.[8,14] Recently, the synthesis of mesoporous bioactive glasses (MBGs), with chemical compositions similar to those of conventional bioactive sol–gel glasses and the textural properties and ordered mesopore arrangement of SMMs has been reported.[15,16] MBGs exhibit fascinating features such as the fastest bioactive response reported till date for bioceramic materials or biomimetic behavior similar to the *in vivo* bone mineralization process.[17] All these aspects and the different chemical strategies carried out to modulate the time of bioactive response are reviewed within this chapter.

This double scope, controlled delivery capability and *in vitro* bioactivity, makes ordered mesoporous materials promising candidates to be used as bioceramics for bone tissue-regeneration technologies.[4,18–20] In addition, it is also possible to organically modify the external surface of silica walls to graft certain biomolecules such as peptides, proteins, or growth factors that act as signals to enhance or stimulate new bone formation. Considering all these properties the question is: do these materials have good potential to be used as bioceramics in clinical medical practice? Their biocompatibility, bioactivity, capability to regenerate bone, and ability to act as controlled delivery systems of biologically active molecules have been confirmed. Actually, the preliminary *in vitro* and *in vivo* tests performed using SMMs have been favorable. So, the current challenge is to optimize all these properties to the concrete clinical need and to evaluate the performance of SMMs in comparison with that of bioceramics that are widely employed in clinical practice such as bioactive glasses.

4.429.2. Ordered Mesoporous Materials: General Remarks

As previously commented, SMMs were reported for the first time in the early 1990s by Japanese researchers[21,22] and Mobil Oil Corporation scientists,[23] who reported for the first time the synthesis of KSW-n and M41S families of mesostructured materials, respectively. Ordered mesoporous materials represent a new generation of structurally unique materials, which exhibit order at the mesoscopic scale (2–50 nm) and disorder at the atomic scale. The mesoporous channels are divided by amorphous silica walls and arranged periodically on lattices such as artificial atoms or molecules in ordinary crystals. The synthesis of mesoporous materials is based on the use of surfactants that act as templates, that is, structure directing agents, for the assembly and subsequent condensation of inorganic precursors.[24,25]

SMMs are characterized by regular arrays of uniform channels, whose dimensions can be tuned through the chemical nature of the surfactant, additives, and synthesis conditions (pH, temperature, etc.) in the so-called *liquid-crystal templating* (LCT) mechanism.[26] This method is based on the formation of liquid crystals in mixtures of polar solvents and surfactants with a nonpolar tail group. However, different investigations in the formation procedures of SMMs led to suggest two different variations of the LCT mechanism (**Figure 1**).

As per the first mechanism, known as *true liquid-crystal template* (TLCT), the surfactant concentration is so high that under certain conditions of temperature and pH a lyotropic liquid-crystalline phase is formed in absence of the inorganic precursor. According to the TLCT mechanism, the amount of surfactant dissolved in the aqueous solution is above the critical micelar concentration (*cmc*), which allows the surfactant molecules to form aggregates called micelles. These micelles are formed because the hydrophobic tails of the surfactant tend to congregate to minimize contact with water while their

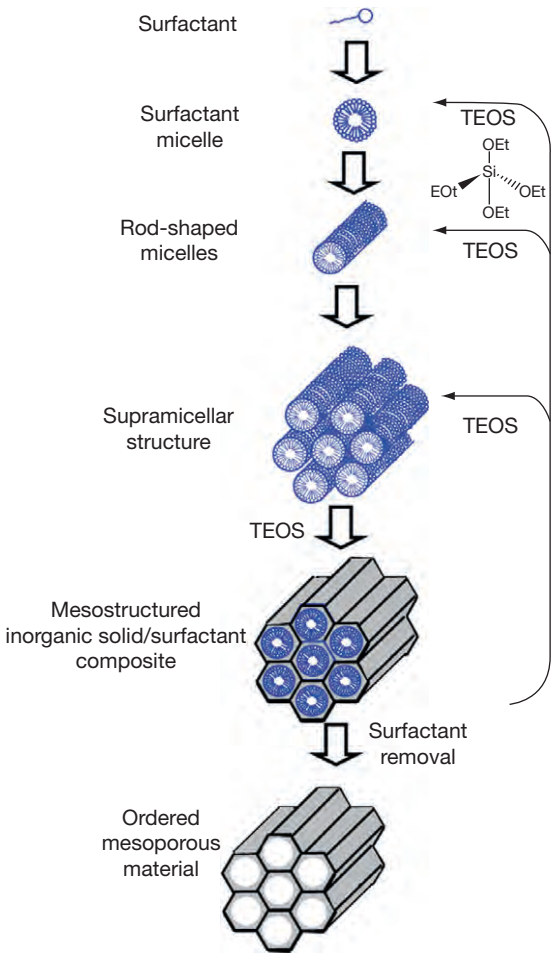

Figure 1 Schematic representation of true liquid-crystal template mechanism and cooperative liquid-crystal template mechanism used to describe the synthesis of silica-based ordered mesoporous materials.

hydrophilic heads orientate to maximize the interaction with the aqueous medium. The shape and size of these micelles depend on the composition and chemical nature of the surfactant and on the solution conditions, such as the surfactant concentration, pH and temperature, presence of cosurfactants, etc. These micelles aggregate themselves forming supramicellar structures with hexagonal, cubic, or laminar geometry depending on the experimental conditions. Thus, the geometry of the resulting mesoporous framework will depend on the geometry of the supramicellar aggregates. Then the silica source, which is normally tetraethylorthosilicate (TEOS) or tetramethylorthosilicate (TMOS), is added, which condenses around the supramicellar structures. The second proposed mechanism is the cooperative liquid-crystal template (CLCT), which suggests that it is also possible that the lyotropic liquid-crystalline phase is formed even at concentrations of surfactant molecules below the *cmc*, existing as a cooperative assembly of the surfactant and the already added silica precursor.

Independently of the synthetic route followed, the last step in the synthesis of SMMs consists in the surfactant removal by calcination or solvent extraction. The surfactant removal leaves a network of cavities within the silica framework that will determine the physical–chemical properties of the resulting materials. These materials exhibit outstanding properties, such as stable mesoporous structure, high surface area ($\sim$1000 $m^2 g^{-1}$), large pore volume ($\sim$1 $cm^3 g^{-1}$), regular and tunable nanopore size (2–50 nm), homogeneous pore morphology (hexagonal or cubic pores), nontoxic and biocompatible behavior, and the possibility of being chemically modified with different organic groups grafted to the silica walls. Different mesoporous structures can be obtained depending on the synthesis pathway, such as MCM (Mobil Composition of Matter) series,[23,26–30] SBA (Santa BArbara) series,[31–33] MSU-n (Michigan State University) series,[34] KIT-n (Korean Advanced Institute of Science and Technology) series,[35] FSM-n (Folded Sheet Materials) series,[36] FDU (FuDan University) series,[37–39] and AMS-n (Anionic surfactant templated Mesoporous Silica) series.[40]

Figure 2 displays the structural models corresponding to different mesoporous structures exhibiting different symmetries. Among them, three well-known mesoporous materials are MCM-41, SBA-15, and MCM-48, whose structural models are displayed in Figure 2. The two MCM-type materials are synthesized by using cationic quaternary ammonium surfactants under basic conditions. They have narrow pore size distributions ranging from 2.5 to 4.0 nm, with 2D-hexagonal *p6mm* structure (MCM-41)[41] and 3D-bicontinuous cubic $Ia\bar{3}d$ structure (MCM-48).[28] SBA-15 mesoporous material is synthesized by using neutral nonionic surfactants (block copolymers) as templates. SBA-15 exhibits large pore sizes in the 6–10 nm range with 2D-hexagonal *p6mm* structure and complementary micropores. These micropores are arranged in a disordered fashion interconnecting adjacent mesopores.[42,43] SBA-15 is currently receiving much attention because of its possible utilization in applications that require materials with easily accessible, uniform, and large-size pores with good stability.[44,45] Besides, different research approaches have allowed the development of new SBA-15-type mesoporous structures with enhanced textural properties to increase the application fields of such matrices. Thus, SBA-15 materials with really large surface areas have been reported.[46]

4.429.3. Biocompatibility of Mesoporous Materials

Bioceramics aimed at bone implant applications must be in contact with physiological fluids. In this sense, long-term biocompatibility, which has been demonstrated to depend on the implantation site, the shape, and size of the material and also on its surface chemistry, is a mandatory requirement that must be satisfied (see Chapter 4.401, The Concept of

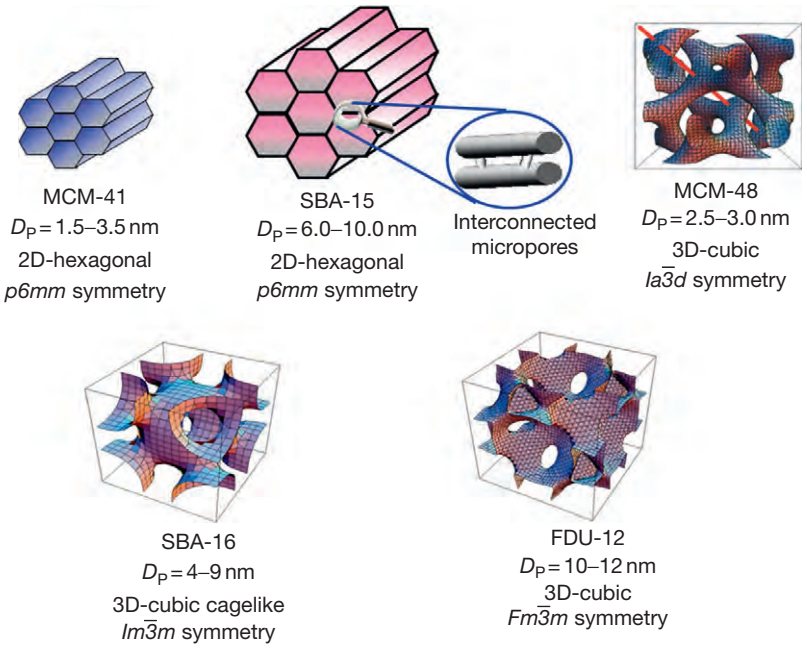

Figure 2 Models of different mesoporous structures, including their pore diameters (D_P) and symmetries.

Biocompatibility and Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing). Among bioceramics, SMMs are good candidates to be used as bone implant materials, because they can host a wide variety of biologically active molecules for the treatment of bone diseases.

Amorphous silica has been generally considered as nontoxic, and it has been reported as biocompatible and degradable in living tissue.[47–49] In fact, amorphous colloidal and porous silica are used as adjuvant in pharmaceutical technology. To date, biocompatibility and degradability with time of different silica materials have been described,[49–52] but few research works have reported the inherent cytotoxicity and biocompatibility of SMMs. The concentration of SMMs has been revealed as an important factor in their *in vitro* toxicity. SMMs showed low toxicity at low concentrations,[53–59] whereas the toxicity increased at high concentrations.[53] It has been also shown that size and concentration of mesoporous silica particles affect the viability of human monocyte-derived dendritic cells as well as the expression of immune regulatory markers by these cells.[60] The results derived from such research showed that mesoporous silica particles have promising properties to serve as immune stimulants/regulants with possible T-cell modulatory properties favorable for vaccine delivery as well as for more neutral drug delivery systems. If intracelullar delivery is the aim in biological applications, it is critical to minimize the particle size of SMM to the nanometer scale. Thus, fluorescein functionalized mesoporous silica nanoparticles, with sizes close to 110 nm have been reported to be internalized into 3T3-L1 fibroblast cells and accumulated into cytoplasm with no apparent cytotoxic effects.[61]

The surface area of an SMM has been also reported as an important factor that causes cell death. Thus, the *in vitro* cytotoxicity of MCM-41 mesoporous material, MCM-41 functionalized with aminopropyl groups (MCM-41-NH_2) and mercaptopropyl groups (MCM-41-SH) and spherical silica nanoparticles (SiO_2), toward human neuroblastoma cells[62] has been investigated. Taking into account that the particles studied were not soluble in aqueous media, authors introduced a new quantity to measure the cytotoxicity of these materials, Q_{50}, which is the number of particles required to inhibit normal cell growth by 50%. This study showed that Q_{50} increased in the order: MCM-41 < MCM-41-SH < MCM-41-$NH_2 \approx SiO_2$. These results would point to MCM-41 as the most cytotoxic of the studied materials. Albeit the chemical basis of the cytotoxic effect of these materials remains unclear, the exposed surface area of the particle could play an important role in cellular death. Therefore, the most toxic mesoporous silica materials were those with the largest surface areas. However, the chemical nature of the attached functional groups should be also considered. Moreover, surface area may not be the origin for cytotoxicity as spherical silica nanoparticles, which exhibited relatively small surface area, displayed cytotoxicity similar to that of MCM-41-NH_2, which had higher surface area. All these findings suggest that cell death could be governed by other factors, such as size and shape.

In vivo studies with rats evidenced low toxicity with small amounts of 1–2 μm SBA-15[63] surgically implanted into the basolateral amygdale of rats. In addition, mesoporous particles (~100 nm) fused with iron oxide and amorphous silica particles exhibited low toxicity when intravenously administrated in mice.[64] Recently, *in vivo* studies using MCM-41, MCM-48, and mesostructured cellular foam (MCF) mesoporous materials have been reported.[65] Histological studies performed after subcutaneous injection of such SMMs at the sciatic nerve in rats evidenced a good biocompatibility at all time points. However, intraperitoneal and intravenous injections in mice resulted in death or euthanasia.

The above-mentioned results clearly show that toxicity of SMMs strongly depends on the administration route to the living body. Therefore, when evaluating the viability of SMMs as biomaterials for bone tissue regeneration, the first step should consist in performing *in vitro* tests with osteoblastic cell cultures. Accordingly, *in vitro* assays with osteoblastic cell culture using several mesoporous materials in the system SiO_2–P_2O_5 with different phosphorus contents have been reported.[66] These preliminary *in vitro* assays indicated that the lowest cellular damage was induced by the sample with the highest P-content (5% in mol). This fact was ascribed to the greatest decrease in the amount of silica leached from matrices with the highest phosphorous content. Recently, the *in vitro* behavior of both unmodified and organically modified SBA-15 materials loaded with osteostatin, which is the sequence 107–111 of the parathyroid hormone-relatedprotein (PTHrP), has been evaluated.[67] The results revealed that the incorporation of osteotatin into the SMMs increased cell proliferation and expression of several osteoblast phenotypic markers (alkaline phosphatase, osteocalcin, osteoprotegerin, receptor activator of nuclear factor-KB ligand, and vascular endothelial growth factor) in mouse MC3T3-E1 osteoblast cell line. Moreover, there was an increase in the matrix mineralization, and the secretion of collagen was stimulated after 12 days. Thus, it has been demonstrated that osteostatin-loaded SBA-15 materials promote osteogenesis in cell culture, which is interesting from the point of view of their potential clinical usage in bone regeneration technologies.

Once these bioceramics successfully passed the *in vitro* tests, they were investigated under *in vivo* conditions.[68,69] Such experiments were performed in healthy and dexamethasone-induced osteoporotic rabbits. Cavitary defects in distal, medial, and lateral condyle were performed and both SBA-15 and SBA-15 loaded with osteostatin were implanted. The histopathological evaluation was carried out after 2 weeks of implantation. The cavitary defects in healthy animals revealed an efficient reparative process, with neoformed bone tissue around the biomaterials after 2 weeks. However, the incorporation of osteostatin into the mesoporous matrices was found to reduce tissue encapsulation, associated with increased cellularity and the appearance of osteoid deposits surrounding the biomaterial. These results open promising expectation for SMMs to be used as bioceramics for bone repair and regeneration technologies.

4.429.4. Mesoporous Materials for Local Drug Delivery

The fascinating structural and textural properties of SMMs made them suitable to act as host systems of a wide range of different drugs for the treatment of bone diseases. This is especially important when dealing with anticancer and

antiosteoporosis drugs for the local treatment of osseous tumors and osteoporosis, respectively. The local administration of therapeutic agents by bioceramic matrices presents advantages over conventional therapies, such as oral intake, because a better control over drug loading and release can be achieved. Moreover, the local sustained administration permits to keep constant drug levels in plasma and to reduce undesired side effects.[70] Sol–gel processed silica controlled release materials were first proposed in 1990s.[52,71–74] Since 2001, when MCM-41 was proposed for the first time as controlled delivery system,[3] several SMMs have been tested as delivery systems of different drugs, such as ibuprofen,[75–82] naproxen,[83] aspirin,[84] piroxicam,[85] gentamicin,[86,87] amoxicillin,[88] erythromycin,[77,89] vancomycin,[90] diflunisal,[90] captopril,[91] nimodipine,[92] itraconazole,[93] alendronate,[94–96] zoledronate,[97,98] ipriflavone,[99] methotrexate,[100] and cisplatin.[101] In addition, SMMs have been also reported as controlled delivery systems of proteins,[5,20,102,103] peptides,[67,104,105] and amino acids.[106]

Molecule adsorption and *in vitro* delivery tests are remarkable steps in the performance of SMMs as controlled delivery systems (**Figure 3**). There are different methods of molecule adsorption, but the most commonly used are impregnation methods, in which the mesoporous carrier is soaked into a concentrated molecule solution. Loading conditions, such as temperature, pH, solvent, etc., must be selected attending to the chemical nature of the targeted molecule.[107] On the other hand, *in vitro* delivery assays are performed by soaking the loaded SMMs into simulated body fluid (SBF)[108] or saline solution at pH 7.4 and 37 °C to try to mimic physiological conditions. Normally, the amount of molecule released is monitored by chromatographic and spectroscopic techniques, such as high-performance liquid chromatography (HPLC) and ultraviolet–visible (UV–vis) spectroscopy.

The research performed since 2001 on ordered mesoporous silica indicates that the textural properties, mesoporous structure, morphology, and organic functionalization of the silica walls are the main factors that govern adsorption and release of molecules from SMMs. All these parameters can be tailored for the design mesoporous matrices, opening many paths in this research field.

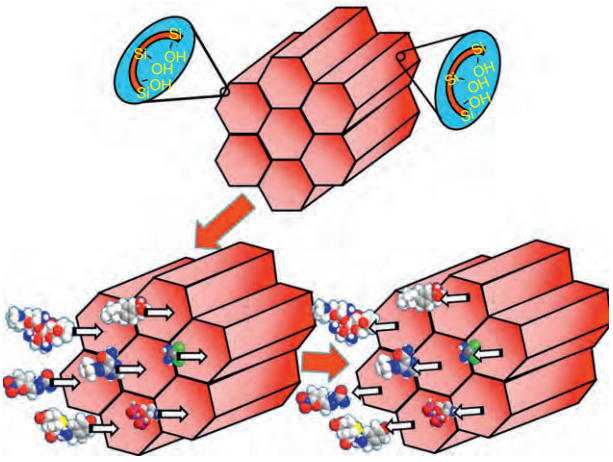

Figure 3 Schematic representation of drug loading and release processes in ordered mesoporous materials.

4.429.4.1. Influence of the Textural Properties

4.429.4.1.1. Pore diameter

The adsorption of molecules into SMMs depends on the mesopore diameter of the host matrix, that is, it follows size-selectivity criteria. Commonly, pore diameters slightly larger than the molecule dimensions (pore/molecule size ratio >1) are enough to allow the adsorption of molecule inside the pores. On the contrary, if the mesopore diameter is smaller than the molecule size, the molecule would adsorb only on the external surface of the material. This molecule-sieve effect is especially remarkable when the adsorption of large-size molecules, such as proteins, is targeted. Some authors have investigated the adsorption of globular proteins on MCM-41 materials.[109] Such studies demonstrated that proteins with dimensions larger than the mesopore diameter were only adsorbed in the outer surface of MCM-41. In addition, adsorption tests into SBA-15 of proteins displaying different dimensions were carried out.[110] These assays also evidenced that only proteins with sizes smaller than the mesopore diameter showed significant adsorption and consequently, that SBA-15 was acting as a molecular sieve.

Among proteins, serum albumins, which are one of the major components in plasma proteins in humans, are of special interest. Albumin is usually composed of a single chain of 582 amino acids with an average length of 10 nm and width of 6 nm.[111,112] Albumins are capable of binding reversibly to a wide variety of ligands. They can also bind different drugs that can be released to sites where the pharmacological action is needed. Therefore, albumins could be employed to store, protect, transport, and deliver different drugs used for the treatment of bone diseases. SBA-15 has been used as host matrix of bovine serum albumin (BSA).[102] However, the size of BSA is quite close to the SBA-15 pore diameter and the diffusion of protein molecules into the mesoporous channels is difficult. For this reason, an attractive strategy would consist in increasing the pore size of SBA-15 by modifying the synthesis conditions, such as using different hydrothermal treatments.[113,114] Recently, Vallet-Regí *et al.* reported BSA adsorption and release tests into SBA-15 with different pore diameters.[103] In such research work, pore diameters ranging from 8.2 to 11.5 nm were obtained for SBA-15 materials synthesized by using hydrothermal treatments ranging from 1 to 7 days. BSA loading tests indicated that there is a direct dependence of protein adsorption on pore size, that is, the greater the pore diameter, the higher is the amount of protein loaded (**Table 1**).

Pore diameter has been also demonstrated to play a key role in molecule release kinetics. This fact was observed when testing MCM-41 matrices of different pore diameters as ibuprofen delivery systems. MCM-41 materials with pore sizes ranging from 2.5 to 3.6 nm were obtained by using short-chain or long-chain cationic surfactants, respectively.[115] Ibuprofen release profiles revealed that the drug release rate was modulated by the pore diameter of SMMs. Thus, the ibuprofen release to the delivery medium was faster as the pore diameter increased, confirming the diffusional nature of drug release.

4.429.4.1.2. Surface area

The adsorption of molecules into mesoporous matrices depends on the adsorptive properties of the silica surface.

Table 1 Pore diameter and amounts of BSA loaded into SBA-15 materials submitted to different hydrothermal treatments ranging from 1 to 7 days

Material	*Time of hydrothermal treatment (days)*	*Pore diameter (nm)*	*Amount of BSA loaded (mg g^{-1})*
SBA-15-1d	1	8.2	151
SBA-15-3d	3	9.5	234
SBA-15-5d	5	10.1	242
SBA-15-7d	7	11.4	270

Table 2 Surface area of MCM-41 materials synthesized using different surfactants and amount of ibuprofen loaded

Surfactant	*Surface area (m^2 g^{-1})*	*Amount of ibuprofen loaded (mg g^{-1})*
85%C_8TAB–15%C_{10}TAB	768	110
70%C_8TAB–30%C_{10}TAB	936	190
C_{12}TAB	1087	230
C_{16}TAB	1157	340

The surfactants used during the synthesis are indicated for each case. C_8TAB, trimethyloctylammonium bromide; C_{10}TAB, decyltrimethylammonium bromide; C_{12}TAB, dodecyltrimethylammonium bromide; C_{16}TAB, hexadecyltrimethylammonium bromide.

Therefore, the chemical interactions between the silanol groups covering the silica surface and the functional groups of the guest molecule will determine the amount of molecule loaded (Figure 3). Surface of SMMs is the textural parameter that indicates the silica surface susceptible of undergoing chemical interactions with the guest molecule and, consequently, it is expected that the higher the surface area, the higher is the amount of molecule loaded. This fact was corroborated when several MCM-41 matrices exhibiting different values of surface area were tested as ibuprofen delivery systems (Table 2).

The same behavior was also observed when carrying out loading and release assays of captopril[91] into several 2D-hexagonal structures with different surface areas. This trend was also confirmed when MCM-41 and SBA-15 matrices, with surface areas of 1157 and 719 m^2 g^{-1}, respectively, were tested as alendronate delivery system.[94] Alendronate is a potent bisphosphonate commonly used for osteoporosis treatments. The maximum loads of alendronate were 139 and 83 mg g^{-1} for MCM-41 and SBA-15, respectively. All these findings demonstrate the direct dependence of the amount of drug loaded on the surface area of the SMM, that is, the highest surface areas promote the greatest amounts of drug loaded.

4.429.4.1.3. Pore volume

The adsorption of molecules into SMMs is a molecule-surface interaction, and consequently, the amount of molecule loaded depends on the pore diameter as the size selective limiting factor, and also on the surface area. However, it has been reported performing successive impregnations of MCM-41 material with ibuprofen solutions is possible, which allows to achieve complete pore filling and leads to higher drug loads.[116] This fact was explained by the increase in the intermolecular ibuprofen interactions, as confirmed by solid-state nuclear magnetic resonance (NMR) spectroscopy measurements.[117] In this case, the amount of ibuprofen adsorbed is limited by the pore volume of the SMM, that is, the larger the pore volume the greater is the amount of drug loaded.

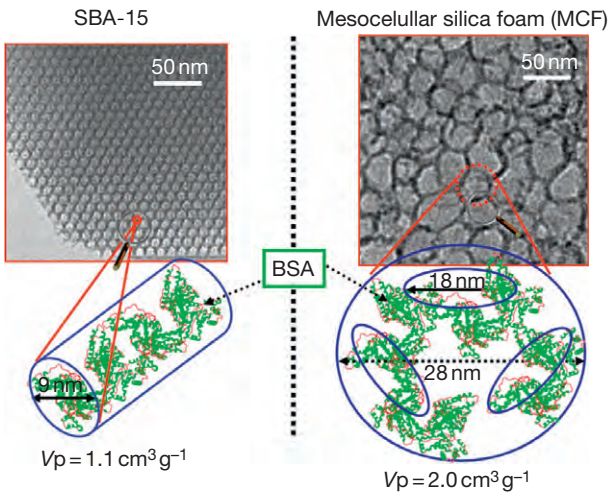

Figure 4 Schematic illustration of host–guest interactions for large-volume molecules, such as bovine serum albumin (BSA) protein, into SBA-15 and mesocelullar silica foam (MCF) matrices.

The pore volume must be also considered when the confinement of large-volume molecules, such as certain proteins, is aimed. With regard to this topic, MCFs have been proposed as host matrices of several enzymes and proteins.[118,119] The synthesis of MCFs is carried out by employing triblock copolymer surfactants and adding a swelling agent, normally trimethylbenzene, into the structure directing template solution.[120,121] For comparison purposes, loading and release tests of BSA were performed on SBA-15 and MCF materials.[4,5] Different transmission electron microscopy (TEM) and N_2 adsorption studies of MCF matrix revealed the existence of spherical cells of around 28 nm with windows of around 18 nm, with the pore volume of 2.0 cm^3 g^{-1} (Figure 4). In the case of SBA-15, such studies indicated the presence of 2D-hexagonal pore networks with pore sizes of around 8 nm, with 1.1 cm^3 g^{-1} as the pore volume (Figure 4). The BSA loading tests indicated that the amount of BSA loaded was higher in MCF (240 mg g^{-1}) than in SBA-15 (150 mg g^{-1}). Certainly, the different BSA loads could be ascribed to the difference in the pore volume, that is, the greater the pore volume, the higher is the amount of BSA loaded. Nevertheless, the contribution of other parameters, such as pore diameter, cannot be overruled. As previously mentioned, the BSA dimensions are very tight to the SBA-15 diameter, which could make the protein adsorption difficult. However, the wide pore size of MCF would be facilitating BSA penetration into the carrier cavities.

4.429.4.2. Influence of the Matrix Structure

The influence of pore connectivity and structure of SMM into drug release kinetics was observed by using different mesostructures as host matrices. Two SMMs with similar pore size, between 2 and 3 nm, and different structures were selected: MCM-41, which contains 2D-hexagonal array of pores, and MCM-48, which consists of a 3D-bicontinuous cubic mesoporous structure with $Ia\bar{3}d$ symmetry (**Figure 2**). Then, loading and release experiments were performed using erythromycin[77] and ibuprofen.[78] MCM-48 matrix exhibits unique penetrating bicontinuous networks of channels that allow easy molecular accessibility and fast molecular transport. As a consequence of this, a faster drug release was observed from cubic matrices than from hexagonal materials, although the release profile was similar from both matrices, which exhibits first-order kinetics.

4.429.4.3. Influence of the Particle Morphology

The particle morphology of the mesoporous matrix represents the extension of the interface between the host material and the body fluid, so the effect on drug release kinetics is predictable. For this reason, MCM-41 was synthesized in the form of irregularly shaped powder and monodispersed spheres ranging from 490 to 770 nm in diameter, and ibuprofen loading and release assays were carried out.[79] Such experiments showed that microsized spheres displayed slower release rate than irregularly shaped powders. In fact, those spherical particles with the smallest sizes exhibited the slowest ibuprofen release kinetics.

The control of the particle morphology of SMMs is also expected to lead to a more reliable and reproducible controlled delivery system. This control has been achieved by employing an aerosol assisted synthesis to obtain different mesoporous structures in the form of micrometric spheres as delivery system of triclosan, a widely used antimicrobial agent.[122]

On the other hand, the use of hollow mesoporous spheres offers the possibility to store higher amounts of guest molecules than conventional SMMs. It has been reported that hollow spheres with mesoporous shells would exhibit more advantages in mass diffusion and transportation compared to conventional hollow spheres of solid shells. Within this porous shell, it is of special interest that porous channels penetrate across the shell for drug storage and delivery systems. This penetrating pore channels can be obtained by using poly(vinylpyrrolidone) (PVP) and cetyltrimethylammonium bromide (CTAB) as co-templates during the synthetic procedure.[123] The authors loaded the hollow spheres with ibuprofen by impregnation, leading to a storage capacity three times higher than that of conventional SMMs, as previously published.[124]

4.429.4.4. Influence of the Matrix Organic Functionalization

The organic modification or functionalization of SMMs using different organic groups has been revealed as the cornerstone to modulate the adsorption and release of molecules from these matrices.[9,125–127] The surface of silica walls contains high density of silanol groups susceptible of organic modification by covalently grafting organic silanes ($(RO)_3SiR'$).[128]

In general, there are two main functionalization methods that are applied to organically modify SMMs for controlled delivery purposes:

(i) *Cocondensation method*: Also known as one-pot route, it involves the addition of the organic group, normally a silane-containing reactive group, such as chloride, methoxy, or ethoxy groups, during the mesoporous synthesis and the entire functionalization process is carried out in a unique way. This route leads to functionalized materials in which the organic groups are grafted to the outer and to the inner surface of the silica walls. For this reason, and to avoid loosening of the mesostructural order, the functionalization degree cannot exceed 40% mol. Two exceptional examples have been given for the vinyl- and thiol-functionalization up to 62 and 50 mol%, respectively, even though the resulting mesoporous silicas were not well-ordered.[129,130] Recently, functionalization up to 60 mol% of SBA-15 with carboxylic acid groups has been also reported.[131]

(ii) *Postsynthesis method*: It involves an organic modification process carried out under anhydrous conditions, once the free-surfactant SMM has been already synthesized. Albeit this method leads to heterogeneous distributions of the functional groups, it results in well-defined structures controlled by the silica matrix. Besides, this route guarantees that the organic groups are placed in the outer surface of mesopore walls, which leads to higher functionalization degrees than that obtained by cocondensation method.

The functionalization method must be selected considering the targeted guest molecule. For instance, MCM-41 organically modified with aminopropyl groups through cocondensation and postsynthesis routes was used as host carrier for ibuprofen.[80] As expected, MCM-41 functionalized by postsynthesis route experienced higher decrease in the textural properties (pore diameter, surface area, and pore volume) than MCM-41 functionalized by cocondensation method. Moreover, ibuprofen release tests on these matrices revealed that drug release rate from MCM-41 functionalized by postsynthesis was smaller than that from MCM-41 functionalized using cocondensation route. This fact can be explained considering that aminopropyl groups are placed in the outer surface of the silica matrix, giving up higher functionalization degree capable of interacting with ibuprofen molecules and promoting higher drug retention. Proton nuclear magnetic resonance (^{1}H NMR) spectroscopy measurements confirmed the existence of ionic interactions between amino groups from modified matrix and carboxylic groups of ibuprofen.[132] More recently, the organic modification of SBA-15 with aminopropyl groups and the two above-mentioned functionalization methods has been reported.[102] For comparison purposes ibuprofen and BSA were chosen as model molecules and loading and *in vitro* release assays were carried out. Such studies indicated that functionalization with aminopropyl groups using postsynthesis route led to the smallest ibuprofen delivery rate, in agreement with the results obtained for MCM-41. Oppositely, the smallest BSA delivery rate was obtained from SBA-15 functionalized by cocondensation. Such behavior was explained by the balance of electrostatic interaction and hydrophilic interaction between BSA and the functionalized SBA-15 matrix that would be more favorable in matrices synthesized by cocondensation synthesis method.

The chemical nature of the matrix-drug host–guest interaction can be modulated by the appropriate choice of the organic groups depending on the targeted molecule and its application. For this purpose, two main approaches have been widely reported. The first strategy concerns the use of different organic groups able to induce attracting interactions with the functional groups of the guest molecule. For this purpose, the influence of host–guest interaction on drug adsorption and release was investigated by functionalizing MCM-41 through postsynthesis method with several organic functional groups (chloropropyl, phenyl, benzyl, mercaptopropyl, cyanopropyl, and butyl) and using ibuprofen as model drug.[133] Because of the different interactions of carboxylic group of ibuprofen with the tested organic functions, diverse load and release behaviors were observed. MCM-41 functionalized with polar groups loaded higher amounts of ibuprofen than MCM-41 functionalized with nonpolar groups. Furthermore, the smallest drug delivery rates resulted from matrices modified with mercapto or amino groups because such functions induced the strongest attracting electrostatic interactions with the carboxylic acid of ibuprofen. The second strategy involves the use of hydrophobic groups to functionalize the mesoporous silica walls. The main aspects concerning both approaches are tackled in the next sections, which are mainly focused on the functionalizations using amino groups and hydrophobic groups.

4.429.4.4.1. Functionalization with amino groups

The organic functionalization of SMMs with amino groups has been widely reported. For instance, MCM-41 and SBA-15 materials functionalized with aminopropyl groups via the postsynthesis route have been proposed as alendronate controlled delivery systems.[94] These research showed that the amount of drug loaded on amino-modified matrices (MCM-41-NH_2 and SBA-15-NH_2) was almost threefold greater than that on unmodified matrices (Table 3). Concerning alendronate release behavior, amino-functionalized matrices exhibited slower release kinetics than that of unmodified materials (Table 3).

Recently, the organic modification of SBA-15 using different aminopropyl functionalization degrees has been reported as a good strategy to modulate alendronate dosage.[96] The functionalization was performed following the postsynthesis route but improved by adding a catalyst during the functionalization process. The results derived from this work pointed to a linear dependence of the amount of drug loaded on the functionalization degree. Besides, the higher the functionalization degree, the smaller the total amount of alendronate released to the delivery medium. For this reason, this gradual functionalization has been demonstrated to allow better control over drug loading and release. These results are of great interest for bone implant technologies, because the high potency of bisphosphonates requires only small local doses.

The organic functionalization of SBA-15 using partially silylated poly(propyleneimine) dendrimers has been also reported as a good strategy to modulate drug dosage.[76] For this purpose, authors employed first, second, and third dendrimer generations and two different nominal degrees of surface functionalization, which led to a wide range of materials with a great variety of amine functionalization and surface coverage. The performance of such systems was tested *in vitro* using ibuprofen as model drug. Such studies revealed that the higher the dendrimer generation, the higher is the host–guest attracting interactions and, consequently, the higher are the drug loads. Moreover, drug delivery patterns exhibit a sustained drug release and the drug dosage is governed by the dendrimer generation.

Amino functionalization of SMMs has been also revealed as a good approach to control adsorption and release of proteins such as BSA.[102,103] As previously commented, SBA-15 materials with different pore diameters, which were synthesized using different hydrothermal treatments, were functionalized by postsynthesis route.[103] It is well-known that organic functionalization following the postsynthesis route always leads to a decrease of pore diameter. In the case of BSA, the protein dimensions are very tight to the SBA-15 mesopore size and consequently, the amount of BSA loaded was smaller in amino-modified matrices than in unmodified materials. Nevertheless, the attracting interactions taking place between amine groups of functionalized matrices and amide groups of BSA strongly influenced protein release behavior (Figure 5).

Table 3 Alendronate (AL) release data from MCM-41 and SBA-15 before and after amine functionalization

Material	*AL loading (mg g^{-1})*	*% AL released after 24 h*	*AL total delivery time (h)*
MCM-41	139.2	58	72
MCM-41-NH_2	366.1	28	264[a]
SBA-15	82.8	56	264
SBA-15-NH_2	223.0	11	264[b]

[a]Incomplete delivery (76%).
[b]Incomplete delivery (69%).

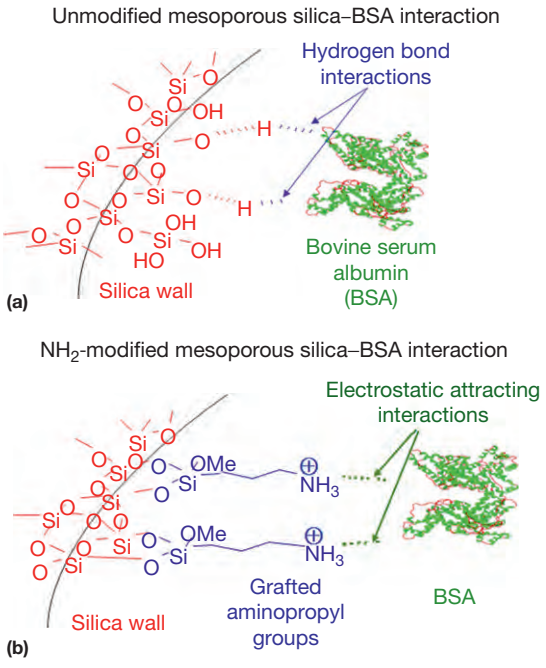

Figure 5 Schematic representation of mesoporous matrix-bovine serum albumin (BSA) host–guest interactions for (a) pure mesoporous silica and (b) aminopropyl-functionalized mesoporous silica.

Thus, the initial burst effect observed in BSA released from unmodified matrices (~90%) was reduced almost three times (~30%) after amino functionalization. Moreover, the BSA release from all SBA-15-NH_2 mesoporous materials was incomplete, whereas the total amount of loaded BSA was released after 192 h from unmodified matrices.

Amino functionalization of large-pore and large-volume MCF materials has also been probed to increase the affinity toward BSA molecule.[4,5] The results revealed that the amount of BSA loaded was higher in amino-modified MCF (MCF-NH_2) than in unmodified MCF (Figure 5). This fact can be easily explained because despite the reduction of pore diameter as a consequence of functionalization, the pore size of MCF-NH_2 (~16 nm) is still big enough to permit the BSA penetration. Regarding BSA release behavior, as expected, functionalization exerts a noticeable effect in BSA delivery patterns. Thus, the initial burst effect of unmodified MCF (~60%) was significantly reduced in MCF-NH_2 (~10%).

All these findings demonstrate that amino functionalization of SMMs is a suitable strategy for the design of controlled delivery systems of many biologically active molecules exhibiting organic groups which are capable of chemically interacting with amino functions.

4.429.4.4.2. Functionalization with hydrophobic groups

The organic modification of SMMs with hydrophobic groups is a commonly used way to control the loading and release of certain molecules. For example, the functionalization of SBA-15 with different alkyl chains, octyl (C_8) and octadecyl (C_{18}), has been carried out and controlled delivery tests of erythromycin, a hydrophobic antibiotic, have been reported.[89] As previously commented, the functionalization always leads to a decrease in the textural properties of SMMs, which in this case, led to a decrease in the amount of erythromycin loaded in SBA-15-C_8 and SBA-15-C_{18} materials, that is, 130 and 180 mg g^{-1}, respectively, compared to unmodified SBA-15 (340 mg g^{-1}). However, erythromycin delivery rate was slower from functionalized matrices than from unmodified SBA-15. This fact can be ascribed to the diminution of the wettability degree of the functionalized surfaces, which makes difficult the penetration of the aqueous release medium inside the mesoporous channels and induces slower drug delivery kinetics.

Tang *et al.* reported the functionalization of MCM-41 matrices with methylsilyl (MS) or dimethylsilyl (DMS) groups and tested their capability as ibuprofen delivery systems.[81] As expected, functionalized materials loaded smaller ibuprofen amounts than unmodified MCM-41. However, MS and DMS groups led to slower drug release caused by the difficult diffusion of the delivery medium inside the mesopore channels. Therefore, the complete drug release was achieved after around 10, 20, or 500 h from MCM-41, MCM-41-MS, and MCM-41-DMS, respectively. These authors also reported the modification of ibuprofen-loaded-MCM-41 using trimethylsilyl (TMS) groups.[82] Again, the *in vitro* release tests revealed that the presence of TMS groups remarkably delayed the drug release compared to unmodified MCM-41 material.

SBA-15 materials functionalized using hydrophobic groups have been also proposed as controlled delivery systems of L-tryptophan (L-Trp),[106] a hydrophobic amino acid present in the 3D structure of many peptides, proteins, and growth factors of interest in bone tissue-regeneration technologies.[134,135] L-Trp exhibits a hydrophobic aromatic indol ring that makes necessary to increase the hydrophobicity of SBA-15, which contains high density of silanol groups. Actually, unmodified SBA-15 loaded less than 5 mg g^{-1} of L-Trp, probably due to the extremely different chemical nature of the hydrophobic amino acid and hydrophilic SBA-15 (Figure 6(a)). Thus, to increase the host–guest interactions, functionalization of SBA-15 using quaternary amines with different alkyl lengths, namely, *N*-trimethoxysilylpropyl-*N*,*N*,*N*-trimethyl ammonium chloride (TMOS-$C_3N^+Me_3Cl$), and octadecyldimethyl (3-trimethoxysilylpropyl) ammonium chloride (TMOS-$C_3N^+Me_2C_{18}Cl$), has been reported. The main forces that governed amino acid adsorption in SBA-15 functionalized with short alkyl chains (~$C_3N^+Me_3$) were coulombic attracting interactions between deprotonated carboxylic groups of amino acid ($-COO^-$) and protonated quaternary amines ($-N^+R_4$) covering the mesoporous surface (Figure 6(b)). In this case, the amount of L-Trp loaded into SBA-15-$C_3N^+Me_3$ matrix increased up to 43 mg g^{-1}. When using long hydrocarbon chains (~$C_3N^+Me_2C_{18}$) two-thirds of the silica surface was functionalized. This high functionalization degree using hydrophobic chains induced strong interactions between mesoporous surface and indol group of L-Trp (Figure 6(c)), leading to L-Trp loading amounts of 82 mg g^{-1} for SBA-15-$C_3N^+Me_2C_{18}$.

4.429.5. Bioactivity of Mesoporous Matrices

When considering any material for biomedical purposes, the first consideration that should be addressed is the interaction between the material and the living body. Thus, the surface of such material must be carefully investigated. SMMs are characterized by exhibiting high surface areas and high surface density of silanol groups (Si–OH). It is well known that the bioactive response of conventional bioactive glasses depends on the presence of silanol groups (see Chapter 1.109, Bioactive Ceramics). In addition, porosity has been evidenced as key factor that modulates the kinetics of formation of the carbonate hydroxyapatite (CHA) layer.[136–141] In this sense, SMMs are expected to induce bioactive response because they exhibit a high density of silanol groups that could act as nucleation sites for CHA. Moreover, these materials exhibit outstanding textural properties that could bring enhanced kinetics of CHA formation.

The first reports on the *in vitro* bioactivity behavior of mesoporous materials involved three well-known structures, MCM-41, MCM-48, and SBA-15.[127,142,143] The evaluation of the bone-bonding capability of bioceramics was performed following accepted *in vitro* protocols at 37 °C by soaking disk-shaped pieces of materials into SBF.[108,144] The modifications of SMM surfaces were monitored using different characterization techniques, such as Fourier transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD). Scanning electron microscopy (SEM) and TEM together with energy dispersive scattering (EDS) and electron diffraction (ED) are also employed. In the case of bioactive materials, all these techniques allow to confirm the formation of a new layer, mainly consisting of CHA, on the materials surfaces. However, MCM-41, MCM-48, and SBA-15 mesoporous materials exhibit different textural and structural features, which induce variations in the rates of

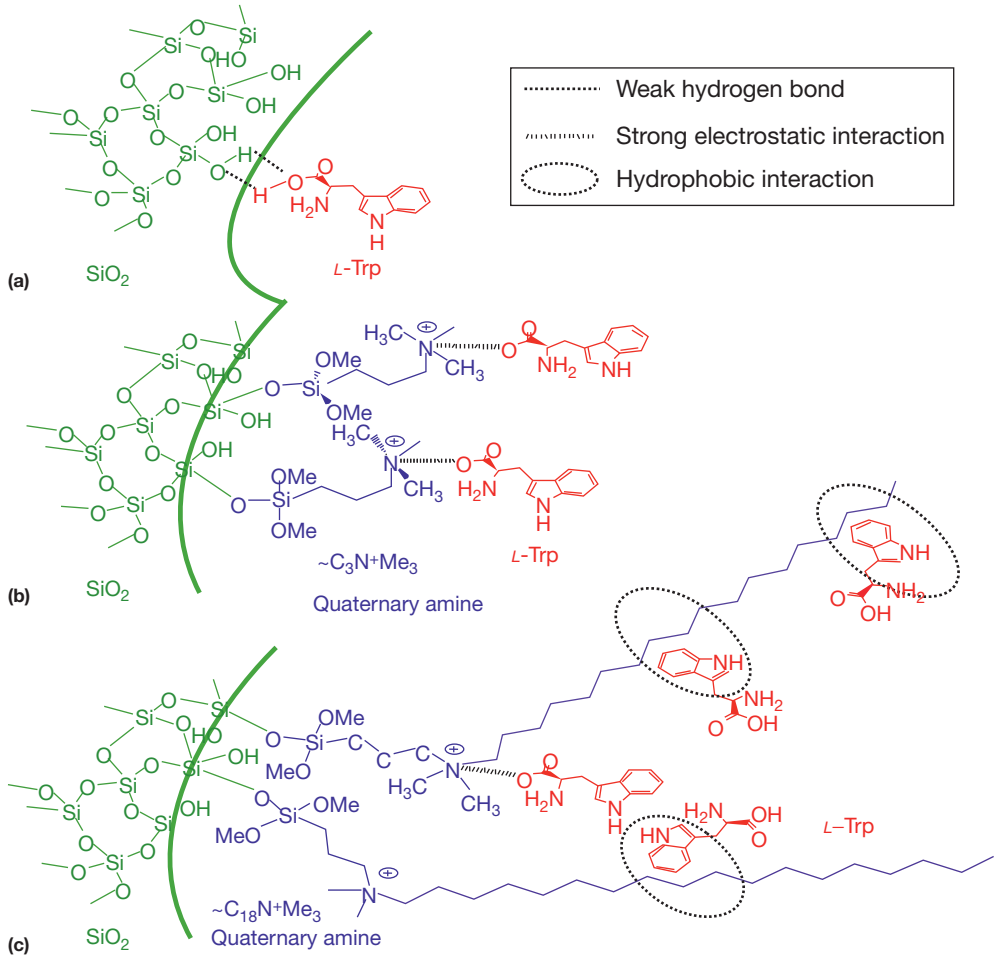

Figure 6 Schematic representation of different chemical interactions between L-Trp and (a) unmodified SB-15: L-Trp is linked by weak hydrogen bond interaction, (b) SBA-15 functionalized with short-chain quaternary amines ($\sim C_3N^+Me_3$), and (c) SBA-15 functionalized with long-chain quaternary amines ($\sim C_{18}N^+Me_3$).

formation of the CHA layer. Thus, SBA-15 and MCM-48 were able to induce the formation of a nanocrystalline CHA layer onto their surfaces after 30 and 60 days of assay, respectively. However, no evidence of formation of such layer was observed on the surface of MCM-41. These different *in vitro* bioactive behaviors could be due to the different concentrations of silanol groups present in each material and their diverse textural and structural properties. In this sense, MCM-41 presents a relatively small silanol density ($\sim$2 mmol Si–OH·m^{-2}) compared to SBA-15 and MCM-48 ($\sim$13 mmol Si–OH·m^{-2}), which could explain its nonbioactive response after 60 days of test. However, SBA-15 and MCM-48, which exhibited similar silanol density, presented very different rates of formation of the CHA layer. Such difference could be related to the different textural and structural properties of the matrices. Hence, mesoporous matrices with large and accessible pore networks should favor the ionic diffusion through the mesoporous framework, which should promote the formation of the CHA layer. This fact is in agreement with the experimental results that indicate that SBA-15, with the greatest pore diameters ($\sim$9 nm) and 2D-hexagonal arrangement of mesopores interconnected by micropores exhibited the fastest bioactive behavior among the three tested materials.

These results clearly indicate that the textural and structural features of SMMs are important factors that are involved in their *in vitro* behavior. However, these are not enough conditions to achieve a timely bioactive behavior to be useful *in vivo* because the formation of the CHA layer on SMMs is much slower than that on conventional sol–gel glasses (around 3 days).[145] Therefore, the chemical composition of materials, mainly the presence of calcium and/or phosphate, has to be also considered. Thus, the next subsections will focus on the different strategies developed to date to accelerate the bioactive response of SMMs.

4.429.5.1. Incorporation of Phosphorous into Mesoporous Silica Matrices

In vitro bioactivity assays performed with bioactive sol–gel glasses revealed that the presence of phosphorous in the glass network affected the formation of the CHA layer.[146] This fact inspired the idea of incorporating small amounts of phosphorous, of around 1% in weight, into the MCM-41 silica network.[147] The structural and compositional characterization of this new material, denoted as P-MCM-41, using XRD,

N_2 adsorption porosimetry, SEM-EDS, and TEM-EDS techniques pointed to the preservation of the 2D-hexagonal *p6mm* mesoporous structure. It was also revealed that the phosphorous content was heterogeneously distributed into the mesoporous silica network and mainly placed in the outer edge of the particles and not in their inner nucleus. The *in vitro* bioactivity assays demonstrated that P-MCM-41 developed a CHA layer on its surface after 15 days of assay. Compared to the bioactive behavior of SBA-15 or MCM-48, the incorporation of phosphorus into the silica network accelerates the bioactive response of SMMs (Table 4).

4.429.5.2. Addition of Small Amounts of Bioactive Glasses

A widely employed strategy to induce bioactivity to different materials consists in preparing biphasic mixtures by incorporating another phase that acts as an accelerator of the CHA nucleation.[148–150] For this purpose, MCM-41 as the main phase (90% in weight) was mixed with a bioactive sol–gel glass in the system SiO_2–CaO–P_2O_5 (10% of weight),[142] which gave rise to the so-called G-MCM-41 material. The *in vitro* bioactivity tests of this material revealed that the formation of the apatite layer started just after 3 h of assay and were completed in 1 day (Table 4). These results indicate that the addition of small amounts of bioactive glasses is a good strategy to reduce the time of bioactive response of SMMs materials to just 1 day.

4.429.5.3. Mesoporous Bioactive Glasses

Recently, another strategy has been developed to accelerate the time of bioactive response. This approach consists in using the synthesis methods of SMMs but with the same compositions of glasses. It was in 2004 when the synthesis of highly ordered MBGs in the system SiO_2–CaO–P_2O_5 was reported for the first time.[16] The synthesis of these MBGs was carried out by using the evaporation-induced self-assembly (EISA) method[151] in the presence of a nonionic triblock copolymer as template (Pluronic® P123, $EO_{20}PO_{70}EO_{20}$) and with the employ of TEOS, triethylphosphate (TEP), and calcium nitrate ($Ca(NO_3)\cdot 4H_2O$) as SiO_2, P_2O_5, and CaO precursors, respectively. The enhanced textural properties of MBGs promoted by the template led to highly bioactive responses compared to conventional bioactive glasses.[152–154] Moreover, it has been demonstrated that the textural and structural properties of MBGs can be modulated by varying the CaO content of the mesoporous glasses.[15] A gradual evolution from 2D-hexagonal to 3D-bicontinuous cubic structure together with an increase in the textural properties was observed when decreasing the CaO content (Figure 7). The possibility of tailoring both structural and textural features of MBGs is an interesting advance toward the development of biomaterials able to fulfill the essential requirements for specific biomedical applications.

The *in vitro* assays carried out in SBF demonstrated that this new family of mesoporous glasses exhibits enhanced bioactive behaviors, with even faster apatite phase formation than

Table 4 Structural characteristics, composition (% in mol), and time of bioactive response of different mesoporous materials

Matrix	*Structure*	*Composition (% in mol)*	*Bioactive*[a]	*Time in SBF*
MCM-41	2D-hexagonal (*p6mm*)	$100SiO_2$	No	60 days
MCM-48	3D-cubic ($Ia\bar{3}d$)	$100SiO_2$	Yes	60 days
SBA-15	2D-hexagonal (*p6mm*)	$100SiO_2$	Yes	30 days
P-MCM41	2D-hexagonal (*p6mm*)	$99SiO_2$–$1P_2O_5$	Yes	15 days
G-MCM41	2D-hexagonal (*p6mm*)	$95.6SiO_2$–4.0CaO–$0.4P_2O_5$	Yes	1 day
MG-S58m	2D-hexagonal (*p6mm*) + wormlike	$58SiO_2$–37CaO–$5P_2O_5$	Yes	1 day
MG-S75m	2D-hexagonal (*p6mm*) + orthorhombic (*p2mm*)	$75SiO_2$–20CaO–$5P_2O_5$	Yes	8 h
MG-S85m	3D-cubic ($Ia\bar{3}d$)	$85SiO_2$–10CaO–$5P_2O_5$	Yes	1 h

[a]Induction time needed for the formation of a carbonate hydroxyapatite (CHA) layer onto the surface of materials.

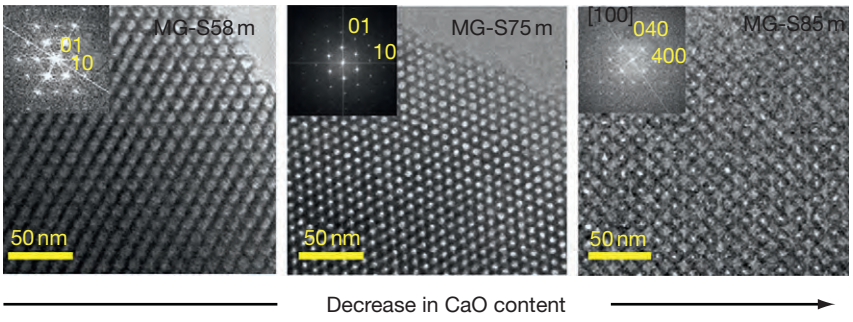

Figure 7 TEM images and their corresponding FT diffractograms of MBGs in the SiO_2–CaO–P_2O_5 system with different CaO contents. TEM images were taken with the electron beam parallel to the pore channels of 2D-hexagonal structures corresponding to mesoporous glasses with compositions (a) $58SiO_2$–37%CaO–5%P_2O_5 and (b) $75SiO_2$–20%CaO–5%P_2O_5, respectively. (c) TEM image taken in the [100] directions of 3D-bicontinuous cubic structure with $Ia\bar{3}d$ symmetry corresponding to a mesoporous glass of $85SiO_2$–10%CaO–5%P_2O_5 composition (see Table 4).

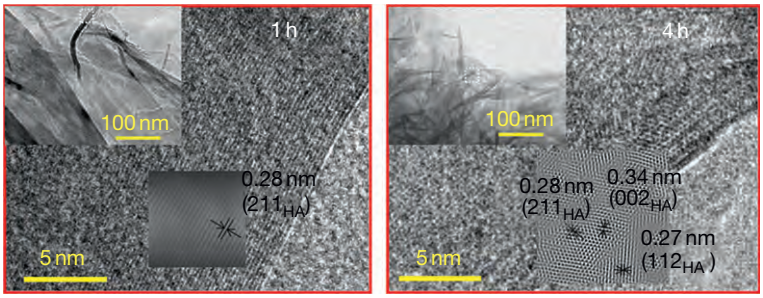

Figure 8 *In vitro* bioactive study in SBF of MG-S85 sample, with 3D-cubic structure by TEM.

conventional bioactive glasses. Hence, it has been revealed that the kinetics of formation of the CHA layer in MBGs is controlled by their textural and structural properties.[155] In this respect, MBGs differ from bioactive glasses, in which the formation kinetics mainly depends on the composition and textural properties.

Thus, the MBG material with the smallest CaO content (MG-S85m) but having 3D-bicontinuous cubic structure and the highest surface area values exhibited faster bioactive response than MBG materials with the greatest CaO content (MG-S58m). FTIR and TEM-ED studies revealed an accelerated bioactive behavior for MG-S85m sample, which was able to form a nanocrystalline CHA layer in just 1 h after coming into contact with SBF[17] (**Figure 8**). In this case, the 3D pore system not only provided high surface area and porosity, but also promoted the ions interchange by increasing mass transport and diffusion processes, which resulted in the fastest bioactive behavior reported till date in silica-based bioactive materials.

Recently, a new property derived from the textural and structural characteristics of MBGs, namely biomimetic behavior, has been reported. This biomimetic mechanism, where there is a sequential transition from amorphous calcium phosphate (ACP) to octacalcium phosphate (OCP) to calcium deficient carbonatehydroxyapatite (CHA) maturation, similarly to the *in vivo* biomineralization process, has been observed for the first time.[17–19]

Many bioceramics develop a CHA phase *in vitro* through the direct crystallization of previously precipitated ACP,[156] without the prior formation of OCP phase which is formed in natural bone biomineralization process.[157–159] OCP is a metastable phase and will appear only if the pH in the crystallization system is below 7.

MG-S58m sample, with 2D-hexagonal mesoporous arrangement and high CaO content allows an intense Ca^{2+}–H_3O^+ exchange as a consequence of the open channel array, the high textural parameters, and the relatively high CaO content. This ionic exchange led to local acid pH values of 6.5 during the first stages, which favor the OCP formation (**Figure 9**). This phenomenon does not take place in the case of bioactive glasses, because the local pH is kept at pH 7.4 or even slightly higher from the beginning of the bioactive process, which would avoid the existence of OCP phase. This biomimetic behavior was monitored by TEM (**Figure 9**). After being soaked in the SBF for 1 h, MG-S58m sample developed a large amount of newly formed ACP layer with a Ca/P ratio of 1.2. This event has been widely observed in many bioactive compounds, and corresponds to the step 4 of the bioactive process as theorized by Hench.[160]

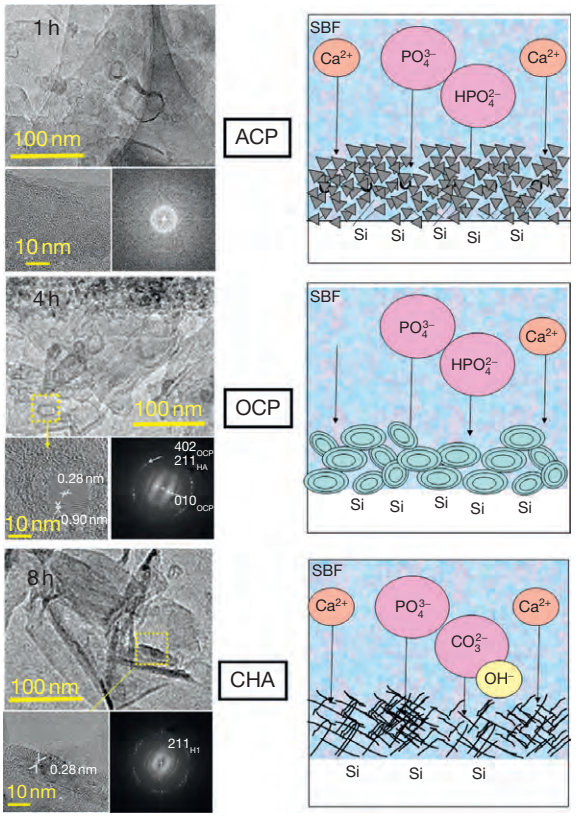

Figure 9 *In vitro* bioactive behavior of MG-S58m mesoporous glass with a 2D-hexagonal structure and $58SiO_2$–37%CaO–5%P_2O_5 composition. High-resolution TEM study of mesoporous glass surface after different soaking times in SBF together with the schematic depiction of the sequential transition from ACP to OCP to CHA observed by TEM are displayed.

To date, the mechanism of *in vitro* bioactivity involves the direct crystallization of CHA phase from the ACP. However, MBGs have shown a unique behavior allowing the growth of nanocrystalline oval biphasic nuclei composed of OCP with a small fraction of HA after 4 h in SBF, with a Ca/P ratio of 1.3. The transformation from oval OCP nuclei to needle-like nanocrystalline CHA was finally evident after being soaked in SBF for 8 h.

All these results bring up the possibility of controlling the reactive properties of MBGs by tailoring their compositional, textural, and structural properties. This new family of ordered

mesoporous materials widens the range of possibilities for the use SMMs as new generation bioceramics with outstanding bone-bonding capability.

4.429.6. Hierarchical Macroporous Scaffolds for Bone Tissue Engineering

The different research results reported so far confirm that ordered mesoporous materials are characterized by two valuable features: controlled delivery capability and *in vitro* bioactive behavior. It would be also feasible to combine both properties to design new bioceramics with an added value. Nevertheless, when dealing with ceramics aimed at bone tissue engineering applications, it is essential to keep in mind that the main role will be played by cells. Pore dimensions of mesoporous materials fall in the 2–50 nm range, whereas the dimensions of cells are in the 1–100 μm range. That is, mesopores are too small to allow cell uptake, which need dimensions in the order of microns. Bone porosity, which ranges between 1 and 3500 μm, is necessary for several physiological functions.[161,162] Bone tissue engineering requires the design of hierarchically 3D scaffolds with interconnected macroporosity, within the 20–1000 μm range.[163–165] Such macroporosity is essential to allow bone cell penetration, adherence, growth, and proliferation leading to bone tissue in-growth and eventually vascularization on implantation (see **Chapter 6.617, Bone Tissue Grafting and Tissue Engineering Concepts**).

SMMs, with ordered mesoporous channels and pore dimensions in the 2–50 nm range, are appropriate for applications in which drugs or biologically active molecules can be loaded and subsequently released where needed. On the other hand, macroporous materials, with pore dimensions in the microns scale, are adequate as scaffolds for bone tissue engineering. So, the challenge is to design and fabricate scaffolds that combine two scales of porosity; macroporosity to allow appropriate bone oxygenation and vascularization and mesoporosity for controlled delivery purposes (**Figure 10**). The aim is to fabricate biomaterials that help the human body to improve its regeneration role by recovering not only the structure of the damaged tissue, but also its function. So the current goal in biomaterials is to fabricate 3D scaffolds with hierarchical interconnected porosity that allows cells to proliferate and form new bone tissue following the natural processes of human tissue.

Several recent research works have been reported concerning the fabrication of 3D scaffolds using the highly bioactive MBGs as starting materials. Thus, Yun *et al.* reported the synthesis of ordered giant-, macro-, and mesoporous bioactive 3D glass scaffolds by using a combination of sol–gel, double polymers templating, and rapid prototyping (RP) techniques.[166] The resulting scaffolds presented three lengths of porosity: mesopores (~5 nm) obtained by using a triblock copolymer template ($EO_{100}PO_{65}EO_{100}$ (F127)), macropores (10–30 μm) produced by using methyl cellulose, and giant-sized pores (30–1000 μm) created by RP methods.[167,168] The *in vitro* tests in SBF revealed that the bioactive behavior of MBG was preserved because a CHA layer was formed onto the material surface after 24 h of assay.

Li *et al.* prepared hierarchically MBG-based scaffolds using P123 surfactant as mesostructure directing agent and polyurethane foam (PUF) as template for the macroporous structures.[169] The resulting materials presented hierarchical porosity with interconnected macropores of 200–400 μm or 500–700 μm and uniform mesopores of 3.7 nm. *In vitro* bioactivity tests showed that these MBG-based scaffolds induced the formation of a CHA layer on their surface after 4 h in SBF.

Other authors also have reported the employment of P123 and PUF to synthesize hierarchically structured 3D MBGs-based scaffolds with four different chemical compositions and their *in vitro* bioactivity and cell adherence evaluation.[170] These scaffolds exhibited similar mesostructural and textural features, showing interconnected macroporous networks with pore diameters in the 200–400 μm range and mesopores of

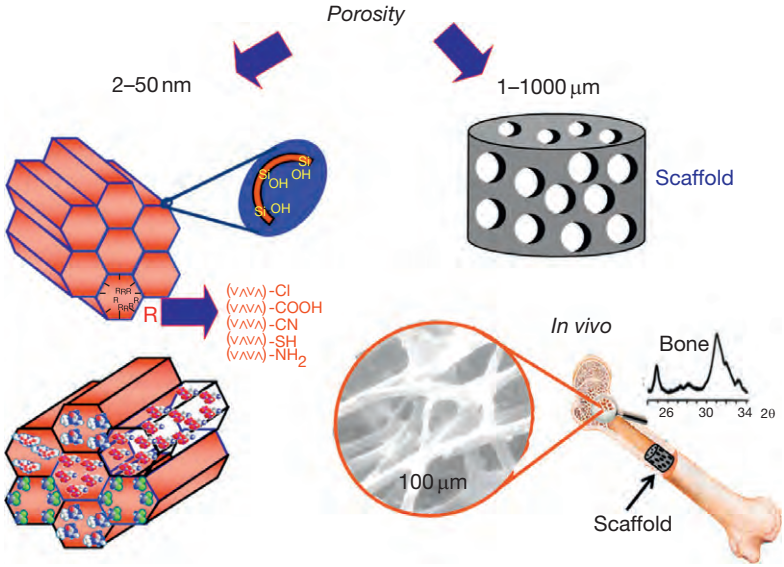

Figure 10 Schematic representation of the two scales of porosity present in an ideal 3D scaffold for bone tissue engineering. Macroporosity is similar to that of natural bone to allow new bone in-growth and mesoporosity to host drugs and biologically active species for controlled delivery functions.

4.9 nm in size. Cell cultures indicated that primary human bone-derived cells were able to attach and spread to different degrees on the different scaffolds. These authors also indicate that the differences observed in supporting cell growth and differentiation observed for different scaffolds could be related to the CHA formation on the surface of scaffold, which has been reported to affect cell activity.[171,172] Additionally, the release of calcium and silicon ions may be contributing to the modulation of cellular attachment.[173]

The design of 3D scaffolds capable to drive cell in-growth is an important challenge in tissue engineering (see **Chapter 6.617, Bone Tissue Grafting and Tissue Engineering Concepts**). The aim is to design and fabricate pieces that support and structure the newly formed tissue and such pieces must be made starting from the most appropriate materials for this purpose. Cells must be cultured onto this scaffold to subsequently give rise to the growth of new tissue. Wolf's law states that the bone remodels itself as a function of those forces acting on it, hence preserving its shape and density (**Figure 11**). The mechanical loads of stress, compression, flexion, and torsion in bones and the interstitial fluid contained in them originate stresses and deformations at the microscopical level, which stimulate the cells. The use of finite element calculation methods contributes to the study of interactions between materials, mechanical stimulations, and biological response. Such a method allows simulating the conditions that take place in bioreactors in the scaffolds. Moreover, the effect and deformation at each point of the scaffold can be quantified, for instance, at each node, and the relationship between mechanical loads and cell differentiation can be also quantified.[174]

One of the most employed approaches in bone tissue engineering involves the initialization of the regeneration process *in vitro* by soaking the scaffold in appropriate cell culture and in the presence of osteogenic agents (**Figure 11**). Then, the scaffold is implanted in the patient.[175,176] However, the current challenge in bone tissue engineering is to chemically graft such osteogenic agents into the 3D scaffold to be directly implanted in the patient, acting as osteoinductive signals for bone regeneration (**Figure 11**).

So, turning back to ordered mesoporous materials, the presence of silanol groups in the external surface of silica walls would allow the organic modification of the scaffold. The choosing of the appropriate functional groups could permit formation of strong chemical bonds between the material surface and different osteoinductive agents, such as certain peptides, proteins, or growth factors, as schematically displayed in **Figure 12**. This approach permits to 'decorate' the scaffold by chemically grafting different active agents, such as certain peptides, proteins, or growth factors, that act as potent osteoinductive signals able to promote the appropriate bone cellular functions in the place where needed.[177–179]

At is has been widely reported, SMMs allow the design of controlled delivery systems for drug loading and release. Among other applications, these systems could be very useful to locally treat several pathologies such as bone infection and inflammation, osteoporosis, cancer, etc. However, although such molecules could fit into the mesopore channels, the confinement of osteogenic agents into the mesopores would impede them in carrying out their function. The role of these molecules is to act as attracting signals for bone formation cells, but these cells are too large to fit inside the mesopores (**Figure 12**). However, it is possible to apply the acquired knowledge from these systems to the grafting of the mentioned peptides, proteins, or growth factors onto the external silica

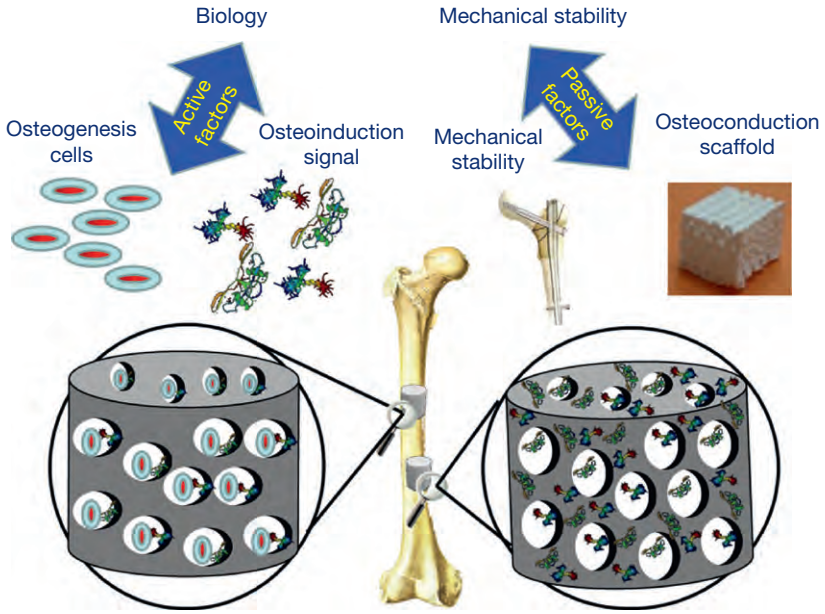

Figure 11 Scheme of the requirements for scaffolds aimed at bone tissue engineering. The biological point of view involves the presence of osteogenic cells. Osteogenesis process can be improved throughout by the presence of osteoinductive signals, which represents an added value. The mechanical aspect involves that bone remodels itself as a function of those forces acting on it. The two approaches used in bone tissue engineering are here displayed. Left down side: bone tissue regeneration starts *in vitro*. Right down side: osteogenic agents are grafted to the scaffold and implanted to allow the *in vivo* regeneration.

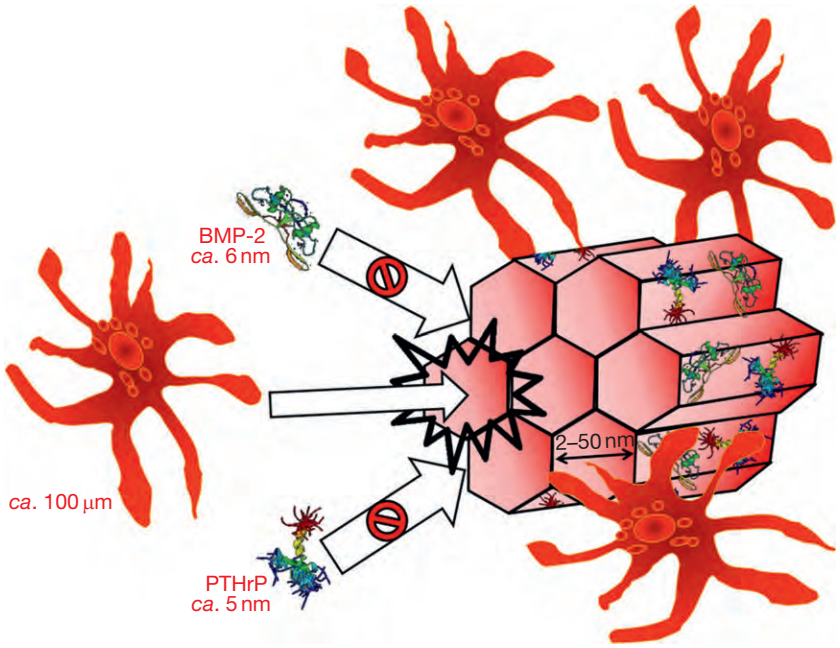

Figure 12 Schematic representation of a mesoporous silica material whose external surface has been organically modified to graft different osteogenic agents, such as growth factors or peptides. It is also schematically depicted that these osteogenic agents could fit inside the mesopores but that would obstruct them from playing their role. Such osteogenic agents act as signals for bone formation cells, and these cells (of ~100 μm) can never fit inside the mesopores (of 2–50 nm in size).

surface to induce bone tissue regeneration. Moreover, the possibility of using mesoporous matrices starting materials for the fabrication of 3D macroporous scaffolds provides these biomaterials an added value, their capability of hosting drugs to locally treat bone pathologies.

4.430.1. Introduction

Over the last two decades, there has been a dramatic development in the synthesis of open-framework inorganic materials with well-defined pore geometry. The development of such materials consisting of, for example, silica and carbon with controlled pore shapes and sizes of high precision is of great importance in diverse fields of modern science and technology.[1–4] These materials have already been used successfully in several fields, such as heterogeneous catalysis, separation processing, and host–guest chemistry. Recent exploration of these materials in bioadsorption, controlled release of biomolecules,

and drug delivery reveals their enormous application potential in biomaterials science.

The development of microporous molecular sieves has been reviewed before.[5–9] In addition, the recently discovered macroporous solids have also been described.[10–17] Under the influence of the discovery of ordered mesophases, newer concepts in periodic porous materials have emerged in recent years.[18–21] These findings have been summarized by Zhao *et al.*,[22] Selvam *et al.*,[23] and Bhattacharyya *et al.*[24] Here, we focus on ordered spherical, mesoporous, silica nanoparticles, giving particular attention to MCM-41 (Mobil Composition of Matter)-based materials. We will adopt the IUPAC definition[25] of mesoporous materials: materials with pore diameters between 2 and 500 nm.

Subsequent to summarizing the history of its discovery, we discuss the general synthesis procedure of mesoporous silica materials. This is followed by a discussion of ways to adopt these synthesis procedures in order to obtain the mesoporous silica-based microspheres and nanospheres. Next, we discuss the physical and chemical properties of these materials along with the general characterization techniques used to characterize them. In the last section, we elaborate on their applications in the field of biomaterials.

4.430.1.1. History

In the early 1990s, Kuroda's group in Japan developed new alkylammonium–clay intercalation complexes by hydrothermal treatment and calcination.[19,21] These complexes had a highly ordered honeycomb mesoporous structure, referred to as folded-sheet mesoporous material (FSM 16). At the same time, research work at Mobil Oil Corporation revealed a series of new porous materials grouped under the name of the M41S family, with striking resemblances to the Japanese materials.[18,20] The process was patented in 1991 and 1992.[26–28] It is of interest to note that Chiola *et al.*[29] had reported the synthesis of low-density silica based on the hydrolysis and condensation of a silica precursor in the presence of a cationic surfactant. This had already been patented in 1971. The unique mesoporous properties of that silica remained unrecognized until 1997 when Di Renzo *et al.*[30] reproduced the experiments described in the patent[29] and showed that the resulting product presented all the characteristics and properties of the MCM-41. Nevertheless, the numerous Mobil discoveries and applications have provided an impetus to the field, as witnessed by the development of many new synthesis methods.[31–34]

In 1992, Mobil researchers disclosed the first family of highly ordered mesoporous molecular sieves, M41S (pore size in the range 2–10 nm), in which long chain cationic surfactants were used as the template or pore forming agents during the hydrothermal sol–gel synthesis.[35] Depending on starting materials and synthesis conditions, different mesoporous silica oxides with ordered structures in the form of hexagonal (denoted as MCM-41),[18,20,35–42] cubic (denoted as MCM-48),[36–42] and lamella (denoted as MCM-50),[20,43,44] were formed (see **Figure 1**). Since then, many synthetic routes and strategies have been developed to yield a wide variety of materials of various frameworks with different chemical compositions and pore structures.

4.430.2. Synthesis of Nonporous Silica Nanospheres

4.430.2.1. The Stöber Technique

The Stöber process is the most common method for synthesizing colloidal silica-based nanoparticles that are <100 nm in size.[45] The process comprises hydrolysis of a silica alkoxide precursor (such as tetraethyl orthosilicate, TEOS) in a mixture of ethanol and aqueous ammonium hydroxide. During the hydrolysis, silicic acid is produced, which nucleates homogeneously and forms silica particles of submicron size when its concentration is above its solubility in ethanol. This method is intended for the preparation of pure silica nanoparticles.

In general, the process involves two steps: first, the hydrolysis reaction with singly hydrolyzed TEOS monomer $[(OR)_3Si(OH)]$ as a reaction product

$$Si(OR)_4 + H_2O \rightarrow (OR)_3Si(OH) + ROH$$

second, condensation of this intermediate reaction product to form silica according to

$$(OR)_3Si(OH) + H_2O \rightarrow SiO_2 \downarrow + 3ROH$$

We have to keep in mind that this is a simplified version of the very complex condensation processes that lead to the formation of the silica particles. Initial research on Stöber particles was mostly concentrated on the empirical prediction of the final particle size for a range of the initial reactant concentrations (0.1–0.5 M TEOS, 0.5–17.0 M H_2O, and 0.1–3.0 M NH_3) that lead to monodisperse colloids, the smallest achievable size being 10 nm and largest being 800 nm.[45,46] Later research was aimed at elucidating the mechanisms behind the formation and growth of the particles.[47–53] A consensus on the processes responsible for the particle formation and growth, and the eventual monodispersity, particle size, and particle shape has not yet emerged. Two models, monomer addition[47–49] and controlled aggregation,[52,53] have been proposed to describe the chemical and/or physical growth mechanisms of silica. The model proposed by Matsoukas and Gulari[47–49] contemplates that the particle formation and growth are solely governed by the kinetic equations that describe chemical reactions.

In their model, particle nucleation is the result of the reaction between two hydrolyzed monomers. Subsequently, the 'particle' grows only by monomer addition. The balance between monomer addition and nucleation determines the polydispersity and final particle size. Particle growth is rate-limited by the slowest step, the hydrolysis of the monomers. On the other hand, Zukoski and coworkers[50–53] described the nucleation and growth by a controlled aggregation of subparticles a few nanometers in size. Zukoski and coworkers assume that it is not hydrolysis that is the rate-determining step in the particle growth but that some step in the condensation pathway is rate-determining. Particle formation results from the aggregation during the entire reaction period. This aggregation process is controlled, in the sense that once the aggregates or 'particles' have reached a certain size (and thereby a certain colloidal stability because of their surface charge), the growth continues only by aggregation with the small subparticles and not by collisions with other (larger) particles. Growth, final particle size, and polydispersity are influenced in this model by parameters such as the surface charge and the size of the subparticles.

More recently, many other investigations have been devoted to the understanding of the particle growth mechanism,[54–56] and such studies have included microgravity experiments.[57]

4.430.3. Synthesis of MSNs

4.430.3.1. General Principles of Synthesis of Mesoporous Silica

A typical synthesis of MCM-41 requires a minimum of four reagents: a solvent (water and/or ethanol), a silica precursor (TEOS, tetramethyl orthosilicate (TMOS), tetrabutyl orthosilicate (TBOS)), an ionic (anionic or cationic) or noncharged surfactant, and a catalyst. Depending on the protocol, the reaction could occur in either an acidic or a basic medium, with different silica/surfactant ratios. The mixture is stirred, aged at room temperature or around 100 °C, and placed in a static autoclave for several hours. The surfactant template is removed by calcination. Novel routes have been proposed based either on a nonsurfactant templated method[58,59] or on a polyelectrolyte/hexadecyltrimethylammonium bromide method.[60]

Another alternative route[61,62] involves microwave treatment of a precursor gel first heated by microwave radiation around 100–150 °C followed by conventional heating. The advantages of the microwave-assisted preparation over the conventional hydrothermal method are a significant decrease in reaction time, and a more homogeneous heating, which leads to a better control of the texture and morphology. However, it has been superseded by faster methods that produce within a few hours materials of the same, if not better, quality.

4.430.3.2. Formation Mechanisms of Mesoporous Silica

Due to the important role of surfactant molecules in the synthesis of mesoporous silica materials, the formation mechanisms of its precursors have attracted much attention. Two typical mechanisms have been proposed so far: liquid crystal templating (LCT) mechanism[20] and mechanism of transformation from lamellar to hexagonal phase.[65]

4.430.3.2.1. Liquid crystal templating mechanism

A key feature of the LCT mechanism is that the liquid-crystalline mesophases, or micelles, act as templates rather than individual single molecules or ions. Accordingly, the final product is a silicate skeleton that contains voids with shapes similar to those of the mesophases. The silicate condensation is not the dominant factor in the formation of the mesoporous structure.[36,63,64] As illustrated in Figure 2, surfactant micelle molecules, assisted by a micelle self-assembly arrange themselves to form liquid-crystalline phases. Silicate species deposit between surfactant 'rods' and then condense to form an inorganic network, with a hexagonal ordering dictated by the interaction between the surfactant and the silicate species. After removal of the surfactant templates, a mesoporosity is obtained with pore size of 2–10 nm.

In general, the overall LCT mechanism is governed by two factors: (i) the dynamics of surfactant molecules to form assemblies, micelles, and ultimately, crystalline structures that function as templates and (ii) the ability of the inorganic oxide to undergo hydrolysis and polycondensation reactions, leading to a network surrounding the organic template. A wide variety of ionic surfactant molecules of different sizes, shapes, functionalities, and charges have been shown to be able to effectively function as pore structure-directing agents. These surfactant molecules can be classified on the basis of their head group chemistry and charge as follows:

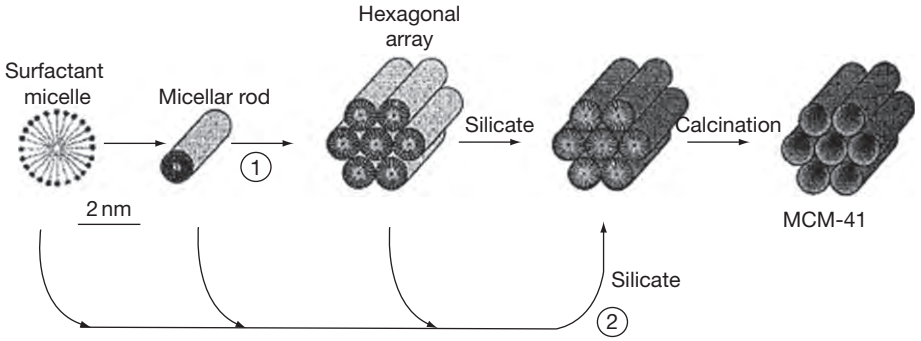

Figure 2 Schematic representation of two possible formation mechanisms of mesoporous silica: (1) liquid crystal templating mechanism and (2) transformation from lamellar to hexagonal phase. Reproduced from Selvam, P.; Bhatia, S. K.; Sonwane, C. G. *Ind. Eng. Chem. Res.* **2001**, *40*, 3237–3261, with permission from American Chemical Society.

Cationic surfactants: the hydrophilic group carries a positive charge, for example, tetraalkylammonium salts (C_nH_{2n+1})(CH_3)$_3$NX, $n = 6, 8, 9, 10, 12, 14, 16, 18, 20, 22$; X = OH, Cl, Br, HSO_4; (C_nH_{2n+1})(C_2H_5)$_3$N, $n = 12, 14, 16, 18$.

Anionic surfactants: the hydrophilic group carries a negative charge, for example, sulfates ($C_nH_{2n+1}OSO_3$ with $n = 12, 14, 16, 18$), sulfonates ($C_{16}H_{33}SO_3H$ and $C_{12}H_{25}C_6H_4SO_3Na$), and phosphates ($C_{12}H_{25}OPO_3H_2$, $C_{14}H_{29}OPO_3K$).

4.430.3.2.2. Transformation mechanism from lamellar to hexagonal phase

This is yet another formation mechanism proposed by Stucky and coworkers[65–67] who focused on the transformation mechanism from lamellar to hexagonal phase.

The mechanism postulates self-assembly of the liquid-crystal-like structures as a result of the mutual interactions between the silicate anion and the surfactant cations in the solution, that is, the silicate species generated in the reaction mixture influence the ordering of the surfactant micelles to the desired liquid–crystal phase. This was suggested by the identification of silica aggregates in the synthesis mixture using ^{14}N nuclear magnetic resonance (NMR) spectroscopy.[68] In addition, the formation of hexagonal, cubic, and lamellar structures through variations in the silica concentration at constant surfactant concentration represented strong support for this putative mechanism.[69] Huo *et al.*[70,71] and Inagaki *et al.*[72] carried out a more detailed analysis of the formation of these mesophases. They observed the formation of a layered silica–surfactant phase upon mixing the reactants that, with time, produced an MCM-41 structure (pathway 3 in **Figure 3**). Davis and Burkett[73] proposed a somewhat similar mechanism (pathway 2 in **Figure 3**) in which, depending on the reaction temperature, the formation of MCM-41 occurs via a disordered or lamellar structure.[74]

4.430.3.3. Synthesis and Growth of MSNs

Following the initial description of mesoporous materials, the synthesis of hierarchically ordered structures on different length scales, such as beads of controlled sizes, generated a great deal of interest, from both a fundamental and practical point of view. Holding centerstage in these studies was the control of the internal pore structure, as it is a challenging aspect of the synthesis of mesoporous M41S-based nanospheres.[75–83]

Grun *et al.*[84] first demonstrated the suitability of adapting the Stöber synthesis[45] of silica spheres for the production of spherical MCM-41 particles under basic conditions. Freshly distilled TEOS is combined with a dilute surfactant solution and ammonia as catalyst in a rapid room temperature preparation. The resultant silica solids are calcined at 550 °C in air to produce mesoporous solids that exhibit the characteristic low-angle X-ray diffraction (XRD) pattern associated with MCM-41 and the familiar reversible type IV nitrogen isotherm typical of these materials.[85] Scanning electron microscopy (SEM) reveals the spherical morphology of these solids. Since their advent, various assembly pathways have been used to produce mesoporous silica spheres[86–92] based on a procedure where TEOS is used as silica source, hexadecyltrimethylammonium bromide (C_{16}TMABr) as surfactant, alcohol as solvent, and aqueous ammonia as catalyst. It is to be noted that spheres can also be obtained in acidic medium by substituting HCl for ammonia.[93]

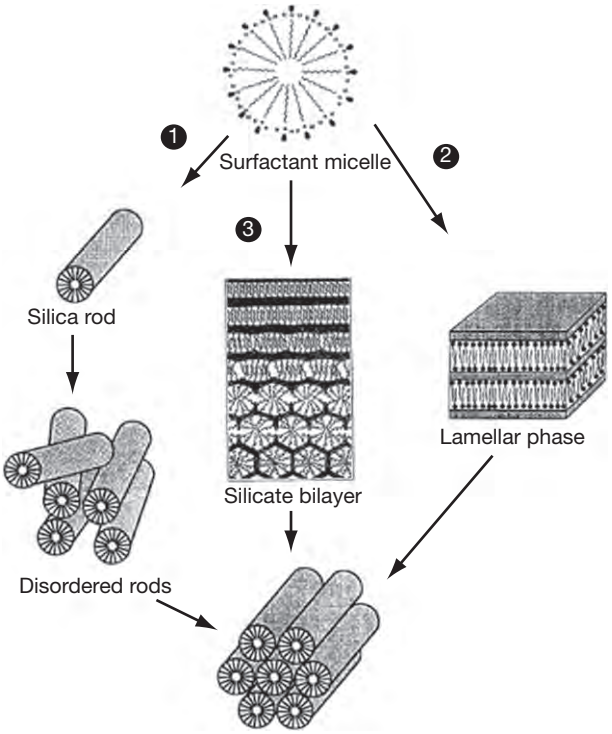

Figure 3 Proposed formation mechanistic pathways by (1) stacking of silicate surfactant rods via the formation of an initial (2) lamellar intermediate and (3) silicate bilayer. Reproduced from Kresge, C. T.; Vartuli, J. C.; Roth, W. J.; Leonowicz, M. E. *Stud. Surf. Sci. Catal.* **2004**, *148*, 53–72, with permission from Elsevier.

4.430.3.3.1. Alternative methods

Another route needs to be mentioned: the synthesis of silica spheres with a spray-drying process. Since the demonstration of the feasibility of this synthesis route by Lu *et al.*,[94] results of the preparation of high-quality mesoporous silica spheres by the evaporation-induced self-assembly (EISA) process[95,96] have been reported.[93,97–99] A sol, composed generally of a precursor of silica (TEOS), a cationic surfactant (C_{16}TMABr) and/or block copolymer (PEO–PPO–PEO), a solvent (isopropyl alcohol, ethanol), and water in an acidic medium, is atomized inside a drying chamber at a constant inlet temperature. Parameters such as C_{16}TMABr/Si molar ratio, pH, solvent quantity, and drying temperature influence the texture and the morphology of the final product. Very recently, Alonso *et al.*[99] have proposed a scheme for the formation of spheres by spray-drying alcoholic sols. Using ^{29}Si and ^{1}H solid-state NMR experiments, the formation mechanism consists of a droplet fragmentation due to the fast solvent evaporation, followed by aggregation and self-assembly of the surfactant molecules with the oxo-oligomers. The resulting mesophase extends inside the particles and forms ordered textures.

4.430.3.3.2. Growth mechanism

Although various morphologies have been achieved, the formation of MCM-41 nanospheres and the control of their morphologies have not been well mastered yet. Different morphologies and textures can be obtained by varying the amount of surfactant and solvents. Huo *et al.*[100] produced

marble-like spheres about 1 mm in diameter using TBOS based on emulsion biphase chemistry, which usually produces hollow mesoporous silica microspheres. Under basic conditions, TBOS undergoes hydrolysis to give butyl alcohol (BuOH), which is immiscible with water. The oil-in-water emulsion formed during the early reaction stage thus contains BuOH and partially hydrolyzed TBOS as the oil phase. The quaternary ammonium surfactants play an important role in the stabilization of this emulsion. Hydrogen bonding between the BuOH and water molecules provides a diffusion pathway for the surfactant and water to penetrate the TBOS/BuOH oil droplets and promotes the hydrolysis of TBOS. The resulting silicate polymerizes under the influence of the structure-directing surfactant and transforms into solid spheres via a soft silicate gel.

Very recently, the formation processes of spherical mesoporous silica were studied[101] in the case of a biphasic system containing a hydrophobic siloxane (TBOS) and an alkali solution with a surfactant. The water pools in the TBOS phase were shown to be connected to each other, and a regularly arranged nanostructure was formed by the self-assembly of the surfactant. Thus, the nanostructure of spherical mesoporous silica was determined to be the reverse of MCM-41, in which continuous mesopores were developed.

The effect of alcohol on the morphology of the spheres was investigated.[102–104] Increasing the ethanol concentration in the TEOS–C_{16}TMABr–ammonia–water system at room temperature led to the formation of a succession of mesophases in the order, MCM-41 (hexagonal phase), MCM-48 (cubic phase), and MCM-50 (lamellar phase). Such phase succession is the result of the cosurfactant behavior of the ethanol. At a lower alcohol concentration, SEM shows only undefined or barely spherical structures; when the alcohol concentration is increased, it mainly acts as a cosolvent, producing spherical particles. It was suggested that increasing the alcohol amount changes the surfactant packing parameter, g,[105,106] given by

$$g = \frac{V}{a_0 l}$$

where V is the total volume of the surfactant chain plus any cosolvent molecules between the chains, a_0 is the effective head group area at the organic–inorganic interface, and l is the surfactant chain length.

The parameter g directs the phase configuration in the synthesis of mesoporous materials. Small values of g stabilize more curved surfaces, such as MCM-41 ($1/3 < g < 1/2$), while larger values stabilize structures with less curvature, such as MCM-48 ($1/2 < g < 2/3$). The proposed mechanism of pore formation is shown in Figure 4.

The MCM-48 crystal core exhibits a truncated octahedron shape, in which each facet plays the role of a substrate for the growth of cylindrical pores in an epitaxial manner (Figure 4(a)). The epitaxial pores are forced to adopt the pore packing of the MCM-48 crystal facet surface. The pores growing on the {111} facets adopt a packing close to the hexagonal MCM-41, and those on the {001} facets, an intermediate packing between MCM-48 and MCM-41. The MCM-48 crystal core exhibits a truncated octahedron shape, in which each facet plays the role of a substrate for the growth of cylindrical pores in an epitaxial manner (Figure 4(a)). The epitaxial pores are forced to adopt the pore packing of the MCM-48

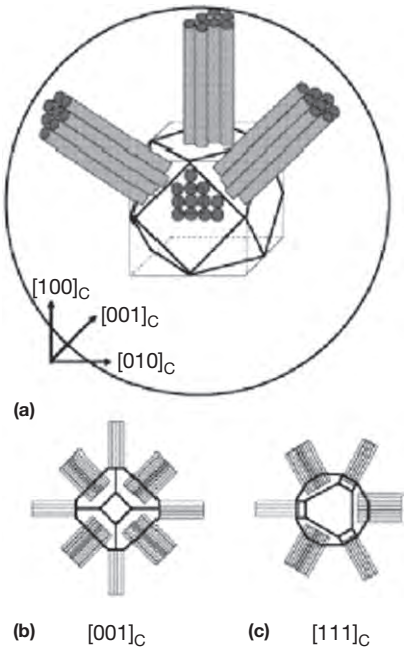

Figure 4 (a) Schematic representation of a spherical particle consisting of a nucleus of cubic MCM-48 and bundles of cylindrical pores grown epitaxially on the $\{111\}_C$ and $\{001\}_C$ facets. (b) and (c) Two projections of the particle, viewed along $[001]_C$ and $[111]_C$, are also presented. Reproduced from Lebedev, O. I.; Van Tendeloo, G.; Collart, O.; Cool, P.; Vansant, E. F. *Solid State Sci*. **2004**, *6*, 489–498, with permission from Elsevier.

crystal facet surface. The pores growing on the {111} facets adopt a packing close to the hexagonal MCM-41, and those on the {001} facets, an intermediate packing between MCM-48 and MCM-41.

4.430.3.4. Morphology Control

After the discovery of surfactant-templated synthesis of mesoporous silica materials in 1992,[18] significant advances were made in the functionalization and utilization of these materials for various applications, such as catalysis,[107] separation,[89] and sensing.[89] In spite of these exciting advancements, there were very few reports, if any, on the utilization of these materials for controlled release and delivery application until the early 2000s. One of the possible reasons is the lack of knowledge regarding the synthesis of MCM-41 with controlled morphology. The conventional synthetic methods for preparing mesoporous silica materials yielded amorphous chunks and particles of different shapes and sizes. In addition, the polydispersity and the amorphous nature of the mesoporous silicas presented a major challenge to the understanding and control of the adsorption and release properties at the nano level, which is of fundamental importance for drug delivery and controlled release in biological systems.

4.430.3.4.1. Particle size

4.430.3.4.1.1. Mesoporous silica microsphere

The synthesis of micrometer-sized mesoporous silica spheres of a narrow size distribution was achieved in the late 1990s.[100,107,108] The various groups focused on the synthesis

of monodisperse mesoporous silica spheres of controlled particle size for chromatographical applications,[89] and the method relies on the well-established Stöber reaction for the synthesis of monodisperse nonporous silica spheres. The reaction involved the cohydrolysis and subsequent condensation of tetraethoxysilane (TEOS) and an alkyltrialkoxysilane in a mixture of ethanol, water, and aqueous ammonia. Ethanol acted as a cosolvent to form a homogeneous solution, ammonia served as a morphological catalyst, and *n*-alkyltrialkoxysilane generated the porosity.[107] Other groups followed later and described a synthesis of mesoporous silica microspheres using surfactant-stabilized emulsion chemistry,[109] static acidic conditions,[108] or cosurfactant methods.[110] The synthesis of spheres of diameters in the submicrometer to micrometer range was successfully achieved by fine-tuning the reaction conditions such as the relative amounts of reagents (alkoxysilane, water, and ammonia) and the reaction temperature. The surface area and pore size of the mesoporous silica microspheres were regulated by using either *n*-alkyltrialkoxysilanes of various kinds or surfactants at different concentrations.[109]

4.430.3.4.1.2. Mesoporous silica nanospheres

The mesoporous silica microspheres are potentially useful for many nonbiological applications, but these particles are too big for many important biotechnological and biomedical applications. For example, these materials cannot serve as efficient agents for gene transfection or as carriers for intracellular drug delivery because mammalian cells cannot efficiently engulf large particles via endocytosis. Also, mesoporous silica microspheres are within the size window of bacteria and could potentially trigger acute inflammatory response *in vivo*.

Ying and coworkers[110] recently reported a fluorocarbon-surfactant-mediated synthesis for MSN. The particle size of the material was tuned from 50 to 300 nm, and different types of mesostructures, including 3D cubic, 2D hexagonal, foam like, and disordered (named IBN series), were successfully produced. The Bein and coworkers[111] recently reported the synthesis of colloidal mesoporous silica (CMS) material by introducing triethanolamine (TEA) to the condensation reaction of TEOS. By tuning the ratio of TEOS to TEA, they demonstrated that the particle size of CMS could be varied from 50 to 100 nm with a high surface area ($>1000\,m^2\,g^{-1}$) and a large pore volume ($\sim 1\,cm^3\,g^{-1}$). The pore geometry in CMS is unique: the pores grow radially from the center of the particle to the periphery.[111] Okubo and coworkers[112] used ethylene glycol (EG) in their synthesis to improve structural order and control particle size and morphology. The pore size of their MSN is around 2 nm when using cetyltrimethylammonium bromide (CTAB) as the structure-directing agent.

Lin and coworkers[113] recently demonstrated that MSN with adjustable pore sizes ranging from 3 to 6 nm could be synthesized by including mesitylene as a pore-expander. Their method took advantage of the well-known synthesis of MCM-41 mesoporous silica, in which TEOS was used as a silica source, a cationic surfactant, CTAB, was used as a structure-directing agent, water was used as a solvent, and sodium hydroxide was used as a morphological catalyst.[81] The template surfactant (CTAB) was then removed from the as-synthesized material either by solvent extraction (HCl in methanol solution) or by calcination to generate pores. Using this method, particles with the following characteristics can be made: an average particle diameter of 100 nm, an average surface area of $900\,m^2\,g^{-1}$, average pore size of 2 nm, an average pore volume of $0.9\,cm^3\,g^{-1}$, abundant surface silanol groups (about 30 mol%), and a hexagonal porous channel structure. Recently, Lelong *et al.*[115] conducted an extensive study on the effect of surfactant (CTAB) concentrations on the morphology of MSN and demonstrated the key role that the Si:CTAB ratio plays on both the texture and the morphology. They proposed that for the smallest surfactant concentration (0.1%), the internal hexagonal arrangements of pores are quite pronounced and in the region of the critical micelle concentration (CMC), and the surfactant molecules remain free or poorly organized into dynamic nanometer-sized spheres or cylinders. In this two-phase system, the positively charged free surfactant molecules present in the water phase become electrostatically adsorbed by the negatively charged silicate oligomers present in the TEOS phase, and a water-in-oil type microemulsion occurs. The nucleation and growth of the particles then obtains fully, following an order–disorder phase transition. The small amount of ethyl alcohol generated by the hydrolysis of TEOS acts as cosurfactant, leading to the formation of spherical objects in order to minimize the surface energy. The excess silicic acid in the medium then condenses around the mesoporous core, leading to the formation of an amorphous silica shell. When the Si:CTMABr ratio is lowered, the mean length of the cylindrical pores and the size of the bundle increase correspondingly. While the amount of TEOS is fixed for all the samples, the ethanol, which is the product of its hydrolysis by water, becomes progressively less efficient as a cosurfactant. Consequently, the mesoporous particles become larger with less rounded shapes, which is consistent with their microscopic observations (**Figure 5**).

4.430.4. Physicochemical Properties and Characterization

4.430.4.1. Properties

4.430.4.1.1. Product crystallinity

Although the pore walls of mesoporous silica materials are amorphous, the particles themselves have a long-range order. They are classified as semicrystalline solids. In general, the surfactants with 12, 14, and 16 carbon atoms, that is, C_{12}, C_{14}, and C_{16}, give good MCM-41 samples. Surfactants that have more than 18 carbon atoms ($\geq C_{18}$) are difficult to dissolve; on the other hand, the lower-molecular-weight surfactants ($\leq C_{10}$) seem to find it difficult to self-organize and, as a result, materials with broader pore size distributions (PSD) are produced. However, the use of a mixture of Gemini $[C_{20}H_{41}N(CH_3)_2(CH_2)_3N(CH_3)_2C_{20}H_{41}]$ and *n*-alkyltrimethylammonium ($n = 20$) surfactants results in the formation of good-quality MCM-41 with five or more well-indexed XRD reflections **Figure 6**.[116] A suitable mixture of *n*-alkyltrimethylammonium and *n*-alkyltriethylammonium surfactant cations ($n = 12 - 22$) gives highly ordered MCM-41 with various pore diameters as a result of the controlled packing of micelles.[71] The crystallinity and quality of MCM-41 materials can be altered by changing the pH of the synthesis gel and by the nature of the pH adjustment process. It has been

shown that the rapid adjustment of pH results in poorly crystallized/less ordered MCM-41, whereas a gradual or delayed adjustment of pH provides more time for the micelles and silica polyionic species to assemble into a more ordered structure.[116] Ryoo and Kim[117] reported that the repeated adjustment of pH can produce highly crystallized MCM-41. Their method include an initial heating of synthesis gel to 100 °C for 1 day. The resulting mixture was cooled to room temperature, and the pH was adjusted to 10 by the dropwise addition of 30 wt% acetic acid and vigorous stirring, followed by heating as before. The latter procedure was repeated twice before the solid product was removed from the reactor. Edler and White[118] reported a further development of the aforementioned method by the optimization of the various acids for maintaining the pH. The best result, with sharp diffraction peaks, was achieved with sulfuric acid and a pH of 9–10. Long-range structural ordering, as well as pore size uniformity, can be achieved by the appropriate choice and control of synthesis conditions, such as the pH of the synthesis gel, such that the polymerization equilibrium is shifted toward the mesophase region of MCM-41 (Figure 6).[117,118]

4.430.4.1.2. Thermal and hydrothermal stability

A material should have good thermal and hydrothermal stabilities in order to be utilized in different practical applications. MCM-41 exhibits a high thermal stability of up to 900 °C in dry air or in air having a low water vapor pressure.[118–122] Furthermore, it is also stable under acidic conditions, but it degrades readily in basic environments because of the known fact that (amorphous) silica dissolves partially in water, especially at high pH.[122,123] On the other hand, MCM-41 has a low hydrothermal stability in water, in aqueous solutions, and even in air saturated with water vapor.[124–126] In addition, the mechanical compressive force builds up because of the hydrolysis of siloxane bonds in the presence of adsorbed water, which results in a structural collapse, as is evident from the XRD patterns shown in Figure 7.[124]

It has been shown that MCM-41 structures can be stabilized by synthesizing in the presence of various salts[125,126] or ion exchange after synthesis.[127] Furthermore, chemical and mechanical stabilities of MCM-41 can be enhanced by post-synthesis treatment with acid,[128–130] modification by silylation,[63,131] or removal of silanol groups by alumina.[132] Igarashi *et al.*[133] have recently reported an increased stability of organically modified MCM-41 by a single-step synthesis procedure.

4.430.4.2. Characterization

Various techniques have been successfully employed to elucidate structure and wall thickness, such as XRD, small angle X-ray scattering (SAXS), and transmission electron microscopy combined with electron diffraction. On the other hand, gas adsorption measurements[134] are the most widely used techniques to determine surface area, pore size, and PSD. A combination of these methods has demonstrated[135] that MCM-41 has a multilevel structure comprising mesopores, crystallites, and grains within the parent particles, as depicted in Figure 8(a). Typically, the crystallites have sizes of 30–50 nm, while the grain diameter is around 0.3–0.8 μm. The fractal interpretation of adsorption data for various compounds has revealed that the mesopore surface is smooth on molecular scales. This is evident from the correlation between monolayer capacity and molecular area,[136] as shown in Figure 8(b), yielding a slope of − 1 on the logarithmic coordinates.

Several techniques are available for estimating the pore sizes of MCM-41. Although each method has a limited length-scale of applicability for probing the structure, N_2 adsorption at its normal boiling point is the most popular because of its utility for both micropores and mesopores, and because of its convenience and low cost.

4.430.4.2.1. Gas adsorption methods

For the design and actual use of porous materials in the field of absorption and catalysis, evaluation of the pore structure is absolutely essential. The pore morphology, that is, PSD and connectivity of the pore network, dictate the transport and reaction properties of porous solids, for example, adsorbents and catalyst supports. The most widely used method, nitrogen sorption isotherms provide the input data for the analysis models to determine pore structure information.[134] For MCM-41, typical sorption measurements follow the type IV isotherm consisting of two steps, as illustrated in Figure 9, with a high porosity ($0.7–1.2\ cm^3\ g^{-1}$) and a large surface area exceeding $900\ m^2\ g^{-1}$. The prevailing adsorption process at low relative pressures ($P/P_0 < 0.25$) is the formation of a monolayer of adsorbed molecules. At higher pressures ($P/P_0 > 0.25$), the adsorption in mesopores leads to multilayer formation until condensation takes place, providing a sharp increase in adsorption volume. As the mesopores are filled, the

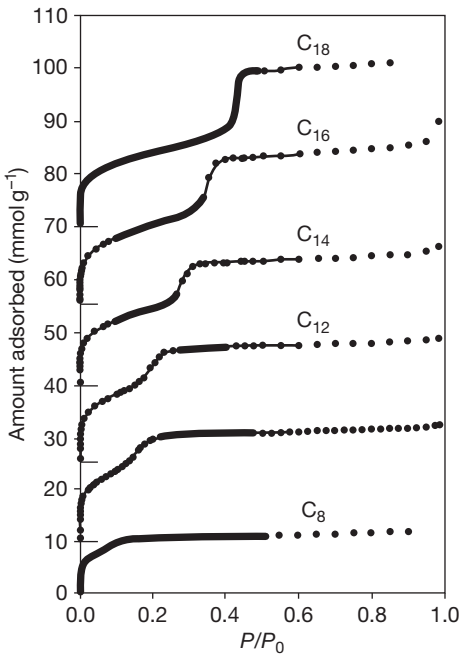

Figure 9 Nitrogen adsorption isotherms at 77.4 K on various MCM-41 samples prepared using surfactants of different carbon chain length (C_x, $x = 8$, 10, 12, 14, 16, 18). Reproduced from Gregg, S. J.; Sing, K. S. W. *Adsorption Surface Area and Porosity*; Academic Press: New York, 1982.

adsorption continues on the external surface. The isotherms are usually reversible for pores smaller than a critical size and exhibit a sharp inflection at $P/P_0 = 0.25 - 0.5$, depending on the pore size of the material. Qualitatively, the step in the isotherms reflects a narrow and uniform distribution of the pore size, while its height indicates the pore volume. The desorption via evaporation of the adsorbate from the mesopores occurs at a pressure lower than that of capillary condensation and results in hysteresis. In the case of disordered samples, the step of the isotherm becomes less sharp for the samples with the largest pores, suggesting a widening of the PSD. In general, the hysteresis originates as a result of the differences in the pore mouth sizes and pore bodies or because of the different adsorption and desorption behaviors in near-cylindrical pores. Materials with uniform pore sizes and shapes exhibit type H1 hysteresis (i.e., parallel adsorption and desorption branches), whereas those with nonuniform pore sizes and shapes show type H_2 hysteresis (i.e., nonparallel adsorption and desorption branches). In the latter case, condensation takes place in each section at the relative pressure provided by the Kelvin equation, but evaporation from the pore body cannot occur while the pore mouth remains filled. On the other hand, in the former case, the meniscus is cylindrical during condensation and hemispherical during evaporation.

Gas adsorption isotherms for a wide variety of gases, including nitrogen, oxygen, argon, water, etc., have been measured for MCM-41. It is interesting to note that MCM-41 adsorbs much greater amounts of organic species than water. For example, the amount adsorbed exceeds 0.4 g g^{-1} for cyclohexane, but is < 0.05 g g^{-1} for water at $P/P_0 = 0.4$,[68] which reveals that the internal surface is quite hydrophobic, albeit with the presence of silanol groups. On the other hand, trimethylsilation renders the materials repellent even to liquid water.[18,26]

4.430.4.2.2. Surface area

The commonly used BET surface area (S_{BET}) represents the total surface area rather than the mesopore area. Recent studies[137] have indicated that the BET method overestimates the surface area of MCM-41, possibly as a result of the considerable overlap of monolayer and multilayer adsorption in the recommended range of relative pressures ($P/P_0 = 0.05 - 0.35$).

4.430.4.2.3. Pore volume

The BET model still remains one of the most widely used methods for estimating the pore volume from adsorption measurements. The density of adsorbed N_2 has been assumed to be equal to the density of liquid N_2 at the same temperature.[134] However, the *t*-plot method is often used to obtain accurate and reliable pore volume data. The method is based on the observation that a plot of the adsorbed volume per unit surface area, that is, the statistical thickness (t) of the adsorbed layer versus pressure follows a single curve, independent of the solid.

4.430.4.2.4. Pore size

Several geometrical and classical methods have been applied for the determination of the mesopore diameter (D) of MCM-41. The Kelvin equation provides a useful model to transform the adsorption data into a PSD.[138,139] This model is widely used but cannot be applied for pore diameters below 2 nm. Below this pore size, the forces exerted by the pore wall become crucial, and the liquid cannot be considered a fluid with bulk properties. Theoretical calculations suggest that the properties of fluids in microporous structures are highly sensitive to the size of the pores. The established methods for the determination of the pore size are based on the Kelvin model or its variants, such as the Barrett–Joyner–Halenda (BJH)[140] and Broekhoff–de Boer (BdB)[141] methods, or other approaches such as the Horváth–Kawazoe (HK)[142] and Saito–Foley (SF)[143] methods and the density function theory (DFT) of Tarazona *et al.*[144] that consider the fluid–solid interaction.

4.430.5. Unique Biomaterial Considerations

As indicated earlier, the marked characteristics of MSNs are as follows:

(i) *Tunable particle size*: the particle size of MSNs can be controlled in the range between 50 and 300 nm. (ii) *Stable and rigid framework*: these MSNs are more resistant to heat, pH, mechanical stress, and hydrolysis-induced degradations than polymeric nanospheres. (iii) *Uniform and tunable pore size*: the controlled synthesis can provide very narrow PSD, and the pore diameter can be tuned between 2 and 15 nm. (iv) *High surface area and large pore volume*. As mentioned earlier, the total surface area (~ 900 m^2 g^{-1}) and pore volume (~ 0.9 cm^3 g^{-1}) are very large.

These unique properties render MSN very attractive for application as molecular hosts and delivery vehicles for drugs

and biological molecules. Here, we discuss some of the important considerations in the use of MSNs as biomaterials, including encapsulation strategies, surface functionalization, and biocompatibility.

4.430.5.1. Host–Guest Encapsulation

Materials that can be utilized in the area of controlled release of biomolecules or drug delivery could have high affinity for absorbing certain drug molecules, yet they would willingly release the same cargo upon reaching the designated sites.

The aforementioned versatility of silica nanospheres makes them ideal for the adsorption and release of a variety of compounds by organically modifying them with the desired functional group that is attached to and within the walls of the pores. Furthermore, the pore size and pore volume can be tuned to protect the encapsulated drug from unwanted leakage and to optimize the drug loading capacity.

Enzymes, proteins, and biocatalysts with high selectivities have been widely used in the food industry. Encapsulated enzymes and other proteins within inorganic host materials (**Figure 10**)[145] and especially in controlled porous glasses (CPG) represent one of the most rapidly growing fields over the past few years. It has already been established that biomolecules immobilized in inorganic matrices retain their functional characteristics to a large extent. However, the main disadvantages of CPG materials in adsorption studies are their high cost and the rapid decrease of the surface area with increasing pore size (30–200 nm). A comprehensive review by Hartmann[146] outlined the advantages of mesoporous MCM-41-based materials in bioadsorption. For the immobilization of biomolecules, the general procedures can be broadly categorized into two types, depending on the interaction between the biomolecules and host: covalent binding and adsorption, or encapsulation. For the applications in the aforementioned area, adsorption or encapsulation is highly preferred as it will not chemically affect the encapsulated molecules and their easy release when needed.

One of the earliest reports on immobilization by adsorption of globular enzymes, cytochrome c (bovine heart), papain (papaya latex), and trypsin (bovine pancreas), in the mesoporous molecular sieve MCM-41 was made by Diaz and Balkus[147] The efficiency of papain and trypsin immobilization was found to be pH dependent and favorable at pH values <7, while immobilization of cytochrome c was more efficient at pH >7 and less susceptible to pH changes. The adsorption of vitamin B2 (riboflavin) onto MCM-41 and MCM-48 was studied by Kisler *et al.*[148] The observation that MCM-41 shows significantly higher adsorption of vitamin B2 than MCM-48 (0.015 vs. 0.005 mmol g^{-1}) was suggested to result from the difference in pore sizes. Adsorbed vitamin B2 has a maximum size of ~60% of the MCM-48 pore size, and thus steric hindrance is believed to play an important role. Desorption experiments have revealed that some vitamin B2 remains adsorbed, showing that the adsorption is not completely reversible. Recently, Farzaneh *et al.*[149] found that Vit-B12/MCM-41 successfully catalyzes the oxygen transfer of tert-butylhydroperoxide (TBHP) to norbornene and trans-2-hexene-1-ol and formation of the corresponding epoxides with 90% reactivity and 100% selectivity.

For controlled-release applications, it has already been established that silica is able to store and gradually release therapeutically relevant drugs such as antibiotics[150,151] and others.[152] Furthermore, silica is used to enhance the biocompatibility of several other drug delivery systems such as magnetic nanoparticles,[153–155] biopolymers,[156] and micelles.[157]

Recently, Lin and coworkers[158–162] showed the ease and efficacy of the MSN materials for controlled release of different drug and biomolecules within the cells. They also showed the

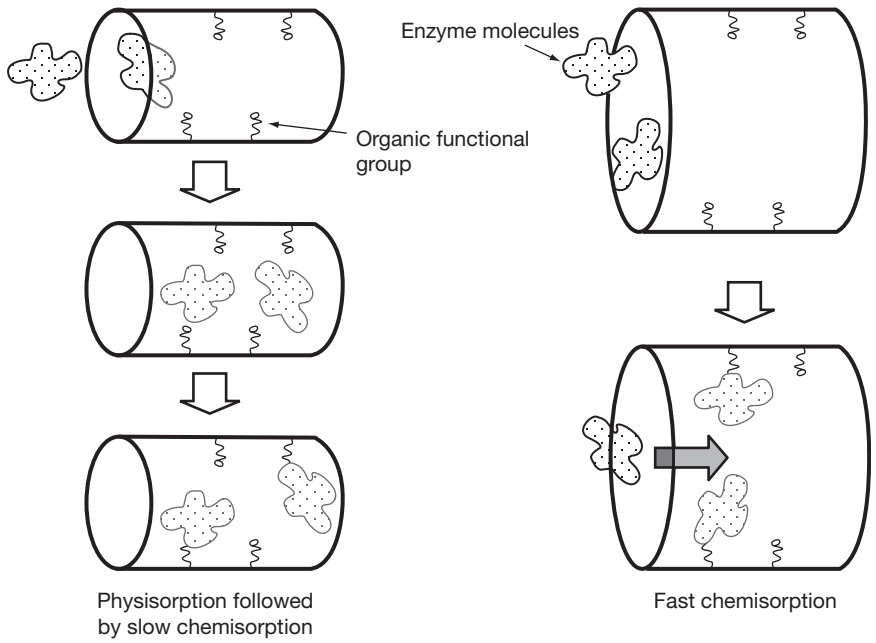

Figure 10 Illustrations showing two possible mechanisms of protein binding onto the functionalized surface of mesoporous silica. Reproduced from Yiu, H. H. P.; Wright, P. A. *J. Mater. Chem.* **2005**, *15*, 3690–3700, with permission from The Royal Society of Chemistry.

biocompatibility of this material. In particular, they successfully demonstrated that phenylboronic acid-functionalized MSN can serve as an efficient codelivery system for saccharide-responsive controlled release of insulin and cell membrane impermeable cyclic adenosine monophosphate (cAMP). The good biocompatibility, cellular uptake properties, and efficient intracellular release of cAMP are encouraging results for future *in vivo* controlled-release biomedical applications.

4.430.5.2. Surface Functionalization

Surface functionalization is a key step for the materials to be used in biological applications. For example, if one needs to formulate a targeted drug carrier, it is absolutely necessary to functionalize the surface of the carrier with cell-specific receptor molecules. At the same time, the availability of functionalization chemistry without the use of harsh chemicals would be an added advantage for biological applications.

In general, three strategies are pursued to tailor the microenvironment of mesoporous silica materials: cocondensation (one-pot synthesis), grafting (postsynthesis modification), and imprint coating method.[163,164] The cocondensation (precipitation) method utilizes various (organo)siloxane precursors in a one-pot (hydrothermal) sol–gel process.[81,165–174] This method is particularly viable for the incorporation of organic moieties into the pore walls as shown in the case of bifunctional periodic mesoporous organosilicas.[175–179] The advantages of this method are (a) it is applicable to a wide variety of organoalkoxysilanes; (b) it is suitable for a wide range of reaction conditions; (c) the coverage of functional groups is homogeneous; and (d) the loading amount of functional groups is high, and there is no dramatic effect on the structural ordering of the pores. Phase separation of the precursors and the cleavage of Si–C bonds during the sol–gel reaction and during surfactant removal have to be avoided in the cocondensation reactions. Lin and coworkers[180] investigated the different electrostatic matching effects of various anionic organoalkoxysilanes, such as thiolate-, carboxylate-, and sulfonate-containing organoalkoxysilane, on the degree of organic functionalization of the MSN. By cocondensation of two organoalkoxysilanes, they were able to introduce both acidic and basic functional groups into MSN.[181] This bifunctionalized MSN possesses interesting chemical properties that suggest a variety of novel applications.

Although the aforementioned approach is proposed to afford a more uniform distribution of functional groups protruding into the channel space, the *postsynthesis* approach allows, in a unique way, the grafting of chemically more precious organic functionalities, prone to hydrolysis and elimination reactions, onto calcined and dehydrated mesoporous silica materials.[182–184]

Grafting is commonly carried out by silylation on free ($\equiv$Si–OH) and geminal silanol ($=$Si(OH)$_2$) groups. If a high surface coverage with functional groups is desired, it is important to maintain a large amount of surface silanol groups after removal of the surfactant. Surfactant removal is usually carried out either by calcination or by appropriate extraction methods. Calcination promotes condensation of unreacted silanol groups, and many surface functional groups are lost at typical calcination temperatures (400–550 °C). Extraction processes (e.g., with acid/alcohol mixtures for cationic surfactants or with alcohols for neutral surfactants) minimize loss of surface silanols.

The most remarkable feature of the grafting method is the ability to selectively functionalize the external or the internal (pore) surfaces of the MSN. For example, we have demonstrated that 1,5,6-epoxyhexyltriethoxysilane (EHTES) can be successfully grafted on the external surface of MSNs before the removal of surfactant CTAB. The externally grafted groups can be further reacted; for example, in the case of EHTES, we were able to polymerize lactic acid on the external surface of MSN.[185] Recently, Tamanoi and coworkers[186] also modified the external surface of MSNs with trihydroxysilylpropyl methylphosphonate (THMP) after particle formation in order to reduce the aggregation and to increase the stability of the particles in aqueous solution.

In the grafting processes described earlier, the silylation reagents were typically added under dry conditions to avoid hydrolysis and self-condensation of the reagents away from the surface of MSN. When silylating under anhydrous conditions, the hydrophilic portion of the silica surface is preserved and the resulting functional groups are relatively isolated. By employing just enough water in the process to form a monolayer on the pore surface, more homogeneous coverage of organoalkoxysilanes can be obtained, leading to a higher concentration of functional groups in the final product.[187]

Recently, Burleigh and coworkers[164] reported a new imprint coating method. They coated the mesoporous surface of MCM-41 with ligands that were already bound to metal ions, not just to the free ligands. When the metal ions were removed, the ligands were already positioned for complexation with metal ions of the same type. The selectivity to binding the original metal ions in competitive binding experiments was greater than in randomly functionalized mesoporous materials.

4.430.5.3. Biocompatibility

Biocompatibility is the key factor for the materials to be used in biological applications. The biocompatibility of sol–gel-derived silica materials is well documented (**Chapter 4.428, Sol–Gel Processed Oxide Controlled Release Materials**).[188–192] Recently, Radin *et al.* extensively studied the *in vitro* and *in vivo* biocompatibility of sol–gel-derived silica micro granules, in our laboratory. They found excellent biocompatibility of silica macro granules both *in vitro* and *in vivo*; furthermore, they showed the potential use of these materials as controlled-release materials for the treatment of bone infections and as carriers for controlled delivery of drugs and larger biologically active molecules.[191,192] Given the particle size of MSN in the nanometer range and the difference in the sol–gel processing methodology, the biological response to these materials has recently come under investigation. Several reviews suggest that silica nanoparticles (solgels, xerogels, etc.) are biocompatible and degrade over time in the body.[193–196] Recently, Fisichella *et al.* studied the cytotoxicity of MSN in Henrietta Lacks (HeLa) and astrocytes cells and found that these materials are nontoxic up to a significant dose level of 100 μg ml^{-1}. More interestingly, they found that the most widely used 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay for evaluation of

cytotoxicity gives false positive results for toxicity as it is also found for other nanomaterials.[197,198] They suggested that at least three different assay techniques be performed for evaluation of the cytotoxicity of these materials. The biocompatibility of MSN with and without surface functionalization has also been tested by different methods. The viability and proliferation of various mammalian cells indicates that these properties are not affected by the internalization of MSN at concentrations below $100\,\mu g\,ml^{-1}$ per 105 cells even after seven cell cycles. Cell membrane integrity is also conserved after uptake of MSN as determined by selective DNA staining followed by flow cytometry.[199] Microscopic analysis shows normal cell morphology upon uptake of MSN. Mitochondrial activity remains at normal levels as determined by colorimetric assay with MTT.[200,201] Growth rates for cells exposed to MSN are similar to those of cells grown in the absence of MSN.[199,202] The long-term biocompatibility and the biodegradation of MSN have not yet been determined and understood, given the fact that this area of research is in its infancy.

4.430.6. Conclusion

In this chapter, we have conveyed the enormous potential of mesoporous silica nanoparticles for applications in the production of new materials and their use as biomaterials.

The increasing number of synthesis routes under development will greatly facilitate the preparation of materials with properties tailored to a specific application. It is remarkable that this explosion in the range of synthetic routes and targeted applications has taken place in little over a decade since the original discovery of the material.[18–21]

As for the utilization of these materials in biology, considerable progress has been made toward their application in the fields of drug delivery, gene delivery, and controlled release. While these results are encouraging and show great potential for future applications, new breakthroughs are still needed for this type of delivery system. Specifically, this system has not yet been extensively studied *in vivo*, so the necessary information regarding the blood circulation time, specificity toward the organs, long-term immunogenicity, and accumulation in different organs has yet to be determined. Such studies include the identification of the most appropriate animal models. In view of the targeted delivery of pharmaceuticals, surface functionalization is very important and needs to be explored with different ligands and receptor molecules.

Given that so much progress was achieved over a relatively short period of time, it can be anticipated that the major potential of mesoporous silica nanoparticles for biological use will soon be realized in the burgeoning field of nano-biomaterials.

Glossary

Autologous chondrocyte implantation (ACI) A medical procedure for the repair of damage to cartilage. It consists of expanding in culture the population of the patient's own chondrocytes followed by their implantation at the site of the damage.

BioSil method The method of coating cells, tissues, or other materials with a thin layer of silicate, where the alkoxysilane derivatives are delivered to a wet surface in a gas face; proposed by Giovanna Carturan.

CP hydrogels Materials formed by grafting poloxamer 407 onto chitosan.

Edmonton protocol A medically accepted procedure for the treatment of type 1 diabetes mellitus. It consists of implantation of isolated human pancreatic islets by infusion into the portal vein.

Extracellular matrix (ECM) ECM is the noncellular part of animal tissues. ECM of connective tissues is made of three major components: (i) fibrous elements such as proteins collagen, elastin, or reticulin, (ii) link proteins such as fibronectin or laminin, and (iii) space filling glycosaminoglycans.

Lower critical solution temperature (LCST) The lowest temperature, at which a temperature-sensitive sol–gel system forms a gel.

Poloxamers (Pluronic®) Poloxamers or, otherwise, Pluronic® are nonionic triblock copolymers composed of a central hydrophobic chain of polyoxypropylene flanked by two hydrophilic chains of polyoxyethylene; invented in 1973 by Irving Schmolka.

RGD The adhesive peptide, Arg–Gly–Asp, which is a part of active-site sequence of cell-adhesive proteins. Surface integration of this peptide promotes cells adhesion.

Sol–gel transition The transition of a suspension of discreet colloidal particles in a liquid (sol) to an apparently solid material (gel) containing a continuous liquid and a continuous solid phase.

Temperature-sensitive sol–gel systems Materials that undergo reversible sol–gel transition with the change of temperature. In this context, the term is used exclusively for the systems that transit from sol at ambient temperature to gel at body temperature.

Abbreviations

CS	Chondroitin sulfate
HA	Hyaluronic acid
PEG	Polyethyleneglycol
PLGA	Copolymer of L-lactic and glycolic acids
PNIPAA	Poly-*N*-isopropyl-acrylamide

4.431.1. Introduction

4.431.1.1. Declaration of Intents

Since its inception in the early 1990s, the biological application of sol–gel materials became the pursuit of many ambitious scientific teams and individual scientists. The sol-to-gel transition offers many opportunities to the design of encapsulation media for biological materials, including biocatalysts, cells, and even organs. The liquid sol allows for mixing components and producing a homogeneous or microheterogeneous environment for biological material without subjecting it to damaging shear. The mixture could then be delivered to a site of application, cast into any geometry, and integrated into architecture by enveloping the mechanical, stress-bearing 'skeleton.' After gelation, the sol–gel material becomes apparently solid, retaining the form into which it was cast, resisting mechanical stress, providing for the sites of attachment and forming a stable environment for the sensitive biological systems.

With a little exaggeration, one may say that the pioneers of sol–gel biomaterials must have felt akin to our ancestors on the verge of the 'Bronze Age.' The stone could be chiseled into a variety of useful forms, but at an enormous expense of brute force and materials. Suddenly, for the first time, it was replaced with metal. The flow of molten metal eased into smooth symmetrical forms ideal for weapons and utensils. Then and now, this feeling of innovation has motivated a wealth of creativity. The number of publications devoted to sol–gel materials and their biological uses expanded almost overnight. Today, it numbers in thousands. Research was immediately followed by patent applications, as useful products, and, especially, medical products seemed within sure and certain reach. One of the reasons that Life Sciences are amply financed, that the Life Science faculty dominates almost every university, is the fact that these Sciences are the theoretical basis of modern medicine. Of course, medicine has immediately become the major theme of sol–gel materials' research. One can safely say that medicine-related publications constitute their majority.

The field of biological and medical applications of sol–gel materials abounds with excellent recent reviews.[1–7]

The life span of research articles and, especially, of reviews appearing in journals is usually limited to a few years. 'Comprehensive Biomaterials,' an ambitious enterprise, cannot afford to be so ephemeral; it has to keep its value for an extended period. Therefore, following a short historical overview, I shall direct the discussion toward applications that are directly relevant to cell immobilization and cell delivery in xenografts, artificial organs, and implants. I will limit myself to a few thoroughly chosen topics as formulated by the editors. I will attempt (i) to formulate the demands which medicine makes on a designer of new materials, (ii) to analyze the current 'state of art' in light of this demands, and (iii) to make an educated guess of future trends in practical medical application of sol–gel materials.

4.431.1.2. Sol–Gel Materials

This review will concern itself with two types of materials: (1) materials based on sol–gel silica and (2) thermosensitive sol–gel systems. The use of the term sol–gel indicates that these materials are colloids. A sol is a colloidal suspension of solid particles (1–0.5 nm) in a liquid. Condensation and precipitation of sol particles (sol–gel transition) lead to the formation of apparently solid gels (Figure 1). Sol–gel transition provides the primary essentials of cell encapsulation and delivery. Cells are dispersed and delivered at low shear in the sol, while the subsequent formation of the gel ensures cell anchorage and sequestration. Gels may be cast filling up cavities deposited on the surfaces in thin layers by dipping or spin coating, and, sometimes, made into fibers and spun.

Unlike free-living unicellular eukaryotes and prokaryotes, the cells of multicellular organisms lack the thick and sturdy cell wall and, thus, are extremely sensitive to conditions in their environment such as shear stress, changes in the pH or temperature, and presence of solvents and detergents. Animal cells need constant delivery of oxygen, complex nutrients, various growth factors, and signal chemicals. Frequently, they require the presence of other types of cells (organ architecture) and of the extracellular matrix with its general and specific interactions, signaling pathways, etc.

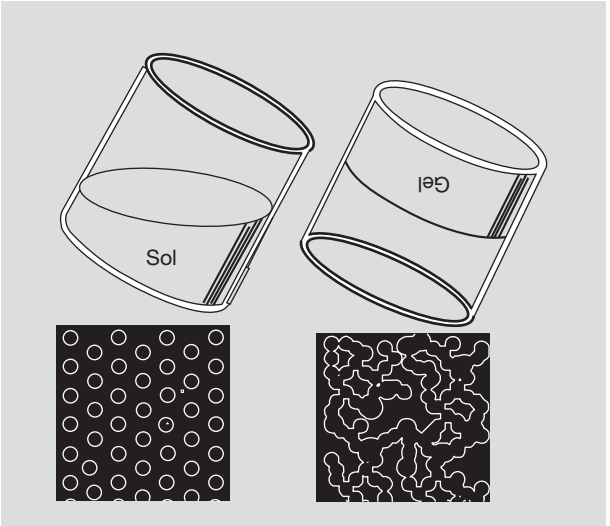

Figure 1 Sol–gel transition. The transition from the sol of discreet colloidal particles suspended in liquid to gel, a continuous solid phase distributed in the continuous liquid phase.

Medical application of encapsulated cells brings them into contact and, every now and then, into a conflict with the host organism. Short- and long-term interactions of the body with the immobilization matrix as well as with the embedded cells have to be considered to be of any practical use. Sometimes, the material should resist degradation, and sometimes, it needs to be degraded within a given period. Biocompatibility is always a problem in need of investigation in all its aspects: inflammation, macrophages' overgrowth, and immune responses, just to mention the most obvious. Not only chemistry but also the surface properties of sol–gel materials influence the interaction of mammalian cells with their substrate.[8]

These complex limitations make the practical application of cell and organ implants a formidable task. Enough to say that despite initial promise and years of highly sophisticated innovative research, there currently are no medically approved procedures using encapsulated cells.

4.431.2. Sol–Gel Silicates

Sol–gel process is a low-temperature method of obtaining porous inorganic materials, mostly silica gels (Figure 2), but also alumina,[9] titania, magnetic ferrihydrite gels,[10] etc. Sol–gel silica has early found its way into a variety of biological and biotechnological applications[11,12] for its presumed biological safety. Nonfibrous forms of silicate are generally accepted as safe and, perhaps, even beneficial to human health.[13] Silica has been approved for use as an ingredient of food or animal feed; it is increasingly used in diagnostic and biomedical research.

Silica-derived ceramic matrices are perceived to possess significant advantages over traditional polymer matrices.[14,15] These inorganic matrices are biologically inert.[16] They can be processed into a variety of shapes, and are not in themselves a source of nutrients for contaminating microorganisms. The sol–gel process is sufficiently tolerant to allow for the use of derivatized alkoxysilanes,[17] co-incorporation of cells with a variety of nutrients, polymers, and environmental protectors thereby reducing various stresses.[18] The large surface area and tunable porosity of sol–gel silica allow for unimpeded mass transport of small molecules, yet prevent contamination by external factors. Wet gels possess a developed system of hydrophilic hydrogen bond-forming silanol groups that may help preserve cell membrane and ternary protein structures, although these interactions may also seriously damage cell integrity and limit survival.[19] The degradation of sol–gel silica is amenable to chemical manipulation,[20,21] thus making it suitable for long- and short-term applications alike. In the last couple of decades, sol–gel immobilization of cells in silica[3,4,12,22] has been developed for a variety of uses ranging from biosensors to artificial organs.

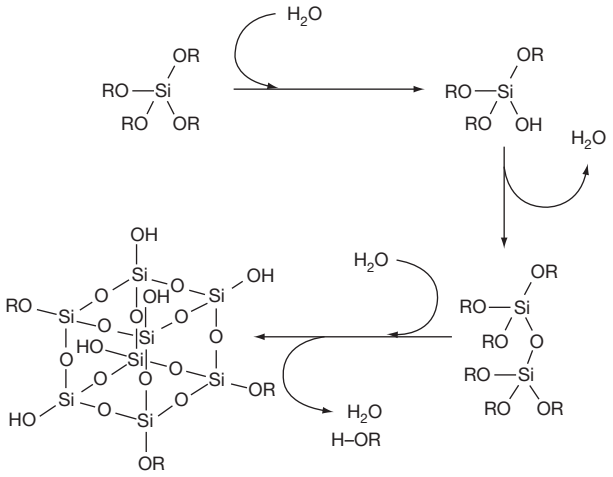

Figure 2 Formation of silica from tetraalkoxysilanes by hydrolysis and condensation. *R* = alkyl, usually, methyl, ethyl, or isopropyl group.

4.431.2.1. Silicon and Life

Silica is a ubiquitous material, and evolution has adapted organisms to tolerate relatively high levels of exposure to soluble silicates as well as to amorphous silica particles. Some sponges, radiolaria and, notably, diatoms (Figure 3)[23] use silica in building exoskeleton. Plants process water-borne silicates by depositing silica in various tissues as small uniform particles of opal. In animals, orthosilicic acid is present in small amounts in all body fluids.[24] Silica concentration in some tissues such as bone, cartilage, and skin are higher than in others, for example, brain or muscle. It seems that no other tissue compartment but mucopolysaccharides contain tightly bound silicate. Carlisle argued for a possible beneficial role of silicate in bone formation and repair.[25] Animals cope well with constant intake of silicate in drinking water by an efficient renal clearance. In normal renal function, silicon intake and clearance rates are well balanced.[26]

The silica xerogel implants produced by the sol–gel methods are slowly degraded.[27] Histological analysis did not show any tissue irritation at the site of the implantation, though fibrotic capsule was formed around the implant. No histological changes were observed in liver, kidney, lymph nodes, and uterus.[28] Nevertheless, high doses of amorphous silica nanoparticles were suspected to be cytotoxic.[29]

The biodegradation of sol–gel silicates may compromise some of their medical applications. Although the versatility of sol–gel silica seems advantageous for the engineering of artificial organs and xenografts, these materials cannot be relied upon as mechanical support or immunological barrier without a considerable chemical manipulation aimed at reducing their solubility in body fluids.

4.431.2.2. Biocompatible Preparation of Sol–Gel Silica

While amorphous silica seems to be quite safe, the sol–gel route to its generation is not gentle enough for the cells of higher organisms, affecting their viability negatively.[30]

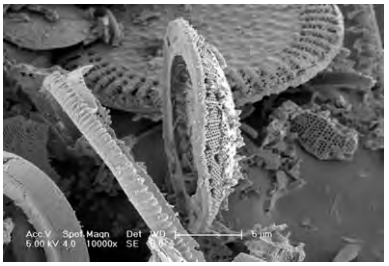

Figure 3 Diatomic earth. Silica-made exoskeleton of fossil diatoms.

The early bulk methods of adding biologicals, such as enzymes[11] in a buffer to tetramethoxy- (TMOS) or tetraethoxysilicate (TEOS), were poorly suitable for immobilization of animal cells due to, among other things, formation of alcohol following the initial hydrolysis of precursors and the high shear forces generated during gelation and shrinking of the maturing gel. The first successful immobilization of a eukaryote, the Baker's yeast in thin layers of sol–gel silica,[31] benefited from the unique sturdiness of these cells. Several techniques involving alcohol removal before entrapment in colloidal silica as well as doping of silica with polymers or other additives have been adapted to preserve cell viability.[32,33] These adaptations of the sol–gel method will be treated under a separated heading below.

A curious 'biological' enzymatic route for cell immobilization in silica was designed using either a recombinant enzyme, silicatein[34] or lysozyme.[35] The enzymes castalized colloid shell formation from a silicate monomer. The viscous silica shell as well as the silicate in the medium did not affect the growth kinetics of *Escherichia coli* and *Pichia pastoris* engineered with silicate-processing enzyme genes.

Elimination of cell contact with acid and alcohol has been achieved in a variety of ways. In two-step sol–gel processing, the acid hydrolysis of the precursors has been carried out to result in a colloidal sol. Alcohol has then been removed prior to the pH-neutral encapsulation–gelation step.[16,33,36,37] Alternatively, tetraalkoxysilanes precursors have been replaced altogether by commercial colloidal silica such as Du Pont's Ludox, which was neutralized prior to the introduction of the cells.[18,38–42]

In a typical sol–gel process, gelation occurs by the aggregation and growth of silica particles without significant volume changes. Loss of water causes shrinking of the gels subjecting immobilized cells to stress exceeding 100 mPa bringing about cell lysis.[18,22] Aging of silicate gels at the neutral pH is accompanied by the contraction of the gel, which may cause damage to shear-sensitive animal cells with their large size and the lack of cell wall. Even sturdy *E. coli* may be sensitive to shear caused by reshaping of the cavities in the aging gel. Thus, Nassif *et al.*[40] observed a 40% loss of cell viability within 1 h after gelation under conditions, where alcohol was avoided and the environmental conditions were favorable. Aged silica gels exhibit poor mechanical stability; they are brittle and easily crack on manipulation. Drying improves the stability of gels, yet very few organisms can survive it undamaged. The use of cryoprotectors such as glycerol[40,42] or D-glucose (21 wt%) may mediate to some extent the damage by preserving cell surface and maintaining the pore size during drying.[27]

Giovanna Carturan and his coworkers pioneered and worked out many variations of an elegant technique that minimizes the contact of immobilized biological materials with harmful chemicals and adverse environment. The central idea of this technique is that the sol–gel precursors are transported to the site of immobilization in the gaseous phase. They are hydrolyzed in the residual surface water layer, and coat the target with a robust silicate membrane, while the gas flow removes the resulting alcohol. Boninsegna *et al.*[43] used this method to coat isolated Langerhans islets.

4.431.2.3. Additives: The Design of Silicate Composites

A variety of additives, polymeric and otherwise has been used to mediate the harmful environmental impact of sol–gel process on the cells as well as to reduce shear during maturation of gels, rigidity, and brittleness of sol–gel matrices.

The material of choice for the preparation of hybrid sol–gel materials is alginate. Alginate is an acidic polysaccharide component of brown algae. It is a copolymer of β-D-mannuronic and α-L-guluronic acids linked by 1,4-bonds (**Figure 4**). Sodium alginate is water-soluble. Divalent ions interact with the neighboring polysaccharide chains. They form salt bridges and increase the apparent molecular size of the polymer, thus reducing its solubility and causing gelation. Ca^{2+} is the ion of choice for biological applications.

Commercial preparations of sodium alginate vary in their molecular weight and in the ratio of guluronic and mannuronic acid monomer units. At the same concentration of Ca^{2+} alginates of a higher molecular weight or with a higher guluronic acid content form harder gels, while low molecular size and higher content of mannuronic acid produce more elastic gels.[44] The preferred method for cell entrapment is the preparation of alginate beads by dropping sodium alginate solution into a receptacle containing a $CaCl_2$ solution. Ca^{2+} ion penetrates the alginate drop by diffusion, and therefore relatively high concentrations of both alginate and $CaCl_2$ are necessary to prevent coalescence of drops or a formation of distorted beads. Depending on the size of the drops, and time in contact with the $CaCl_2$ solution, beads may have a highly cross-linked firm outer skin and relatively elastic inner core. Poly-L-lysine (**Figure 4**) may replace Ca^{2+} ion as a skin-former partially or completely, if high concentration of alginate and $CaCl_2$ should be avoided or a more fluid inner core is required. Poly-L-lysine-alginate skin provides a barrier to immune system components,[45] yet one should be aware of possible toxic effects of poly-L-lysine.[46]

More uniform distribution of Ca^{2+} ions throughout the gel is achieved by mixing the sodium alginate solution containing, for example, D-glucono-δ-lactone with poorly soluble $CaCO_3$ particles. Spontaneous hydrolysis of gluconolactone acidifies the mixture releasing Ca^{2+}. This method results in uniform gels that may be made in casts.

A comparative study of cell stress and viability with yeast as a model has been performed by Perullini *et al.*[47] The ability

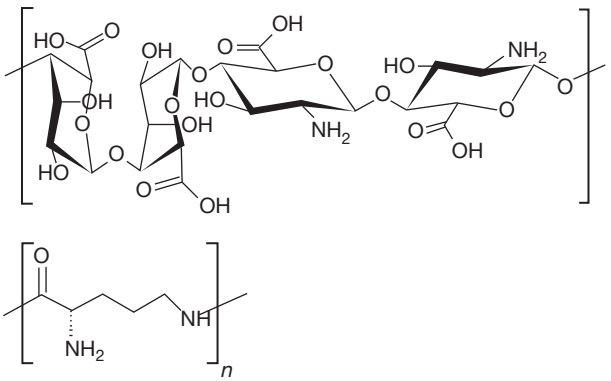

Figure 4 Alginate: the basic unit.

of the recombinant yeast to produce green fluorescent protein (GFP) in an exponentially growing culture has been employed as the reporter of stress. The authors used several well-established sol–gel cell immobilization procedures deemed biocompatible. Thus, they produced gels *via* (1) the Ludox colloidal silica route.[18] They also (2) performed the alcohol-free procedure of[33] with either tetraethoxysilane (TEOS) alone or (3) a mixture TEOS and glycidoxypropyl-trimethoxy-silane (GPTMS). Hydrolysis of precursors resulted in the formation of acid silica sol to which Perullini and his coworkers added cells suspended in 0.5 M phosphate buffer, pH 6.5. Finally, (4) yeast was immobilized in calcium alginate beads. The beads, in turn, were incorporated into silica gels using the same range of precursors as shown above. High concentrations of sodium alginate needed to obtain sturdy beads were damaging to yeast cells due to ionic stress, while lax beads with low alginate content did not protect cells during the stress generated by immobilization in silica. The results indicated that the mixture of TEOS and GPTMS in the alcohol-free procedure offers the best protection against stress.

In the system of trade-offs, offered by various methods of immobilization, the damage to cells caused by high concentrations of Na^+ ion during the preparation of silicate–alginate gels is considered a minor evil compared with advantages such as their unique sturdiness leading to successful applications.[48,49] There are several variations of these techniques. A mixture of colloidal silica with alginate[49] leads to the formation of homogenous silicate–alginate slabs. Silicate–alginate beads prepared by the immersion of alginate beads in the organic solvent (**Figure 5**) containing sol–gel precursors[50] cause extensive silica formation in the whole alginate network, although the outer shell is denser than the core.

Formation of thin silica membrane coating the outer surface of an alginate bead was achieved by multilayering techniques such as cross-linking alginate with positively charged poly-L-lysine, which could (i) activate silica condensation from diluted solutions of sodium silicate,[51] or (ii) catalyze hydrolysis of tetraalkoxysilane, thus driving deposition of a thin silica layer on the bead surface. A major consideration in favor of producing alginate core within the silicate membrane coat is the opportunity of liquefying alginate by removing Ca^{2+}. This becomes critical in applications where high cell density is required. The initial cell load that may be insufficient for the required purpose or may deteriorate in time, while cells confined in a hard alginate hydrogel cannot divide.[22] Liquefaction replaces Ca^{2+} ion with Na^+, thus limiting the concentration of alginate for the fear of ionic stress, therefore the use of cross-linkers to contain a semiliquid core of the bead is a necessity. The technique has been initially developed for yeast, *Sacharomyces cerevisiae*, and bacteria, *E. coli* and *Bacillus subtilis*,[52] but is now in use for plant[53] and animal cells[54] as well. Multilayer alginate–polylysine–silicate capsules[51,55] have shown improved mechanical stability and diffusion properties after liquefaction, when compared to an alginate–polylysine–alginate shells.

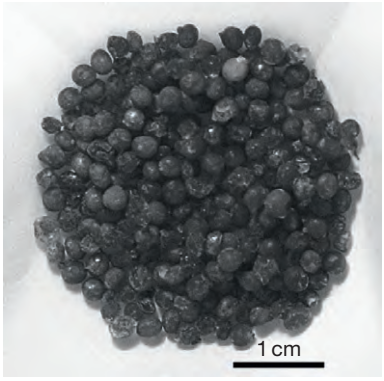

Figure 5 *Aspergillus terreus* mycelia immobilized in silicate–alginate beads according to Bressler *et al.*[48]

In a typical procedure,[53] a plant cell culture is mixed with Na alginate ($15\,g\,l^{-1}$) in a ratio 1:100. It is added dropwise under stirring to 0.1 M $CaCl_2$ solution. Following hardening for 10 min, the beads are separated and cast into suitable forms filled with a mixture of 1.25 M sodium silicate, commercial colloidal silica (LUDOX HS40, Aldrich) and succinic acid (5 wt%) at a ratio 2:1:1. Once gelation of silica occurs, the gels are immersed in potassium citrate ($5\,g\,l^{-1}$) to solubilize the Ca–alginate matrix creating liquid-filled cavities in the blocks of silicate. The citrate is then replaced with the suitable medium for the growth of cells.

In another approach to generation of macrocavities in TEOS and poly-dimethyl-siloxane (PDMS) scaffold formed by a sol–-gel method, sieved sucrose particles have been used as a pore-former. In these scaffolds, human hepatocellular carcinoma cells (HepG2) proliferated actively and formed cell clusters.[56]

Polymers other than alginate such as chitosan[57] and polyacrylamide–TMOS–TEOS[58] have also been widely applied. Some of these applications will be reviewed below in the 'case' studies.

4.431.2.4. Self-Organizing Systems

The common drop generation method to produce alginate beads is cumbersome and difficult to conduct aseptically. It may be considerably rationalized by a procedure involving stabilization of alginate in oil emulsions by porous microparticles of $CaCO_3$.

According to Liu *et al.*,[59] when one mixes a suspension of $CaCO_3$ particles in sunflower oil with a solution of sodium alginate in water, a stable water in oil emulsion is produced, which is stabilized solely by $CaCO_3$ particles residing at the oil–water interface (**Figure 6**). Addition of D-glucono-δ-lactone promotes the gelation of alginate. This results in a 'colloidosome' with an average diameter of 04 ± 01 nm. It is an important technical achievement, which considerably improves the control of the gel particle size thereby allowing for a better sterility of the preparation and, thus, reducing the stress due to high Ca^{2+} concentration.

However, alginate is not a perfect medium for medical applications. A recent thorough investigation[60] compared the stability of alginate implants at conditions imitating neuronal interfaces. Although some preferences have been formulated, all the implants exhibited fragmentation due, probably, to the leaching of Ca^{2+}, loss of polylysine coating and a general deterioration of the mechanical properties. The lability of

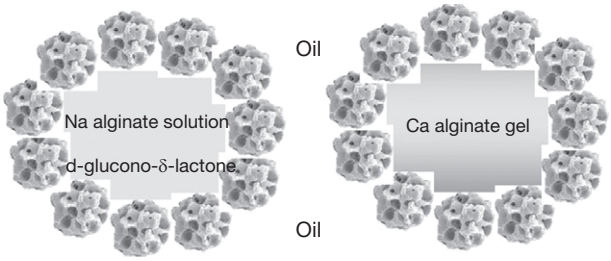

Figure 6 Preparation of colloidosomes. Porous microparticles of $CaCO_3$ self-assemble (left) at the alginate–oil interface. Hydrolysis of D-glucono-δ-lactone generates protons, which release Ca^{2+} ions and cause gelation (right) of the alginate. Reproduced from Liu, H. X.; Wang, C. Y.; Gao, Q. X.; Liu, X. X.; Tong, Z. *Int. J. Pharm.* **2008**, *351*, 104–112.

alginate membranes makes a strong argument in favor of composite encapsulation media.

Such a medium could be designed by coating or impregnating alginate colloidosomes with sol–gel silica, for example, using one of the three alternative procedures described by Callone *et al.*[61] In a wet coating method (i), alginate beads were immersed in a silica sol containing SiO_2 at the concentration of 100 g dm^{-3}, obtained by acid hydrolysis of $Si(OEt)_4$ in which ethanol was removed under reduced pressure. A better control of sterility may be achieved using another procedure (ii), whereby nitrogen saturated by passage through $Si(OEt)_4$ at 80 °C is bubbled through an emulsion of ethylene chloride in water (at a ratio 1:1, wt/wt). Alternatively (iii), air dried alginate beads may be taken through a gas coating method, in which air saturated with $CH_3Si(OEt)_3$ flows across the microspheres. In the last two procedures, the thickness of the coat is controlled by the amount of silica precursors available, while in the first procedure it is adjusted by the time of immersion.

An exciting possibility to engineer the structure, geometry, porosity, and the size of sol–gel silicate materials in self-organizing systems was provided by the discovery of mesoporous materials by Kresge *et al.* and Beck and Vartuli.[62,63] These authors observed that silicon alkoxides spontaneously form ordered micellar systems of varied morphology such as rods or spheres, when mixed with surfactants. Hydrolysis of silicon alkoxides results in sol–gel transition at the micellar interface. As a consequence, ordered structures are formed, whish retain their geometry even after the removal of the surfactants. This work was seminal in designing a wealth of self-organizing systems using a variety of templates (see Brinker *et al.*,[64] Davis,[65] and Soler-Illia *et al.*[66] for excellent reviews). Thus, large pore, 0.15–0.20 nm, wormlike and highly oriented cubic and hexagonal mesostructured xerogels were synthesized by what the authors termed evaporation-induced self assembly (EISA). Structure control was attained by changing the ratio of template (nonionic block copolymer) and water.[67]

Application of EISA to cell immobilization was developed by Baca *et al.*[68] This group observed that, when lipid-directed assembly of silica precursors was conducted in the presence of wet yeast biomass, the yeast cells seemed to mobilize lipids, which form around the yeast multilayered lipid vesicle, thus, modifying the forming ordered silica mesophase. This procedure called cell-directed assembly (CDA) provides for the biointerface, which maintains cells' functionality.[69]

4.431.2.5. Design of Prosthetic Organs: A Case Study

The ultimate goal of cell and tissue encapsulation, in their medical applications, is the design of organ prostheses. Scarcity of immunologically compatible tissue sources drives the investigator to the use of poorly compatible cells and tissues and eventually to xenographts. Thus, the primary function of encapsulation material is, while being biocompatible, to provide the barrier between the immune system of the body and the implant. The same or another material needs to function as the substrate compatible with cell maintenance or proliferation: respiration and supply of nutrients, removal of waste, transduction of signals. Yet another function of the material is to serve for engineering purposes, giving the construction the necessary mechanical stability. The variety of functions presupposes the use of several materials in an engineered environment.

The simplest construction of an implant is a small vesicle of functioning tissue. An example of this approach to implant engineering is the Edmonton protocol. The Edmonton protocol is a medically accepted method of implantation of isolated pancreatic islets for the treatment of type 1 diabetes mellitus.[70] The implant containing 11 000–12 000 human islets per kilogram of recipient body weight is infused into the portal vein. Use of immunosuppressant drugs prevents implant rejection. In the follow-up international trial,[71] 72% of subjects had full or partial control of diabetes following transplantation, 28% had complete loss of function within 1 year, 44% required insulin again at 2 years, and 14% retained the functional implant at 3 years. It seems that the size of isolated islets and their site of implantation satisfy the demand of the transplanted tissue for the functional maintenance of the cells in terms of blood supply, requirement for extracellular matrix and other factors. Thus, the Edmonton protocol, with its simplicity of operational procedure, sets the minimal criteria for a medically accepted implant. Encapsulation should provide for durable and biologically compatible xenograft without lowering the performance level.

The priority in the design of organ implants based on the sol–gel silica belongs to the group lead by Pope *et al.*[12] Pope and his coworkers encapsulated isolated murine islets by overlaying them with silica prepared by neutralization of acidic sol. The islet capsules collected from three donors per single recipient have been implanted intraperitoneally into mice rendered diabetic with streptozotocin injections. At least one mouse maintained full control of blood glucose for 10 weeks, after which the implant function was lost. The work has a very preliminary character, the statistic is lacking; it is primarily important as a pioneering application of sol–gel silicate chemistry for organ transplant research.

4.431.2.5.1. Silica precursors in the gas phase: the BioSil method

One of the most promising and widely published technologies in preparing silica gel encapsulated cells is the BioSil method developed by Giovanna Carturan.[3,72] According to BioSil technology, sol–gel precursors, usually a defined mixture of $(CH_3O)_4Si$ and $(CH_3O)_4SiCH_3$ are transported to the site of encapsulation in the gas phase. This allows for the precise control of the thickness, porosity, pore size, and composition

of the forming siliceous membrane. The hydrolysis of precursors occurs at the surface water layer covering cells or cell clusters. The gas flow removes the harmful products of hydrolysis leaving a smooth rather flexible silicate membrane.

It was shown[43] that isolated rat pancreatic islands may be safely coated with a silicate membrane in batches of 200–300 without loosing their viability and function, although some damage to the cells in the peripheral areas of the islet was observed and permeability of the membrane limited the insulin output by about a factor of 2 in comparison with an uncoated tissue. Surgical transplantation of silica-encapsulated islands (~800 islets per recipient) under left kidney capsule in incompatible rats provided the diabetic recipient with an adequate control of glycaemia for at least 8 weeks, when the experiment was terminated. Unencapsulated islets failed within the first week.

A prototype of membrane bioreactor for an artificial liver is described in Muraca *et al.*[73] A 0.5-mm-thick collagen layer was spread over rat hepatocytes, which was cultured to confluence on another 0.25-mm-thick collagen gel layer. This 'sandwich' was then exposed to silica precursors in the gas phase resulting in a 0.05–0.15 μm-thick silicate membrane. The construct showed unaffected viability and metabolic function typical of liver cells; some activities were even enhanced. There were indications that the membrane posed no transport limitations on the albumin-bound substrates.

For an easier handling of large amounts of cells and tissues necessary for grafting, a more elaborated procedure has been designed. Silicon precursors in the air flow were put in contact with microdroplets of Na alginate solution containing the tissues.[74] The droplets were hardened by falling into a $CaCl_2$ solution. The 0.2 μm-thick membrane formed on the droplet prior to the contact with $CaCl_2$ solution eliminated coalescence of droplets resulting in very uniform beads.[72] More important, this membrane prevented the activation of peripheral blood polymorphonucleate cells and deposition of connective tissue on the surface of the implant. When placed in the peritoneal cavity of a mouse, BioSil microcapsules were not colonized by peritoneal resident cells.

An attempt to implant BioSil microcapsules containing encapsulated pig islets ($1.0–1.2 \times 10^4$ islets per kilogram) in diabetic dogs using a close analog of the Edmonton protocol resulted in functional xenograft. However, its function deteriorated within 5 weeks.[72] Ten weeks past implant, there were no signs of inflammation or any immune reaction in the liver tissue at the site of implantation. Thus, it seems that the deterioration of the function should be attributed to the dedifferentiation of the islet cells. *In vitro*, the encapsulated islets lose their function within a few days.

It appears that the BioSil project has, currently, come to a standstill. The 2008 publication[72] reproduces in the same detail data presented in Carturan *et al.*[3]; there were no additional publications since. The Internet site of IRB srl, the Italian biotech company involved in the animal trials, contains no mention of further activity.

4.431.2.5.2. Aminopropyl-silicate membrane electrically bonded by external anionic polymers

The rigidity of sol–gel silicate matrix may present a problem for an implanted tissue or a growing mass of immobilized cells. Shinji Sakai and his group overcame this problem by constructing a liquid alginate reservoir surrounded by 3-aminopropyl-silicate membrane fortified and elastified by an external layer of alginate.[54,75,76]

Freshly isolated rat pancreatic islets were suspended in the 1.5 wt solution of sodium alginate in Ca^{2+}-free Krebs–Ringer–HEPES buffer. The suspension was extruded into 0.1 M $CaCl_2$ solution through an air-jet droplet generator set at preparing beads with a diameter of 0.6 ± 0.2 mm. The beads were put in *n*-hexane at the volume ratio of 10:14 followed by 3-aminopropyl-trimetoxysilane at 8% of the hexane phase, and finally by TMOS at 3%. After a short exposure at 4 °C, the positively charged silica precursor was absorbed at the negatively charged bead surface, whereby it underwent hydrolysis and condensation. The beads now coated in silicate membrane were transferred in 0.05% sodium alginate solution. Then, the free amino groups in the outer layer of the bead reacted with alginate coating the beads with an external alginate layer. Finally, Ca^{2+}-ions in the inner Ca alginate gel were exchanged with Na^+ (by incubation in 1 mM EGTA) causing the dissolution of the gel and formation of a microcapsule surrounded by a silicate–alginate membrane stabilized by salt bridges and containing the suspension of viable pancreatic islets (**Figure 7**).

When implanted in rat peritoneum, the empty beads coated with a silicate membrane prepared from the combination of 3-aminopropyl-trimetoxysilane and TMOS were superior to TMOS-derived coatings in the lack of fouling with proteins and fibrotic overgrowth[77] due to their anionic outer layer. However, the alginate–silicate–alginate beads containing the encapsulated islets were more prone to clumping and overgrowth, probably due to the release of attractants following necrosis.[78] The membrane, which had minimal resistance to the diffusion of glucose and insulin, hindered the diffusion of ovalbumin ($M_r = 45$ kDa) and completely excluded Bovine serum albumin ($M_r = 67$ kDa). The permeability of the alginate–silicate–alginate membrane depends upon the ratio of silicate precursors,[78] the sequence of their addition, and the time of contact of the precursors with the beads.[79] Molecular weight of alginate as well as the ratio of mannuronic to guluronic acid are also of importance.[76,80]

Peritoneal implantation of encapsulated rat pancreatic islets in mice (~10^3 islets per recipient) made diabetic by streptozotocin injection, resulted in normoglycemia for at least 100 days in the majority of implants.[78] It is postulated that the limitation has not been dictated by the stability or biocompatibility of microcapsules, but rather by the functional life span of the isolated islets.

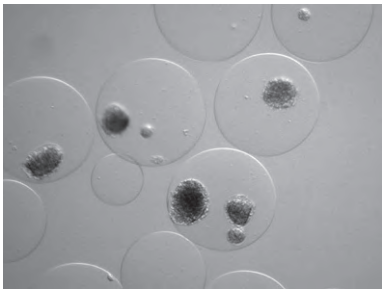

Figure 7 Rat pancreatic islets in microcapsules bounded by a flexible alginate–silicate membrane. Courtesy of Dr. Shinji Sakai.

In this respect, insulinoma cells with their ability to proliferate may be considered a viable alternative. Silicate–alginate–silicate membrane vesicles (~0.5 mm in diameter) have been applied for encapsulation of pancreatic β-cell line (MIN6) at the initial density of 4×10^7 cells ml^{-1}.[54,76] The cells happily proliferated in the inner compartment, forming, within 5 weeks, a spheroid roughly half of the bead diameter. Then, the cell population stabilized, probably, due to the constrains of mass transfer. The MIN6 cells, which were enclosed in the microcapsule, secreted insulin in a glucose-simulated manner. When inserted in the peritoneum of a diabetic mouse, they successfully maintained its blood glucose level for a month. The guluronic acid content of the alginate pool at the core of the vesicle influenced the quality of the preparation. The intermediate guluronic content was optimal for the MIN6 cells proliferation and for the long-term viability as measured by maintaining the blood glucose level maintained by the experimental animals.

Despite the undisputed elegance of vesicle construction, the project has not had practical implications yet. Mouse insulinoma cells are looked upon with suspicion for practical purposes. Long-term stability and biodegradation of alginate and silicate may counter-indicate the use of direct implantation of proliferating cell lines. Dr. Sakai informed me that there have not been follow up medical research and development of his vehicles, and that the work with his membranes has been abandoned.

4.431.2.5.3. Rational engineering of tissues and organs

If one agrees that organ implants are the major drive supporting the design of media for cell encapsulation, one should necessarily arrive to the conclusion that, so far, this drive produced no medical success. There are several gaps inherent in the use of encapsulated xenografts, which cannot be breached by a single research group or even a consortium of specialized laboratories and, perhaps, not ever within the limitations of current science. The difficulties may be divided in several categories, which will be reviewed subsequently. For the simplicity of illustration, the most common example of xenograft is used, almost exclusively investigated in the designs presented in this chapter – that of the pancreas.

Insulin replacement therapy is the main treatment for both type 1 and type 2 diabetes. However, periodical subcutaneous insulin delivery is blamed on many complications due to its nonphysiological periodicity and site of delivery.[81–83] It seems that currently artificial pancreas, rather than xenograft, has priority. In 2006, the FDA defined the continuous glucose monitoring-based artificial pancreas as a priority within its Critical Path Initiative. Successful clinical trials of closed loop systems have been reported.[84] The advantage of an implant over the system that automatically dispenses insulin, a hormone whose overdose could kill a patient, is its potential of safety.

Since it is quite impossible for all practical purposes, that a xenograft may deliver an overdose of insulin, what has to be done to make a functional implant? There are a number of physiological hurdles, which severely limit the useful life span of a transplant.

1. Pancreas consists of various types of tissues organized in a well adapted architecture. Since it is impossible to transplant the whole organ from an immunologically incompatible donor, one has to use only isolated Langerhans islets. Isolation, in itself, is a procedure, which reduces the viability of the tissues by depriving them of oxygen supply as well as causing chemical and mechanical damage. Further, it deprives the islets of the interactions and signals coming from the extracellular matrix and other surrounding tissues. The frequent result of such deprivation is dedifferentiation. The isolated islets in culture lose the ability to respond to glucose within days. The Edmonton protocol teaches us that, at best, one could expect a transplant to function for no more than a year.
2. This poses an additional constraint on the implant. One would not leave large amounts of useless foreign tissue, however, well protected against immune response, within the patient's body. Thus, the implant should be easily retrievable. This demand rules out the delivery of unbound microcapsules containing isolated islets delivered into a portal vein or into peritoneum, where their weight to surface ratio guarantees them adequate oxygen supply. Large retrievable macrocapsules have to be engineered in proper geometry and from materials (membranes) with large enough surface and permeability for oxygen.
3. The membranes should obey an additional large number of demands: they have to be biocompatible, but not biodegradable, should not elicit any immune response, should not bound any biopolymers abundant in body fluids for the fear of fouling the membrane, and should not anchor resident cells. Finally, all these properties should be stable within the life time of the device.
4. It is difficult to imagine a thin flat membrane with all the properties listed above that is also mechanically sturdy. Therefore, one should design a rough sturdy support membrane of suitable geometry.

As one sees from the above, a thorough engineering of the implant is the key priority in the practical application of a bioartificial pancreas using either hydrogels or any other biomaterials for foreign tissue encapsulation. The design of implants is a multiprofessional enterprise involving specialists of various sciences: material science, biology, physiology, as well as engineers and members of medical professions including clinicians. Organization of such a team and location of suitable funds should require a good promise of success and a change of priorities by regulatory agencies such as the FDA.

Two recent publications,[85,86] although not strictly within the reviewed field, mark the beginning of a multidisciplinary effort to devise a bioartificial pancreas. The group includes polymer scientists and engineers from the University of Akron, Ohio, medical professionals and clinicians from the Northeastern Ohio Universities College of Medicine and from the Cleveland Clinic Foundation. Their device has a complex design: it contains a thoroughly designed membrane, which is assembled from hydrophilic poly-(*N*,*N*-dimethyl acrylamide) and hydrophobic/oxyphilic PDMS chains cross-linked with hydrophobic/oxyphilic polymethylhydrosiloxane chains. This membrane, with an extraordinarily high oxygen permeability and small hydrophilic channel dimensions (3–4 nm), contains porcine islet cells. The key components are (i) a 5–10 μm-thick semipermeable amphiphilic conetwork

membrane reinforced for mechanical stability by (ii) the electrospun nano-mat of PDMS-containing polyurethane and (iii) a laser-perforated nitinol scaffold. The implant was tested on pancreatectomized dogs. The bioartificial pancreas protected pig islets from toxic environments *in vitro* and *in vivo*. Islets remained viable for up to 3 weeks without signs of rejection. Unfortunately for the concept, hyperglycemia was not reversed, possibly, because of insufficient islet mass.

4.431.3. Cell Delivery in Temperature-Sensitive Sol–Gel Systems

Answering the increasing demand for sophisticated delivery vehicles, pharmaceutical and biotechnological industry developed a variety of biocompatible nonimmunogenic polymers, primarily, for localized or extended drug delivery, but increasingly also for recombinant human hormones, genes, RNA, and other modern therapeutic vectors. Within the last 10 years, this technology has produced a multibillion industry. The vision of stem cells as the frontline of medical research has gradually shifted the attention more and more into the design and development of polymeric cell delivery systems. Not just future, but also current and proximal therapies create demand for cell delivery vehicles. Repair of cartilage, filling up cavities caused by large wounds, restoration of damaged retinas, restorative treatment of Parkinson disease, etc., could benefit from minimally invasive bio-supportive cell delivery technologies.

One may envision an ideal cell delivery procedure as being done by injection into the target cavity or space using a small gauge needle. This is precisely what the temperature-sensitive sol–gel systems can provide. The cells to deliver are mixed at ambient temperature with a low viscosity sol, which may also contain various soluble factors. At the injection site, the sol undergoes the transition into a mechanically stable gel induced by the higher temperature of the body. Although the sol–gel transition may be brought on by a variety of physical and chemical changes such as pH, change of a solvent or a chemical reaction, the *in situ* temperature shift is the least damaging to the sensitive animal cells and ensures homogeneity of the transition. Injectable hydrogels as a solid support either by themselves or by admixing other components can be designed to mimic extracellular matrix for cellular attachment and proliferation.

4.431.3.1. Mechanisms of Sol–Gel Transition in Temperature-Sensitive Materials

As in the case of silicates, the sol–gel transition in other systems is the function of solubility. In polymers, the solubility, among other factors, depends upon the aggregation state of the polymer. Polymeric sols are stabilized by polymer–solvent interactions favoring large surface area of contact between the polymer and the solvent. Thus, growth of large particles on the account of mass transfer from small ones or agglomeration of sol is energetically unfavorable. When the solvent is water, polymer–solvent interactions are governed by hydrogen bonding with water molecules and by hydration of charged residues. Interactions within and between the polymer molecules such as hydrophobic interactions, internal H-bonding, and formation of internal salt bridges favor phase separation with the preference of water–water and polymer–polymer interactions and, consequently, shrinking of the polymer–water contact surface area by growth of the particles until they form a continuous gel. In physical terms, the free energy of association in a given polymer–water system is given by: $\Delta G = \Delta H - T\Delta S$. Increase in temperature should eventually make the entropic component $T\Delta S$ larger than ΔH making the ΔG term negative, that is, favoring association of sol particles. The lowest temperature, at which sol–gel transition occurs, is termed the lower critical solution temperature (LCST). At LCST, the polymer system dehydrates. Alternatively, in some amphiphilic polymers, the previously stable micelles transit at the LCST to a continuous hydrophobic phase, this is so-called micellar mechanism of sol–gel transition.

4.431.3.2. Composition of Temperature-Sensitive Gels

Guided by the decision to limit the discussion by the principle of relevance to medicine, we shall review only these systems, which are biocompatible, and gel *in situ*, that is, possess LCST between the ambient and body temperature (for review see Ruel-Gariepy and Leroux[6]).

4.431.3.2.1. Natural and semisynthetic polysaccharides

Alkyl-substituted celluloses (Figure 8) such as methylcellulose (MC) and hydroxypropyl MC (HPMC) in diluted aqueous solutions exhibit thermosensitive gelation. Tate *et al.*[87] explored the use of MC solutions as cell carriers and scaffolds for the repair of brain trauma. MC solutions in concentrations below 8 wt% were free flowing at 23 °C and formed soft gels at

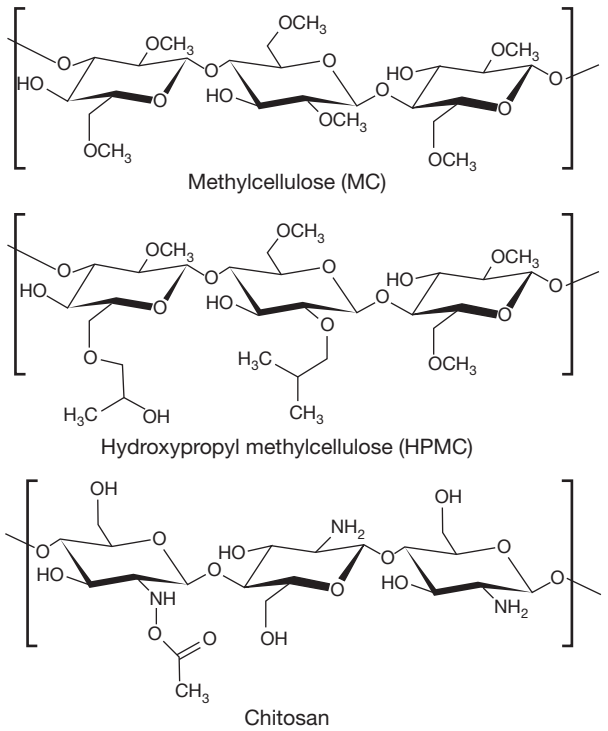

Figure 8 Natural and semi-synthetic polysaccharides.

37 °C. When microinjected into rat brain, they did not elicit neuron or astrocyte death and even promoted the formation of the glial scar.

Another biocompatible polysaccharide that attracted considerable attention due to its low cytoxicity is chitosan. Chitosan (**Figure 8**) is a linear polysaccharide containing β-(1→4)-linked chains of D-glusosamine. It is produced commercially by alkaline *N*-deacetylation of chitin and, therefore, contains various amounts of randomly distributed residues of *N*-acetyl-D-glusosamine. Chitosan is soluble in acids but forms gel-like precipitates at neutral pH. Ruel-Gariepy *et al.*[88] and Chenite *et al.*[89] proposed a composition of chitosan (~2 wt% solution) with β-glycerophosphate (~0.25 mol l^{-1}[90]), which forms stable neutral sols in cold. At ambient temperature, the viscosity of the solution increases after 3 months in storage indicating a slow process of gel formation. At 37 °C, a solid gel forms within 5 min for a mixture (1:1) of 84% and 94% deacetylated chitosan.

Solubility of chitosan in water is increased by β-glycerophosphate forming ionic pairs with its amino groups and by additional hydration of the complex by hydrogen bonding of the polyol residues to water. Dehydration of the polymer chains and increased polymer–polymer interactions govern the gelation at elevated temperatures. The LCST of chitosan complexes decreases with the degree of deacylation; for 91% deacylated chitosan, the LCST is 37 °C.[89] Subcutaneous injection of the sol in rats demonstrated that low deacylation of chitosan promoted both the rate of degradation of the implant and the inflammatory reaction. The 91% deacylated chitosan implant had a residence time of several weeks and produced no noticeable inflammation. Chitosan implants formulated with chondrocytes promoted the formation within the implant of proteoglycan-rich areas typical of normal cartilage.

Interested in understanding the ability of chitosan to promote the healing of cartilage microfractures, Simard *et al.*[91] investigated the recruitment of neutrophils by chitosan implants as the function of the degree of deacylation. While 80% deacylated chitosan attracted neutrophils in dose-dependent manner, 90% decylated chitosan was not an attractant. Nevertheless both chitosan preparations failed to elicit the release of granule enzymes or the generation of superoxide anions. Both chitosan preparations were internalized by polymorphonuclear neutrophils.

4.431.3.2.2. Chitosan-based cell-assisted cartilage repair vehicles

In the recent review of musculoskeletal tissue engineering in clinical applications, Roberts *et al.*[92] wrote: "Current gold standard for the repair of bone, cartilage and skeletal muscle entail intense surgical processes for reparative or replacement therapy … Therapies, which are utilized today for cartilage defects, include autologous chondrocyte implantation,[93] osteochondrial autografts[94] and in extreme case total joint replacement." Out of these, the autologous chondrocyte implantation (ACI) is the least damaging. In approximately 80% of patients, the current techniques of repairing cartilage defects by implantation result in function restored within 2 years. The cells are implanted with minimal surgical damage by injection. However, to speed up and improve recovery, proliferation of the chondrocytes in the cavity requires protection from shear stress and the facilitation of assembly in the tridimensional tissue. All of this may be provided for by a biodegradable artificial scaffold, on condition that the scaffold is injected with the cells and either self-assembles from solution or gels within the cavity after filling the defect.

Injectable cell delivery vehicles must not only meet such general demands for tissue engineering materials as biocompatibility, they also need to be biodegradable without producing debris and allow for complete integration with the repair tissue without forming discontinuities. They must form a perfect attachment interface with the damaged tissues including cartilage and the subchondral bone. In this sense, chitosan-β-glycerophosphate compositions, mentioned above, seem to be an attractive alternative, especially after the observation[95] that gels made with the admixture of whole blood form solid implants within cartilage microfractures, adhere well to the surrounding tissues and elicite improved cartilage healing compared to untreated microfractures. Chitosan clots stimulated cell recruitment, chondrogenic proliferation, hyaline matrix production, and subchondral angiogenesis.[96] The chitosan–glycerophosphate–blood scaffold was further commercially developed by BioSynTech under the trade name of BST-CarGel® (see Relevant Websites). This product now undergoes extensive human studies. It was reported that the nitial results completed by 2009 have been successful.

So far, BST-CarGel® has only been used as a scaffold for tissue regeneration. The same group reported an injectable adhesive vehicle for autologous cell transplantation.[97] This self-gelling system contains chitosan, glycerophosphate, glucosamine, and hydroxyethyl-cellulose. The addition of hydroxyethyl-cellulose allowed for gels with LCST within physiological limits and improved osmolarity due to lower glycerol phosphate content. Later, it was found that the effective agent in the mixture was not one of the components used purposefully, but rather the glyoxal additive present in the hydroxyethyl-cellulose. Glyoxal formed a covalent modification with chitosan. Chitosan–glycerol phosphate–glyoxal gels performed optimally, when the cross-linker was below the cytotoxic level of 1 mM.[98] Although primary chondrocytes were proliferating in the gel *in vitro*, the results of *in vivo* models were disappointing. In implants subjected to mechanical shear, the gel strength was insufficient. Inflammation and formation of fibrous or granulation tissue[97] bodes badly for tissue regeneration.

Recently, Cheng *et al.*[99] attempted to improve biocompatibility of thermosensitive chitosan/glycerol phosphate disodium salt hydrogels by adding gelatin (C/G/GP hydrogel) for its application as a cell carrier for nucleus pulposus (NP) regeneration. The sol–gel transition temperature of the C/G/GP hydrogel containing 1% gelatin was in the range of 31–34 °C at neutral pH. At the body temperature, the C/G/GP solution gelled in less than a minute. The gel strength was improved compared to the C/GP hydrogel. The gel supported the function of nucleus pulposa cells *in vitro* producing more extracellular matrix per DNA than surface culture of these cells. Undoubtedly, this research, which used only GRAS materials of acknowledged biocompatibility, is a good candidate for future use in minimally invasive intervertebral disk surgery.[99]

4.431.3.2.3. Copolymers of N-isopropyl-acrylamide

Water solutions of poly-*N*-isopropyl-acrylamide (PNIPAA) undergo sol–gel transition at the LCST of 32 °C.[100] The mechanism of this transition lies in the balance between the relatively hydrophilic linear poly-acrylamide chain and the hydrophobic isopropyl side chains. At LCST, hydrophobic interactions between the side chains govern the transition from sol to insoluble gel form. This 'main chain–side chain' balance may be modified either in the side chains or in the main chain by adding copolymers, thereby rendering the polymer more or less hydrophobic and thus tailoring both the LCST and the biocompatibility of the matrix for the desired use.

PNIPAA and its copolymers are nonbiodgradable and generally are not accepted as safe; therefore, if at all, they only may be suitable as implants for very long-term functioning artificial organs. Classical xenografts rarely perform for years due to dedifferentiation or necrosis. Thus, an acrylate (~2%) – acrylamide copolymer with the gelation temperature of 35 °C was investigated as a temporary cell carrier in a refillable hollow fiber pouch or in a diffusion chamber-type macrocapsule. The advantage of this copolymer over PNIPAA stems from the perfectly reversible sol–gel transition with no hysteresis and no swelling with change of temperature. Langerhans islets in the solution of this copolymer were injected into an immunoprotecting pouch installed in the patient.[101–103] Formation of the gel protected the islets, which resulted in their prolonged function compared to the free islets. Replacement of the islets required just lowering the pouch temperature below LCST rendering the content liquid and removing the liquid through a port. Further improvement of the system was achieved by using hemoglobin-PEO conjugate of the acrylate acrylamide copolymer.[104–107] The beneficial influence of the hemoglobin conjugate was, supposedly, due to improved supply of oxygen to the islets. A similar approach was used to build an artificial liver.[108]

4.431.3.2.4. PNIPAA composites

The thermosetting properties of PNIPAA attracted several attempts of tissue engineering, in which the polymer has been used in combination with the natural elements of the extracellular matrix or with materials mimicking ECM. Thus, injectable compositions were designed with PNIPAA chains grafted on denatured gelatin backbone.[109,110] About 30 graft chains of PNIPAA (MW ~10^5) were grafted on the gelatin molecule through the ε-amino group of lysine derivatized with dithiocarbamoyl residue. The graft copolymer has LCST of 34 °C; at 37 °C, a 5% solution forms an opaque gel.[111] During the period of the experiment (12 weeks), chondrocytes from rabbit articular cartilage, seeded in the hydrogel, accumulated *de novo*-produced extracellular matrix. The mechanical properties and the appearance of the 12-week old artificial cartilage were similar to that of normal rabbit hyaline cartilage. Similar results were obtained with a composite (of an unclear structure) obtained by the polymerization of *N*-isopropylamide in the presence of chitosan[112] (**Figure 9**).

A more complex graft was developed based on a copolymer of *N*-isopropylacrylamide, acrylic acid, *N*-acrylosuccinimide, and a macromer poly-trimethylene carbonate-hydroxyethyl methacrylate linked with collagen and chondroitin sulfate (CS).[113] Collagen and CS (mimicking the ECM) slightly

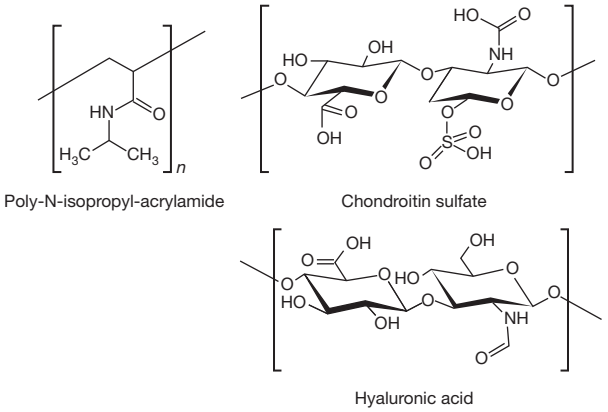

Figure 9 PNIPAA composites' components.

increased the LCST of the polymer in a concentration-dependent manner from about 24 to 27 °C. The 20% solution of the polymer gelled at 37 °C. The gel degraded slowly in the PBS *in vitro* losing about 10% of weight in 2 weeks. Without the ECM-mimicking components, mesenchymal stromal cells adhered to the surface of the gel about half as well as to the tissue culture plate. Cell adhesion has been dramatically improved in the graft containing collagen and CS. The cells encapsulated in the gel proliferated only in the presence of the growth factor IGF-1. Collagen alone graft performed better than one made with both collagen and CS.

Chen and Cheng[114] experimented with chitosan and hyaluronic acid (HA) grafted on PNIPAA. The material forms sturdy gels at 37 °C. Although inclusion of HA residues in the graft seemed to assist the surface chondrocyte proliferation on the polymer films, the results were not clear, since there was no report of experiments performed with encapsulated cells.

4.431.3.2.5. Polyoxyethylene–polyoxypropylene (poloxamer or Pluronic®) aqueous gels

"Poloxamers are nonionic triblock copolymers composed of a central hydrophobic chain of polyoxypropylene flanked by two hydrophilic chains of polyoxyethylene. The word 'poloxamer' was coined by the inventor, Irving Schmolka, who received the patent for these materials in 1973. Poloxamers are also known by their trade name Pluronics" (see Relevent Websites).

Concentrated poloxamer solutions in water undergo thermoreversible sol–gel transition by the micellar mechanism.[115] Thermosensitive sol–gels of the commercial poloxamer 407 (Pluronic® F127) have been suggested for use in short-term treatments such as pain management, infection treatment, fertility control, and in topical drug delivery.[6] Pluronic® F127 is generally accepted as safe, although in animal studies injection of doses exceeding 27.5 mg kg^{-1}[1116,117] caused serious increases in blood cholesterol and triglycerides (**Figure 10**).

Solutions of poloxamer 407 (~25%) are viscous liquids below 25 °C; at body temperature they form a semisolid gel. Weak mechanic strength, relatively high solubility in body fluids, and nonbiodegradability are the main hurdles for the use of poloxamer 407 in cell delivery systems. Introduction of the carbonate linkage between poloxamer 'blocks' and linking of poloxamers into structures of a higher molecular mass[118] were attempted to overcome these disadvantages. However,

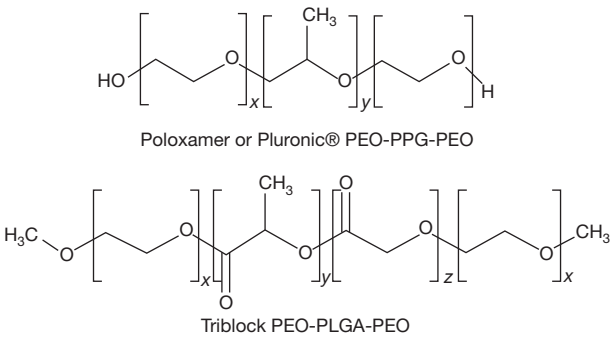

Figure 10 Poloxamers and their composites.

only more sophisticated synthetic procedures offering graft copolymers hold promise for the application as injectable cell carriers.

4.431.3.2.6. Graft copolymers with poloxamer blocks

One of the possible strategies to improve the stability, biocompatibility, and adhesion of poloxamer gels to extracellular matrix was explored by Chung *et al.*[119] in grafting poloxamer 407 onto chitosan using soluble carbo-di-imide and *N*-hydroxysuccinimide as coupling agents. The resulting graft materials (CP hydrogels) were water-soluble at neutral pH and displayed sol–gel transition at 30–35 °C at lower concentrations of the polymer than Pluronic® F127 alone (depending upon the grafting percentage of chitosan). It was proposed that the transition is governed by hydrophobic interactions between poloxamer chains in the same manner as in ungrafted poloxamer gels, while larger complexes are formed owing to the participation of chitosan chains. Similar hydrophobic–hydrophilic sol–gel transition mechanisms were demonstrated in aqueous solutions of acrylate/thiol-modified poloxamer 407 mixture[118] and poly (ethylene glycol)-polycaprolactone triblock and multiblock copolymers.[120] CP hydrogels are also considerably sturdier than poloxamer hydrogels, show less concentration-dependent swelling, and have a slower degradation rate. The swelling rate of CP hydrogels increases *in vitro* for up to 3 days reaching the ratio of 1.1–1.3. After 10 days, the swelling ratio decreases due to degradation of the esteric bonds in the hydrogel. The gels lose mechanical integrity within 30 days.[121] In contrast to alginate gels used as the control in this research, the chondrocytes proliferated, albeit slowly, in CP hydrogel matrix, accumulated glucosamineglucan (GAG) and expressed extracellular matrix proteins.

Besides CS, another analog of extracellular matrix, HA, grafted with Pluronic® F127 copolymer was investigated as a biomimetic hydrogel for cell delivery.[57] The graft copolymer was synthesized by conjugating amine end-capped Pluronic F127 to carboxylic groups of HA. Copolymers with vinyl groups were introduced to prepare more robust hydrogels by photo-cross-linking. For improved cellular adhesion and proliferation, cell-adhesive peptide (Arg–Gly–Asp (RGD)) was additionally conjugated to the HA backbone. The synthesized graft material exhibited thermosensitive sol–gel transition behaviors over the temperature range of 20–40 °C. The gels supported proliferation of bovine chondrocytes *in vitro*. The copolymer containing RGD supported linear growth kinetics of chondrocytes for 4 weeks. A tissue containing cartilage-like components such as GAG and type II collagen was successfully produced within the hydrogels. Although some of these materials seem promising, the complexity of chemical procedures for their synthesis, probably precludes their routine use.

4.431.3.2.7. Triblock copolymers containing poly-hydroxylic acids

Standard triblock copolymers (poloxamers) do not readily biodegrade but dissolve at physiological conditions from the surface resulting in the delivery of a soluble material with uncertain GRAS status into body fluids, thus rendering them rather impractical. Usefulness of the poloxamer compositions is also limited by their rheology: they are relatively viscous at 20 °C and have a low transition temperature. Recently, Jeong *et al.*,[122] Jeong *et al.*,[123] and Chung *et al.*[124] proposed biodegradable hydrogels with thermosensitive sol–gel transition based on triblock copolymers of polylactic-*co*-glycolic acid (PLGA) and polyethyleneglycol (PEG). PLGA has a long history of use in biodegradable surgical sutures and is considered safe. PEG–PLGA–PEG triblock copolymers have no surface erosion and have a lower content of nonbiodegradable polymer than poloxamers. The PEG–PLGA–PEG copolymers were synthesized using chemistry that allows for mass production. It consisted of obtaining diblock PEG–PLGA by ring-opening polymerization of lactide and glycolide onto PEG, followed by coupling of the diblocks with hexamethylene-diisocianate to obtain the desired triblock copolymers. The sol–gel transition of these copolymers from a free-flowing sol to gel depended moderately on the concentration; within the range of 17–14%, the LCST decreased from 36 to 30 °C at lower concentration. The gelation mechanism of the PEG–PLGA–PEG copolymers is similar to that of poloxamer gels. However, the aggregation number of micelles in the gel state is much higher, counting in thousands and resulting in much stronger gels. When implanted in rats, these gels remained mechanically intact even after a month.[123] The weight reduction on account of implant hydrolysis is accounted for by the loss of PEG-rich segment. The PEG-rich segment's loss results in a decrease of molecular size of the copolymer to a half and approximately 30% drop in weight over a month. It seems that following subcutaneous implantation, there was neither an inflammatory response nor formation of fibrous tissue on the surface of the implant.

4.431.3.3. Availability of Injectable Cell Carriers for Practical Medicine

Injectable cell delivery vehicles hold a considerable promise for the repair of lesions and cavities resulting from pathology or injury. Many efforts have been invested into the development of materials that would combine all the desired properties: biocompatibility with complete biodegradability, convenient rheology of the sol with mechanical stability of the gel, and cell adhesion with cell proliferation. However, these ideal cell carriers are not currently available. As concluded in the most recent review,[125] "current biomaterials are unable to meet all the design parameters simultaneously."

Evidently, the injectable cell delivery is still in its infancy. Yet, the clinical trials for the second generation ACI of such

gel-based, even though not sol–gel-based, seeded scaffolds as the bioresorbable fibrin–polymer matrix BioSeed-C® of BioTissue Technologies GmbH, Freiburg, FRG,[126] and hyaluronan-based Hyalograft C® of Fidia Advanced Biopolymers (FAB), Italy,[127,128] were highly successful. This success indicates that tissue engineering may, in the future, deliver on its high promises.

4.431.4. Conclusion and Future Directions

Alexander Pope once made an observation which perfectly describes the difficulty of discovery in Life Sciences:

> "... Following life through creatures you dissect.
> You lose it at the moment you detect".

Intervention in the function of the living organism, whether for the sole sake of investigation or for repairing a malfunction, is never simple, usually dangerous to the organism and always imperfect.

Achievement in Life Sciences necessitates the use of novel technologies. Life Sciences and their main practical application, the modern medicine, are, primarily, instrumental disciplines. Each new gadget, every new means of dissecting an organism, is producing a wave of innovation. Scientists are easily becoming enchanted with their new gadgets. They create a wealth of imaginative, novel work, frequently quite removed from practicality. Paraphrasing the famous dictum of Sir Isaac Newton: "I do not know what I may appear to the world, but to myself I seem to have been only like a boy playing on the seashore ...," I term this playful aspect of scientific innovation: Playing-on-the-Sea-Shore Syndrome or PSSS. The combination of advanced materials with medicine, which is the topic of this review, is fraught with PSSS.

This is not to accuse either Sir Isaac Newton or my learned colleagues of futile activity. No one can predict which research will start the chain of events, leading to a useful medical application. Nevertheless, it is clear that the majority of publications dealing with medical applications of sol–gel materials do not take into account the maxim of Alexander Pope and the complexity of the human body. Many teams lack specialists able to appreciate medical aspects of the work. Overt enthusiasm of some publications, the playful exhilaration over a new material constitutes precisely what I termed PSSS. In the body of this review, I have tried, with the benefit of hindsight, to discriminate between the practical and impractical.

After reading the rich collection of publications devoted to the medical use of sol–gel silica, I arrived to the conclusion that the promise of this material has not materialized yet in anything approaching medical practicality. The solubility in body fluids and complicatedness of stable incorporation of physiological elements such as ECM components, signals, etc., impair the usefulness of sol–gel silicate-based chemistry. The answer to both problems may be found in the increase of molecular mass of, and association of, sol–gel silica precursors. Oligomers of a high molecular mass, especially self-assembling into structures stabilized by noncovalent bonds could produce stable and biologically 'friendly' media. It seems that synthesis of trialkoxysilane compounds bearing silicon–carbon bonded linkers may open the road to derivatized silica membranes containing such ECM motives as gelatin, fibrinogen, or GAG-derived polysaccharides.

In Section 4.431.2.5.3, I discussed the desirability of engineering xenografts encapsulated in sol–gel silica-based macrocapsules, which ensure a convenient removal of the graft in case of failure. The life of a graft is usually quite short and rarely measures in years. The main reasons for this short life span are the lack of supportive tissues and difficulties in supplying macrocapsules with nutrients. Both could be overcome by engineering the tissues of the xenograft. An example of such engineering is shown in Hasson *et al.*[129] The authors took a cell therapy approach to induce angiogenesis. They implanted small skin or lung fragments (microorgans) in a microcapsule, which induce an angiogenic response causing capillary outgrowth on the surface of a synthetic membrane. One could use these microorgans and other tissue types to support the prolonged useful life of isolated Langerhans islets.

The research in thermosensitive sol–gel materials fared somewhat better in practicality than sol–gel silicates. Injectable cell delivery materials benefitted from the lesser complexity of the task they were expected to perform, which is to fill up a cavity caused by injury or pathology, providing protection of the wound and supplying cells able to regenerate the damaged tissue. However, even here the expected advantages of sol–gel materials did not manifest themselves in well-advanced practical solutions. In fact, the main argument for the use of sol–gel materials is that it makes major surgery during implantation redundant. Ideally, one would just use a small gauge needle to inject the implant into a cavity. Unfortunately, all reported injectable delivery vehicles are not completely bioresorbable and the majority does not have a clear GRAS status. In many cases, the defective tissue requires *a priori* surgical intervention for the debriefing of the wound, preparation of the surfaces, etc. No wonder, that all medically approved or nearly approved seeded gels are based on surgical delivery.

Of course, one should not underestimate the other advantage of sol–gel transition – the ability of the liquid sol to snuggly adhere, to form a well fitted contact with the surface of the wound. This advantage might be decisive in, for example, neurosurgical application. However, to be able to realize this advantage, one needs to develop entirely bioresorbable and biocompatible sol–gel products.

I hope that the effort and resourcefulness invested in the development of sol–gel materials will pay off, and that the future will substantiate the high hopes of the pioneers in this field.

Acknowledgments

The author is indebted to Drs. Ovadia Lev and Eduardo Mitrani of the Hebrew University for their valuable insights and helpful discussion, and to Ms. Deworah de Vries for the critical reading of the manuscript.

4.432.1. Introduction

The efficient delivery of biomolecules to a specific target at an intended time has attracted great interest in recent years because targeted delivery maximizes the value and utility of the biomolecules.[1–3] A targeted delivery system not only diminishes the adverse effects caused by excessive dosage, but it can also increase the activity of drugs or other therapeutic molecules.[2,4] Generally, biomolecules are physically, chemically, and biologically vulnerable to the harsh external conditions, and therefore, protection by durable inorganic nanoparticles can stabilize these biomolecules. In this sense, inorganic nanoparticles such as aluminosilicates,[5–11] layered double hydroxides (LDHs),[12–19] silicas,[20–25] and calcium phosphate[26–30] have been widely studied as reservoirs or delivery carriers of biomolecules (see **Chapter 3.319, Characterization of Nanoparticles in Biological Environments**).

Among these nanoparticles, layered materials are attractive candidates for such applications as it is relatively simple to prepare heterostructured nanohybrids through an intercalation route which involves the reversible insertion of a guest species into a two-dimensional host lattice. By rearranging the orientation of molecules in the interlayer nanospace, it is possible to maximize the advantages of the introduced molecules and even expect synergistic effects from the interaction between the host (inorganic layers) and the guest (molecules). Various intercalative systems, such as inorganic/inorganic, organic/inorganic, and bio/inorganic nanohybrids, have been reported which can be used to develop new materials with unusual physicochemical properties.[13,14,31–37]

LDHs, also known as anionic clay, are potential candidate materials that can act as a reservoir or a delivery carrier for biomolecules. Similar to other layered inorganic materials, LDH lattices can tolerate severe conditions compared to the biomolecules themselves. Furthermore, LDHs exhibit characteristic merits that are suitable for storage of biomolecules such as high anion exchangeability, pH-dependent solubility, and comparatively low toxicity.

Various biomolecules and biofunctionalized molecules including deoxyribonucleotides, therapeutic antisense genes, peptides, proteins, drugs, organic acids, food ingredients, and vitamins have been successfully intercalated into LDHs in order to enhance their stability and for safe preservation.[12–15,38–45] In addition, they can be retrieved whenever necessary without any structural deformation, and their release profile can be controlled by manipulating the size, morphology, chemical

composition, charge density, and surface properties of LDHs, as well as by using various release conditions such as salt concentration, pH, etc. LDHs can easily permeate the plasma membrane and can therefore transport intercalated biofunctionalized molecules efficiently into intracellular organs. As the controlled release properties of LDHs depend on pH or salt concentration, the biofunctionalized molecules are expected to be liberated in lysosomes, which are slightly acidic and full of electrolytes.

In this chapter, we summarize techniques used for the stabilization and controlled release of biofunctionalized molecules into and out of LDHs, and also discuss how the enhanced cellular uptake and intracellular release of biofunctionalized molecules from LDHs can be applied as a drug delivery system.

4.432.2. LDHs and Intercalation

4.432.2.1. Structure

Layered metal hydroxides can be categorized into two classes. The most prevalent type, LDHs are known to have a hydrotalcite-like structure, in which positively charged layers of the general formula $\left[M^{2+}_{1-x}M^{3+}_{x}(OH)_2\right]^{x+}$ (M^{n+} stands for metal cations of M^{2+} = Mg^{2+}, Zn^{2+}, Ni^{2+}, Cu^{2+}, ...; M^{3+} = Al^{3+}, Fe^{3+}, ...) are stacked and their interlayer spaces filled with anions (A^{m-} = CO_3^{2-}, NO_3^-, SO_4^{2-}, and other anionic species) and H_2O molecules.[37] One layer of LDH consists of $M(OH)_6$ octahedrons which share their edges to form two-dimensional sheets; and the isomorphic substitution of M^{2+} with M^{3+}, in a brucite-like layer ($M^{II}(OH)_2$), results in a permanent positive charge. There is another type of layered metal hydroxides, the structure of which is often referred to as hydroxy double salts (HDSs). They have the general formula $\left[\left(M^{2+}_{1+x}Me^{2+}_{1+x}\right)(OH)_{3(1-\gamma)}\right]X^{n-}_{(1+3\gamma)/n}zH_2O$, where M^{2+} and Me^{2+} indicate divalent metal cations such as Zn^{2+}, Cu^{2+}, or Ni^{2+}, and X^{n-} is the interlayer anion.[46] Similar to LDHs, divalent metal ions in the HDS form two-dimensional sheets of edge-sharing $M(OH)_6$ octahedrons; however, HDSs periodically contain vacant sites, which are filled by $M(OH)_4$ tetrahedrons that are positioned above and below the hydroxide layers. An example of an HDS is a zinc basic salt (ZBS), which has the formula of $Zn_5(OH)_8(NO_3)_2{\cdot}nH_2O$, where a quarter of the O_h sites are vacant, thus forming tetrahedra (T_d).

4.432.2.2. Preparation and Intercalation

LDHs can typically be synthesized by coprecipitation of mixed metal cations by base titration, either with or without hydrothermal treatment, which can enhance crystallinity. Various sizes of LDH particles can be prepared by adjusting the synthetic parameters during coprecipitation or during postprecipitation treatment. LDHs with large particle sizes can be prepared by titrating the metal solution with a weak Brønsted base, like urea ($pK_b = 13.8$). The urea is slowly hydrolyzed to release ammonium and carbonate.[47] As the hydrolysis occurs uniformly and in a temperature-dependent manner, it is possible to maintain a low degree of supersaturation during precipitation, and as a consequence, large particle sizes can be achieved.[48]

$$CO(NH_2)_2 \rightarrow NH_4CNO : \text{slow}$$

$$NH_4CNO + 2H_2O \rightarrow (NH_4)_2CO_3 : \text{fast}$$

In addition, postprecipitation processes, such as hydrothermal treatment, can enhance the crystallinity and particle size of the LDHs. According to the equation $dL/dt = C\ \exp(-1/RT)$ (C: constant), where L is particle size and T is the reaction temperature,[49] both aging time and reaction temperature appear to be key factors controlling size. LDH particles, with homogeneous particle sizes from 80 to 4000 nm, can be successfully prepared based on the synthetic parameters above.[50] **Figure 1** shows a few selected scanning electron microscopic images for LDH particles synthesized by the urea hydrolysis method (**Figure 1(d)–(f)**) and hydrothermal treatment (**Figure 1(a)–(c)**).

In order to intercalate biomolecules into LDHs, any one of three synthetic routes, coprecipitation, anion exchange, and reconstruction, can be utilized[51] (**Scheme 1**). The coprecipitation route is the most frequently employed as it enables a one-step synthesis of both the LDH layer and its intercalation. Furthermore, it is possible to easily fine-tune the charge density of the layer and control its framework composition, anion properties, treatment conditions, etc., in the coprecipitation route. During typical syntheses, the metal solution is blended with the solution containing biomolecules and then titrated with an alkaline solution to the pH at which metal hydroxides will precipitate. In LDH synthesis, it is important to prevent contamination by airborne carbonate. In the anion exchange route, LDHs with readily exchangeable ions (NO_3^- or Cl^-) that have been prepared by the conventional coprecipitation can be utilized. In this method LDHs are dispersed in decarbonated water, and the solution containing excess biomolecules is added. The biomolecules are incorporated into the LDH layers according to their concentration gradient. Biomolecules can also be intercalated into LDHs via the reconstruction method. First, LDHs having carbonate anions are heat-treated to remove the H_2O and CO_2 moieties, and the resulting layered oxides are mixed with the biomolecule solution to provide H_2O and anionic species that facilitate reconstruction of the LDH lattices. Bio-LDH nanohybrids prepared using these methods are known to exhibit (i) stabilization, (ii) controllable release of biomolecules, and (iii) enhanced cellular uptake, all of which are essential for drug delivery (see **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**).

4.432.3. Stabilization of Biomolecules via Intercalation

The sandwich structure made by the two-dimensional LDHs can be considered as pocket nanocapsules for biomolecules that are either thermodynamically unstable or kinetically labile.

Nucleotide monophosphates such as adenosine-5′-monophosphate (AMP), guanosine-5′-monophosphate (GMP), and cytidine-5′-monophosphate (CMP) and also deoxyribonucleotides (Herring testis DNA 100–2000 base pairs in length) have been successfully intercalated into MgAl-LDHs via ion-exchange reactions.[15,17,41] **Figure 2** shows schematic illustration of the interlayer orientation of DNA strands that have been intercalated into LDH and their circular dichroism (CD) spectra,

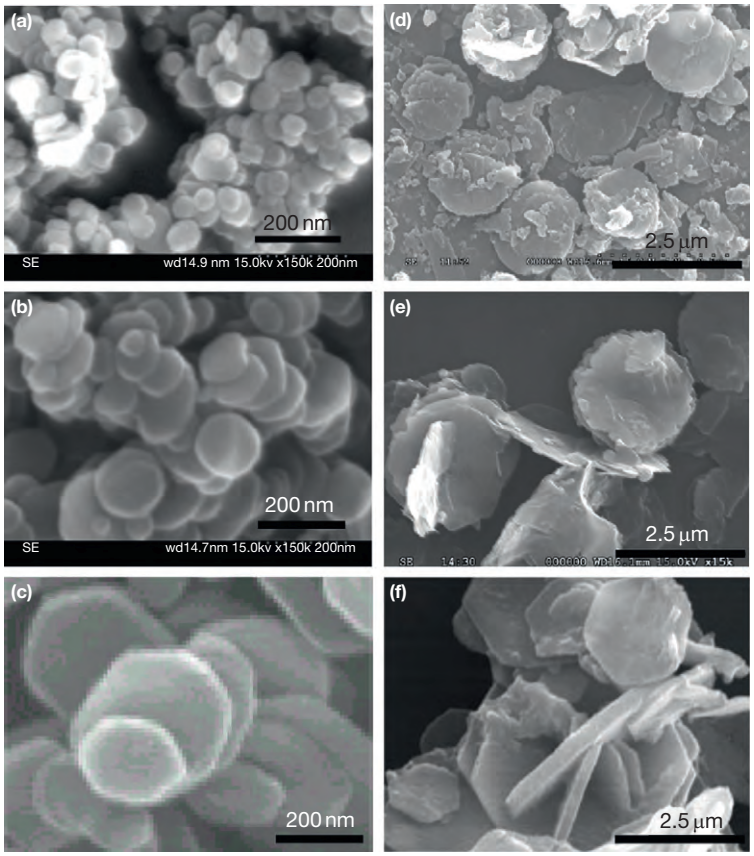

Figure 1 Scanning electron microscopic images for size controlled LDH particles (a) 80 nm, (b) 120 nm, (c) 350 nm, (d) 850 nm, (e) 2100 nm, and (f) 2800 nm. The particles sizes were controlled according to synthetic conditions such as total metal concentration, basicity of alkaline solution, aging time and reaction temperature. Reproduced from Oh, J. M.; Hwang, S. H.; Choy, J. H. *Solid State Ionics* **2002**, *151*(1–4), 285–291, with permission from Elsevier.

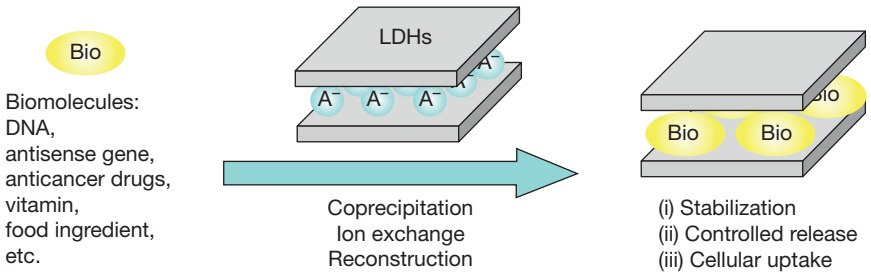

Scheme 1 Schematic illustration of biomolecule intercalation into layered double hydroxides. A^- stands for the exchangeable interlayer anion and Bio for biomolecules.

which indicate that the anionic DNA strands are tightly bound to the positively charged LDH layers, thus forming stable structures.

Generally, the phosphate group ($-PO_4^{2-}$) of the B-type DNA occurs every 3.4 Å, and the diameter of the double helix is ~20 Å. Thus, the DNA strands require 34 $Å^2$ of area per single negative charge. However, from X-ray diffraction patterns, it was determined that the positive charge of LDHs generated from trivalent cations can only provide 24.9 $Å^2$ of area per unit charge. Therefore, it can be concluded that the intercalated DNA becomes more twisted than free DNA in order to fit into the available area in the LDH lattice (Figure 2(a)).

i) Area demand per unit charge of DNA molecule:

$1\ bp = 2e^-$

therefore area per unit charge = 3.4 Å/1 bp × 20 Å/$2e^-$ = ~34 $Å^2/e^-$

ii) Area provided per unit charge by LDH lattice:

$a = 3.1\ Å/[Mg_{0.66}Al_{0.33}(OH)_2]^{0.33+}$

unit cell area = $a^2 \times \sin 60^\circ = 8.3\ Å^2$

therefore area unit charge = ~8.3 $Å^2 \times 3$ = ~24.9 $Å^2/e^-$

The CD spectra, shown in Figure 2(b), also support the concerted orientation of DNA in LDHs.[17] CD analysis is an effective method to examine conformational changes in the helical structure of DNA because CD sensitively reflects the change in polarization caused by any change in the helicity of

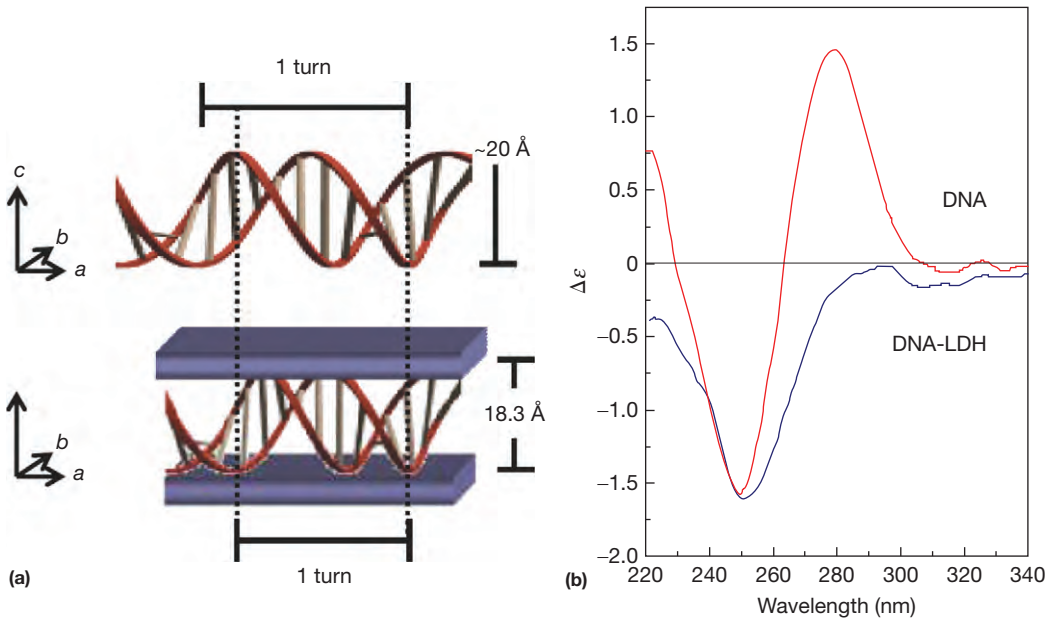

Figure 2 (a) Schematic illustration of the interlayer orientation of DNA strands and (b) circular dichroism spectra for free DNA in solution and DNA-LDH. Reproduced from Oh, J. M.; Kwak, S. Y.; Choy, J. H. *J. Phys. Chem. Solids* **2006**, *67*(5–6), 1028–1031, with permission from Elsevier.

nucleic acids or proteins. Compared to free DNA, the spectrum of DNA-LDH shows a collapsed CD band at around a wavelength of ~275 nm. A similar kind of band collapse can also be observed for DNA strands in high salt concentrations in which cation–anion interactions are better facilitated.

As trivalent ions such as aluminum readily form stable complexes with the phosphates on the DNA backbone, it has been difficult to prepare DNA-LDH intercalates by direct coprecipitation. Recently, however, Desigaux *et al.*[52] succeeded at intercalating DNA fragments of various sizes (100–500 and 6000–8000 bp) into an MgGa-LDH through coprecipitation. The intercalation of therapeutic genes, such as antisense oligonucleotides, into LDHs has also been reported.[13] Thyveetil *et al.*[53] computed the stability of DNA-LDH intercalates utilizing molecular dynamics simulations and showed that the phosphate backbone exactly aligns with the lattice of the trivalent ions. This result also suggests that the intercalated DNA molecules are stabilized by strong electrostatic interactions with the LDH layers.

The biological stability of DNA in a DNA-LDH intercalate can be quantitatively evaluated using a DNase I resistance test. DNA-LDH or DNA alone, with the same initial optical density of 0.4 at 260 nm, were identically treated with 192 units of DNase I and DNA degradation by DNase I was estimated by the change in optical density at 260 nm recorded as a function of time (Figure 3). By comparing the slopes of the degradation curves, which indicate the velocity of degradation, it was found that degradation of the DNA-LDH complex was negligible, while degradation of the naked DNA could be observed within a few minutes. This high resistance of the LDH against nuclease attack is highly advantageous and makes it a delivery material for DNA under

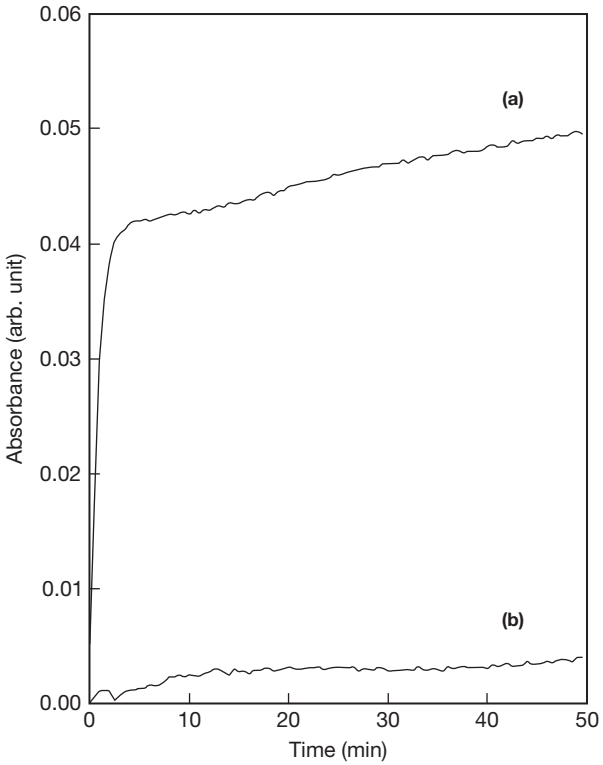

Figure 3 Profiles of UV absorbance for (a) DNA and (b) DNA-LDH hybrid treated with DNase I as a function of time. 500 μl of DNA-LDH hybrid (OD 0.4) was treated with 2 μl of DNase I (96 unit μl^{-1}) in 7.5 mM HEPES (pH 7.3) containing 75 mM NaCl at room temperature. The change in absorbance at 260 nm was recorded to estimate DNA degradation.

physiological conditions where DNA degradation through nuclease attack can take place.

Besides DNA, large biopolymers such as polysaccharides and proteins can be intercalated into LDHs. Darder *et al.*[54] prepared composites of LDHs with natural biopolymers such as alginic acids, pectin, carrageenan, and others by both the coprecipitation and the coorganized assembly routes. Shi *et al.*[55] intercalated the large protein bromelain, a mixture of proteolytic enzymes derived from pineapples, into LDHs by utilizing a reconstruction method in which calcined MgAl-LDH was mixed with bromelain/phosphate buffered saline (PBS). Another example of protein intercalation into LDHs was provided by Rahman *et al.*[18] They successfully incorporated lipase molecules onto LDH surfaces through physical and chemical adsorption which included electrostatic interactions. The incorporated enzymes were shown to have improved thermal stability, with more than 50% of their activity preserved.

Drug molecules and other biofunctional molecules require stabilization because they can easily be destroyed or expelled by various drug-resistant mechanisms in biological systems. We have recently reported the intercalation of folic acid and its derivatives into LDHs for use as a drug stabilization and delivery system.[31] Folic acid (*N*-(4-{[(2-amino-4-oxo-1,4-dihydropteridin-6-yl)methyl]amino}benzoyl)-L-glutamic acid) and its derivative, folinic acid ((*S*)-2-[4-[(2-amino-5-formyl-4-oxo-5,6,7,8-tetrahydro-1H-pteridin-6-yl)methylamino] benzoyl] aminopentanedioic acid) are used in cancer therapy and in the treatment of vitamin deficiencies. Another folate derivative, methotrexate (MTX: (2 *S*)-2-[(4-{[(2,4-diamino-7,8-dihydropteridin-6-yl)methyl] (methyl)amino}phenyl)formamido] pentanedioic acid), is known to act as a folic acid antagonist and inhibits the proliferation of certain cancers by regulating the biosynthesis of thymidylate.[56,57] Unfortunately, these are quite unstable in biosystems, with short plasma half lives of 6.2 h and 3–15 h (depending on dose) for folinic acid and MTX, respectively. The intercalation of these molecules into LDHs is thought to stabilize them physically, chemically, and biologically, and consequently we could expect longer half lives and lower dosage requirements (see **Chapter 1.115, Calcium Phosphates for Cell Transfection**).

As shown in X-ray diffraction patterns (**Figure 4(a)**), the intercalation of folic acid and its derivatives resulted in a significant increase in interlayer space. Given that the thickness of a brucite-like LDH sheet is 4.8 Å, the gallery heights are estimated to be 17.1, 14.3, and 15.1 Å for folic acid-, folinic acid- and MTX-LDH intercalates, respectively. These values are smaller than the longitudinal molecular dimensions of folic acid (≈19.7 Å), folinic acid (≈21.5 Å), and MTX (≈21.2 Å). These results suggest that the intercalated molecules are oriented in a tilted monolayer with tilt angles of ∼60°, 42°, and 45° between the LDH layer and folic acid, folinic acid, and MTX, respectively (**Figure 4(b)**).[31] Assuming that these molecules are packed in a zig-zag, the electrostatic interactions between the anionic terminal carboxylates and the cationic hydroxide layers can be maximized. The strong electrostatic interaction between folic acid species and the LDHs was also verified by infrared and UV–vis spectroscopy as well as thermogravimetric analyses.

LDHs can be utilized to encapsulate labile but bioactive substances like vitamins to protect them against rapid degradation by light, temperature, oxygen, alkali metals, etc.[42,58,59] In fact, their fast degradation greatly limits their application as active ingredients in cosmetics and foods. In particular, vitamin C oxidation is facilitated in the presence of oxygen and a small amount of metal ions. For effective protection and controlled delivery, vitamin C (VC) or E (VE) molecules were intercalated into ZnAl-LDH[42] or ZBSs.[59] The X-ray diffraction patterns (**Figure 5(a)**) for the pristine LDHs (host LDHs before intercalation) and LDH intercalates exhibit well developed (00 *l*) reflections showing *d*-spacing of 8.7, 10.5, and 53.8 Å for pristine, VC-LDH and VE-LDH, respectively. Based on the longitudinal dimensions of the vitamin molecules and the observed gallery space, a schematic illustration of the vitamin-LDH structures are shown in **Figure 5(b)**. The VE molecules are arranged as J-like aggregates with a tilting angle of 62°. It was also verified, using UV–vis spectroscopy, that α-(+)-tocopherol acid succinate molecules stack diagonally with respect to the basal plane, suggesting that the stabilization of vitamin molecules occurs via electrostatic interactions.

Recently, the intercalation procedure has been employed in food science to increase the stability and applicability of additives. For instance, essential fatty acids, such as conjugated linoleic acid (CLA) and γ-linolenic acid (GLA), and flavor molecules such as vanillic acid (VA) have been successfully introduced into layered materials. Won *et al.*[60] have reported that the intercalation of CLA and GLA into zinc hydroxide through coprecipitation greatly enhanced their thermal stability during storage. CLA alone, stored in a 50 °C chamber, completely decomposed in 7 days, while intercalated CLA exhibited long term thermal stability, for 49 days at 50 °C. Similar thermal stability was observed with GLA intercalates; the intercalated GLA preserved 50% of its fatty acid moieties after 28 days at 50 °C, whereas all unprotected GLA molecules were oxidized after 14 days in the same chamber. The X-ray diffraction pattern of these LDHs suggests that the interlayer orientation of fatty acids forms a close zig-zag packing of linear molecules. Both the electrostatic stabilization and the intermolecular hydrophobic interactions of fatty acid packing are considered to play important roles in the observed enhancement in thermal stability.

Vanillic acid (VA: 4-hydroxy-3-methoxybenzoic acid), which is frequently used as a flavoring or food additive, has been successfully intercalated into ZnAl-LDH with various metal ratios.[61] Data from X-ray diffractometry and infrared spectroscopy show that LDHs can well preserve VA molecules via electrostatic interactions, regardless of the metal ratio used. Similar to fatty acid intercalates, interlayer VA molecules appear to be arranged in a zig-zag orientation that maximizes their intermolecular π–π interactions. It has also been reported that the extra chemical stabilization energy from electrostatic interactions and intermolecular packing could strongly enhance thermal stability of the VA. VA molecules intercalated in a ZBS maintained most VA moieties for 1 h at 200 °C, but naked VA molecules readily melted within 20 min and were expected to decompose within 30 min.[62]

Yang *et al.*[63] have recently demonstrated the intercalation of indole-3-acetic acid (IAA) into ZnAl-LDH and ZBS for safe preservation and controlled release. IAA is a type of plant auxin

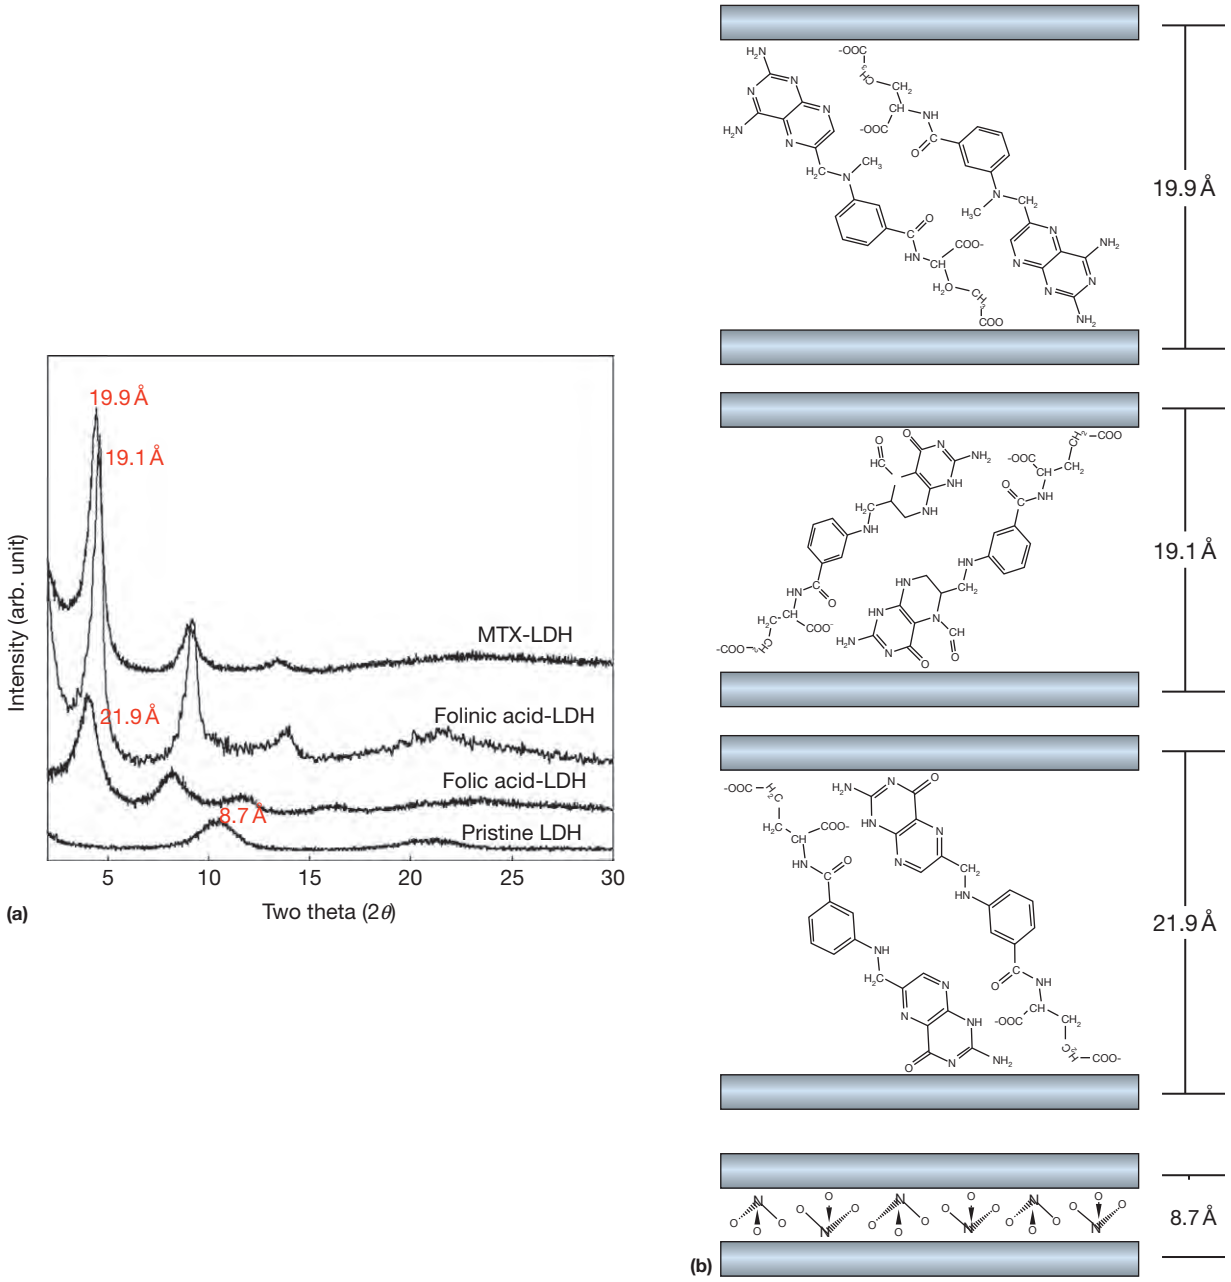

Figure 4 (a) X-ray diffraction patterns for various folate derivatives intercalated in LDH and (b) corresponding structures. Reproduced from Choy, J. H.; Jung, J. S.; Oh, J. M.; *et al*. *Biomaterials* **2004**, *25*(15), 3059–3064, with permission from Elsevier.

and has great potential as a prodrug or as a cosmetic or dermatological ingredient. However, it is very unstable in the presence of UV–vis irradiation and oxygen. In order to measure the enhancement in stability due to LDH interaction, IAA, IAA-LDH, and IAA-ZBS were dispersed in water and their concentrations were monitored for 10 days. As shown in Figure 6(a), over 10 days, the active concentration of the free IAA molecules decreased gradually to 40% of the initial concentration. However, IAA molecules stabilized with either LDH or ZBS retained most of their active moieties over the same time period. It was notable that, in this chapter, molecular orientation and stabilization could be determined by the type of lattice (Figure 6B (a) and (b)). Structural differences in the interlayer orientation result from the different charge densities of the ZBS and ZnAl-LDH ($5.8e^{-}/100\ Å^2$ and $5.0e^{-}/100\ Å^2$ for ZBS and LDH, respectively).[63] Consequently, ZBS can contain more IAA molecules per unit charge than LDH, resulting in a more compact molecular packing with a smaller tilting angle.

Infrared spectroscopy revealed that the IAA molecules are more tightly bound to a ZBS layer than to an LDH. For quantitative analysis, infrared spectra for IAA itself, Na^{+}-IAA salt, IAA-LDH, and IAA-ZBS were obtained, and the stretching modes of the IAA carboxylates were investigated. It was shown that the wave number difference between two stretching modes of carboxylate, $\Delta\nu_{as\text{-}s} = \nu_{as}(COO^{-}) - \nu_{s}(COO^{-})$, became larger when it was coordinated to a metal.[64–66] As described by

Yang *et al.*, the Δν value for Na^+-IAA, IAA-LDH, and IAA-ZBS were determined to be 161, 162, and 179 cm^{-1}, respectively. IAA-ZBS has a greater Δν value than Na^+-IAA, which is good evidence for coordination between COO^- of the IAA molecules and the exposed Zn^{2+} ions of the host ZBS.[63] In contrast, the Δν values for Na^+-IAA and IAA-LDH were almost the same, showing that electrostatic interactions occurred between IAA and the LDH lattice.

4.432.4. Controlled Release of Intercalated Biomolecules

As demonstrated in the above sections, intercalation into LDHs is a powerful method to stabilize biomolecules or biofunctional molecules. In addition, the intercalated molecules can be released intentionally, and their release properties can be controlled by various factors: particle size and charge density of layers, chemical interactions between host layer and guest molecules, pH and electrolyte conditions of release media, etc.

As LDHs can accommodate biomolecules via anion exchange reactions, the intercalated molecules can be reversibly released by an ion-exchange pathway. We have investigated the influence of anionic concentrations on the rate of release. For effective concentration monitoring, we intercalated the fluorescent molecule 5′-fluorescein-isothiocyanate (FITC) into MgAl-LDHs. FITC-LDH, thus obtained, was added to solutions with various concentrations of NaCl (1, 1×10^{-1}, 1×10^{-2}, 1×100^{-3}, 1×10^{-4}, 1×10^{-5}, and 1×10^{-6} M). After incubation at 37 °C for 8 h, the supernatant was collected and subjected to fluorophotometry for concentration check. The amount of released FITC as a function of NaCl concentration is displayed in Figure 7. As the concentration of NaCl solution increased, the amount of FITC released also increased significantly. Considering that the concentration-axis is displayed on a logarithm scale, the amount of released FITC increases

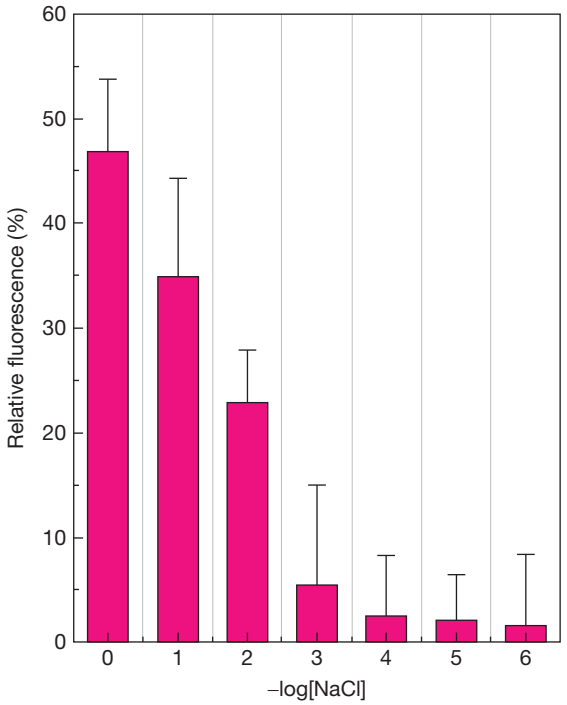

Figure 7 Histogram for the amount of disintercalated FITC at various NaCl concentrations. A fixed amount of FITC-LDH was added to 1, 1×10^{-1}, 1×10^{-2}, 1×10^{-3}, 1×10^{-4}, 1×10^{-5}, and 1×10^{-6} M NaCl solutions and incubated at 37 °C for 8 h.

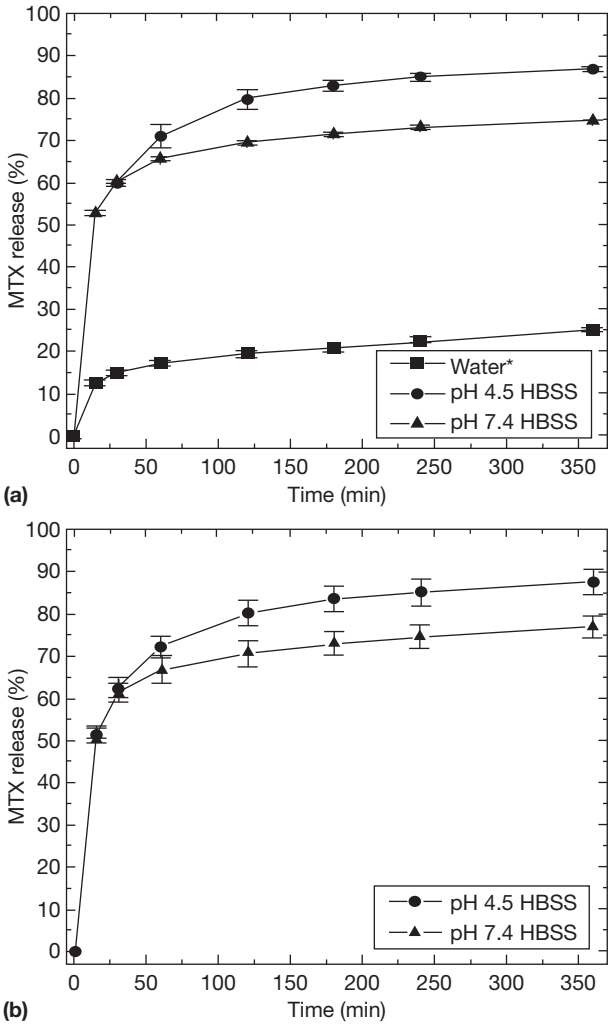

Figure 8 (a) Release profile of MTX from MTX-LDH in deionized water (rectangle) and in Hank's balanced salt solution (HBSS) (circles and triangles). (b) Release profile under the same conditions in the presence of protease. Reproduced from Kim, J. Y.; Choi, S. J.; Oh, J. M.; Park, T.; Choy, J. H. *J. Nanosci. Nanotech.* **2007**, *7*(11), 3700–3705, with permission from ASP.

exponentially with increasing NaCl concentration, before reaching a plateau. It is noteworthy that 23–35% of intercalated molecules can be released within 8 h at Cl^- concentrations of 1×10^{-2} or 1×10^{-3}M, which is similar to the electrolyte concentration in body fluids.

As biosystems have various subcellular organs with a variety of pH and enzymes, it is important for drug delivery studies to evaluate the dependence of release patterns of intercalates on pH and enzyme conditions. We prepared hybrid nanomaterials in which anticancer MTX drugs were intercalated into MgAl-LDH and examined the release patterns of MTX under a variety of conditions.[67] Figure 8 illustrates the release profile of MTX from MTX-LDH intercalates in a simulated body fluid, Hank's balanced salt solution (HBSS). In order to mimic endosomal and lysosomal conditions, the pH of the release media was adjusted to 7.4 (endosome) and 4.5 (lysosome), and the experiments were carried out with and without a lysosomal enzyme, protease. All the release patterns showed two distinct steps, an initial burst followed by a sustained release. This kind of two-step release is characteristic of a diffusion-controlled release process. Gu *et al.*[68] have also investigated this two-step release with low molecular weight heparin (LMWH) intercalated to LDHs. The cumulative release amount at 6 h was determined to be 75 and 90% for pH = 7.4 and 4.5, showing facilitated release in acidic media. The MgAl-LDH lattice is slightly soluble in acidic conditions, and this partial dissolution of LDH is thought to accelerate the release rate. It is interesting to note that the release patterns were not influenced by the presence of a protease (Figure 8(b)). This result indicates that the release of intercalated drug molecules is mainly dependent on ion exchange and the pH-dependent solubility of LDHs.

Several biomolecules such as VC and VE have been intercalated into LDHs for cosmetic applications. As cosmetics are applied on the skin, it should be investigated if the release pattern of intercalated vitamins can be controlled by atmospheric conditions like CO_2 concentration rather than body fluid conditions. We examined the release kinetics of VC-LDH and VE-LDH in a CO_2 saturated aqueous and a 50% ethanol solution, respectively.[42] As VC is spontaneously oxidized, we had to calibrate the release profile to account for the decomposition of released VC. The solid line in the inset of Figure 9 shows that the content of free VC in aqueous solution decreases exponentially, and the original release profile of VC-LDH before calibration (dotted line in the inset of Figure 9) showed a decrease after 8 h.

While biomolecule-LDH intercalates in simulated body fluid solution showed a rapid release profile during the early stages, vitamin release was observed to be relatively sustained under these conditions (Figure 9). The Henry's constant k_H of CO_2 is 29.41 l atm mol^{-1} ($\approx H_2CO_3$ concentration of 3.4×10^{-2} mol l^{-1}), and the pK_{a1} and pK_{a2} of carbonic acid are 2.5×10^{-4} and 5.6×10^{-11}, respectively. From these values, the saturated HCO_3^- and CO_3^{2-} concentrations were calculated to be lower than 10^{-5} mol l^{-1}, which is much lower than the electrolyte concentration in simulated body fluid solutions. Although the release rates were slow, both VC-LDH and VE-LDH showed an L-type release pattern that is typically observed in diffusion-controlled ion-exchange reactions. It is notable that the intercalated vitamins can be liberated in a controlled manner even in ambient conditions.

The release patterns of intercalated molecules can be controlled by the charge density of LDH layers. For the VA-LDH intercalates, three different LDHs with various M^{2+}/M^{3+} ratios were prepared.[61] The equivalent volume per unit charge ($Å^3/e^-$) of the three LDHs, Zn_2Al-, Zn_3Al-, and Zn_4Al-LDHs were determined to be 248.85, 338.31, and 418.01 $Å^3/e^-$, respectively. The release pattern of VA molecules from each of these intercalates was evaluated in a 0.9% NaCl solution, the simplest simulation of body fluid. Similar to the release patterns of other biomolecules in body fluid solutions, these profiles showed two steps, an initial burst followed by sustained release (Figure 10). It was also clearly demonstrated that VA release was fastest in the LDH with the highest layer charge, Zn_2Al-LDH, and the rate was slower in the LDHs with a lower layer charge, Zn_3Al-LDH and Zn_4Al-LDH. These results can be explained by the affinity of LDH host lattices to electrolytes in the release media; the highly positive LDH layer of Zn_2Al-LDH could accelerate anion exchange reactions with Cl^-, resulting in fast VA release.

Structure and interlayer interactions are also important factors in controlling release. In the previous section, we noted that IAA molecules, intercalated into LDH and ZBS, showed different interlayer conformations and interactions with the host lattice. As a result, it would be expected that the release profiles of IAA-LDH and IAA-ZBS would also be different. Yang *et al.* investigated the release profile of IAA from both intercalates in a 0.08% (w/w) NaCl solution. As shown in Figure 11, the release profile consists of two steps: a rapid release of IAA in the early stage, followed by slow disintercalation. In the first step, till 0.25 h, the fraction of the released IAA molecules was determined to be ~14% and ~45% for IAA-ZBS and IAA-LDH, respectively. It is notable

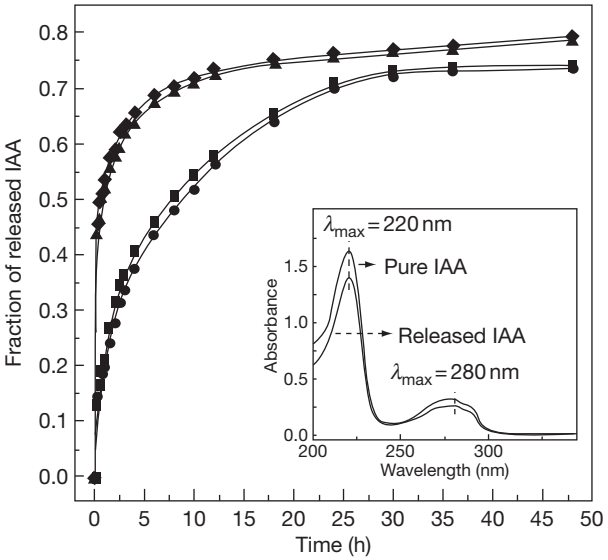

Figure 11 Time-controlled release profiles of IAA from IAA-ZBS prepared by ion exchange (squares), IAA-ZBS by coprecipitation (circles), IAA-LDH by ion exchange (triangles), and IAA-LDH by coprecipitation (diamonds). The inset represents the UV–vis spectra of pure IAA and the guest IAA released from IAA-ZBS or IAA-LDH. Reproduced from Yang, J. H.; Han, Y. S.; Park, M.; Park, T.; Hwang, S. J.; Choy, J. H. *Chem. Mater.* **2007**, *19*(10), 2679–2685, with permission from ACS.

that more than half of the intercalated IAA molecules were released from the LDH lattice within 1 h, while the IAA-ZBS preserves half of the intercalated molecules for longer than 7 h. Such a difference in release pattern originates from the differences in the chemical bonds between IAA and the layers. The strong coordinative interaction between the Zn^{2+} ions and the carboxyl groups of IAA contribute to the slower release rate in the ZBS intercalates. Thus the ZBS-type metal hydroxide can be developed as a powerful mode of sustained release for molecules like IAA.

4.432.5. Enhanced Cellular Uptake

As discussed above, intercalated molecules have good stability in LDHs, and their release can be controlled by the properties of the LDHs and the release conditions. In addition to safe protection and controlled release of biomolecules, developing a biomolecule delivery system also requires targeted delivery with enhanced cellular permeability.

We have investigated the enhanced cellular uptake of FITC intercalated into MgAl-LDHs. In order to evaluate concentration dependent cellular uptake, various concentrations of FITC-LDH (0, 5, 10, 20, 30, and 40 μM) were added to fibroblast NIH3T3 (8×10^4) cell culture lines and incubated for 2 h. Also, 10 μM of FITC-LDH was added to another cell culture line and incubated for 1, 2, 4, 6, and 8 h to study time-dependent cellular uptake.[13]

As shown in Figure 12(a), cellular uptake becomes increasingly more significant with increase in concentration and time. This implies that the FITC-LDH intercalates can effectively enter cells in both time- and dose-dependent manners. Further evidence of cellular uptake of the FITC-LDH hybrid was obtained from laser scanning confocal microscopy. NIH3T3 cell culture lines were treated with 1 μM of FITC-LDH or 5 μM of FITC alone, followed by incubation for 1, 4, and 8 h. Figure 12(b) shows that FITC-LDH is detected in cells within 1 h of incubation, and the fluorescence intensity increased continuously up to 8 h. In contrast, the cells treated with 5 μM FITC alone remained dark regardless of the incubation time. It can therefore be concluded that LDH plays an important role in mediating the cellular uptake of intercalated biomolecules. It is interesting to note that the punctuated fluorophores are distributed primarily around the cellular periphery during the early stages, suggesting the possibility of cellular uptake of LDHs through endocytosis.

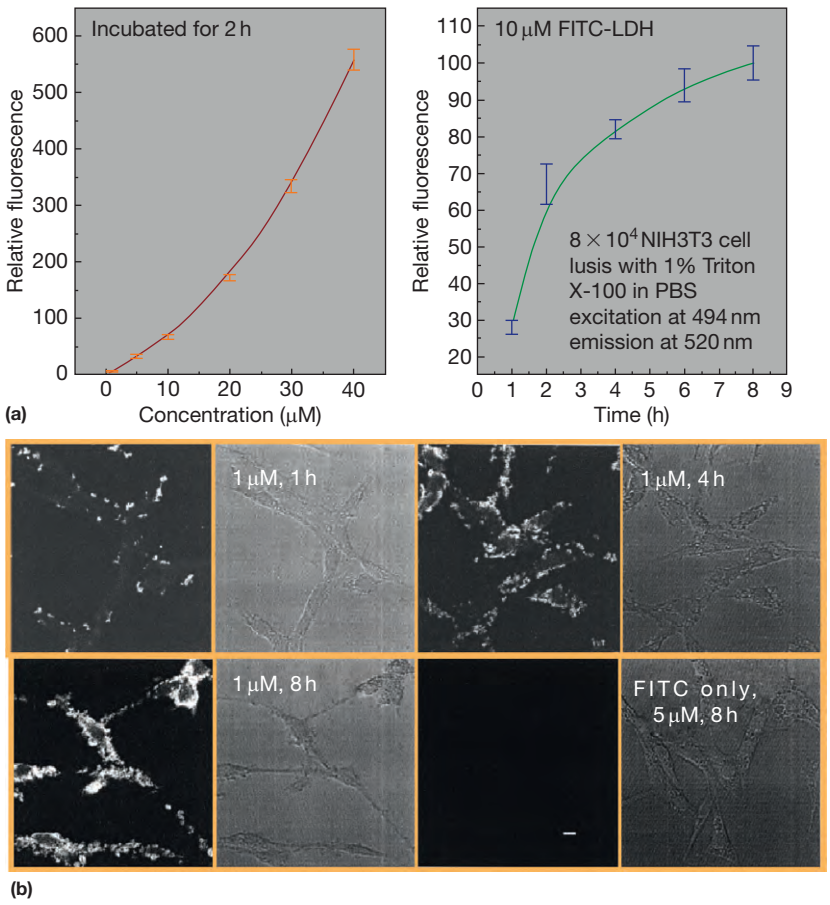

Figure 12 (a) Cellular-uptake kinetic profile of FITC-LDH into cells at various concentrations (left) and different incubation times (right). (b) Laser confocal fluorescence microscopy of the fluorophore in NIH3T3 cells. 6×10^4 cells per well were incubated with 1 μM FITC-LDH for 1, 4, and 8 h. The last fluorescence microphotograph was obtained with 5 μM FITC only. The bar is 10 μm. Reproduced from Choy, J. H.; Kwak, S. Y.; Jeong, Y. J.; Park, J. S. *Angew. Chem. Int. Ed.* **2000**, *39*(22), 4042–4045, with permission from Wiley.

In subsequent research, the cellular uptake mechanism of LDH was clarified.[35] As demonstrated above, the biomolecule-LDH intercalates possibly entered the cells through endocytosis; and there are several reports that describe cellular uptake pathways of inorganic nanoparticles as being mediated by endocytosis. Depending on the type of vesicle involved and its related proteins, endocytosis is divided into four subgroups: clathrin-mediated endocytosis, caveolae-mediated endocytosis, macropinocytosis, and phagocytosis.[69] In clathrin- or caveolae-mediated endocytosis, the most well known of all the processes, small vesicles (~100 and ~50 nm, respectively) develop at the plasma membrane which engulf foreign substances. On the other hand, macropinocytosis and phagocytosis typically show large pocket-shaped vesicles (0.5–5 μm in diameter) which are used to swallow the extracellular fluid or to devour microorganisms. Considering the size of the punctuations in **Figure 12(b)**, the endocytosis process involved in LDH uptake would either be clathrin- or caveolae-mediated. As shown in **Figure 13**, LDHs are likely to be internalized into cells via clathrin-mediated endocytosis. Two typical endocytic proteins, clathrin and caveolin-1, were stained with the red fluorophore Texas Red in human osteosarcoma MNNG/HOS cell culture lines and visualized by immunofluorescence and confocal microscopy. The nuclei were stained with blue DAPI dye. **Figure 13(a)** shows both clathrin (red fluorescence, TR) and LDH (green fluorescence, FITC) to be well colocalized, whereas no red fluorescent caveolin-1 staining was observed. The confocal microscope images also revealed that FITC-LDHs are highly colocalized with clathrin. These data show that LDHs efficiently enter cells through clathrin-mediated endocytosis.

It is well known that foreign substances internalized into cells by clathrin-mediated endocytosis are sequentially transported to early endosomes (EE), late endosomes (LE), and lysosomes. Endocytic compartments such as LEs and lysosomes are acidic with a pH ~4.5 and have abundant electrolytes. As the release of biomolecules intercalated into LDHs is facilitated by both electrolyte concentration and acidic pH, internalized drug-LDHs are likely to release their drug moiety in the LEs or lysosomes.

4.432.6. Conclusion and Perspectives

Hitherto, we have briefly reviewed the stabilization and controlled release of biomolecules after their intercalation into

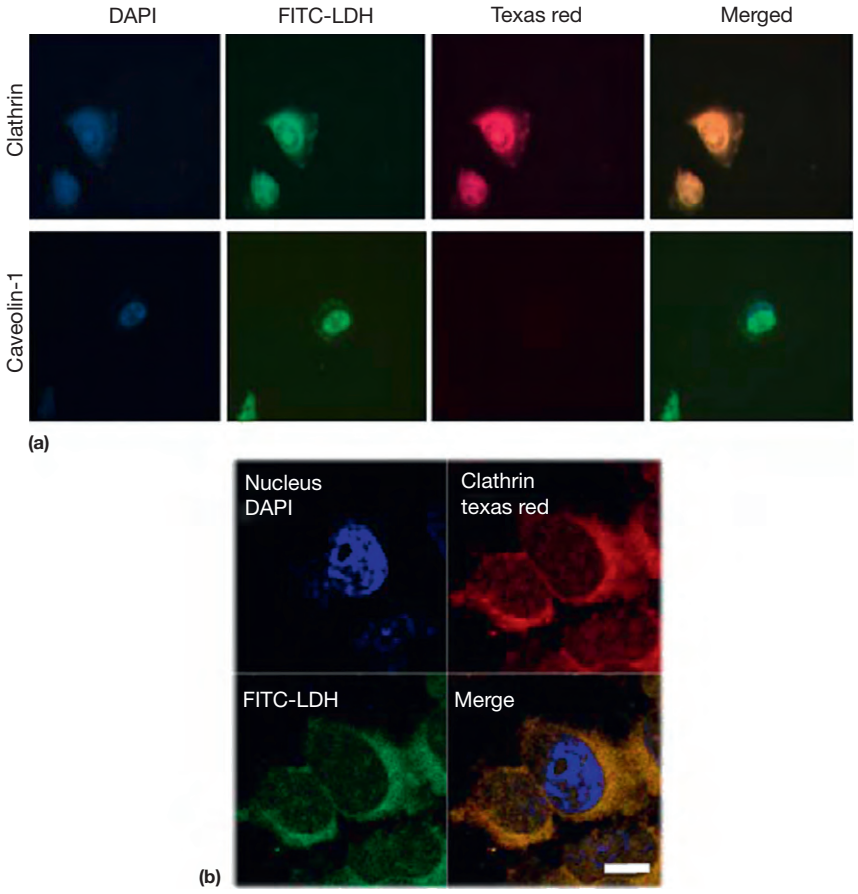

Figure 13 (a) Immunofluorescence microscope images showing the colocalization of clathrin and LDH in MNNG/HOS cells. (b) Confocal microscopy: colocalization of FITC-LDH and clathrin in MNNG/HOS cells. Cells were incubated with FITC-LDH for 2 h, treated with clathrin antibodies, and stained by TR and DAPI. Scale bar represents 10 μm. Copyright ACS, Reproduced from Oh, J. M.; Choi, S. J.; Kim, S. T.; Choy, J. H. *Bioconjug. Chem.* **2006**, *17*(6), 1411–1417, with permission from ACS.

LDHs, discussed the enhanced cellular uptake of LDHs, and described the intracellular release of biofunctionalized molecules as the end point of a drug delivery system. Intercalating unstable biomolecules into LDHs enhanced their physical, chemical, and biological stability. The stabilized biomolecules can be disintercalated intentionally, and the release pattern is mainly mediated by a diffusion-controlled ion-exchange process. The rate of release and the amount released could be controlled by the properties of the carrier LDH, such as charge density, host–guest interaction, and release media conditions such as electrolyte concentration, pH, CO_2 solubility, etc. Furthermore, the LDH intercalates showed enhanced cellular uptake through clathrin-mediated endocytosis. Finally, the molecules were released in lysosomal conditions of low pH and abundant electrolytes. Therefore, it can be concluded that three definite properties of biomolecules intercalated into LDHs (stabiliztion, controlled release and enhanced cellular uptake) would be favorable for the development of a cellular drug delivery system. Further intense studies to control the release rate of LDHs will be required to allow extensive applications in bio-related fields.

4.433.1. Introduction

Porous solids are of an economic importance as they are related to industrial applications typically in catalysis, separation or fine chemistry. It concerns mostly the crystalline (inorganic) silica-based zeolites and organic activated carbons. Recently, within the last two decades, hybrid inorganic–organic porous solids, denoted MOFs (metal–organic frameworks) or PCPs (porous coordination polymers) have emerged.[1–4] These are built up from the association of an inorganic part, either metal clusters, chains, layers or 3D networks, and various types of organic linkers possessing complexing groups, typically carboxylates. The linkage between the inorganic subunit, comprised of almost all elements from the periodic table including alkaline earths (Ca, Mg), transition metals (Fe, Zn), or lanthanides (Gd, ...), is typically made of strong ionocovalent or dative bonds (Figure 1). This leads to the formation of hybrid porous frameworks. The key advantage of MOFs in comparison to their purely inorganic (zeolites, mesoporous silica) or organic (carbons) counterparts, concerns the huge number of available linkers leading to thousands of possible structures including aliphatics or aromatics organic spacers, associated with one or several complexing functions chosen among carboxylates, phosphonates, sulfonates, imidazolates, amines, pyridyls, ... or a combination of them. As a result, a huge number of MOFs with various pore sizes, typically within the 3–60 Å range, shapes (tunnels, cages, ...) and organic functionalities (polar, apolar) have been reported. Their synthesis is achieved under hydro or solvothermal conditions and pores are filled with solvent molecules or residual molecules of linker that are usually removed by solvent exchange followed by a heating and/or vacuum treatment. Finally, the resulting porous MOFs are light materials with density, typically between 0.2 and 1.5 $g\,cm^{-3}$, large pore volume (up to $3\,cm^3\,g^{-1}$) and high specific surface areas, up to $5000\,m^2\,g^{-1}$.

Most topical MOFs are those built up from metal clusters such as dimers, trimers, tetramers, or hexamers of metal polyhedra. For instance, the copper trimesate denoted HKUST-1 (dimers),[5] the iron or chromium trimesate MIL-100 (trimers),[6] the zinc terephthalate MOF-5 (tetramers)[2] and the zirconium

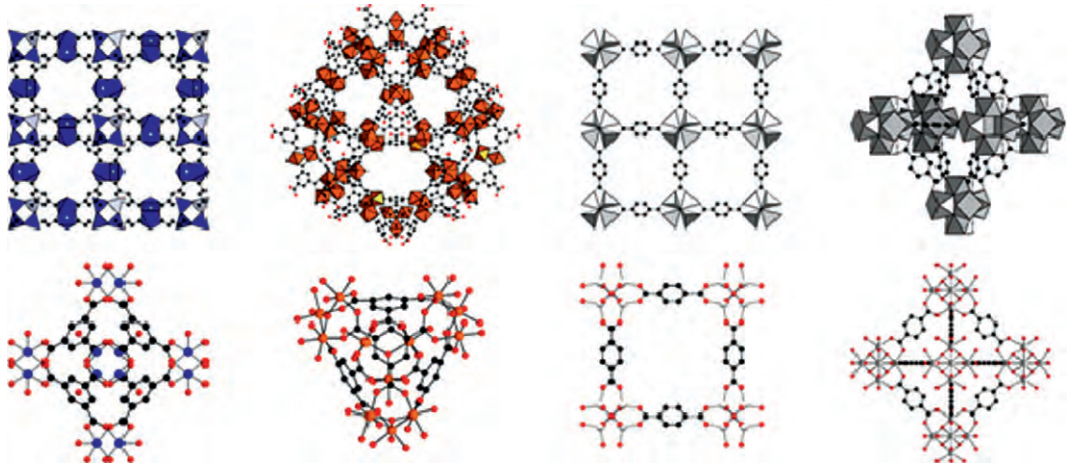

Figure 1 Top view of the structures of a few topical metal–organic frameworks. Bottom view of the corresponding hybrid building units. Copper, iron, zinc, and zirconium are in blue, orange, gray, and gray, respectively while oxygen and carbon atoms are in red and black, respectively.

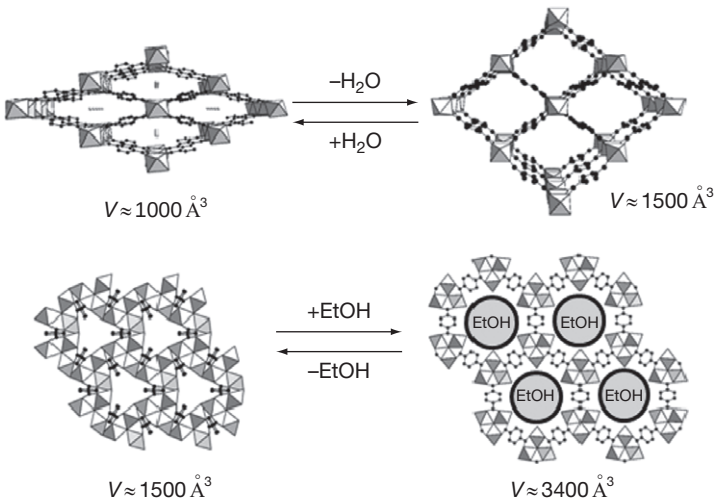

Figure 2 The breathing behavior of the iron terephthalates MIL-53 (top) and MIL-88B (bottom). Metal octahedra and carbon atoms are in white and gray, respectively.

terephthalate UiO-66 (hexamers),[7] result in all cases in large pore sizes (6–29 Å) and Brunauer–Emmett–Teller (BET) surface areas between 1200 and 3800 $m^2 g^{-1}$, respectively (Figure 2).[8,9]

Another interesting aspect of MOFs is the possibility of keeping the same structure type while increasing the size of the organic spacer thus enlarging the pore size.[5,10] For a given structure, pores can also be functionalized through grafting of a functional group either by substituting a proton of the linker by a functional group (apolar, polar, basic, acidic, ...) or through postsynthetic modification whilst keeping the same structure type, in order to tune its properties.[11]

MOFs possess usually a rigid framework like traditional porous solids but some of them swell or breathe in the presence of change in pressure, temperature, or during the adsorption of a gas or a solvent.[4d,12] Most topical examples are the metal terephthalates denoted MIL-53 (Al, Cr, Fe...),[13] or MIL-88 (Fe, Cr) (Figure 2),[10b,14] which exhibit a reversible and selective breathing amplitude between the solvated forms and the dried ones from 40 to 230% (in cell volume).

Such large and selective variations in volume might lead in a near future to new applications in terms of adsorption, storage and facile delivery of gases or biological molecules.[15,16]

Finally, it is interesting to point out that the stability of MOFs is on the whole lower than that of the pure inorganic (zeolites) or organic (carbons) porous solids. The thermal stability of MOFs is usually comprised between 150 and 400 °C under air while most MOFs degrade upon a long time exposure to water which restrict their domains of applications, even if a recent study has shown that some of them exhibit a reasonable hydrothermal stability.[17]

4.433.2. Adsorption and Delivery of Therapeutic Molecules

Controlled delivery systems present many advantages in comparison with conventional drug administration, which often involve toxicity issues and low efficiency values due to lack of

tissue/cell selectivity. Moreover, the discovery of macromolecules arising from biotechnologies (peptides, proteins, nucleic acids, etc.) makes necessary the development of new carriers for their use since they are either unstable in biological media with poor intracellular diffusion or poorly soluble. Thus, many drug candidates fail to reach clinical applications because of short blood half lives and inability to bypass natural barriers. Despite the increasing success of drug delivery systems (abraxane, doxil, ambisome, ...), there are still a large number of drug molecules of high therapeutic interest not with no adequate controlled release system. Consequently, the development of new carrier systems is needed to ensure the right drug plasmatic levels in the active sites, increasing the efficiency, decreasing the toxicity as well as increasing their half life, by protecting sometimes the drug from rapid metabolization.[18] Liposomes and polymeric nanodevices are actually the most common carriers for the controlled release of drugs.[19,20] An inorganic alternative based on amorphous porous silica solids[21–25] led, more recently, to a new approach based on ordered porous solids such as ordered mesoporous silicas[26–29] or zeolites.[30–33] However, both organic or inorganic routes can suffer from important drawbacks such as either a low drug loading and/or a rapid delivery,[34,35] as well as sometimes toxicity restrictions.[36–38]

Recently, a hybrid alternative was proposed using porous MOFs,[39] which combine a highly regular porosity with a crystalline hybrid inorganic–organic framework easily tunable. Some of these solids exhibit many interesting features suitable for their successful use as drug carriers: (1) low toxicity of numerous available porous MOFs structures, built up from low toxic metals (Fe, Ca, Mg, ...) and ligands (carboxylic or phosphonic acids); (2) biodegradability, tunable according with composition and structure; (3) a hydrophilic–hydrophobic internal microenvironment adapted to a large variety of active molecules; (4) drug encapsulation and delivery easily modulated by a controlled diffusion, through the control of the porous structure (interconnectivity, pore size, flexibility) and by an optimization of the host–guest interactions (functionalization of the organic linker).

4.433.2.1. Model Drugs

Our group has initiated recently the use of porous MOFs as new drug carriers,[39] starting from a model system with (1) ibuprofen (2-(4-(2-methylpropyl)phenyl)propanoic acid), an antiinflammatory and analgesic model drug, bearing a simple chemical structure with a carboxylic group, involved in 80% of the active drug molecules; and (2) two rigid mesoporous chromium carboxylates, MIL-100 (Cr) and MIL-101 (Cr) (MIL for Material of Institut Lavoisier). These Cr compounds were selected, despite the well-known toxicity of chromium, due to their excellent thermal and water stability allowing a better structural control of the drug insertion and release, MIL-101 (Cr)[40] and MIL-100 (Cr)[41] are indeed based on octahedral oxo-centered chromium trimers coordinated by benzene di or tricarboxylate linkers, respectively, resulting in giant hybrid structures with a cubic zeotype architecture delimiting two types of spherical cages (25 and 29 Å in MIL-100; 29 and 34 Å in MIL-101 (Cr)) accessible through microporous pentagonal or hexagonal windows.

In both cases, that is, MIL-100 and MIL-101, Ibuprofen was adsorbed by simple impregnation, suspending the previously dehydrated powder MOFs into a concentrated hexane drug solution. MIL-101 (Cr) showed an unprecedented amount of adsorbed drug, up to 1.4 g of Ibuprofen per gram of dehydrated MOF, which represents for each 'small' cage hosts ~56 Ibuprofen molecules and for the 'large' cage ~92 molecules. This exceptionally high loading capacity can be considered as a major result since one would require only very small amounts of transporter material even for a high dosage. Despite its important pore volume, MIL-100 (Cr) retains only 0.35 g of drug per gram of dried solid whatever the different parameters studied. This is due to the selective adsorption of the drug in the larger cages only considering the small free aperture of the accessible pentagonal windows of the smaller cages (0.5 nm), which are very close to the one of Ibuprofen (1.0×0.5 nm).

The integrity of the Cr-MOFs after the drug adsorption was checked by X-ray powder diffraction, N_2 adsorption performed at 77 K after the incorporation indicates almost no residual porosity, in agreement with the presence of large amounts of Ibuprofen located inside the cages. Monte Carlo computing simulation of Babarao *et al.*[42] have further confirmed the extraordinary drug loading capacity of MIL-101 (Cr).

Concerning the nature of the drug-guest interactions, it is interesting to note that the Ibuprofen molecules as shown by ^{1}H solid state nuclear magnetic resonance (NMR), are partially deprotonated, and it is likely that some of these molecules might be coordinated to the Lewis acid metal sites of the MOF through its carboxylate group. Dynamic fault tree (DFT) calculations have estimated the corresponding heat of adsorption being of $-73.17\,\mathrm{kJ\,mol^{-1}}$ (estimated by DFT calculations).[42] Thus, considering the number of metallic centers per unit formula (two Lewis acid sites per trimer), one can estimate that ~40% of the drug is coordinated to the Lewis acid metal sites. The remaining Ibuprofen moieties are probably interacting either with the framework through π–π interactions between the aromatic rings of Ibuprofen or simply interacting at the centre of the pores with other drug molecules.

Likewise, all adsorbed Ibuprofen can be delivered under simulated physiological conditions (simulated body fluid (SBF) at 37 °C under continuous stirring to avoid external diffusion processes) after 3 or 6 days, from the compacted Ibuprofen-containing MIL-100 (Cr) and MIL-101 (Cr) solids, respectively.[39] If one looks deeply into the Ibuprofen release profiles, three different stages can be distinguished according to the drug location/interaction in the cages: (1) Ibuprofen not in direct contact with the pore walls and thus quickly delivered in the first hours through a diffusion process; (2) a slower release of the Ibuprofen fraction located close to the pore wall into the larger cages; (3) and finally, with the slowest rate, the drug fraction in direct contact with the smaller cage walls. Therefore, the last two stages would be governed by a combination of diffusion and interactions phenomena. Thus, the slower release in MIL-101 (6 days) compared with MIL-100 (3 days), could be due to: (1) the higher proportion of aromatic rings (Ar/Cr = 1.0 [MIL-101]; Ar/Cr = 0.66 [MIL-100]) and (2) the larger proportion of accessible Lewis acid sites in MIL-101 since both small and large cages are available against the large cages only for MIL-100.

Table 1 Pore characteristics and encapsulation/release results of Ibuprofen of various porous solids

	Pore diameter (Å)	*Pore volume ($cm^3\,g^{-1}$)*	*S_{BET} ($m^2\,g^{-1}$)*	*Ibuprofen loading (g ibu/g dehyd. solid)*	*Time release (days)*
MIL-101 (Cr)	29–34	1.9–2.3	3500–4500	1.38	6
MIL-100 (Cr)	25–29	1.2	2200	0.35	3
MIL-100 (Fe)	25–29	1.1	1900	0.35	3
MIL-53 (Cr)	8.5	0.5	1400	0.22	21
MIL-53 (Fe)	8.5	0.5[a]	–	0.21	21
Faujasite	11.2	0.3	650	0.16	7
MCM-41	36	1.0	1150	0.34	2
MCM-41_NH_2	28	0.4	780	0.22	5

The release was achieved in PBS at 37 °C.

[a]MIL-53 (Fe), while nonporous in its dehydrated form, possesses in its open form, that is, in the presence of gases, vapours, or liquids, an equivalent pore volume of ~0.5 g cm^{-3}.

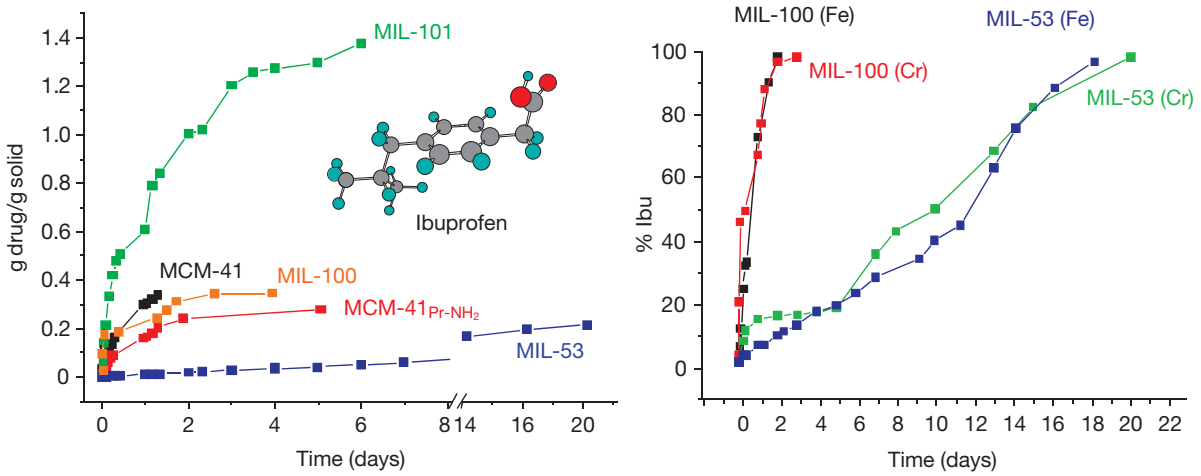

Figure 3 Left: delivery profiles of Ibuprofen from several porous carriers (PBS, 37 °C); right: delivery profiles from the flexible MIL-53 (Cr) and MIL-53 (Fe) solids compared to the one of MIL-100 (Fe) and MIL-101 (Cr).

From these results, the proof of principle of the use of MOFs for controlled drug encapsulation and release has been successfully evidenced, but what about their performances in comparison to other porous materials? MOFs offer higher drug loadings (up to 1.4 g g^{-1}) and longer delivery times (6 days) than other inorganic porous solids, such as the ordered mesoporous silica MCM-41 (pore diameter of 36 Å),[43] which releases its cargo (0.34 g g^{-1}) within 2 days (Table 1, Figure 3).

Furthermore, several nontoxic iron analogues MOFs are now available,[6,44] (rat oral dose: DL_{50}(Fe) = 30 g kg^{-1},[45] DL_{50}(trimesic acid) = 8.4 g kg^{-1},[46] DL_{50}(terephthalic acid) = 5 g kg^{-1}[47]) and have shown similar loadings and delivery rates as the toxic-chromium MOFs. This indicates that changing the nature of the metal does not drastically modify the release properties. Finally, one can establish that a new route in the drug delivery field has been initiated.

4.433.2.2. The Role of Flexibility

As afore-mentioned, some MOFs possess a flexible framework,[48] leading to a modulation of their pore size. This reversible 'breathing' effect induces a variation in cell volume from 40 to 235%, depending on the structure, the metal, and the organic spacer.[49,50] For instance, the microporous metal carboxylate MIL-53 (Cr, Fe) solids, exhibit a highly flexible framework built up from chains of corner-sharing metal(III) octahedra and terephthalate anions delimiting a one-dimensional pore channel system (ϕ~8 Å). These solids possess a different pore opening according to the size of the molecule located within of the cages, as evidenced by the reversible contraction/opening of the pores along *b* axis. This is in agreement with the breathing of the MIL-53 solids in the presence of gases,[51,52] liquids,[53] or vapors.[54] Our aim was thus to determine the effect of the breathing on the drug encapsulation and delivery properties.

Once more, Ibuprofen was chosen as model drug and both chromium- and iron-based MIL-53 were selected as flexible porous hybrid solids. Please note that in the presence of gas or vapors, the Cr and Fe compounds exhibit a different breathing behavior. The dried Cr solid denoted MIL-53 (Cr) ht (high temperature) has a fully open structure,[49,55] while the iron analogue has a closed structure.[44] However, upon adsorption of Ibuprofen by impregnation in the liquid phase, the Cr or Fe Ibuprofen-containing-MIL-53 solids exhibit a very close drug loading (20 wt%). In addition, the pore opening of the Ibuprofen loaded form is similar for both solids and can be considered as being intermediate between the one of the closed and opened forms of MIL-53 (Figure 4). The Ibuprofen-MIL-53 (Fe) X-ray powder pattern was indexed in a monoclinic

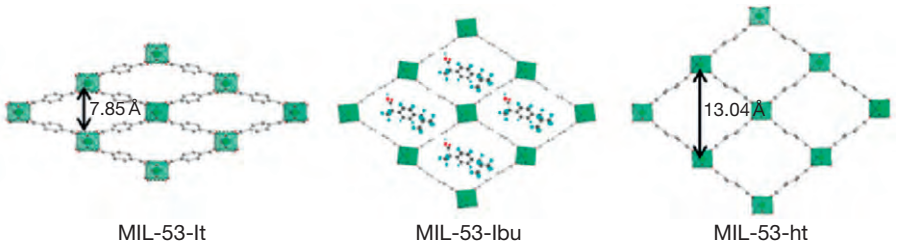

Figure 4 Comparison of the different pore opening of the MIL-53: left: water, center: Ibuprofen, right: open form. Metal octahedra, oxygen and carbon atoms are in green, red, and black, respectively.

cell (space group C2/c).[56] These results did not only show that the flexible MIL-53 solids are breathing while hosting drugs, but also indicate that one can follow the drug insertion by X-ray diffraction powder diffraction (XRPD) characterization.

The behavior of the MIL-53 flexible solids as drug carriers is also very different from those observed previously with the rigid large pores MIL-100 and MIL-101 materials. First, the time required for reaching the maximum loading of Ibuprofen is equal to 3 days for MIL-53 against 1 day for both MIL-100 and MIL-101. This is probably due to the smaller pore size ($\phi \sim 8$ Å) and the presence of a one-dimensional porosity, which leads to a slower diffusion rate of the drug into the channels of MIL-53. It is possible also that MIL-53 exhibit a stronger relative affinity for the solvent used through the impregnation process (hexane). Second, the amount of Ibuprofen adsorbed in the MIL-53 solids is much lower compared with the mesoporous solids, that is, only 20 wt%, which is in agreement with the smaller pore volume of MIL-53. Please note also that the drug content does not depend here on the nature of the metal.

Concerning the drug delivery profile, performed using the same conditions as the one described above, a very slow and progressive release of Ibuprofen from MIL-53 Cr or Fe up to 3 weeks was achieved with an unexpected zero-order kinetics, thus fully predictable and independent from the drug concentration within the solid. In order to gain understanding, one has to consider three different aspects: nature of host–guest interaction, flexibility and diffusion. First, a slow delivery rate is easily explained by the presence of strong interactions between the drug and the hybrid network. This is consistent with solid state NMR results that show a stronger confinement effect in MIL-53. This results from its smaller pore size and the presence of specific hydrogen bonds between the OH groups of the inorganic subunit and the carboxylic group of Ibuprofen, present in its protonated form contrary to the case of MIL-100 and MIL-101 whereas the molecule was in its anionic form. This was confirmed by infrared spectroscopy while computer modeling has estimated a heat of adsorption of Ibuprofen in MIL-53 by DFT calculation of $\sim -57\,\mathrm{kJ\,mol^{-1}}$. Of course, additional weaker interactions between the aromatic rings of MIL-53 and the organic part of Ibuprofen (phenyl, propyl) are also contributing to the total interaction with the framework.

Second, the zero order kinetics cannot be explained only through the presence of specific interactions but also through the maintenance of constant local environment throughout the whole delivery process. XRPD indeed shows that the structure, and thus the degree of pore opening, before and after drug delivery are very similar. Thus, the breathing phenomenon is an interesting advantage for drug delivery since it allows a better optimization of the interactions between the drug and the framework through the adaptation of the pore size to the one of the molecule of interest.

These exceptional features could be of great importance for drug delivery with a unique administration for very long therapies.

The study of Ibuprofen as a model drug has been done with several other porous carriers, which allows a direct comparison of their drug loading capacity and delivery profiles, with our porous hybrid solids (**Table 1**, **Figure 3**). For instance, microporous zeolites ($\phi \sim 7.4$ Å) possess drug capacities close to the one of MIL-53, but with much faster release rates.[57] Ordered mesoporous silica MCM-41 solids exhibit a drug loading higher than MIL-53, close to MIL-100, but much lower than MIL-101.[38] However, Ibuprofen is released much slower from the hybrid MILs solids (from 3 to 21 days, against 1 day for MCM-41). This is related to an increase in the interaction between the drug and the hybrid framework due to the presence of organic groups within the MOF, and maybe also to the presence of Lewis acid sites. Nevertheless, the presence of aminopropyl groups at the surface of functionalized MCM-41 solids slows down the delivery rate to reach a delivery up to 5 days, but with an unfortunate decrease in the drug capacity.[58] Thus, the combination of a regular porosity and the presence of organic group within the framework allow direct and efficient interactions between the drug and the hybrid skeleton without decreasing the drug loading capacity.

In conclusion, flexible MOFs represent excellent candidates for drug delivery with their easily tunable porosity, which leads to an optimization both of diffusion process and drug–matrix interactions for a controlled-manner drug release.

4.433.2.3. Nanoplatforms

4.433.2.3.1. Synthesis of nanoparticles

Control of particle size is essential for the administration of the drug carrier system by different routes such as intravenous (i.v.), intraperitoneal (i.p.), subcutaneous (s.c.), intranasal (i.n.), intraocular (i.o.), etc., in order to avoid tissular damages caused by embolism.

Intravenous administration of MOFs requires thus the elaboration of highly water stable homogeneous nanoparticles smaller than 200 nm to avoid unwanted phenomena such as aggregation, reactivity or precipitation. Up to now, the synthesis of MOFs has typically been performed using hydro/solvothermal conditions in polar solvents by adjustment of several parameters such as the temperature, pressure, the nature of the solvent, pH, stochiometry, and so on.

For structure determination purpose, the objective was also to produce as large as possible single crystals of a sufficient quality. However, recent studies have shown that synthetic methods such as (1) reverse emulsions[59–61] and (2) microwave assisted hydro/solvothermal routes[62–64] are suitable for the formation of narrow distributed nanoparticles of MOFs (nanoMOFs) (Figure 5).

1. Reverse-phase emulsions consist in performing a microemulsion of the metal source and linker in the presence of the cationic cetyltrimethylammonium bromide (CTAB)/isooctane/1-hexanol/water system. This simple and easily generalized method has been applied to different nonporous MOFs with imaging properties (based on lanthanides and Mn). For instance, nanorods of a gadolinium terephthalate (40×100 nm) or nanoplates of a gadolinium trimellitate (35×100 nm) could be obtained,[56] as well as block-like particles of a gadolium benzene hexacarboxylates ($25 \times 25 \times 100$ nm)[57] and nanorods of manganese trimesate (50×1000 nm) and terephthalate (50×750 nm).[58] Interestingly, the morphology of the manganese trimesate ($Mn_3(BTC)_2(H_2O)_6$) can be tuned by modifying some synthesis parameters, that is, from spiral nanorods of 50×1000 nm using a conventional microemulsion method to block-like nanoparticles of 50–300 nm range by combining reverse-phase microemulsion and microwave synthesis.[58] The main drawback of such inverse emulsion method is its low yield since very important volumes of emulsion are needed to obtain low amounts of nanoparticles. In addition, the toxicity of the components used to produce the emulsion is of concern for a practical *in vivo* use (CTAB LD_{50} (intravenous (i.v.) rats) = 44 mg kg^{-1},[65,66] isooctane LD_{50} (oral rats) = 3310 mg kg^{-1},[67] LD_{50} (oral rats) = 720 mg kg^{-1}).[68]
2. Microwave assisted hydro/solvothermal synthesis is a faster method which leads to high yields of nanoMOFs with a good control of the particle size and a narrow size distribution. Several examples have been recently reported, such as the mesoporous chromium terephthalate MIL-101 (22 nm, but highly toxic),[60] the microporous zinc imidazolate ZIF-8 (40 nm),[69] the flexible microporous iron terephthalate MIL-53 (350×1000 nm) and the mesoporous iron trimesate MIL-100 (200 nm) or the iron aminoterephthalate MIL-101_NH_2 (120 nm).[61]

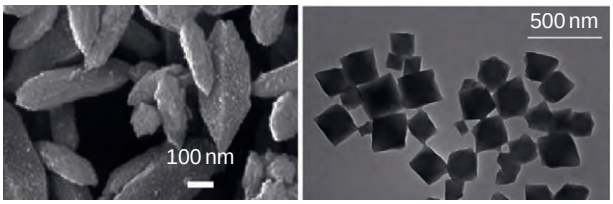

Figure 5 Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) images of nanoparticles of MIL-88A (on the left) and MIL-101_NH_2 (on the right) made from solvothermal and microwave synthesis, respectively.

Additionally, it is nevertheless possible to obtain nanoMOFs using traditional hydro/solvothermal routes by playing on different parameters such as decreasing the synthesis time and/or the temperature, changing the concentration, modifying the pH or by the addition of moieties that slow down the reactivity (acetic acid, hydroxybenzoic acid, ...). For instance, nanoMOFs of the porous zinc terephthalate MOF-5,[70] and the flexible porous iron muconate MIL-89 (30 nm)[71] or iron fumarate MIL-88A (150 nm)[61] have been obtained as nanoparticles. However, this route usually leads to lower yields and a higher degree of polydispersity of the particle size compared with the microwave hydro/solvothermal method.

4.433.2.3.2. Surface engineering

Particle surface engineering, especially concerning nanoparticles, is another fascinating issue. Firstly, surface modification is helpful to increase the stability of nanoparticles, preventing from aggregation in solution to avoid embolism after i.v. injection. Indeed, grafting some molecules directly on the surface of the nanoparticles leads to a modification of the surface charge of the particles (Z-potential) required to avoid aggregation by electrostatic or by hindrance repulsion. However, the external functionalizing of the surface of MOFs with an appropriate organic molecule results also in the introduction of other biologically attractive properties such as furtivity (or stealth properties), targeting (or addressing to active sites) and/or bioadhesion (Figure 6).[72–74]

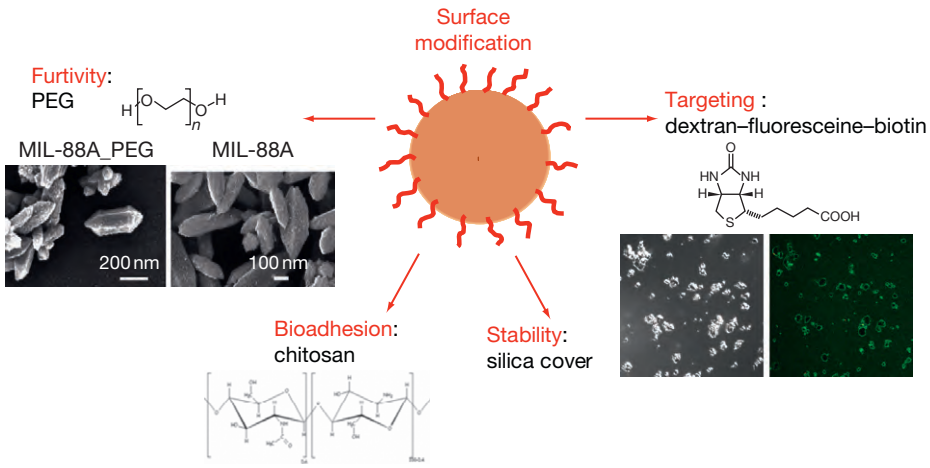

Figure 6 Examples of organic surface modification of metal–organic frameworks nanoparticles.

Engineered surface porous iron carboxylate nanoMOFs have been recently reported.[61] The surface of the nanoMOFs can be coated with organic modifiers using preformed nanoparticles either through postsynthetic functionalization or directly during the synthesis of the nanoMOFs.

Several examples of MOF surface engineering can be given. The most obvious one, commonly used for other carriers such as polymers, concerns the surface coatings using the hydrophilic polymer poly(ethylene glycol) (PEG) in order both to prevent normal interaction between the carrier and cells and avoid other destabilizing factors. The objective is to avoid the sequestration of the nanoMOFs by the reticuloendothelial system (RES) and thus increase after intravenous administration the longevity of the carrier in the bloodstream from minutes up to several hours.[75,76] Therefore, the mesoporous iron trimesate (MIL-100) and the flexible microporous iron fumarate (MIL-88A) or muconate (MIL-89) were superficially PEGylated, either through postsynthetic methods or during the synthesis, achieving PEG contents up to 17 wt%,[61] which is higher than those required to ensure 'stealth' properties.[77] Chitosan, a naturally occurring polysaccharide with bioadhesive properties (mucoadhesion and permeation enhancement),[78] has been also grafted on the external surface of MIL-88A nanoparticles (~20 wt%).[61] The surface of MIL-100 nanoparticles was also modified by amphiphilic polysaccharides dextran–fluorescein–biotin for addressing[79] and *in vitro* imaging.[61] Similarly, Lin and coworkers have modified different silica-covered nanoMOFs to ensure addressing or stealth properties. First, manganese terephthalate or trimesate MOFs were functionalized with a fluorescence moiety (rhodamine) and a c(RGDfK) ($\alpha_V\beta_3$ integrin; overexpressed in many angiogenic cancers) for *in vitro* imaging and targeting, respectively.[59] Second, nanoparticles of several lanthanide terephthalates MOFs were grafted with a Tb-complex and dipicolinic acid for imaging[80] and finally, nanoparticles of the iron aminoterephthalate MIL-101 were modified with an *in vitro* imaging agent (1,3,5,7-tetramethyl-4,4-difluoro-8-bromomethyl-4-bora-3*a*,4*a*-diaza-*s*-indacene) and a cisplatin prodrug (ethoxysuccinato-cisplatin).[81]

The possibilities of surface engineering of MOFs are almost infinite given the presence of diverse superficial reactive groups (metals, counter-anions, non-coordinated complexing functions, functional groups of the linker (amino)) that might interact with the organic polymer. For instance, in order to obtain specific stronger interactions for a given organic polymer, the surface of the nanoparticle can be functionalized with an appropriate organic moiety prior to the introduction of the organic polymer.

4.433.2.3.3. Adsorption of challenging drugs

So far, extensive research has been carried on to develop injectable nanocarriers such as liposomes, nanoemulsions, nanoparticles, or micelles, to enable the delivery of drugs that suffer from many administration drawbacks such as a low solubility in aqueous media, strong tendency to crystallize, short blood half lives and/or inability to bypass natural barriers.[18,19,82] Thus, there are still several clearly identified drugs that require new nanocarriers, especially in the field of cancer and AIDS treatment. Among the drug of interest are busulfan (Bu), tamoxifen, azidothimidine (AZT), or cidofovir (CDV). These anticancer or antiviral compounds are, indeed, encapsulated in currently available nanotechnologies with great difficulties and they are too rapidly released after administration ('burst effect').[83]

Busulfan (1,4-bis(methylsulfonyloxy)butane or Bu) is an amphiphilic alkylating agent widely used in combination with high-dose chemotherapy regimes in leukemias, especially in pediatry since it represents a good alternative to the total body irradiation.[84,85] However, Bu suffers from important drawbacks such as its poor aqueous stability and an important toxicity due to its possible crystallization in blood leading to hepatic veno-occlusive diseases.[86] Bu has been entrapped so far in several known nanocarriers such as liposomes or polymers resulting, however, in poor loadings, never exceeding of 5–6 wt%,[87] as well as inducing fast 'burst' releases'.[88] To overcome these problems, Bu was thus loaded in nanoparticles of several porous iron carboxylates using impregnation of the title solids in Bu concentrated solutions.[61] Note the relevance of the choice of the solvent for the drug encapsulation, not only considering the solubility of the drug but also considering the competitive adsorption of the solvent and the drug within the pores of the MOF. Solvent has also a major effect on the breathing behavior in flexible porous MOFs that might create diffusion problems when considering the adsorption of the drug.

Bu capacities were always higher than in existing nanocarriers whatever the MOF considered; from 8.0 to 25.5 wt%, depending mainly on the pore volume (**Table 2**). Indeed, Bu loading in the rigid mesoporous iron trimesate MIL-100 is 5 times higher than the previously highest reported loadings obtained using polymer nanoparticles (5–6 wt%)[84] and 60 times higher than with liposomes (0.4 wt%).[83,89] According to these results, the administration of the actual therapy of Bu would require a very low amount of MIL-100, around 20 mg kg^{-1} day^{-1}, during 4 consecutive days. Furthermore, such formulation would avoid the administration of toxic solvents such as the *N*,*N*-dimethylacetamide, present in the actual commercially available i.v. dosage of Bu (Busilvex®).[90]

In the treatment of cancer and viral infections, the mononucleosides exhibit a remarkable activity. However, the clinical use of phosphorylated nucleotide analogues is limited either by their poor stability in biological medium, resulting in short half-lives and low bioavailabilities,[91] or their highly hydrophilic character, which strongly limits their intracellular penetration.[92,93] For instance, anti-HIV AZT is a water stable drug but suffers from a poor intracellular activation by cellular kinases, while the corresponding active triphosphate azidothimidine triphosphate (AZT-Tp) molecule is highly water unstable. Additionally, both AZT and AZT-Tp exhibit a low membrane permeability. Nanocarriers could help to overcome such resistances but due to the very high hydrophilic character of these drugs, existing drug delivery systems are unable to achieve high drug loadings while, in addition, showing in all cases a 'burst' release profile.[94] In this context, we have shown that nanoMOFs could entrap very large amounts of AZT-Tp and also other active drugs such as CDV, the monophosphorylated form of the anticytomegalovirus phosphonate CDV, and doxorubicin, an antitumoral molecule (**Table 2**).[61] In this case, although drug aqueous solutions used for encapsulation were diluted, active ingredients could be nevertheless easily adsorbed with very high efficiencies

Table 2 Drug capacities of different drugs on several iron carboxylates nanoparticles

	MIL-89	*MIL-88A*	*MIL-100*	*MIL-101_NH$_2$*	*MIL-53*
Flexible solid	Yes	Yes	No	No	Yes
Pore size (Å)	11	6	25 (5.6) 29 (8.6)	29 (12) 34 (16)	8.6
Particle size (nm)	50–100	150[a]	200	120	350[a]
Busulfan	9.8	8.0	25.5	–	14.3
Azidothimidine triphosphate	–	0.60	21.2	42.0	0.24
Cidofovir	14	2.6	16.1	41.9	–
Doxorubicin	–	–	9.1	–	–
Ibuprofen	–	–	33	–	22
Caffeine	–	–	24.2	–	23.1

Benzophenone 3	–	–	1.5	–	–

[a]Bimodal distribution of sizes, with micrometric particles.

(in most cases, >80%). For instance, MIL-100 nanoparticles hosted up to 21 wt% of AZT-Tp, 16 wt% CDV, and 9 wt% doxo, while the MIL-101_NH$_2$ nanoparticles uploaded the unprecedented amount of 42 wt% of both, AZT-Tp and CDV. These results are exceptional, as loadings lower than 1 wt% were reported previously, using other carriers, with these drugs.[91]

In order to know if nanoMOFs could be considered as 'universal' drug nanocarriers, other cosmetic active molecules with different composition and polarities were encapsulated using these nanoMOFs (Table 2). In all cases, important loadings were also obtained with the amphiphilic caffeine (liporeductor), hydrophilic urea (hydrating agent), hydrophobic benzophenone 3 and hydrophilic benzophenone 4 (UVA and UVB filters).[61] These MOFs materials have also proved previously being efficient for the encapsulation and release of hydrophobic Ibuprofen.[39,56] In conclusion, the exceptional loadings of drugs in MOFs whatever the polarity and structure of the active molecule is mainly due to their adapted internal microenvironment (amphiphilic: polar metal, oxygens from the linker and nonpolar organic spacer) suitable for a large number of host molecules.[95]

AZT-Tp, CVD, and doxo were found to be progressively released from MIL-100 nanoparticles under simulated physiological conditions showing no 'burst effect.' A total drug delivery was achieved *in vitro* after 3–5 days for AZT-Tp and CDV, and up to 2 weeks for the hydrophobic doxo (Figure 7). Considering the degradation profile of MIL-100, one can suggest that drug delivery is a consequence of a combination of interactions (drug-framework) and diffusion processes. If one cannot exclude a partial degradation of the MOFs that could trigger the release, this is not here (MIL-100) the main parameter since after 3 days, most of the AZT-Tp has been released while only 10% degradation of the MOF was observed.

With the exception of our work, other examples of drug delivery from MOFs are still very scarce. An *et al.*[96] have recently reported the adsorption and delivery of a cationic drug, the antiarrythmic agent procainamide, within the cationic zinc adeninate MOF showing an interesting capacity of 22 wt% and a total released in 3 days under biological simulated conditions. A cisplatin prodrug (ethoxysuccinato-cisplatin) was also encapsulated in a silica covered iron terephthalate MIL-101

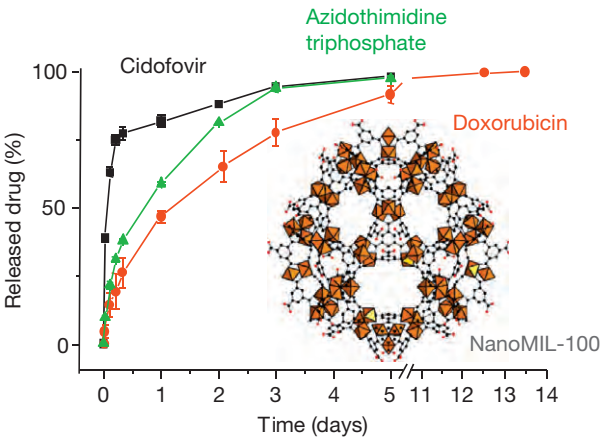

Figure 7 Drug delivery kinetics of cidofovir (black), azidothimidin triphosphate (green), and doxorubicin (red) from nanoparticles of iron trimesate MIL-100. Adapted from Horcajada, P.; Chalati, T.; Serre, C.; *et al*. *Nature Mater*. **2010**, *9*, 172–178.

(loading of 12.8 wt%) and delivered after 3 days under phosphate buffer solution (PBS) physiological conditions.[81]

4.433.2.4. *In Vitro* Activity Tests

Considering the promising data obtained with the challenging antiretroviral AZT-Tp and antitumoral Bu using the iron trimesate MIL-100, the *in vitro* activity of both drug-containing nanoparticles of MIL-100 was investigated.[61] Firstly, the cytotoxicity of the Bu-loaded MIL-100 in human leukemia (human T cell lymphoblast-like cell line, CCRF-CEM) and human multiple myeloma (RPMI-8226) cell lines were compared with those of empty nanoparticles of MIL-100 and free Bu. MIL-100 nanoparticles were able to deliver the intact form of Bu to the culture medium, showing no decrease in activity upon loading within the pores of the nanoparticles.

In addition, the *in vitro* activity of MIL-100 nanoparticles loaded with AZT-Tp was also evaluated in human peripherical blood mononuclear cells (PBMCs) using blood from healthy donors infected by HIV-1-LAI virus. Viral replication was measured by quantifying reverse transcriptase (RT) activity in cell

culture, confirming a significant anti-HIV effect only for AZT-Tp-containing MIL-100 nanoparticles (~90% of inhibition).

Remarkably, these results have evidenced the availability to these nanoMOFs carriers to entrap and deliver, in a controlled manner, in their active form, two challenging drugs such as Bu and AZT-Tp.

4.433.2.5. BioMOFs

4.433.2.5.1. The use of active linkers

MOFs are built up from the association of a linker and a metal. Encapsulation of drugs or biogases is the most obvious and easiest way to use MOFs for bioapplications. The degradation of the MOF carrier will however lead to a release, in contact with the body, not only from the biomolecule but also the metal and the linker issued from the MOF itself, introducing corresponding additional toxicity issues. To address this important problematic, the use of endogenous linkers is an acceptable solution. Several MOFs based on amino acids or exogenous linkers that exhibit a therapeutic activity, have been reported recently using zinc as the metal.[97]

Improving this approach consists in the development of biologically active MOFs. In fact, so far, the controlled release of drugs has been performed using a typical encapsulation/impregnation/release approach. The drug loading and the kinetics of release depend thus both on the pore volume of the carrier and the nature of the host–guest interactions between the drug and the framework. As a consequence, the presence of a MOF with a sufficient porosity is required while the release of the biomolecule is related to the nature of the interactions as well as the degradation of the MOF, raising additional toxicity concerns. A more convenient solution deals with the direct association of biomolecule, as the linker, and the metal to form the MOF (Figure 8). There is thus no need anymore of making a porous framework and the delivery of the drug is achieved directly through the degradation of the hybrid compound, ruling out the toxicity concerns from the use of traditionally nonbiologically active linkers. As a proof of principle, we have reported the use of iron and nicotinic acid (pyridine-3-carboxylic acid or niacin or vitamin B3).[2] This latter is an endogenous acid with pellagra-curative, vasodilating and antilipemic properties. A bioactive and degradable MOF denoted also Bio-MIL1 or $Fe_2^{III}Fe_{1-x}^{III}Fe_x^{II}O_{1-y}(OH)_y[O_2C\text{-}C_5H_4N]_5[O_2CCH_3]$ (x~0.15) (Bio-MIL for bioactive material from Institut Lavoisier) has been synthesized.

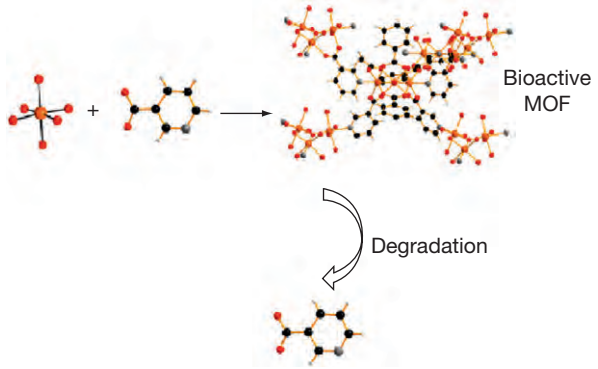

Figure 8 Schematic view of the formation of a BioMOF (Bio-MIL1) built up from bioactive linker and ist delivery. Here the bioactive linker is nicotinic acid. Iron, oxygen, nitrogen, and carbon atoms are in orange, red, gray, and black, respectively. Adapted from McKinlay, A. C.; Morris, R. E.; Horcajada, P.; *et al. Angew. Chem. Int. Ed.* **2010**, *49*, 6260–6266.

The delivery of nicotinic acid has been achieved in SBF at 37 °C, within 1 h.[98] This results from a rapid degradation of the bioactive MOF. This is in agreement with the poor stability observed previously with the iron aminoterephthalate MIL-101(Fe).[97] However, a much slower degradation rate was reported for other porous iron carboxylates such as the iron fumarate MIL-88A and the iron trimesate MIL-100 solids with a degradation time over 1 week in PBS. This shows that depending on the MOFs, that is, its structure, composition (metal, spacer, complexing group, ...), and the nature of the bioactive linker, one expects that different bioactive MOFs will exhibit different stabilities. Depending on the requirements for a given application, the choice of the metal and structure will thus be of a great importance to produce a bioactive MOFs with a suitable stability.

As most drugs are made from one or several complexing groups such as carboxylates, phosphates, phosphates, amines, and/or heterocycles, ..., our method can be considered as an alternative for the controlled released of biomolecules using biomaterials with a known toxicity and activity.

4.433.2.5.2. The use of biologically active metals

Another possibility of making a bioactive MOFs is to use an active metal. For instance, the activity of paramagnetic gadolinium complexes as magnetic resonance imaging (MRI) contrast agents is well known. This idea was reported by Lin *et al.* with the synthesis of nanoparticles of a Gd^{III}-based carboxylate MOF.[60,80,99] Large relaxivity values, several orders of magnitude higher than those of typical Gd^{III} complexes used as MRI contrast agents were obtained (Figure 9). However, the toxicity of the Gd^{III} combined with the degradation of MOFs in body fluid might rule out their clinical use. An alternative was the synthesis of nanoparticles of Mn^{II} carboxylates since Mn is much less toxic than rare earths.[61] The particles were however coated with silica to prevent from rapid degradation. The resulting relaxivities were lower than for the Gd carboxylates nanoparticles but probably for imaging.

A final use of active-metal-based MOFs for bioapplications would be theranostics. This would consist in following the drug release within the body using the imaging properties of the bioactive MOF. For instance, nanoparticles of the iron terephthalate MIL-101 have been surface-modified using the amino groups of the aminoterephthalate linkers. An anticancer drug (loading of 12.8 wt%) and a fluorophore (loading up to 11.6%) were introduced within the MOFs in order to associate *in vitro* optical imaging (fluorophore) and anticancer activity (drug). Once again, nanoparticles were covered with silica to prevent from the rapid degradation of the MOF and decrease the kinetics of release of the drug/fluorophore.

More recently, we have proposed a more suitable approach for theranostics. Nanoparticles of several nontoxic porous iron (III) carboxylates were shown to exhibit interesting relaxivity times (Figure 10), with R_2 relaxivities up to $50\,s^{-1}\,mM^{-1}$ (at 9.4 T), considered sufficient for an *in vivo* use.[100] Some of them also proved their ability to encapsulate very high

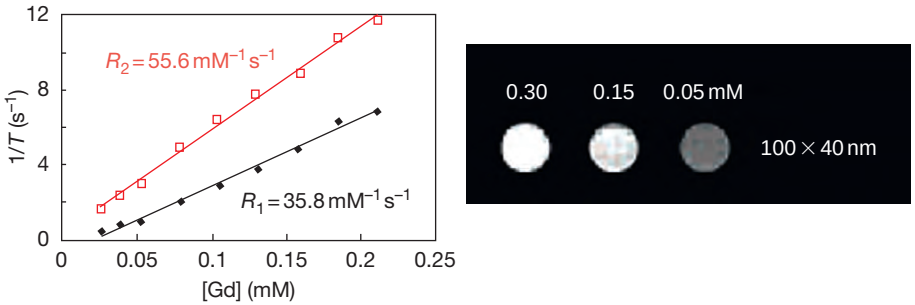

Figure 9 Left: R_1 and R_2 relaxivity curves of the Gd carboxylate nanoparticles of 100 × 40 nm dimensions; right: T1-weighted MR images of suspensions of 1 in water containing 0.1% xanthan gum. Adapted from Xie, Y.; Yu, Z.; Huang, X.; *et al. Chem. Eur. J.* **2007**, *13*, 9399–9405.

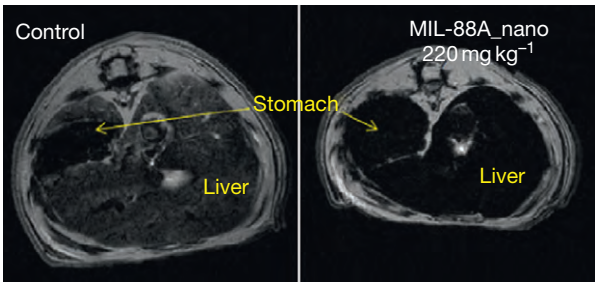

Figure 10 Magnetic resonance images collected at 9.4 T with gradient echo sequence of (left) control rats and (right) rats injected with 220 mg kg^{-1} of nanoparticles of MIL-88A in liver regions (results from C .Sebrie and B .Gillet from CNRS-Gif/Yvette, France). Reproduced from Horcajada, P.; Chalati, T.; Serre, C.; *et al. Nature Mater.* **2010**, *9*, 172–178.

loadings as well as controlled delivery of several challenging cyto-toxic drugs. If the high loading capacities are due to the presence of large pore volumes, the imaging properties are due to the paramagnetic iron trimers associated with a 3D pores system whereas free or bound water molecules bound to the acidic Lewis metal centers that can easily exchange their protons.

4.433.3. Adsorption and Delivery of Biological Gases

MOFs with their large pore volumes and their great structural and chemical diversity, are attractive candidates for the storage, capture and separation of strategic gases (H_2, CO_2, CH_4).[101] This concept can be further extended to bioactive gases such as NO, CO and even H_2S, which are highly toxic gases but are also, at very low concentration levels, part of several important mammalian biological processes. Nitric oxide (NO) has been recently studied with, for instance, first reports of cardiovascular system activity while the role of carbon monoxide (CO), still under investigation, plays an important role in several biological processes such as injury repairs involving heme oxygenase.[102] These results paved the way for the development of intense biomedical research involving these biogases. We will focus here our attention to the biological properties of NO, which is of an utmost importance in several biological processes such as signaling molecules, antibacterial, antithrombotic and wound healing applications.[103] The problem of NO or CO, besides its high toxicity above a certain concentration level, consists in its short life duration within the body fluid (<1 h for CO but less than a few minutes for NO)[2b] as well as the difficulty of delivering it at the right biological level (>10 ppm) on a controlled manner. Thus, controlling the release of NO using materials that store NO is an attractive alternative for many related applications.[104,105] Several types of carriers have been tried so far such as polymers,[106,107] porous inorganic silicas,[108] and zeolites.[109,110] For different reasons, these carriers suffer from serious drawbacks (toxicity, pro-inflammatory by products, fast release…) that restrict their use for certain applications.[111]

A nice feature of some porous MOFs is the presence of coordinatively unsaturated metal sites within their framework (Figure 11). At room temperature, under air atmosphere, these metal sites are nevertheless 'poisoned' by water molecules and only a careful thermal and/or vacuum treatment allows in most cases the full removal of the coordination water molecules.[112] The metal which has decreased its coordination number down to four- or fivefold, offers an accessible Lewis acid metal site, whose strength depends both on the oxidation state, usually +II or +III, and the environment of the metal (linker, structure). Thus, NO can easily be chemisorbed in large amounts, directly on the metal sites. Desorption of NO occurs then, more or less on a controlled manner, when one exposes back the solid to water moisture. So far, only a few selected MOFs have been tested for NO adsorption and release tests, such as the copper trimesate, denoted HKUST-1, and the metal(II) dihydroxoterephthalates series denoted CPO-27 (M = Co, Ni, Mg, …).[113]

In both cases, very large amounts of NO could be chemisorbed at room temperature and 1 bar, up to 7 mmol g^{-1}.[13] NO can be released upon exposure to water vapor for both solids (11% H_2O in nitrogen atmosphere). However, the profile of release strongly differs from HKUST-1 to CPO-27. The copper MOFs exhibit a rapid NO burst release over a few minutes followed by a residual desorption of NO over a few hours.

In the case, of CPO-27, a regular flux of pure NO is delivered on a controlled manner over a few hours (Figure 12), at a level ~7000 times higher than one of the copper MOFs, over the same duration and conditions. The initial 'antibacterial NO burst' that some MOFs exhibit upon

water triggered NO release, could however be useful for some cosmetic applications. One could imagine making composite creams based on NO-loaded MOFs in order to deliver gases onto human skin, such as those previously reported using zeolites. Depending on the nature of the cream, the delivery rate of NO can be tuned, in accordance with the composition of the formulation.[110] However, a controlled NO release is required to avoid unwanted side effects for most biomedical applications. Morris *et al.* have shown that CPO-27 materials loaded with NO could be used to control the vasodilation of porcine arteries.

The controlled release of NO at biological levels prevents platelet aggregations and thus such NO-loaded MOFs could be used as antithrombosis materials.

Another approach of using MOFs to deliver NO, reported by Rosseinsky and coworkers,[114] consists in coordinating an amine through one of the basic amino groups, directly on the Lewis acid site, that will further chemically react with NO to form diazonium moieties. The release of NO is then achieved through hydrolysis when exposed back to water moisture. However, the use of a toxic cobalt-based MOF rules out its use for any clinical use. More recently, a small pores and flexible copper sulfonate–carboxylate was shown to adsorb selectively only NO.[115]

In between these different methods or desorption behaviors, considering the large number of other existing MOFs with accessible metal sites, it is expected that other NO-delivering MOFs with various delivery capacity or release character will be available soon. Thus, tunable NO delivery systems might be designed by selecting the right material with the right NO capacity, kinetics of release as well as a suitable biodegradability and toxicity.

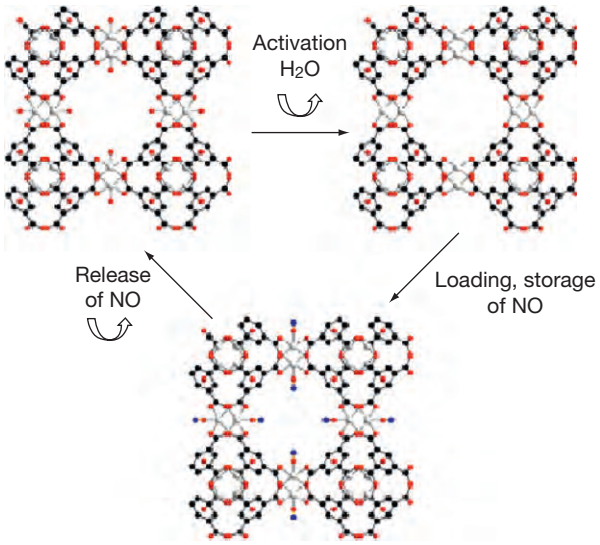

Figure 11 Schematic view of the activation/loading and release of NO in metal–organic frameworks with accessible metal sites (here, HKUST-1) with copper, carbon, nitrogen, and oxygen atoms in white, black, blue, oxygen. 4.433.4. Toxicity and Stability Issues

Developing bioapplications of MOFs requires the study of their toxicity. This issue can be studied sequentially in three steps: (1) the stability of the MOF in the biological medium; in the absence of biodegradation toxicity effects would arise caused by to the accumulation of MOF particles within the body; (2) the cytotoxicity of the nanoparticles; preliminary tests might help to gain understanding of the toxic effects at a cellular level; and finally, (3) *in vivo* toxicity.

4.433.4.1. *In Vitro* Biodegradability

Depending on the application, the carrier has to be stable enough to complete its function but degradation with time is necessary in order to allow body removing/recycling of the MOFs's components to prevent endogenous accumulation, and potentially toxicity effects. The stability of MOFs in general has been widely questioned due to first evidences of the low water stability of the well-known MOF-5.[17] However, the chemical and structural versatility of MOFs allows to tune the matrix biodegradation by changing either the composition (coordination number and oxidation state of the metal, solubility of the linker, complexing group (phosphonate, carboxylate, ...) and so on) and the structure type (pore size and

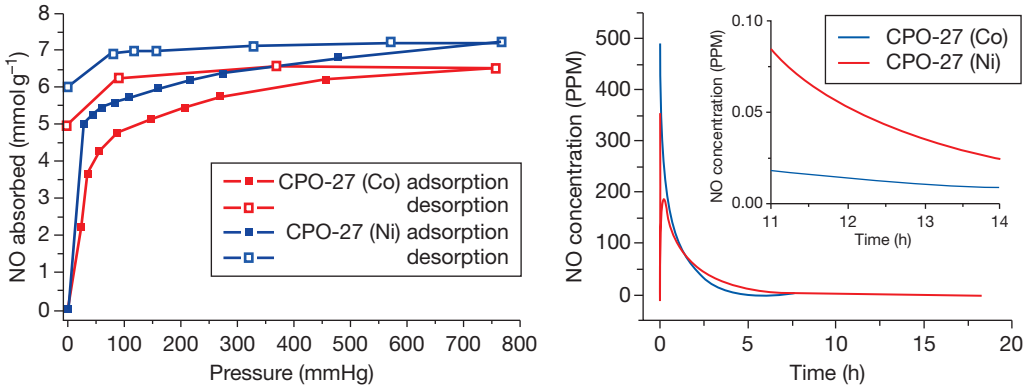

Figure 12 Left: adsorption, desorption isotherms of NO at 1 bar and 298 K; right: delivery profiles of NO from CPO-27 solids under a flux of wet nitrogen (11% humidity rate) at 298 K (results of Prof. R. Morris from St Andrews University). Adapted from McKinlay, A. C.; Xiaou, B.; Wragg, D. S.; Wheatley, P. S.; Megson, I. L.; Morris, R. E. *J. Am. Chem. Soc.* **2008**, *130*(31), 10440–10444.

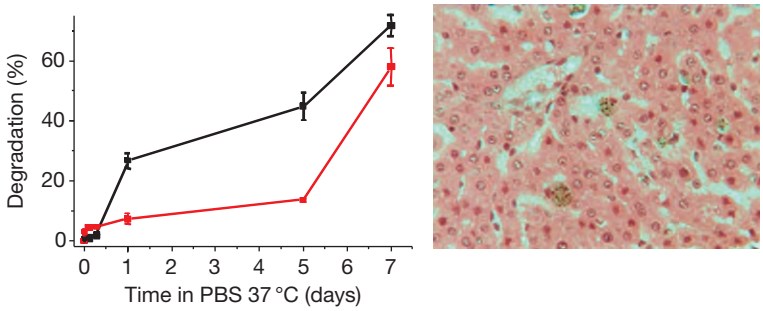

Figure 13 Left: *in vitro* degradation tests of MIL-100 (red) and MIL-88A (black) nanoparticles under simulated physiological conditions (PBS pH 7.4, 37 °C). Right: hepatic histology after the intravenous administration of 220 mg kg^{-1} of MIL-100 nanoparticles to rats (hematoxylin-eosin staining).

volume, pore connectivity, ...), the size of the nanoparticles and the type of formulation, in agreement with the desired application.

Hinks *et al.* have reported that the series M-CPO-27 (porous metal (II) hydroxoterephthalate (Ni, Co, ...)) are stable under physiological simulated conditions (PBS and bovine serum) for days, weeks and even longer.[116] Similarly, a tablet formulation of the flexible microporous iron terephthalate (MIL-53 (Fe)) has shown a stability over 3 weeks in a (SBF; same inorganic composition as human plasma).

NanoMOFs have also shown an acceptable stability. Recent studies, concerning the degradation of the iron carboxylates nanoparticles MIL-88A and MIL-100, have evidenced a partial degradation of 44% and 14%, respectively, after 5 days of incubation under physiological simulated conditions (PBS, pH 7.4, 37 °C; **Figure 13**). Other types of iron carboxylates such as amino-modified MIL-101(Fe) or the iron nicotinate Bio-MIL-1, showed a very rapid and total degradation, within a few hours, under similar conditions. This points out the diversity of biodegradability of MOFs as a result of their various structures and compositions. As an alternative, when degradation is too fast, it is possible to apply an external covering of the MOFs nanoparticles with silica to prevent fast degradation and thus achieved a better and targeted drug release.[95]

4.433.4.2. *In Vitro* Toxicity Tests

Cytotoxicity of two iron carboxylates nanoMOFs has been studied through 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay.[62] The IC50 (half maximal inhibitory concentration) of the iron fumarate MIL 88A nanoparticles on mouse macrophages (J774.A1) was 57 ± 11 μg ml^{-1}. This value is comparable with those of currently available nanocarrier systems, thus confirming the lack of cytotoxicity of our nanoMOFs carriers.[117]

The same method has been used for the iron trimesate MIL-100 nanoparticles on human leukemia (CCRF-CEM) and human multiple myeloma (RPMI-8226) cells. Similarly, studies performed using human PBMCs have shown no cytotoxic effects even at the high doses.

4.433.4.3. *In Vivo* Toxicity Assays

In order both to determine what are the toxicity levels (doses) and the nature of the risks (toxicity effects), *in vivo* toxicity assays of nanoMOFs have been carried out. Therefore, three iron carboxylates have been selected: (1) flexible MIL-88A based on the hydrophilic aliphatic linker, fumaric acid, an endogenous molecule involved in the Krebs cycle, (2) rigid mesoporous MIL-100 based on the hydrophilic and exogenous aromatic trimesic acid, and (3) flexible MIL-88_4CH_3 with the hydrophobic exogenous aromatic tetramethylterephthalic acid. Different amounts of the nanosolids were intravenously administered to rats Wistar females over 4 weeks to determine the lethal dose 50 (LD_{50}). Surprisingly, the maximal dose was limited only by the stability of the suspension of nanoparticles in the glucose solution, used for the injection, and not due to their toxicity. After 7 days of administration of the maximal dose, 220 mg kg^{-1}, any sign of toxicity was observed. Note that the administered doses, up to 220 mg kg^{-1}, are considerably high compared to those of usual carriers.

For a more thorough evaluation of the toxicity of nanoMOFs, the first *in vivo* toxicity assay was performed through a unique intravenous administration of the maximum dose. Throughout three consecutive months, several parameters were followed such as weight, serum parameters to evaluate the hepatic function, the inflammatory and immunitary reaction and organs histology, as well as the hepatic enzymatic activity. Remarkably, no severe toxicity of iron carboxylate nanoMOFs was evidenced, even after the administration of very high doses. Nanoparticles were rapidly sequestered by the reticuloendothelial organs, spleen and liver, since in our case, no-stealth PEG coating of their surface was applied. Thus, as a consequence, an important iron accumulation can be detected in these target organs. However, after 1–3 months of injection, spleen and liver came back to normality (**Figure 13**), in agreement with the mobilization of the iron deposits that occurred the first moments after injection. The absence of any immune or inflammatory reactions, as well as the preservation of liver function, after the administration, support the lack of toxicity of the nanoMOFs. Moreover, the activity of Cytochrome P450 was not significantly modified in comparison with the control group, indicating that the nanoMOFs are probably not metabolized by the liver. The absence of the metabolization of the linker together with the high polarity of the polyacids, suggest a direct excretion of the ligand. Additionally, endogen acids as the fumaric acid might be reused by the body. Note that some currently approved iron oral prescribed drugs have the same chemical composition as the MIL-88A solid (i.e., iron fumarate or 'Ferrets®').

From the above results, one can clearly claim that iron carboxylate nanoMOFs exhibit no severe toxicity, even after the administration of important doses.

4.433.5. Formulation

One of the major concerns for developing real applications of MOFs, not only in biomedicine but also in other fields of interest such as separation, catalysis, and others, is their physical form. Some applications need very specific forms (tablets, pellets, extrudates, packed columns, ...). In the case of bioapplications, where one can think of various administration routes (topical, enteral, or parenteral), specific formulations are required. For most formulations, a control of the particle size is of interest. As described previously (see Section 4.433.2.3.1), this will limit the scope of the various administration route, but also influences other parameters (rheology, packing, external surface, ...) decisive for the processing of stable and reproducible formulations.

MOFs nanoparticles can be also used to make thin films other useful or types of formulations such as patches or coatings. Homogeneous thin films of MOFs can be prepared from stable colloidal solutions by a simple dip or spin coating method. This route allows the control of the film thickness by multilayer deposition or by controlling particle size and deposition conditions.[61,69]

Bottom: Atomic force microscopy (AFM) of the surface of a MIL-101 thin film. Adapted from Demessence, A.; Horcajada, P.; Serre, C.; *et al. Chem. Commun.* **2009**, *46*, 7149–7151.

Finally, one could make composite materials from MOFs by mixing two nonmiscible materials, either integrating the MOF into a matrix or by a coating procedure (core–shell). Organic (i.e., polymers) or inorganic materials (i.e., silica) combine their properties to those of the MOFs within the final composite. A first example of MOFs composites has been recently reported by entrapping the copper trimesate HKUST-1 into a monolithic macroporous hydrophilic polymer (polyHIPEs) (Figure 14).[118]

Cream/ointment formulations of MOFs, very useful for biological gas release onto human skin, might also be produced in a near future. This concept has been already prepared using zeolites.[21]

Finally, the core–shell approach has been extended recently using several MOF nanoparticles, a polyvinilpyrrolidone polymer and a silica shell in order to avoid fast degradation and release of toxic metals.[59,78,79]

4.433.6. Conclusion and Perspectives

MOFs are a unique class of crystallized porous hybrid solids. Their composition, structure, pore size and volume can easily be tuned by changing either the metal (transition metal, lanthanide, or calcium/magnesium, ...), the linker (carboxylate, phosphonates, or imidazolates, ...) or through postsynthesis functionalization. This represents an advantage for optimizing their properties for a given application, compared with other porous solids (zeolites, carbons) with various structures but a unique composition. Some iron carboxylates based MOFs have been proven, at the preclinical level, to be nontoxic with injection doses in rats as high as 220 mg kg^{-1}. In addition, their *in vitro* degradability has been evidenced while modifying the composition and structure of MOFs strongly affects their kinetics of degradation from a few hours to weeks. Another advantage of MOFs is their loading capacity of drug molecules or gases over those of other carriers (polymers, zeolites, ...), with the possibility of encapsulating challenging anticancer or antiretroviral drugs with record loading capacity, followed in some cases by their controlled release into the environment. One can also introduce bioactivity in MOFs by directly selecting a bioactive molecule (drug, ...) as the linker and/or an active metal (Gd, Fe, ...) as the inorganic subnetwork, leading in some cases (Gd, Mn, Fe) to imaging properties useful for theranostics. The synthesis of MOFs nanoparticles suffers from no specific technical issue and can be achieved using either emulsion techniques or microwave assisted hydro or solvothermal conditions, even if in some cases their rapid degradation or the presence of reactive groups at their surfaces, leads to particle aggregation. Stealth, addressing or imaging properties of MOFs nanoparticles can be ensured through surface modifications with various organic biomolecules (PEG, chitosan, ...), either during or after the synthesis. The presence of both organic and inorganic moieties in MOFs renders also easier to produce composites of MOFs based either on polymers or inorganic matrixes suitable for patches, creams or any related applications.

Despite these promising results, the use of MOFs for biomedical applications is still in its infancy and several critical issues have still to be sorted out. First, from a fundamental point of view, if it is possible that MOFs drug loading capacity

can exceed that of other existing carriers, controlling the kinetics of delivery of biomolecules often times is major challenge. To determine the key parameters for controlled release, this might require to perform systematic encapsulation/release studies of model drugs with a full set of characterizations as well as state-of-the-art modeling techniques, in order to predict which is the best MOF materials for a given drug molecule and the related delivery time. Other important concerns are related to the origin of the difference in degradability from one MOF to another, in order to be able to design a specific MOF with a suitable stability for a given application. Finally, the synthesis of MOF nanoparticles and the corresponding surface modification, are time consuming processes that have been tested only for a few selected MOFs and extending these methods to other MOFs of interest will require in a near future a strong research investment.

Finally, the use of MOFs for biomedical applications is of a great interest with several breakthrough results, indicating that these hybrid crystallized porous carriers possess many advantages over existing systems. Considering the huge number of remaining existing encapsulation challenges such as the controlled release of the drug molecules that have not been commercialized due to their poor bioavailability (solubility, stability, ...), this confirms the high interest in further developing new bioapplications from MOFs.

Acknowledgements

EU for the funding via the ERC-2007-209241-BioMOFs. Prof. Gérard Férey, coworkers and students, related to bioapplications of MOFs, from Institut Lavoisier and Université Paris Sud are also thanked.

5. MOFs are given a code such as HKUST-1, MIL-100, etc. This corresponds to the place of the first synthesis – for example MIL stands for Material from Institut Lavoisier – and generally define the structure of the materials. A different labelling corresponds to different shapes of pores and often a different chemical composition.

4.434.1. Introduction

Magnetism and medicine are sharing a fascinating common history for several tenths of centuries.[1] Some of the earlier applications of magnetic materials include removal of metallic objects from the bodies of animals and humans and the use of magnetite grains as antidote for the accidental swallowing of rust. In ayurvedic therapies, various kinds of iron oxides are still used as iron supplements for humans, especially children and pregnant women. More recently, miniaturization of electromagnets, development of superconducting electromagnets, and introduction of strong permanent magnets (Sm–Co and Nd–Fe–B) have stimulated the medical use of magnets in fields as diverse as radiology, dentistry, cardiology, neurosurgery, oncology, and immunoassays.

Moreover, well-calibrated magnetic nanoparticles (MNPs) in the size range 1–100 nm are currently produced in large quantities thanks to reproducible synthetic protocols. Several chemical routes allow modification of their surface for ensuring their colloidal stability in physiological media, protecting them from corrosion/dissolution, and making them less cytotoxic and derivatizable with biorelated molecules.

MNPs are of particular interest in medicine. First, they are smaller than cells (10–100 μm) and comparable to viruses (20–450 nm), proteins (5–50 nm), or genes (2-nm wide and 20–450-nm long). Therefore, they are able to circulate in the bloodstream (even in the thin lung capillaries), to cross biological membranes and to interact closely with biomolecules. Second, when their diameter is lower than about 10 nm, MNPs display unusual magnetic properties, that is, superparamagnetism, making them tractable in magnetic field gradients, capable of creating local magnetic fields, but not concerned with remanence magnetization. Because living tissues are transparent to magnetic fields, MNPs may be remotely manipulated *in vitro* or *in vivo*. Moreover, they may disturb the relaxation times of surrounding protons. Lastly, they may generate heat when they are subjected to AC magnetic fields, thanks to hysteresis, Brownian and/or Néel loss phenomena. So, formulated in aqueous liquids called magnetic fluids (MFs), MNPs became recently inescapable tools for biologists, pharmacologists, and physicians. They are now routinely used as contrast agents in magnetic resonance imaging (MRI) and very next applications are expected in the field of cancer thermal treatment, magnetic targeting, and heat-triggered drug release.

Even if some publications deal with oral MRI contrast agents for the gastrointestinal tract,[2] the majority of published studies concern the intravenous (i.v.) administration route. The use of MNPs in the blood compartment depends on

specific requirements with respect to their plasma half-life and their final biodistribution. The problem of the nonnatural stealthiness of the nanoparticles toward the immune system, and the possibilities for resolving it, have been widely studied in the field of drug delivery from liposomes and polymeric nanoparticles.[3] Indeed, retention of drugs in circulation is a key step in the design of drug delivery carriers. Even the most active compound *in vitro* is useless if it does not reside *in vivo* in the blood long enough to reach its target, while managing to avoid, to some extent, premature metabolism, immunological reactions, toxicity, rapid excretion and captation by undesired tissues.[4] Presently, many pieces of information are available concerning the immune system mechanisms, the factors affecting the biodistribution of nanoparticles, such as their size and shape, the hydrophobic/hydrophilic balance of their surface, their surface charge, and the solutions envisaged for targeting specific organs, tissues, or cells.

The aim of this review is to present simultaneously the basic knowledge and an updated survey of the potential of MNPs for *in vivo* applications through an understanding of the problems involved from the viewpoint of their overall requirements, their synthesis and their bulk and surface properties. One main intention of this contribution is to impart information about both the state of the art as well as the need for further progress and clinical development. Only typical examples among the most promising ones will be reported and discussed and a special emphasis will be made on cancer diagnosis and therapy. Only general references are provided for the reader to turn to for more information. It may be noted that, even if they are not within the scope of this chapter, MNP technology concerns also non-*in vivo* bioapplications, for example, cell sorting,[5,6] detoxification of biological fluids,[7] radionucleide and gene delivery (magnetofection),[5,7,8] retinal detachment,[6] cell membrane manipulation,[7,9] and magnetorelaxometry.[6]

4.434.2. Magnetism of MNPs

4.434.2.1. Behavior in Static Magnetic Fields and Gradients

4.434.2.1.1. Materials magnetism background

The magnetism of a solid is originated from the contributions of the electrons constituting a solid, thanks to their quantum properties, that is, their spin angular moment and their orbital angular moment, which contribute to their magnetic moment. These electrons also determine the strength of the interaction between atoms in a solid, making the basis of the different macroscopic behaviors observed in nature. Massive materials can thus be classified into diamagnetic, paramagnetic, ferromagnetic, ferrimagnetic, and antiferromagnetic according to the arrangement of their magnetic dipoles in the absence and presence of an external magnetic field.[10,11]

If a magnetic material is placed in a magnetic field of strength H, the individual atomic moments in the material contribute to its overall response, the magnetic induction B:

$$B = \mu_0(H + M) \quad [1]$$

where μ_0 is the vacuum permeability, and the magnetization $M = m/V$ is the magnetic moment per unit volume, where m is the magnetic moment on a volume V of the material.[8] All materials are magnetic to some extent, with their response depending on their atomic structure and temperature. They may be conveniently classified in terms of their volumetric magnetic susceptibility χ, where

$$M = \chi H \quad [2]$$

describes the magnetization induced in a material by H.

Figure 1 shows schematic diagrams of these five different situations. If a material does not have magnetic dipoles in the absence of an external field and has weak induced dipoles in the presence of a field, the material is referred to as diamagnetic. The magnetization of a diamagnet responds in the

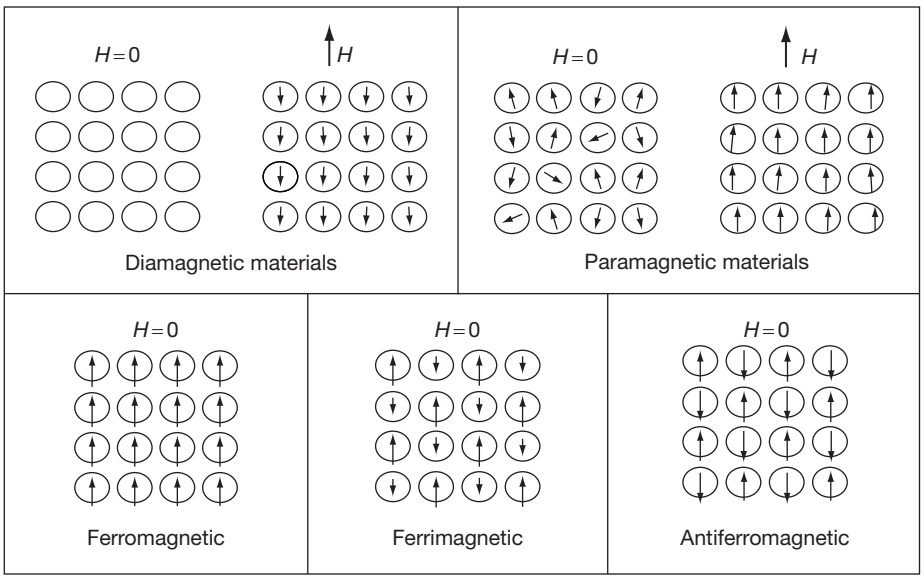

Figure 1 Scheme illustrating the arrangements of magnetic dipoles for five different types of materials in the absence or presence of an external magnetic field (H). Redrawn from Jeong, U.; Teng, X.; Wang, Y.; Yang, H.; Xia, Y. *Adv. Mater.* **2007**, *19*, 33–60.

opposite direction to the external field, with χ in the range -10^{-6} to -10^{-3}. If a material has randomly oriented dipoles that can be aligned in an external field, it is paramagnetic. The magnetization of a paramagnet responds in the same direction as the external field ($10^{-6} < \chi < 10^{-1}$). The magnetic interactions derived from the above two types of materials are very weak because the thermal agitation at room temperature can make the magnetic moments to flip over continuously.

However, some materials exhibit ordered magnetic states and are magnetic even without a field applied. For a ferromagnetic material, the magnetic dipoles always exist in the absence and presence of an external field and exhibit long-range order (Figure 1). Macroscopically, such a material displays a permanent magnetic moment and M is typically 10^4 times larger than would appear otherwise. The difference in the source of the net magnetic moment can also be used to distinguish ferromagnetism from both ferrimagnetism and antiferromagnetism. In a ferrimagnetic material there are always weaker magnetic dipoles aligned antiparallel to the adjacent, stronger dipoles in the absence of an external magnetic field. For an antiferromagnetic material, the adjacent dipoles are antiparallel in the absence of an external field and cancel each other.

That is why magnetic materials are referred to those characterized by either ferro- or ferrimagnetic features. Both ferro- or ferrimagnetic materials can be described using a number of basic parameters derived from the magnetization curve, where the magnetization M or flux density B is plotted against the magnetic field strength H (Figure 2). Although a ferromagnetic material should have all its magnetic moments pointing in the same direction, a macroscopic piece of material cannot have this configuration because the amount of magnetostatic energy stored should be huge.[12] The way in which a solid can reduce this otherwise huge magnetostatic energy is to break itself up into regions called magnetic domains, or Weiss domains. Within a single domain, all magnetic moments remain parallel, but each domain is randomly oriented so that the net magnetic moment of the sample is nearly cancelled (Figure 3(a)). This situation generates interfaces between domains called domain walls or Bloch walls, where adjacent magnetic moments are in a nonfavorable configuration, so that these domain walls are highly energetic. Even though some energy is stored inside domain walls, the overall decrease in the total magnetic energy favors the multidomain configuration. Being formed by a competition between magnetostatic and exchange energies, domain walls have a finite width, determined by the ratio between these energies.

The susceptibility in ferro- and ferrimagnetic materials depends not only on temperature, but also on H, which gives rise to the characteristic sigmoidal shape of the magnetization curve (M–H curve), with M approaching a saturation value at large values of H (Figure 2). Furthermore, one often sees hysteresis: it characterizes the irreversibility in the magnetization and demagnetization processes that are related to the pinning of magnetic domain walls at defects, dislocations, or vacancies within the material, as well as to intrinsic effects such as the magnetic anisotropy of the crystalline lattice. This gives rise to open M–H curves, called hysteresis loops. Actually, domain walls can move in response to an applied field: creation, growth, and extinction of domains can be induced by an external magnetic field because the external field imposes a preferred direction for the magnetic moments. For the spins in a given domain to change their orientation, it is required that the walls of that domain displace. However, the magnetic field required to eliminate all domain walls (i.e., to align all magnetic moments in the same direction) has a definite value for a given sample, and is very reproducible.

The saturation magnetization M_S (the maximum value of M), the remanence magnetization M_R (the residual magnetization at zero applied field strength), and the coercivity H_C (the external field required to reduce the magnetization back to zero) are deduced from the magnetization curve (Table 1). A material is called a soft magnet if it can be magnetized readily in a weak field of $\sim$10 Oe ($1\,\text{Oe} = 1000/4\pi\,\text{A m}^{-1}$). On the other hand, hard magnets have very strong H_C and require large external fields applied to the opposite direction in order to be demagnetized.

Lastly, as the temperature increases, thermal motion, or entropy, competes with the ferromagnetic tendency for the spins to align. When the temperature rises beyond a certain point, called the Curie temperature T_C, there is a second-order phase transition and the system can no longer maintain a spontaneous magnetization, although it still responds paramagnetically to an external field (Table 1).

4.434.2.1.2. Magnetism of nanoparticles

Magnetism is highly volume and temperature dependent because this property arises from the collective interaction of atomic magnetic dipoles.[13] When the size of a ferro- or ferrimagnet decreases to a certain critical value D_C, MNPs change from a state with multiple magnetic domains to one with a single domain (Figure 3(b)). In that transition situation, H_C is maximal and the hysteresis loop is broader (Figure 2). This critical

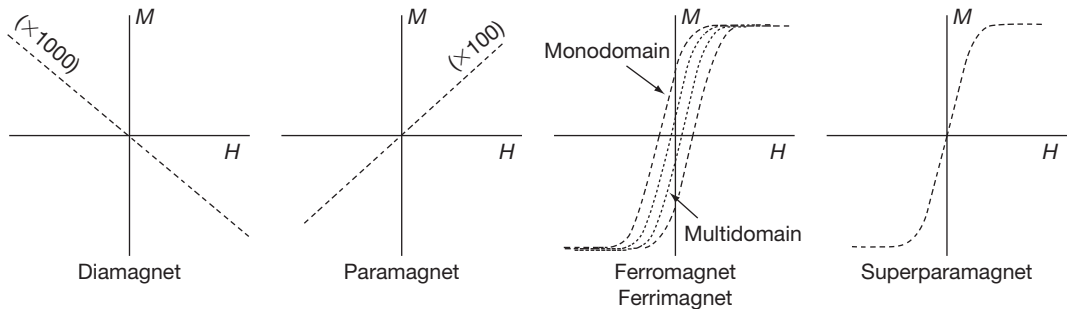

Figure 2 Typical M–H magnetization curves for the different types of magnetic materials.

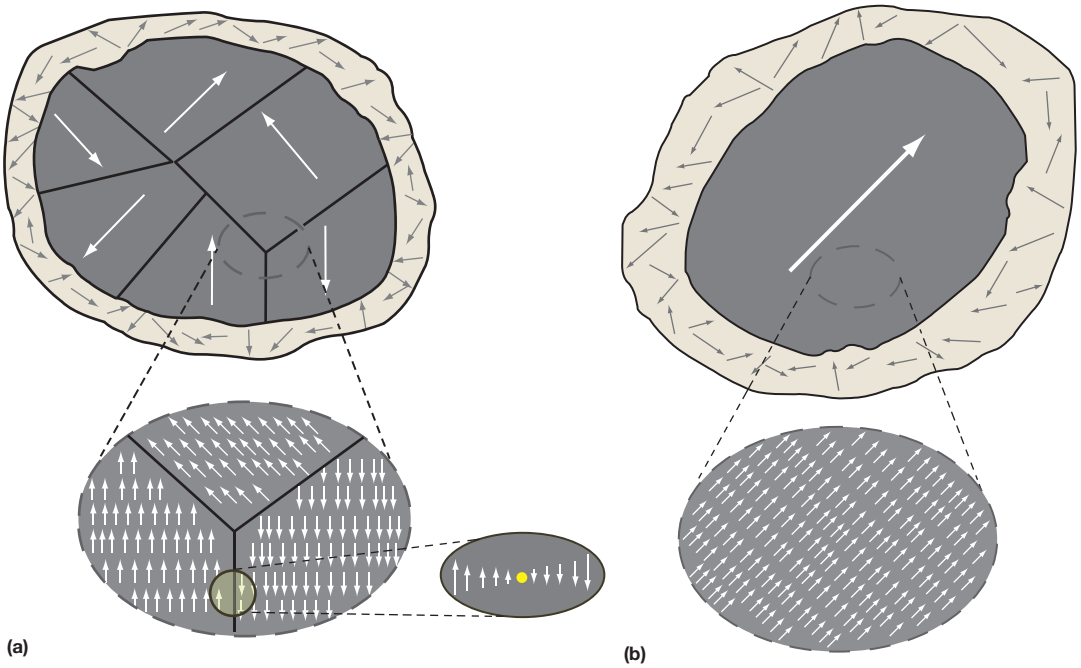

Figure 3 (a) Schematic view of magnetic domains in a multidomain ferromagnetic particle having size larger than the critical diameter ($D > D_C$). For this particle, the whole material breaks down into randomly oriented magnetic regions. At the interface between domains, magnetic moments are twisted to fit the orientation at both sides of the domain walls. (b) Schematic view of magnetic domains in a monodomain ferromagnetic particle having size smaller than the critical diameter ($D < D_C$). The spin disorder at the particle surface is represented by an annular region in both cases. Redrawn from Goya, G. F.; Grazú, V.; Ibarra, M. R. *Curr. Nanosci*. **2008**, *4*, 1–16.

Table 1 Typical values characterizing magnetic materials commonly used in biomedical applications

Magnetic material	M_S (*emu g*$^{-1}$)[a]	T_C (*K*)

$BaFe_{12}O_{19}$	72	703
FePt	68	750

[a]At room temperature.

size is achieved when the magnetostatic energy, which increases in proportion to the volume of the materials, becomes equal to the domain wall energy, which varies proportionally with the interfacial area between domains. For spherical and noninteracting MNPs, the critical size can be given as

$$D_C \approx \frac{18\sqrt{AK_{eff}}}{\mu_0 M_S^2} \quad [3]$$

where A is the exchange constant and K_{eff} is the effective anisotropy constant. This critical size, which is generally of a few nanometers to a few tens nanometers, varies from material to material.

Below the critical size D_C, the coercivity decreases to zero with the size. MNPs with zero coercivity simultaneously have zero remanence and are known as superparamagnets, in the sense that they behave as paramagnetic materials, but display much higher susceptibilities (there is a giant moment inside each particle). This leads to anhysteretic but still sigmoidal, M–H curves (**Figure 2**). In that situation, thermal fluctuations overcome anisotropy forces, and hence, magnetization of particle gets reversed easily from one easy direction to another one even in the absence of a magnetic field. It means that the energy barrier, which separates the two energetically equivalent easy directions of magnetization, is

$$K_{eff} V \leq k_B T \quad [4]$$

where K_{eff} is a function of magnetocrystalline, shape and surface anisotropies, V is the particle volume, k_B is the Boltzman's constant, and T is the absolute temperature.

The reversal of magnetization for superparamagnetic MNPs occurs as soon as the applied external magnetic field is removed according to two relaxation mechanisms: spin rotation (rotation of magnetic spin within the particles) or particle rotation (the actual physical rotation of the particle). Néel relaxation time (τ_N), which occurs due to the spin rotation, is related to the magnetic anisotropy of the material and can be expressed as follows:

$$\tau_N = \tau_0 \exp\left(\frac{K_{eff} V}{k_B T}\right) \quad [5]$$

where τ_0 is the time constant ($\sim 10^{-9}$ s).

The characteristic time for the randomization of the magnetization due to the physical rotation of the particle is known as Brown relaxation time (τ_B) and can be expressed as

$$\tau_B = \frac{3\eta V_H}{k_B T} = \frac{4\pi\eta R_H^3}{k_B T} \quad [6]$$

where η is the viscosity of the carrier liquid, V_H is the hydrodynamic volume of the particle, and R_H is the hydrodynamic radius of the particle.

The characteristic fluctuation time for the moment of a particle varies exponentially with temperature and the magnetization reappears to switch sharply to a stable state as the temperature is reduced. Hence, if a superparamagnetic nanoparticle is cooled below a critical temperature (blocking temperature T_B), it regains its ferro- or ferrimagnetic behavior. T_B is determined experimentally from the magnetization–temperature curve using a magnetometer. In a standard procedure, the sample is cooled from room temperature to 5 K or lower using helium with no applied magnetic field (the zero-field cooling (ZFC)) and then magnetization is measured when the sample is warmed up under a weak external field (~100 Oe). On the contrary, with the field cooling (FC) protocol, the sample is first cooled down under a magnetic field. During the ZFC protocol, the magnetization increases and then decreases as the temperature increases. The temperature corresponding to the maximum point is defined as the blocking temperature T_B (Figure 4). It depends on the effective anisotropy constant, the size of MNPs, the applied magnetic field, and the experimental measuring time.

At temperatures well below T_B (or for relaxation times much longer than the characteristic measurement time), the net moments of superparamagnetic MNPs are quasistatic. Whereas, at temperatures well above T_B (or for relaxation times much shorter than characteristic measurement time), the moment reversals are so rapid that in zero external field the time-averaged net moment on the particles is zero.

4.434.2.1.3. Surface effects

As the particles size decreases, a large percentage of all the atoms in a nanoparticle are surface atoms, which implies that surface and interface effects become more important. For example, for face-centered cubic (fcc) cobalt with a diameter of around 1.6 nm, about 60% of the total number of spins are surface spins.[14] Owing to this large surface atoms/bulk atoms ratio, the surface spins make an important contribution to the magnetization. As shown in Figure 3, MNPs have large number of spins over their surfaces. Owing to the high surface activity of spins, the magnetization value of MNPs is reduced compared to the bulk value. The decrease of magnetization is also attributed to the presence of a magnetic dead layer on the MNP surface, spin-glass-like behavior of the surface spins, or the presence of canted spins. Another surface-driven effect is the enhancement of the magnetic anisotropy (K_{eff}) with decreasing particle size. Lastly, a magnetically inert surface coating, for example, silica or organic polymer, may modify the extent of the dipolar coupling between MNPs because its thickness controls the minimum distance between them. Overall, it must be concluded that the magnetic response of a system to an inert coating is rather complex and system-specific, so that no firm correlations can be established at present.

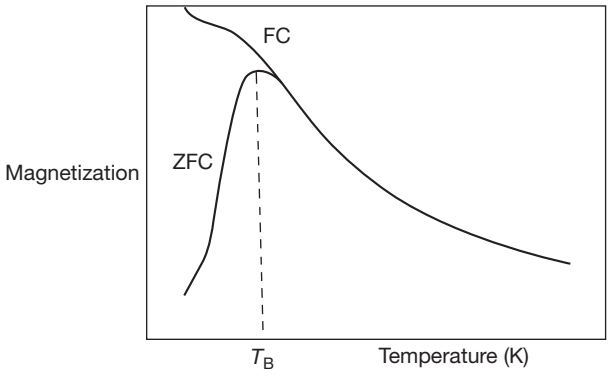

Figure 4 Typical magnetization versus temperature curves measured under zero-field cooling and field cooling conditions, respectively.

4.434.2.1.4. Forces exerted in magnetic field gradients

Magnetic field gradients are used to manipulate MNPs, because they are capable of exerting a force at a distance, whereas a uniform field gives rise to a torque, but no translational action.[8,15] For the case of a dilute suspension of MNPs in pure water (<5 vol%), it may be demonstrated that the magnetic force is

$$F_m = V(\chi - \chi_w)\nabla\left(\frac{B^2}{2\mu_0}\right) = V(\chi - \chi_w)\nabla\left(\frac{1}{2}BH\right) \quad [7]$$

where χ_w is the magnetic susceptibility of water. Therefore, the magnetic force is related to the differential of the magnetostatic field energy density $\frac{1}{2}BH$. Thus if $\chi > \chi_w$, the magnetic force acts in the direction of the steepest ascent of the energy density scalar field.

If the magnetic field gradient must immobilize MNPs by capturing them from a flowing liquid, this force needs to overcome the hydrodynamic drag force acting on the magnetic particle:

$$F_d = 6\pi\eta R_H(\upsilon - \upsilon_w) \quad [8]$$

where η is the viscosity of the liquid, and υ and υ_w are the velocities of MNPs and water, respectively. Equating the hydrodynamic drag and magnetic forces and writing:

$$V_H = 4/3\pi R_H^3 \quad [9]$$

gives the velocity of the MNPs relative to the fluid carrier as:

$$\Delta\upsilon = \frac{R_H^2\Delta\chi}{9\mu_0\eta}\nabla(B^2) = \frac{\xi}{\mu_0}\nabla(B^2) \quad [10]$$

where ξ is the magnetophoretic mobility of the particle, which indicates how 'manipulable' the MNPs are. The magnetophoretic mobility of magnetic microparticles can be much greater than that of nanoparticles, due to their larger size.

4.434.2.2. Behavior in AC Magnetic Fields

Returning to the hysteresis which gives rise to the open M–H curves seen for ferro- or ferrimagnets, it is clear that energy is needed to overcome the barrier to domain wall motion imposed by the intrinsic anisotropy and the pinning of

magnetic domain walls in the material. This energy is delivered by the applied field and can be characterized by the area enclosed by the hysteresis loop. This leads to the concept that if one applies a time-varying magnetic field to a ferro- or ferrimagnetic material, one can establish a situation in which there is a constant flow of energy into that material, which is perforce transferred into thermal energy. A similar argument regarding energy transfer can be made for superparamagnets, where the energy is needed to coherently align the particle moments to achieve the saturated state.[16]

4.434.2.2.1. Specific absorption rate

The heating ability of MFs in the presence of AC magnetic fields can be estimated by calorimetric method and it is termed as specific absorption rate (SAR). SAR is estimated on the basis of direct observation of temperature rise and can be defined as the amount of heat generated in a second by one gram of magnetic element:

$$\mathrm{SAR_T} = C\frac{m_\mathrm{S}}{m_\mathrm{M}}\frac{\mathrm{d}T}{\mathrm{d}t} \qquad [11]$$

where C is the specific heat capacity of the MF (or water in the case of diluted dispersions), $\mathrm{d}T/\mathrm{d}t$ is the slope of temperature versus time graph at the considered temperature T, m_S is the mass of MF and m_M is the mass of the magnetic element in the fluid.

Concerning the electromagnetic devices used for calorimetry experiments, the technology of an AC magnetic field is still under development. Most experiments were done with laboratory-made generators in the frequency range of 50 kHz to 1 MHz, with magnetic field amplitudes up to a few tens of kiloampere per meter. These parameters depended more on the technical availability of the generators used rather than on theoretical predictions for optimized SAR. Indeed, a frequency scan is technically tricky in this broad frequency range because of frequency-dependent skin effects and resistance of magnetic applicators. The majority of hyperthermia experiments were performed in an induction coil or in the air-gap of a magnetic inductor, cooled by water or air (Figure 5).

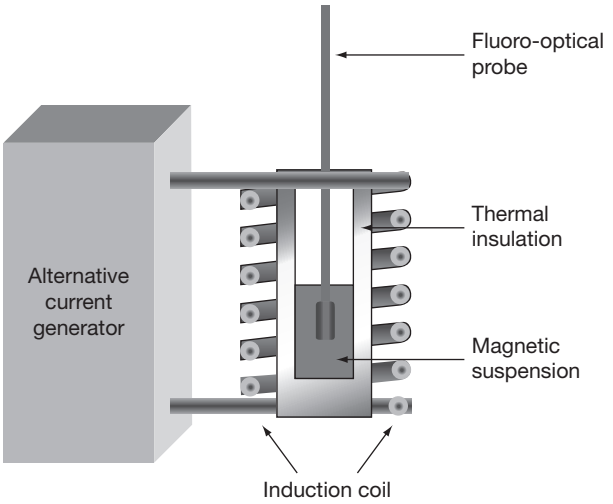

Figure 5 Typical laboratory inductor for the specific absorption rate measurement.

For clinical purposes, the heat generation, and hence, the SAR value, is very crucial. The higher the value, the lower is the injected dose. However, the SAR values measured by various scientists differed because of their strong dependence on factors such as the physical and chemical properties of the carrier fluid, the frequency and amplitude of the applied field, and the size, shape, surface coating, and chemical composition of the MNPs.[17] It is very difficult to give a general theoretical expression of SAR because of the large number of parameters.

4.434.2.2.2. Loss mechanisms

For ferro- or ferrimagnetic particles, their heating capability mainly results from hysteresis losses, and therefore, SAR is proportional to the field frequency and the area of the hysteresis loop.

The power loss of MFs based on superparamagnets in the presence of AC magnetic fields can also be determined on the basis of Néel and/or Brownian relaxation by:

$$P = \frac{(mH\omega\tau)^2}{2\tau kT\rho V(1+\omega^2\tau^2)} \qquad [12]$$

where ω is the angular frequency, ρ is the MNP density, T is the working temperature, and τ is the relaxation time (τ_N or τ_B).[17] It is worth mentioning that the Néel relaxation time depends exponentially on the core volume (V), while the Brown mechanism involves the hydrodynamic volume of the particles (V_H) that may differ from that of the crystalline cores due to the presence of a stabilizing shell or due to agglomeration.[18] The resulting diameter dependency of the corresponsive relaxation times is presented in Figure 6. In realistic systems, the faster process will dominate the overall remagnetization process, and for similar time scales, both mechanisms will contribute:

$$\tau_\mathrm{eff} = \frac{\tau_\mathrm{N}\tau_\mathrm{B}}{\tau_\mathrm{N}+\tau_\mathrm{B}} \qquad [13]$$

The power loss is expected to be maximum when $\omega\tau = 1$.

It is then observed that below a critical size of the particles, the Néel loss mechanism is more effective while above this the Brownian loss mechanism plays a major role. Near to the critical size, both types of losses act equivalently.

The Brownian losses generally depend upon hydrodynamic size of the particles, but not on the size of the magnetic cores. Therefore, the type and thickness of coating over the magnetic

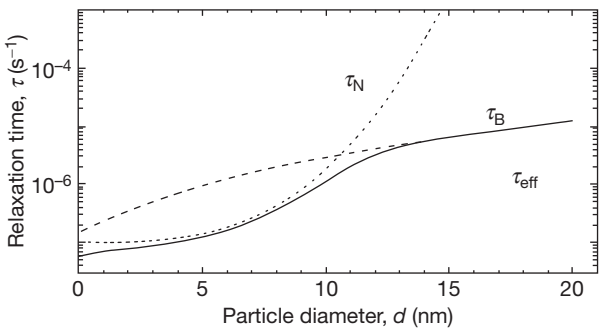

Figure 6 Theoretical Néel (τ_N) and Brown (τ_B) relaxation times and effective relaxation time (τ_eff) for Fe_3O_4 magnetic nanoparticles versus particle diameter. Reprinted with permission from Schmidt, A. M. *Colloid Polym. Sci.* **2007**, *285*, 953–966. Copyright © 2007 Springer Science.

materials can greatly influence heating. Lastly, in some situations, MFs based on ferro- and ferrimagnetic particles may also be concerned by Brownian losses.

4.434.3. MF Design and Preparation

4.434.3.1. Synthesis of MNPs

MNPs can be synthesized by a wide variety of techniques ranging from mechanical (top-down approach) to chemical processes (bottom-up approach). For *in vivo* applications, chemical processes are generally preferred, because they allow a better control of the purity, crystallinity, and size distribution. These processes include aqueous coprecipitation, thermal decomposition, sonochemistry, microemulsion, sol–gel, self-combustion, microwave refluxing, etc., for the synthesis of maghemite, magnetite, substituted iron oxides (γ–$M_xFe_{2-x}O_3$ or $M_xFe_{3-x}O_4$, where M = Al, Mn, Mg, Zn, Ni, Co, and Cu), metallic iron or cobalt and alloys such as FePt. For a detailed description of these synthetic routes, the reader will report on general review papers[13,14,19,20] or review papers more specifically dedicated to iron oxide MNPs for biomedical applications.[21–24]

These synthesis processes have their own benefits, but the achieved features of the MNPs depend strongly on the control of the experimental conditions. For instance, coprecipitation is a simple technique, but the type of salts (e.g., chlorides, sulfates, and nitrates), the cation oxidation states, the reaction temperature, the pH value and ionic strength of the media greatly influence the size, shape, and composition of the final particles. Moreover, the morphology and size of the nanoparticles synthesized by thermal decomposition process greatly depend upon the ratios of the organometallic precursor, solvent, and surfactant, the temperature, and the reaction duration.

4.434.3.2. Colloidal Stabilization in Physiological Medium

Like other dispersions, aqueous MNPs dispersions are subjected to a number of destabilizing forces that can lead to phase separation due to flocculation and sedimentation.[18] One of the main causes of phase separation is the Van der Waals interactions between the high-surface particles that result in the formation of agglomerated material. In contrast to this, the sedimentation of single particles by gravitational force is prevented by thermal motion in the size range up to 20 nm. However, by the formation of small agglomerates due to the Van der Waals interactions, thermal motion is greatly reduced, and sedimentation may play an important role in the destabilization of a magnetic colloid.

As an additional challenge, the magnetic dipolar particles also possess magnetic interactions in relation to their relative distance that may be further enhanced by alignment of the dipoles in outer magnetic field gradients.[25] Consequently, the colloids have to be stabilized against agglomeration by creating a protecting shell for each particle that prevents the particles from coming too close in contact with each other. This is possible using classical concepts from colloid chemistry, including electrostatic stabilization and steric stabilization.

As an example of electrostatically stabilized MFs, maghemite-based cationic fluids are easily prepared according to the method described by Massart.[26] In this process, magnetite nanoparticles are initially prepared by alkaline coprecipitation of iron (II) and iron (III) precursors in aqueous solution with an excess of concentrated ammonium hydroxide. Magnetite is oxidized into maghemite by heating in the presence of HNO_3 and iron (III) nitrate. Maghemite particles are peptized in dilute HNO_3 solution to create positive surface charges on the particles. Washing and decantation with acetone using a magnet can remove the acidic precipitates. Simply by dispersing these particles into water produces aqueous MFs. For *in vivo* applications, surface-charged nanoparticles are not advised and steric stabilization is generally preferred to electrostatic stabilization for physiological reasons (*cf.* **Section 4.434.4.2**). That is why the MFs are often prepared into aqueous solution of hydrophilic macromolecules or such macromolecules are grafted onto MNPs in a second step.

4.434.4. Size/Surface Requirements with Regard to i.v. Administration

4.434.4.1. Biocompatibility

Similar to other biomaterials, the biocompatibility of MNPs is assessed successively *in vitro* with animal or human cells, followed by *in vivo* tests with animals, before human clinical trials[27,28] (see **Chapter 1.109, Bioactive Ceramics**).

For *in vitro* cytotoxic assays, the animal or human cells are generally grown on the culture plates. Well-grown cells are then treated with bare or surface-modified MNPs or MFs for several hours (up to 96 h). The effect of the nanoparticles on the cells is then estimated by the comparative study of treated and untreated cells (control) by visual counting of the viable cells. More sophisticated cell viability assays are generally performed. MTT assay is based on the reduction of the tetrazolium salt MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenytetrazolium bromide) to formazan by succinate dehydrogenase. The formazan product is then quantified spectrofluorometrically, and hence, directly correlated to the activity of mitochondrial reductase enzymes. In sulforhodamine-B (SRB) assay, SRB binds to the basic amino acids of the cellular proteins. Thus, colorimetric measurement of the bound dye provides an estimate of the total protein mass that is related to the cell number.

The distribution of MNPs on the cells can also be estimated by staining the treated or untreated cells with Pearl's Prussian blue (which stains mainly Fe^{3+}) or with Turnbull's reagent (which stains Fe^{2+} ions).

Animals such as mice, rabbits, dogs, and sheep are often chosen for experimental *in vivo* studies. The animals are grown under the prescribed guidelines of the animal ethics committee. The required dose of MF is then injected into the body of the animal and all the clinical changes are observed very carefully. For different time periods, blood samples are collected for hematological and serum biochemical analysis. During hematological analysis, the amount of hemoglobin, platelets, erythrocytes, leukocytes, neutrophiles, lymphocytes, monocytes, basophiles, eosinophiles, and hematocrit are generally compared with that of the untreated animal. In serum biochemical analysis, serum level of total protein, bilirubin,

albumin, glucose, cholesterol, alanine transaminase, aspartate transaminase, triglyceride, blood urea nitrogen, phosphorus, creatinine, calcium, and lactic acid dehydrogenase are compared with those of normal untreated animals.

It seems difficult to assert today which nanoparticles are toxic and which ones are not. MNPs absorption, distribution, metabolism, excretion, and toxicity depend on multiple factors derived from inherent physicochemical properties such as concentration, size, surface charge, nature of the surface chemical groups, and redox activity. First, the toxicity of particles that may dissolve in physiological conditions even at a very low rate has to be considered also from the viewpoint of the toxicity of the released metal cations. In such situations, endogenous elements such as iron cations are preferred because the soluble iron becomes part of the normal iron pool (e.g., ferritin, hemosiderin, transferritin, hemoglobin).[29] The lethal dose LD_{50} of pristine iron oxide nanoparticles is 300–600 mg_{Fe} per kilogram of body mass. A barrier coating may be engineered around each nanoparticle in the case of toxic metal elements. Second, in the case of insoluble particles, surfaces matter more than chemical composition, and efforts are in progress for embedding MNPs in biocompatible coating, often made of hydrophilic macromolecules and/or silica.

It is obvious that the MNPs toxicity is directly related to the concentration required for the diagnostic or therapeutic effect. Once the active targeting strategies (*cf.* **Section 4.434.4.3**) become efficient, and hence, allow concentrating MNPs essentially in the targeted organs, MNPs nontoxicity will become a less-acute requirement.

4.434.4.2. Biodistribution and Passive Targeting Strategies

As soon as bare particles are, intentionally or otherwise, injected in the blood compartment, they are subjected to the action of the mononuclear phagocyte system (MPS).[30,31] It is defined as the cell family comprising bone marrow progenitors, blood monocytes, and tissue macrophages (such as Kupffer cells in liver). These macrophages are widely distributed and strategically placed in many tissues of the body to recognize and clear senescent cells, invading microorganisms or particles. The first step of the clearance mechanism is the opsonization process. Opsonins are circulating plasma proteins (various subclasses of immunoglobulins, complement proteins, fibronectin, etc.), that adsorb themselves spontaneously onto the surface of any invading entity. They are capable of interacting with the specialized plasma membrane receptors on monocytes and macrophages, thus promoting particle recognition by these cells. The second step consists in the endocytosis/phagocytosis of the particles by the circulating monocytes or the fixed macrophages, leading to their elimination from circulation and their simultaneous concentration in organs with high phagocytic activity. Therefore after i.v. administration, particles are cleared up within minutes from the bloodstream; their typical final biodistribution is 80–90% in the liver, 5–8% in the spleen and 1–2% in the bone marrow.[4] Consequently, the remarkable organization of the immune system is not compatible with long circulation times of any invading nanoparticle and MPS-mediated clearance is a major factor in determining their biodistribution. Nevertheless, it has provided an opportunity for the efficient delivery of therapeutic agents to these phagocytic cells, and therefore, to the related organs and more generally to any area where the macrophage activity is high, for example, infection/inflammation regions. Such an MPS-mediated targeting is called passive targeting.

If monocytes and macrophages are not the desired target, minimizing or delaying the nanoparticle uptake by the MPS is mandatory. The most satisfactory strategy consists of designing macrophage-evading nanoparticles (stealth nanoparticles) with plasma half-life as long as possible in order to increase the probability to attain the desired target. The more efficient route is to prevent the opsonin adsorption and therefore to avoid the macrophage recognition. Among the physicochemical factors which are known to affect the opsonization process, the size, the surface charge density, and the hydrophilicity/hydrophobicity balance have been widely studied.[30] Therefore, the smaller, the more neutral, and the more hydrophilic the carrier surface is, the longer is its plasma half-life.

In particular for hydrophobic particles, many studies concerned the development of core-corona structures where the corona is made of hydrophilic macromolecules for creating polymer brushes, acting as a steric surface barrier and reducing opsonin adsorption. Among the natural or artificial macromolecules, linear dextrans and derivatives are widely used. Other biological macromolecules have been investigated, for example, poly(sialic acid), heparin, and heparin-like polysaccharides complement regulatory proteins, etc., but because of their high cost and/or the possible immunological consequences associated with bacterial-made macromolecules, efforts have been directed to design synthetic hydrophilic macromolecules. Among these synthetic macromolecules, great efforts have dealt with the covalent anchorage of poly(ethylene glycol) (PEG) macromolecules onto the particle surface. Such a route is well known in galenical pharmacology where drugs (small molecules, but also peptides, proteins, antibodies, and oligonucleotides) are conjugated to PEG macromolecules to improve their circulation lifetime and bioavailability, and to decrease their immunogenicity, renal clearance rate, and dosing frequency.[4] This process is so widely used that it is called 'PEGylation.' In fact, PEG is a flexible polyether, hydrophilic (but also soluble in some organic media), not biodegradable, but easily excreted from living organisms. Its functional endgroups are available for derivatization leading to numerous routes for covalent attachment onto preformed functional surfaces or anchoring during the synthesis of particles. PEG has been shown to be the most effective polymer for suppressing protein adsorption, the optimal molecular weight varying between 2000 and 5000 g mol^{-1}.[30] These values are still in debate, and in particular, the surface density appears to be as important as the molecular weight.[31]

The escape of macrophage-evading particles from the circulation is normally restricted to sites where the capillaries have opened fenestrations as in the sinus endothelium of the liver or when the integrity of the endothelial barrier is perturbed by inflammatory processes (e.g., rheumatoid arthritis, infarction, infections) or by some types of tumors. Therefore the idea of exploiting such vascular abnormalities for extravasating and accumulating nanoparticles in these inflammatory sites or tumors is also particularly attractive. Such a strategy is also considered as a passive targeting one, but independently of the MPS mediation.

4.434.4.3. Active Targeting Strategies

For increasing the probability of redirecting long-circulating particles to the desired target, their surface has to be labeled with ligands that specifically bind to surface epitopes or receptors on the target sites (molecular recognition processes such as antibody–antigen interactions). Such a strategy should open the possibility of targeting specific cell types or subsets of cells within the vasculature and even elements of vascular emboli and thrombi.[31–34] In the case of cancer therapy, active targeting could allow the selective destruction of cancer cells, even if they have escaped the tumor mass and disseminated as metastatic cells.

These ligands must be coupled to the surface of stealth carriers. They include oligosaccharides, oligopeptides, folic acid, antibodies, and their fragments. The antibody coupling has at least two drawbacks: the overall dimensions of the antibodies (~20 nm), which cause particles to diffuse poorly through biological barriers, and their immunogenicity, that is, the property of being able to evoke an immune response within an organism. For this reason, the coupling of small nonimmunogenic ligands has been also investigated. Therefore, as an example of tumor targeting, folic acid (vitamin B essential for cell-division processes) may be used to take advantage of the frequent overexpression of folate receptors onto the surface of human cancer cells.[35] Interestingly, nanoparticles conjugated with folic acid appeared to interact more efficiently with folate receptors than free folic acid. This amazing result was interpreted as the consequence of the multivalent (and hence stronger) interaction of conjugated nanoparticles with the folate receptors, which are often arranged as clusters.

4.434.4.4. Surface Activation and Bioconjugation

In particular for active targeting purpose, the surface of MNPs shall be derivatized. The process of proper linkage of biomolecules with nanoparticles under mild conditions is commonly called bioconjugation. Two main approaches to attach biomolecules on the surface of MNPs are physisorption and chemisorption. In physisorption, biomolecules directly attach to the surface of particles owing to weak interaction (electrostatic or Van der Waals forces), whereas, in chemisorption, biomolecules attach by the formation of covalent chemical bonds.

Oxide or metal nanoparticles, by themselves, may not be capable of covalent attachment to biomolecules owing to their poor surface chemical properties. Hence, surface activation is required to create the chemical functions needed for coupling biomolecules to MNPs. The direct surface modification of metal oxides generally uses carboxylic acids, alkyltrialkoxysilanes, or alkyl phosphonates. A reactive function such as amino, thiol, aldehyde, carboxylic group is generally present on the alkyl fragment and becomes the main surface group. A coupling agent is generally required for linking this surface function with biomolecules (Table 2).

In numerous situations, the direct coupling with the inorganic surface is not preferred and one alternative strategy consists in taking advantage of the intrinsic reactivity of the hydrophilic macromolecules used for embedding and sterically stabilizing MNPs. In this way, the creation of nanoparticle libraries was recently reported on the basis of MNPs of iron oxide entrapped in a cross-linked corona of dextran bearing amino functions (Figure 7).

Table 2 Nonexhaustive list of coupling strategies of biomolecules on the activated surface of MNPs

Surface reactive function available on MNPs	*Reactive function available on biomolecules*	*Possible coupling agent*
Surface reactive function available on MNPs	Reactive function available on biomolecules	Possible coupling agent
$-COOH$	$-NH_2$	Sulfo-*N*-hydroxysuccimide
$-NH_2$	$-COOH$	Sulfo-*N*-hydroxysuccimide
$-NH_2$	$-NH_2$	Glutaraldéhyde
$-NH_2$	$-SH$	Sulfo-SMCC[a]
$-SH$	$-NH_2$	Sulfo-SMCC[a]
$-OH$	$-NH_2$	Carbonyl diimidazole

[a]SMCC: succinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate.

4.434.5. MNPs as Contrast Agents for MRI

4.434.5.1. MRI Background

Medical applications of MRI have steadily widened over the past decade and MRI is now one of the preferred cross-sectional imaging modalities.[8,36] It is based on nuclear magnetic resonance (NMR) signal of protons from water in tissues, membrane lipids, proteins, etc., through the combined effect of a static magnetic field B_0 up to 3 T in current clinical apparatus and a transverse rf-field (5–100 MHz). After the rf-sequence, the net magnetization vector is once again influenced by B_0 and tries to realign with it along the longitudinal axis as protons attempt to return to a state of equilibrium: this phenomenon is called relaxation. This relaxation can be divided into two different, independent processes: (i) longitudinal relaxation, which is the return of longitudinal magnetization in alignment with B_0 and is termed T_1-recovery; and (ii) transverse relaxation, which is the vanishing of transverse magnetization and is termed T_2-decay. As the hydrogen atoms release the previously absorbed energy to the surrounding tissue (lattice) in their attempt to realign with B_0, T_1 recovery is also referred to as 'spin–lattice' relaxation. As a time constant, T_1 is the time it takes for 63% of the longitudinal magnetization to recover in the tissue. On the contrary, T_2 decay is not a process of dissipation or absorption of energy into tissue. During the rf-pulse, hydrogen nuclei are spinning in phase with each other. After the rf-pulse, the magnetic fields of all the nuclei interact with each other; energy is exchanged between those nuclei. The nuclei lose their phase coherence and spin in a random fashion. Because T_2 decay is the result of the exchange of energy between spinning protons, it is referred to as 'spin–spin' relaxation. Therefore T_2 is the time it takes for the transverse magnetization to decrease to 37% of its initial value. Owing to their different T_1 and T_2 relaxation, tissues may be differentiated.

In order to correlate the signal to its spatial origin, at least one of the two fields (i.e., B_0 or the rf-field) has to vary over space. Relaxation data are collected by a computer which applies a two-dimensional (2D) Fourier transform to give the amplitudes of NMR signals and permits reconstruction of the 3D images. Thanks to sequence parameters such as the repetition time TR (elapsed time between successive rf excitation

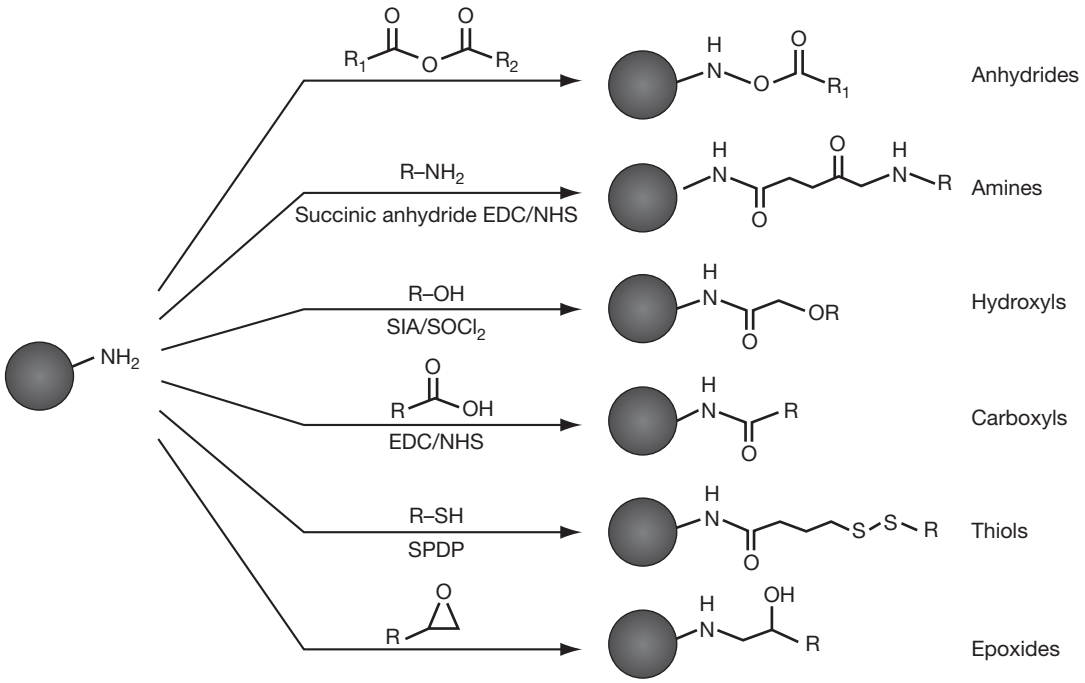

Figure 7 Conjugation strategies from iron oxide magnetic nanoparticles entrapped in a cross-linked corona of dextran bearing amino functions. Redrawn from Sun, E. Y.; Josephson, L.; Kelly, K. A.; Weissleder, R. *Bioconjugate Chem.* **2006**, *17*, 109–113.

pulses) and the delay time TE (time interval between the rf-pulse and the measurement of the first signal), the operator obtains the desired type of image contrast. Basically, short TRs increase T_1 effects, whereas long TRs allow tissues to reach complete longitudinal magnetization, reducing T_1 effects. Short TEs minimize T_2 effects of tissues whereas long TEs allow the loss of transverse signal, enhancing T_2 effects.

Therefore T_1-weighted imaging is obtained by utilizing a short TR and a short TE, allowing full recovery of tissues with a short T_1 (e.g., fat) while allowing only partial recovery of tissues with long T_1 (e.g., cerebrospinal fluid). On the other hand, for T_2-weighted imaging, long TRs and long TEs are used. Fluids have a very long T_2 and they are frequently associated with pathologies (e.g., internal injuries, cancer lesions), so T_2-weighted images are generally preferred for such diagnostics.

4.434.5.2. MR Contrast Agents

In actual practice, tissues may be differentiated on MR images because T_1 and T_2 depend on proton environment. However, in many clinical situations, these intrinsic differences are small and exogenous contrast media are sometimes required for a better delineation of tissues. These media are paramagnetic substances that allow altering the proton relaxation times. This ability to increase the relaxation rates of surrounding proton spins is called relaxivity $r_{1,2}$ and defined as:

$$(1/T_{1,2})_{\text{in presence of contrast agent}} = (1/T_{1,2})_{\text{without contrast agent}} + r_{1,2}[\text{contrast agent}]$$

where [contrast agent] is the contrast agent concentration in millimolars.

The first generation of these contrast agents consisted of high spin paramagnetic ions, usually Gd^{3+} in very stable nontoxic chelate form obtained through complexation by low molecular weight chelating molecules, such as diethylenetriaminepentaacetic acid.[37] Gd-chelates have an extracellular distribution before their excretion by the kidneys. Hydrogen atoms of water in proximity to such chelates experience a faster T_1-relaxation ($r_1 = 3.7\,\text{mM}^{-1}\,\text{s}^{-1}$). Consequently, differences in agent concentration result in contrast enhancement on T_1-weighted images ('positive' contrast). They have to be administered in concentrations of about $0.1\,\text{mmol}\,\text{kg}^{-1}$ of body mass to produce visible effects on the images. Gd-chelates are routinely used for distribution into the intravascular and interstitial space to enhance signal of fluid compartments or lesions (renal function, status of the blood–brain barrier, etc.). Their main disadvantages are their short plasma half-life and their relatively low relaxivity.

Superparamagnetic MNPs have also been developed as MR contrast agents because of their larger magnetic moment in the presence of B_0 (susceptibility agents).[2,38] Therefore, their relaxivity is much higher ($r_1 = 10$–$15\,\text{mM}^{-1}\,\text{s}^{-1}$ and $r_2 = 40$–$190\,\text{mM}^{-1}\,\text{s}^{-1}$) than that of Gd-chelates. In most situations, they are used for their significant capacity to produce predominantly T_2 relaxation effects, which result in signal reduction on T_2-weighted images ('negative' contrast). Basically, the phenomenon may be described from the large magnetic field heterogeneity around the nanoparticle through which water molecules diffuse. This predominant effect on the T_2 relaxation time does not prevent their use on the T_1 relaxation time on the condition of low concentrations and appropriate imaging sequences.

This new generation of contrast agents is often called (U)SPIO for (Ultrasmall) SuperParamagnetic Iron Oxide. They consist of nonstoechiometric iron oxide cores (3–10 nm in diameter), whose chemical composition varies continuously

from Fe_3O_4 to γ-Fe_2O_3. For i.v. administration, they are generally synthesized in a one-step process by alkaline coprecipitation or iron (II) and iron (III) precursors in aqueous solutions of hydrophilic macromolecules, essentially dextran or carboxydextran (see **Chapter 1.109, Bioactive Ceramics**). The role of this macromolecular corona is the limitation of the magnetic core growth during the synthesis, their steric stabilization in water (and later in physiological medium) and *in vivo* the reduction of the opsonization process. Interactions between magnetic cores and macromolecules are weak (essentially Van der Waals and hydrogen interactions) and generally prevent any efficient derivatization of dextran corona without macromolecule depletion.

(U)SPIO pharmacokinetics, biodistribution, and toxicity properties were studied and allowed to define the potential uses of these contrast agents. The lethal dose LD_{50} of a dextran–iron oxide complex was found to be 2000–6000 mg_{Fe} per kilogram of body mass, whereas it is 300–600 mg_{Fe} per kilogram for pristine iron oxide. (U)SPIO have in common their specific uptake by the MPS, explaining why, if they are not entirely captured by the liver and the spleen, they are currently widely evaluated as MRI contrast agents for the diagnosis of inflammatory and degenerative disorders associated with a high macrophage phagocytic activity. The nanoparticles are metabolized in lysosomes and it may be noticed that the iron load resulting from administration of the clinical dose ($\sim$1 mg_{Fe} per kilogram of body) is low compared with the total store in the human body (about 3500 mg).

4.434.5.3. Liver MR Imaging

SPIO, with a hydrodynamic diameter over 50 nm (up to 150 nm), are efficiently accumulated in MPS-organs ($\sim$80% of the injected dose in liver and 5–10% in the spleen with plasma half-life lower than 10 min). So, SPIO decrease liver and spleen signal within several minutes after i.v. administration. Malignant tumors or metastases as small as 2–3 mm, which are typically devoid of a substantial number of phagocytic Kupffer cells, appear as hyperintense (bright) lesions contrasted against the hypointense (black) liver on T_2-weighted sequences (**Figure 8**). The first SPIO, Endorem® (Guerbet, France), was marketed in Europe more than 15 years ago.

4.434.5.4. Metastatic Lymph Node MR Imaging (MR Lymphography)

Nodal disease is an independent adverse prognostic factor in many types of cancer. Thanks to their smaller size (lower than 40 nm) and the hydrophilicity of their dextran corona, USPIO may act as stealth particles; their plasma half-life is higher than 20 h and some particles leak to the interstitium, where they are cleared by the macrophages of the lymphatic system or drained via the lymphatic system and subsequently accumulated in the lymph nodes. So, they allow diagnosing hyperplastic and tumorous lymph node by MR lymphography. A decrease in signal intensity indicates active uptake of particles into macrophages in normally functioning nodes, whereas metastatic nodes remain isointense with the precontrast image (**Figure 9**). Clinical trials have reached phase III using Sinerem® (Guerbet, France) for the detection of lymph node metastases (head and neck and pelvis regions).[2]

4.434.5.5. Blood Pool Imaging

Because USPIO are more slowly up taken by the liver and spleen than SPIO, they remain in the blood circulation for a longer time. On the other hand, USPIO have a much more favorable T_1/T_2 ratio that facilitates T_1-weighted MR techniques at low B_0 (lower than 0.5 T). So, USPIO significantly shorten the T_1 of blood during the first hours after i.v. injection and may be used as T_1-agent. Thanks to these combined features, Sinerem® has been evaluated as MR blood pool agents for indications such as evaluation of cerebral perfusion, myocardial or renal perfusion, angiography or detection of hepatic vascular lesions.[2]

4.434.5.6. Macrophage MR Imaging

Animal experiments and clinical studies are currently dedicated to USPIO-tagged macrophage imaging in several inflammatory and degenerative diseases. This modality could be used not only primarily for disease detection, but also for prediction and follow-up of the therapeutic efficacy.[2] Encouraging results were obtained in the case of cerebral ischemic lesions

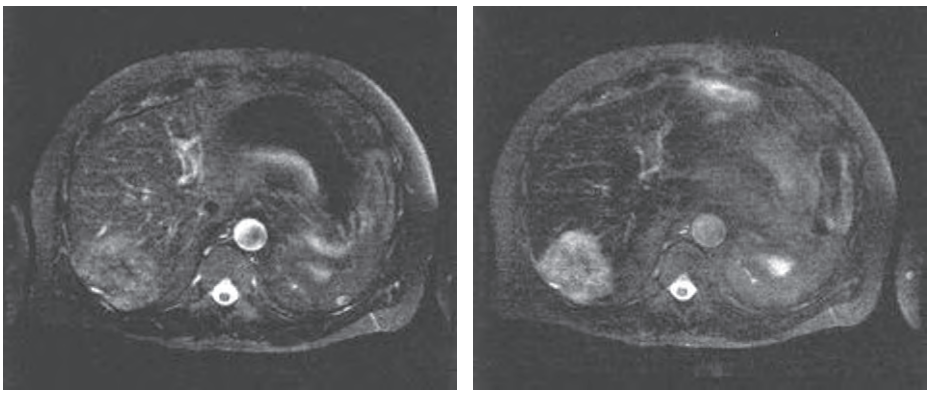

Figure 8 Axial T_2-weighted sequence of human liver with signal metastasis in segment 6: (a) before and (b) following infusion of Endorem®. Reprinted from Wallis, F.; Gilbert, F. J. *J. R. Coll. Surg. Edinb.* **1999**, *44*, 117–125, with permission from Elsevier.

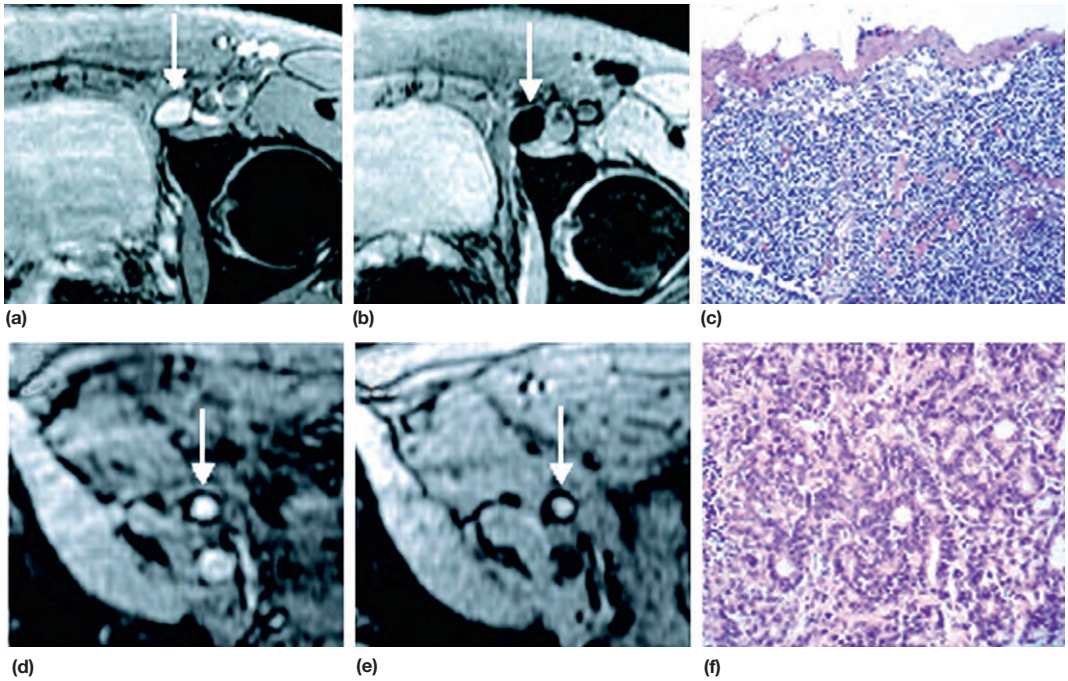

Figure 9 Magnetic resonance imaging nodal abnormalities in two patients with prostate cancer. As compared with conventional MRI (Panel A), MRI obtained 24 h after the administration of lymphotropic USPIO (Panel B) shows a homogeneous decrease in signal intensity due to the accumulation of lymphotropic superparamagnetic nanoparticles in a normal lymph node in the left iliac region (arrow). Panel C shows the corresponding histologic findings (hematoxylin and eosin, ×125). Conventional MRI shows a high signal intensity in an unenlarged iliac lymph node completely replaced by tumor (arrow in Panel D). Nodal signal intensity remains high (arrow in Panel E). Panel F shows the corresponding histologic findings (hematoxylin and eosin, ×200). Reprinted with permission from Harisinghani, M. G.; Barentsz, J.; Hahn, P. F.; *et al. New Engl. J. Med.* **2003**, *348*, 2491–2499. Copyright © 2003 Massachusetts Medical Society.

and brain inflammations, atheromatous plaques prone to rupture, multiple sclerosis, kidney disease, arthritis, infection caused by Staphylococcus aureus, and kidney and cardiac graft rejection. Moreover, USPIO are now reputed to be useful to evaluate (i) areas of blood–brain barrier dysfunction related to tumors and other neuroinflammatory pathologies, (ii) the cerebrovasculature using perfusion-weighted MRI sequences, and (iii) *in vivo* cellular tracking in central nervous system disease or injury.[39]

4.434.5.7. Molecular MR Imaging

Molecular MR imaging is one of the main MRI developments in progress, because clinicians dream about a contrast agent that would accumulate highly and specifically in malignant tumors, allowing an accurate diagnosis at a stage when the disease would be still treatable (see **Chapter 1.109, Bioactive Ceramics**). Such tools would also be of a great interest for cardiovascular, inflammatory and degenerative diseases. It concerns tissue-specific MR contrast agents.[37,40,41] Ligand-labeled (U)SPIO were designed (e.g., human polyclonal IgG, anti-carcinoembryonic antigen, anti-glioma, L6 antibody, anti-epidermal growth factor receptor, etc.) and investigations in small animals revealed that it is possible to achieve a distinct concentration of the magnetic label at the target. However, the required dose of the labeled antibody is still too high to make a commercial development realistic. That is why the use of small ligands, in particular, folate-mediation, appears more realistic for tumor MRI diagnostic. Lastly, spatial resolution is the key parameter for the detection of low concentrations of ligand-labeled (U)SPIO and the development of high magnetic field (up to 7 T) would allow achieving a high spatial resolution while maintaining a satisfactory signal-to-noise ratio.

4.434.5.8. Stem Cell Tracking

The development of stem-cell-based therapies requires quantitative and qualitative assessment of stem cell distribution to target organs (in the case of systemic administration), differentiation outcome, and engraftment. If labeled with MR contrast agents, they could be visualized and tracked by MR imaging. In the reported experiments, stem cells are generally labeled *in vivo* by using eventually a transfection agent (e.g., protamine sulphate, polylysine, cationic liposome, or cationic dendrimers) for USPIO, which are less efficiently internalized than larger SPIO. Labeled cells showed a gradual decline of intracellular iron oxide particles with increasing time after incubation, which can be attributed to cell division and exocytosis or release of iron from nonviable cells. Several experiments on animal models were reported and recently reviewed.[2]

4.434.5.9. Next Developments

Even if (U)SPIO contrast agents are now routinely used in hospitals, no precise structure/activity relationship has been

described to predict entirely their stability, as well as their pharmacokinetics and safety.[22] An extended physicochemical characterization is required but remains difficult owing to their small dimensions, reaching the analytical resolution limits of many commercial instruments.

In addition to the clinical developments presented in the previous sections, current efforts are concerning the improvement of the (U)SPIO platforms. In particular, their chemical stability is insufficient, if dextran macromolecules must be derivatized for bioconjugation (*cf.* Sections 4.434.5.2 and 145.5.7). Improvement may be achieved when dextran macromolecules are cross-linked in a second step for enhancing the mechanical entrapment of magnetic cores[42] or when they are chemically bonded to the magnetic cores through the use of coupling agents.[43]

In order to improve the MR contrast and/or decrease the magnetic core size, metal MNPs are currently investigated. Indeed, because of their higher saturation magnetization, larger effects on proton relaxation are expected. Moreover, below ~8 nm, inorganic nanoparticles can be readily excreted from the body by renal clearance.[44] For instance, cobalt, iron or FePt MNPs were recently obtained and evaluated as T_1 or T_2 contrast agents. Preliminary results were promising, nevertheless, chemical stability against oxidation, surface chemistry for bioconjugation, and toxicity/pharmacokinetics concerns shall be reconsidered in comparison to the well-known (U)SPIO. Enhanced MRI sensitivity was also achieved with $MnFe_2O_4$ MNPs that displayed the highest magnetic susceptibility and the strongest r_2 relaxivity value of $358\,mM^{-1}\,s^{-1}$ (to compare to $40–190\,mM^{-1}\,s^{-1}$ for conventional (U)SPIO). They would enable the MR detection of tumors as small as 50 mg ($2 \times 5 \times 5\,mm^3$).

Lastly, a significant development for the future of magnetic imaging in the human body concerns a new imaging modality, magnetic particle imaging (MPI), initially developed by Philips Research.[44] The technique takes advantage of the nonlinear magnetization curve of small magnetic particles to generate harmonic responses to time-varying fields that can be detected using standard lock-in methods to a high degree of precision, and with very little background signal to contend with. The imaging capability is the result of the following concept: that in the presence of a large enough DC magnetic field, the magnetization curve is flat, and as such, the harmonic signals disappear. The corollary of this is that if one applies a DC field to all but a small 'field-free point' on the sample, the only harmonic signal received comes from that field-free point, and all other signals are damped out. MPI has great potential for medical applications such as vascular or small intestine imaging, where fast dynamic information is required, and the targets are located relatively deep below the skin, the latter because the MPI signal is virtually unattenuated by intervening tissue.

4.434.6. MNPs as Mediators for Magnetic Hyperthermia

4.434.6.1. Hyperthermia Modalities

The choice of therapies against cancer such as surgery, radiation therapy, chemotherapy, hormone therapy, or biological therapy depends to a great extent upon the type and location of the cancer, the stage of the disease, age, and general health of the patient. Each has its own limitations, as they cause severe side effects to the surrounding tissues in the case of localized therapy and to the whole body in the case of systemic therapy. Heat, due to its intrinsic nature, can be applied locally or to the whole body according to the requirements and found to cause comparatively less side effects. Further, both *in vitro* and *in vivo* studies and clinical experiments showed improved results when hyperthermia is applied in combination with other therapies such as chemo- or radiotherapy.[45]

As the name indicates, the hyperthermia treatment is generally carried out in the temperature range of 42–46 °C, which is above physiological growth temperature (for humans, it is above 37 °C). This is termed as mild hyperthermia. In the above temperature range, tumor hypoxic (poorly oxygenated) cells are more heat-sensitive compared to the normal euoxic (well oxygenated) cells. Hence, the normal cells survive, while the cancerous cells get killed; this creates an interesting way for the therapy of cancer with minimal side effects. In addition, the cancerous tissues have inadequate blood supply, and thus, are not able to dissipate heat energy at the same rate as that of normal ones. Hyperthermia is applied sometimes above 46 °C and it is termed as thermoablation. The effect of hyperthermia exclusively depends upon the treatment temperature and on the exposure time at that temperature. Interestingly, it has been observed that a temperature decline of 1 °C in the temperature range of 42.5–47 °C required doubling of the exposition time, whereas below 42.5 °C, the heat exposure time has to be prolonged by four times to get the same effect.

Hyperthermia during *in vitro* studies can cause several morphological changes in the cells and can detach them from the culture flask and finally kill them.[46] The mechanism of heat-induced cell death causes numerous cellular changes such as in the cell membrane, pH, nuclear and cytoskeleton structures, cellular metabolism, macromolecular synthesis, intracellular signal transduction in hormone–receptor interactions, expression of the heat shock proteins, chromatin organization, and synthesis of DNA and RNA. The degeneration of mitochondria, enzymes, and various kinds of proteins also get induced by hyperthermia.

The cell death due to hyperthermia could be classified either by apoptosis or necrosis. Apoptosis is an orderly process of programmed cell death and can be characterized by distinct morphological features such as nuclear condensation, membrane blebbing, blisters, and echinoid. On the other hand, thermoablation treatment induces necrotic cell death, which is a pathologic phenomenon; it usually occurs when the cells find it difficult to survive following a major external damage. Necrotic cells have swollen nuclei without chromatin condensation, and can be characterized by a gradual dissolution of cell structure and lysis of the plasma membrane.

The selection of hyperthermia modalities that can be applied locally or to the whole body generally depends upon the heating source and on the types of cancer. On the basis of types of heating source, it can be divided into three groups, namely, heat applied from external source (e.g., hot bath, air, wax, blanket), contactless sources (e.g., radiofrequency, ultrasound, microwave, and infrared devices), and heat source inserted into body (e.g., probes, antenna, laser fibers, and mediators).[43]

The advanced hyperthermia devices such as ultrasound or electromagnetic radiation have their own limitations as the heat energy generated by them cannot be delivered to deeply situated cancer tissues without destroying the surrounding normal one. However, this could be overcome by inserting the heating source mediators inside the body where the electromagnetic energy applied on these deep situated mediators by an external electrical or magnetic field gets transformed into heat.

The inserted mediators can be either of macro-, micro-, or nanometric size and they can be stimulated either by capacitive applicators using the electrical component of electromagnetic fields (E-field), or by inductive applicators using magnetic component (H-field). Macroscopic mediators must be inserted within the body by surgical intervention, whereas micro- or nanoscale mediators can be injected as particle dispersion. However, during capacitive heating, E-field may cause heating of the surrounding tissues due to their conducting nature. Further, the difference in the dielectric permeabilities of different tissues leads to inhomogeneous temperature rise. On the other hand, in inductive mediator heating, this problem could be overcome as body tissues do not produce any heat in the presence of AC magnetic field. However, to negate the effect of E-field completely, the optimized value of the product of Hf (where H is the amplitude and f the frequency of the AC magnetic field) is restricted to $4.85 \times 10^8\,\mathrm{A\,m^{-1}\,s^{-1}}$ for a patient treated for an hour.[17] Depending on the diameter of the exposed body region, on the duration of treatment, and on the seriousness of the illness, this critical product may be exceeded. Moreover, to avoid neuromuscular electrostimulation, the frequency should be higher than 50 kHz and it should be lower than 10 MHz for appropriate penetration of the rf-field.

4.434.6.2. Magnetic Fluid Hyperthermia

Even by stressful intervention, the macroscopic inductive heating mediators such as ferromagnetic rods or seeds (1-mm diameter and 1–7-cm of length) cannot be accessible to all tumors. Nevertheless, lack of uniform temperature may also cause potential thermal underdosage to some critical regions. Hence, the magnetic fluid hyperthermia (MFH), in which colloidal dispersion of inductive heating mediators of micro- or nanoscale is used, appears as the most promising therapy. In this case, the particles could be homogeneously distributed due to their ultramicron size, and hence, could produce uniform temperature all around the tissue. It has already been discussed that the cells uptake MNPs by endocytosis and the uptake by the cancerous tissue is even higher owing to their leaky vasculature, which is further helpful during cancer therapy. There is the benefit of stable deposits of MNPs surrounding the tumor tissues in the sense that once the particles are applied, then repeated thermotherapy can be performed without any further addition of particles. Even the daughter cells from a particle-containing parent cell should contain up to 50% of the particle amount of the parent cell, and thus, the descendants would still be cured by future MFH sessions.

The concept of using magnetic hyperthermia as cancer therapy was initiated by Gilchrist and coll. in the late fifties.[47] After a considerable gap, investigations were renewed *in vitro*, and now, *in vivo*. Today, in oncology, there are at least two complementary clinical strategies being developed by Australian and German research teams, using nanocomposite magnetic microparticles and surface-modified superparamagnetic nanoparticles, respectively.

4.434.6.2.1. Nanocomposite magnetic microparticles administered by arterial embolization

This administration route exploits the fact that liver tumors are irrigated mainly by the hepatic arterial system, while healthy liver cells are supplied by the portal vein system. Experiments have been carried out on rabbits and pigs, yielding iron concentrations in the tumor five times higher than in the healthy tissues. The first experiments used 150-nm maghemite particles suspended in lipiodol (a mixture of iodine and vegetable oil, known for its ability to trap anticancer molecules in the chaotic network of blood vessels in tumors). Under magnetic induction conditions of 53 kHz and $30\,\mathrm{kA\,m^{-1}}$, an intratumoral temperature of 48 °C was reached in 5 min. However, since lipiodol proved to be too vasoocclusive for hepatic use, leading to extended necrosis, the maghemite particles were then encapsulated in polymer beads of average diameter 32 μm, dispersed in a 1% aqueous solution of dispersant (Tween) (Thermo-spheres®, registered trademark of SIRTeX Medical Ltd, Sidney). These beads have been shown to be nontoxic and well tolerated and positive results were obtained on animals.[48]

4.434.6.2.2. Superparamagnetic nanoparticles injected directly into the tumor

The first studies used magnetite nanoparticles surrounded by a dextran corona similar to the (U)SPIO contrast agents developed for MRI. *In vitro* experiments showed that these nanoparticles were internalized by cancer cells. Applying an alternating magnetic field (520 kHz, $7–13\,\mathrm{kA\,m^{-1}}$) caused the tumor to diminish in the same way as it would in a bath of hot water. Subsequently, dextran was abandoned because it would appear to degrade too soon. It was then shown that direct injection of particles into the tumor has an advantage (still not fully understood) called the thermal bystander effect: even though the particles are concentrated at the deposition points before applying the alternating magnetic field, they distribute themselves much more uniformly after the first application of the alternating magnetic field.[49]

Jordan, Maier-Hauff and their collaborators at Clinique Charité in Berlin are now the most famous clinical research team, because they developed a full-sized human magnetic field applicator (MFH® 300 F, Hyperthermiesystem GmbH, Berlin at a frequency: 100 kHz, variable field strength: $2.5–18\,\mathrm{kA\,m^{-1}}$, **Figure 10**) and a biocompatible MF made now of surface-aminated magnetite nanoparticles (MagForce Applications GmBH, Berlin and MagForce Nanotechnologies AG, Berlin, Germany), and they performed the first-ever clinical studies based on MFH. The MNPs dispersion is injected within the tumor under general anesthesia. To solve the problem of the temperature distribution, numerical simulations based on tomographic images of the tumor allow optimizing the position of the MNPs deposits (**Figure 11**). The expected heat distribution within the tumor is estimated by the NanoPlan® software planning system (MagForce Nanotechnologies AG, Berlin, Germany).

Phase I clinical trials (feasibility studies) were performed to patients having prostrate carcinoma,[50] as well as glioblastoma multiforme.[51] This last study involved 14 patients receiving treatment via a combination of fractionated external beam radiotherapy and several sessions of thermotherapy. Aminated-MNPs were injected into multiple sites throughout each tumor. The choice of injection sites was based on data from a comprehensive series of MRI scans of the cranium coupled with the NanoPlan® software. The SPIO nanoparticles (core size 15 nm) were dispersed in water at a concentration of 112 $mg_{Fe}\,ml^{-1}$. Each tumor was injected with 0.1–0.7 ml of the MF per milliliter of tumor and then exposed to a magnetic field of 3.8–13.5 $kA\,m^{-1}$ alternating at 100 kHz. The study successfully demonstrated that this form of thermotherapy using MNPs could be safely applied to the treatment of brain tumors and that hyperthermic temperatures could be achieved. Follow-up computed tomography scans and reproducible temperature measurements confirmed that these deposits were stable over several weeks. Patient survival and local tumor control were not considered primary endpoints of this study; however, clinical outcomes were observed to be promising with the therapy being well tolerated by all patients. More complete evaluation of clinical outcomes is to be assessed in a phase II study (efficacy study) on 65 patients with recurrent glioblastoma multiforme. Phase I clinical trials concerning pancreatic and esophageal cancers and local recurrences of residual tumors (e.g., cervical and prostate cancers, sarcomas) are also in progress.

The rather long period of gestation from first *in vitro* studies to eventual clinical application reflects the considerable technological and regulatory difficulties to be overcome in any attempt to develop a clinically acceptable and useful therapy of this type.[44] It is not merely enough to develop MNPs that heat upon exposure to an AC magnetic field, although that is clearly an important prerequisite. It is also important to know how to appropriately administer enough of the particles to the intended target tissue and to be able to generate enough heat from them by exposure to a tolerable level of AC magnetic field that does not in itself cause any undesirable side effects. The methodology developed by the MagForce group successfully addresses each of these issues.

4.434.6.3. Next Developments

It is clear that if magnetically induced hyperthermia is to achieve the desired results, a certain number of aspects need to be improved. This includes not only the synthesis and properties of the MNPs-based mediators but also a better understanding of the physics involved in the loss phenomena, modeling of the *in vivo* temperature distribution, and development of a safe, efficient, and reasonably priced active targeting strategy.

4.434.6.3.1. Mediators improvement

Improving SAR values remains a challenging task, because the higher the SAR of the MNPs dispersion, the lower the dose to inject to the patient. Among the improvement routes, that which consists in the preparation of narrowed size-distribution MNPs is particularly pertinent for superparamagnetic mediators. Indeed, in conventional synthetic routes, the MNPs are far from being monodisperses in size, resulting in a distribution of relaxation times in the MNPs ensemble (eqn [5]). As a consequence, for a specific frequency of the AC magnetic field, only a small fraction of MNPs heat efficiently (those whose relaxation times are fitting). Therefore, narrowing the size distribution could greatly improve the SAR values, because all the MNPs will heat efficiently at the same frequency.

However, very efficient mediators should not forget that the temperature *in vivo* must be tuned very precisely (*cf.* Section 4.434.6.1) because, on the one hand, heat conduction and energy adsorption *in vivo* are widely unknown, and on the other hand, local overheating may damage safe tissue. An original route could exploit the temperature-dependence of magnetic properties of ferro-/ferrimagnets. So, it would consist in designing MNPs with a T_C adjusted to just above the temperature that should not be exceeded *in vivo*. In this way, should that temperature be reached, each nanoparticle mediator would function as its own fuse by losing its magnetic properties, and hence, also its heating capability. Such a strategy has already been developed for alloy seeds (macroscopic mediators) in order to prevent local tissue overheating and reduce the need for invasive thermometry. For MNPs, manganites ($La_{1-x}Sr_xMnO_3$) are promising materials whose T_C can be tuned in the range of 32–60 °C by varying the amount of Sr. The stabilization of temperature near T_C was observed for such MNPs when they were kept under AC magnetic fields.[52]

Their synthesis in the form of narrowed size-distribution MNPs, their biocompatibility, and surface chemistry are currently under investigation by several groups.

Some of these constraints pull in opposite directions, for example, under physiological conditions, maximal SAR values are attained for superparamagnetic compounds, while in principle, only ferromagnetic or ferrimagnetic compounds allow self-regulation. The aim here will thus be to find the best possible compromise. In addition, it does seem somewhat risky to depend only on Brownian relaxation to reach sufficiently high values of the SAR from the therapeutic point of view, because unfortunately, once in the target tissues, or target cells, it is not obvious that the particles will be able to turn round owing to a high local viscosity or strong interactions with the cell membranes.

4.434.6.3.2. Physics of magnetic loss phenomena

If the heating capacities of the mediators are to be improved, the models used up to now will need to be refined and extended, to increase their predictive power and to cover the whole range of sizes and magnetic behaviors. They must be systematically validated by experiment and the difficulties inherent in this approach will not be overcome without close collaboration between chemists and physicists, both in theory and practice. In particular, it is probably crucial to understand the influence of local clustering of MNPs in order to fully optimize the heating from real samples.[44] Moreover, SAR measurements by calorimetry must be performed in strict adiabatic conditions, that is, considering all the probable heat losses by convection, conduction, and radiation.[53]

As already discussed (*cf.* **Section 4.434.2.2.1**), SAR parameter is an extrinsic parameter which depends not only on the magnetic heating properties of the MNPs themselves, but also on external factors such as the AC magnetic field magnitude and frequency. In an attempt to allow better comparisons between measurements, the concept of intrinsic loss power (ILP) was recently introduced.[44] The ILP parameter is simply the SAR parameter normalized to H^2f. It may be easily derived from measured heat loss data, namely, the ILP measured in $\mathrm{nH\,m^2\,kg^{-1}}$ equals the SAR (in $\mathrm{W\,kg^{-1}}$) divided by the square of the field strength H (in $\mathrm{kA\,m^{-1}}$) and the frequency f (in kHz). The ILP concept may be a useful way to compare results from different groups who often obtain their results using different AC magnetic field conditions from one another. It would be also useful in making direct comparisons with theoretical models.

Lastly, modeling the temperature distribution *in vivo* remains a priority for determining the optimal ways of depositing energy, for example, continuously or in pulses.

4.434.6.3.3. Targeting strategies and limits

One of the last challenges will be to develop the intracellular hyperthermia route, which is based on i.v. administered stealth MNPs designed for selective uptake by tumor cells and which would be the optimal method allowing to selectively overheat tumor cells even in disseminated metastases in any region of the body. However, certain problems still exist as mentioned later.

The first one is the ligand-mediated targeting to improve the colloidal mediator uptake by cancer cells. Among several *in vitro* studies, a single group worked *in vivo*, with the use of ^{111}In-chimeric L6 monoclonal antibodies grafted onto dextran-coated iron oxide cores for human breast cancer in mice.[54] They reported a mean concentration of MNPs per gram of tumor of about 14% of the injected dose, equivalent to around 0.315 mg per gram of tumor (315 μg ml). This is an exceedingly small amount of MNPs being used to heat the tumor mass compared, for example, with the intratumoral concentrations obtained by the direct injection method of Jordan *et al.*, which were greater than $10\,\mathrm{mg\,ml^{-1}}$ of tumor.

The second one is the tissue distribution monitoring prior to the heating sequence. MRI appears to be the most suited method, and therefore, a great interest exists to investigate a unique and versatile magnetic device that will be able to reveal tumors and metastases and treat them by hyperthermia.

The last one concerns the debate about the expected higher efficacy of intracellular thermotherapy, that is, obtained with magnetic particles internalized within cells, with regard to extracellular thermotherapy. According to a theoretical model, it would seem that there is no thermotherapeutic effect on the nanoscale (the scale of the MNPs) or the microscale (the scale of the cells). In fact, thermotherapy operates on the millimeter scale (the scale of the tumor), since the thermal insulation behavior of the cell membrane is negligible.[55] Any difference that may be observed between intracellular and extracellular thermotherapy would thus appear to be due to a mechanical effect of rotation or vibration of the particles in the cell.

Extending this work to highlight the difficulties of using currently available MNPs to heat anything smaller than a 10-mm diameter tumor, an excellent analysis of the various opportunities and limitations was recently published.[56] The issue is essentially one of heat loss into the surrounding tissue. If one wishes to generate and sustain a large temperature imbalance within a tumor, the heat flow into that tumor has to be so large as to overcome the heat flow out. Roughly speaking, the bigger the tumor, the smaller the surface area to volume ratio, the less important the outward heat flow, and the easier it is to heat. Following this argument, the authors concluded that the MNPs SAR must be unrealistically high (certainly several orders of magnitude greater than the best currently reported) to heat a 3-mm cluster of cells, even with concentrations of iron in the cellular mass of $10–50\,\mathrm{mg\,ml^{-1}}$. These figures are relevant given that ~3 mm is the size of a subclinical metastasis that is undetectable by normal imaging techniques, and $10\,\mathrm{mg\,ml^{-1}}$ is substantially more than was used *in vivo* by DeNardo *et al.*, but in the realm of that used by Jordan *et al.* The situation becomes even worse if the aim is to heat individual cells.[44]

4.434.7. MNPs Within Carriers for Drug Delivery

The development of targeted delivery systems for drugs, proteins, genes, and Si-RNA has been one of the most sought after domain of research over the past decade in the broad area of nanotechnology. For the pharmaceutical industry, novel drug delivery technologies represent a strategic tool for expanding drug markets. Delivery systems offer many advantages over conventional dosage forms, including improved efficacy, reduced toxicity, improved patient compliance, and cost-effective therapeutic treatment. Drug delivery systems

capable of simultaneous targeting and controlled release can have an incredible impact on therapeutics.[57] Embedded in such systems, MNPs could become innovative tools for controlling the drug biodistribution in space (targeting) and time (controlled release kinetics).

4.434.7.1. Magnetic Guidance for Carriers

The principle of the magnetic guidance of drug delivery systems is based on submicronic particles containing simultaneously MNPs and drug molecules. When the carriers have entered the bloodstream, external high-gradient magnetic fields are used to concentrate them at a specific target site within the body (physical targeting).[8,13,58] Over the last few decades, a strategy has developed that uses nanocapsules, which are vesicular systems in which the drug is confined to a cavity along with MNPs surrounded by a unique polymer membrane, or nanospheres that are polymer matrix systems in which the drug and MNPs may be uniformly dispersed. The drug of interest may be also adsorbed or attached onto the surface.[21]

The main difficulties to overcome are the stealthiness toward the MPS, the *in vivo* aggregation of the particles and the inherent risk of embolization, the development of strong enough magnets for the targeting of deep tissues, and the disappointing results obtained in larger animal tests.[5] Indeed, preliminary investigations suggested that for most magnetite-based carriers, flux densities at the target site should be of the order of 0.2 T with field gradients of $\sim 8\,\mathrm{T\,m^{-1}}$ for femoral arteries and greater than $100\,\mathrm{T\,m^{-1}}$ for carotid arteries.[59]

A phase I clinical study was reported 10 years ago and concerned 14 patients with advanced unsuccessfully treated cancers or sarcomas.[60] The magnetic carriers were starch particles (50–150 nm) containing magnetic cores of iron oxyhydroxides and capable of adsorbing antitumoral drugs. Although rather a low response to the treatment was seen in the majority of the patients, the magnetic targeting was well tolerated. Evidences of the accumulation of carriers in the tumor mass were given and relatively light side effects were noticed.

Other clinical efforts were performed by FeRx, Inc., a privately held drug delivery company (currently out of business) pursuing the development and commercialization of its proprietary magnetic targeted carrier (MTC) drug delivery technology.[61] MTCs are microparticles composed of metallic iron and activated carbon, which serve as delivery vehicles for the site-specific targeting, retention, and release of pharmaceuticals. FeRx's completed phase I/II safety and dose escalation trial, conducted at seven sites throughout the United States, was designed to deliver MTC-doxorubicin to primary liver tumors. Thirty patients were treated, with no dose limiting toxicities observed, and with MTCs shown to successfully localize the drug in the tumor as demonstrated by MRI and tumor response. Unfortunately, the subsequent phase II/III clinical trials concerning 240 patients with primary liver cancer (hepatocellular carcinoma) were prematurely stopped because the endpoints appeared impossible to be met with statistical significance. The primary objective of this study was to detect a clinically and statistically significant increase in median survival time for MTC-Doxorubicin treated patients relative to patients treated with IV Doxorubicin. Other magnetic carriers are being in the pipeline of some companies.[62]

However, encouraging results emerged from a more recent clinical study concerning four patients and combining magnetic targeting and MRI, in which the authors were able to monitor the trans-catheter delivery of magnetically targeted doxorubicin to the hepatic artery using intra-procedural MRI.[63] The study demonstrated selective targeting to the tumor with a final fraction of treated tumor volume of 0.64–0.91 compared with only 0.07–0.30 in the normal liver tissue.

In order to create high-gradient magnetic fields, recent works demonstrated the interest to insert magnetic needles and meshes at the target site.[44] The potential advantages of planar, periodic magnetic bandages, and Halbach arrays for enhanced targeting were also modeled and evaluated.

The next challenges are a better knowledge of the hydrodynamics/field gradients correlation, the design of carriers of higher drug capacity, the combined use of specific ligands for increasing the targeting efficacy and retaining the particles in the vicinity of the target after removal of the external magnet, and an accurate control of the drug release.

4.434.7.2. Enhanced Drug Release Under the Mechanical Stress of an Oscillating Magnetic Field

The use of an oscillating magnetic field to modulate the rates of drug delivery from a polymer matrix was one of the first methodologies investigated to achieve an externally controlled drug delivery system. The field application leads the particles to oscillate and the drug to be released in these mechanical stress conditions. For instance, the release rate of insulin from poly (ethylene-*co*-(vinyl acetate)) loaded with 1-mm particles of $SmCo_5$ may be 50 times higher than in the absence of the magnetic field (0.5–60 Hz).[64] Today, as far as we know, this route seems to be abandoned since no recent paper deals with this strategy.

4.434.7.3. Heat-Triggered Drug Release Under AC Magnetic Field Control

A second strategy could take advantage of the ability of MNPs to heat in AC magnetic fields (see **Sections 4.434.2.2** and **145.6**). The temperature increase could greatly accelerate the drug diffusion across the carrier matrix. Some cross-linked hydrophilic polymers (hydrogels) are known to be thermosensitive (see **Chapter 1.109, Bioactive Ceramics**). It means that the homogenous solution of polymer starts undergoing phase transition from a soluble to insoluble state at a certain temperature, which is termed as cloud point or lowest critical solution temperature. So, even if its biocompatibility has not yet been demonstrated, copolymers based on N-isopropylacrylamide units suddenly collapse the structure causing a 'burst' release of the carried drug. A preliminary experiment was recently reported using ferromagnetic particles in an induction coil working at 10–50 $\mathrm{kA\,m^{-1}}$ and 300–500 kHz.[65]

4.434.8. Conclusion

In this chapter, recent advances in biomedical applications of MNPs are reviewed. Iron oxide MNPs are now routinely used as contrast agent in MRI and very next applications are expected

in the field of cancer thermal treatment, magnetic targeting, and remotely triggered drug release. These devices will be nanomaterials of higher and higher added value because they are expected to be multifunctional, smart, and versatile. Therefore their chemical composition shall be more and more hybrid combining inorganic, organic, and biologic components. Nevertheless, optimization efforts remain for improving the repeatability of surface functionalization, diagnostic or therapeutic efficacy, biodistribution, and *in vivo* stability and safety.

It is now expected that the next developments will also concern multifunctional platforms that will enable targeting specific organs, tissues, cells, or subcellular compartments, to be monitored by MRI, to carry drug and release it at the right place and time. Nevertheless, targeting remains the main challenge, for which concentrated efforts are required.

Such developments of medicine-directed nanotechnology are probably among the best examples where physicians, pharmacologists, biologists, chemists, and physicists are working together. In this day, when the public opinion worries rightly about the possible nanotechnology consequences on mankind and its environment, it is important to mention that the single aim of a large number of these research efforts on nanoparticles is the humanity survival and comfort.

5.501.1. Introduction

Tissue engineering has the ability to revolutionize the medical field and the treatment of patients. One methodology which is often used in tissue engineering combines cells, scaffolds, and signals to regenerate functional tissues (Figure 1). In this general model, scaffolds serve as the architecture that supports and directs cell growth in the presence of appropriate signals. While it is important to provide a three-dimensional structure to the cells for tissue development, the use of a scaffold introduces some obstacles that must be overcome in order to achieve a successfully engineered tissue. Some of the design challenges when using a scaffold include biocompatibility, mechanical stability, biodegradation, and mass transport. Likewise, a common design challenge is the introduction and sustenance of uniform cell distribution throughout the construct of isotropic tissues (for more information).[1]

5.501.2. Mass Transport within Scaffolds

The necessity for mass transfer within most tissues is evident from the fact that, in general, in native tissues, cells are not found further than 100 μm from blood capillaries.[2] Likewise, in tissue culture, the maximum cell layer thickness for which oxygen can be supplied by diffusion alone is 100–200 μm.[3] Simple diffusion through three-dimensional tissue-engineered scaffolds often does not provide sufficient amounts of oxygen and soluble nutrients needed for tissue regeneration *in vitro*.[1,4] Specifically, the boundary layer between the medium and the construct is resistant to mass transfer.[5] Therefore, specialized bioreactors have been designed to overcome this resistance to mass transfer through the boundary layer, including spinner flasks and rotating wall vessel bioreactors. In a study by Sikavitsas *et al.*,[6] differentiating osteoblasts cultured on scaffolds in spinner flasks and rotating wall vessel bioreactors exhibited high concentrations of cells and mineralization, in the form of calcium, around the exterior portion of the construct compared to statically cultured constructs. However, even if the boundary layer is overcome, mass transfer restrictions increase as we move further into the construct.[5]

Due to mass transfer limitations within scaffolds, many attempts to statically culture tissues *in vitro* led to constructs with viable cells and deposited extracellular matrix (ECM) on the exterior portion of the scaffold, leaving the interior devoid

of cells and ECM.[7] For example, poly(glycolic acid) scaffolds seeded with chondrocytes exhibited glycosaminoglycans (GAGs) on the outer surface of the scaffold with the interior relatively devoid of GAGs.[8,9] Likewise, osteoblasts cultured on biodegradable polymer scaffolds were only able to penetrate and develop mineralized tissue to a depth of ~200 μm.[10,11]

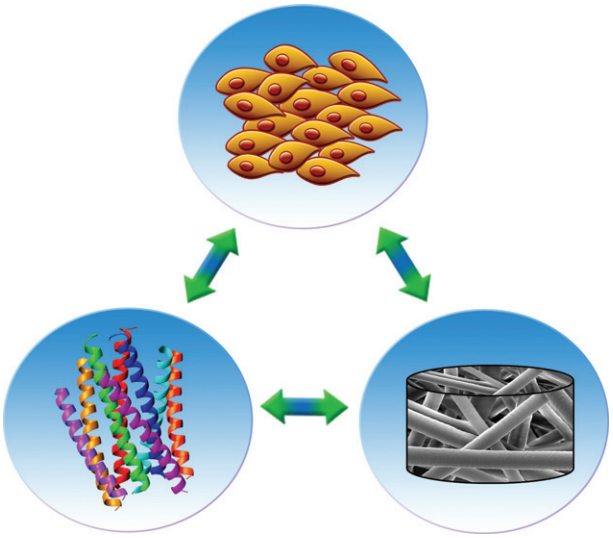

Figure 1 Tissue engineering paradigm. Cells, scaffolds, and signals are combined to regenerate functional tissues.

Beyond these cell penetration depths, necrosis occurs if adequate amounts of oxygen are not delivered to the cells throughout the entire scaffold.[12] For example, it has been shown that large cell spheroids will develop into a shell of thriving cells, ~200-μm thick, around a necrotic core due to limited oxygen availability at the center of the spheroid.[13]

As a result of deficiencies in oxygen transport, engineered tissues develop with inhomogeneous cellular distributions. The inability of cells to distribute uniformly throughout a tissue-engineered construct is extremely detrimental to the intended function of developing isotropic tissues. The issues of improving mass transport and maintaining a uniform cell distribution can be ameliorated by controlling culture conditions through the use of bioreactors.

5.501.3. Perfusion Bioreactors

In many cases, the term perfusion bioreactor refers to a system in which the culture medium is simply circulated into and out of the culture vessel. The simplest design incorporates a gas permeable bioreactor bag in which medium is pumped in using a syringe pump and flows out via hydrostatic pressure into a waste container (**Figure 2(a)**).[14] While this particular

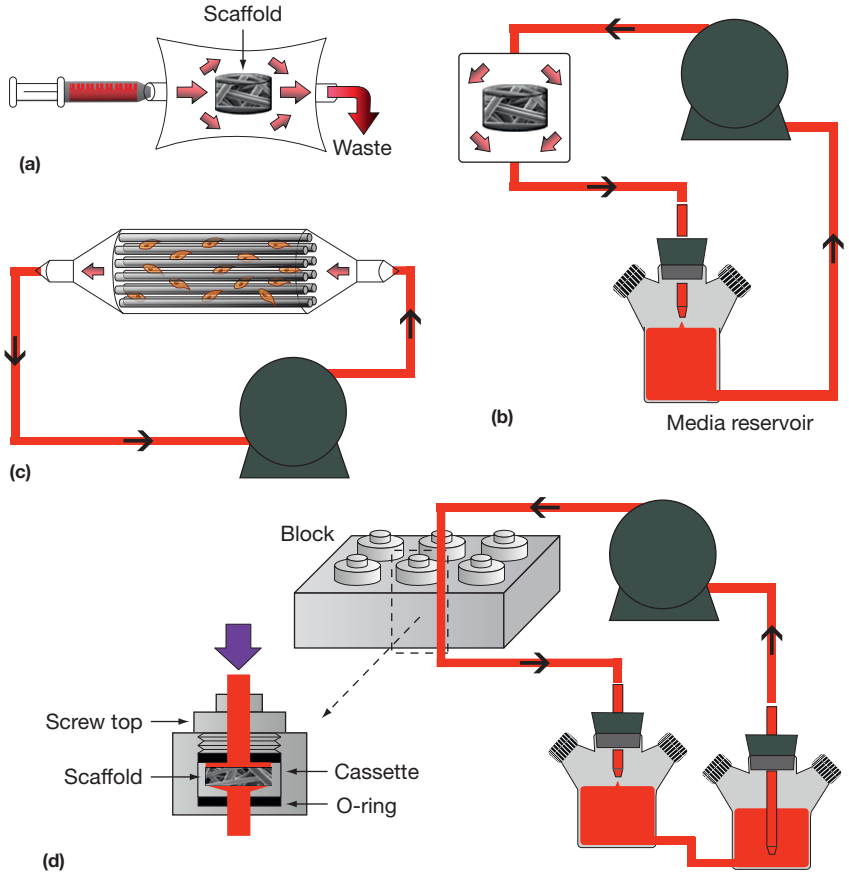

Figure 2 Diagram of different flow perfusion bioreactor designs. Bioreactor bag with syringe pump at the inlet and direct waste disposal at the outlet (a), bioreactor with perfused culture chamber and a closed media flow loop (b), hollow fiber bioreactor (c), direct perfusion bioreactor complete with two media reservoirs (d).

bioreactor design offers the benefit of automatically replenishing medium, it does not recycle any of the used media, thus depriving the culture system of the growth factors, cytokines, matrix proteins, and other signals secreted by the cells during tissue development which are beneficial to tissue generation.[15–17]

Slightly more sophisticated perfusion systems are composed of a culture chamber connected to a medium reservoir in a closed loop. In this case, scaffolds are suspended in a culture chamber into which medium is pumped (**Figure 2(b)**).[18,19] These systems allow circulation of the medium throughout the culture chamber and constant aeration of medium. However, simple perfusion bioreactors do not actively perfuse the interior of the scaffolds with medium. Patterns of medium flow that bypass the interior of the scaffold will not greatly improve the transfer of nutrients and oxygen to the interior of thicker constructs. As was discussed previously, sufficient mass transfer levels throughout a scaffold in its entirety are vital to the success of engineered tissues.

Hollow fiber bioreactors are another type of perfusion bioreactors that have been developed for the culture of various cell types. These systems use cells that have been immobilized within a culture chamber that has hollow capillary-like tubes through which the medium is perfused (**Figure 2(c)**).[20,21] The hollow fibers have pores that are impermeable to cells. However, nutrients and oxygen are able to freely diffuse through the fibers. The capillary-like function of the fibers in these hollow fiber bioreactors allow cells to be cocultured without coming into physical contact with each other. The absence of physical contact between different cell populations retains the benefits of coculturing that come from chemical signaling between different cell types while still maintaining separate cell populations that can be easily harvested.[21] Hollow fiber bioreactors do not have a traditional scaffold. Instead, in addition to being simply immobilized within the system, oftentimes, cells will adhere to the fibers of the bioreactor. In order to harvest cells from the bioreactor, traditional cell removal techniques such as trypsinization and mechanical agitation are used.[21] Also, cells cultured in the hollow fiber bioreactors are subject to flow-induced shear stresses, which have been shown to support cell differentiation in certain cell types.[21–25]

Perfusion is a natural process that takes place in all tissues and is required for the survival of cells. Body fluids permeate the interior of tissues to supply oxygen and nutrients while removing wastes.[26] For this reason, it is important that bioreactor designs account for perfusion through the interior of scaffolds. Flow perfusion bioreactors pump media through the pores and internal network of scaffolds allowing delivery of nutrients and removal of waste throughout the construct (**Figure 2(d)**).[27]

Direct perfusion of constructs will enable cells to thrive and evenly distribute throughout the interior of scaffolds, thus increasing the viability of engineered tissues. Pham *et al.*[28] showed that bilayered electrospun scaffolds, composed of micro and nanofiber layers, cultured in a flow perfusion bioreactor display greater cellular infiltration, compared to statically cultured constructs, by a factor of 5 (**Figure 3**). Likewise, as seen in **Figure 4**, complete cellular infiltration was seen only in scaffolds cultured in the flow perfusion bioreactor. Flow perfusion has an extremely positive effect on cellular distribution. Culturing tissues in a flow perfusion bioreactor enables cells to infiltrate nanofiber scaffolds, which under static conditions may hinder cellular migration due to decreased pore sizes.[28]

Medium flow throughout the construct is also incredibly beneficial, as it stimulates the cells by shear stresses. The application of shear stress on cells *in vivo* induces mechanotransduction signaling, which has been shown to be beneficial in the culturing of many tissues, including bone, cartilage, and cardiac tissue.[22–24]

It is thought that shear stress is a beneficial stimulus in tissue development because, as native tissues are loaded, interstitial fluid flows throughout the intercellular spaces in the tissue stimulating mechanotransduction pathways.[24,29] In the bone, fluid flow is responsible for inducing new bone formation and increasing the metabolic activity of osteoblasts.[30–32] Likewise, compressing cartilage subjects chondrocytes to shear stresses, among other mechanical stimuli.[33] Compression has been shown to induce tissue remodeling and increase the production of ECM elements in the cartilage.[34] Use of flow perfusion bioreactors mimics the conditions of interstitial fluid flow much better, thus harnessing the benefits of flow-induced shear stress to improve tissue development.[35]

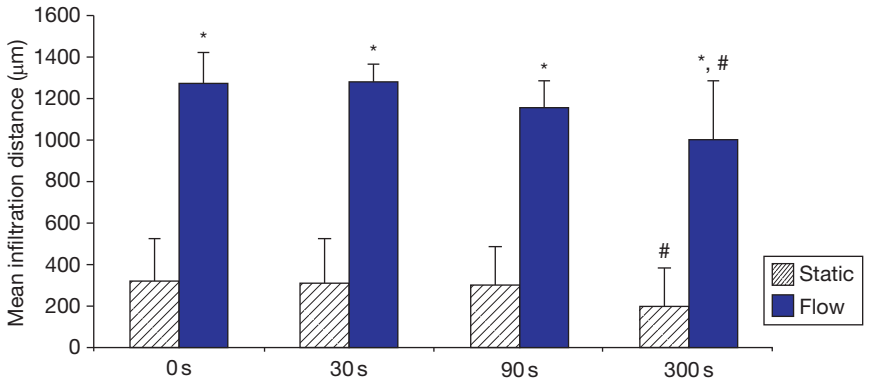

Figure 3 The mean infiltration distance achieved by mesenchymal stem cells cultured under static and flow conditions. The mesenchymal stem cells were cultured on scaffolds in which the top nanofiber layer was spun for 0, 30, 90, and 300 s. * indicates statistical significance between static and flow culture; # indicates statistical significance for that culture condition ($p < 0.01$). Reproduced with permission from Pham, Q. P.; Sharma, U.; Mikos, A. G. *Biomacromolecules* **2006**, *7*, 2796–2805.

5.501.4. Design Parameters of Flow Perfusion Bioreactors

There are a variety of parameters and design challenges that need to be considered when designing a flow perfusion system. In general, all of the design challenges arise from the central goal of having to provide proper culture conditions for a three-dimensional scaffold. These culture conditions include complete perfusion of the scaffold, media flow pathways, environmental control, and maintenance of sterility.

5.501.4.1. Direct Perfusion of Scaffolds

In order to achieve media flow directly through the scaffold, it may be necessary to restrict the media to unidirectional flow. If media flow is not restricted, the fluid will take the path of least resistance and one cannot guarantee perfusion of the entire scaffold (Figure 5). In the absence of true perfusion of the entire scaffold, uniform mechanical stimulation of the cells within the scaffold cannot be realized.[15]

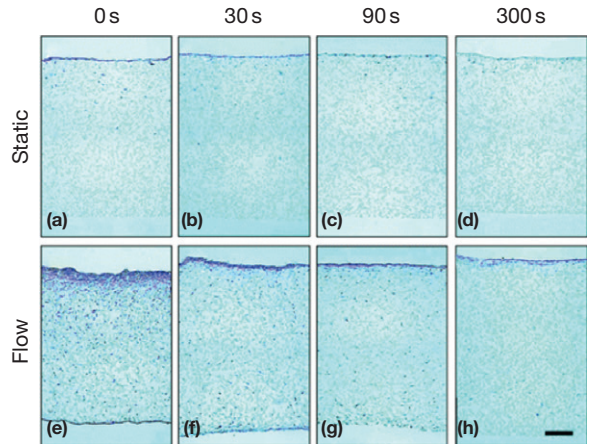

Figure 4 Images of histological sections stained with hematoxylin and eosin. (a–d) were cultured under static conditions. (e–h) were cultured under flow perfusion conditions. The scaffolds consisted of a bottom microfiber layer 5-μm thick, with a top nanofiber 600-nm thick spun for 0, 30, 90, and 300 s. Reproduced with permission from Pham, Q. P.; Sharma, U.; Mikos, A. G. *Biomacromolecules* **2006**, *7*, 2796–2805.

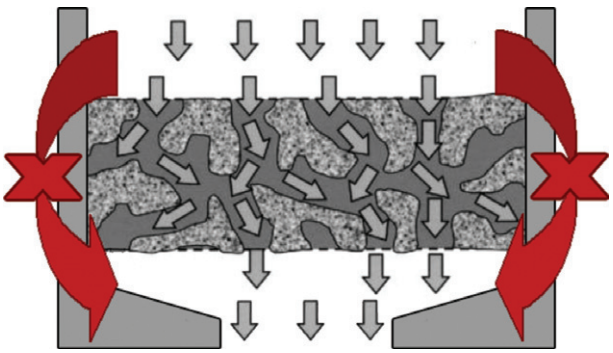

Figure 5 To ensure that media directly perfuses the scaffold, media flow around the scaffold perimeter must be prevented. Adapted and reproduced with permission from Bancroft, G. N.; Sikavitsas, V. I.; Mikos, A. G. *Tissue Eng.* **2003**, *9*, 549–554.

The bioreactor design must allow the media to flow in at one end of the scaffold and out the other end. To assure unidirectional flow, a bioreactor system must form a tight seal between the perimeter of the scaffold and the wall of the bioreactor.[15,27] A tight scaffold mount in the bioreactor is achieved in two primary ways: press-fitting scaffolds into bioreactor cassettes (Figure 2(d))[36–38] or applying low levels of compression to the scaffold by placing gaskets on either side of the scaffold.[39–41]

5.501.4.2. Media Flow Pathway

It is vital to provide a means of automatically forcing the medium through the scaffold and the rest of the system. Many bioreactor designs utilize a peristaltic pump to control media flow.[23,40–43] One concern with using a peristaltic pump is the degradation of the relatively low-durability gas permeable tubing.[27] For a bioreactor system design to be successful in the long term and prevent the tubing from degrading and mixing with the culture medium, more durable tubing should be used in media circuit that is in direct contact with the peristaltic pump. Wendt *et al.*[38] have completely avoided the issues involved with using a peristaltic pump by using a vacuum pump as an alternative. Vacuum pumps have the additional attribute of making medium flow easily reversible.

It is necessary to regulate the flow rate of media through the system so as to modulate the shear stress imposed on the constructs. The bioreactor design utilized by Carrier *et al.*[40] places four scaffold cartridges in series within the same media circulation loop. In a serological cartridge arrangement, it is difficult to ensure that identical flow conditions are achieved throughout all the four scaffolds in the series. When cultivating larger tissues, a serological arrangement may eventually lead to variation in the tissues that have developed due to the different levels of shear stresses throughout the flow pathway. It is for this reason that, in addition to the electrical controls for the pump, flow rate may be monitored using a flow meter in the media flow pathway.

It is also vital to tailor the flow rate of the bioreactor system to the specific tissue being cultured and the desired cellular response. Tailored flow rates are necessary because different native tissues possess varying levels of mechanical stimulation that are useful in promoting ECM production.[30,41,44–46] In order to achieve reproducible beneficial effects within constructs cultured in a bioreactor, fluid flow rate from the pump must be translated into shear stresses experienced by cells within the scaffold. Given that scaffold architectures are oftentimes random and complex, it is difficult to accurately estimate shear stresses within the constructs.[47,48] Due to the difficulty involved in estimating internal shear stresses, currently, most bioreactor systems utilize the trial and error method to elucidate the intended beneficial results within the tissue-engineered constructs.

Removing undissolved air from the bioreactor is imperative as trapped gas bubbles within the system disrupt the smooth distribution of media flow through the scaffolds.[27,49] In order to keep gas bubbles off the scaffolds and maintain an even distribution of fluid flow, Bancroft *et al.*[27] have described a system in which flow is directed in a top-down fashion. In this

design, any gas bubbles in the system will rise in the tubing, leaving the scaffold surfaces free of gas bubbles.

The bioreactor used by Grayson *et al.*[49] addresses the issue of trapped gas in a more direct manner. In this design, a syringe in a three-way connector is included in the media flow pathway just upstream of the inlet. Gas bubbles may be removed from the system by using the syringe, and when not in use, the syringe is blocked from fluid flow.

5.501.4.3. Maintenance of Sterility

Given that bioreactors are used to culture cells and developing tissues, it is necessary to ensure that the system is sterile at the beginning and remains so throughout the entire culture period. In order to guarantee system sterility in the beginning, it is important that the individual pieces of the bioreactor be able to withstand sterilization procedures, such as ethylene oxide and autoclave treatments. Materials that are commonly used for bioreactor assembly include: polycarbonate, poly (methyl methacrylate), poly(tetrafluoroethylene), silicone, glass, and stainless steel.[27,41,43,50]

A sterile culture environment with minimal exposure to the surroundings may be maintained by designing a system that can fit within an incubator.[51] Using an incubator confers size constraints on the system and the resulting throughput of the scaffold. In an effort to garner extra space within the incubator, it is possible to design a system so that the pumps may be placed outside the incubator.[43] Designs that use external pumps increase the amount of space available within the incubator and reduce any risk of contamination that may arise from the pump residing within the incubator during culture.

Contamination risks may be mitigated by limiting the number of scaffolds that are cultured within each flow circuit. Wang *et al.*[52] have used a system in which each scaffold is cultured individually in a single closed circuit with separate medium reservoirs. While the use of separate media reservoirs does greatly reduce the spread of contamination between scaffolds, it is also rather inefficient with regard to space constraints and the requirements of medium volume. Consequently, a successful bioreactor design must have a balance between efficiency and the number of scaffolds in each culture loop.

It is also important to enable quick and simple medium changes in order to reduce the risk of contamination within the system. One way to accomplish fast medium changes is to provide a method for exchanging medium without removing the entire bioreactor from the incubator. Du *et al.*[53] have connected silicone tubing from one of the medium reservoirs inside the incubator to fresh medium reserves in a culture hood outside the incubator.

The proper choice of medium reservoirs also plays a key role in ensuring fast medium changes. Reservoirs that are most amenable to quick medium changes possess easily removable caps such as side-armed flasks[27] and Schott bottles.[50]

5.501.4.4. Environmental Control

One of the primary purposes of any bioreactor is to provide a means of controlling the tissue culture environment. Maintaining a proper environment is fundamental to culturing viable tissues. The parameters that must be monitored and sustained include pH, oxygen tension, temperature, nutrient availability, and waste removal. It is relatively simple to regulate the temperature in a bioreactor by simply designing a system that is compact enough to operate from within an incubator (for more information, see **Chapter 5.502, Engineering Scaffold Mechanical and Mass Transport Properties**).

5.501.4.4.1. Nutrient supply and waste removal

As in any long-term method of culturing tissues, it is necessary to provide a method for delivery of fresh nutrient supplies and removal of waste from the culture system. Nutrient delivery and waste removal is accomplished by simply changing the medium at defined culture periods. As flow perfusion bioreactors are closed systems through which a medium is constantly pumping, medium changes are slightly more complicated. Also, while designing any tissue culture system, it is important to note that frequent medium changes increase the risk of contamination.[15,27] Therefore, it is necessary to design a bioreactor in which the medium can be exchanged quickly and without difficulty.

Most flow perfusion bioreactors enable quick and simple medium changes by including a medium reservoir in the medium flow loop. To exchange the medium, the researcher simply has to empty all of the medium into the reservoir, interrupt medium flow, remove the spent medium from the reservoir and replace it with fresh medium.[37,40] The primary issue with medium exchange in a bioreactor with only one reservoir is that medium flow must be interrupted, which allows air to enter into the system. As discussed previously, air bubbles trapped in the bioreactor obstruct the even distribution of medium flow through the constructs.[27,49]

In order to perform a complete medium change without interrupting the flow of medium through the construct, two medium reservoirs may be utilized as shown in the design outlined by Bancroft *et al.*[27] (**Figure 2(d)**). In a two reservoir system, there are two medium reservoirs connected by a small length of tubing. While the bioreactor is functioning normally, the medium is able to freely transfer from one reservoir to the next simply by the force of gravity. Medium changes are accomplished by simply clamping the tube connecting the two reservoirs. Then, after filling the first reservoir with new medium, the fresh medium flushes the used medium out of the system and into the second reservoir. Once the entire used medium has been pumped out of the system, the second reservoir is emptied and the clamp is removed, allowing the system to function normally.[27] As the flow of medium was never completely interrupted, a bioreactor which utilizes two medium reservoirs reduces the amount of air that gets into the system, thus reducing the amount of trapped gas within the system that could disrupt fluid flow through the constructs.

Sophisticated systems are used to monitor the medium throughout the culture period in order to analyze the biological components within the medium. In the bioreactor described by Zhao and Ma,[43] sampling ports are placed in the medium flow pathway on either side of the culture chamber. The inclusion and arrangement of medium sampling ports enables the measurement of glucose and lactate to determine the metabolic activity of the tissue.

Another improvement on common flow perfusion bioreactor designs would be the incorporation of an automatic method of pH monitoring. pH monitoring would allow the researcher to

gauge metabolic activity of the tissue and determine the optimal medium exchange periods. Automatic medium pH measurements may be accomplished by including a pH meter within the medium flow circuit[54,55] or an innovative noncontact optical measurement device.[56] An optical measurement device may be used to measure the pH in a culture environment through the change in the optical properties of the medium due to color changes with the pH indicator, phenol red.[56] Optical pH meters permit pH monitoring without coming in contact with the culture medium, thus reducing the risk of contamination.

5.501.4.4.2. Gas exchange

Due to the fact that flow perfusion bioreactors are designed as closed systems with one of the primary objectives being the increase of oxygen transport within the constructs, it is necessary to provide a method for gas exchange in the design of a bioreactor. Many flow perfusion bioreactor designs allow gas exchange through the use of gas permeable silicone in the form of tubing, membranes, and medium reservoir bags.[39,40,42,57] When using gas permeable materials for gas exchange, the oxygen tension within the medium will equilibrate with the gas concentration in the incubator inside which the bioreactor is housed. Another method of gas exchange in the medium utilizes mixing of the fluid flow with the headspace in the medium reservoir to incorporate oxygen in the medium.[50] In contrast, gas may be pumped directly into the system. Zhao and Ma[43] have accomplished direct gas exchange by pumping air into the medium reservoir through a sterile filter.

Monitoring oxygen tension within the bioreactor may be useful not only for ensuring that oxygen levels are satisfactory, but also for designing a bioreactor that enables tissue-engineered products to be produced under good manufacturing practices (GMP). Some bioreactors include oxygen sensors within the medium flow loop.[50,54] In the bioreactor design outlined by Janssen *et al.*,[37] oxygen sensors are placed in the medium pathway at both the inlet and the outlet. Oxygen sensors arranged on either side of the culture chamber allow the dynamic supervision of dissolved oxygen. They also provide information about the patterns of oxygen consumption within the constructs, thus enabling inferences to be made about cell proliferation. Zhao and coworkers[43,58] have monitored oxygen tension by taking a sample of the medium through specialized ports. The dissolved oxygen in the medium is then measured using a blood gas analyzer. While the testing of media samples using a blood gas analyzer is quite effective, it is more labor intensive than using an oxygen sensor that operates automatically in real time.

5.501.5. Current Flow Perfusion Bioreactor Designs and Functions

Flow perfusion bioreactors are utilized for two primary functions, namely, dynamic cell seeding and long-term tissue culture.

5.501.5.1. Dynamic Cell Seeding

Seeding techniques are responsible for initially establishing required cell numbers and distributions within the scaffolds. In turn, cell numbers and their distributions affect cellular processes such as proliferation and differentiation, which have a profound influence on the developing engineered tissue as they affect functions such as cell-to-cell interactions.[59,60] Similarly, in tissue engineering, it is extremely important to seed cells with the highest possible seeding efficiency as limited cell numbers are available owing to the restrictions in biopsy expansion.

The most prevalent seeding technique employed in tissue engineering is static seeding. Static seeding oftentimes leads to low seeding efficiencies (ratio of initial cell content in a scaffold to the total number of cells seeded) and nonuniform cell distributions.[61–63] In an effort to improve seeding efficiency and obtain a more uniform cell distribution, dynamic seeding techniques may be used. More specifically, cell seeding within flow perfusion bioreactors enables more efficient seeding and homogeneous cell distributions.[59]

Dynamic seeding of chondrocytes using perfusion for 3 days increased cell content by 80%, compared with statically seeded constructs.[64] Also, the flow rate utilized for dynamic seeding has a significant influence on the resultant cell content.[64] Therefore, it is imperative that the flow rate used for dynamic seeding be optimized for different scaffold types and architectures in order to achieve the most advantageous results.

It is also possible to dynamically seed cells on scaffolds by using oscillatory medium flow. Oscillatory flow is accomplished by simply reversing medium flow at a defined frequency. Like seeding with simple direct perfusion, seeding using oscillatory flow leads to significant increases in seeding efficiency over traditional static seeding techniques.[38,59] Likewise, dynamic seeding is successful in distributing cells throughout the entire scaffold while the cells remain localized at the top of statically seeded scaffolds.[38,59]

The bioreactor design used by Zhao and Ma[43] improves upon other bioreactors used for dynamic seeding in that it contains a dedicated inoculation loop in addition to the medium circulating loop. The inoculation loop allows direct injection of a cell suspension into the perfusing medium while bypassing the medium reservoirs. Bypassing the medium reservoirs reduces the dilution of the cell suspension, resulting in a more efficient application of the cells to the scaffolds.

5.501.5.2. Tissue Culture

Flow perfusion bioreactors are used for the long-term culture of a variety of different tissue types. The tissues that are being developed under a perfused medium flow are tissues that benefit not only from increased mass transport but also from the mechanical stimulation resulting from fluid flow through the constructs, tissues such as cartilage, bone, and cardiac tissue (for more information, see Chapter 5.506, Effects of Mechanical Stress on Cells).

5.501.5.2.1. Cartilage

Mechanical stimulation, such as fluid-induced shear stress, is extremely beneficial in cartilage development due to its ability to stimulate GAG and collagen synthesis in chondrocytes.[65] Flow perfusion bioreactors that perfuse media through the interstitial spaces of scaffolds cause internal shear stresses, and achieve larger amounts of ECM production and more homogeneous cell and ECM distributions compared to tissues

cultured statically or otherwise. In the study described by Pazzano *et al.*,[42] flow perfusion of chondrocytes over a period of 4 weeks led to dramatic increases in cell number, sulfated GAGs, and total collagen content compared to statically cultured chondrocytes.

Likewise, cells cultured in flow perfusion bioreactors tend to align in the direction of fluid flow within the scaffold.[42] The capability to induce cellular alignment, as a byproduct of perfusion, may be very favorable for the development of cartilage as it naturally exhibits regions of oriented cells and ECM.[66,67]

Also, it has been shown that chondrocytes cultured under dynamic conditions exhibit a flattened morphology with filopodia, while statically cultured chondrocytes are more likely to display rounded or less desirable morphologies.[41] Similarly, statically cultured chondrocytes display membrane vesicles, a sign of apoptosis in diseased cartilage, while chondrocytes cultured under perfusion exhibit smooth cell surfaces.[41] For the success of engineered tissues, it is imperative that culture conditions support the desired cell phenotype and morphology.

5.501.5.2.2. Bone

Bone-like tissue, when cultured under flow perfusion, displays a more homogeneous cell and mineral distribution throughout the entire scaffold, as opposed to being confined to the scaffold perimeter when statically cultured.[7,36,52,57] Similarly, cellularity in flow perfusion cultured constructs is significantly higher than in statically cultured bone-like tissue.[68,69] Furthermore, in a study performed by Bancroft *et al.*,[36] pore-like structures lined with cells, indicating *de novo* tissue modeling, were observed throughout constructs that were cultured under flow perfusion. These results show that the conditions provided by flow perfusion bioreactors increase the capacity of the constructs to develop into bone-like tissues.

Also, flow perfusion has a significant influence on osteogenic differentiation of mesenchymal stem cells (MSCs). When considering bone-like tissue development, increased mineralization is consistent with further osteo-differentiation. Holtorf *et al.*[69] indicated that MSCs in titanium meshes with different fiber diameters cultured under direct flow perfusion displayed significantly different amounts of mineralization, as indicated by the calcium content (**Figure 6**). Models also suggest that a decrease in the scaffold mesh size leads to an increase in fluid shear stress. Holtorf *et al.*[69] used 20 μm titanium mesh scaffolds and obtained an increase in shear stresses within the constructs, yielding an increase in mineralization at 16 days compared to 40 μm mesh constructs.[69]

Furthermore, flow perfusion may be used to induce osteogenic differentiation of MSCs even in the absence of the common induction agent, dexamethasone.[70] A similar study showed that the presence or absence of dexamethasone does not have a significant influence on the culture of osteoblasts under flow perfusion conditions.[71] Likewise, alkaline phosphatase (ALP), a marker of osteoblast differentiation, increases throughout the duration of perfused culture of MSCs on porous biphasic calcium phosphate ceramics. ALP levels in the perfused constructs were also significantly higher than in the static cultures.[57] These results indicate that the stimulation achieved through flow perfusion is sufficient to induce osteogenic differentiation without the traditional induction factors.

5.501.5.2.3. Cardiac tissue

As with the tissues mentioned above, culturing cardiomyocytes under perfusion greatly increase the spatial distribution of cells throughout the scaffold. Cardiomyocytes, cultured statically, develop a 100-μm thick external layer of cells with a relatively acellular scaffold interior.[40] In contrast, image processing supports the observation that perfused scaffolds maintain reasonably constant cell numbers per unit area.[40]

Likewise, cardiac tissue cultured under flow perfusion maintains a more favorable cell phenotype and function.

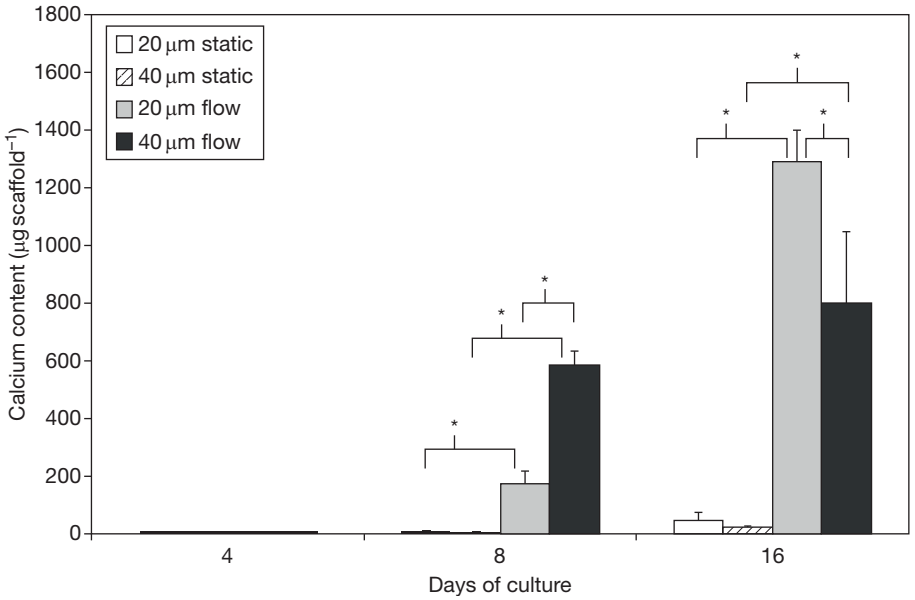

Figure 6 Calcium content in the extracellular matrix produced by mesenchymal stem cells cultured under static or flow perfusion conditions on titanium scaffolds with 20- or 40-μm fiber sizes for 4, 8, or 16 days. *indicates significant difference between groups ($p < 0.05$). Reproduced with permission from Holtorf, H. L.; Datta, N.; Jansen, J. A.; Mikos, A. G. *J. Biomed. Mater. Res.* **2005**, *74A*, 171–180.

Constructs cultured under perfusion display cardiac-specific markers and evidence of aerobic metabolism consistently throughout the entire scaffold.[40] In contrast, scaffolds cultured statically exhibit these traits only in the outer 100-μm thick section of the construct.[40] Similarly, cardiomyocytes cultured under pulsatile perfusion are more hypertrophic than cells grown in static culture.[39]

In addition to the differentiation markers, cardiac tissues cultured under perfusion retain more cardiac-like function than constructs cultured statically. For instance, cells cultivated under pulsatile flow are more contractile than statically cultured cells. A significantly lower excitation threshold and a higher contractile amplitude indicate an improvement in construct function upon pulsatile perfusion culture.[39]

5.501.6. Future Progress

Many studies have shown that flow perfusion bioreactors are valuable in successfully culturing tissues and obtaining clinically relevant amounts of ECM. Flow perfusion bioreactors also provide a means to overcome the problem of mass transport within scaffolds and allow better cellular infiltration and uniform distribution. Furthermore, the mechanical stimulation due to flow shear stress is quite useful in guiding cellular differentiation. While all of these characteristics have been demonstrated at the research level, there is still more progress that must be made in flow perfusion bioreactor design to make it more practical for widespread use.

5.501.6.1. Improving Efficiency

Most of the flow perfusion bioreactors described previously have been placed within the confines of an incubator. Incubators are used to maintain uniform and controllable temperature and atmospheric conditions to culture tissues. If incubators continue to be used in tissue culture with flow perfusion bioreactors, it is necessary to maximize the number of scaffolds per bioreactor on each shelf of the incubator. Current designs, which exhibit relatively low throughput with regards to space requirements, will be difficult to scale up in the future.

One approach to improve the efficiency of space utilization in flow perfusion bioreactors is to avoid using a traditional incubator altogether. To circumvent the use of a traditional incubator, the flow perfusion bioreactor system can be designed to manage environmental conditions autonomously. Stand alone, benchtop systems that are able to maintain the temperature, gas tension, and humidity necessary for tissue culture are more user-friendly and simple.[54,72] Bioreactor systems that are independent of traditional incubators also allow continuous 3D imaging of the developing tissue under flow conditions.[73]

Many tissue culture systems require the use of growth factors and other signaling chemicals to stimulate and maintain cellular differentiation.[74–76] Growth factors are rather expensive, costing hundreds of dollars for mere micrograms. Thus, to manufacture tissues that are economically viable, it is vital to design flow perfusion bioreactors that make efficient use of the culture medium. Using medium efficiently means reducing the ratio of medium volume to scaffold number within each bioreactor.

The bioreactor described by Flaibani *et al.*[77] is reasonably efficient in its use of culture medium, completely avoiding the use of a traditional medium reservoir. In the culture cassette, extra empty space is included to act as a medium reservoir (**Figure 2 (d)**). Eliminating a traditional medium reservoir greatly reduces the volume of medium needed for each scaffold. However, it is extremely important to consider the end effects and maintain fully developed fluid flow throughout the culture cassette. Therefore, for some systems, the utilization of a medium reservoir that is separate from the culture cassette may be necessary.

5.501.6.2. Scaling Up

A common challenge throughout tissue engineering is the issue of scaling up tissue development from the research scale to the industrial level. When scaling up a bioreactor, it is necessary to consider reproducibility and safety, and simultaneously furnish a design that is also fiscally competitive and clinically relevant.[78] Currently, bioreactor systems that have been scaled up focus on aseptically growing relevant tissue sizes within closed systems at high throughput.[79]

In order to take the research level bioreactors to the market, it may be important to make the transition from tissue culture to tissue implantation. Current bioreactor systems at the research level focus primarily on tissue development and culture. However, a more complete industrial level design would incorporate cell seeding, tissue formation, and product delivery in one system.[79,80] A more complete bioreactor design will enable the tissue (product) produced using the bioreactor to more easily meet GMP guidelines, such as protection against contamination and provision of quality assurance, by controlling components and processes. A full circle bioreactor more easily meets GMP guidelines because the number of processing and handling steps, and thus risk of contamination from production to delivery, will be reduced.[79,80]

5.501.6.3. Standardizing Bioreactor Systems

Engineering tissues is a difficult endeavor because different tissues of the body require different conditions and geometries for successful development.[5] Due to the differences in tissue requirements, it is necessary that both bioreactors and the various culture condition parameters be optimized and standardized to the specific tissue being cultured. A study by Bancroft *et al.*[36] determined that higher mineralization levels could be achieved using elevated bioreactor flow rates (**Figure 7**). While medium flow rate and the resulting mineralization were determined to be related, they were not linearly proportional. The absence of linearity indicates that there is a limit to the amount of mineralization that may be stimulated by fluid flow in a flow perfusion bioreactor. In order to achieve the best possible benefit, the parameters of flow perfusion bioreactors must undergo optimization.

The majority of bioreactor systems used in tissue engineering currently were developed individually, by separate laboratories, to suit specific research objectives. While the various systems presently employed bear many similarities, there is no standard system in use. In order to be able to generate reproducible results, it is necessary to produce a standardized bioreactor design that may be used by various members of

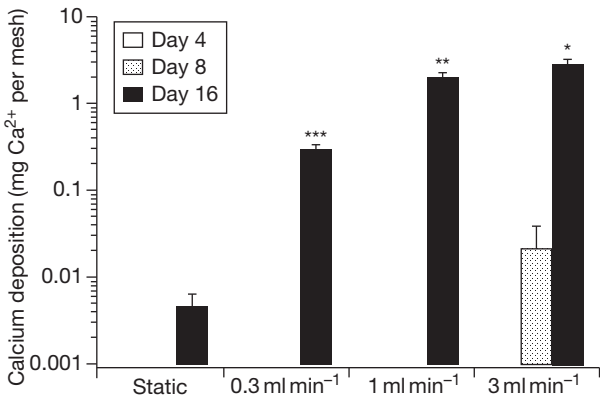

Figure 7 Calcium content of cultured scaffolds. Perfusion conditions from left to right: static, 0.3, 1, and 3 ml min^{-1}. Indicators: * highest, ** second highest, and *** third highest calcium content. All groups are statistically different ($p < 0.05$). Reproduced with permission from Bancroft, G. N.; Sikavitsas, V. Copyright 2006 National Academy of Sciences, USA.

the tissue engineering community. In addition, a standard design would enable the comparison of results among different researchers. It would also facilitate the difficult transition that occurs while converting a specific technology from the research level to industrial scale production.

Future flow perfusion bioreactor studies should also move toward presenting medium flow as the resulting shear stresses within the construct, rather than simply as the flow rate through the bioreactor. Presenting medium flow as the resulting internal shear stress is very important because, currently, there is no standardized flow perfusion bioreactor system in use. Given that various researchers use slightly different systems, the same flow rate used in two different bioreactors may deliver dissimilar levels of mechanical stimulation inside the constructs, resulting in tissues with different properties.

5.501.6.4. Determining Shear Stresses within Constructs

Scaffolds with different microarchitectures cultured at the same flow rate in a perfusion bioreactor may exhibit very different results. Datta *et al.*,[81] reported significantly higher mineralization quantities with composite titanium/ECM constructs compared to bare titanium scaffolds (**Figure 8**). While the presence of *in vitro* generated ECM in a scaffold has been shown to have a positive influence on cellular differentiation,[82,83] smaller scaffold pore sizes have been shown to increase shear stress within constructs, thus eliciting different cellular responses.[69] Due to the effect of scaffold architecture on fluid flow-induced shear stress and thus on cellular responses, it is extremely important to report fluid flow within flow perfusion bioreactors as shear stress within the constructs.

In an effort to standardize the field of tissue engineering and enable the generation of reproducible culturing environments and the resultant tissues, it is important to model the shear stress that can occur within the interstitial spaces of the scaffolds. Elucidating the internal shear stress due to medium flow would also provide information about the shear stress experienced by the cells within the constructs, thus garnering more information about the cellular effects of mechanical stimulation, which will enable better design of scaffold architectures. Also, the internal shear stress may be used to optimize fluid flow conditions to match physiological conditions, rather than optimization through trial and error, which is the current norm.[5]

However, it is a difficult task to accurately estimate the shear stress due to flow within a tissue engineering scaffold, given the extremely irregular scaffold architectures that exist within constructs. At present, the more accurate method of estimating internal shear stress uses microcomputed tomography to determine the complex microarchitectures of the irregular scaffolds. Then, a computational fluid dynamics code is used to calculate the localized shear stress within the scaffolds.[47,48,84] In the future, improvements may be made to the 3D modeling of the shear stresses within irregular scaffolds by examining, more closely, the effects of boundary conditions and assumptions, on the accuracy of the models (for more information, see **Chapter 3.309, Fluid Mechanics: Transport and Diffusion Analyses as Applied in Biomaterials Studies**).

5.501.7. Conclusions

In tissue engineering, scaffolds are necessary for providing a three-dimensional architecture on which cells may proliferate and develop into a functioning tissue. However, mass transfer limitations within scaffolds are an extremely common issue in tissue engineering. Oftentimes, cells cultured statically on scaffolds develop a shell of viable cells and ECM, with the interior portion of the construct relatively devoid of cells. Flow perfusion bioreactors may be used to overcome the challenge of mass transfer within scaffolds.

To design a successful flow perfusion bioreactor, it is necessary to consider a variety of different design objectives. The primary objective of a flow perfusion bioreactor is to supply media directly through the scaffold so as to improve mass transport and impose beneficial shear stress on the cells within the scaffold. It is also important to consider methods for controlling environmental conditions within the bioreactor, including, the atmosphere, temperature, and sterility.

Currently, flow perfusion bioreactors are used for two primary purposes: dynamic cell seeding of scaffolds and long-term tissue culture. Dynamically seeding cells onto scaffolds using flow perfusion bioreactors has been shown to significantly improve seeding efficiencies and cell distributions within the scaffolds. Dynamic perfusion for long-term culture is currently being used for the development of cartilage, bone, and cardiac tissues. The shear stresses within the scaffolds, which result from media perfusion, have been shown to have a beneficial effect on cellular differentiation, ECM production, and cell distribution for these tissues.

The scaling up of flow perfusion bioreactors to achieve clinically relevant amounts of tissue will be a major challenge. For flow perfusion bioreactors to make a successful transition from the research level to an industrial scale, it will be necessary to standardize bioreactor systems. Also, it is extremely important to improve the efficiency of current systems with regards to space constraints, throughput, and media volumes. In the future, at both the research and industrial levels, it will be necessary to report media flow as the internal shear stress that occurs within the scaffolds.

Despite the advances that still need to be made in the design of bioreactors, flow perfusion bioreactors show immense promise for tissue engineering. Flow perfusion bioreactors provide the means to overcome many of the current issues that arise while attempting to develop tissues using three-dimensional scaffolds.

Acknowledgments

Work on fabrication of cell/scaffold constructs with flow perfusion bioreactors for tissue engineering applications has been funded by the National Institutes of Health (R01 AR57083). 5.502.1. Introduction

5.502.1.1. The Need for Engineering Scaffolds with Controlled Effective Properties

Biomaterial scaffolds fill critical roles in regenerative medicine. Scaffolds are needed to (1) provide anatomic fill and shape in tissue defects, (2) provide temporary function in anatomic defects while tissue regenerates, and (3) enhance tissue regeneration through material–cell interaction and delivery of biologics, including cells, proteins, and/or genes. In essence, we can summarize these requirements as the 4Fs: Form, Fixation, Function, and Formation. While there is agreement over these general 4F requirements, there is virtually no information on how these general scaffold requirements translate into specific scaffold design requirements. We must be able to quantitatively define these specific design requirements in order to have scaffold design targets. Obviously, both the type and magnitude of these design requirements is likely to vary between tissues and anatomic sites.

The need to fill anatomic defect shape (Form) is a readily defined requirement. Although typically not quantifiable using a mathematical equation, the anatomic shape is readily defined using an appropriate patient imaging modality such as computed tomography (CT) for bone and blood vessels with contrast agent and magnetic resonance imaging (MRI) for soft tissues. The mode of surgical fixation of the scaffold (Fixation) will be highly dependent on the shape of the surrounding tissue segments. Both the anatomic defect and the fixation segment shape can be defined using various imaging processing software such as MATLAB™ (www.mathworks.com), MIMICS™ (www.materialise.com), ANALYZE™ (www.analyzedirect.com), AMIRA™ (www.amira.com), or IDL™ (www.ittvis.com), to name a few. The resulting anatomic region is then defined by voxels within that region grouped in a set or mask, or a surface representation of triangular facets as in the .STL file format.

There is more uncertainty in defining temporary function (Function) than anatomic shape. Although function may be defined with regard to mechanical, electrical, or chemical, depending on tissue type, this chapter will focus on mechanical function. It is clear that the scaffold should not mechanically fail under physiologic forces within the anatomic site. Ideally, one would design the scaffold so that stresses under physiologic forces are below the scaffold material failure stresses. However, it is very difficult to determine boundary conditions on most tissues, thus introducing significant uncertainty into scaffold stress analysis. Alternatively, since native tissues adapt themselves to physiologic loads, scaffolds that match native tissue properties should be able to withstand physiologic loads. This design principle has been espoused in different forms by a variety of groups. Yaszemski *et al.*[1] stated the bone tissue engineering scaffolds should provide 'adequate strength' in bone defects, while Brekke and Toth[2] stated that scaffolds should be rigid enough to avoid tissue prolapse but otherwise possess 'certain minimum mechanical characteristics.' Hutmacher[3] suggested that scaffold mechanical properties should match those of the native tissue at implantation time. Engelmayr *et al.*[4] also reiterated the design target of matching native tissue properties when they sought to create polymer scaffolds that matched the tangent elastic modulus of rat myocardium.

Although native tissue properties are a plausible scaffold design target for function, the key question is "What properties should scaffolds match?" There are a wide range of constitutive models that have been used to characterize tissues including linear elasticity, nonlinear elasticity, viscoelasticity, and poroelasticity. Again, the choice of appropriate functional design target will depend on the tissue. Linear elasticity is appropriate for bone, but it is unclear whether linear elasticity (as utilized by Engelmayr *et al.*[4] for myocardium) is an appropriate design target for soft tissues exhibiting nonlinear stress strain relationships under large deformation and viscoelastic strain-dependent behavior. In addition to defining the appropriate constitutive model design target, there is also a need to define the appropriate magnitude of the constitutive model coefficients for use as design targets. Stating that scaffold effective mechanical properties should match those of native tissue is problematic on two fronts. First, what is the definition of native tissue? Is this tissue from a male or female, a 30-year old or a 60-year old? Second, although widely postulated, the hypothesis that scaffold mechanical properties matching native tissue mechanical properties produces better outcomes has never been rigorously tested, or really tested at all for that matter. Still, the postulate that scaffold mechanical properties should match native tissue properties remains the most plausible scaffold function design target (for more information on the native mechanical properties of bone see **Chapter 3.307, Finite Element Analysis in Bone Research: A Computational Method Relating Structure to Mechanical Function**; for more information on native cardiac tissue properties see **Chapter 3.308, The Mechanics of Native and Engineered Cardiac Soft Tissues** in this volume).

The third general scaffold requirement, that scaffolds should enhance tissue regeneration through cell–material interaction and biologic factor delivery (Formation), remains the most ambiguous of the four scaffold requirements. While the need to replicate anatomic shape can be addressed through patient image data, the need for fixation defined by the stiffness and strength that will avoid separation of scaffold and host tissue, and the need to provide temporary function addressed by matching tissue constitutive model parameters, the characteristics that are best related to enhanced tissue regeneration remain largely undefined. Although it is clear that biologics like growth factors and stem cells can enhance tissue regeneration, a question arises with regard to the choice of the scaffold material and porous architecture that can best

integrate and deliver these biologics. O'Brien *et al.*[5] and Van Cleynenbreugel *et al.*[6] have noted increased cell adhesion with increased scaffold surface area, suggesting the increased surface area will positively affect cell–material interaction. However, this may only be the case if the material itself is hydrophilic and provides the appropriate ligands for cell attachment.

Furthermore, mass transport issues, including the capacity for vascularization, will have a substantial influence on tissue regeneration. Vascularization remains a difficult objective to achieve, requiring either delivery of proangiogenic factors such as vascular endothelial growth factor (VEGF), or engineering of an arteriovenous loop within the scaffold. Beyond immediate perfusion and vascularization, mass transport within scaffolds can also be characterized by effective permeability and diffusivity. In fact, for *in vitro* bioreactor approaches, Lovett *et al.*[7] suggest that increased diffusivity is key to providing sufficient oxygen to seeded cells. Thus, with current capabilities lacking in the ability to produce an arterial–capillary–venous loop, effective permeability and diffusivity may be the best way to define scaffold mass transport characteristics (for more information on characterizing mass transport and diffusion, see **Chapter 3.309, Fluid Mechanics: Transport and Diffusion Analyses as Applied in Biomaterials Studies** in this volume).

Increasing efficacy of regenerative medicine scaffolds requires testing of specific hypotheses concerning how potential scaffold design targets affect tissue regeneration. By testing these design hypotheses, we can, theoretically, iterate until we hone in on the requirements for optimal regenerative medicine scaffolds. This iterative cycle, termed iterative scaffold engineering (ISE) would start with posing a set of scaffold design targets, proceed to designing scaffolds through material choice and hierarchical microstructure geometry, manufacturing the scaffolds according to design specifications, and finally evaluating the scaffolds using nondestructive imaging, bench tests, and *in vivo* testing (**Figure 1**).

ISE is a significant undertaking in itself, requiring multiscale computational design, biomaterial synthesis, multiscale manufacturing, biomaterial surface modification, nondestructive image-based evaluation, mechanical testing, *in vitro* cell testing, *in vivo* large functional animal testing, and ultimately, human clinical trials. It is beyond the scope of this chapter to discuss all aspects of ISE in detail. This chapter will largely focus on engineering the geometric/physical aspects of scaffolds (multiscale design, manufacturing, and evaluation) as opposed to the material aspects (biomaterial synthesis).

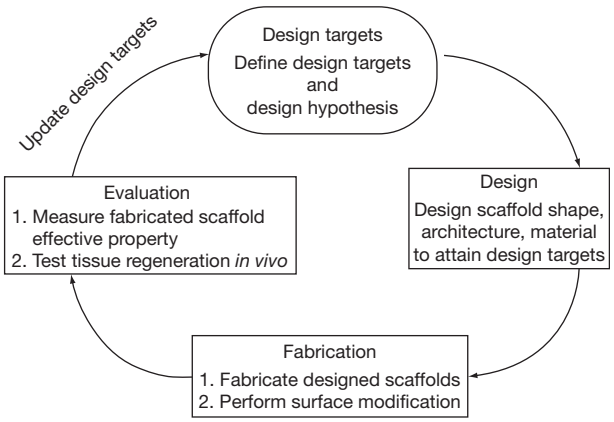

Figure 1 Iterative scaffold engineering cycle testing of scaffold parameters to determine optimal scaffold characteristics.

5.502.1.2. Choosing Effective Properties as Design Targets

Once effective properties are postulated as scaffold design targets, we need to specify what specific effective properties we should propose to govern the geometrical, functional, and tissue regeneration aspects of scaffold performance. Geometrically effective properties are the defect shape and volume determined by imaging data, as well as adjunct surgical fixation. Functional mechanical properties can be defined with appropriate constitutive models. Bone can be characterized as an anisotropic linear elastic material, while soft tissues are best characterized as isotropic or anisotropic nonlinear elastic or viscoelastic. Although a number of factors influence a scaffold's ability to enhance tissue regeneration, in this chapter, we will focus on physical characteristics and briefly touch upon biomaterial surface modification. The scaffold effective physical characteristics that most closely relate to tissue regeneration and biologic delivery are surface area/volume ratio, and mass transport. Surface area/volume ratio, also known as specific surface area, is related to cell–material interaction. Mass transport is not only related to the nutrient diffusion to and waste removal from cells within the scaffold, but can also define the ease or difficulty of cell migration and tissue ingrowth within the scaffold. Mass transport for both bone and soft tissues may be characterized using effective permeability and diffusion, although for soft tissues undergoing large deformation, both permeability and diffusion will be deformation-dependent. Thus, for the scaffold requirements of (1) maintaining/defining tissue defect volume, (2) providing temporary mechanical function, and (3) enhancing tissue regeneration, we can propose effective properties as design targets (**Table 1**).

Knowing if a proposed effective property design target is relevant, and more specifically, what magnitude is most appropriate, requires the iterative design testing proposed in ISE. Attaining design targets requires design variables or parameters that may be altered to reach the proposed targets. Most generally, design parameters for scaffolds are (1) the distribution of pores and material in three-dimensional (3D) space and (2) the choice of material(s) from which to fabricate the scaffold. The successful testing of design hypotheses for ISE then rests on developing computational schemes to manipulate these design parameters to achieve desired design targets, fabricating the resulting scaffold designs, and evaluating the results in both bench tests and *in vivo* models.

5.502.2. Hierarchical Computational Scaffold Design

The first step in ISE is actually designing the scaffold. Design includes both the external scaffold shape along with adjunct surgical fixation, and an internal porous architecture that can achieve the effective property design targets. Performing this design requires that the overall scaffold topology be represented computationally in a form for both analysis and manufacturing. Second, it requires that effective properties can

Table 1 Effective property design targets to fulfill scaffold requirements for shape filling, temporary mechanical function, and enhancement of tissue regeneration

Tissue	*Shape filling*	*Temporary mechanical function*	*Tissue regeneration and biologic delivery*
Bone	Segmented voxels within defect	Linear elasticity, E_{ijkl}	Diffusivity D_{ij} Permeability, K_{ij} Specific surface area, *SA*
Soft tissue	Segmented voxels within defect	Nonlinear elasticity, *W* Viscoelasticity, $G(t)$	Diffusivity, D_{ij} Permeability, K_{ij} Specific surface area, *SA*

E_{ijkl} denotes the fourth-order tensor of effective linear elastic constants, D_{ij} denotes a second-order tensor for effective diffusivity constants, K_{ij} denotes the tensor for effective permeability constants, SA denotes specific surface area (a scalar), *W* denotes nonlinear elasticity as an effective strain energy function, and $G(t)$ denotes a stress relaxation function for viscoelasticity.

be directly calculated from the porous architecture design to determine the relevant effective properties of a given architecture design.

5.502.2.1. Computational Representation of Hierarchical Scaffold Structure

Prior to performing any design operation, we must be able to represent complex 3D anatomy and hierarchical structure within a suitable data structure. Although parametric solids based on fundamental mathematical entities such as cylinders, spheres, etc., are widely used for engineering components, their use in anatomic biomaterial scaffold design is limited for two reasons. First, the tremendous complexity of anatomic structures frequently precludes representation by discrete mathematical formula. Second, the hierarchical nature of both tissues and porous biomaterial scaffolds makes it difficult to project solid geometry between different scales easily. A more natural computational representation of complex anatomy and hierarchical structure is voxel-based data structures, since they are generated directly from imaging modalities such as CT and MRI. Voxel data structures represent topology as a density distribution within a structured dataset, whose elements are isotropic or anisotropic cube structures. Each cube is identical; the only change is the density within the cube, with the aggregate density defining the topology. Although patient anatomy is represented by a single scalar value, it is straightforward to extend data representation in each cube to tensor fields such as the effective design targets in Table 1. Thus, anatomic defects of arbitrary 3D complexity can be represented using the same data structures.

Voxel datasets, in addition to being directly generated from patient imaging modalities, offer additional advantages for topology representation in hierarchical scaffold design. First and foremost, interpolation and boolean operations are straightforward using the image processing software noted in Section 5.502.1.1. Boolean operations are important for scaffold design, since we often design scaffold architecture separately from the anatomic scaffold design, and use boolean operation like intersection to place voxel datasets to different length scales. The length scales are matched using linear or cubic interpolation algorithms available in the image processing softwares noted in Section 5.502.1.1. Since boolean operations require features defined at the same length scales, it is necessary to interpolate anatomic voxel datasets to higher resolution equivalent to architecture datasets. Indeed, this equivalent feature requirement motivates the use of multiple image datasets to represent scaffold topology. Finally, voxel datasets are suitable and readily utilized as springboards to other data representations, including the direct calculation of surfaces for rapid manufacturing using marching cube algorithms and the direct conversion of voxel datasets into voxel finite element models for finite element analysis (FEA), topology optimization, and computational fluid dynamics (CFD).

5.502.2.2. Computing Effective Scaffold Properties Using Homogenization

Once we can represent scaffold architecture using voxel datasets, the next requirement is to compute the relationship of scaffold design parameters (basically, the distribution of material and pore in 3D space) to the resulting effective mechanical and mass transport design targets. Computing these scaffold structure–function relationships allows us to design for target effective properties by controlling scaffold architecture. To compute scaffold structure–function relationships, effective elasticity, permeability, and diffusivity properties must be calculated by solving the appropriate field equations at the architecture level and then averaging the results to determine the effective properties. These field equations include stress equilibrium for elasticity, creeping Stokes fluid flow for permeability, and local diffusivity for effective diffusivity.

Deriving structure–function relationships requires a mathematical theory that provides a consistent and rigorous derivation of the relationship between local and global scales. Homogenization is one such rigorously defined theory, that is specifically developed to analyze multiscale materials.[8,9] It has also been utilized to analyze multiscale tissue mechanics by our own group[10–12] and others.[13,14] Since 2000, our research group[15–21] has also applied homogenization theory as a means to analyze and design hierarchical tissue engineering scaffolds.

Homogenization theory assumes that a microstructured material is periodic, that is, the complete material volume can be made by repeating a basic unit mathematical cell in 3D space. The unit cell may be different at different locations in the material, allowing for heterogeneity. Homogenization theory addresses multiscale physics problems by first taking an asymptotic expansion of the relevant field variable as:

$$u_i^{\varepsilon} = u_i^0 + \varepsilon u_i^1 + \cdots \quad [1]$$

where u_i^ε is the total value of the field variable, u_i^0 is the average value at the global level, u_i^1 is the perturbation of the average value due to the presence of a microstructure, and ε is the ratio of the microstructure scale to the global scale, which is much less than 1. This field variable expansion is substituted with the associated gradient into the governing equations for elasticity, Stokes fluid flow, and diffusivity. By substituting the relevant field variable expansion and gradient into the governing equilibrium equation we obtain a microstructural equilibrium equation and a global equilibrium equation. These two scale equilibrium equations are linked by the effective physical property. For elasticity, we obtain the governing microstructural elasticity equation:

$$\frac{\partial}{\partial x_j^1} E_{ijkl} \frac{\partial \chi_k^{pq}}{\partial x_l^1} = \frac{\partial}{\partial x_j^1} E_{ijpq} \qquad [2]$$

For which χ_k^{pq} represent nine different microstructural displacements due to nine global unit strains and E_{ijkl} are the elastic properties of the base scaffold material. We can then directly calculate the effective elastic properties E_{ijkl}^{eff} as a function of base material elastic properties E_{ijkl} and the architectural arrangement of materials and voids in 3D represented by $\delta_{kp}\delta_{lq} - \frac{\partial \chi_p^{kl}}{\partial x_q^1}$ through the following integration over the microstructure:

$$E_{ijkl}^{\text{eff}} = \frac{1}{|V_{\text{micro}}|} \int_{V_{\text{micro}}} E_{ijpq} \left(\delta_{kp}\delta_{lq} - \frac{\partial \chi_p^{kl}}{\partial x_q^1} \right) \mathrm{d}V_{\text{micro}} \qquad [3]$$

Equation [3] thus gives us a direct mathematical way to compute the intuitive concept that effective scaffold elastic properties are determined by the base scaffold material elastic properties and the way these materials and pores are arranged in 3D space.

Similarly, for diffusion and electrical conductivity (which have the exact same form) we expand species concentration (for diffusion) or voltage (electrical conductivity) to obtain the following governing equation:

$$\frac{\partial}{\partial x_i^1} D_{ij} \frac{\partial \chi^p}{\partial x_j^1} = \frac{\partial}{\partial x_i^1} D_{ip} \qquad [4]$$

where χ^p represents local species concentration or voltage under three unit global concentration or voltage gradients. Again, we can directly calculate the effective diffusivity or electrical conductivity D_{ij}^{eff} by integrating the base scaffold diffusivity or conductivity D_{ij} times the quantity $\delta_{ip} - \frac{\partial \chi^p}{\partial x_j^1}$ that gives the architectural influence of material and pores arrangement in 3D space:

$$D_{ij}^{\text{eff}} = \frac{1}{|V_{\text{micro}}|} \int_{V_{\text{micro}}} D_{ip} \left(\delta_{jp} - \frac{\partial \chi^j}{\partial x_p^1} \right) \mathrm{d}V_{\text{micro}} \qquad [5]$$

Again, eqn [5] provides a mathematical computation for the concept that effective diffusivity (conductivity) depends on base scaffold material diffusivities (conductivities) and the way these materials and pores are arranged in 3D space.

A second effective mass transport property of interest is permeability. Permeability is defined by how easy or difficult it is for fluid to flow through a porous matrix. Thus, since we expect creeping flow, we solve Stokes flow at the microstructural level by expanding both the fluid pressure and velocity. This leads to the following equation that is solved to determine scaffold level pore fluid velocity under three unit pressure gradients:

$$\frac{\partial p^{1k}}{\partial x_i^1} - \frac{\partial}{\partial x_j^1} \left(\frac{\partial v_i^{0k}}{\partial x_j^1} \right) = e_i^k \qquad [6]$$

where p^{1k} is the internal pore pressure, v_i^{0k} is the average pore fluid velocity, and e_i^k represents three unit externally applied pressure gradients. The effective scaffold permeability K_{ik}^{eff} is then computed directly from the average pore fluid velocity as:

$$K_{ik}^{\text{eff}} = \frac{1}{\mu |V_{\text{micro}}^{\text{pore}}|} \int_{V_{\text{micro}}^{\text{pore}}} v_i^{0k} \mathrm{d}V_{\text{micro}}^{\text{pore}} \qquad [7]$$

where μ is the fluid viscosity and $V_{\text{micro}}^{\text{pore}}$ represents the pore volume occupied by fluid. It is interesting to note that permeability is only determined by the average pore fluid velocity and thus the 3D pore arrangement. Assuming the basic scaffold material is impermeable, effective scaffold permeability does not depend upon scaffold material.

The one effective design target that does not require the solution of a local field equation is specific surface area. This quantity is defined simply as the structural surface area divided by the total volume in which the structure exists. Surface area can most readily be calculated by generating an isosurface triangular facet from architecture voxel data, and then calculating the surface area from the resulting triangular mesh. Thus, we now have the capability to compute effective properties as design targets directly from voxel representations of scaffold architecture.

5.502.2.3. Bounds on Effective Design Targets

Although this section describes techniques by which we can calculate effective properties based on scaffold architecture, a number of questions remain regarding how effective properties are determined by scaffold architecture. A more important question is 'what are the possible range of effective properties that we can attain for a given amount of material?' The question relates to the absolute bounds that we can obtain on effective elasticity, permeability, diffusivity, and specific surface area for a given amount of material arranged in 3D space. If the bounds are rigorous, they define the range of effective properties attainable for a given amount of material, although realizing the actual design (discussed in **Section 5.502.2.4**) and actually fabricating the resulting design (discussed in **Sections 5.502.3.1** and **155.3.2**) remain significant hurdles.

The best known bounds regarding the relationship of volume fraction to attainable effective properties are the Voight and Reuss bounds, named after their respective developers. The Voight bound is known to be an absolute upper bound on attainable effective properties for a given volume fraction. This bound states that the effective property is equal to each individual material phase property; thus, for an effective tensor property, we have:

$$D_{ijkl}^{\text{eff}} = \sum_{n=1}^{N} v_f^n * D_{ijkl}^n \text{ for elasticity}$$

$$D_{ij}^{\text{eff}} = \sum_{n=1}^{N} \left(1 - v_f^n\right) * D_{ij}^n \text{ for mass transport} \qquad [8]$$

where D^{eff} with four indices denotes the effective elasticity tensor and with two indices, it denotes the effective diffusivity tensor, D^a with four indices v_f^a denotes the elasticity tensor of phase a and with two indices, it denotes the diffusivity tensor of phase a, and denotes the volume fraction (ranging between 0 and 1) of phase a. In the case of a two-phase material in which one phase is a solid and the other a pore, the effective elasticity is simply the volume fraction times solid phase elasticity and the effective diffusivity is simply one minus the volume fraction times the porous phase diffusivity (if one makes the assumption that diffusivity of the solid phase is zero). The Reuss bound is the complement of the Voight bound, with the inverse effective tensor properties weighted by volume fraction:

$$\left[D^{\text{eff}}_{ijkl}\right]^{-1} = \sum_{n=1}^{N} v_f^n * \left[D^n_{ijkl}\right]^{-1} \quad \text{for elasticity}$$

$$\left[D^{\text{eff}}_{ijkl}\right]^{-1} = \sum_{n=1}^{N} \left(1 - v_f^n\right) * \left[D^n_{ijkl}\right]^{-1} \quad \text{for mass transport} \qquad [9]$$

If any phase of a material or scaffold is zero, say, for example, zero elasticity for a pore or zero diffusivity for a solid, then the lower Reuss bound of any effective property is zero. This indeed holds for any bounds derived for porous materials. To illustrate, consider theoretically a collection of solid particles in a volume that are not connected. Even though the volume fraction is not zero, these particles could not carry any load and their effective elasticity would be zero. With regard to diffusion or permeability, we simply have to consider a closed cell (here cell is used in the sense of a cellular material as defined by Gibson and Ashby[22]; not a biological cell) structure where the pores are surrounded by solid walls, which will exhibit zero effective permeability and diffusivity.

Although the Voight bound is an absolute upper bound on effective properties, it is derived based on an idealized notion that the primary field variable (e.g., stress in elasticity) may be averaged in each phase solely based on the volume fraction in each phase, while the complementary field variable used to calculate energy (strain in elasticity) is constant across phases. Likewise, the Reuss bound is an absolute lower bound on effective properties because it assumes that the complementary field (strain in elasticity) variable may be averaged in each phase solely based on volume fraction, while the primary variable (stress in elasticity) is constant across phases. These conditions can only be approximated when the microstructure is as anisotropic as possible, which is when material is oriented as nonconnected fibers in one direction for elasticity or nonconnected pores in one direction for diffusivity and permeability (Figure 2). In other words, the red areas would be material fibers in Figure 2 for elasticity bounds while the red areas in Figure 2 would be pores for diffusivity/permeability bounds.

Indeed, if a homogenization calculation for elasticity is performed on Figure 2(b), assuming the red fibers are material, the effective elastic modulus is equal to the volume fraction times the elastic modulus of the base material, while the transverse effective elastic moduli are zero. Likewise, if we perform a homogenization diffusion analysis assuming the red fibers in Figure 2(b) are pores surrounded by material, the effective diffusion or permeability is equal to the volume fraction times the base diffusion, while the transverse diffusion

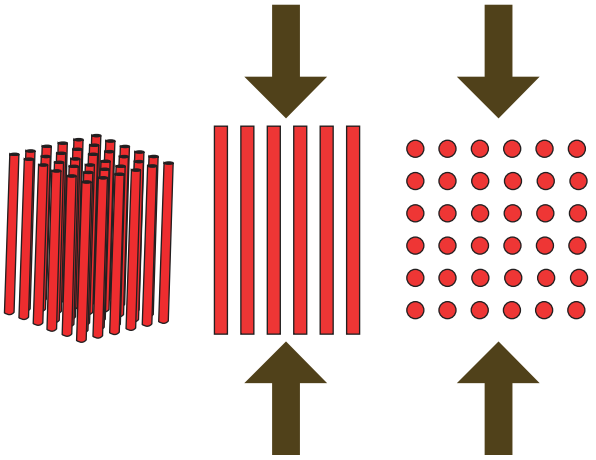

Figure 2 Example of anisotropic architectures that fulfill absolute Voight upper and Reuss lower bounds on effective properties. (a) Isometric view of a microstructure that satisfied Voight and Reuss bounds. (b) Fiber orientation parallel to axis of deformation/diffusion leads to Voight upper bound. (c) Fiber orientation perpendicular to axis of deformation/diffusion leads to Reuss lower bound. Note that fibers would be material for elasticity bounds while fibers would be pores for diffusivity/permeability bounds.

is zero. These structures represent the most anisotropic effective properties that are theoretically attainable.

Of course, structures such as that depicted in Figure 2 are not physically realistic for scaffold architectures. To withstand mechanical loading and provide shape deposition of tissue structures, scaffold architectures require material distributions along axes in 3D space. Once material is taken from the fiber direction and oriented across the fibers for elasticity (or conversely, pores are introduced perpendicular to the longitudinal axis, Figure 2(b)), we will obviously reduce the properties in the longitudinal direction along the fibers, and increase the properties in the transverse axes perpendicular to the fibers. Thus, any 'realistic' scaffold architecture will exhibit properties less than the upper bound completely anisotropic Voight prediction, and greater than the lower bound completely anisotropic Reuss prediction. Indeed, one can note that for many materials there is a wide spread between the Voight and Reuss bounds that can be realized by a wide variety of designed architectures.

At the opposite end of the spectrum from these maximally anisotropic structures are structures that demonstrate isotropic and cubically symmetric effective properties. For these structures, tighter bounds on effective elasticity and diffusivity have been obtained through the well known Hashin–Shtrikman bounds.[23] These bounds are derived using variational principles, and provide the most well-known bounds for effective isotropic elasticity and diffusivity. For a two-phase microstructure in which one of the phases is a void, the Hashin–Shtrikman bounds for isotropic (and cubic) effective diffusivity are:

$$D^{\text{eff}}_{ij} = \frac{2 - 2v_f D^{\text{pore}}}{2 + v_f} \qquad [10]$$

where D^{eff} is the effective diffusivity, v_f is the volume fraction of solid material, and D^{pore} is the intrinsic diffusivity of the

pore. The Hashin–Shtrikman bounds for elasticity (specifically bulk modulus) of a two-phase material consisting of a solid and void is:

$$K^{\text{eff}} = \frac{\left(\frac{3}{4}\right) v_f K^{\text{solid}} G^{\text{solid}}}{(1 - v_f) K^{\text{solid}} + \left(\frac{3}{4}\right) G^{\text{solid}}} \quad [11]$$

where K^{eff} is the effective bulk modulus, K^{solid} the bulk modulus of the solid material, G^{solid} the shear modulus of the solid material, and v_f is again the volume fraction of the solid material.

Deriving bounds on nonlinear elastic behavior is even more difficult than deriving bounds for linear elasticity. General Voight type bounds have been derived for general nonlinear elastic materials by Ogden[24] which state that the effective strain energy function for a porous nonlinear elastic material with one solid phase is bound by the volume fraction of material times the strain energy function of the base material:

$$W^{\text{eff}} = v_f W^{\text{solid}} \quad [12]$$

where W^{eff} is the effective strain energy function, v_f is the solid volume fraction, and W^{solid} is the strain energy function of the solid phase. The strain energy function depends on model constants and the right Cauchy deformation tensor that when differentiated with respect to the right Cauchy deformation tensor gives the second Piola–Kirchoff stress. Closer estimates for bounds on Neo-Hookean isotropic strain energy functions have been derived by Lopez-Pamies and Idiart,[25] but only for 2D porous elastomers.

No definitive analytical bounds are known for specific surface area as an effective property design target. The best guidelines come from work on bone-specific surface area in relationship to bone remodeling. Martin[26] first proposed a specific surface area curve versus volume fraction for bone tissue. Fyhrie *et al.*[27] later proposed a mathematical model fit for cancellous bone-specific surface area versus volume fraction in the form:

$$SA^{\text{eff}} = a_1 v_f (1 - v_f) \quad [13]$$

where SA^{eff} denotes the effective specific surface area, v_f is the material volume fraction, and a_1 is a model constant fit to experimental data. The expression in eqn [7] gives a bell shaped curve with a maximum specific surface area at a volume fraction of 0.5. Note that when there is no material ($v_f = 0$) or there is complete material ($v_f = 1.0$), the specific surface area by default becomes zero. In this chapter, a generalization of the Fyhrie model (eqn [7]) is proposed for general porous materials. This proposed model has the form:

$$SA^{\text{eff}} = a_1 v_f^{a_2} (1 - v_f)^{a_3} \quad [14]$$

where now a_2 and a_3 are additional model constants that dictate the shape of the curve relating specific surface area to volume fraction, and a_1 is a model constant that determines the maximum amount of surface area than can be contained within a given volume. This constant is scale dependent, as smaller the features in the structure, the greater is the surface area that we can generate within that volume. To ensure a physically realistic positive surface area, we restrict a_1, a_2, and a_3 to be strictly positive. If we further specify that a_1 be equal to the maximum of the specific surface over the volume fraction, then we can ensure that SA^{eff} will be normalized to a maximum of 1 as:

$$SA^{\text{eff}}_{\text{norm}} = \frac{1}{\max\left(v_f^{a_2}(1 - v_f)^{a_3}\right)} v_f^{a_2} (1 - v_f)^{a_3} \quad [15]$$

The maximum feasible upper bound is that all microstructures will produce a normalized surface area of 1, while the minimum lower bound consistent with results proposed by Fyhrie *et al.*[27] is that all microstructures will produce a surface area of 0, except at a volume fraction of 0.5. Based on the normalized specific surface area (eqn [9]), the absolute upper bound can be written using two Heaviside functions, denoted $H(x)$, as:

$$SA^{\text{upper}}_{\text{norm}} = H(1) - H(0) \quad [16]$$

which gives a step function that has value 1 between 0 and 1, and value 0 elsewhere. The absolute lower bound is given by a sequence of Gaussian functions, which in the limit as a goes to zero (a is much less than 1) and reaches to the Dirac Delta function:

$$SA^{\text{lower}}_{\text{norm}} = \frac{1}{M} \frac{1}{a\sqrt{\pi}} e^{-\frac{(v_f - 0.5)^2}{a^2}} \Rightarrow M = \text{Max}\left(\frac{1}{a\sqrt{\pi}} e^{-\frac{(v_f - 0.5)^2}{a^2}}\right) \quad [17]$$

Thus, based on previous mathematical bounds and physical reasoning, we can establish upper and lower bounds for all effective porous scaffold property design targets postulated in Table 1 for scaffold mechanical function and tissue regeneration performance, as summarized in Table 2.

Normalized lower and upper bounds for all effective mechanical and mass transport properties are plotted in Figure 3.

The absolute bounds for normalized specific surface area are plotted in Figure 4 along with the Fyhrie model of specific surface area for human cancellous bone.

The bounds given in Table 1, Figures 3 and 4 represent the absolute lower and upper bounds on effective properties that can be obtained for multiphase materials in which one phase is void. The scaffold base material elastic properties modulate the upper bound for effective elastic properties, but the lower bound will always be zero. Scaffold architecture design is the prime determinant of what effective properties can be obtained within the bounds. The bounds tell us, before the design and manufacturing process begins, what effective properties are theoretically attainable. As such, these bounds provide guidelines for designing scaffolds. What effective properties can be attained, and thus our ability to test how effective properties influence tissue regeneration, depends on computational methods for designing architecture and manufacturing methods that can actually make the designed architectures.

5.502.2.4. Designing Scaffold Architecture

Theoretically, any combination of effective properties will map into a specific architecture, just as the upper Voight bound and the lower Reuss bound can be mapped back into the parallel fiber architectures shown in Figure 2. However, there are no computational methods currently proven to map directly into a specific architecture for an arbitrary set of

Table 2 Proposed absolute lower and upper bounds for mechanical, mass transport, and surface area of porous microstructures

Effective property bounds	*Mechanical function: elasticity*	*Mass transport: diffusivity; permeability*	*Surface area (normalized)*
Bone: lower bound	0	0	$\frac{1}{M}\frac{1}{a\sqrt{\pi}}e^{\frac{-(v_f-0.5)^2}{a^2}}$, for $a \ll 1$
Bone: upper bound	$E^{\text{eff}}_{ijkl} = \sum_{n=1}^{N} v_f^n * E^n_{ijkl}$	$D^{\text{eff}}_{ij} = \sum_{n=1}^{N} (1-v_f^n) D^n_{ij}$ $K^{\text{eff}}_{ij} = \sum_{n=1}^{N} (1-v_f^n) K^n_{ij}$	$H(1)-H(0)$
Soft tissue: lower bound	0	0	$\frac{1}{M}\frac{1}{a\sqrt{\pi}}e^{\frac{-(v_f-0.5)^2}{a^2}}$, for $a \ll 1$
Soft tissue: upper bound	$W^{\text{eff}} = \sum_{n=1}^{N} v_f^n * W^n$	$D^{\text{eff}}_{ij} = \sum_{n=1}^{N} (1-v_f^n) D^n_{ij}$ $K^{\text{eff}}_{ij} = \sum_{n=1}^{N} (1-v_f^n) K^n_{ij}$	$H(1)-H(0)$

Note that v_f with superscript n refers to the volume fraction of phase n within a material, and that one phase of the material is a void (pore). $H(*)$ denotes the Heaviside function. M for the lower bound surface area denotes the maximum of the Gaussian sequence as specified in eqn [11].

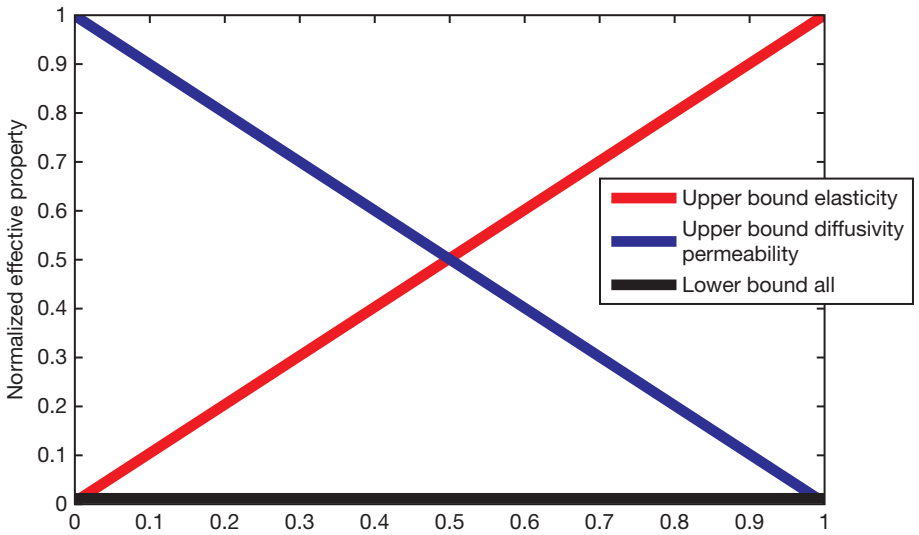

Figure 3 Normalized lower and upper bounds for effective elasticity and mass transport properties plotted versus volume fraction. Normalized upper bound elasticity (red solid) versus volume fraction in addition to lower and upper bound diffusivity and permeability (blue solid) versus volume fraction. Lower bounds for all effective properties are zero for porous materials denoted by the solid black line. (b) Normalized lower (dashed red) and upper (solid red) for specific surface area.

feasible (i.e., within defined bounds, **Section 5.502.2.3**) effective properties. Broadly, we can define computational methods for designing scaffold architecture as forward scaffold design methods (FSDM)[17] and inverse scaffold design methods (ISDM).[18,19,21,28–34] Both methods utilize the homogenization methods defined in **Section 5.502.2.2** to compute effective properties from a given voxel representation of architecture. In addition, both methods use a base unit mathematical cell that is periodically repeated in 3D space to create the final architecture. Note that this does not preclude heterogeneous or functionally graded architectures, as these are created by simply utilizing different unit cells.

In the forward method, we a priori design an architecture and then compute the effective properties from this designed architecture using eqns [3]–[7]. This is often done using a range of architectures from similar geometric families, for instance, interconnecting cylinders or interconnecting spheres. Hollister *et al.*[17] utilized this approach to design craniofacial scaffolds. In this approach, voxel-based data structures were generated based on geometric equations for cylinders, spheres or even wavy fiber structures. Such structures were created with a range of parameters, for instance, spherical diameter that could be modified to cover a range of volume fractions from 0 to 1. Effective properties computed for these structures using homogenization theory could then fit to polynomial functions. Thus, within this restricted topology, design parameters could be picked to fit a limited range of desired effective properties. The advantage of the FSDM is that architectures can be designed a priori to have manufacturable feature sizes (discussed in **Section 5.502.3**), as well as being targeted to

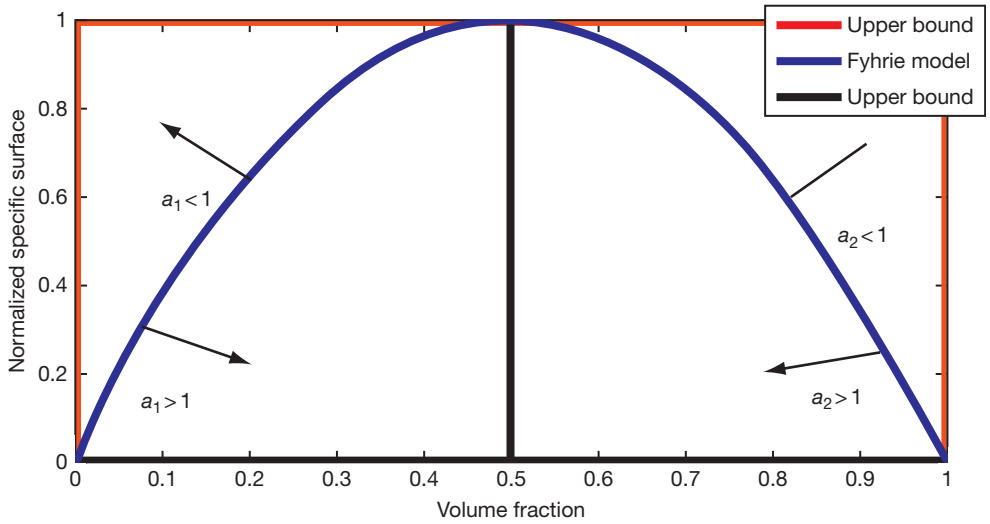

Figure 4 Normalized specific surface area bounds plotted versus volume fraction. Upper bound is plotted in red, lower bound in black, and the Fyhrie model is plotted in blue. The model coefficients a_1 and a_2 refer to the model of eqn [15]. As the coefficients increase from 1 the model in each half decreases towards the lower bound, while as the coefficients decrease from 1 the model increases toward the upper bound.

have more general changes for using heuristic design rules based on geometric models for cellular solids.[22] The limitations of the FSDM is that targeting specific effective properties becomes a trial and error approach.

The inverse method, as the name implies, starts from a set of desired properties and then attempts to calculate an architecture that fits these properties. This inverse homogenization problem was first formulated by Sigmund in 1994.[30] In this approach, an optimization problem is formulated in the general form of:

$$\begin{aligned}&\underset{v_f}{\text{Min}} \sum_{n=1}^{N}\left\{A^n_{ij(kl)} - \left[A^n_{ij(kl)}\right]^{\text{target}}\right\}^2\\ &\text{subject to :}\\ &B^n_{ij(kl)} \le \left[B^n_{ij(kl)}\right]^{\text{bound}}\\ &\int_{Vol} v_f \mathrm{d}Vol \le Vol^{\text{bound}}\\ &0 \le v_f \le 1\end{aligned} \qquad [18]$$

where $A_{ij(kl)}$ denotes the second (diffusion or permeability) or fourth rank (elasticity) tensor representation of effective property whose difference from a target value is minimized, $B_{ij(kl)}$ denotes a tensor whose value is constrained to be less than a bound value, Vol^{bound} is a bound on the total amount of material that may be used, and v_f is the volume fraction of material. Since optimization problems are inherently nonlinear (even if the effective target properties are linear) we must specify a starting material distribution. The chosen iteration algorithm (in many cases, the method of moving asymptotes, developed by Svanberg[35] is used) then sequentially updates the volume fraction in each voxel element of the mesh. At each step, the current material distribution, which defines the 3D scaffold architecture, is utilized in eqns [3]–[7] to solve the local homogenization equations in order to calculate effective properties. This process is repeated until a final optimized architecture is created.

Such inverse approaches could theoretically generate the full range of architectures to cover the range of effective property bounds. However, inverse approaches (in addition to forward approaches) are limited in general by the assumption of a single scale of architecture if a binary material/void solution is sought. In general, the unit cell volume typically covers a physical size scale of 0.5–3 mm. Within this volume, a typical voxel/element discretization may range up to 50 elements on a side, for a voxel resolution of 0.01 mm or 10 μm, due to computing limits for the nonlinear problem that may require up to 100 or more iterations. Thus, the minimum material feature that can be resolved is likely to be 2–3 voxel lengths or 20–30 μm. Beyond computing, most manufacturing techniques capable of creating controlled architectures (i.e., solid-free-form fabrication (SFF) techniques), are limited in resolution to features sizes above 100 μm. Because of both these computing and manufacturing limitations, inverse (and forward) design methods are realistically limited to one scale materials. Achieving structures that cover the complete range of possible effective properties requires architectures with multiple scale resolution, as nature itself shows in the construction of biologic tissues.

Examples of inverse scaffold design method (ISDM) for multiphysics problems (i.e., combined mass transport and mechanical property design targets) were presented by our group.[19] In this case, the architecture was designed to achieve the desired effective elastic and diffusivity properties simultaneously with a tight constraint on the range of volume fraction (typically $v_f \pm 2\%$):

$$\begin{aligned}&\text{Min } w_1\left(\frac{K^H}{K^*}-1\right)^2 + w_2\left(\frac{D^H}{D^*}-1\right)^2 + w_3 f_{\text{cubic}}\\ &\text{subject to } v_f^{\text{lower}} \le v_f \le v_f^{\text{lower}},\\ &0 < v_f(x_i) \le 1\end{aligned} \qquad [19]$$

where K^H denotes the homogenized (effective) bulk modulus, K^* denotes the target bulk modulus, D^H denotes homogenized (effective) bulk diffusivity, D^* denotes target diffusivity, w_i are

weighting functions, v_f denotes overall material volume fraction, $v_f(x_i)$ denotes the material volume fraction within a given voxel element, and the superscripts lower and upper denote the lower and upper bound on the overall volume fraction. The function $f3$ denotes a constraint that the effective elasticity has cubic symmetry and is defined as:

$$f_{\text{cubic}} = \left(\frac{E^{\text{H}}_{2222}}{E^{\text{H}}_{1111}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{3333}}{E^{\text{H}}_{2222}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{1111}}{E^{\text{H}}_{3333}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{2233}}{E^{\text{H}}_{1122}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{1133}}{E^{\text{H}}_{2233}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{1122}}{E^{\text{H}}_{1133}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{1313}}{E^{\text{H}}_{2323}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{1212}}{E^{\text{H}}_{1313}} - 1\right)^2 + \left(\frac{E^{\text{H}}_{2323}}{E^{\text{H}}_{1212}} - 1\right)^2 \quad [20]$$

where E^{H} are the nine independent nonzero components of the effective elasticity tensor. Essentially, eqn [20] requires that the normal modulus related components are equal, the shear modulus related components are equal, and the Poisson's ratio/modulus components are equal to enforce cubic symmetry.

Kang *et al.*[19] demonstrated that the simultaneous elasticity/diffusion ISDM could produce architectures with different elasticity/diffusion coefficients that were near theoretical cross-property bounds (Figure 5).

An important point to note from Figure 5, which applies to ISDM approaches in general, is that predictions of distinct single scale architectures with binary material/void structures are generally predicted near the upper cross-property bounds. When ISDM is used to predict architectures within the cross-property bounds away from the boundaries, more grey material (in between solid material and void) is predicted. This indicates that the algorithm is predicting material of intermediate density that cannot be represented by single scale architectures, but require microstructures of multiple scales. Such multiple scale microstructures occur naturally in biological tissues, but are very difficult to realize in computational design, and especially in manufacturing.

5.502.2.5. Integrating Hierarchical Design

Once the scaffold anatomic design or scaffold envelope with fixation is defined using methods of Section 5.502.2.1 and the scaffold architecture has been defined using the methods of Sections 5.502.2.2 and 5.502.2.4, these two scales must be integrated to complete the final scaffold design. Using the image-based design techniques described by Hollister and colleagues,[15–18,21,36–38] integration of the two design scales is readily achieved by interpolating the envelope design represented in voxel format to the same resolution as the architecture design in voxel format. After interpolation, the voxel design datasets are combined using Boolean operations. Density values in the scaffold envelope design dataset serve as flags to locate density values from the appropriate architecture design database. In this way, the architecture topology represented by voxel density values is substituted into the appropriate location. Figure 6 illustrates this integrated design process for a mandibular reconstruction scaffold.

5.502.2.6. Hierarchical Scaffold Design: Summary

In summary, scaffold design techniques must account for the 4Fs of scaffold engineering: Form, Fixation, Function, and Formation. Form and Fixation are dictated by patient defect anatomy, and therefore, require the ability to process and design directly from CT or MRI image data at scales of multiple millimeters and larger. Function and mass transport aspects of Formation can be characterized by effective elastic, permeability, diffusivity, and specific surface properties. These effective properties are determined at the same scale as characteristics of the 'Form' level of

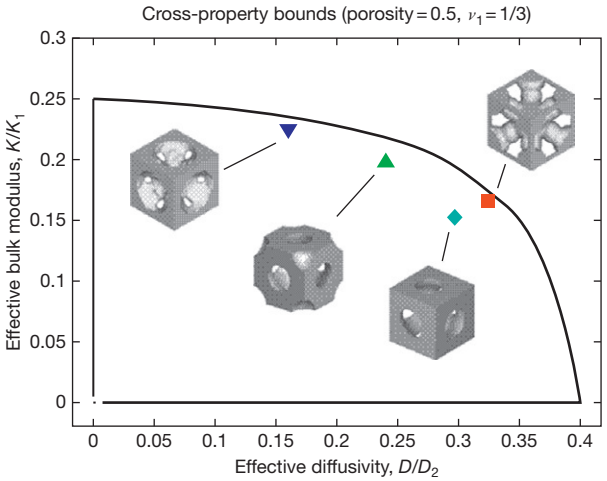

Figure 5 Representative architectures designed using the simultaneous elasticity/diffusion inverse scaffold design method approach by Kang *et al*. Note the wide variations in architecture that produce the different effective properties. Reproduced from Kang, H.; Lin, C. Y.; Hollister, S. J. *Struct. Multidisciplinary Optim.* (in press), with permission from Springer-Verlag.

design (multiple millimeters or larger), but by architectural features at the scale of 0.1–1 mm. In addition to effective mass transport and mechanical properties, formation is determined by growth factors and extracellular matrix proteins coupled to architecture features through surface modification, typical at scales of single microns or nanometers. Incorporating all these features requires both a data structure and a mathematical model that can represent multiple structural levels. Voxel-based methods are a natural method to represent hierarchical data. Homogenization theory provides a natural mathematical methodology to compute effective properties directly from architectural features. Voxel-based homogenization methods together provide a means to compute desired effective mechanical, mass transport, and specific surface properties for any anatomical defect. Both FSDM and ISDM can be used to directly design scaffold architecture to achieve desired effective properties. Finally, composite bounds give initial guidance as to the range of effective properties that can be expected even before computational design is performed.

5.502.3. Fabricating Designed Scaffolds

There are numerous techniques to fabricate scaffolds using both synthetic materials and natural extracellular matrix (for a review see Taboas *et al.*,[39] Hollister,[15,40] Hutmacher,[3,41] Hutmacher *et al.*,[42] Sachlos and Czernuszka[43]). These techniques include porogen leaching, electrospinning, gas foaming, emulsion, super critical fluid, and SFF. All these techniques offer advantages and disadvantages with regard to architecture feature size, control over architectural features, flexibility of use with different materials, and cost. In addition, these techniques can be combined to increase fabrication flexibility.[39,44] However, controlled architectures designed to achieve target effective properties (as in Figures 5 and 6), can only be fabricated using SFF techniques. SFF covers a broad range of technologies that build scaffolds (or any complex 3D structures) on a layer-by-layer basis using a variety of physical means including direct nozzle deposition, spraying chemical binders on material powders, sintering powders by laser, and photopolymerization. A schematic representation of different SFF processing methods is shown in Figure 7.

Sacrificial material or supports are used to hold hanging material in position. Furthermore, a design file, most commonly based on the STL file format that represents topology by triangular surface facets, directs material distribution in the layer. SFF scaffold building approaches can be categorized as direct or indirect.

5.502.3.1. Direct Solid-Free-Form Fabrication

Direct SFF means that the biomaterial of interest is built on the SFF system directly. Since each SFF method uses a different physical technique to process material, each biomaterial must be specifically adapted to each different machine. For example, stereolithography (SLA) techniques require materials in a form of polymerizable liquid resin that can be photo-cross-linked by ultraviolet (UV) light.[45] Selective laser sintering (SLS) techniques require materials that can be processed in powder form having particle sizes <125–150 μm[46,47] that have melting temperatures between 50 and 150 °C. 3D printing technologies also require particle sizes <150 μm that can be bound using specific chemical binders. Nozzle-based systems are more forgiving in their material requirements, mainly requiring materials that have low enough viscosity such that they can be dispensed under appropriate temperature and pressure, while having sufficient viscosity to maintain form after deposition. For ceramics and metals, this requires a slurry with appropriate viscosity. For polymers, this may require dissolution in a solvent. For some special nozzle-based systems such as fused deposition modeling, the material may have to be processed in a filament that can be fed into the system. These requirements for direct SFF manufacturing have two significant impacts on scaffold fabrication and attainable effective properties. First, it is obvious that the range of biomaterials that can be manufactured by direct SFF is limited, and that developing the means to process even one material, let alone a range of materials, for direct SFF requires significant effort. Second, and less obvious, is the fact that the physical processing method itself will determine the properties of the base material (both mechanical and mass transport), which in turn will affect the effective properties as defined in eqns [2]–[12].

SLA techniques have been primarily utilized with poly(propylene fumarate) (PPF) polymer, a degradable polyester made by synthesis of diethyl fumarate (DEF) with propylene glycol. PPF is created as a liquid resin by dissolving PPF in DEF, and adding bisacrylphosphrine oxide (BAPO) as a photoinitiator.[45] Different mixtures of PPF, DEF, and BAPO change the viscosity and molecular weight of the resulting liquid, thus affecting the scaffold base material properties and fabrication resolution, both again affecting the resultant effective properties. Using a commercial viper SLA system, Lee *et al.*[45] found that different ratios of PPF, DEF, and BAPO led to a base PPF compressive modulus ranging from ~20 to 140 MPa, with standard deviations ranging from 4 to 41% of the mean. Interconnected cubic and hexagonal pore scaffolds were fabricated using this technique, with a strut thickness of 300 μm and pore sizes ranging from 446 to 913 μm. This results in an effective compressive moduli 14–40 MPa, with standard deviation ranging from 6% to 17.5% of the mean. Thus, the physical material makeup created larger variability in properties than the fabrication process. Lee *et al.*[48] (a different group) introduced a customized microstereolithography with smaller laser beam spot size capable of building scaffolds with strut sizes of 120 μm and pore sizes of 250 μm. They reported base compressive modulus of 780 MPa, with a standard deviation of ~220 MPa, 28% of the mean. Effective compressive modulus ranged from 200 to 580 MPa, with standard deviations ranging from 6 to 45% of the mean.

SLS and selective laser melting have been used to manufacture materials and scaffolds from biomaterials that can be processed into the appropriate particle size range (<125–150 μm) with an appropriate melting temperature. For tissue engineering, this has mainly focused on polycaprolactone (PCL), polyetheretherketone (PEEK), PCL/hydroxyapatite (HA) composites, and titanium. Our group demonstrated the capability to fabricate designed PCL scaffolds with microstructures similar to those presented in Section 5.502.2 using laser sintering.[38,46,49] Pore sizes ranging from 1 to 2 mm and strut sizes ranging from 1 to 1.5 mm were achieved. Solid specimens had compressive moduli ranging from 120 to 317 MPa, with standard deviations

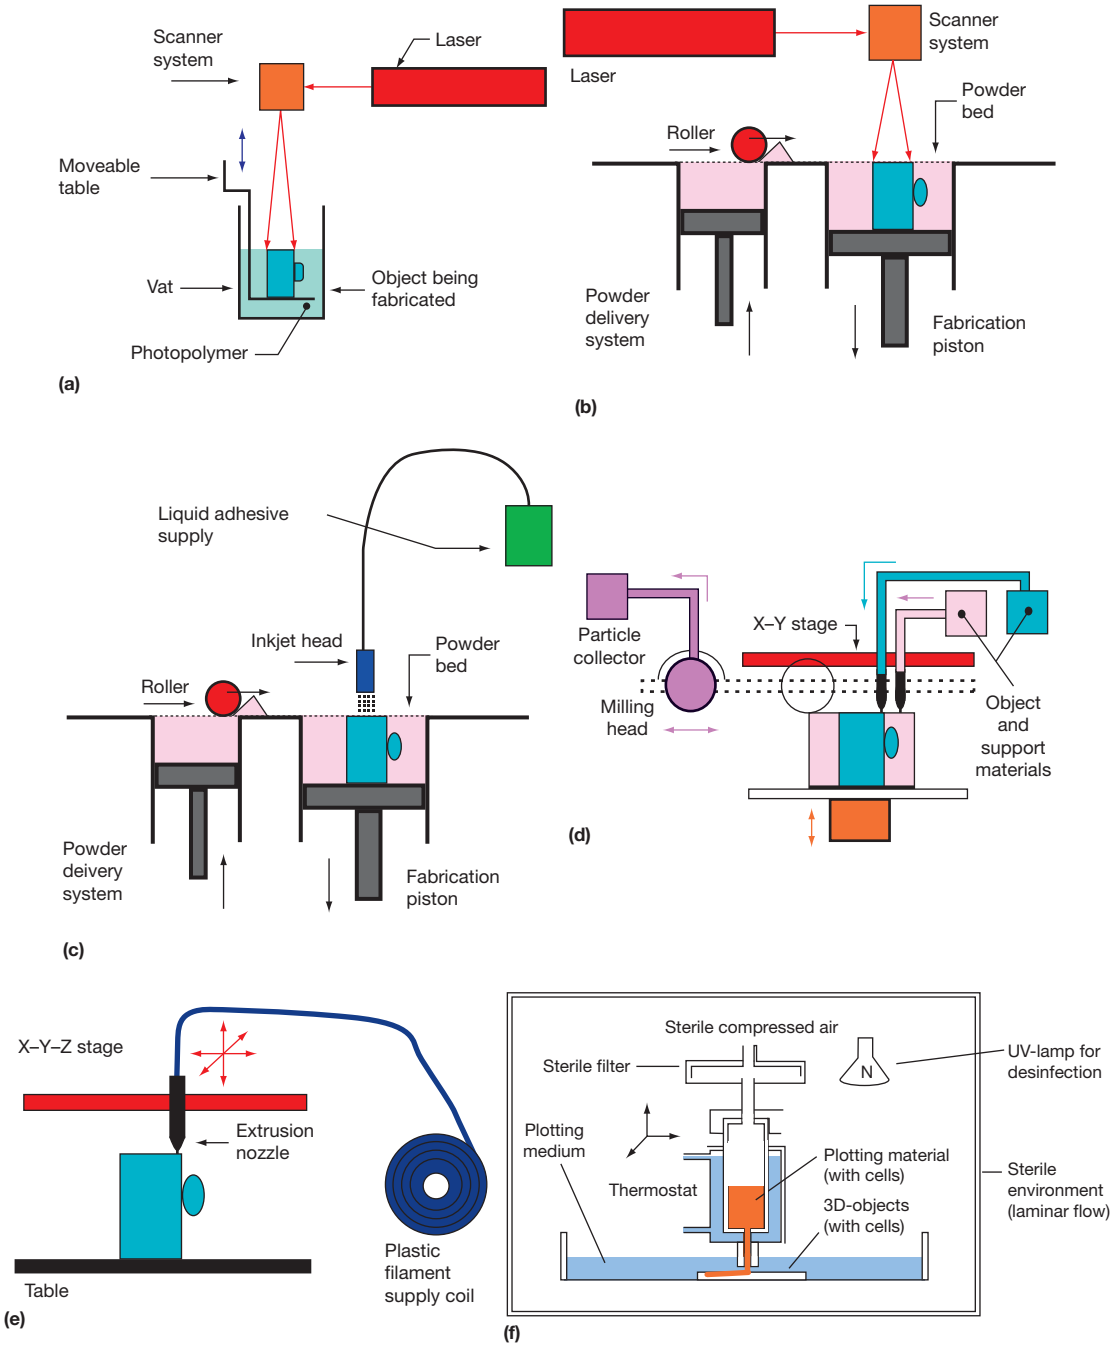

Figure 7 Schematic of solid-free-form fabrication technologies used to build biomaterial scaffolds. (a and b) Laser-based processing systems that either photopolymerize liquid (stereolithography) or directly sinter material particles together (laser sintering). (c and d) Printing-based systems that print by directly printing chemical binder onto powdered materials (3D printing) or by directly printing wax (Wax-based printer). (e and f) Nozzle-based systems that deposit material from a nozzle (fused deposition modeling) or deposit material in solvent through a syringe. Reproduced from Hollister, S. J. *Nat. Mater.* **2005**, *4*, 518–524, with permission from Nature Materials.

from 1 to 10% of the mean. For porous scaffolds with porosity ranging from 37 to 55%, effective compressive moduli ranged from 52 to 65 MPa with standard deviations ranging from 3 to 6% of the mean. Williams *et al.* also performed homogenization analysis for the scaffold designs, showing an R^2 correlation of 0.56 between computational and experimental results. This was one of the first instances of being able to accurately predict actual manufactured scaffold effective properties from computational designs. Cahill *et al.*[50] also performed a study comparing finite element predictions of PCL effective moduli to experimental measures. They were able to manufacture scaffolds, 659 μm pores and 431 μm struts. Solid PCL had a compressive modulus of 47 MPa, with a standard deviation that was 10.6% of the mean. PCL scaffolds had a

compressive modulus of 6 MPa, with a standard deviation that was 15% of the mean. Cahill *et al*. noted finite element predictions of modulus were 67% different than experimental measures, likely due to micropores and surface roughness artifacts from the manufacturing process. Chua, Leong, and colleagues also demonstrated fabrication of PCL solid discs from different materials[47,51,52] in addition to scaffolds.[53] Wiria *et al*.[47] reported compressive moduli for PCL/HA composites ranging from 33 to 102 MPa, dependent on the ratio of the composite phases. Standard deviations ranged from 8 to 18% of mean values. Yeong *et al*.[53] reported scaffolds with porosity ranging from 48 to 74%, with resulting compressive moduli ranging from 5 to 18 MPa.

Nozzle-based techniques have become widely adapted to directly build a range of scaffolds from ceramics to polymers. These systems include both commercial systems and custom-built systems. Wagoner-Johnson and colleagues[54–57] developed a micro-robotic ceramics slurry deposition techniques to produce 3D scaffolds by laying down rods of HA. By further incorporating 2–8 μm diameter polymethylmethacrylate (PMMA) beads that were burnt out after sintering, Wagoner-Johnson and colleagues were able to create ceramics scaffolds with two scale porosity. They determined effective compressive moduli ranging from 670 to 1240 MPa, with standard deviations ranging from 7 to 49% of the mean. Hutmacher, Teoh, and colleagues [3,58–60] developed a fused deposition modeling approach to fabricate PCL and PCL/TCP composite scaffolds to be used for craniofacial reconstruction and spine fusion. Zein *et al*.[60] fabricated PCL scaffolds with compressive moduli ranging from 42 to 77 MPa, with standard deviations ranging from ~7 to 11% of the mean. van Blitterswijk, Woodfield, Malda, Moroni, and colleagues[44,61–68] have done a substantial amount of work on fabricating copolymer polyethyleneoxide-terephtalate (PEOT) and polybutyleneterephtelate (PBT), as well as titanium scaffolds using a nozzle deposition system. Woodfield *et al*.[66] varied the spacing of deposited struts, creating different architectures for a narrow range of porosity between 60 and 87%. They measured equilibrium moduli ranging from 0.1 to 2.5 MPa, with standard deviations ranging form 15 to 40% of the mean. These equilibrium moduli covered the range of measured articular cartilage equilibrium moduli. Moroni *et al*.[63] performed an elastic FEA similar to a homogenization analysis to compute effective elastic properties for comparison to those measured from nozzle fabricated scaffolds. They found dynamic moduli ranging form 0.46 to 13.49 MPa, with standard deviations ranging form 17 to 81% of the mean. Effective elastic modulus calculations matched experimental data within 15% for most scaffold architectures.

5.502.3.2. Indirect Solid-Free-Form Fabrication

Although direct SFF provides significant advantages in terms of reproducibly building a large number of scaffolds, it presents challenges to implement as a platform for fabricating a range of biomaterials. SLA and SLS techniques have very specific material requirements to allow processing and often require significant quantities of material (in the 0.5–2 kg range) in order to build parts. Given the great expense of many polymeric biomaterials, it is often difficult to fund an experimental study using such techniques. Nozzle-based systems allow a broader range of materials, but there is still a significant effort required to adapt a given biomaterial to a nozzle-based system, whether it is fine tuning the material viscosity in slurries or solvents, or processing the material into a filament. In addition, nozzle-based systems have greater restrictions in terms of the final shapes of both pores and struts that can be manufactured for the resulting scaffolds.

Due to these limitations, many researchers desiring the architecture control provided by SFF but also desiring the capability to build from a wider range of biomaterials have turned to indirect SFF methods. Indirect SFF is so named because the biomaterial scaffold is not built directly on the SFF system. Instead, a mold is built on the SFF system into which a biomaterial is then cast, with the mold being removed using a lost wax technique (**Figure 8**).

Using the indirect SFF method, research groups have been able to fabricate scaffolds for a wide range of materials including HA, PCL, poly(lactic-*co*-glycolic acid) (PLGA), polyoctane diol citrate (POC), polyglycerol sebacate (poly(glycerolsebacate), PGS), and collagen, a much broader range of materials than have been built using direct SFF.

Chu *et al*.[69] presented one of the first reports of indirect SFF to create 40% porous HA scaffolds, which had a compressive modulus of 1400 MPa, and compressive strength of 30 MPa. Standard deviations for compressive modulus were 28.5% of the mean. Wilson *et al*.[70] used a similar inverse SFF technique in which a ceramic slurry was drawn into a mold fabricated using SFF, but did not present effective property data. Our group[39] generalized the inverse SFF technique to create polymer, ceramics, and polymer/ceramics composites. The inverse SFF was also combined with traditional porogen leaching and emulsion techniques to create hierarchical pore structures. We have further extended the inverse SFF techniques[71–74] to build a variety of degradable polymers including PCL, POC, and PGS. We then characterized the effective permeability, elastic, and nonlinear elastic properties of these scaffolds relative to the computationally designed properties. Kemppainen and Hollister[74] fabricated 3D PGS scaffolds under different curing times and molar ratios of glycerol to sebacic acid, measuring the nonlinear elastic properties and tangent moduli. We found that increased curing time and higher sebacic acid to glycerol ratios increased the nonlinear elastic response. We also found that effective elastic moduli calculated by homogenization matched closely with experimental tangent moduli (0.57 MPa experimental vs. 0.6 MPa computational), and that tangent moduli ranged from 0.03 to 1.13 MPa. The standard deviation was 42% of the mean. Jeong and Hollister[71] fabricated 3D designed porous POC scaffolds using image-based design methods and inverse SFF. We found that increasing the scaffold porosity not only decreased the tangent moduli, but also decreased the nonlinearity of the elastic response, as could be predicted by the nonlinear elastic bounds given in **Table 2**. Standard deviations in tangent compressive moduli ranged from 12 to 49% of the mean. We also measured effective scaffold permeability, which ranged 0.54×10^{-6} (32% porosity) to 5.24×10^{-6} $m^4\,Ns^{-1}$ (62% porosity) with standard deviations ranging from 7 to 22 of the mean. Jeong and Hollister[72] also fabricated PCL, PGS, and POC scaffolds of the same architecture using inverse SFF to compare the influence of scaffold material

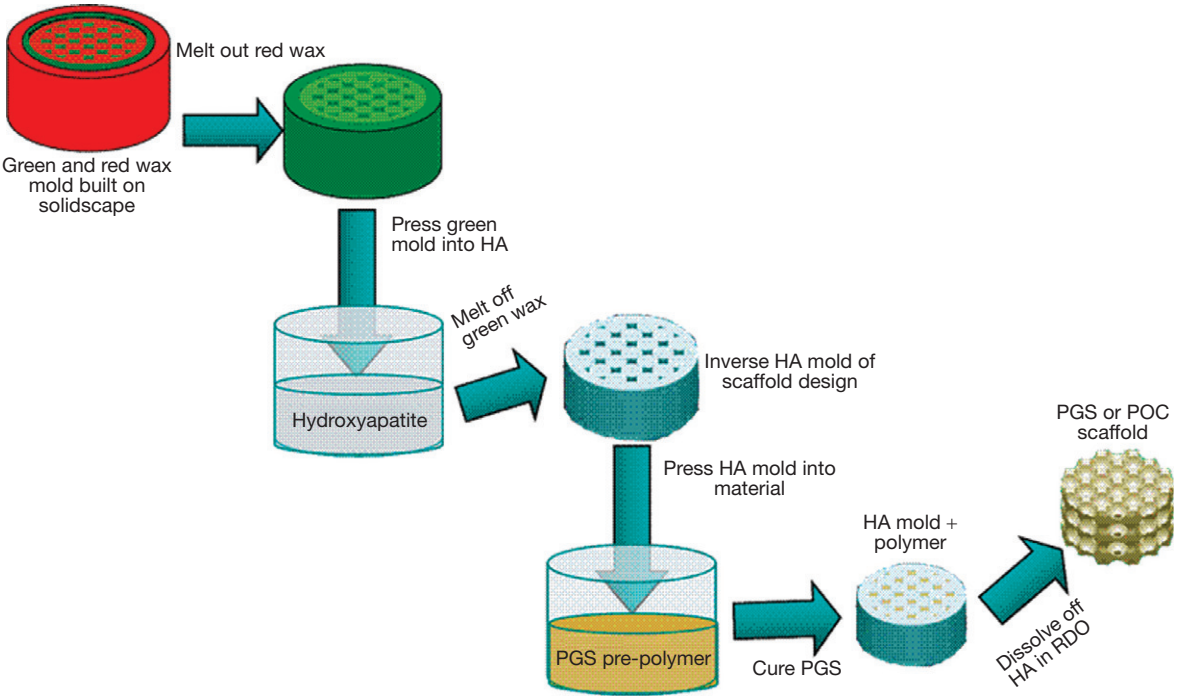

Figure 8 Schematic of indirect solid-free-form fabrication process for manufacturing 3D polymeric scaffolds. A wax mold is built on a 3D printing system. Hydroxyapatite is cast into the mold, and the wax is removed. The HA second mold is then pushed into the pre-polymer, which is then cured. The HA is removed by decalcification.

on effective properties and cartilage regeneration. As expected, PGS and POC as elastomers exhibited nonlinear elastic behavior with tangent moduli at 10% strain of 0.13 MPa for POC and 0.19 MPa for PGS. Standard deviations were 31% for POC and 30% for PGS. PCL exhibited linear elasticity with a tangent modulus of 21.8 MPa, and a standard deviation 20% of the mean. Effective permeability was also significantly dependent on material type, being $2.93 \times 10^{-7}\ m^4\ N\ s^{-1}$ for PCL, $3.51 \times 10^{-7}\ m^4\ N\ s^{-1}$ for POC and $8.31 \times 10^{-7}\ m^4\ N\ s^{-1}$ for PGS. Standard deviations ranged from 24 to 47% of the mean. Czernuszka, Sachlos, Liu and collegues[75–78] developed an inverse SFF technique to create collagen I scaffolds. A type I collagen dispersion was cast into wax molds, frozen at 20 °C with the wax and ice crystals removed using ethanol. All scaffolds were dehydrated under vacuum pressure with some scaffolds subsequently crosslinked using lysine. Storage moduli ranged from 0.1 to 1 MPa with higher moduli found for crosslinked collagen. Moduli decreased with increasing strain, indicating a nonlinear response (for more information on scaffold fabrication, see **Chapter 5.542, Organ Printing** in this volume).

5.502.3.3. Postfabrication Surface Modification

Controlled manufacture of scaffold architecture determines effective scaffold mechanical and mass transport properties, generally affecting large aggregates of cells. Effective properties, however, likely represent only average effects over local cell behavior. Cell behavior and differentiation are also significantly influenced by cell–material interactions, governed by cell–integrin interactions with local material chemistry and surface topography. The desire of course is then to directly affect cell attachment and differentiation on scaffolds by modifying cell–material interactions, essentially manufacturing features on the order of the cell or smaller, that is <10 μm. Viewed in the same hierarchy as design and manufacturing, these surface modification techniques can be thought of as 'manufacturing' materials at scales of 50 μm or less. It is obviously very difficult to build 3D structures that are cubic centimeters in volume by depositing material in 10–20 μm^3, or $1 \times 10^{-12}\ cm^3$, at a time. Therefore, to rapidly deposit 10 μm features or less within a 3D structure that is cubic centimeters in size, it is more feasible to first rapidly build the complex 3D structure at coarser 100–1000 μm^3 increments and then modify this base structure with either material features or extracellular matrix proteins that can influence cell attachment, and possibly, cell differentiation.

Of course, we can certainly contemplate doing micro or even nano solid fabrication. However, if the ultimate goal is a macroscopic scaffold aimed at reconstruction of a large defect, it is not realistic with the current state of the art to build such a structure directly only with micro- or nanofabrication. Therefore, the most realistic approach to distributing features <50 μm in size or biologic molecules in 3D space over large volumes is to first build a 3D substrate structure using one of the SFF techniques described in **Sections 5.502.3.1** and **155.3.2**, and then modifying the surfaces of this 3D substrate structure. The difficulty is that these manufactured 3D scaffold substrates will contain complex interconnected pore structures that cannot be modified using solid based manufacturing techniques.

A more feasible approach to modify 3D fabricated scaffold substrates is through the use of fluid or gas-based methods, which can enable perfusion through the interconnected pores. Such methods would include simulated body fluid (SBF) methods in which the scaffold is soaked in a circulating fluid (SBF),[79,80] conjugation methods in which a chemical cross-linker is perfused through the pore structure followed by a fluid containing the molecule of interest (e.g., RGD, IKVAV, BMP2, etc.), or chemical vapor deposition (CVD)[81,82] in which a substance is sublimated, carried at high temperature through a pyrolysis zone using an argon gas carrier, and then deposited on a substrate material. In this chapter, such methods will be denoted as postfabrication surface modification methods, or postfab surface modification, for short. Of note, the methods for design and manufacture for effective permeability and diffusivity will also affect the efficiency of these flow-based surface modification techniques.

Our own group has used fluid-based aminolysis techniques to modify 3D designed PCL scaffold subtrates for chemical conjugation.[83] In this technique, the scaffold is immersed in a solution of 1,6-hexanediamine and isoproposanol, which exposes NH_2 groups on the PCL surface. These groups allow the use of a chemical cross-linker, sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC) to attach to the glycine portion of the arginine-glycine-aspartic acid (RGD) sequence. RGD is a peptide sequence known to improve cell adhesion through integrin binding. Zhang *et al.* demonstrated that there was a significant increase in both cell attachment and cell survival of rat bone marrow stromal cells (BMSC) on RGD-modified PCL scaffolds compared to unmodified PCL surfaces. Using this method, we obtained a relatively homogeneous distribution of RGD throughout the 3D scaffold. We found that RGD-modified PCL scaffolds demonstrated increased attachment and survival of BMSC. We also noted that the RGD-modified PCL scaffolds upregulated the integrin-mediated FAK-P13K-Akt pathway. Activation of Akt is associated with inhibition of proapoptotic factors, and thus may affect cell survival and growth.

A second approach to generate NH_2 groups on a PCL surface is through CVD. Hu *et al.*[84] used the CVD techniques developed by Lahann *et al.*[81,82] to deposit a reactive polymer poly[(4-amino-*p*-xylylene)-*co*-(*p*-xylylene)] (PPX-NH_2) on the surfaces of PCL scaffolds. The NH_2 groups created on the PCL surface were conjugated to amine–PEO_3–biotin. Adenovirus was also biotinylated and docked with the biotinlyated PCL surface. Hu *et al.* demonstrated that the adenovirus was conjugated to the PCL surface and was able to transduce fibroblasts in a spatially controlled manner on 3D PCL scaffolds. These results again demonstrate the usefulness of postfab surface modification to spatially distribute biologics (in this case viral vectors for gene delivery) in a controlled manner to enhance tissue regeneration.

A postfab fluid-based surface modification technique designed to create osteoconductive surfaces is biomineralization generated by mineral precipitation on material surfaces from SBF. This process has been applied to a variety of material surfaces[85–88] and was first described for application to porous degradable polymers by Murphy and colleagues.[79,89] In this method, the scaffold is bathed in a fluid solution containing many of the ionic constituents of blood plasma with the same pH and temperature. This solution leads to nucleation and growth of mineral on a template material negatively charged or polar oxygen functional groups.[90] Again, successful application of this fluid-based method to 3D interconnected porous scaffolds requires penetration of the fluid throughout the pores. Segvich *et al.*[91] addressed this issue by attaching a filtration system to a servohydraulic Instron system which forced the porogen-leached polymer scaffolds through a fluid bath. They noted that a uniform mineral coating could be obtained throughout the scaffold. Suarez-Gonzalez *et al.*[90] addressed the issue of fluid penetration by a rod system which forced SBF through alginate scaffolds with 200 μm pores fixed in a holder. Using micro-CT scanning, Suarez-Gonzalez *et al.* demonstrated that mineral was distributed throughout the scaffolds uniformly, while for scaffolds without forced fluid flow, mineral was only distributed on the scaffold periphery. They also demonstrated that the mineralized scaffolds supported increased proliferation of BMSC. Both of these studies show the need to incorporate forced fluid flow to increase efficiency and spatial distribution of biomineralization (for more information on scaffold and biomaterial surface modification, see **Chapter 1.113, Bioactive Layer Formation on Metals and Polymers**; **Chapter 2.201, Bio-inspired Silica Nanomaterials for Biomedical Applications**; **Chapter 4.411, Peptide- and Protein-Modified Surfaces**; and **Chapter 4.420, Drug Delivery via Heparin Conjugates** in this volume).

5.502.3.4. Scaffold Fabrication: Summary

In summary, significant progress has been made in scaffold fabrication using SFF technology since Giordano *et al.*[92] reported the first use of 3D printing for biomaterial fabrication. SFF in different forms, direct and indirect, can be used to fabricated 3D scaffolds with controlled architecture from almost any biomaterial utilized for tissue engineering. The first 10–15 years of SFF-based scaffold fabrication have been largely focused on the feasibility of the technology for actually making scaffolds from a range of biomaterials. In addition, recent work has demonstrated that SFF-manufactured scaffolds can be further modified post fabrication using fluid- and gas-based methods to enhance cell adhesion through the attachment of peptide sequences, and to localize, bind, and release proteins and genes that stimulate tissue growth. Thus, hierarchical manufacturing techniques are beginning to mature, with many more published studies existing than can be summarized in any review. Going forward, there are two significant, related issues for SFF scaffold technology that must be addressed: (1) benchmarking and quality control and (2) better integration of fabrication with computational design and evaluation. Benchmarks and quality control are needed to better understand the strengths and limitations of various fabrication technologies. It is clear that the physical process parameters for different machines and material formulation all can significantly alter resulting scaffold effective properties. Variations in scaffold effective properties ranged from lows of 1% to highs of over 80% of the mean values. It will be critical while going forward to have a better grasp of how material formulations and machine processing parameters affect the reproducibility of scaffold properties. This is

important not only for rigorous testing of scaffold design hypotheses, but also in moving toward clinical implementation to satisfy FDA quality control requirements for current good manufacturing processes (cGMP). Specifically, the influence of processing parameters on measured scaffold properties will have to be delineated, for example, using design of experiment (DOE) approaches as presented by Partee *et al.*[49] and Hoelzle *et al.*[54] Quality control can also be better studied across the research community by implementing benchmarks of standard scaffold designs that can be built and tested using different manufacturing methods for comparison. Quality control and evaluation measures will also be critical to assessing distribution of surface attached biologics (cells, genes, and proteins) in controlled 3D architectures. Better integration of fabrication with computational design and evaluation is critical to testing scaffold design hypotheses. Enhanced tissue regeneration via improved scaffold designs requires that we know if – and how – effective mechanical and mass transport properties influence tissue regeneration, and if so, what magnitudes of these effective properties are best. As stated in the introduction, although many researchers have postulated that optimal scaffolds should match tissue properties, these postulates remain untested.

5.502.4. Designed Scaffold Architecture Influences Tissue Regeneration

Given that controlling scaffold architecture and material through hierarchical design and manufacturing is a significant undertaking in itself, the blunt question is "Does it matter?" More diplomatically, does scaffold design actually influence tissue regeneration? If the answer is yes, then the ability to control scaffold architecture with different biomaterials should become a top priority in the tissue engineering and regenerative medicine community, in terms of testing scaffold design hypotheses, funding fabrication-centric research, and developing quality standards and benchmarks to support FDA regulation of scaffold-based therapies. Failure to fund research and development of controlled scaffold fabrication will significantly impede progression of these technologies to clinical application.

5.502.4.1. Cartilage

Articular cartilage is a singularly unique tissue in terms of its regenerative challenges and its effective properties. It is basically an avascular tissue that relies on mechanical compression and subsequent fluid movement to provide cell nutrition. Articular cartilage has the lowest effective permeability of any tissue, in the range of 10^{-14} to 10^{-15} $m^4\,N\,s^{-1}$. Although cartilage matrix is nonlinear elastic,[93] most researchers have reported effective aggregate or Young's modulus in the range of 0.03–1.13 MPa.[74] These effective mass transport and mechanical properties present a difficult challenge for articular cartilage scaffold design. Most commonly used degradable polyesters (poly-L-lactic acid (PLLA), polyglycolic acid (PGA), and PCL) have base material moduli ranging from 200 to 1500 MPa. Based on effective property bound estimates in Section 5.502.2.2, achieving effective moduli of 1 MPa or less would require a porosity ranging between 95% to over 99%. Of course, creating scaffolds with such large porosity would defeat the purpose of creating a scaffold with extremely low permeability, since 95% porous scaffolds with a non-woven mesh structure were shown by Li and Mak[94] to have permeability ranging from 2.5 to 4.5×10^{-6} $m^4\,N\,s^{-1}$, more than 8 orders of magnitude higher than the normal articular cartilage.

Of course, given that it is highly unlikely that the current most widely used scaffolding polymers can be designed to simultaneously match articular cartilage effective mass and mechanical properties, this leaves two paths to pursue. First, there are a number of biodegradable elastomers that can achieve properties in the range of articular cartilage, including POC and PGS. Second, given that the hypothesis that scaffold effective properties should match native tissues has not been proven, it is worthwhile to test tissue regeneration in scaffolds whose properties are much different than those of the native tissue to test the native tissue properties design hypothesis.

A first report of controlled 3D scaffold architecture effects versus porogen-leached architectures was presented by Malda *et al.*[67] Malda *et al.* compared biodegradable poly(ethylene glycol)-terephthalate/poly(butylene terephthalate) (PEGT/PBT) scaffolds made using 3D nozzle-based deposition (3DP) to those using compression molding and particle leaching (CM). CM scaffolds had 81% porosity with an average pore size of 182 μm and an effective modulus of 1.82 ± 0.33 MPa. 3DP scaffolds had 77% porosity with an average pore size of 525 μm and an effective modulus of 4.33 ± 0.52 MPa. Primary bovine chondrocytes were seeded into both the CM and 3DP scaffolds. A much greater penetration of cartilage matrix and increased sGAG content was seen in the 3DP scaffolds compared to the CM scaffolds. The interesting point to note is that the 3DP scaffold had a larger accessible pore volume than the CM scaffolds (680 vs. 120 μm), which suggests higher mass transport in the 3DP scaffolds, although effective permeability was not measured. These results would seem to go against the native tissue properties design hypothesis since the 3DP scaffold would presumably have much higher permeability than the CM scaffolds.

Our own group, Kemppainen and Hollister[73] specifically studied the relationship of designed scaffold effective permeability to chondrogenesis using PCL scaffolds with designed spherical pores. By changing the interconnectivity of spherical pores, we created scaffolds with effective permeability of $2.9\pm0.73\times10^{-7}$, $7.4\pm1.4\times10^{-7}$ ($2.5\times$ low), and 15.4 ± 2.8 10^{-7} $m^4\,N\,s^{-1}$ ($5.25\times$ low). The scaffolds of low-to-high permeability were 30, 47, and 60% porous. Each scaffold design was seeded separately with primary chondrocytes or chondrogenically pulsed BMSC. Scaffold permeability had a significant influence on chondrogensis by both chondrocytes and BMSC, although the effect was opposite on the two cell types. Low permeability scaffolds were associated with increased chondrogensis for primary chondrocytes, as measured by sGAG expression and type II/type I collagen gene expression ratio. For BMSC, high permeability scaffolds lead to increased type II/type I collagen gene expression, suggesting an increased tendency of the BMSC to become chondrogenic. Since BMSC are likely to be more highly metabolically active than chondrocytes, and since chondrogenic nutrition transport is key to chondogenic differentiation of BMSC, having higher permeability scaffolds is an advantage. The results for primary chondrocytes likely suggest

that chondrocytes may favor more hypoxic environments. However, the results of Malda *et al.* also suggest that there may be a lower bound or floor on the value of permeability that is beneficial to chondrogensis by primary chondocytes. Indeed, both results taken together suggest that there may be an optimal permeability zone for chondrogenesis by primary chondrocytes, and this zone, at least based on current *in vitro* and *in vivo* results, may be much higher than native articular cartilage as measured by permeability. It is definitive, however, that neither of these results and the resulting insight into cartilage tissue engineering could be obtained with the use of scaffold with designed and controlled 3D architecture (for more information on cartilage tissue engineering, see **Chapter 5.515, Cartilage Tissue Engineering** and **Chapter 5.514, Chondrocyte Transplantation and Selection** in this volume).

5.502.4.2. Bone

Bone is the tissue on which most studies have been performed relating scaffold architecture and effective properties to bone regeneration. Unfortunately, after over 30 years of research, there is no consensus regarding the effect of porous architecture on bone regeneration and ingrowth due to the confounding nature of the reported studies.[95] Early studies suggested that there was an optimal pore size of porous materials that favored bone ingrowth. Bobyn *et al.*[96] found that a pore size range between 50 and 400 μm was optimal for bone ingrowth in porous metal, as determined by the pushout strength measurements. The pore size, measured by 2D scanning electron microscopy (SEM) in porous metal represented a mean pore size, with a significant variation. Galois and Mainard[97] studied bone ingrowth into both HA and beta tricalcium phosphate (β-TCP) scaffolds with a range of pore sizes 45–80, 80–140, 140–200, and 200–250 μm. Scaffolds 6 mm in diameter and 10-mm long were implanted into rabbit femoral condyle defects. Results showed that bone ingrowth was significantly greater for pore sizes above 80 μm up to 120 days for both materials. After 120 days, bone ingrowth was not significantly different between pore sizes. Bone ingrowth occurred more rapidly in β-TCP implants, but again by 120 days there was no difference between materials. The pore size again represents a mean pore diameter with a range of pore sizes and pore interconnectivity.

The previous studies suggesting an optimal pore size were all performed using scaffolds in which that optimal pore size represented the mean of a range of pore sizes and interconnectivity. The conclusion that an optimal pore size exists was made using studies of scaffolds with a wide range of pore sizes. Other researchers have suggested that it is pore interconnectivity, which is significantly correlated with effective permeability, that is more strongly correlated with bone ingrowth than pore size. Li *et al.*[98] fabricated titanium cage scaffolds with controlled pore architecture that had pore sizes ranging from 160 μm in one design to a maximum of 680 μm in another design. Respective effective permeability ranged from $\sim 3.7 \times 10^{-7}$ to 8.2×10^{-7} $m^4\,Ns^{-1}$. When implanted in the transverse spinal processes of goats, they found that the total area of bone ingrowth and depth of bone penetration were only significantly different between the very lowest and very highest permeable scaffolds, although they stated that there was a trend toward greater bone ingrowth with greater permeability. Otsuki *et al.*[99] examined accessible pore space in titanium implants manufactured without controlled architecture. They found that implants with narrow pore throats (and likely lower effective permeability) were associated with less bone penetration and ingrowth. In a rigorous study looking at both controlled and uncontrolled scaffold architectures, Jones *et al.*[100] measured accessible pore volume for scaffolds manufactured by nozzle deposition with controlled pore architecture as well as scaffolds with uncontrolled architecture manufactured by compression molding of particles. Jones *et al.* also computed effective permeability and diffusivity using numerical methods similar to those outlined in **Section 5.502.2.2**. Their results showed that significantly less bone ingrowth was found in scaffolds with accessible pore radius of 100 μm or less. For accessible pore radii <100 μm, the computed effective permeability was $<1 \times 10^{-8}$ $m^4\,N\,s^1$ and the relative effective diffusivity was 0.05, in other words, the effective diffusivity was <5% of the base diffusivity of completely open space. For accessible pore radii >100 μm associated with significant bone ingrowth, the effective permeability was between 3×10^{-8} and 5×10^{-7} $m^4\,N\,s^{-1}$, with effective diffusivity ranging between 0.1 and 0.5. Jones noted that these results supported the concept of a threshold mass transport level supportive of bone ingrowth, as measured by effective permeability of 3×10^{-8} $m^4\,N\,s^{-1}$ and effective diffusivity of 0.1. They noted that this correlated well with the results of Hui *et al.*,[101] who found that obtaining effective permeability above a threshold value of 3×10^{-8} $m^4\,N\,s^{-1}$ was necessary with bone grafts to obtain significant integration with the host bone and bone formation.

Our own results with scaffolds having controlled architecture supports the notion of a threshold mass transport value necessary to obtain bone formation versus an optimal mass transport value. We implanted HA scaffolds with controlled architectures having designed pore sizes of 400, 900, and 1200 μm in 8 mm defects in Yucatan minipig mandibles.[36] The porosity values for all designs ranged from 42 to 50% and computed effective permeability ranged from 0.96×10^{-7} to 2.3×10^{-7} $m^4\,Ns^{-1}$, well above the 0.3×10^{-7} $m^4\,Ns^{-1}$ (equivalently, 3×10^{-8} $m^4\,Ns^{-1}$) given by Hui *et al.*[101] and Jones *et al.*[100] as a threshold value. At 16 weeks, there was no significant difference in bone ingrowth between designs, with all ingrowth values ranging from 70 to 78% of available scaffold pore volume. In studies of scaffolds delivering human gingival fibroblasts transduced with BMP7, we have also shown that there is no difference in bone ingrowth for pore sizes between 300 and 800 μm.[102,103] The study by Schek *et al.* also created exactly the same scaffold architecture from two different biomaterials, HA and a composite of PPF and TCP. For the same scaffold architecture design and delivered biologic, the HA scaffolds had twice the amount of bone as the PPF/TCP scaffolds. Thus, although the biomaterial results were intuitive, the ability to create scaffolds of different materials with exactly the same architecture eliminates architecture as a confounding variable.

The ability to create bone tissue engineering scaffolds has generated significant insight into the effect of both scaffold architecture and material on bone tissue ingrowth and regeneration, especially when viewed in contrast to scaffolds with

uncontrolled architecture. For one, by engineering scaffolds with regular interconnectivity but a wide range of pore sizes, it seems that the idea of an optimal pore size for a bone tissue engineering scaffold is largely debunked. Instead, the use of scaffolds with controlled pore sizes combined with tools for computationally and experimentally determining effective permeability and accessible pore space, suggests instead that there is a threshold value above which bone ingrowth is readily achieved but below which only fibrous tissue ingrowth is largely seen. It appears that there is at best a weak correlation and probably no correlation with bone growth increasing as effective permeability increases. It is interesting to note, however, that effective permeability and accessible pore size are a much better mass transport variable related to bone ingrowth than mean pore size or porosity. Indeed, there is a theoretical correlation between accessible pore size and permeability. Since permeability is determined by fluid flow and boundary layers, the smaller the accessible pore volume, the greater the boundary surface area and the more difficult it is to get flow through the material. Indeed, for the same porosity, we can achieve four orders of magnitude reduction in effective permeability by reducing the accessible pore size from 700 μm down to 70 μm. Using eqns [6] and [7], we reduce permeability from 10^{-7} to 3×10^{-11} m^4 Ns^{-1} just by reducing the accessible pore size from 700 to 70 μm no matter what the porosity, which correlates well with the findings of Jones *et al.*[100] In addition, Lu *et al.*[104] demonstrated the pore interconnections of at least 20 μm were necessary to allow osteoblast migration, and the 40 μm pore sizes or larger were preferable for osteoblast migration. This again correlates well with a minimum threshold of accessible pore volume for bone growth that can be characterized by effective permeability (for more information on bone tissue engineering, see **Chapter 6.617, Bone Tissue Grafting and Tissue Engineering Concepts**; **Chapter 5.521, Calcium Phosphates and Bone Induction** and **Chapter 5.518, Endocultivation: Computer Designed, Autologous, Vascularized Bone Grafts** in this volume).

5.502.4.3. Neural Tissue

Central nervous tissue is not often thought of with regard to scaffold design influences. However, investigations of scaffold architecture have become increasingly insightful in regeneration of neural tissue in both spinal cord and traumatic brain injury. Madigan *et al.*[105] noted that scaffold macroengineering (architecture engineering) was important to mimic the intrinsic spinal cord mechanical properties, allow vascularization of the construct, and provide 100–1000 μm tracts to support axonal outgrowth. In this sense, directed anisotropic permeability (given that permeability is a second-order tensor), may be associated with directed vascularization and axonal growth. Our own group fabricated PCL scaffolds with both controlled macro-architecture coupled with traditional porogen-leached architecture for application in a rat spinal cord transection model.[106] Five designs were created, three being the traditional channel design and two having an open core design (**Figure 9**).

Scaffolds were implanted empty without cells or neurotrophic factors. Axon growth was characterized using Tuj-1 staining and astrocyte activity was characterized using glial

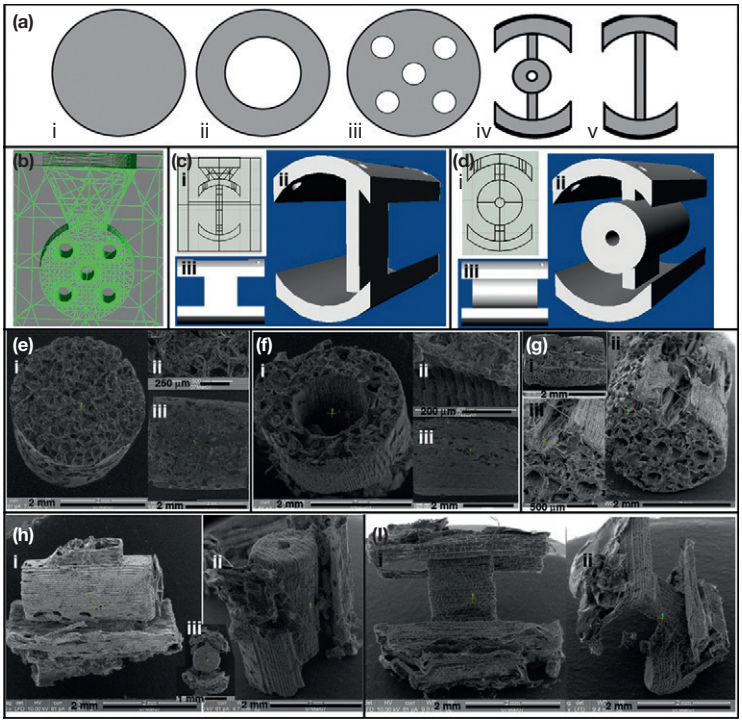

Figure 9 Example of spinal cord scaffolds with different designed macroarchitectures created by solid-free-form fabrication and microarchitectures created by porogen leaching. Scaffold designs iv and v demonstrated the best maintenance of neural tissue. Reproduced from Wong, D. Y.; Leveque, J. C.; Brumblay, H.; Krebsbach, P. H.; Hollister, S. J.; Lamarca, F. *J. Neurotrauma* **2008**, *25*, 1027–1037, with permission from Journal of Neurotrauma.

fibrillary acidic protein (GFAP). Scaffold architecture had a significant effect on axonal growth and death surrounding the initial 3 mm transection. Neuronal death resulting in an increased gap width was noted in traditional channel designs, while the open core scaffold architectures retained or even decreased the initial transected gap width, supporting axonal growth. Similarly, we also found that scaffolds with designed channels supported cell migration and showed significantly greater GFAP staining than porogen-leached channels without designed architecture. These results clearly demonstrate that scaffold architecture alone significantly influences neuronal growth and regeneration even without the delivery of cells or neurotrophic factors. Again, it is likely that success in scaffolds with designed architecture is due to mass transport factors that are related to cell migration and nutrition (for more information on neural tissue engineering, see **Chapter 5.531, Peripheral Nerve Regeneration**; **Chapter 5.532, Nerve Tissue Engineering**; **Chapter 5.533, Biomaterials for Central Nervous System Regeneration**; and **Chapter 6.630, Biomaterials for Spinal Cord Repair** in this volume).

5.502.4.4. Summary

Designed scaffold architecture and the resulting controlled effective properties significantly affect tissue regeneration. In most cases, controlled architecture and the resulting control of mass transport significantly increases tissue regeneration over scaffolds without designed architecture. Perhaps more importantly, controlled architecture allows us to test hypotheses concerning both scaffold design and material clearly without confounding experimental variables. This allows us to define basic scaffold design principles for tissue regeneration. For example, there is now strong evidence for the existence of a minimum effective permeability threshold that must be passed to effectively regenerate bone. This minimum threshold could not be established without experiments utilizing designed scaffolds. Furthermore, the existence of such design principles suggests that we may err on the side of more structurally dense scaffolds to support load bearing while still maintaining sufficient mass transport to allow bone ingrowth. For cartilage, the effect of mass transport on matrix regeneration is cell source-dependent. Chondrocytes benefit from low effective permeability, while BMSC benefit from high effective permeability. Whether a threshold of desirable mass transport exists for cartilage similar to bone is unknown. What is clear is that the ability to control scaffold architecture within different biomaterials is critical to testing design hypotheses and ultimately elucidating scaffold design principles that will lead to improved tissue engineering treatments.

5.502.5. Conclusion

Biomaterial scaffolds will play a critical role in potential regenerative medicine therapies. It is generally agreed that scaffolds must be engineered to satisfy the 4Fs: Form, Fixation, Function, and Formation. Form and fixation are readily defined as the scaffold filling specific anatomic defects and the attachment of the scaffold to surrounding host tissues, respectively. Specific requirements for function and formation are more difficult to pin down. Function in terms of load bearing is often defined in terms of mechanical properties (linear elasticity, nonlinear elasticity, and viscoelasticty) but the specific forms and magnitudes of the constitutive model and coefficients remains to be defined for most tissue applications. Formation remains even more ambiguous, given that several factors influence tissue formation, including mass transport, cell–material interaction factors such as specific surface area and hydrophobicity/hydrophilicity, and the ability to deliver biologics (cells/genes/proteins) in a local, controlled manner. Given that mass transport affects many aspects of tissue formation, including cell migration, nutrition, and biologic delivery, effective permeability and effective diffusivity as measures of mass transport are potential design targets for influencing formation. Specific surface area is another effective property design target, since it is one factor governing cell–material interaction.

Defining potential design targets (effective elasticity, permeability, diffusivity, specific surface area) is a critical first step since it allows us to develop specific scaffold design hypotheses. Tissue-specific mechanical and mass transport design targets fundamental to scaffold design hypotheses have been reviewed by Hollister *et al.*[107]. Testing these design hypotheses will then lead to the development of scaffold design principles, effectively design rules that can be followed to optimize scaffolds for a specific tissue application. The difficulty in testing scaffold design hypotheses concerning effective properties is that these properties must be first designed and controlled in scaffolds. If we seek to determine not only if effective properties are correlated with tissue formation, but perhaps whether thresholds for effective property influences on tissue regeneration exist (as likely exists for effective permeability and bone formation), then we must first be able to determine what are the possible extreme ranges of effective properties that may be attained, then devise computational algorithms to realize these ranges, and finally, develop scaffold manufacturing techniques to build the designs.

Each step becomes more difficult as we proceed from effective property bounds to design for specific effective properties to manufacturing specific designs. Absolute bounds (Voight and Reuss bounds) already exist for all effective properties, including nonlinear elasticity. These bounds, however, are extremely broad for porous materials, being zero at the lower bound. As such, absolute bounds provide useful information on the upper end, but relatively little information on the lower end. Tighter bounds have been derived for isotropic materials, including classic Hashin–Shtrikman bounds,[23] have been derived for linear effective properties, and also, in restricted cases, for nonlinear elasticity. Limited bounds exist for anisotropic materials.

Bounds on effective properties outline what effective properties are theoretically achievable, but do not provide any information on how to arrange material and void in 3D space to generate these properties. Homogenization based FSDM and ISDM do provide a basis for designing scaffold architecture, and recent advances have been made in simultaneous mechanical and mass transport design using ISDM. However, although ISDM can generate designs de novo to obtain desired effective properties near isotropic cross-property bounds, generating designs away from cross-property bounds

remains a challenge. FSDM remains a trial and error proposition, although significant insights into scaffold design have been made using this technique. Thus, the current state of the art for computational design is that architectures can be designed to fit some portions, but not all regions of mechanical-mass transport cross-property bounds. Design for nonlinear effective properties remains the purviews of FSDM, which themselves are in their infancy.

Controlled scaffold manufacturing has seen significant strides in the past 10 years. A range of both direct and inverse SFF techniques have been developed to fabricate polymer, ceramics, and metallic biomaterial scaffolds. Direct SFF feasibility has been proven for a limited range of materials, namely, PCL, PEOT/PBT, PPF, hydrogels, and titanium. Direct nozzle methods are more adaptable to a wider range of materials, but provide more limited pore architecture geometry. SLS and SLA techniques provide a broader range of pore architectures, but are more challenging in terms of adapting different biomaterials. Inverse SFF methods provide a wider potential range of both materials and pore architecture, but are much less automated and more time consuming than direct SFF methods.

Going forward, it is clear that our ability to rigorously test scaffold design hypotheses and advance regenerative medicine therapies is intimately coupled to our prowess in scaffold design and manufacturing.[40] The significant insights already gained by testing the influence of scaffold architecture and material on tissue regeneration clearly motivate expansion of scaffold design and manufacturing technologies. However, these technologies must be rigorously tested within *in vivo* applications, further refining scaffold design principles. Finally, the integration of scaffold design and manufacturing with *in vivo* system testing will form the foundation satisfying FDA current good manufacturing processes (cGMP) and moving scaffolding technology into clinical application.

Acknowledgments

The author gratefully acknowledges the graduate students and alumni of the Scaffold Tissue Engineering group whose work is reviewed in this article including Dr. Huina Zhang, Dr. Jessica Kemppainen, Dr. Claire Jeong, Dr. Juan Taboas, Dr. Elly Liao, Mr. Heesuk Kang, Ms. Colleen Flanagan, Dr. Chia-Ying Lin, Dr. Rachel Schek, Ms. Erin Moffitt, and Dr. Cheng-Yu Lin. He is also grateful for the input and discussion with many colleagues including Dr. Bill Murphy, Dr. Paul Krebsbach, Dr. Joerg Lahann, Dr. Gabriel Chu, Dr. Matt Wheeler, Dr. Steve Feinberg, and Dr. Frank LaMarca. The authors work presented in the review was funded by grants from the NIH R01 DE13608, R01 DE016129, R01 DE13416, and R01 AR 053379, as well as from the Coulter Foundation.

Abbreviation

bFGF	Basic fibroblast growth factor
CAM	Chick chorioallantoic membrane
ECM	Extracellular matrix
ePTFE	Expanded PTFE
FBR	Foreign body response
hGH	Human growth hormone
hMSCs	Human bone marrow-derived mesenchymal stem cells
MMP	Matrix metalloproteinase
MVN	Microvascular networks
NO	Nitric oxide
PDGF	Platelet-derived growth factor
PEG	Poly(ethylene glycol)
PEO	Polyethylene oxide
PEO	Polyurethane with silicone and polyethylene oxide
PTFE	Polytetrafluoroethylene
PU	Polyurethane
PVA	Polyvinyl alcohol
SC	Subcutaneous
SCID	Severe combined immunodeficient
VEGF	Vascular endothelial growth factor

5.503.1. Introduction

Nearly a century ago Alexis Carrel, a pioneer in the fields of cell culture and tissue transplantation, published a series of papers describing sustained growth of animal cell and tissue cultures.[1–4] Carrel sought to create the conditions whereby cultures could achieve 'permanent life.' Recognizing that nutrient transport was essential to *ex vivo* tissue viability, he noted that cells on the periphery of tissue culture flourished whereas internal cells isolated from the nutrient broth struggled to survive. As an alternate approach, Carrel used a patch of silk as a primitive scaffold, prompting planar rather than spherical growth, and in doing so took the first step toward enhancing the viability and durability of cultured tissues.

The principles illustrated by this experiment were further clarified when Carrel and Charles Lindbergh developed a mechanical perfusion system capable of sustaining organs *ex vivo*.[5] Using this perfusion system, cat hearts continued to beat for 12 h and thyroid glands remained viable and functional for up to 30 days.[6] By enabling continuous nutrient transport, this system prolonged the *ex vivo* survival of complex organs and tissues for the first time, providing a glimpse of the expansive potential of organ transplant and tissue engineering applications.

Almost 100 years later, the challenge of adequate nutrient transport remains one of the primary issues limiting the utility of tissue engineering applications. Perfusion of implanted tissue is essential to nutrient and oxygen supply and waste removal, and also is critical to enabling the complex molecular cascades that underlie cellular communication. As the viability of most cell types is dependent on proximity to blood vessels, the successful introduction of engineered tissues and organs *in vivo* is limited by the extent to which a microvascular network can develop *in situ*. Neovascularization *in situ* can be achieved by a number of methods. Regardless of the method by which it is achieved, neovascularization is a critical factor in the viability not only of engineered tissues and organs, but also of implanted sensors, cell-based gene therapy, and other bioengineering applications. These applications will be briefly reviewed and provide motivation and framework for the subsequent discussion of the factors that appear to govern neovascularization in and around biomaterial implants. Factors to be examined include the structural and mechanical features of biomaterials such as macrostructure, microarchitecture, and stiffness. The impact of chemical features (e.g., surface energy, hydrophobicity, and protein adsorption) and biochemical features (e.g., integrin-binding sites, enzymatic degradation sites, and specific angiogenic factors) will be reviewed. Lastly, case studies will be described that illustrate how recent successes in the development of microvascular networks for various biomedical applications can be largely understood in the context of the structural, mechanical, chemical and biochemical factors reviewed in this chapter.

5.503.2. Biomedical Engineering Applications Dependent on Neovascularization In or Around Biomaterials

5.503.2.1. Tissue Engineering

The measure of success for most tissue engineering applications is survival and functionality *in vivo*. Unfortunately, loss of cell viability and function following implantation often occurs to an extent that limits the utility of the engineered tissue. The decrease in viability and function of cells within engineered tissues often can be attributed to the lack of a functional microvascular system and subsequent transport deficiencies in the engineered tissue.[7,8] Since it is unlikely that implanted tissues could survive for the days or weeks likely required for host vessels to vascularize a larger avascular engineered tissue, a critical challenge is how to decrease the time required to establish functional (i.e., perfused) neovascularization within implanted tissues. Various methods of facilitating the formation of microvasculature derived from the host or the implant have been investigated. When implanted intraperitoneally, porous polymeric implants were invaded by vascularized fibrous tissue.[9] Though the ingrowth substantially decreased the porosity of the implant,[9] these prevascularized implants improved the survival of hepatocytes introduced subsequently.[10] With the eventual goal of improving the viability of grafted tissue-engineered skin, Black *et al.* constructed, *in vitro*, a microvascular network within the tissue-engineered graft.[7] This engineered microvasculature would be expected to anastomose with existing vessels in the host, as seen with native skin grafts,[11] thus facilitating vascularization and improving viability. This assertion is supported by reports that tissue-engineered microvascular networks formed by seeding endothelial cells on fibrous polyglycolic meshes[12] or embedding endothelial cells in extracellular matrix (ECM) gels,[10,13–15] incorporate with host vasculature and/or increase vascularization within the implants. Implantation of intact vascularized islets or avascular aggregates of pancreatic cells yields functional islet-specific vasculature; the former obtained a perfused microvasculature more quickly,[16] further highlighting the impact of an established microvasculature within implanted tissue. An elaborate method intended to facilitate the establishment of microvasculature in engineered tissue was explored by Griffith *et al.*, who employed three-dimensional (3D) micropatterning to facilitate self-organization of endothelial cell– hepatocyte cocultures into liver-like architecture *in vitro*.[17] Subsequent efforts to create microfabricated microvascular networks have created *in vitro* systems with spatially well-defined vascular networks lined with endothelial cells.[18,19] By rationally designing such networks, mass transport properties can be optimized.[20,21]

5.503.2.2. Cell-Based Gene Therapy

Two major approaches to cell-based gene therapy are implantation of genetically modified cells within the engineered tissue or in an isolation device, which may be considered similar to the tissue engineering or isolation devices (see **157.2.3**) and the techniques they employ. An alternative approach to cell-based gene therapy is the use of the microvasculature not to facilitate transport, but rather as a location from which genetically modified endothelial cells can deliver gene products directly to the circulation.[22,23] Engineered microvascular networks formed by endothelial cell progenitors[23,24] or microvascular endothelial cells[25] embedded in extracellular matrix gels have been shown to provide long-term stable delivery of transgene products to the circulation.

5.503.2.3. Isolation Devices and Biosensors

The use of semipermeable membranes to isolate implanted cells, e.g., for treatment of chronic pain,[26] neurological disease[27] as well as local[28] and systemic cell-based gene therapy[29] and implanted tissues, e.g., allogeneic islets[30] has been investigated in a number of contexts, primarily to isolate the implanted material from the host immune system. The survival of cells within an implanted isolation device is dependent on adequate transport of oxygen, nutrients, and metabolites, a task normally facilitated by the microvasculature. Additionally, efficient transfer from an isolation device is necessary for delivered

therapeutics to reach their targets (see Chapter 4.431, Encapsulation of Cells (Cellular Delivery) Using Sol–Gel Systems and Chapter 5.509, Cell Encapsulation).

Implanted biosensors can provide near real-time measurements of analyte concentration, which can be used to control the delivery of insulin or other therapeutics.[31] Inefficient transport between the microcirculation and the biosensor may potentially confound real-time measurements and result in inaccurate measurement of steady concentrations of analytes such as glucose or oxygen that are consumed or reacted within the tissue.

5.503.3. Survey of Neovascularization

5.503.3.1. Types of Neovascularization

The two major forms of neovascularization are angiogenesis and vasculogenesis. Angiogenesis, the sprouting of vessel offshoots from existing vessels, is achieved following the migration of vascular endothelial cells and subsequent assembly into capillary buds (Figure 1(a)). In contrast, vasculogenesis involves the development of de novo blood vessels from the migration and differentiation of endothelial precursor cells in the absence of local vasculature (Figure 1(b)). The details of angiogenesis and vasculogenesis have been extensively described in the literature.[32,33] Native neovascularization can also be accomplished by intussusception (or intussceptive angiogenesis). The defining event in intussusception is the formation of transvascular tissue pillars that divide one vessel into two (Figure 1(c)).[34,35] A final method of neovascularization, vascular tunneling (Figure 1(d)), is less clearly defined but may have an important role in biomaterial applications. In one model of vascular tunneling, monocytes/macrophages burrowed through the basement membrane gel Matrigel, forming tunnels filled with columns of monocytes/macrophages and various forms of progenitor cells after ~1 week.[36,37] By 4 weeks, some of these tunnels appeared to have matured into capillaries featuring endothelial walls and containing erythrocytes, while others had not fully matured. In both stages of maturation, bundles of collagen fibers were observed along the length of the tubes.

5.503.3.2. Neovascularization and the Foreign Body Response

One form of neovascularization of particular importance in several biomaterial applications is angiogenesis associated with the foreign body response (FBR). Biomaterial implants interact closely with the *in vivo* environment in which they are placed.[38] The mechanisms of this response include inflammation, immunological reactions and fibrosis, all of which can hinder the development of a microvasculature critical to implant viability. Initially, healing inflammation is marked by the formation of granulation tissue, which involves invasion of fibrovascular tissue due to angiogenesis and fibroblast proliferation. Granulation tissue, which may be seen as early as 3–5 days following implant, can be remodeled into vascularized tissue. However, formation of this tissue is often followed by a FBR, in which foreign body giant cells and the components of granulation tissue form a relatively avascular capsule around an implant (Figure 2(a)). This foreign body capsule isolates the implant and impairs angiogenesis, limiting the transport of biomolecules and nutrients between the microvasculature and implanted biomaterials and ultimately affecting the functionality of the implant. This is particularly important with engineered tissue implants and glucose sensors, both of which depend on the development of microvasculature, derived from the host or within the implant itself, for survival and functionality *in vivo*. The degree of the FBR is influenced not only by the local host environment but also by the physical and chemical characteristics of the implant, which will be reviewed in the following sections.

5.503.3.3. *In Vitro* Models of Neovascularization

As reviewed in detail by others,[39] there are numerous *in vitro* models of neovascularization. Some *in vitro* models focus on the assembly of isolated cells into multicellular structures, which resembles vasculogenesis, while other models focus on the sprouting of endothelial cells from endothelial monolayers, clusters, or intact vessel segments. When attempting to compare results between *in vitro* models or to extrapolate *in vitro* results to *in vivo* neovascularization, it is important to consider the strengths and limitations of the experimental model. For example, is it a model of angiogenesis or vasculogenesis? Does the model include only endothelial cells, or are important nonendothelial supporting cells also present? While some of these issues are relatively apparent, others are more subtle. For example, the planar culture of endothelial cells on top of various biomaterials is the basis of several *in vitro* models of neovascularization. In one such model, endothelial cells are seeded at a subconfluent density on top of preformed Matrigel. Over the course of several hours to days, the cells assemble into interconnecting, multicellular structures resembling an *in vivo* capillary network. While it is tempting to assume that a model using this arrangement is a faithful 2D analog of a biologically relevant 3D environment, the difference between 2D and 3D can be of paramount importance to the cells involved, literally representing the difference between life and death. Endothelial cells embedded within a 3D gel of Matrigel remain spherical and die within several days. This is not due to an inherent inability of the endothelial cells to survive within Matrigel, as the presence of fibroblasts or glass fibers in the Matrigel enables the endothelial cells to survive and elongate. Though somewhat simplified, the 2D Matrigel model can capture some of the effects of angiogenic and antiangiogenic factors. The point of this discussion is not to criticize a particular model system or simplified models of neovascularization in general. In contrast, these models can be powerful tools to address specific questions, provided their limitations are acknowledged and the extrapolation of their outcomes to other systems is performed with care.

5.503.4. Properties of Biomaterials Regulating Microvascular Network Formation In, On, and Around Biomaterials

5.503.4.1. Structural and Mechanical Features of Biomaterials

5.503.4.1.1. Macrostructure

Several studies have suggested that a greater implant thickness will lead to a greater capsule thickness and an increased FBR.

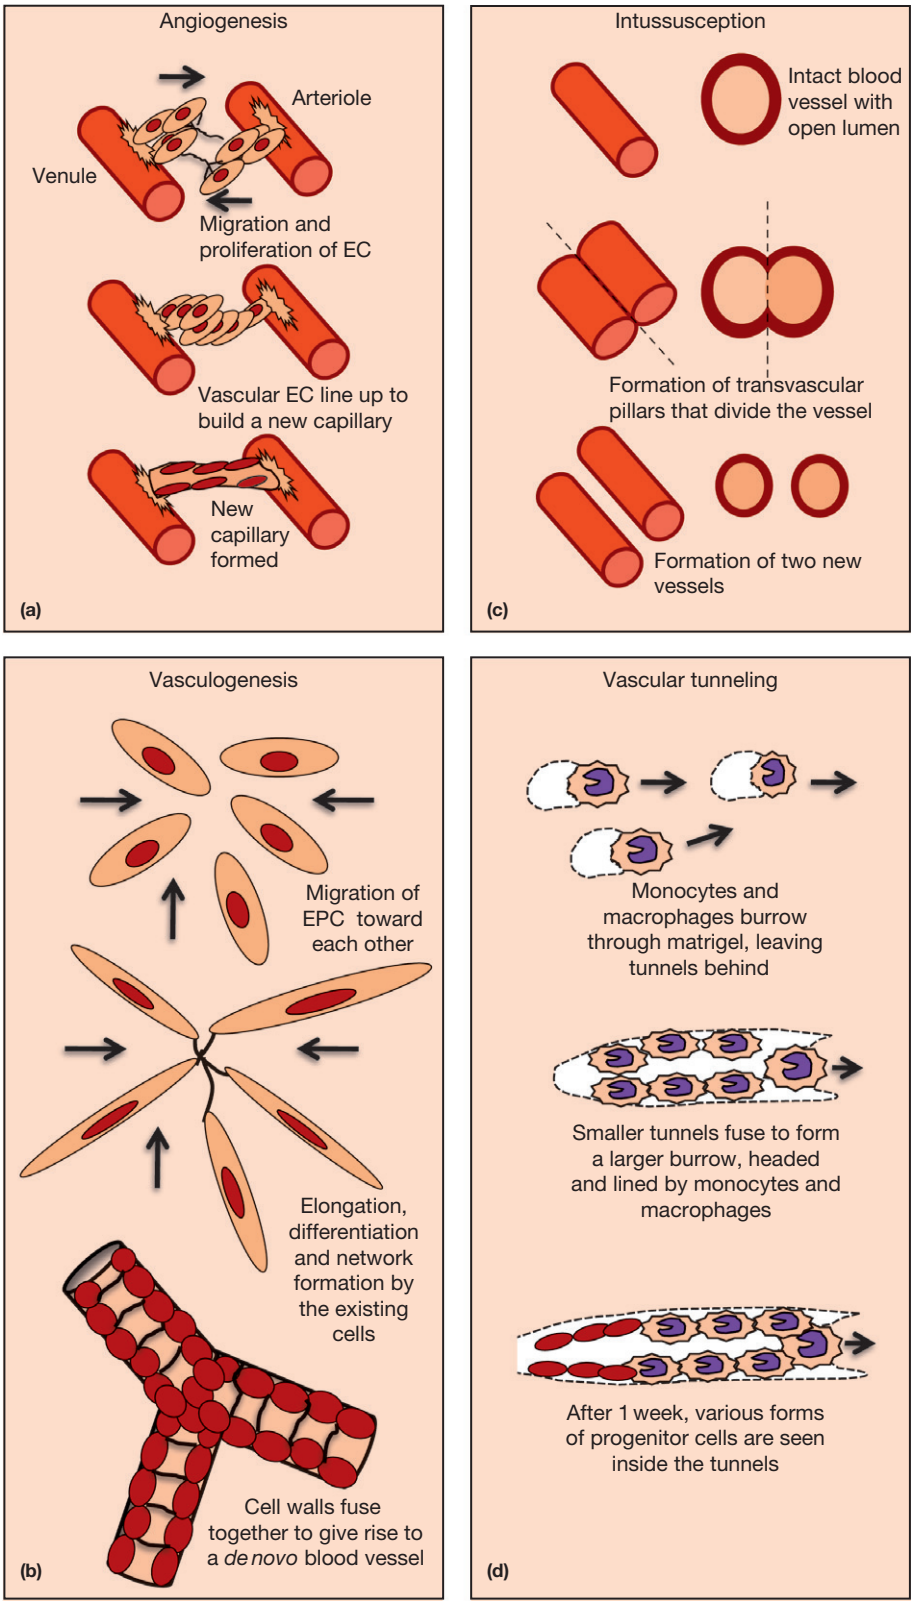

Figure 1 (a) Angiogenesis involves the sprouting of vessel offshoots from existing vessels, following the migration of vascular endothelial cells and subsequent assembly into capillary buds. (b) Vasculogenesis involves the development of *de novo* blood vessels from the migration and differentiation of endothelial precursor cells in the absence of local vasculature. (c) Intussusception is the formation of transvascular tissue pillars that divide one vessel into two. (d) In vascular tunneling, monocytes/macrophages burrow through Matrigel, forming tunnels filled with columns of monocytes/macrophages and various forms of progenitor cells after ~1 week.

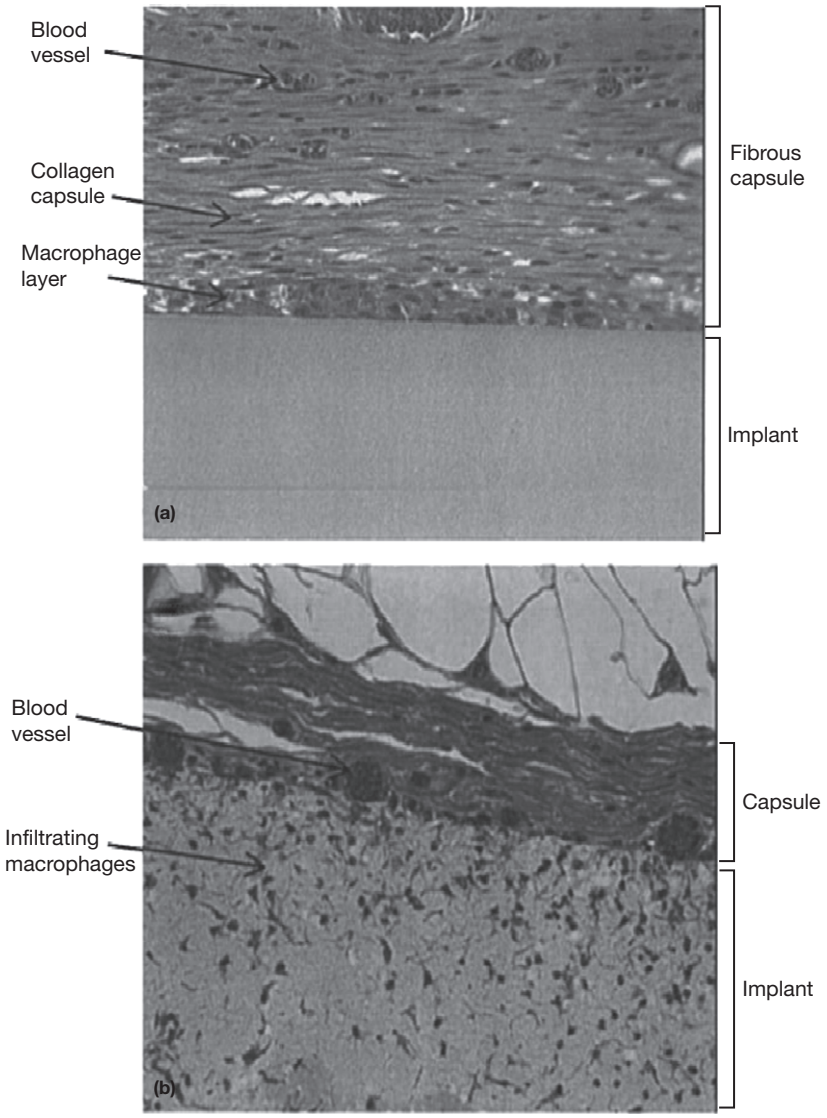

Figure 2 An example of a histological section stained with hematoxylin and eosin showing (a) a typical fibrous capsule surrounding a nonporous subcutaneous implant. Note the layer of macrophages at the implant surface, the dense, parallel arrangement of the collagen capsule, and the blood vessels in the granulation tissue. (b) A highly vascularized, thin capsule surrounding an implant with 8 μm pores. Note the blood vessels in contact with the implant and the macrophages within the pores. Original images kindly provided by Dr. Robert Padera. Reproduced from Sieminski, A. L.; Gooch, K. J. *Biomaterials* **2000**, *21*(22), 2232–2241, with permission from Elsevier.

Ward *et al.* observed a direct relationship between the thickness of implants composed of polyurethane with silicone and polyethylene oxide (PU–S–PEO) and the associated FBR response; the capsule that developed around a thin (300 μm) implant was significantly less than that which developed around a thick (2000 μm) implant (see **Chapter 4.413, Patterned Biointerfaces**).[40]

5.503.4.1.2. Porosity of biomaterial

Porous scaffolds allow for cellular penetration which in turn enables the integration of an implant within the host vasculature and leads to better implant function. Porous scaffolds allow for the ingrowth of fibrovascular tissue, which can improve the survival of implanted cells.[9] In another study, implantation of solid versus porous hydroxylapatite ceramics and their effects on healing bone defects into newly drilled beagle mandibular bone were compared. After 40 days, histological comparison indicated the presence of newly formed bone around both implants, but only the defects filled with porous hydroxylapatite showed bone incorporation and evidence of vascularization within the implant.[41] Thus, implantation of porous materials allows the ingrowth of tissue, enabling a more vascularized response in the surrounding tissue.

5.503.4.1.3. Microstructure of biomaterial: pore size

Given the benefit of using porous material for implants, one might assume that increasing the pore size would increase the degree of vascularization in and around the implants. However, there appears to be an optimum range of pore size that evokes the most vascularized FBR around implants regardless of the

implant material. Early studies by Campbell and von Recum[42] have shown that the thickness of foreign body capsules developing around samples of Versapor filter paper varied according to the paper's pore size, irrespective of the implant chemistry. Implants with pore diameters <0.5 μm showed nonadherent, contracting capsules and larger (≥3.3 μm) pore sizes became infiltrated with inflammatory tissue. However, an implant with pores sizes 1.4–1.9 μm evoked thin, tightly adherent fibrous capsules without inflammatory cells. After 12 weeks, there were a few small blood vessels around the outer edge of the capsule, and there were occasional capillaries or small vessels inside the capsule, lying directly against the implant.

The FBRs elicited by more than 150 membranes (including cellulose acetate, mixed-esters cellulose, polytetrafluoroethylene (PTFE), and acrylic copolymer) of various pore sizes (0.02–15 μm) were evaluated following subcutaneous implantation in rats.[43] Irrespective of composition, membranes with pore sizes of 5–15 μm resulted in vascularized capsules with blood vessels directly adjacent to the membrane surface (**Figure 2(b)**). In contrast, avascular capsules typical of a FBR surrounded membranes with smaller pore sizes (**Figure 2(a)**). Salzmann *et al.* showed that ePTFE implants with a pore size of 60 μm were associated with more rapid vascularization and thinner fibrous capsules than implants with pores of 30 or 100 μm.[44] Similar results were observed in studies investigating FBR around implants in which pore size was expressed in terms of fibril length or internodal distance. Implants with fibril lengths of 60 μm evoked the thinnest capsules and resulted in the largest degree of vascularization. Following implantation of porous PTFE vascular grafts into baboon iliac arteries,[45,46] grafts with an internodal distance of 60 μm (but not 30 μm) induced microvasculature to grow through the graft wall with capillaries ~100–500 μm apart.[45] Similarly, later studies of varying fibril lengths in porous ePTFE implants showed that neoendothelial healing on grafts with 60- and 90-μm-long fibrils was better than that observed on 20- and 40-μm-long fibril grafts.[47] These and additional studies suggesting that the size of pores in biomaterial affects the structure of neovascularization are summarized in **Table 1**.

An implanted biomaterial with an appropriate pore size allows formation of a vascularized capsule, which should facilitate transport of biomolecules and nutrients between the implant and host. Sharkawy *et al.* quantified the effects of biomaterial microarchitecture on parameters influencing transport from the host circulation to the implanted biomaterial, including vessel permeability, diffusivity, vessel density, and effective tissue response times.[51–53,57] The studies investigated porous (5–700 μm pore sizes) polyvinyl alcohol (PVA)

Table 1 Summary of vascularization in/around porous implanted biomaterials

Investigator	*Porous material*	*Optimal pore size (μm)*	*Application and test subject*	*Duration of investigation and outcome*
Brauker *et al.*[43]	PTFE	5	Membrane implanted in rat subcutis	3 weeks Vascularized membranes were maintained for up to 1 year.
Menger *et al.*[48]	PTFE	1–30	Membrane implanted in the skin flap of hamster	10 days Porous membranes with larger fibril lengths (30 μm) leading to stable vascularization at membrane surface. No vascular infiltration.
Clowes *et al.*[45,46]	PTFE	30–60	Membrane implanted in the artery of baboon	12 weeks and 3 months respectively Implanted porous vascular grafts allow microvessels to grow through. Effect is more pronounced with 60 μm intermodal distance.
Salzmann *et al.*[49] and Williams *et al.*[50]	PTFE	30–100	Membrane implanted subcutaneously or in fat of rats	Up to 5 weeks Implanted porous vascular grafts allow vascularization. Effect is most enhanced with 60 μm internodal distance.
Sharkawy *et al.*[51–53]	PVA	5–700	Membrane implanted in rat subcutis for 12–16 weeks	4 weeks, and 3–4 months Implanted porous membranes lead to increased vascularization of capsule. Intermediate size (60 μm) is most pronounced
Ward *et al.*[40]	ePTFE and PVA	ePTFE: 1 PVA: 47	Membrane implanted in rat subcutis	7 weeks Angiogenesis in both implants.
Updike *et al.*[54]	ePTFE	5–10	Glucose sensor implanted in dog subcutis	162 days[a] (best of six sensors)
Yu *et al.*[55]	Epoxy-enhanced polyurethane	Not specified	Glucose sensor implanted in rat subcutis	56 days[a] (best of nine sensors)
Gilligan *et al.*[56]	ePTFE	Not specified	Glucose sensor implanted in human subcutis	185 days[a] (best of five sensors)

ePTFE, expanded polytetrafluoroethylene; PVA, polyvinyl alcohol.
[a]Maximum time sensor remained functional *in vivo*.

grafts implanted subcutaneously in rats for 3–4 weeks; PTFE implants (0.5 or 5 μm pore sizes) were also evaluated.[52,53] The permeability of vessels around implants with 60 μm pores was comparable to normal tissue, whereas vessels within capsules around implants of other pore sizes had permeabilities 63–85% lower than normal tissue.[52,53] Typically, the capsule around an implant is relatively avascular, with the blood vessels nearest the implant concentrated in the tissue surrounding the capsule. Transport from the vasculature to the implant would be facilitated by decreasing this distance, either by increasing the vasculature within the capsule or by decreasing the capsule thickness. Capsules around implants with 60 μm pores contained 40% more blood vessels than found in normal tissue.[52,53] Additionally, vessels in these capsules, as well as those in the tissue that had grown into the pores, persisted for at least 12 weeks.[51–53]

Proposed mechanisms by which pore size influences neovascularization in and around implanted biomaterials focus on the prevention of undesirable cellular infiltration, improved tissue integration, and modulation of macrophage shape. Several researchers[44–47] who reported that pore sizes of ~60 μm evoked the maximum amount of vascularization in and around implants speculated that pore sizes >60 μm may allow undesired inflammatory cell infiltration, resulting in the formation of a capsule that ultimately hinders effective microvessel formation. Results from subcutaneous implantation of smooth or textured (surface irregularities of 10–50 μm) polyethylene disks in rats led Rosengren *et al.* to speculate that implant motion relative to host tissue shears adjacent cells, causing necrosis and inflammation. Textured or porous implants were associated with less necrosis and formation of smaller capsules, which the authors attributed to an ingrowth of tissue that minimized relative motion.[58] Similarly, enhanced tissue attachment to textured implant surfaces (but not to solid and smooth surfaces) has been suggested to ultimately reduce the foreign body capsule thickness *in vivo* (**Figure 3**). von Recum and van Kooten investigated whether a grooved surface presented to a connective tissue implantation bed could allow fibroblast attachment, potentially eliminating micro motion between cells and substrate and favorably influencing the overall tissue response to the implant; they found that macrophages and giant cells were absent whenever fibroblasts attached to the implant's surface.[59] Padera *et al.* hypothesized that the formation of a loosely packed, vascularized capsule rather than a well-organized avascular capsule may depend on the shape of the macrophages that interact with the implant.[60] They suggested that a larger pore size (8 μm in their study) allowed macrophages to remain round, which may have favored the secretion of angiogenic factors. In contrast, smaller pore sizes that did not permit cell infiltration led to macrophage spreading on the implant surface, which may have encouraged fibroblast proliferation and collagen secretion.[60] Although it is uncertain which of these hypotheses best explains the available data, the overall body of research illustrates the broad influence of biomaterial microstructure and especially pore size on the structure and function of the microvasculature.

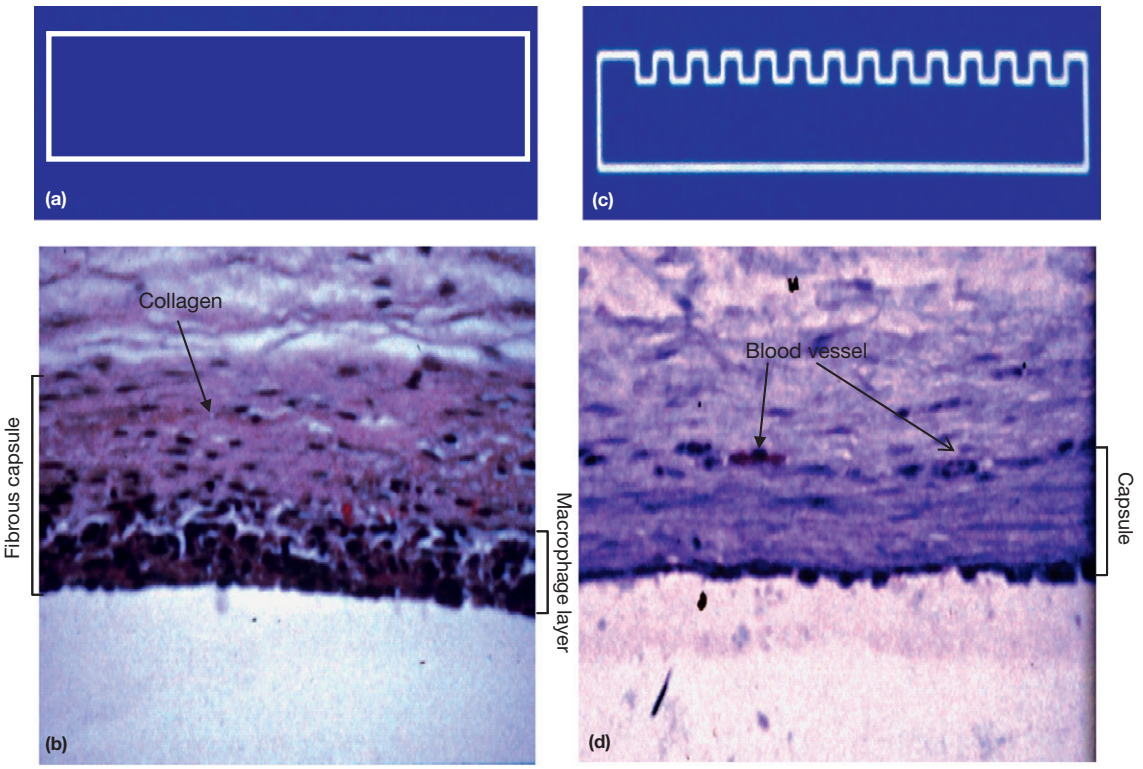

Figure 3 FBR around smooth and textured implants. Images kindly provided by Dr. Andreas Von Recum. Smooth surfaced solid bulk implants (a) show the development of a thick capsule (b), whereas the same implant when texturized to create grooves (c) shows the development of a less densely packed capsule with infiltrating cells in and around the implant (d).

5.503.4.1.4. Microstructure of biomaterial: fibrous materials

The studies reviewed in the previous section clearly demonstrate that biomaterial microstructure is an important, perhaps dominant, determinant of the microvascular structure in tissue surrounding implanted biomaterials. In these *in vivo* studies, the characteristic size of the microstructural elements stimulating neovascularization is on the order of 50 μm. Other studies, primarily conducted *in vitro*, suggest that microstructural elements on the submicron scale play important roles in the assembling of isolated endothelial cells into multicellular structures such as microvascular networks. The *in vitro* formation of microvascular networks from isolated endothelial cells on or within a scaffold or matrix resembles *in vivo* vasculogenesis. In both cases, isolated cells must come together to form an interconnected, branching, multicellular structure.

A recent study of endothelial cells cultured on polyacrylamide gels suggests that cells communicate mechanically through compliant substrates.[61] Adjacent cells on stiff gels (33 000 Pa) appeared relatively uninfluenced by nearby cells while those on gels of intermediate stiffness (2500–5500 Pa) repeatedly contacted and separated without moving far from one another. Endothelial cells on the most compliant gels studied (500 Pa) tended not to separate once contact had been made. By tracking fluorescent particles embedded in the gels, it was shown that endothelial cells were able to deform a larger area of softer gels relative to stiffer gels. The authors suggested that in compliant gels, separated cells could communicate with each other across ~50 μm by straining the intervening substrate. In stiffer gels, however, matrix deformation was of smaller magnitude and was limited to the regions closest to the cells, impairing intercellular communication. In another study[62] it was noted that relative to fibroblasts and mesenchymal stem cells cultured on modified polyacrylamide gels, cells on fibrin gels affected the orientation of other cells at much larger distances. These long-range effects with fibrin gels resulted in large-scale cellular patterning not seen with cells on polyacrylamide. Winer *et al.* attributed the longer-range signaling and organization in fibrin to either its fibrous nature or its strain-stiffening relative to polyacrylamide's linearly elastic behavior.[62]

The notion that cells exploit the effective transmission of forces by fibers to facilitate organization of multicellular structures is well supported in several 2D and 3D systems. In a series of elegant microscopy-based studies, Vernon, Sage and others showed that by exerting tension, endothelial cells on top of ECM gels remodeled the matrix to form bundles of ECM that connected nearby cells.[63,64] The cells then appeared to preferentially migrate along these fibers to form interconnected multicellular networks resembling a 2D or planar vascular plexus. Similarly, when small clusters or spheroids of endothelial cells were embedded within type-1 collagen gels, cells sprouted from individual clusters and moved toward one another. As in the 2D system, imaging revealed that aligned collagen fibers provided connections in which cells, initially separated, appeared to migrate toward one another. To confirm that collagen fiber alignment was the cause and not the result of directional fiber alignment, Korff and Augustin strained the collagen, thereby aligning the collagen fibers, before cell migration had begun.[65] Consistent with the notion that migration was in the direction of aligned fibers, the sprouting cells preferentially moved in the direction of the externally imposed collagen fiber alignment. Interestingly, Korff and Augustin noted that sprouting endothelial cells did not migrate toward other sprouts within fibrin, an observation that they attributed to the significantly shorter length of the fibrin fibers relative to the collagen fibers. To our knowledge, the only other gel material that supports robust 3D microvascular network formation *in vitro* resembling capillary networks *in vivo* is fibrin,[66] which has a fibrous structure, and self-assembling peptide gels, which possess a fibrous structure very similar to collagen gels.[67,68]

While the previous studies demonstrating the influence of fibrous materials on the migration and aggregation of isolated endothelial cells were all conducted *in vitro*, Vernon and Sage present arguments that similar tension- and fiber-mediated guidance of endothelial cells might account for the well-known ability of sprouting capillary tips to find one another and connect during angiogenesis, thereby forming a continuous route for blood flow. Additional evidence for the role of fiber guidance in endothelial cell migration *in vivo* includes intravital microscopy observations of newly forming capillaries. In three different forms of angiogenesis (normal tissue development, wound healing, and application of angiogenic factors), the large majority of new capillaries remained in contact with, and aligned with, preexisting elastin fibers, suggesting that the migration of endothelial cells and pericytes is guided by elastin fibers during capillary sprouting.[69] Based on the effect of endogenous ECM fibers on the directional sprouting of capillaries *in vivo*, Anderson *et al.* suggested that fibers in a tissue engineering construct could be rationally designed to control neovascularization of engineered tissues.

In both the *in vitro* and *in vivo* experiments described above, the fibrous matrices directing endothelial cell migration share similar properties. In each case, the diameter of the fibers are small relative to cells (on the order of 0.1–1 μm), have relatively long persistence lengths (e.g., the fibers are relatively straight on the length scale of the cell), and form interconnecting networks. Taken together, these experimental results suggest the following conceptual model of microvascular networks in a fibrous matrix summarized in **Figure 4**. Initially separated cells interact within a 3D ECM gel consisting of fibrous proteins (**Figure 4(a)**). The cells exert forces on the fibers, thereby remodeling the matrix by aligning fibers between cells (**Figure 4(c)**). These aligned fibers effectively transmit stresses over relatively large distances and the cells migrate along the aligned fibers to form multicellular structures (**Figure 4(d)**). As an initial step toward rigorously evaluating this conceptual model, Ma *et al.* used confocal reflectance microscopy images of endothelial cells and adjacent collagen fibers as a basis of finite element analysis of force transmission (**Figure 5(a)**).[70] This analysis revealed that collagen fibers can effectively transmit stresses over long distances (>100 μm) between separated cells in a cell-populated gel (**Figure 5(b)**). In contrast, their simulations revealed that in nonfibrous gels with the same bulk stiffness as the fibrous gels, stresses are not transmitted beyond ~10 μm from the cells (**Figure 5(c)**). These simulations provide quantitative support for the notion that the fibrous nature of stromal ECM and some synthetic biomaterials greatly increases the distance over which endothelial cells can transmit forces, thereby facilitating their assembly into multicellular microvascular networks.

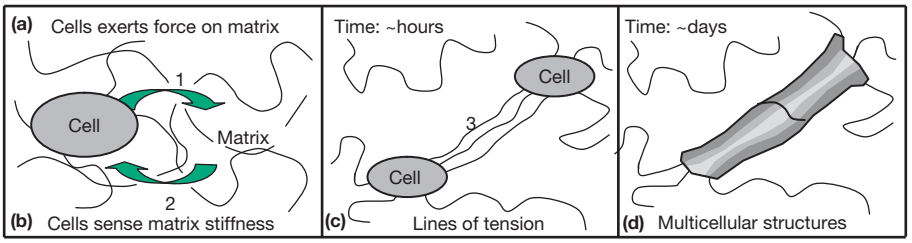

Figure 4 Dynamic reciprocal interactions between cells and matrix. (a) Cells exert forces on the matrix. (b) Mechanical properties of the matrix are sensed by cells and affect cellular function, including force generation. (c) Over a period of hours, cell-derived forces reorganize the matrix including aligned stress-bearing fibers connecting nearby cells. (d) Over a period of days, complex multicellular structures form. The architecture of these structures depends on the mechanical properties of the biomaterial.

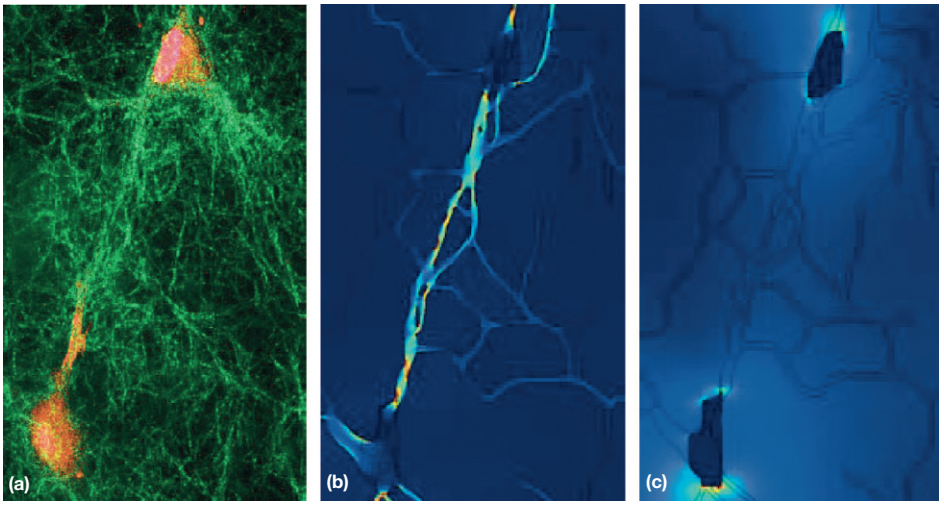

Figure 5 Confocal images (a) reveal the location of collagen fibers (green) and cells (red). Two cells realign the collagen fibers between them (a). Finite element analysis reveals that these fibers effectively carry forces over relatively large distances between the two cells (b). To ensure the concentration of stresses in the fibers is not a meshing or computational artifact, for the mesh used for (b), the modulus of the fiber and nonfiber regions were made the same, thus creating a homogenous material with a FE mesh the same as a fibrous material. In this homogeneous material (c), stress fields decayed rapidly, thereby diminishing the potential for effective, long-range mechanically mediated communication. Reproduced from Ma, X.; Gooch, K. J.; Sieminski, A. L.; Hart, R. T. Finite element modeling of the cellular mechanical environment. In *2008 BMES Annual Fall Meeting*, 2008.

The important role that the fibrous structure of the stromal ECM plays in *in vitro*, and potentially *in vivo*, neovascularization raises the question of whether a fibrous matrix is essential for neovascularization. Evidence suggests that although fibrous matrices are an important factor for neovascularization, they do not need to be directly provided. First, in porous scaffolds placed *in vivo*, cells invade pores and lay down new matrix, forming vascularized tissue which fills the porous volume, though the tissue does not enter the solid phase of the biomaterial.[9] Second, *in vitro* endothelial cells do not elongate or form microvascular networks within Matrigel, which lacks the fibrous structure of stromal ECM. However, if endothelial cells and fibroblasts are cocultured within Matrigel, the fibroblasts elongate, providing an alternative structural support upon which the endothelial cells can then elongate upon a rudimentary microvascular network form. In addition, upon implantation *in vivo*, Matrigel can become neovascularized as a result of vascular tunneling (described in **Section 5.503.3.1**). In this process, bundles of collagen fibers often run along the length of the resulting vascular tubes, suggesting that even in cases where stromal ECM fibers were not initially present, endogenous fibrous ECM are laid down and aligned before or during capillary formation.[37] Endothelial cells suspended within poly (ethylene glycol) (PEG) diacrylate hydrogels functionalized with the cell adhesive peptide RGDS, vascular endothelial growth factor (VEGF), and a collagenase-degradable motif formed tube structures and interconnecting networks, though the cells did not appear as elongated or interconnected as typically observed with endothelial cells in collagen gels or *in vivo*.[71] Interestingly, the endothelial cell seeding density used in modified PEG was 30-fold greater than typically used for collagen gels, suggesting that an impaired ability to transmit forces over long dimensions might be compensated by decreasing intercellular distances. Thus, the action of nonendothelial cells or perhaps very large concentrations of endothelial cells might enable at least rudimentary microvascular network formation in nonfibrous matrices. Another question is whether normal vascular structure and function can be achieved in biomaterials that do not have a fibrous structure. Though there are inadequate data to conclusively answer this question, results

thus far indicate that microvascular networks formed *in vitro* have more physiological structures (e.g., are more continuous, contain lumens) when created within natural or synthetic biomaterials with a fibrous structure resembling stromal ECM.

5.503.4.1.5. Biomaterial stiffness

While biochemical signals from soluble (e.g., growth factors) and insoluble ligands (e.g., integrin-binding sites) are known to affect numerous cell functions, only recently has biomaterial stiffness been recognized as an important factor regulating cellular proliferation, adhesion, migration, spreading, and differentiation. Though the focus of this chapter is primarily on the microvasculature, it is important to note that many studies have suggested that substrate stiffness affects the function of virtually all cell types, though the relevant absolute magnitude of stiffness varies with cell type. For example, the spreading of various cell types is dependent on both the density of binding ligands on a surface and the material's compliance, with spreading favored on stiffer surfaces.[72–74] Substrate stiffness also has been shown to affect the migration rate of numerous cell types including endothelial cells,[61] fibroblasts,[75] and smooth muscle cells[76] and to influence the differentiated activity of neurons,[77] myofibroblasts,[78] and mesenchymal stem cells (see **Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation**).[79]

A review of studies investigating the effect of biomaterial stiffness indicates that surface formation of endothelial cell networks is generally enhanced by seeding on softer substrates. Stiffening Matrigel[80] or collagen[81] by glycosylation decreased network formation by endothelial cells plated on the surface of the gels, although cells on stiffened Matrigel attached, spread, and proliferated as they had on unmodified Matrigel.[80] Trends towards decreased network formation by endothelial cells were also seen when cells were plated on collagen[82] or fibrin[83] gels stiffened by increasing the ECM concentration. Endothelial cells on ECM-coated polyacrylamide gels of decreasing stiffness were more rounded and began to form network-like structures.[84,85] In an early study highlighting the role of matrix mechanics and influence of boundary conditions, endothelial cells were seeded on Matrigel which had been gelled on a slant to provide a continuum of matrix thickness[82]; the cells increasingly formed networks as the Matrigel thickness increased, corresponding to a decrease in perceived stiffness.

As decreasing substrate stiffness has been associated with enhanced surface formation of microvascular networks on substrates, similar trends have been reported for cells within biomaterials. Recent studies extending 2D work into a 3D context have shown that cell spreading and migration depend upon matrix stiffness,[86,87] and numerous studies have shown that stiffness affects capillary morphogenesis in 3D biomaterials. One system designed to study capillary morphogenesis involves endothelial cells seeded on microcarrier beads which are embedded within, and subsequently sprout into, fibrin gels. Enhanced capillary morphogenesis within fibrin gels has been observed in more compliant gels when stiffness is modulated by changing the fibrin concentration,[13,88] or pH,[89] or by adding Factor VIII.[90] Similar results were observed in studies of endothelial cells suspended singly within collagen gels, where decreasing collagen concentration (and thus stiffness) was associated with more extensive capillary morphogenesis.[66,91] This trend was also observed in a study of endothelial cell network formation using self-assembling peptide gels, synthetic polypeptide-based biomaterials with microstructures similar to collagen.[68]

Because material properties of polymeric biomaterials are frequently altered by changing the monomer concentration, crosslink density or other aspects of the polymerization conditions (e.g., pH, cofactors), isolation of the key factors influencing network formation can be difficult. For example, changes in matrix structure (e.g., increased fiber density or decreased pore size) might impact both the ability of cells to penetrate the material and the diffusion of key growth factors,[92] while modifying the extracellular matrix concentration changes the density of integrin-binding sites. To more carefully decouple key parameters, many groups have developed synthetic polymeric systems, frequently based upon PEG with tethered cell adhesion sites (often RGD) in which binding site density and stiffness can be independently altered.[71,86,93] Alternately, materials such as self-assembling peptides show minimal changes in microarchitecture over broad changes in stiffness and concentration, minimizing the effect of changing pore size.[67] As adhesion to these materials is thought to be via adsorbed adhesion proteins,[67] their use may also minimize variation of adhesion sites while changing concentration. It is important to recognize that the stiffness perceived by cells is also a function of geometry and boundary conditions of the material due to cell-generated traction.[94] Though the difficulty in separating variables necessitate caution in generalizing results obtained in these different systems, the overall trend appears to be that biomaterial stiffness is an important determinant of endothelial cell function, with a tendency for capillary morphogenesis to be favored in relatively soft supports.

As described in **Section 5.503.4.1.5**, traction forces exerted by endothelial cells are an important aspect of capillary morphogenesis; network formation is dependent on functional contractile machinery and related signaling pathways.[95–97] Though not considered a primary function, endothelial cells clearly generate force, as demonstrated by their compaction of collagen gels,[82,94,98,100,101] with force generation increasing with 2D substrate stiffness.[101] In a comparison of endothelial cells from different sources cultured under different biochemical conditions, the extent of network formation correlated with the extent of force generation, as measured by gel compaction.[102] Further, a population of endothelial cells exerting higher forces showed enhanced network formation in relatively stiff collagen gels,[103,104] while cells exerting less force require more compliant gels to form extensive networks.[94] In comparison, the stiffness required to support robust network formation in self-assembling peptide gels is nearly an order of magnitude lower than that of collagen gels.[68] It has been hypothesized that this is due to a relative decrease in the strength of endothelial cell adhesion to peptide gels. This is consistent with the decrease in network formation seen when endothelial cell adhesion to collagen gels was blocked with blocking integrin antibodies.[102] Based on this body of work, capillary morphogenesis within a biomaterial appears to be modulated by a balance of the ability of a cell to apply force to the matrix (based on contractile or adhesion strength) with the ability of the biomaterial support to resist deformation. Endothelial cell traction force generation is a key aspect of the local remodeling

of fibrous biomaterials (also described in Section 5.503.4.1.5) important in capillary morphogenesis. Recent microscopic work investigating network formation in collagen gels demonstrates this sort of local remodeling.[105,106] This is consistent with the complex profile emerging for many cell types that the cell–matrix interaction is both reciprocal and dynamic.

A conceptual model that considers microvascular network formation as a balance between cell traction force and matrix stiffness[94] offers a framework to answer questions such as: Why do some endothelial cell lines appear to tolerate stiffer matrices while others require more compliant matrices for proper microvascular network formation? Why is the ideal stiffness for microvascular network formation by a particular endothelial cell line in one biomaterial several-fold greater than the ideal stiffness in another? Cell traction is a function of the cells' ability to generate force and to transmit force to the matrix, with the latter being dependent on cell–matrix adhesion. As illustrated in Figure 6, in this conceptual model, there is no ideal absolute value of matrix stiffness or endothelial traction for microvascular network formation. Instead, a proper ratio of cell traction and matrix adhesion is required. When cell traction is large relative to matrix stiffness, the cells compact the matrix excessively, leading to very high cell densities and a loss of cell viability. When cell traction is small relative to matrix stiffness, cells fail to form microvascular networks. Only when cell traction and matrix stiffness are balanced do microvascular networks form. The legend of Figure 6 discusses specific experimental results in the context of this conceptual model that illustrate the models to account for the effects of cell force generation, cell–matrix adhesion, and matrix stiffness on the formation of microvascular networks in natural and synthetic biomaterials. With a more complete understanding of the mechanical and molecular basis by which material stiffness regulates cellular function, we can provide answers to these questions and move toward the rational design of scaffolds to support the formation of microvascular networks for tissue engineering and regenerative medicine.

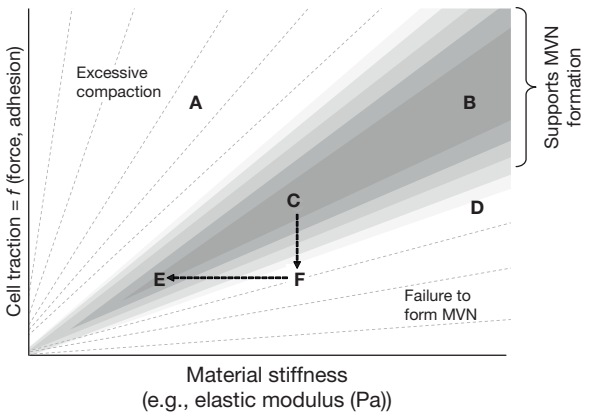

Figure 6 A schematic relating stiffness, traction and MVN formation on semiquantitative axes of cell traction and matrix stiffness. Material stiffness can be changed by changing concentration, polymerization conditions, cross-linking, and boundary conditions. Cell traction can be varied by using different cell sources with different force generation capability or by changing cell adhesion strength. For example, HBOEC in collagen gels exert more force (a, b) than HUVEC (c, d) as described in Sieminski, A. L.; Hebbel, R. P.; Gooch, K. J. *Exp. Cell Res.* **2004**, *297*(2), 574–584. Further, HUVEC in collagen gels (c) exert force more effectively than those in SAP gels (e, f), thus requiring a decrease in SAP stiffness to promote MVN formation (e) as described in Sieminski, A. L.; Was, A. S.; Kim, G.; Kamm, R. D. *Cell Biochem. Biophys.* **2005**, *49*(2), 73–83. The balance of these factors determines whether cells form MVN (gray region; b, c, and e) or do not (white regions) – with the region above the MVN-supporting area representing extreme compaction (a) and the region below representing failure to elongate and/or form multicellular structures (d, f). This framework allows us to understand why HUVEC form MVN in very soft SAP gels (e) and in moderately soft collagen gels (c) and HBOEC form MVN in considerably stiffer collagen gels (e.g. b). Schematic modified from Sieminski, A. L.; Hebbel, R. P.; Gooch, K. J. *Exp. Cell Res.* **2004**, *297*(2), 574–584.

While the previous examples come from *in vitro* studies, there is growing appreciation of the influence of tissue stiffness on cellular function *in vivo* as well. For example, there is evidence that the increased stiffness found in tumors is an important epigenetic factor regulating the expression of the transformed phenotype by oncogene expressing cells.[107] It is tempting to further speculate that the elevated stiffness in the tumor and surrounding tissue may contribute to atypical microvasculature morphology found in tumors such as the unusually large lumen areas, perhaps similar to the irregular capillary networks with excessively large lumens observed in an *in vitro* collagen-based assay performed with endothelial cells cultured in stiff matrices.[94] Along similar lines, tumor-derived endothelial cells show increased stiffness-dependent spreading and increased activity of Rho and ROCK, key players in contractility, and also form irregular structures with large lumens when cultured in Matrigel.[108] One could also speculate that the impaired angiogenesis observed in diabetics may be attributed to tissue stiffening mediated by cross-linking via advance glycosylation products,[81] or that the decreased angiogenesis and wound healing associated with aging could be linked to increasing collagen stiffness.[109]

5.503.4.2. Chemical and Biochemical Features of Biomaterials

5.503.4.2.1. Endothelial cell adhesion to biomaterials in vitro

The physiochemical properties of synthetic and naturally occurring biomaterials play a crucial role in biomaterial–microvasculature interactions. Investigations designed to clarify the nature of cell adhesion to biomaterials using endothelial cells and other adherent cell types have yielded generalizable trends. Some biomaterials contain cell adhesion sequences, either intrinsic (e.g., many ECMs) or by design (e.g., RGD-tethered materials). In the absence of these sequences, cellular adhesion must occur indirectly, typically via adsorbed adhesion proteins. The surface energy of the biomaterial has a great influence on the amount and structure of adsorbed proteins. Increasing hydrophobicity has been associated with increased adsorption of proteins[110] as well as increasing cell adhesion and spreading.[111,112] However, some functional groups on biomaterials have been noted to have an effect on cell adhesion independent of hydrophobicity.[49,113,114] Further, even materials with apparently similar surface properties may show drastic differences in protein adsorption and, thus,

behavior *in vivo*. The surface energy can also change the conformation of adsorbed proteins, which can affect the availability of cell adhesion motifs and influence the behavior of endothelial and other cell types.[115,116] In particular, proteins may become denatured on extremely hydrophobic surfaces,[116,117] limiting cell adhesion.[116]

5.503.4.2.2. Endothelial network formation on and in functionalized biomaterials

Endothelial network formation has been explored on 2D surfaces with adsorbed or covalently bound adhesion molecules. Early work investigating network formation as a function of collagen IV or fibronectin coating concentration on tissue culture plastic showed that network formation was promoted at an intermediate ECM concentration, with networks starting to form at high fibronectin concentrations if cell seeding density was increased.[73] More recent work in which collagen I density on polyacrylamide gels was precisely controlled showed an interplay between substrate stiffness and collagen density, with low collagen density promoting network formation on stiffer substrates.[84] PEG hydrogels functionalized with RGD-binding motifs have also been shown to promote formation of networks by endothelial cells seeded upon their surfaces.[118] Various PEG-RGD systems have been used to show that tethering the adhesion ligand, ephrin A1,[118] increases the length of network structures and that adding matrix metalloproteinase (MMP)-releasable thymosin β4, an actin-binding peptide, speeds up network formation.[119] Organization of endothelial cells into cord or tube-like structures has also been promoted by constraining their adhesion onto adhesive stripes micropatterned with ECM molecules or RGD-PEG.[119,120]

Only recently have several reports of *in vitro* angiogenesis assays within functionalized synthetic biomaterials been reported. The Chen group reported that PEG gels with RGD and MMP-sensitive sites support angiogenic sprouting from embedded chick aortic arch explants. They show that the longest sprouts occur in gels with the most highly degradable MMP sites.[121] In another study by the West group, endothelial cells cocultured with 10T1/2 cells in PEG gels functionalized with RGD and MMP-sensitive sites began to form tubular structures, with an intermediate concentration of PEG supporting cell structures for up to 6 days.[122] Functionalizing fibrin gels with a $\alpha_v\beta_3$ adhesion site, L1Ig6, enhanced sprouting of endothelial cells seeded on microcarrier beads and embedded in the gels.[123]

5.503.4.2.3. The role of chemistry in FBR in vivo

To some degree, development of a favorable FBR around an implant can be achieved through customization of an implant's chemical composition. An implant can have a chemical composition or surface tethered groups that will potentially inhibit FBR and capsule formation around the implant. For example, Ward *et al.*[40] showed that hydrophilic PEO implants developed much thinner capsules compared to PU implants. Another useful modification to implant chemistry may be designing implants that would release angiogenic factors such as nitric oxide (NO), potentially reducing FBR and capsule formation around the implant. Hetrick *et al.* implanted NO-releasing polymers in to Sprague-Dawley rats and showed that the FBR was decreased compared to controls. Additionally, more blood vessels in proximity to NO-releasing implants after 1 week were located compared to controls.[124]

5.503.4.2.4. Angiogenic factors

As described by Judah Folkman in his partially autobiographical account of the origin of controlled-release technology, many early attempts at prolonged, spatially controlled delivery of proteins focused on elucidating the role of specific proteins on the angiogenic response.[125] Using various *in vivo* systems, a variety of factors that stimulate angiogenesis have been identified. Controlled delivery of these factors to other vascular beds also promotes angiogenesis, with the effects of VEGF and basic fibroblast growth factor (bFGF) among the most widely studied.

In the first generation of controlled delivery systems, localized delivery of the angiogenic protein at a constant rate was often considered the ideal goal. Continuous delivery of angiogenic proteins has been achieved for more than a month,[126] and can lead to enhanced angiogenesis.[127–133] Depletion of the angiogenic factor in the controlled delivery system is often followed by regression of the new vessels, an effect similar to that observed following wound healing. More recently, efforts to improve the longevity of newly formed vessels have included localized delivery of cDNA or viral vectors coding for angiogenic proteins, with the rationale that genetically modified cells within the target area would represent a more permanent local source of angiogenic factors.[134] Animal studies as well as early stage clinical trials support the potential of gene delivery to stimulate and maintain new vessel formation as reviewed elsewhere.[135,136] Specific challenges associated with clinical implementation of this approach have recently been reviewed.[137] For example, early efforts to deliver VEGF via gene therapy resulted in overstimulation and the formation of hemangiomas.[136]

Rather than prolonging the delivery of angiogenic factors, an alternative approach to maintaining newly formed microvasculature is the introduction of biological factors that stabilize new vessels. One example of this approach employed a porous polymeric scaffold in which VEGF was associated with the surface and platelet-derived growth factor (PDGF) was embedded in the polymer. With this dual-delivery system, the majority of VEGF is delivered over the first ~10 days to promote the formation of new vessels, whereas the release of PDGF occurs over a longer period (~1 month) to facilitate the recruitment of mural cells to stabilize the newly formed vessels.[138] When implanted subcutaneously in rats for 4 weeks, the dual-delivery system increased the number and average size of vessels in the surrounding tissue relative to either factor alone and resulted in approximately fourfold increase in the number of mature vessels, as assessed by immunostaining for α-smooth muscle actin. An injectable version of a similar dual-delivery system also resulted in improved vessel maturity and tissue vascularization in a mouse model.[139]

The approaches described above represent attempts to achieve a predefined delivery rate of the desired factor(s). Others have explored methods in which the delivery rate of angiogenic factors from matrices is controlled by biological stimuli (so-called 'active-release' or 'cell-demanded release'). One example of this approach is the covalent modification of VEGF to a PEG gel via MMP-sensitive peptide linkers.[140] The release of biologically active VEGF from these gels would be triggered by exposure to MMP-2 or plasmin, the former likely

acting by cleaving peptide linkers and the latter by cleaving VEGF at a previously described plasmin-sensitive site. PEG gels containing covalently bound VEGF have been shown to induce angiogenesis when placed on a chick chorioallantoic membrane (CAM) and were invaded by vascular tissue when implanted subcutaneously in rats. Similarly, the use of factor XIIIa to covalently bind fibrin to a modified form of VEGF resulted in a fibrin gel exhibiting plasmin- and MMP-mediated VEGF release.[141] As with the PEG-based system, the covalently bound VEGF-fibrin gels induced angiogenesis in the CAM following subcutaneous implantation in the mouse. Interestingly, the very permeable or leaky vessels often associated with VEGF-induced angiogenesis were not present, suggesting that coupling the availability of VEGF to cellular activity (or perhaps by simply reducing local VEGF concentrations) enabled retention of the permeability barrier of the microcirculation.

5.503.5. Case Studies

In the final section, we will consider attempts at bioengineering neovascularization using biomaterials. The goal of this section is not to provide a complete review of these areas but to illustrate how the results of many of these studies can be understood in light of the principles discussed in this review.

5.503.5.1. Implantation of Preformed Microvascular Networks

Long-term function of 3D tissue constructs depends on adequate vascularization after implantation, which represents one of the major challenges in tissue engineering. Creation of microvascular networks within 3D tissue constructs *in vitro* prior to implantation may facilitate the introduction of engineered blood vessels that retain functional stability *in vivo*. Early work in this area was conducted in the context of cell-based gene therapy approaches in which preformed microvascular networks of genetically modified endothelial cells were implanted *in vivo* with the hopes of releasing the desired gene product directly into the circulation. Hemangioblasts implanted into 3D gels of Matrigel resulted in the formation of microvascular networks with a fraction of the cells expressing markers of endothelial cell differentiation.[22–24] If the hemangioblast cells were first stably transfected so that they secreted human growth hormone (hGH), implantation of hemangioblast/Matrigel constructs resulted in systemic delivery of hGH. In contrast, cultures of adult endothelial cells failed to form microvascular networks in Matrigel or to systemically deliver hGH *in vivo*.[25] To explore the potential role of nonendothelial cells in stabilizing microvascular network formation *in vitro* and *in vivo*, Sieminski *et al.* mixed hGH-expressing adult endothelial cells with non-hGH-expressing fibroblasts within a 3D gel of Matrigel.[25] Endothelial cell/fibroblast mixtures formed microvascular networks *in vitro* and delivered hGH systemically for at least 6 weeks.

Koike and Jain *et al.* showed that a stable, long-lasting network of blood vessels could be established in mice by implantation of 3D constructs made from human umbilical–vein endothelial cells and 10T1/2 mesenchymal precursor cells seeded and cocultured in a 3D fibronectin-type I collagen gel.[14,142] The formation of blood vessels *in vivo* was tracked by incorporation of enhanced green fluorescent protein into the endothelial cells. After 4 days, the endothelial and 10T1/2 mesenchymal precursor cell constructs formed long, interconnected tubes with branching, but no evidence of perfusion. However, at 4 weeks the tubes began to connect to the mouse's circulatory system and became perfused. After 4 months, the number of perfused vessels was increased and nonperfused vessels were not evident. The networks formed were stable and functional for 1 year *in vivo*.[14] Furthermore, the engineered vessels responded to vasoactive stimuli and demonstrated higher vascular permeability than normal blood vessels.[14] In contrast, the control 3D constructs that were made from endothelial cells alone showed evidence of minimal perfusion and disappeared after 1 month *in vivo*. More recent studies by Patrick and Jain *et al.*[142] suggested that human bone marrow-derived mesenchymal stem cells (hMSCs) may also serve as a source of cells for use in vascular tissue engineering. They showed that although hMSCs did not differentiate into endothelial tubes capable of carrying blood, they did function as perivascular cells when coimplanted with endothelial cells *in vivo*. These hMSC-derived perivascular cells constricted in response to stimulation by the endogenous vasoconstrictive peptide, endothelin-1, and were found to stabilize nascent blood vessels that remained functional for more than 130 days *in vivo*.

Studies from other groups have also shown that isolated and intact microvessel fragments retain their angiogenic potential and are capable of forming a microvascular bed when cultured in a 3D collagen I gel.[143] Further implantation of this microvascular construct into mice rapidly inosculated vessels from the construct into the host circulation after the first day of implantation. After 28 days, evaluation of these constructs revealed the presence of a mature functional microvascular bed.[144]

These studies, in conjunction with those in **Section 5.503.2.1**, demonstrate progress toward the creation of microvascular networks within engineered tissues and the ability of engineered microvascular networks to stably integrate with the host vasculature. The successful studies all shared a common element: the introduction of nonendothelial cells, either intentionally[14,25,102,142] or likely unintentionally as part of the microvascular fragments.[143] Furthermore, a comparison of the quality of microvascular networks across these studies indicates that those present in fibrous collagen were superior to those present in Matrigel.

5.503.5.2. Extravascular Wraps for Grafted Veins

Human saphenous veins are widely used for coronary artery bypass grafts despite the lower long-term success relative to arteries. Grafting a saphenous vein into the arterial circulation represents an abrupt transition from a mild mechanical environment (i.e., low pressure and shear stress with minimal pulsatility) to the more strenuous mechanical environment of the arterial circulation. It is often suggested that the elevated pressure (or pulsatility) in the arterial circulation subjects the vein to excessive circumferential stresses (or cyclic strains), which it is not designed to withstand, thereby mechanically injuring the vein and initiating a cascade of events that leads to intimal hyperplasia.[145–147] It has been suggested that introduction of a

supportive, tight-fitting extravascular wrap to reduce the mechanical stresses in the wall of grafted veins might improve their performance. Contrary to this hypothesis, supportive vascular wraps in a porcine model did not improve the performance of grafted veins; however, somewhat unexpectedly, performance of vein grafts was improved when sheathed in looser nonrestrictive wraps that did not mechanically support the veins. It was determined that the loose-fitting wraps were beneficial only when they were made of porous materials; loose-fitting wraps made from nonporous materials were not beneficial. Veins with the loose-fitting porous wraps developed a distinct 'neoadventitia' with abundant microvasculature in the perivascular space between the graft and the stent[148] which was not evident in unstented grafts or in grafts stented with a nonporous stent.[149] While not commented on by the authors of these studies, the vascularizing effects of the porous wraps are similar to that observed with biomaterials implanted subcutaneously (**Section 5.503.4.1.3**). Studies by Nugent and Edelman[150] have shown that gel foam sponges seeded with endothelial cells and wrapped around blood vessels prevent intimal hyperplasia, providing a potential link between the neovascularization of the extravascular space with porous loose-fitting vascular wraps and the observed inhibition of intimal hyperplasia.[148]

5.503.5.3. Glucose Sensors

Principles of enhancing vascularization have been utilized to prevent the formation of a fibrous capsule around implantable glucose sensors. Attempts to incorporate growth factors such as VEGF induced significant neovascularization surrounding the implanted sensor and greatly enhanced the glucose sensor function *in vivo* in an *ex ova* chicken embryo CAM-glucose sensor model.[151,152] Other groups have attempted to increase the diffusivity of the analyte glucose from the sensor to the host tissue by applying water soluble PVA hydrogel coatings.[153] This approach tends to reduce inflammation around the implant and therefore can increase vascularization. Combining these principles, Norton and Reichert have shown that glucose sensors coated with VEGF-releasing hydrogels increased vascularity and inflammation in the surrounding tissue after 2 weeks of implantation compared to hydrogel-coated sensors alone.[152] Finally, efforts to create porous coatings to improve vascularization around glucose sensor implants have been successful. In a study by Koswanez and Reichert[154] porous poly lactic acid coatings with pore sizes ranging from 36 to 84 μm applied to the sensor surface when implanted *in vivo* reduced fibrosis and promoted microvessel formation in adjacent tissues. Furthermore, the porous coatings did not interfere with sensor accuracy or its response rate *in vitro*.[154] All of these studies collectively demonstrate strategies to reduce FBR and enhance vascularization around implants as discussed previously.

Glossary

Extracellular matrix The network of biological polymers assembled into a three-dimensional architecture that surrounds and provides anchorage sites for cells.

Young's modulus Ratio of the uniaxial stress over the uniaxial strain. Often this is measured in units of Pascal (Pa), which is a Newton per square meter.

Abbreviations

AFM	Atomic force microscopy
ECM	Extracellular matrix
ERK	Extracellular signal-regulated kinase
ESC	Embryonic stem cell
G	Guluronic acid
HA	Hyaluronic acid
M	Mannuronic acid
MSC	Mesenchymal stem cell
MSD	Mean squared displacement
PA	Polyacrylamide
PDMS	Polydimethylsiloxane
PEG	Polyethylene glycol
SMC	Smooth muscle cell
UV	Ultraviolet

5.504.1. Introduction

A cell's surrounding environment is composed of a variety of different components: adjacent cells to which they adhere via cadherin proteins, interstitial fluid containing soluble growth factors, and extracellular matrix (ECM), a three-dimensional (3D) protein scaffold to which cells adhere via heterodimers of α and β integrins. While ECM comes in many different forms and can be composed of many different proteins, cells can use the ECM to actively 'feel' their surroundings by pulling against it to transmit forces to adjacent cells. Neighboring cells can then use a series of mechanosensitive pathways to sense and respond to these forces via mechanical cross-talk. The nature of this communication between cells and their environment is regulated by several important properties of the ECM. One notable observation over the last decade has been that the ECM's Young's modulus, which is commonly referred to as 'stiffness' in biological literature, can direct cell response and drive specific functions. Studies examining how ECM properties affect cells have often employed synthetic hydrogels, which serve as an underlying substrate where one can decouple many of the chemical and physical properties that native ECM cannot. By studying each component independently, one can determine how a specific ECM property, for example, stiffness, topography (see **Chapter 4.409, Surfaces and Cell Behavior**), composition (see **Chapter 2.203, Protein-Engineered Biomaterials: Synthesis and Characterization**), etc., regulates cell behaviors, for example, spreading, migration, and differentiation, over a range of physiological conditions. Here, we first outline the techniques and materials used to modulate substrate modulus before describing how changes in modulus affect cell function and differentiation in widely studied 2D culture systems. In a concluding discussion, we contrast the behavioral differences of cells grown in 2D and 3D cultures.

5.504.2. Young's Modulus

5.504.2.1. Definition and Measurement

Young's modulus (abbreviated as E) is an intrinsic material parameter that describes the relationship between the unitless percent elongation of a material, that is, strain (ε), and the force applied per area, that is, stress (σ). Young's modulus can often be described by the linear relationship $E = \sigma/\varepsilon$, especially at low strain and is measured in units of Pascal (Pa) or Newton per square meter. Materials that are palpably stiffer will exhibit higher elastic moduli compared to softer materials. For biological tissues, most moduli range between the two extremes of bone and brain: the modulus of calcified bone is on the order of ~5 GPa,[1] though bone cells live within the nonmineralized 'osteoid,' while that of brain tissue is on the order of 1 kPa.[2] Such numbers are determined from small (< 20%) strain measurements, where many tissues and biomaterials exhibit a constant modulus.[3] At larger deformations, these materials tend to stiffen, in a process called strain stiffening, as materials begin to irreversibly deform, that is, fibrils within ECM permanently rearrange, causing a nonlinear modulus.[4,5] To account for this behavior, numerous nonlinear models have been developed,[6] but for cells in general, the strains generated do not exceed the 20% threshold.[7] Thus, our discussion here will be limited to techniques that determine Young's moduli at small strains.

The modulus of materials is most easily determined by applying a small force to a sample and measuring the resulting strain. As many biological tissues and cells experience smaller forces on the order of nano- or pico-Newtons, advanced methods have been developed to characterize the mechanics of cells and their surrounding tissue. Three of these techniques, microsphere indentation, microindenters, and atomic force microscopy (AFM), are summarized below. While we focus on micro- and nanoindentation methods here due to the length scale of cells and the magnitude of forces that they generate, it is important to note that there is a correlation between bulk mechanical properties and microscopic properties for many standard materials, for example, polyacrylamide (PA).[8] However, there are important deviations from this correlation, as in the case of poly(vinylpyrrolidone) hydrogels.[6,9] In subsequent sections, we will extend our description of these techniques to the materials of interest, for example, synthetic hydrogels and natural materials, where their mechanical properties depend on chemical composition and material structure.

5.504.2.1.1. Microspheres under gravitational forces

Microsphere indentation determines a material's Young's modulus by measuring the indentation depth of a metal microsphere on top of a substrate and comparing it to the gravitational force of the sphere[10] (**Figure 1(a)**). Beads typically a few hundred nanometers in diameter are confined in the substrate, and images of their positions before and after microspheres are placed on the substrate to enable one to compute indentation depth or displacement. The Young's modulus is then calculated from the sphere indentation model developed by Hertz[11]:

$$E = \frac{3(1-\nu^2)f^2}{4\delta^{3/2}r^{1/2}} \quad [1]$$

where ν is the Poisson's ratio, f is the buoyancy-corrected weight, δ is the depth of the indentation created by the ball, and r is the radius of the ball. This simple technique works with a high degree of reproducibility for E~2.2–33 kPa on both PA and gelatin substrates, where indentation is small but measurable.[12] However, determining Young's modulus of relatively thin (<100 μm) or exceedingly soft substrates, which are optimal for microscopy, requires a correction factor as the vertical displacement of the beads is affected by the underlying glass substrate. Moreover, this measurement technique requires confocal microscopy to accurately determine 3D bead positions, and, compared to more sensitive techniques, for example, AFM or microindenters, with moderately small displacements and beads, it can be prone to overestimate moduli. This technique also applies a single force determined by ball density and volume and thus cannot determine if the magnitude of indentation falls within the small strain linear range of the material or not. Despite such drawbacks, this measurement method is relatively straightforward and easy to perform.

5.504.2.1.2. Microindenters

Microindenters, originally developed to measure the Young's modulus of very stiff materials,[13] have recently been adapted to measure the Young's modulus of soft materials with

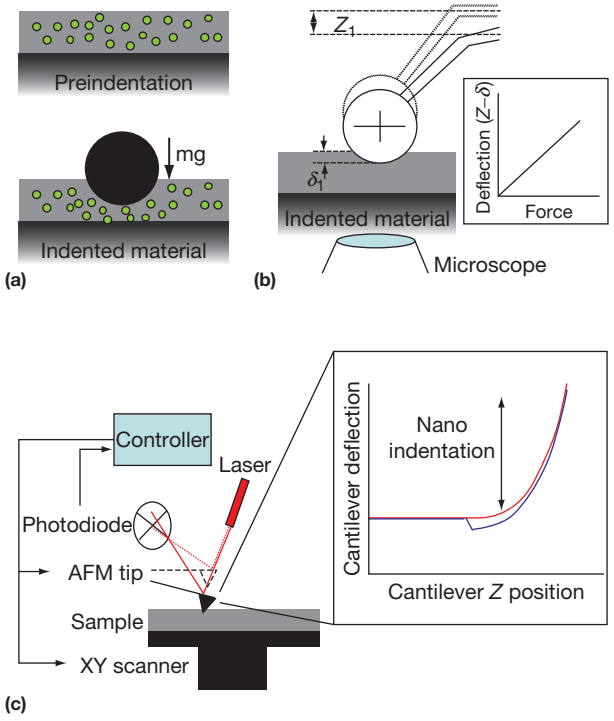

Figure 1 Techniques used to determine the Young's modulus of materials. Schematic representation of the experimental setup for microspheres (a), microindenters (b), and atomic force microscopy (c) to measure the Young's modulus of substrates.

biologically relevant stiffness in the range of kilo- and mega-Pascals (see **Chapter 3.306, Microindentation**).[14] Microindentation for soft materials typically uses a spherical tip with a radius of several microns, which is attached to the end of a flexible microneedle to probe the substrate (**Figure 1(b)**). Deformation of the tip is measured by optical microscopy and the resulting displacement compared to a standard curve to obtain the modulus as determined by the Hertz model (eqn [1]).[11] By tuning the stiffness of the indenter arm, varying ranges of substrate moduli can be measured. As such, microindentation measurements of soft hydrated materials such as PA substrates have been shown to correlate well with AFM measurements over the range ~2.5–40 kPa.[15] As with the microsphere technique, microindenters yield accurate moduli measurements when strains are kept small and when sample thickness is in the range of >100–150 μm. This technique relies on visual determination of tip position, and thus error from inaccurate vertical measurements can dramatically affect the modulus determined from the experiment. However, microindentation is performed on a microscope stage, and therefore offers an economical measuring technique for tissues over a wide range of sample geometries.

5.504.2.1.3. Atomic force microscopy

AFM was developed for imaging applications at microscale resolution (see **Chapter 3.302, Atomic Force Microscopy**) but has been extensively used to assess the mechanical properties of hydrated substrates.[16–19] This technique uses a precalibrated flexible cantilever with a pyramidal or spherical tip mounted on a piezoelectric device to indent the sample through a controlled amount of tip deflection (**Figure 1(c)**). A laser reflects off the backside of the tip, which is typically fabricated out of silicon nitride with a reflective gold coating on the top, onto a position-sensitive photodetector that measures the tip deflection during indentation. Since the tip behaves similarly to a Hookean spring, the indentation depth can be converted to force (f) using the tip spring constant, much like for microindenters. By separately comparing tip deflection when pressing on a hard material (where deflection scales perfectly to the piezomotor position), for example, glass, to the deflection when pressing into a soft material, it is possible to determine the actual indentation (δ) into the material. Using indentation models of a pyramid/cone developed by Sneddon (eqn [2])[20] or a sphere developed by Hertz (eqn [1]), it is possible to determine the Young's modulus, E:

$$f = \left[\frac{2\tan\alpha}{\pi}\right]\left[\frac{E}{1-\nu^2}\right]\delta^2 \qquad [2]$$

where α is the half opening angle of the pyramidal or conical tip. A thin film correction can be introduced to accurately determine the Young's modulus of substrates for sufficiently thin samples where the underlying support could dominate the mechanics absent this correction.[21] While the degree of correction is material-specific, for near linearly elastic materials, for example, PA gels, the correction enables one to measure Young's moduli of a sample independent of its thickness, provided that the sample thickness is a known quantity. For PA substrates, the correction has been shown to be necessary for gels below 20 μm thickness, independent of the material's actual bulk stiffness.[18] With these advantages, AFM is a preferred measurement technique over the other indentation methods to perform repeated measurements over small sample areas with high accuracy. However, instrument cost, limited longevity of cantilever tips, and adhesive interactions between the tip and the gel may make AFM difficult to implement for the average user.[22]

5.504.2.1.4. Additional considerations for measurement techniques

While many synthetic materials used in biological applications are hydrogels that are nearly linearly elastic, natural ECM is often not. Thus, it is important to note that materials are often anisotropic, meaning that their Young's modulus for the measured axis of indentation may not be identical to another axis of the material. In such instances, one must not rely solely on one indentation method but instead employ measurement techniques that probe different mechanical modes, for example, rheology. Though we will not go into great detail, rheology measures a shear modulus as it applies a force parallel to the top surface of a material rather than perpendicular as with the indentation techniques previously described. By converting shear to Young's moduli, direct comparison from multiple force modes is possible. So far, comparisons of AFM- and rheology-determined Young's moduli have shown good agreement for hydrogels.[23]

5.504.2.2. Development, Maintenance, and Variation of Young's Modulus in Biology

Cell and tissue modulus changes drastically during development and establishes the wide variation of elasticity in the body. Before producing materials on which to culture cells, it

is important to develop an understanding of the physiological context in which the cells of interest live, from development through aging, and ultimately disease.

5.504.2.2.1. Development and maintenance of tissue stiffness

In early development, the embryo is a conglomerate of cells with little architecture and is very compliant, that is, soft.[24,25] Further development into the three germ layers that comprise all tissues requires cell migration into the appropriate spatial configuration.[24,26] The ability of these cells to self-segregate into cells of similar type has been shown to depend on expression of particular markers such as E-cadherin and β-catenin involved in cell adhesion,[27] which has lead to the development of the idea of 'tissue affinity' or topobiology as coined by Edelman and colleagues.[28] However, cell sorting *in vivo* has also been attributed to the mechanics of the ECM.[26,29] For example, the stiffness of mesoderm dorsal tissue is orders of magnitude stiffer than endoderm in early amphibian embryos.[30] Additionally, amphibian embryos show a ~2-fold increase in stiffness during gastrulation,[24] which is specific to the germ layer in question as shown in zebrafish.[31] Young's modulus may therefore be a driving force in the development of tissues at the embryonic stage and not simply a consequence of development. Yet, once fully developed, biological tissues exhibit tremendous variation in stiffness. Appreciating this variation and designing materials to meet the needs of the cells of interest is critical for therapeutic applications, as discussed in **Section 5.504.4**. However, it is easy to appreciate this variation by considering the two extremes of bone and brain again: the bulk modulus of calcified bone is on the order of ~5 GPa[1] while that of brain tissue is on the order of 1 kPa or less.[2] While this variation is six orders of magnitude, it may represent a common misconception; the actual environment that osteoblasts inhabit is actually more representative of a highly cross-linked, collagenous environment with a modulus of 30–40 kPa.[32] Osteoblasts do not typically inhabit calcified regions of bone.[33] Nevertheless, it is absolutely critical to appropriately mimic one's *in vivo* surrounding *in vitro* (see **Figure 4**) to obtain meaningful cell behavior in culture.

5.504.2.2.2. Aging and disease

It should also be noted that the modulus of many tissues changes naturally with time and after the onset of certain diseases. For example, as we age our skin becomes less elastic,[34] and blood vessels[35] and articular cartilage[36] become progressively stiffer. At the root of these mechanical changes are protein level changes in ECM composition and cross-linking of adjacent matrix fibers. However, abnormal variations in modulus can also play a role in the development of many diseases.[35,37] Arthritis patients exhibit cartilage softening from progressive breakdown of the cartilage collagen meshwork[36] whereas patients with liver disease or myocardial infarction manifest enhanced stiffness due to the onset of fibrosis,[5,37] that is, the abnormal deposition of ECM. These changes impact the function and behavior of cells, owing to the constant cross-talk between cells and their microenvironment, and result in disease progression. With myocardial infarction, stiffening of the myocardial wall is accompanied by cell apoptosis, wall thinning, and a decrease in cardiac output as measured by ejection fraction.[5]

5.504.3. Fabrication of Substrates with Defined Material Modulus

To mimic the properties mentioned and measured above, we will profile a variety of natural and hydrogel-based supports that are often used in cell culture. For the former, close biomimicry provides a distinct advantage over all other materials. On the other hand, the latter provides materials with high water content that closely mimic physiological environments while at the same time allowing one to decouple variables, for example, ECM chemistry and mechanics, and observe how one matrix property in particular may influence cell behavior. Mechanical properties of both natural and synthetic matrices are based on (a) pore size, (b) polymer concentration, (c) polymer molecular weight, and (d) the degree of cross-linking among other parameters and can be varied by changing any one or a number of these factors. Below we offer material-specific discussions of how Young's modulus is changed using these parameters, starting with natural matrices and concluding with synthetic ones.

5.504.3.1. Natural ECM Components

With the complexity of the natural cellular environment, we focus on popular examples of several classes of biopolymers: collagen – representing the class of large network-forming matrix proteins, including fibronectin and laminin,[38] hyaluronic acid (HA) and alginate – representing the large carbohydrate polymers called glycosaminoglycans,[39] and Matrigel – a commercially available reconstituted basement membrane product. Though these matrices have shown particularly interesting results in how they regulate cell behavior, our discussion here will be limited to how these materials can be controlled to display a range of stiffness for cells.

5.504.3.1.1. Collagen

Fibrillar collagen is the most abundant ECM protein and constitutes a large portion of our connective tissue. There are a number of readily available sources, for example, rat tail, where collagen can be easily isolated.[38] By simply adjusting the pH of the solution[40] or collagen density,[38] polymerized matrices can be produced in the presence of cells (as a 3D matrix) or they can subsequently be added to the culture to provide a flat culture substrate (using collagen as a 2D coating). Given the relative ease with which one can produce these gels and the flexibility one has when using it, collagen has become a widely used cell scaffold. However, there are important mechanical considerations to be taken into account when using collagen. Altering collagen polymerization conditions or pretreating with pepsin can alter the pore size in the final product.[41] Changing the collagen concentration from ~0.1 to 3 mg ml^{-1} will also increase material modulus,[38,42] and these changes can also be presented in concentration gradients that also yield stiffness gradients.[43] Yet collagen gels have inherently coupled collagen density and stiffness: the more collagen ligand present, the stiffer the gel. Nonadhesive 'stiffening agents' can be introduced to try to decouple these components,[44] but as in the case of many 3D materials, smaller pores and ligand accessibility may alter cell adhesion and overall behavior in 3D,[45,46] making a link between stiffness and cell behavior more challenging.

That said, a number of applications of 2D and 3D collagen gels have actually been realized. Collagen has long been used as a surface coating and can dictate heart fibroblast behavior in 2D.[47] Collagen gels also have been engineered into sheet-based 3D models to study cell behavior[48] and compressed around cells to provide high-stiffness 3D environments similar to native tissue.[49] Overall, collagen gels exhibit good cytocompatibility, but given their mechanochemical coupling, they also possess drawbacks compared to more tunable synthetic systems, for example, PA, when examining *in vitro* cell characteristics.[50]

5.504.3.1.2. Hyaluronic acid

HA is a negatively charged linear polysaccharide made up of D-glucuronic and D-*N*-acetylglucosamine and commonly found in the ECM and connective tissue (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**). Unique physical and chemical properties make HA an attractive biological substrate, but due to suboptimal mechanical properties and rapid degradation, chemical modification of the HA backbone is often performed to induce hydrogel formation and to build in specific functionality. For example, HA hydrogels can be formed by modifying the HA backbone and adding in cross-linkers, for example, thiolation to form disulfide bonds[51] or addition of polyethylene glycol (PEG)-diacrylate to the thiols,[52] or via direct conjugation of synthetic polymers, for example, PEG, poly(L-lysine) acid, poly(*N*-isopropylacrylamide), etc.[53] Copolymerization to form an interpenetrating network using collagen, alginate, or gelatin also yields stiffer hydrogels.[54,55] Most single-chemical modifications provide gels that are best suited to mimic the mechanics of soft tissues ~10–3500 Pa, such as brain.[55,56] HA can also readily undergo multiple, sequential modifications, such as being methacrylated for dithiol cross-linking via Michael-type addition and then undergoing radical polymerization via the free methacrylated sites (similar to photolithography techniques outlined in **Figure 3(b*ii*)**). This process enables multiple cross-linking steps to provide maximal flexibility and produce moduli ranging from 1 to 100 kPa.[58] As a natural polymer, HA is often used as an injectable material, and it has been shown to maintain left ventricle wall thickness during the normal remodeling process postmyocardial infarction.[59] While it is not certain if HA restores normal ventricle mechanical properties altered by the infarct,[5] it certainly implies that HA could be a promising natural material for regenerative use.

5.504.3.1.3. Alginate

Alginate is a derivative of sea algae that is often used for drug delivery, to encapsulate cells, or as a cell culture support.[60] Alginate gels are composed of interspersed elements of mannuronic (M) and guluronic acids (G) and divalent ions, for example, Ca^{+2}, which cross-link the alginate monomers into a reversible hydrogel. The M/G ratio has been shown to regulate how tightly cross-linked the hydrogel can become: gels with a low M/G ratio swell less than gels with a higher M/G ratio and thus yield stiffer hydrogels.[61] Alginate hydrogel stiffness can also be modulated by alginate concentration and chemical composition as well as the cationic species used. Increasing alginate and divalent ion concentration allows for higher cross-link density, yielding more rigid gels with moduli ranging from ~1 to 120 kPa.[62,63] Use of these gels in cell culture, however, reduces their stiffness up to 10-fold as the Na^{+} and Ca^{2+} present in culture media can interfere with cross-links,[64] but this can be overcome in part by using high-molecular-weight alginate and introducing covalent cross-links.[65] Gels composed of alginate derivatives such as poly(aldehyde guluronate) have been reported to achieve compressive modulus up to 1 MPa.[66]

5.504.3.1.4. Matrigel

Matrigel is a preparation of solubilized basement membrane proteins extracted from mouse sarcoma,[67] which typically contains varying amounts of laminin, collagen IV, heparan sulfate proteoglycans, entactin, and nidogen. To vary the mechanical properties of the material as with collagen, one must change the Matrigel concentration, and stiffness has been reported to range from 10 to 50 Pa, depending on concentration.[68] Copolymerization with type I collagen as an inner penetrating polymer network can further increase the composite's Young's modulus, but again over a limited range.[69,70] The lack of stiffness variation is an important consideration, but Matrigel is often used as a ligand coating or supporting matrix in conjunction with a synthetic material that independently varies stiffness, for example, mammary acinar cultures with Matrigel and PA hydrogels.[71] In this capacity, it is more often used in studies that want to ensure that the correct matrix composition is present, for example, during self-renewal of human embryonic stem cells (hESCs) in tissue culture.[72] Matrigel is not without its distinct advantages though; it is easily able to be cast into channels and shapes to pose questions about mechanics in pseudo-3D or 3D environments[73] without requiring functionalization.

5.504.3.2. Synthetic Hydrogels

5.504.3.2.1. Polyacrylamide

PA gels are inert, synthetic hydrogels most commonly used for protein separation in gel electrophoresis. As PA gels are easy to fabricate, have widely tunable mechanical properties, and are easily functionalized with adhesive ligands, these substrates are also well suited to study the effects of substrate modulus on a variety of cellular functions detailed in **Section 5.504.4**. Polymerization of PA hydrogels occurs through a free radical-driven reaction where acrylamide and bis-acrylamide solutions in varying concentrations are mixed with a free radical source, most commonly ammonium persulfate.[74] The mechanical properties of the synthesized gels vary from ~0.1 to 100 kPa (**Figure 2**),[18,75] where moduli values are based on common principles of condensed matter physics[76,77]; higher concentrations of acrylamide monomer yield stiffer gels (insets *iii and iv*) due to increased chain entanglement. Increasing cross-linker concentration, on the other hand, generates more physical tethers between the polymer backbone, thereby reducing individual chain flexibility and increasing the Young's modulus of the material (insets *ii* and *iv*). Uniform distribution of the free radical source or even mixing of the monomer and cross-linker generates static gels,[9] which are most commonly used for cell culture as they generate a roughly even cell response, making them suitable for many biochemical assays. However, PA gels can also be micropatterned with step or smooth gradients of Young's modulus made by polymerizing adjacent gels of different moduli (**Figure 3(a)**)[10,78] or by photoactivation of the

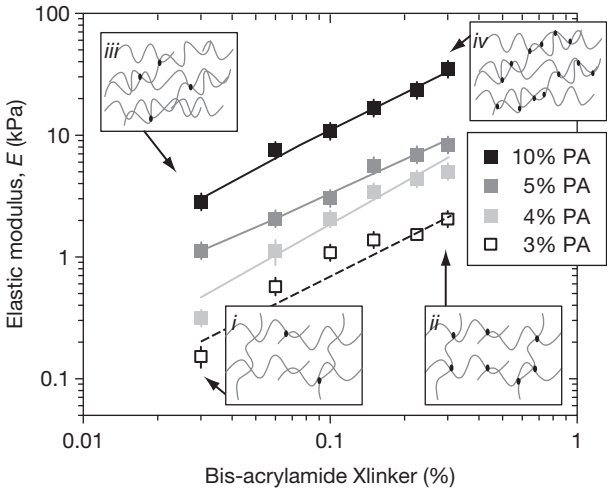

Figure 2 Elastic modulus of range of polyacrylamide gels. Elastic modulus of polyacrylamide substrates for gels with different concentrations of acrylamide monomer and bis-acrylamide cross-linker. Substrates polymerized in solutions with higher concentrations of acrylamide monomer yield stiffer gels (insets *iii* and *iv*) due to increased chain entanglement and nonspecific interactions between polymer chains. Adding increasing amounts of cross-linker in the polymerization mixture generates more physical tethers between the backbone of polymers and increases the Young's modulus of the material (insets *ii* and *iv*).

free radical initiator Irgacure 2959 via gradients of UV initiation (**Figure 3(b*i*)**)[79,80] or cross-linker concentration established in microchannels (**Figure 3(b*ii*)**),[57] respectively. Ultimately, these gradients study a cell's ability to undergo durotaxis ('duro' being latin for hard), that is, the characteristic movement of a cell along a stiffness gradient, and each of these techniques yields different gradient strengths, which has recently been shown to be important for cell behavior.[81] However, one of the main drawbacks to using PA substrates is acrylamide and initiator cytotoxicity. Gels must often be soaked in buffer before use to allow unreacted species to diffuse out of the substrates, thus limiting these polymers to 2D *in vitro* studies.

To facilitate cell attachment to the nonadhesive PA, proteins are usually covalently attached to the PA gel surface. Incubation with *N*-sulfosuccinimidyl-6-(4′-azido-2′-nitrophenylamino) hexanoate (sulfo-SANPAH), a UV-activatable cross-linker,[4] or hydrazine hydrate[82] allows for covalent tethering of ECM proteins such as fibronectin,[83] collagen,[84] or combinations of proteins[85] onto PA gels. In addition, spatial distribution of proteins has been achieved on PA gels using micropatterning[86,87] and microcontact printing.[85] Varying the concentration of solubilized protein added to these synthetic matrices allows for more or fewer cell attachment sites, allowing investigators to control the adhesion strength of cells on these matrices.[8]

5.504.3.2.2. Polydimethylsiloxane

Polydimethylsiloxane (PDMS) is a silicone elastomer most often used in microfluidic or lab-on-a-chip applications to form devices with defined microstructures. Many formulations of PDMS exist, with Sylgard 184 being the most commonly used in biological-based research.[88] Fabrication of polymer substrates involves mixing of a 10:1 ratio of elastomer to curing agent, degassing, and baking for a few hours at 90 °C. This polymerization process provides good strength, optical clarity, and ability to irreversibly bond glass, making PDMS an ideal substrate for studies that require both microscopy and defined physical gel features. As the elastomer maintains its shape after curing, PDMS is often poured over micropatterned substrates fabricated using soft photolithography to obtain gels with defined topographical features down to ~10 μm. By varying the ratio of the curing agent to the PDMS or baking time, substrates with a Young's modulus between ~12 and 2500 kPa can be achieved,[78,89] making it a suitable system for more contractile cells where the microenvironment is often >10 kPa.[7] Pouring the curing PDMS solution over micropatterned surfaces made by photolithography can also create useful surface topologies, such as with high-density pillar arrays, where posts can be engineered to have an effectively lower apparent substrate stiffness of ~2–130 kPa simply by changing the physical dimensions of the pillars on which the cells pull.[90] Deformable pillars are useful not only to generate compliant substrates but also to quantify substrate deformation and traction forces exerted by crawling cells. Photolithography has also been used to generate PDMS master molds capable of creating PA hydrogels with spatially varying mechanical properties, for example, step (**Figure 3(a)**)[78] or smooth 1D gradient (**Figure 3(b*i*)**).[57] Such micropaterning techniques can also create stiffness gradients to study durotaxis. PA hydrogels have been made via micropatterning using PDMS microchannels to study durotaxis. As with PA hydrogels, the surface of PDMS gels is easily modified to absorb proteins to facilitate cell attachment.[91] While this system can generate polymer substrates with considerably higher substrate moduli than the other systems discussed, it is not well suited to fabricate gels within a small range of moduli.

5.504.3.2.3. Other systems

A number of other synthetic systems have been used to investigate the role of stiffness on cellular function, each having a unique property not easily produced by the previously covered materials. Semi-interpenetrating polymer networks consisting of poly(*N*-isopropylacrylamide-*co*-acrylic acid) modified with synthetic peptides provide a different stiffness range and are more easily modified by cell adhesion ligand. In this context, they have been used to study the effects of matrix stiffness and ligand density of hESCs.[92] Interpenetrating polymer networks purposefully mix polymers to create domains on one polymer within the other and photolithography can segregate solutions to yield domains,[78] but incomplete free radical polymerization can also result in the formation of soft and stiff polymer domains within a material. For example, the nanodomains that form in bulk poly(vinyl pyrrolidone) hydrogels are due to nanoscale incomplete free radical polymerization,[9] though it is not clear if cells can sense those differences on such a small length scale. Biosynthetic hydrogels, particularly composed of PEG, are now more readily used due to their controlled chemical and mechanical properties, not to mention their lack of cytotoxicity, which enables them to be used to encapsulate cells in a 3D environment.[46] Purely synthetic PEG hydrogels also have the additional functionality of being able to undergo photoactivated degradation, effectively softening the

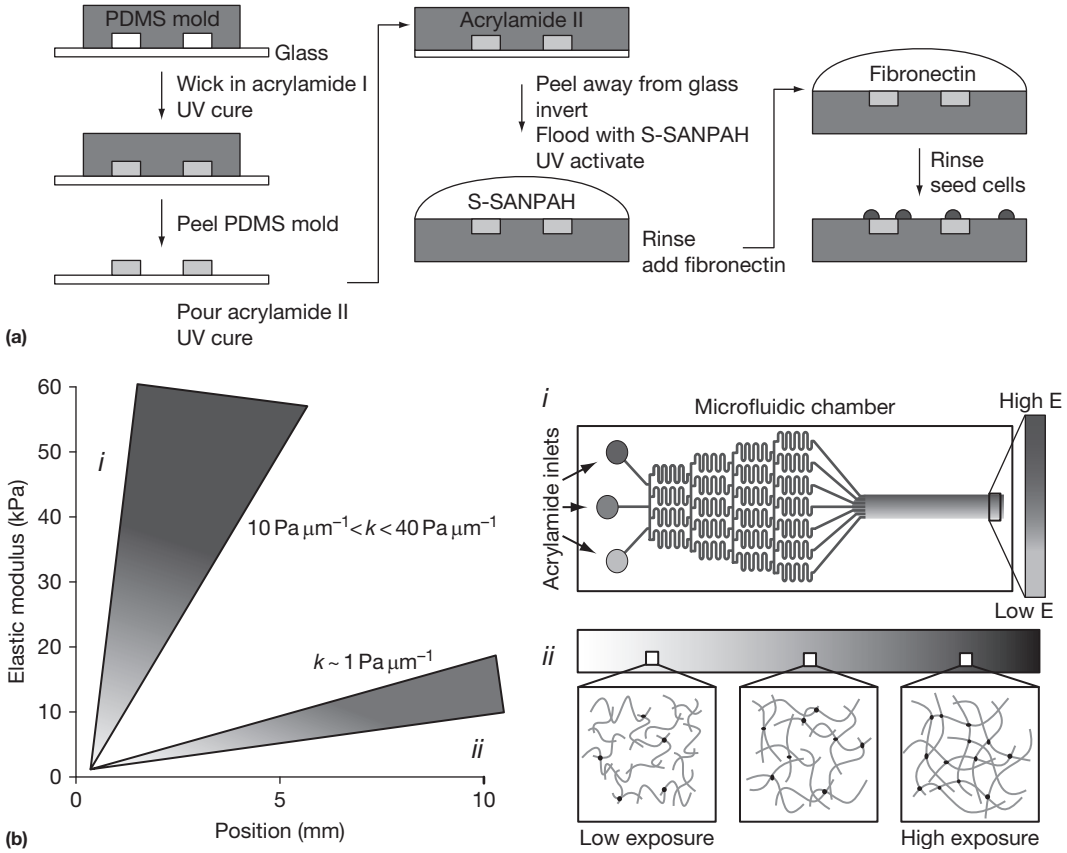

Figure 3 Methods to generate stiffness gradients. Several photolithographic methods have been used in synthetic systems to generate spatial gradients of stiffness, including (a) using sequential polymerization to generate step gradients and (b) photoactivatable methods where gradients are formed either by spatially controlling solution exposure to UV (*i*) or by employing microfluidic mixing to have cross-linker gradients with uniform activation (*ii*). Each of the latter cases can yield moduli of different ranges, which is critical for cell sensing.

hydrogel,[93] and the addition of diacrylate groups provide spatially tunable stiffening[94] as with HA hydrogels.[58] As with the biosynthetic hydrogels, PEG hydrogels can be polymerized into a 3D shape, enabling encapsulation. However, none of the systems highlighted above are without limitations. While some hydrogels provide better physical characteristics than others, careful consideration of each system and the specifics of the study should drive the choice of material.

5.504.4. Cell Functions and Differentiation

Though we have limited our discussion thus far to how matrix stiffness varies throughout the body (**Figure 4(a)**) and how one can generate environments of varying mechanical properties, treatment of the subject would be incomplete without discussing the impact of stiffness on various cell functions, for example, migration,[10] adhesion,[23] morphology,[75] differentiation,[32] and its interplay with ECM composition.[85,95] While the molecular mechanism(s) behind how substrate compliance drives cellular function are still debated, it should become apparent that the functions previously mentioned are optimal in environments that most closely match the *in vivo* environment and suggest that potential sensing mechanisms must be tuned to such an optimum. While we provide a description of several cell types and a table with addition cell types (**Table 1**), it is by no means an exhaustive list, and other reviews on this area should also be consulted for cell types not covered.[7,17,101–104]

5.504.4.1. Neutrophils

Neutrophils are short-lived phagocytic cells that circulate in the bloodstream before becoming active and migrating through the vascular endothelium and surrounding matrix to the site of infection. Given that neutrophils must move through tissues of varying stiffness, they have a variety of atypical behaviors not present in cells that are adherent throughout their lives. Upon activation, neutrophils adhere to substrates and spread, even on soft hydrogels.[23] Though the degree of spreading is uncertain, investigations all have reported that as with normally adherent cells, neutrophils noticeably spread more on stiffer substrates[105,106] and may even display optimal spreading.[106] Given the highly migratory state of these cells, cell migration is also a critical metric to follow. On soft substrates, neutrophils cannot generate sufficient traction forces, which hinders their ability to migrate while on stiff substrates, strong adhesion to the hydrogel prevents detachment and hence

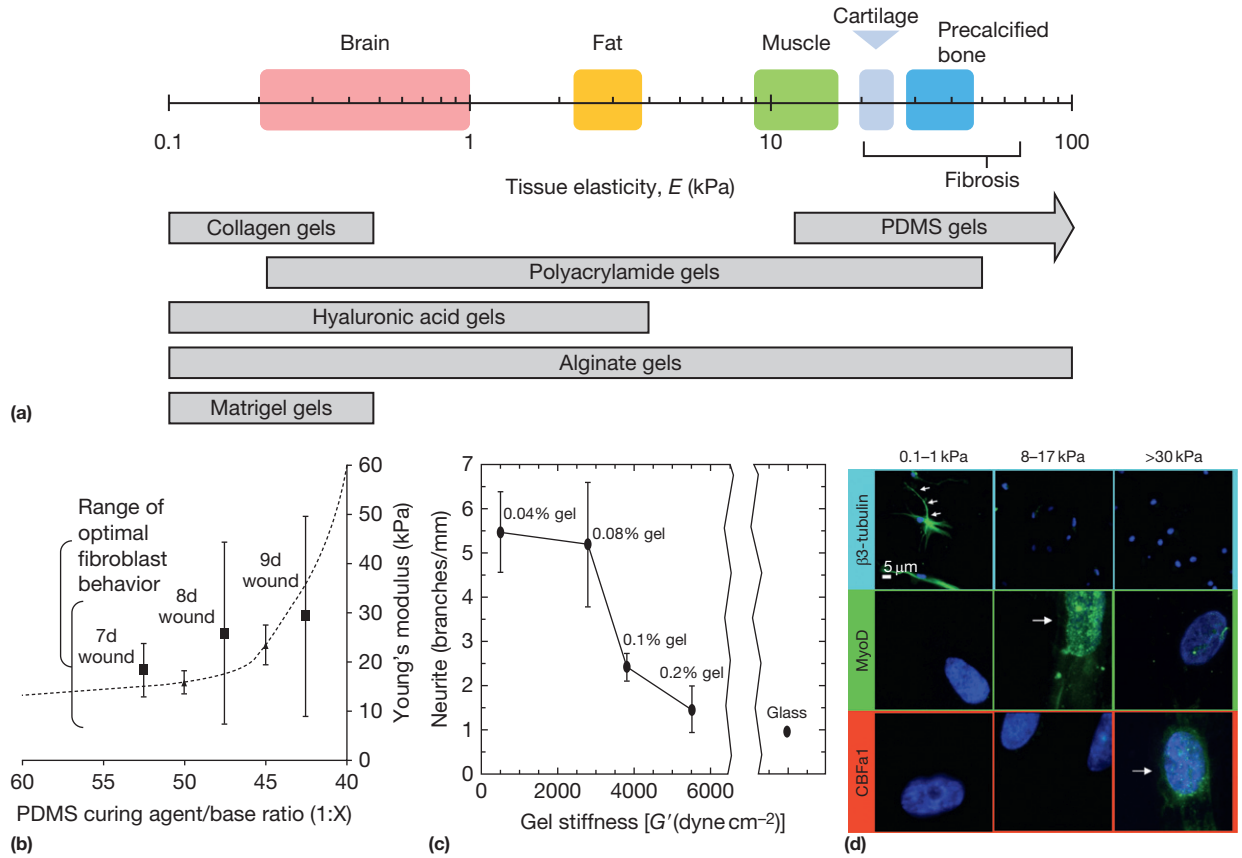

Figure 4 Natural variation in tissue elasticity and resulting cell behavior. (a) Schematic depicting the normal variation in elasticity of the indicated tissues and the hydrogel systems that span these ranges. (b) Stiffness of the wound environment of a fibroblast. (c) Neural cell behavior is optimal on matrices that have a stiffness that mimics brain. Reproduced from Flanagan, L. A.; Ju, Y. E.; Marg, B.; Osterfield, M.; Janmey, P. A. *Neuroreport* **2002**, *13*, 2411–2415. (d) Mesenchymal stem cell differentiation is specific to the stiffness of the original tissue. Engler, A. J.; Sen, S.; Sweeney, H. L; Discher, D. E. *Cell* **2006**, *126*, 677–689.

movement. Neutrophils thus exhibit a biphasic motility profile, with peak velocities occurring on 4–7 kPa hydrogels, depending on fibronectin coating density.[106] The shift in optimal stiffness may be explained by the ligand coating modulating adhesion strength, a trend also observed with smooth muscle cell (SMC) spreading.[8] Since traction stress scales with hydrogel stiffness,[105] it would appear that as with cardiomyocytes[107] there is an optimal amount of work done by adhesions to propel the neutrophil forward.[106] Though there is an optimal speed, the persistence time of migrating neutrophils is higher on substrates with increasing stiffness.[106] Thus regardless of net migration distance, the mean square displacement (MSD) of neutrophils is similar on substrates of varying moduli.[105] Given that these observations have been performed on static hydrogels and most tissue naturally varies within itself,[7,102] gradient hydrogels provide an interesting system to resolve these components in the future.

5.504.4.2. Fibroblasts

Fibroblasts play an important role in wound healing, synthesis, and deposition of ECM proteins such as collagen and fibronectin at the site of injury. To do so, they migrate through connective tissue to the site of injury in a mesenchymal mode by spreading and assembling highly adhesive focal interactions with the ECM[108]; fibroblasts durotax toward stiffer matrix[10] and assemble focal adhesions in a highly stiffness-dependent process that regulates the tension generated within these maturing adhesions.[109] While fibroblasts can form actin microfilaments on substrates as soft as ~3–4 kPa[23] and remain spindle-shaped,[75] they cannot maintain those behaviors on even softer hydrogels.[110] Fibroblasts exhibit drastically reduced proliferation on soft hydrogels, and the cell itself is less stiff, presumably from its inability to assemble a cytoskeleton.[110] What results is optimal behavior on substrates that most closely mimic the *in vivo* wound environment (**Figure 4(b)**),[109] where fibroblasts exhibit stronger traction forces than on softer hydrogels[111] and show an increase in fibroblast tyrosine phosphorylation.[75] These cells may therefore sense matrix rigidity through Src family kinases to activate downstream signaling effects[112] such as controlling the retrograde flux of actin filaments at focal adhesions in the lamella region.[113] As with other cell types, fibroblast traction forces are inversely correlated with cell migration speed[75,110] to the point where, on much stiffer >500 kPa substrates, migration favors not the typical protrusive model

Table 1 Studies on the effects of substrate compliance on cell behavior

Cell type	*Substrate*	*Modulus*	*Findings*
Vascular SMCs	Polyacrylamide/type I collagen	15, 28 kPa and ~1 Pa μm^{-1} gradient	Faster motility on intermediately stiff gels, preferential cell accumulation on stiff portion of gradient (durotaxis)[80]
		1–80 kPa, 10–40 Pa μm^{-1}	Cellular durotaxis increases on steeper stiffness gradients irrespective of absolute values of substrate elasticity[81]
SMCs	Poly(L-lysine) and hyaluronan with 20–60 layers	40–300 kPa	SMC spreading generally increases with increasing elastic modulus[96]
Aortic SMCs	Polyacrylamide/type I collagen, $(PLL/HA)_{20}$[96]/type I collagen	1–35 kPa (PA), 85 kPa $(PLL/HA)_{20}$	SMC spreading increases with increasing elastic modulus according to a hyperbolic fit, biphasic dependence of spreading on collagen density[18]
Bovine chondrocytes	RGD-functionalized alginate	12–127 kPa	Adhesion scales with matrix stiffness, rounded morphology on soft substrates compared to flat with stress fibers on stiffer gels[63]
	Poly(ethylene glycol) dimethacrylate	34–1370 kPa	Type II collagen synthesis in observed intermediate stiffness gels (360 kPa) and glycosaminoglycans diffuse through gels with large equilibrium swelling ratios[97]
MC3T3-E1 osteoblasts	Polyacrylamide/type I collagen	11–40 kPa	Maximum cells speeds on gels of intermediate stiffness, higher proliferation rates, and actin stress fiber formation on stiff substrates[84]
Bovine aortic endothelial cells	Polyacrylamide/RGD	0.5–33 kPa	Mean squared displacement (MSD) increases with gel stiffness for single cells, smaller increase for cell pairs. Cell pairs remain in contact on 5.5 kPa and dissociate on stiffer substrates[98]
Mouse aortic endothelial cells	Collagen/PA/glass 'sandwich gel'	0.45, 14 kPa	Spindle morphology with more pseudopodial branches on soft gels than on stiff substrates[99]
Human umbilical vein endothelial cells	Matrigel, copolymerization with collagen, polyacrylamide	–	Tube-like structures formed on soft substrata[69]
Human blood outgrowth endothelial cells, human umbilical vein endothelial cells	Type I collagen gels	6–10 kPa	Compliant substrates support capillary morphogenesis, but this effect is cell-type dependent within specific endothelial cell populations based on force generation capabilities[100]
MDCK epithelial cells	PDMS micropillars	1–100 kPa	Higher forces generated on stiffer gels, constant substrate deformation[90]

but rather a form of ameboid migration.[89] However, such measurements were made using PDMS, which also showed markedly less spreading on stiffer substrates[89] than did PA hydrogels,[10] further emphasizing the importance of material and ligand choice.

5.504.4.3. Neural Cells

Neural cells, including glia, sensory neurons, dorsal root ganglia, motor neurons, and interneurons, make up a large portion of the human nervous system. Neurons are known for sending out cell projections, or neurites, to form networks of processes that extend large distances to innervate muscles.[114] In light of the soft nature of brain tissue, that is, $\ll$1 kPa,[2,115,116] neurons had a significant threefold decrease in branch number, suggesting that neuronal morphology is acutely sensitive to substrate mechanical properties (**Figure 4(c)**).[117] Similar results were obtained with chick dorsal root ganglia cultured in 3D agarose hydrogels where the elongation rate of neurites was found to be decreased on hydrogels with increasing stiffness.[118] Astrocyte and glial cell behavior was also found to depend on substrate mechanics, but in a way that opposes the behavior of neurons: astrocytes on soft PA hydrogels display small, round morphologies that lack stress fibers in comparison with highly spread morphologies on harder hydrogels. While neurons grow well in mixed cultures on laminin-coated soft hydrogels, astrocytes do not proliferate and exhibit reduced adhesion.[115] Even glial cells failed to proliferate and did not survive on soft, deformable substrates.[117] In contrast, astrocytes and glial cells overgrow postmitotic neurons on stiffer hydrogels.[115,117] These findings suggest that various neuronal cell types respond differentially to matrix stiffness: neurons prefer to live in soft matrices of 0.1–1 kPa while astrocytes and glial cells, such as fibroblasts, appear to prefer stiffer matrices to spread and proliferate.

5.504.4.4. Myoblasts

Skeletal muscle formation involves the activation, proliferation, and differentiation of myoblasts into myocytes and subsequent fusion to form multinucleated myofibers.[119] While skeletal myoblast proliferation and differentiation have been shown to depend on surface ligand density,[120] matrix mechanical properties play an important role in the higher order functions of

muscle, for example, striation and contraction. For example, C2C12 skeletal myoblasts will fuse into myotubes after 48 h in culture, regardless of substrate stiffness, but myosin striations were maximal on hydrogels that exhibited muscle-like stiffness, for example, ~10 kPa.[121,122] Multinucleated myotubes on soft (<5 kPa) and stiff (>23 kPa) hydrogels showed little to no striations after 4 weeks of culture.[122] Similar reports have indicated that myoblast lines could spread and proliferate but not form myotubes on <1 kPa hydrogels,[62] and though subtle differences in behavior exist, they may be the result of different ligand type: fibronectin versus type I collagen. This again hints at the coupling of matrix chemistry and mechanics. Myoblasts seeded atop a layer of confluent myoblasts of the appropriate stiffness also differentiated into myotubes, forming myosin striations after 4 weeks in culture, but when plated on top of cells with suboptimal stiffness, striation was not apparent.[122] Together, these data support the claim that hydrogels that mimic the stiffness of native tissue are optimum for myotube differentiation. Freshly isolated primary myoblasts also exhibit a stiffness-dependent behavior, forming myotubes on 45 kPa hydrogels.[62] Given that these cells were allowed to form syncytially whereas normal muscle is aligned, studies using micropatterned collagen, where fusion and striation are tightly controlled by muscle-like stiffness, are perhaps more mimetic.[122] This implies that both mechanical and geometrical cues from the matrix are involved in myoblast function.

In addition to skeletal myocytes, cardiomyocytes have been studied significantly in terms of their stiffness sensitivity. Embryonic quail cardiomyocytes produce optimal work on their substrates and maintain rhythmic contraction[107] at matrix stiffness that mimics normal myocardium.[5] Neonatal rat ventricular myocytes were also found to generate the largest forces and beat most effectively as measured by large calcium transients present on muscle-like ~10 kPa PA substrates.[123] Rhythmic contraction of these cells seeded on a 3D PEG-containing fibrinogen matrix showed a dependence on substrate elasticity, but for hydrogels that were only 25–150 Pa. Increasing fibrinogen concentration, and thus Young's modulus, drastically reduced contractile activity,[124] but since ligand type and concentration significantly affects myoblast function,[120] this difference in behavior may be attributed to the large difference in ligand presentation in addition to the differences in dimensionality.

5.504.4.5. Stem Cells

Stem cells are a broad class of progenitor-type cells that have the ability to undergo self-renewal and can differentiate into many mature lineages when sufficiently stimulated to do so.[125] Adult bone-marrow-derived mesenchymal stem cells (MSCs) and embryonic stem cells (ESCs) are two commonly studied stem cell types whose differentiation is typically controlled by soluble factors. Having not yet committed to a lineage, stem cells have the ultimate ability to respond to local matrix cues such as stiffness.[126] True progenitor cells, those that are not fully committed to a lineage but that are not stem cells, also express some ability to mature in response to stiffness. For the latter case, MC3T3-E1 preosteoblast cells have increased growth rates on hydrogels of increasing stiffness, with moduli ranging from 20 to 110 kPa, but exhibit optimal differentiation on substrates mimicking osteoid stiffness.[32,127] This observation has been noted in other bone precursors[128] and in murine MSCs (D1). Similar behavior has been observed when cells are co-induced into an osteogenic lineage by growth factors.[129] MSCs plated on 34 kPa type I collagen- and fibronectin-coated PA hydrogels differentiated optimally down the osteogenic lineage as evident by the expression of a number of osteogenic markers (**Figure 4(d)**, bottom).[32,95]

MSCs have also been differentiated down myo-, neuro-, and adipogenic lineages by tuning substrate compliance. For instance, MSCs encapsulated in RGD-presenting alginate hydrogels differentiated down the adipogenic lineage best in 2.5–5 kPa hydrogels,[45] in agreement with the mechanical properties of adipose tissue *in vivo*.[130] On softer 0.1–1 kPa type I collagen-coated hydrogels that mimic the mechanical properties of brain tissue,[2,116] MSC morphologically resembles branched neuron-like structures, expressing neuron-specific markers such as nestin, β_3 tubulin, and neurofilament light chain, among others.[32] Similar neural induction has been obtained with rat adult neural stem cells, where cells preferentially differentiate into neurons on soft hydrogels (100–500 Pa) and into glial cells on hydrogels of intermediate stiffness (1–10 kPa).[131] When plated on hydrogels of intermediate stiffness, MSCs expressed myoD and desmin, indicating myogenic commitment.[32] It is interesting to note that MSC myogenic differentiation was maximal on type I collagen-coated PA hydrogels, where the stiffness was strikingly similar to the optimum stiffness for myoblast fusion and striation formation (**Section 5.504.4.4**), indicating that early and late differentiation toward mature myofibrils occurs on matrices with nearly identical mechanical properties as those reported for muscle tissue.[32,122] It is also important to note that all of these expression data are dependent on the ligand used for cell attachment; type I collagen and fibronectin permit stiffness-dependent differentiation but type IV collagen and laminin are not supportive, indicating again that the coupling of matrix-related cues many be more subtle than previously appreciated.[95]

In contrast to MSCs, little work has been done to determine to what extent ESC differentiation is stiffness dependent. Osteogenic differentiation of ESCs has been reported on PDMS substrates, but only with moduli >1 MPa.[132] While most of these moduli are supraphysiological, these data at least suggest that expression of pluripotency and early differentiation of genes may be modulated by substrate mechanics and certainly warrant further exploration.

5.504.4.6. Cancer Cells

The hallmarks of cancer include limitless replicative potential, sustained angiogenesis, loss of contact inhibition, and the ability to form new tumor foci in foreign tissues.[133] Cancer progression has previously been linked to differential integrin expression,[134] which in turn has been implicated in the maintenance of both the normal and transformed phenotype of mammary epithelial cells.[135] One factor that more recently has been proposed to contribute to the transformed phenotype is modification of the mechanical properties of the extracellular milieu, which can change how a cell 'feels' and reacts to this changing environment. Indeed, ECM stiffening has been implicated as a plausible prerequisite for carcinogenesis due

both to the onset of fibrosis[136] and the more tactile sensation one gets by feeling the stiff lump associated with a tumor mass, most notably in breast cancer.[71] Numerous examples now have immerged in the literature; neuroblastomas cultured on hydrogels >1 kPa grew longer neurites than on soft hydrogels,[137] in marked contrast to the previous section on neurons (**Section 5.504.4.3**). However, these cells still retain compliance sensitivity despite their transformed state[115] unlike other soft tumors,[71] illustrating the complexity of cancer.

In an effort to understand why cancers would prefer a stiffer environment, breast mammary epithelial cancers have been linked to increased tension and compressive forces as a result of ECM stiffening, implicating both mechanotransduction and tensional homeostasis as regulators of cancer development.[138] Accordingly, ECM stiffening disrupts mammary epithelial organization and acini formation in 3D Matrigel–PA hydrogels, forming gradients of stiffness in the affected stroma surrounding the tumor.[71] Since cancer cell motility is stiffness-sensitive[139] but often erratic,[111] cells may possibly see these gradients as durotactic cues for directed migration to new tumor sites. Again, migration is perhaps even more complex than these data may indicate as ligand density couples with this modulation; DU-145 human prostate carcinoma cells migrate fastest in 3D Matrigel gels with storage moduli $G' \sim 30$ Pa, but in hydrogels with lower concentrations of ligand, maximal migration speeds were observed on softer hydrogels.[68]

Increased cytoskeletal tension and extracellular signal-regulated kinase (ERK) activation due to the less compliant environment also influences cellular proliferation, and is a first step toward a cancerous phenotype. However, a partial normal phenotype can be restored in malignant mammary epithelial cells if the mechanosensing pathways, such as ERK activity and Rho signaling, are disrupted, which links cytoskeleton tension and focal adhesion assembly with mechanosignaling and repression of the malignant phenotype.[71] These studies suggest that there is perhaps an additional angle for cancer therapies: controlling the compliance of the environment or how cancer cells 'feel' their environment may be an avenue to prevent or delay cancer progression or even restore a normal phenotype.

5.504.4.7. Other Cell Types

Substrate compliance modulates behavior – adhesion, proliferation, migration, contraction, and ECM production – of many other cell types such as SMCs, chondrocytes, endothelial cells, and epithelial cells. While these are too numerous to describe in detail, we have summarized the findings of a number of studies involving matrix stiffness and these cell types in **Table 1**, and we refer the reader to the works cited for additional information.

5.504.5. Conclusion

From the discussion here, it is hopefully clear that there are various materials to test stiffness responses in cells, there are various means of measuring stiffness, and that cell types are affected by mechanical signals in different ways, ultimately changing behaviors, including migration, spreading, and differentiation. Thus, it is reasonable to conclude that substrate compliance may play an important role in embryonic development, angiogenesis, homeostasis, cancer, and disease progression. As a final consideration, it should be noted that our discussion was largely limited to 2D tissue culture results, and that while investigations performed in 2D are convenient to study cellular responses, they do not accurately mimic the 3D environment of tissues that surround cells *in vivo*. In fact, important differences exist between 2D and 3D studies; for instance, fibroblasts alignment is perpendicular to strain direction in 3D but parallel in 2D,[140,141] and human MSC morphology in 3D is independent of matrix stiffness unlike in 2D.[45] More striking is the observation that matrix stiffness has little effect on SMC proliferation in 3D, possibly due to the differential assembly of focal adhesions in 3D hydrogels compared to 2D hydrogels of comparable stiffness.[46,142] Taken together, these data in nascent 3D systems[44–46,126] strongly motivate the further refinement of mechanically tunable 3D models with similar flexibility to current 2D systems to gain a better perspective on the effect of substrate compliance on cellular functions. These new material models as well as a greater understanding of the molecular mechanics behind cellular mechanosensing will be instrumental in revolutionizing the current paradigms of cellular mechanobiology.

5.505.1. Introduction

The use of cells in clinical therapies holds great promise for the treatment of a wide array of disorders and diseases. However, the control of the fate of transplanted cells remains a significant challenge, because cellular phenotypes are regulated by various signals from soluble factors (e.g., cytokine and growth factors), extracellular matrices (ECMs), and neighboring cells. It is well known that these signals are transmitted through specific bonds, such as those between cellular receptors and soluble factors, cellular integrins and adhesion ligands of ECMs, and cadherin bonds between adjacent cells.[1,2] Specifically, cells tend to probe and respond to the chemical and mechanical properties of their ECM environments, to which they adhere, using integrin–ligand bonds. For instance, the deposition of stiff fibrotic tissues in wounds causes fibroblasts to differentiate into a myofibroblast phenotype, and growth factor binding sites in the ECM can sequester the chemical cues necessary to promote or inhibit cellular differentiation.

Integrin ligation is a major component in maintaining cellular homeostasis and also stimulating cellular activities in response to external stimuli, including soluble factors and cyclic mechanical forces. The integrin family of cellular receptors are heterodimeric transmembrane glycoproteins that bind to epitopes and modulate cellular adhesion to the ECM. Cellular adhesion through integrin ligation is not only specific, but also requires divalent cations, Ca^{2+} or Mg^{2+}, for the binding process.[3] The type and quantity of integrin–ligand bonds and the forces exerted on these bonds have been shown to direct cellular fate and activity. Recently, numerous studies have demonstrated that several cellular ECM adhesion proteins (e.g., fibronectin, laminin, collagen, etc.) bind with specific cellular integrins (e.g., $\alpha 2\beta 1$, $\alpha 6\beta 1$, $\alpha V\beta 3$, etc.) and regulate cellular activities with densities and spatial organization of the cell adhesion molecules at varied length scales. In addition, these specific integrin–ligand bonds modulate the effects of soluble signals including various cytokine, growth factors, and antibodies, and insoluble signals such as the mechanical rigidity of the matrix and cyclic mechanical forces. Note that these aspects are discussed elsewhere.[4]

Therefore, extensive efforts have been made to develop methods to characterize the engagement of integrins with adhesion ligands and their effects on cell adhesion, signaling activation, and phenotypic activities, both *in vitro* and *in vivo*. These methods are largely categorized into two groups: quantifying the forces associated with integrin–ligand bonds and quantifying the number of these bonds formed between cells and their environment. This chapter therefore summarizes methods developed to quantitatively evaluate (1) cell adhesion forces and (2) the number of integrin–ligand bonds formed on two-dimensional (2D) and within 3D platforms, all of which can be examined with respect to cellular phenotypic properties and cellular fates.

5.505.2. Quantifying Integrin–Ligand Forces

Cells are continually exposed to various mechanical stimuli in their dynamic tissue environments. They exert forces on a matrix to which cells adhere and interpret mechanical forces from their surroundings through focal adhesion complexes (FOCs). FOCs are large macromolecular assemblies at sites of integrin binding through which mechanical forces and regulatory signals are transmitted to the cell, and have been shown to regulate cellular activities and phenotypic properties.[2] For instance, mesenchymal stem cells (MSCs) cultured within a stiff ECM tend to proliferate at higher rates than in softer environments, but were shown to have specific lineage and commit to phenotypes with extreme sensitivity to tissue-level elasticity.[1] To ultimately understand how mechanical forces translate into cellular phenotypic characteristics, it is important to understand the forces associated with integrin–ligand interactions.

There are several methods used to measure the binding forces between cellular integrins and ECM ligands. Some of these methods include atomic force microscopy (AFM), magnetic twisting cytometry (MTC), various forms of traction force microscopy (TFM), and fluorescence resonance energy transfer (FRET), all of which have their own unique advantages for quantifying the binding forces between integrin and ligands. Using these methods, the forces of these individual molecular bonds have been shown to range from 1 to 100 nN, depending on the types of ligands and integrins, cell types, and other external cellular variables.[5]

5.505.2.1. Atomic Force Microscopy

Since its introduction in 1986, AFM has been one of the most widely used biophysical tools used in cell biology. It is a high-resolution scanning probe microscopic technique developed to image various surface morphologies of biological and nonbiological materials on the nano- and microscale. AFM consists of a cantilever with a sharp tip that scans the surface of a specimen, and when the tip comes in contact with a surface, forces between the tip and the sample lead to a deflection of the cantilever. The deflection distances and forces are directly related to an image of the specimen and are measured, respectively. Depending on the specific situation, AFM can be used to measure mechanical contact forces, van der Waals forces, capillary forces, solvent forces, and chemical binding forces. In various biological studies, AFM has been widely used to study individual biomacromolecules, cell nuclei, and subcellular structures. Additionally, it has been used to examine the viscoelastic properties of cells and alterations in stiffness associated with cellular differentiation.[5]

Recently, AFM has emerged as a powerful tool for examining single-molecular conformational and binding properties. The forces associated with integrin ligation have been examined using AFM by measuring the unbinding force between integrins and ligands covalently immobilized on the tip and substrate, respectively (or vice versa). Lehenkari and Hortan used this technique to examine the adhesion forces between extracellular integrins and cell adhesion epitopes.[6] They immobilized various forms of oligopeptides containing the Arg-Gly-Asp (RGD) sequence, a cellular binding epitope, on AFM tips and measured the resulting unbinding forces from osteoclast bone cells. They determined that the specific adhesion force between RGD epitopes and osteoclast integrins ranges from 32 to 97 pN, depending on RGD amino acid sequence, pH, and divalent cation composition. Similarly, Wojcikiewicz *et al.* used the same AFM technique to study leukocyte migration and subsequent binding at injury sites.[7] They examined the inhibitory effects of external chemical cues on integrin binding. More specifically, they examined the role of soluble factors (e.g., phorbol myristate acetate) in mediating the binding affinity of the antigen LFA to the ligand ICAM-1.

AFM is a useful tool to examine the binding forces between ligands and integrins. It allows one to examine the specific ligand–integrin engagement and measure the subsequent cellular adhesion force. However, the cell adhesion forces measured by AFM often depend on the dynamic properties applied to the cells. For example, Merkel *et al.* demonstrated that increasing the rate at which forces were applied to cells alters the magnitude of the cell adhesion force up to 10-fold, which demonstrates the complexities involved with the deformation and relaxation of integrin–ligand bonds.[8] Additionally, AFM measurements are limited to examining integrin–ligand forces for cells adhered to a 2D substrate. Therefore, certain supplemental methods should be employed to fully understand how various soluble and insoluble factors of a 3D microenvironment affect cellular activities.

5.505.2.2. Magnetic Twisting Cytometry

MTC is a technique that examines controlled mechanical stresses applied to specific cell surface receptors using ligand-coated ferromagnetic beads under a magnetic field and was first employed for mechanotransduction studies by Wang *et al.*[9] Similar to AFM, MTC applies forces directly to cells, however, in the form of torque compared to tensile/compressive forces. MTC has been used to characterize multiple aspects of integrin–ligand bonds by applying mechanical stress to cells, for instance, (a) measurements of ligand–receptor adhesion strength, (b) mechanical linkages between a cell surface receptor and the cytoskeleton, (c) rheological properties of the cytoskeleton, and (d) intracellular biochemical changes.[5,10] Specifically, cells are incubated with ferromagnetic or superparamagnetic beads coated with ECM or cell adhesion proteins, typically with ~20 beads per cell. Upon the application of a magnetic field, the beads orientate according to their dipoles, which ultimately applies a torque to the cell surface (**Figure 1**). The shear stiffness of the specific binding is calculated by measuring the bead rotation and angular bead strain using a magnetometer.

Using this method, Wang *et al.* demonstrated a limited rotation of RGD-bound beads in comparison to beads coated with metabolic receptor antibodies.[9] This result addressed that ECM-bound integrins engage with the cellular cytoskeleton through FOC, subsequently demonstrating a mechanically coupled cytoskeleton–ECM interaction. They also demonstrated that specific integrin receptors, such as β1, αV, and α2, transfer forces across the cellular surface to the cytoskeleton, while other transmembrane proteins, such as scavenger receptors and endothelial cell adhesion molecules, do not.[11,12] This method can also be used to examine the rheological properties

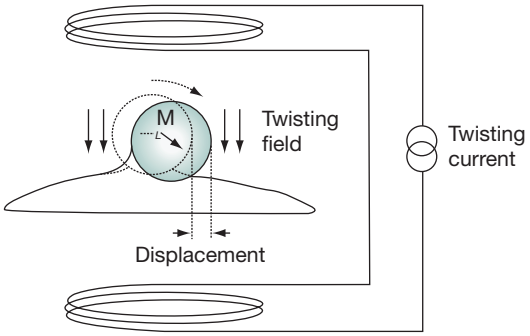

Figure 1 Magnet twisting cytometry (MTC). In MTC, a homogenous magnetic twisting field applied to cell surface-adhered beads causes the bead to rotate and to displace, thereby inducing shear stresses on the cell. Reproduced from Sen, S.; Kumar, S. *J. Biomech.* **2010**, *43*(1), 45–54.

of the cell membrane and cytoskeleton. For instance, using the β1 receptor–RGD complex, Wang and Ingber determined that cellular cytoskeleton stiffness was directly proportional to the level of stress applied to the cells and that the slope of the linear stiffening response differs depending on the shape of the cell.[12]

Additionally, MTC has been modified with an oscillating magnetic field to examine cellular responses under dynamic mechanical forces. For instance, Chen *et al.* examined endothelial cell expression of the endothelin-1 (ET-1) gene, which transcribes vascoconstricting peptides, using MTC with magnetic fields having varied amplitudes, durations, and frequencies.[13] Oscillating the magnetic field at controlled frequencies caused magnetic bead, oscillatory rotation, and resulted in a twofold increase of ET-1 expression compared to nonoscillatory conditions. Using this modified technique, mechanotransduction studies can be carried out to examine cellular responses to mechanically dynamic environments.

MTC is a useful technique that allows the examination of cellular activities and/or phenotypic changes in response to a controlled torque applied dynamically or statically to the cellular integrin–ligand adhesions. It also allows the rheological examination of cytoskeletons coupled with various environmental conditions. Although MTC is a useful tool for mechanotransduction studies, it is difficult to apply this technique in 3D environments, which are representative of native cellular environments. Also, these studies cannot account for potential alterations in cellular activities induced from the magnetic fields applied for MTC.

5.505.2.3. Traction Force Microscopy

Unlike AFM and MTC, where forces are applied directly to cells, TFM measures forces exerted by cells on their environments. During the early 1980s, cells were shown to visibly wrinkle silicon substrates as they migrated, demonstrating that they exert forces on their adhesion substrates.[14] This prompted the development of TFM, which quantitatively measures cellular traction forces exerted on a substrate to which cells adhere. TFM consists of embedding fluorescent beads in materials, such as silicon rubber, and observing the displacement of the beads due to the contractile activity of cells cultured on or in the material. The displacement of the fluorescent beads can be directly related to the force exerted by the cells, termed cell traction force, according to the mechanical properties of the substrate.[5]

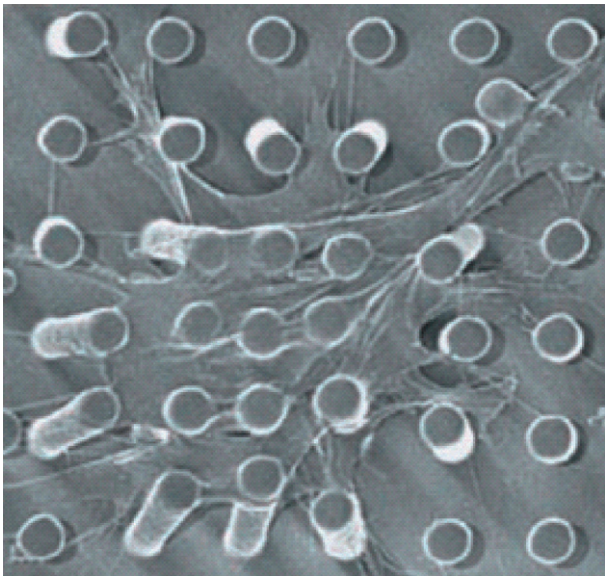

Figure 2 Smooth muscle cells cultured on arrays of posts coated with fibronectin applying traction forces, causing posts to bend. Reproduced from Tan, J. L.; Tien, J.; Pirone, D. M.; Gray, D. S.; Bhadriraju, K.; Chen, C. S. *Proc. Natl. Acad. Sci. USA* **2003**, *100*(4), 1484–1489.

Pelham *et al.* were some of the first to use this technique with polyacrylamide gel substrates, which are linearly elastic, optically transparent, and amenable to protein conjugations, allowing a simple platform for studying cell-generated forces.[15] The most widely used method for adding cell-binding ligands to a substrate for TFM is through the adsorption of natural ECM proteins. Even though this results in a random distribution of binding domains on substrate surfaces, it has been shown that cells tend to bind in 'island' patterns with nonuniform distributions due to the adsorption properties of the substrate (which is also extremely variant on substrate type and processing).[16]

With advances in polymer process technologies, TFM has been employed using a variety of different substrates, cell types, and ECM proteins. The stress–strain relationships have been further transformed into Fourier transform for improved analysis. Additionally, several micropatterning techniques have been used to examine cellular traction forces at FOC, independent of one another.[17] Tan *et al.* developed a new TFM technique to examine the forces cells apply to their adhesion substrates.[18] Using soft lithographic techniques, they developed a platform of microarray posts with varying geometries which can be displaced by cells cultured on top of them (**Figure 2**). This method allows the examination of contractile forces independent of neighboring forces, thus directly eliciting their subcellular distributions. They demonstrated that the magnitude of the tractile forces was modulated by the size of the posts, indicating a relationship between the subcellular force and the number of integrin–ligand adhesions.

As the uses of confocal and two-photon (2P) microscopic techniques have become increasingly popular, TFM has been

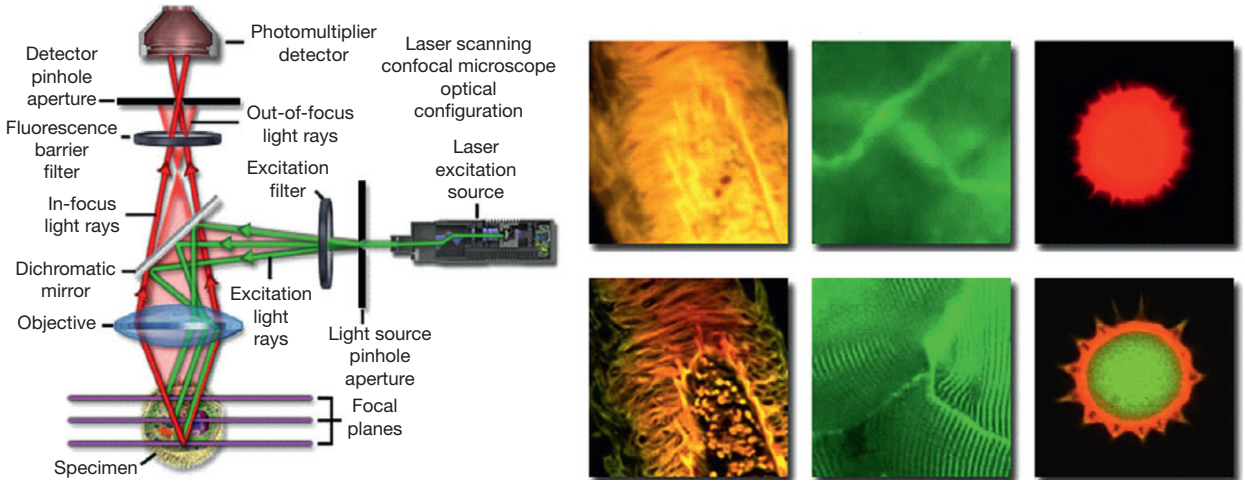

Figure 3 A diagram of confocal microscope that demonstrates the blocking of out-of-focus light (left). A comparison of images using normal fluorescence microscopy (right, top row) to the higher resolution of confocal microscopy (right, bottom row). Reproduced with permission from Fellers, T. J. and Davidson, M. W. – National High Magnetic Field Laboratory, The Florida State University, Tallahassee, Florida, USA.

adapted to examine cellular activities in 3D environments. Compared to normal fluorescence microscopy, confocal microscopy blocks background fluorescence, allowing a clear image of the excitation in a single focal plane; by stacking these plains in the *z*-axis, a 3D image is created (Figure 3). With these 3D images, the displacement of fluorescence beads encapsulated with cells in a biomaterial system can be monitored and related to cellular forces. These biomaterial systems can also be engineered to have specific types and concentrations of cellular binding domains (ligands) and other properties, which can be related to contractile forces and other cellular activities. Additionally, comparisons between 2D and 3D cellular environments can be made to develop a better understanding of cell–matrix interactions. Fraley *et al.* used TFM to examine the mechanism for cellular migration in 3D versus 2D environments, by embedding cells and marker beads in collagen matrices (3D environment) and adhering cells to collagen substrates with embedded marker beads (2D environment) (Figure 4).[19] They demonstrated distinct differences in migration mechanisms between 2D and 3D environments, in particular that focal adhesion proteins including vinculin, paxillin, and talin modulate migration speed in 3D, but had no distinct role in controlling 2D migration.

Various TFM techniques, including microarray TFM (MATFM), have also been combined with additional fluorescence techniques to examine the relationship between the forces exerted by cells and the formation of FOC. Balaban *et al.* used cells expressing green fluorescence protein (GFP)-tagged vinculin with MATFM to demonstrate that local forces exerted by cells are correlated to the orientation and fluorescence intensity and area.[17] By using additional fluorescence techniques, relationships between tactile forces and cellular activities, such as protein–protein interactions, can be developed.

Overall, TFM is a powerful technique for developing relationships between the forces exerted by cells on their adhesion matrices and cellular behavior and/or phenotypic activities. Advances in matrix design and microscopic imaging have allowed TFM measurements of cellular forces in both 2D and 3D microenvironments.

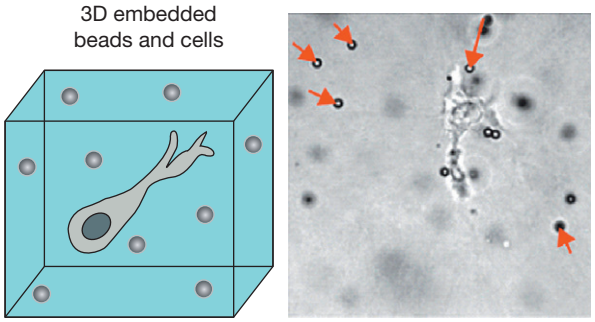

Figure 4 Schematic of cells embedded in three-dimensional environment with fiduciary beads that are monitored for traction force measurements (left). Cell Biol.* **2010**, *12*(6), 598–604.

5.505.2.4. Fluorescence Resonance Energy Transfer

FRET, which is a form of nonradiative energy transfer between two fluorescence molecules, has been extensively used to examine protein–protein interactions. When a donor fluorescence probe is in proximity (10 nM or less) to an acceptor fluorescence probe, energy is transferred through nonradiative dipole–dipole coupling, causing an excitation of the acceptor probe, which is then measured. FRET has two distinct advantages over typical immunofluoresence techniques. First, the distance required for energy transfer is so short that it allows the probing of molecular interactions, and second, the observable excitation range of the acceptor is very narrow and thus easily observed.[10] Since the distance required for energy transfer between fluorescence probes is so small, high-resolution images are produced to allow examination of molecular interactions on the nanoscale.

FRET is a useful technique that has been used to relate cellular activities and/or phenotypic characteristics with cellular traction forces. Kong *et al.* developed a method using FRET to quantify the forces exerted by preosteoblasts adhered on

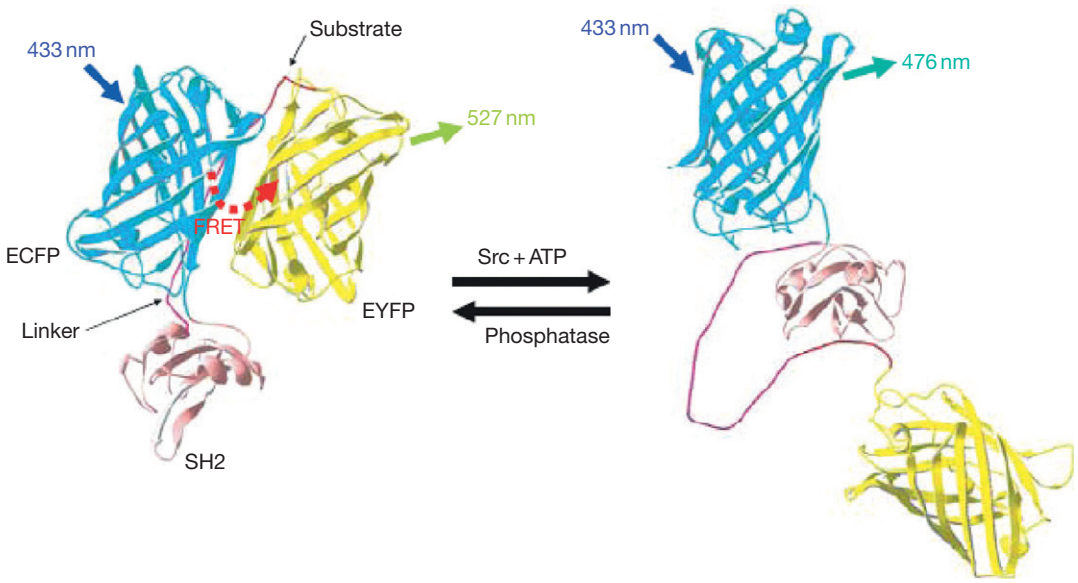

Figure 5 A schematic of an Src homo-FRET probe illustrating the effect of the Src reporter upon the activation of Src kinase or phosphatase. Reproduced from Wang, Y. X.; Botvinick, E. L.; Zhao, Y. H.; *et al*. *Nature* **2005**, *434*(7036), 1040–1045.

alginate gels through bonds between cellular integrins and RGD peptides linked to the gel.[20] They covalently attached two different fluorescence probes (a donor and an acceptor) to RGD peptides that were covalently attached to alginate polymers. As the cells exerted forces on gels through integrin–RGD binding, the emission of donor probes was decreased in the presence of the acceptor probe, and the quantified FRET efficiency was converted to the force exerted by cells. Recently, this FRET technique was extended to measure traction forces of cells encapsulated within hydrogel matrices. Huebsch *et al.* determined that specific elastic moduli of alginate hydrogels correlated to a maximal traction reorganization of integrin–ligand bonds for cells encapsulated within the gels.[3]

FRET can also be used in mechanotransduction studies to measure the dynamics of protein–protein interactions. Recently, FRET was used as a sensor to examine the phosphorylation of Src, a tyrosine-kinase, in endothelial cells subjected to external forces. In the study, a synthetic protein containing two fluorescent protein regions, a donor and an acceptor (CFP and YFP), were used to undergo homo-FRET.[21] More specifically, the conformational change, resulting from the phosphorylation of Src, causes proximity between the donor and acceptor probes, leading to fluorescence excitation (Figure 5). This real-time analysis allows measurements of cellular activity on the molecular level resulting from changes in a cell's mechanical environment.

5.505.3. Quantifying Type and Number of Integrin–Ligand Binding

There are numerous types of binding domains in natural ECM proteins, to which cells adhere. The role of the type of integrin–ligand bond in modulating cellular phenotypes is regulated by the density and spatial organization of cell adhesion ligands at nanometer and micrometer scales. Since these matrix variables affect the number of integrin–ligand bonds, various methods were developed to quantify the number of bonds. These methods include immunochemical techniques, genetic labeling, and FRET.

5.505.3.1. Immunochemical Techniques

Immunochemical techniques involve the use of antibodies that have a high affinity for specific peptides. These antibodies can be labeled with a variety of detectable probes, including fluorescence molecules, also known as immunofluorescence (IF), and bind to epitopes specific for particular integrins and ligands. Using IF techniques, the number and distribution of integrin–ligand bonds can easily be quantified by examining the excitation intensity and distribution of the labeled antibodies, respectively.[22] For instance, fluorescently labeled antibodies specific for the β_1 integrin–RGD ligand complex will bind to this specific cellular adhesion, and its subsequent excitation intensity and distribution will elicit the number and distribution of focal adhesions for a specific environment (Figure 6). Additionally, IF can be used to examine conformation and topography of adsorbed molecules and the bioavailability of antibody-binding epitopes.

IF is extensively used to characterize both the behavior of focal adhesion molecules (integrins) and downstream signaling (gene expression). It is a useful tool to examine emergent cellular behavior, but is limited to dynamic examination of cell–ECM interaction without noninvasive imaging techniques, including second-harmonic generation imaging and optical coherence tomography. An additional limitation to this method is the potential perturbations associated with the binding of fluorescent probes to FOC.[10] More specifically, the binding of antibodies with labeled probes can cause slight conformation changes to adhesion complexes, dissipating or attenuating their real physiological effects.

Additional methods used to examine the number and specificity of cell–ECM adhesions are immunoblotting

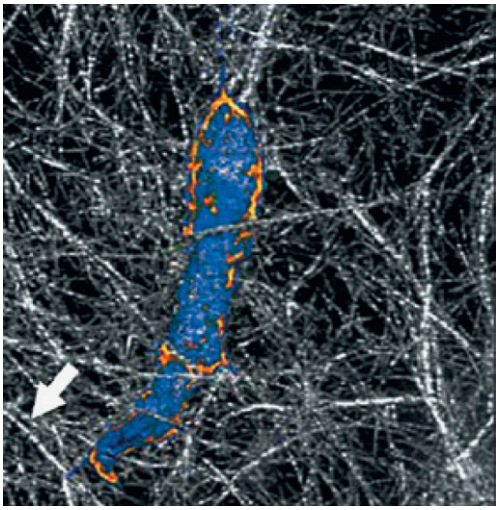

Figure 6 Image of a fibrosarcoma cell migrating within a three-dimensional collagen lattice, stained with nonblocking anti-β1 integrin antibody K20. Reproduced from Friedl, P. *Histochem. Cell Biol.* **2004**, *122*(3), 183–190.

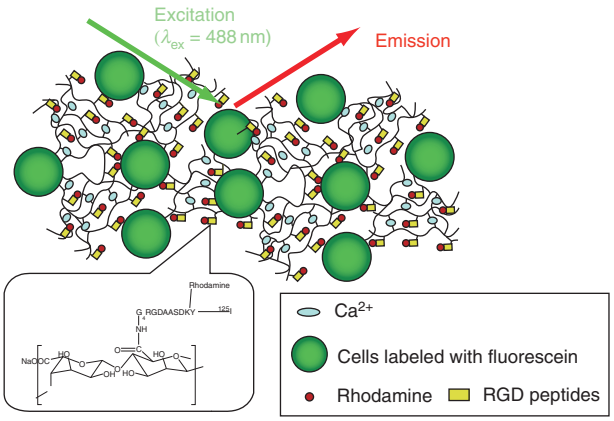

Figure 7 Schematic of the fluorescent cells that were mixed with various numbers of rhodamine–RGD–polymer molecules and the subsequent FRET emission. Gels were formed by cross-linking polymer chains with Ca^{2+} ions. Reproduced from Kong, H. J.; Boontheekul, T.; Mooney, D. J. *Proc. Natl. Acad. Sci. USA* **2006**, *103*(49), 18534–18539.

and enzyme-linked-immunosorbent serologic assays (ELISAs). Immunoblotting, more specifically known as Western blots, is a useful tool to examine the presence and quantity of integrins, ligands, or integrin–ligand complexes. This method consists of using gel electrophoresis, typically SDS-PAGE, which separates proteins according to their molecular weights in a polyacrylamide gel. The proteins, including the proteins of interest (integrin–ligands), are transferred from the polyacrylamide gel onto a membrane, normally nitrocellulose, where they are probed by antibodies specific for the desired protein. Western blots can be used to identify the presence of a variety of specific ligands and integrins by probing with a variety of antibodies. Additionally, running a naive gel electrophoresis alone can separate integrins and integrin–ligands due to the conformational change associated with binding, thus quantifying the amounts of bound and unbound integrins. ELISA is a method used to quantify the amount of a specific protein (integrin–ligand) in a solution. An ELISA consists of an antigen affixed to a surface, on which an antibody (integrin–ligand) is applied and binds to the antigen. The antigen is linked to enzymes that convert a specific substance into a detectable signal in accordance with the antigen–antibody binding. Western blots and ELISAs readily quantify the amount of specific integrin–ligands; however, they cannot be used in a dynamic cellular environment – cells have to be lysed to obtain protein solutions containing adhesion complexes.

5.505.3.2. Fluorescence Resonance Energy Transfer

Recently, FRET has been modified for quantifying the number of integrin–ligand bonds. Kong *et al.* labeled RGD peptides linked to hydrogel-forming polymers with acceptor fluorescent probes, and also labeled cells with donor fluorescent probes.[23] The fluorescently labeled cells were encapsulated into hydrogels with controlled quantities of RGD peptides. As cells formed adhesion complexes with the RGD peptides, the donor markers excited the acceptor markers, resulting in a measurable emission (Figure 7). This FRET technique enables the quantification of ligand–integrin bonds according to the degree of FRET, or in other words, the magnitude of the subsequent emissions. The number of adhesion bonds was further related to the proliferation and differentiation of the encapsulated cells and the subsequent relationships were dependent on the specific cell type encapsulated.

Quantifying the number of integrin–ligand bonds through FRET is a useful technique for examining their effects on cellular activities. Fischbach *et al.* examined the relationship between integrin engagement of cancer cells and their angiogenic capacity.[16] More specifically, they quantified the degree of integrin–ligand bonding for cells in 2D and 3D environments using FRET and determined that the cellular secretion of angiogenic factors was modulated by the number of integrin–ligand bonds formed. Huebsch *et al.* also used FRET for examining the effects of ECM mechanical properties on the fate of stem cells. They determined that the ECM stiffness regulated integrin–ligand binding and organization of adhesion ligands, which both correlated with osteogenic differentiation.[3] These examples demonstrate some of the numerous applications of FRET for quantifying integrin ligation in cellular studies.

5.505.4. Conclusion

The use of cells in clinical therapies has great promise for the treatment of a wide array of disorders and diseases; however, the control of the fate of transplanted cells is a significant challenge. Cellular phenotypic characteristics are strongly regulated by cell interactions with their physical and chemical environments. Studies quantifying the forces, type, and extent of ligand–integrin binding are extremely important to develop an understanding of how cell–environmental interactions contribute to cellular phenotypic characteristics. The microscopic and spectroscopic methods reviewed in this chapter, including AFM, MTC, TFM, IF, and FRET, are highly useful for examining the role of integrin–ligand engagement in cellular events at

varied length scales. As the understanding of biomechanical processes advances, new and improved techniques to elicit their functions on cellular activity will be developed. Taken together, characterization methods of integrin–ligand engagement will greatly advance matrix design and controllability of cellular activities, to further enhance the efficacy of cellular clinical treatments for biomedical applications.

5.506.1. Introduction

Mechanical stresses modulate and orchestrate cellular responses from the very beginning through the entire lifespan of an organism. Evidence for the fact that virtually every cell, not just highly specialized cells, such as cells for hearing and touch, is mechanoresponsive is growing. Cells have mechanical sensory capabilities and the ability to convert mechanical signals into a biochemical response. There are a variety of different mechanical signals acting on cells and a multitude of proteins involved in signal transduction, and the responses range from short-term changes in the cytoskeletal arrangement to long-term changes in gene expression. Often, multiple signaling pathways are activated by mechanical forces, and the orchestrated response enables the cell to adapt to changing mechanical conditions, which in turn modulates tissue morphology and remodeling.

One of the first tissues to be recognized as mechanoresponsive is bone. In the nineteenth century, the German anatomist and surgeon Julius Wolff described the relationship between bone architecture and function.[1] He stated that mechanical stress was responsible for the architecture of bone and that bone would adapt to mechanical changes. When loading on a bone increases, the structure of the bone will change to support the new loading and, conversely, when loading decreases, the bone becomes less strong. The decrease in bone density in astronauts during periods of weightlessness and the increase in it with exercise are some examples illustrating bone's adaption to changes in mechanical loading.

A living higher order organism is subject to and generates different type of stresses, through tension, compression, and shear. The mechanical stress is transmitted to the cellular level, and the magnitude and localization of the resulting force depend on both the mechanical environment and the mechanical properties of the cells. Cells can be shielded from stresses, or, in contrast, stress can be focused at specific locations. At these spots, the actual conversion of mechanical to biochemical signals takes place through specialized proteins or protein complexes.

The goal of this chapter is not to exhaustively review the broad literature on cellular mechanotransduction and its role in tissue homeostasis and remodeling but to show general schemes of how cells sense and respond to mechanical stimuli. Given the crucial role of mechanical stimuli for proper cell function, the importance of controlling stresses in tissue engineering constructs is discussed at the end of the chapter.

5.506.2. Mechanical Environment of the Cell

Cells are continuously exposed to different sources of mechanical stimulation, such as strain transmitted from contracting muscles, shear stress and pressure from blood or interstitial fluid flow, and forces generated from contracting neighboring cells. To what extent cells are exposed depends on their specific location in the body. Some cells are more susceptible to one stress than to another depending on their function. It seems that not just specialized cells, such as hair cells involved in hearing, or touch-sensitive neurons sense these stimuli but virtually every cell is competent to sense and respond to mechanical stresses.

Stresses are transmitted from the whole body system to the organs, tissues, and cells through the extracellular matrix (ECM). To what extent stresses are transmitted to the cell level is highly dependent on the pericellular mechanical behavior, the extracellular matrix (ECM), and the relative material properties of the cell itself.

The three basic mechanical stresses acting on cells are tension, compression, and shear (Figure 1). For example, tendon and ligaments sustain large tensile stresses, arteries are stretched and sheared from the pulsatile blood flow, and bones resist compressive and tensile stresses. But the predominant stress is not always the most important stimulus for cells. In bone, the strains induced by physiological compression are very small (on the order of 100 microstrains) and not sufficient to trigger a cellular response. Indeed, the current paradigm is that small strains squeeze interstitial fluid flow through a network of small channels, the canaliculi, much as a sponge does when a load is applied. The moving fluid leads to shear stress, and the magnitudes of shear stress estimated to occur physiologically in these channels have been shown to be potent stimuli for bone cells *in vitro*.[2,3] Additionally, flow through the canalicular network in the absence of strain has been shown to induce bone formation.[4] It is therefore crucial to understand the environment of the cell to know which type of stress is acting on the cell and which temporal patterns and magnitudes of stimulation elicit a cellular response.

Thus, in order to understand cellular mechanotransduction, it is critical to determine how stresses are transmitted from the organism level, down to the tissue and cellular levels by the ECM and pericelluar matrix, or directly from neighboring cells via cell–cell contact. The properties of the ECM differ from tissue to tissue, and a complete description is beyond the scope of this chapter. Furthermore, the micromechanical behavior of the pericellular matrix and its interaction with cellular mechanics is a topic that has received very little attention.

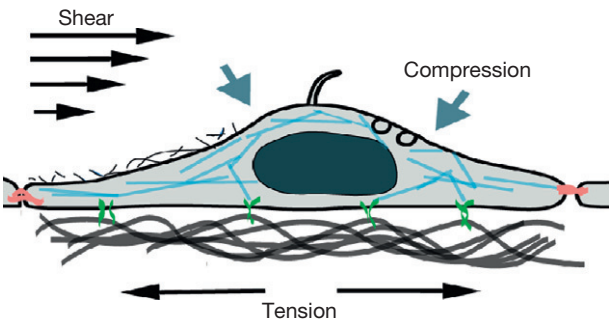

Figure 1 The basic mechanical stresses acting on a cell are shear, compression, and tension.

5.506.2.1. Mechanical Properties of the Cell

Understanding the mechanisms of mechanotransduction requires an understanding of the mechanics of the cell. Biophysical studies have revealed that the cell is far from a homogeneous material. The complex composition and architecture of the cell influence how stresses are transmitted, distributed, and focused. Here, we want to briefly describe the cytoskeleton, the cell membrane, and the glycocalyx in terms of composition and mechanical properties.

5.506.2.1.1. Cytoskeleton

Stresses are not equally distributed throughout the cells due to their complex architecture and the heterogeneous material properties of subcellular components. The shape and spatial organization of a cell are often mainly determined by the cytoskeleton, which is a highly dynamic and cross-linked mesh of microtubules, actin, and intermediate filaments. Microtubules are the most rigid cytoskeletal polymer and can support compressive forces. Actin filaments are less rigid than microtubules, but due to the high concentration of cross-linkers, they can also form stiff structures. The intermediate filaments are the least stiff cytoskeletal polymer and they resist tensile forces more than compressive forces.[5]

The cytoskeleton is linked to the ECM by focal adhesions (FAs) and to neighboring cells via adherens junctions. Both structures represent strategically important locations, and both are involved in mechanotransduction.

The architecture of the cytoskeletal network plays a crucial role in transmitting cellular stresses.[6] The network of cytoskeletal polymers has been described by the tensegrity model, a term invented in architecture for structures for which stability is based on compressive and tensional elements. Prestress is needed for the integrity of such a structure. In the case of a living cell, the prestress arises from the action of nonmuscle myosin that pulls on the actin filaments. These contractile forces are balanced by microtubules, which resist the compression, and by extracellular adhesions to the ECM and other cells.[7] Prestressed fibers allow immediate transmission of forces to distant sites. There is experimental evidence that physiological forces acting on FAs propagate over long distances into the interior of the cell.[8]

A passive property of such a network of polymers is the stiffening in response to shear as a result of filament entanglement and entropic elasticity of individual filaments, which resist further deformation.[9] Stress-induced deformations of the cytoskeleton are coupled to changes in plasma membrane tension and displacement of fluid in the cytoplasm.[5] It is important to recognize that the cytoskeleton is not a static structure but indeed highly dynamic. Actin filaments and microtubules are constantly polymerizing and depolymerizing, and the cytoskeleton can adapt and reorganize in response to external stresses.

5.506.2.1.2. Cell membrane

Cell membranes define the border between the extracellular and intracellular space. In many cells, they are a primary target of fluid shear stresses. Whether fluid shear acts directly on the lipid bilayer or if it is transmitted via the glycocalyx is discussed below. First, the direct effects of fluid shear, such as changes in bilayer tension and curvature, that potentially activate mechanosensitive proteins are considered.

The concept of membrane fluidity is based on the observation that proteins and lipids diffuse relatively freely in the plane of the lipid bilayer, with some restrictions by structural proteins and connections to the ECM or other cells. The rapidity of diffusion depends on membrane fluidity, which, in turn, depends on the bilayer composition. Unsaturated phospholipids or cholesterol decreases the fluidity of the membrane and influences the lateral diffusion rates of membrane molecules. Interestingly, it has been shown that fluid shear stress on the membrane leads to an increase of membrane fluidity.[10] This observed phenomenon can have an effect on diffusion-limited processes,[11] as long as a nonequilibrium condition is dominant. However, as soon as a new equilibrium is reached, the overall dynamics will be the same, even with altered membrane fluidity. One example of such a diffusion-limited process that could potentially be affected by shear stress is G-protein hydrolysis.[12,13] For example, it was shown that G-proteins isolated in lipid vesicles become activated by shear and that this activation is linked to membrane fluidity.[13]

Changes in shape and curvature of the cell membrane have the potential to alter the conformation of membrane proteins. Cell membranes become thinner when stretched, which means that the hydrophobic interior will decrease in width. Therefore, the thinning of the membrane might lead to a hydrophobic mismatch of membrane proteins forcing the protein to adapt a new conformation by compression, tilting or twisting their domains.[14] As a result, the functionality of a protein can be regulated by membrane stretch; the opening of ion channel is just one example. The same idea applies to changes in curvature, in which the three-dimensional (3D) arrangement of proteins can be altered. This effect is particularly important in caveolae that are highly sensitive to changes in membrane tension.

5.506.2.1.3. Glycocalyx

Eukaryotic cell membranes are covered with the glycocalyx – a layer of polysaccharides, which is covalently linked to glycoproteins and glycolipids residing in the membrane and attached to the cytoskeleton via membrane proteins. It is known from theoretical considerations that this porous collection of proteoglycans and glycoproteins has an important effect on fluid flow. The fluid velocity is vanishing small inside the matrix, and as a consequence, the effective shear stress on the cell membrane is highly attenuated.[15] But if shear stress on the membrane is almost absent, how can endothelial cells (ECs) respond to changes in blood flow?

One possibility is that the shear stresses acting on the glycocalyx are transmitted through the matrix to the cell body. An elastohydrodynamic model developed by Weinbaum[16] assumes that the brush-like structures of the glycocalyx have a flexural rigidity that withstands physiological ranges of fluid flow. In this case, the hydrodynamic forces acting on the tip of the core proteins lead to a deflection, which in turn acts as a bending moment on the underlying actin cortical cytoskeleton. Another model considers the glycocalyx to be a multicomponent material of interstitial fluid and a charged proteoglycan/glycoprotein/glycosaminoglycan solid matrix.[17] In this case, hydrodynamic drag will lead to tension in the glycocalyx, and, due to the connection to the cytoskeleton, the tension acts also on the underlying cortical cytoskeleton. In both cases, the glycocalyx serves as a transmitter of mechanical stresses and can explain the fact that cells can respond to changes in fluid flow even if the shear stress on the cell membrane is almost zero.

In vitro and *ex vivo* experiments with ECs showed that the fluid flow specific response is dependent on the intactness of the glycocalyx.[18–20] The shear-stress-induced increase of nitric oxide production in cultured ECs was inhibited when heparan sulfate, a major glycosaminoglycan of the glycocylyx, was dissolved with heparitinase.[19] In isolated canine femoral arteries, a similar effect was observed when hyaluronic acid glycosaminoglycans were degraded with hyaluronidase.[18] In addition, the thickness of the glycocalyx seems to correlate with the shear stress profile,[21] and the amount of hyaluronan increases in human umbilical vein ECs exposed to shear stress.[22] These studies suggest that specific components of the glycocalyx are necessary for the flow-induced increase in nitric oxide in ECs and that the composition and thickness of the glycocalyx can be modulated by fluid flow, which may be a positive feedback mechanism.[23] Interestingly, treatment with chondroitinase, which breaks down chondroitin sulphate, does not affect the characteristic nitric oxide production in response to flow,[24] and another key response of ECs to shear, the production of prostacyclin (PGI_2), is not affected by degradation of the glycocalyx with the above mentioned enzymes.[25] Therefore, no single mechanism can be responsible. Shear stress will also be transmitted to other attachment sites of the cell, such as the basal adhesions, which can lead to glycocalyx-independent activation of shear-stress-dependent signaling responses.[26]

5.506.3. Subcellular Structures Involved in Mechanotransduction

Cells are mechanically coupled to the ECM and neighboring cells through FAs and adherens junctions, respectively. Both structures have been implicated in mechanotransduction and their role is discussed in the following section, together with other mechanosensitive subcellular structures.

5.506.3.1. Interactions with the ECM: FAs

The actin cytoskeleton is mechanically coupled to the ECM via large and dynamic protein complexes called FAs. FAs anchor the cell to the ECM, and they have been shown to be involved in bidirectional signal transduction and mechanotransduction, by interacting with ligands in the ECM and responding to mechanical cues. Integrins, a family of dimeric transmembrane proteins, composed of α and β subunits complex to form the major connection between the actin cytoskeleton and the ECM. The extracellular domain has a high affinity for the RGD sequence, present on many ECM proteins such as fibronectin, collagen, laminin, and vitronectin. Intracellularly, the cytoplasmic

domain interacts with many signaling proteins, such as focal adhesion kinase (FAK), members of the Src family protein kinases, and Fyn and $p130^{CAS}$, and with cytoskeletal proteins, such as vinculin, paxilin, talin, tensin, and α-actinin.[27,28] Many of these FA-associated proteins bind to actin either directly or indirectly, thereby anchoring the cytoskeleton to the ECM.[29] Binding of integrins to ECM proteins results in a conformational change, which leads to a clustering of receptors and activation of kinases, such as FAK and src, and the small GTPase Rho, promoting the assembly of FAs and enhancing adhesion.[30]

Given the strategic position at the interface between the extracellular and the intracellular spaces, it is no surprise that FAs are involved in mechanosensation. Manipulation with magnetic beads coated with antibodies directed against integrins showed that force results in a local rearrangement of cytoskeletal filaments and force-dependent cell stiffening,[31] whereas application of similar forces to integrins via antibodies that do not bind to the RGD sequence does not.[32,33] This integrin-dependent cell stiffening response enables the cell to adapt to and sustain changes in the mechanical environment within seconds to minutes after application of external stresses.[32,34]

Activation of the GTPase Rho and its downstream effectors, Rho-associated kinase and mDIA, are required for the stress-dependent formation of FAs[34] and eventually leads to increased stability of the actin filaments. For instance, activated ROCK1, one of the downstream effectors, phosphorylates and activates LIM kinase, which in turn, phosphorylates cofilin, inhibiting its actin-depolymerizing activity. In ECs, shear stress is transmitted to the FAs and leads to the activation of integrin receptors,[35] which in turn activate FAK, paxilin, c-Src, Fyn, and $p130^{CAS}$, and finally the Ras-ERK pathway.[36,37] Another pathway involved is cAMP signaling, which was shown by micromanipulation of integrins with magnetic beads.[30] These examples show that stresses not only locally regulate the assembly of FAs but also will activate different signal pathways that modulate the cytoskeleton and gene expression, with effects on cell function at a longer timescale.

5.506.3.2. Interaction with Neighboring Cells: Adherens Junction

Cell–cell interactions seem to play another important role in mechanotransduction. Adherens junctions are a protein complex that mediate cell–cell contact. This dynamic structure is based on cadherins and shares many similarities with FAs[29]: Both link the actin cytoskeleton to the external environment and both structures consist of a large number of signaling and structural molecules that cluster and interact at the junction, some of which are present at both sites, including α-actinin, Arp2/3, zyxin, moesin, and vinculin.[38] The role of adherens junctions in mechanosensation is, however, less clear. Vascular endothelial cadherin, a specific type of cadherin present in ECs, is thought to associate with PECAM-1 and VEGFR2 to form a mechanosensory complex.[39] In this putative system, the vascular EC cadherin functions as an adaptor, PECAM-1 as a direct transmitter of mechanical force, and VEFGR2 as an activator of phosphatidylinositol-3-OH kinase. PECAM-1 and VE-cadherin knock-out mice show abnormal responses to shear stress, indicating that these proteins are required for mechanotransduction. But more investigation is required to elucidate the precise function of adherens junction in mechanotransduction and the question of whether other cell–cell junctions, such as desmosomes or tight junctions, are involved in sensing mechanical stimuli.

5.506.3.3. Primary Cilia

The primary cilium is one example of a specialized cellular substructure that has recently been implicated in mechanosensation. It is a hair-like protrusion from the apical cell membrane into the extracellular space present on the majority of mammalian cells. Its structure is based on nine doublet microtubules, which originate from the basal body and form a radially symmetric axoneme.

Although primary cilia have received little attention during most of the time since their discovery, it is becoming clear that they are a center of chemical and mechanical signal transduction during vertebrate development[40] in bone,[41,42] kidney, and liver.[43] Dysfunction is associated with many diseases[44] such as cancer,[45] polycystic kidney and liver disease,[43] adiposity,[46] and retinal degeneration.[47] A specialized protein transport system called intraflagellar transport mediates the assembly and dissociation of the primary cilium[48,49] and the trafficking of ciliary proteins. Among the variety of proteins present on the primary cilium, many signaling molecules localize to the ciliary membrane, including receptors for Sonic hedgehog, Wnt, platelet-derived growth factor, serotonin, and somatostatin.[42]

The mechanosensory role of the primary cilium was first demonstrated in renal epithelial cells. Fluid-shear- or micropipette-induced bending of the primary cilium in MDCK cells leads to an increase in intracellular calcium.[50] This mechanosensory response is mediated by polycystins 1 and 2 (PC1 and PC2) in kidney cells. Both transmembrane proteins localize to the base of the cilium, and functionality of both proteins is required for flow-induced increase in intracellular calcium.[51] PC1 has a large extracellular domain, which has been implicated as a sensor for mechanical forces,[52] but a nanometer scale structure may not experience enough force to directly sense shear and may be sensitive to thermal noise. Alternatively, one of the motifs present on the extracellular domain may bind to either an ECM protein or to another membrane protein. In this case, rather than direct sensing of shear, a displacement of the cilium could lead to a conformational change in PC1. This hypothesis is supported by the fact that the extracellular domain of PC1 exhibits remarkable mechanical strength.[53] A conformational change of PC1 could activate PC2 via the intracellular C-terminal of PC1 and thus lead to an opening of the PC2 channel. In any case, more investigation of the molecular mechanisms involved is clearly warranted.

In bone, primary cilia are required for the dynamic fluid flow-induced osteogenic and bone resorptive responses that are independent of Ca^{2+} flux and stretch-activated ion channels.[54] Further investigations showed that fluid flow leads to a decrease in intracellular cAMP, which depends on the primary cilium and, on a molecular level, on adenylyl cyclase isoform 6 (AC6) and Gd^{3+}-sensitive channels. Furthermore, this pathway was shown to mediate flow-induced cyclo-oxygenase-2 (COX-2) gene expression.[55] This suggests that the primary cilium mediates mechanosensitive signaling responses that

are tissue specific. In the bile duct, the primary cilia on cholangiocytes mediate a fluid-flow-induced change in both intracellular Ca^{2+} and cAMP through PC1, PC2, and AC6.[56]

In addition to the flow-sensing role of the primary cilium, it is also involved in direct transmission of strains in the ECM in cartilage. Chondrocytes reside in fibrillar-walled chondrons, which are embedded in the interchondronal matrix. Their primary cilia interdigitate among collagen fibers and condensed proteoglycans.[57] During compression, the fibrillar meshwork is strained and the chondron becomes flattened. As the chondrocyte cilium is attached to the fibrillar mesh via surface receptors such as integrins and NG2 at electron-opaque plaques, the strain will be transmitted and will lead to a bending of the cilium.[57,58] Which molecular mechanisms are ultimately responsible for the downstream signaling response remains unclear. Mechanosenory function of primary cilia has been suggested in other cell types as well, such as human airway smooth muscle cells[59] and ECs.[60]

5.506.3.4. Caveolae

Caveolae are another type of subcellular structure implicated in mechanotransduction. They are microdomains that are 50–100 nm invaginations of the plasma membrane present on many cell types. They contain a specialized proteome enriched with many receptors, ion channels, and protein kinases.[61] The link between caveolae and mechanotransduction was established initially in ECs.[62–64] Cultured ECs exposed to chronic shear stress alter the expression and distribution of caveolin, the scaffold protein of caveolae. The plasma membrane levels of caveolin as well as the surface density of caveolae increase with increasing shear stress. These shear-stress-induced changes result in increased mechanosensitivity in response to hemodynamic forces, increased phosphorylation of caveolin 1 (CAV1), and activation of signaling pathways such as endothelial nitric oxide synthase (eNOS) and mitogen-activated protein kinase (MAPK).[63] Cav1 knock-out mice showed an impaired blood-flow-dependent vasodilation and vascular remodeling. Reconstitution of Cav1 rescued both phenotypes, suggesting that CAV1 involved in mechanotransduction of shear stresses is critical to vascular function.[65] A redistribution of CAV1 to focal contacts in response to cyclic stretch was also observed in smooth muscle cells.[66]

Although evidence of the mechanosensory function of caveolae is growing, the underlying molecular mechanisms remain unclear. Due to their spherical structure, connected via a neck to the plasma membrane, it is plausible that caveolae are sensitive to changes in membrane tension. From a biophysical perspective, caveolae may act as equilibrated membrane reservoirs with tension regulated by their mechanical properties.[67] Which proteins would be affected by changes in membrane tension or which other mechanical stimuli are responsible for the observed mechanosensitivity of caveolar proteins needs further investigations.

5.506.3.5. Nucleus

Interestingly, there is evidence supporting a direct role of the nucleus in mechanotransduction (reviewed in Wang *et al.*[68] and Dahl *et al.*[69]). Stress on the cell can lead to deformation and rearrangement of the nucleus. This effect is not surprising, as the nucleus is directly integrated with the cytoskeleton. Some researchers speculate that the nuclear deformation might affect gene expression by changing the arrangement of chromatin. It is well known that gene expression is dependent on the accessibility of the promoter and the coding sequence in the highly condensed chromosomes; however, a mechanism by which specific genes can be regulated, and not others, remains elusive. If the nucleus is involved in mechanotransduction, mechanisms must be present to activate only specific genes. This could be possible by nuclear receptors activating transcription factors or other cell signaling pathways, but as of now, no such mechanosensors have been discovered.

5.506.4. Molecular Mechanotransduction

The transduction of a mechanical signal into a biochemical response is mediated by proteins. Their functionality depends primarily on their 3D structure. For example, catalytic sites often include amino acids that are distant in the protein sequence, but spatially close once the protein is correctly folded. The folding of the protein into a spatial conformation is driven by noncovalent interactions such as hydrophobic packing, Van der Waals forces, and hydrogen and ionic bonds. Application of forces on a protein can disrupt such interactions and deform or unfold domains or move one domain with respect to others by sliding or rotating around a flexible hinge.[70] Given that mechanical forces can change protein conformation, the function of any protein could potentially be altered by mechanical stress.[7] Indeed, many proteins undergo conformational changes during activity,[71] and by influencing the conformation, the kinetics of the reaction can be changed. For example, the rate of ATP hydrolysis decreases with increasing force in many motor proteins.[72,73]

However, not every protein is a potential mechanosensor. Candidate proteins are localized to strategic areas of the cell where they are more likely to experience mechanical loading, for example, the periphery[74] and specialized subcellular structures. Some general criteria can be advanced for a mechanosensitive protein. First, the function of the molecule should be titrated to the level of mechanical force applied to it, and second, the mechanosensor should participate in a response known to be mechanically regulated.[75,76] Extracellular forces act on the cellular membrane and are transmitted to the cytoskeleton. As a logical consequence, candidate mechanosensing proteins are either residing in the cell membrane or tethered to structural elements of the cell, or both. Examples of how mechanically induced conformational changes can lead to biochemical responses include opening of ion channels that can rapidly change intracellular ion concentrations, exposure of cryptic or apolar peptide sequences by unfolding or lid-opening, which might catalyze reactions or enhance binding affinities to biomolecules, and receptor–ligand interactions that act like a catch bond, which leads to more stable interactions with load.[74]

5.506.4.1. Mechanosensitive Ion Channels

Mechanosensitive ion channels are one example of a subset of proteins that translate mechanical signals into a biochemical

response. Three different concepts have been advanced for how the conductance of mechanosensitive ion channels can be changed in response to a mechanical stimulus. One concept is based on membrane tension, which directly acts on the channel and induces a conformational change; the second concept is based on the physical connection of the channel to the ECM and the cortical cytoskeleton and the third mechanism is indirect activation, where a primary mechanosensor sends a chemical signal that opens the ion channel (see **Figure 2**).

One example of a mechanosensitive ion channel that is specifically activated by membrane tension is the bacterial K^+ channel MscL. This channel serves as a security valve, which opens at high membrane tension, preventing lysis. The structure of the protein is known, and computational modeling as well as observations with electron paramagnetic resonance spectroscopy suggest that the increased tension in the membrane leads to tilting of the transmembrane helices similar to the iris of a camera, which opens and wets the pore interior.[77] Reconstituted MscL, MscS, and other prokaryotic mechanosensitive ion channels in liposomes are still mechanosensitive, demonstrating that lipid bilayer tension alone is sufficient for channel gating.[78] The required tension for channel opening is close to the lytic tension of the bilayer. However, typical physiologic membrane tensions in animal cells are a thousand-fold lower.[74,79] It is not clear if mechanosensitive ion channels in animal cells open by the same mechanism or if other out of plane forces are needed in addition to the in plane membrane tension.

The second concept requires connections between the channel and force bearing filaments. Opening of the channel needs a relative displacement of these structural proteins. In fact, many mechanosensitive ion channels in animal cells are tethered to the cytoskeleton or to the ECM,[78] but the simple fact of connectivity does not necessarily imply force transmission.[77] Inner ear hair cells provide a clear example in which a tether is responsible for gating mechanosensitive channel. However, even in this case, the molecular components have not totally elucidated,[80] and it is not clear if the tether directly pulls on a domain of the ion channel or if an indirect mechanism leads to the gating response. Thus, it appears likely that some eukaryotic mechanosensitive ion channels require connections to the cytoskeleton or respond to local deformation of the cell membrane while others respond to physiological changes in membrane tension.

Ion channels might also be indirectly mechanically regulated. In this model, a mechanosensitive protein is activated by mechanical stress and releases signaling molecules, which bind to and change the gating properties of an ion channel. No physical connections of the channel to other structures are necessary; the ion channel is just an intermediate of a mechanically induced signaling cascade.

5.506.4.2. Exposure of Cryptic Sequences

Many extracellular and FA-associated proteins consist of tandem repeats, forming multimodular domains. Talin, titin, fibronectin, cadherins, α-actinin, and dystrophin are only some of the many examples. Experimental and computational studies show that application of force on such proteins unfolds their domains, often in a stepwise manner, due to the breaking of hydrogen bonds.[81,82] Through this process of unraveling, peptide sequences that were buried inside the protein become exposed to the solvent and potentially become biochemically active. If different molecular recognition sites are present within these domains, different magnitudes of force could be converted into distinct molecular signals.

Fibronectin, a cell adhesive component of the ECM, consists of over 50 modular repeats. This protein binds via its RGD sequence to integrins and is therefore linked to the contractile cytoskeleton. Intracellular contraction forces are sufficient to, at least partially, unfold fibronectin.[83] Many cryptic sites that are buried in the folded state and are accessible only after extension of the protein and a change in conformation occurs.[84,85] These cryptic sequences have the potential to include phosphorylation sites or other enzymatic activity. For example, a partially cryptic disulphide isomerase[86] and a cryptic metalloprotease site[87] can be found in fibronectin, but it is unclear whether their activity is mechanically regulated.[74]

Talin and vinculin are important proteins involved in cell signaling, adhesion, and migration that localize to FAs. Talin links integrins to the actin cytoskeleton and recruits vinculin in response to tensile forces. In the unloaded configuration, the vinculin-binding sites are embedded. However, physiologically

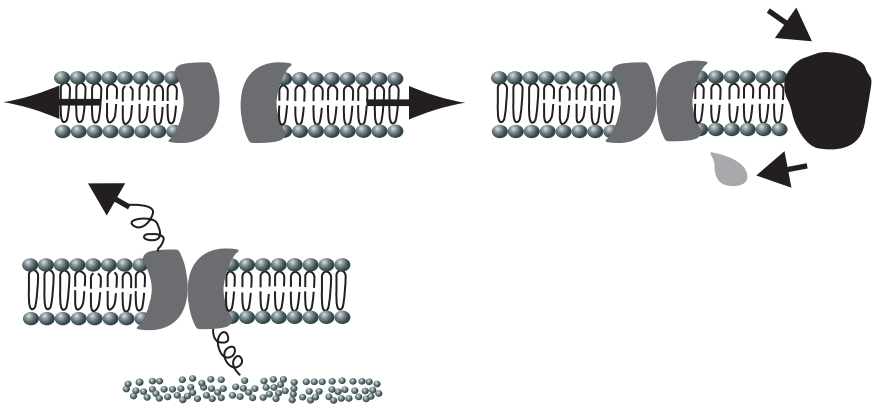

Figure 2 Activation of mechanosensitive ion channels. (top left) Membrane tension may directly induce a conformational change that opens the channel. (top right) An unknown primary mechanosensor releases a signaling molecule that activates the channel. (bottom) Physical coupling of the channel to the ECM and the cortical cytoskeleton transmit forces that open the ion channel.

relevant forces have been shown to cause stretching of single talin rods that expose these cryptic vinculin-binding sites.[88] Simulation studies predict that the binding site on talin rotates out of the hydrophobic core of a helix when the protein is stretched[89] or that the talin rod is fragmented into three helix subbundles that expose the binding site.[90]

Additionally, when the unraveling force on multimodular proteins is reduced, they generally refold properly. This refolding is necessary to return to the original conformation when the mechanical stimulus is removed or reduced. Whether ligand binding to cryptic sites inhibit or even prevent refolding is yet unknown.[84]

5.506.4.3. Receptor–Ligand Interactions that Strengthen if Strained

Normally, forces applied on noncovalent bonds diminish the bond lifetime, but there are certain bonds that strengthen with load. The dissociation lifetime of the so-called catch bonds increases with tensile forces, as long as the force does not exceed a certain limit. Evidence for catch bonds exists for the bacterial adhesion protein FimH[91] and P-selectins on leukocytes.[92] Recently, a study showed that $\alpha5\beta1$ integrin switches between a relaxed and tensioned state in response to myosin II-generated cytoskeletal force. Under normal conditions, integrin binds to the RGD sequence on fibronectin. In the tensioned state, a catch bond between integrin and fibronectin forms which requires the engaging of the synergy site in fibronectin in addition to the RGD-binding site.[93] This additional binding site increases the overall affinity and allows the complex to sustain larger tensional forces.

5.506.5. Response of Cells to Mechanical Stress and Implications for Tissue Engineering

Mechanical signals modulate almost all aspects of cell function, including cell growth, differentiation, migration, adhesion, and apoptosis.[94] Nonetheless, mechanical stimulation of cells has received little attention in tissue engineering. The process of cell differentiation and proliferation has to be robustly controlled for functional structural tissue engineering constructs that will be clinically successful. If undifferentiated cells remain pluripotent for example, they tend to form teratomas, which is a dramatic failure to regulate differentiation. The importance of chemical signals to direct these processes is well established. It has also become clear that cells respond differently to distinct types of materials and that the elasticity is one important property which is sensed by cells and is critical for lineage commitment. These two approaches are certainly very important in guiding cell proliferation and maturation, but mechanical stimuli have received relatively less attention. Studies in the field of bone and vascular biology show that mechanical stimulation of tissue engineering constructs yields promising results.

It is well-established that bone is regulated by mechanical loading *in vivo*. Some attempts have been made to mimic the mechanical environment of bone cells in 3D scaffolds. Different types of stimuli including compression, stretch, and fluid flow seem to be beneficial for *in vitro* tissue formation. For example, osteoblastic cells seeded in polyurethane open cell foam scaffolds loaded in compression at 1 Hz, 5% strain for 2 h every 5 days showed that mineralization compared to static controls and the mRNA expression of type I collagen, osteopontin, and osteocalcin was higher after one cycle of loading.[95] The effect of cyclic uniaxial strain on osteoblastic precursor cells cultured in 3D type I collagen matrices was examined by Ignatius *et al.*[96] They analyzed mRNA expression of different genes involved in cell proliferation, matrix production, and osteoblastic differentiation, such as histone H4, core-binding factor 1, alkaline phosphatase, osteopontin, osteocalcin, and collagen type I. Physiological stretching of the matrices increased cell proliferation and slightly elevated the expression of nearly all investigated genes. Previous 2D *in vitro* studies suggest that fluid flow is a more potent regulator of bone cell behavior than compression or substrate deformation. Bancroft *et al.* studied the effect of perfusion flow on differentiating marrow stromal osteoblasts in 3D constructs.[97] Different flow rates were applied, and all flow conditions increased mineral matrix production drastically and total calcium content increased proportionally to the flow rate. Perfusion flow *per se* has two effects, it increases the biochemical exchange and generates shear stresses on the cells. To date, it is not clear which, or if both together, are responsible for the observed increase in matrix mineral production.

The important role of mechanical stimulation of endothelial and smooth muscle cells has been recognized, and different types of bioreactors have been designed to mechanically stimulate engineered vascular grafts with physiological fluid shear stress and strain.[98] Hoerstrup *et al.* developed an *in vitro* pulse duplicator system for vascular graft engineering which provides a biomimetic environment and yields more mature, implantable grafts.[99] Ovine vascular myofibroblasts and ECs were seeded on a bioabsorbable polymer and grown for 4 days in static culture and then in the pulse duplicator bioreactor for up to 28 days. The pulsed graft showed a continuous increase in burst strength, whereas in static controls the burst strength decreased. The suture retention strength was more than fivefold higher in pulsed grafts compared to controls. In addition to the improved mechanical outcome of mechanically stimulated vascular grafts, it was shown by Jeong *et al.* that vascular smooth muscle cells aligned in the direction radial to the distention direction, similar to native tissue, when seeded on 3D PLCL scaffolds subjected to pulsatile strain and shear stress.[100] The expression of smooth muscle α-actin increased by 2.5-fold in the pulsed bioreactor compared to static control, which indicates a more differentiated phenotype of smooth muscle cells. Thus, a physiological mechanical environment can promote tissue maturation and enhance mechanical stability of vascular grafts.

In conclusion, the mechanical stimulation of tissue engineering constructs, in addition to biochemical stimulation, might overcome current challenges in tissue engineering, such as guiding cell differentiation, maintaining the cells in a differentiated state, and improving the mechanical properties of the engineered tissue. Future studies that simultaneously consider the mechanical, the material, and the biochemical environment of native and engineered tissues will hopefully provide new clinically successful therapies in the field of regenerative medicine.

5.507.1. Why Do Tissue Engineering Approaches Need a Cell Source?

Organ and tissue replacement is an increasingly unmet clinical need. According to the Organ Transplant Procurement Network, from 1988 to 2010, over 485 000 total organ transplants have been performed in the United States, including those of kidney, liver, heart, pancreas, intestine, and lung. In 2010, over 116 000 patients were registered on organ transplant lists (http://optn.transplant.hrsa.gov), and current statistics suggest that organ wait-list mortality hovers between 4% and 12%, depending on the organ type (http://www.ustransplant.org/). As the incidence of damaged, diseased, and missing tissues keeps growing, current clinical options such as self, donor, or cadaveric tissues are no longer able to meet the rapidly increasing demand. Furthermore, purely mechanical replacement devices, such as prosthetic limbs or heart valves, can only be used in limited applications and these devices do not fully restore complete organ function. Therefore, incorporating a cell source as part of the solution allows clinicians and bioengineers to capitalize on the unique biochemical features of the human cell, to aid in basic functions that no drug product or material can mimic (**Figure 1**).

Interestingly, cell-based strategies for improving human health are not new ideas. The first recorded human blood transfusion was performed in 1667 by Jean-Baptiste Denys, who successfully transfused sheep's blood into a 15-year-old boy.[1] Thereafter, subsequent patients of Denys died after receiving transfusions of animal blood, and the procedure was officially banned in France and Britain in 1670.[2] Close to 300 years later, Charles Lindbergh and his mentor, Alexis Carrel, described a new organ perfusion system, a technology that could cultivate organs and keep them sterile for extended periods of time outside the body. This new technology laid the foundation for modern day sterile cell culture.[3,4] Subsequently, Robert Good, a pioneer of modern immunology, established the first successful bone marrow transplant in 1968 to treat diseases other than cancer.[5] In 1994, Brittberg and Petersen developed a cartilage repair strategy based on autologous chondrocyte implantation, which has subsequently become a

In 2010, according to the Organ and Transplant Procurement Network, 116 949 patients are enrolled in organ waitlists across the United States.

	Waiting list in 2010	Donated in 2009
Kidney	91 164	13 636
Liver	16 785	6958
Pancreas	1477	1741
Heart	3153	2281
Lung	1784	1569
Intestine	253	189

Data as of June 25, 2010.

Figure 1 These statistics highlight the need for alternative cell-based therapies, where the current number of donated organs is *4*× less than the clinical need. These data do not include statistics associated with nerve, bone, vessel, and other tissue grafts that *also* currently require human sources of donated tissue. Data collected from the National Organ Procurement Network.

clinically accepted procedure (Carticell®, Genzyme).[6] In 2000, clinical trials for entire organ replacement began with Anthony Atala and colleagues. Here, damaged bladders were replaced with an autologous cell source grown on an appropriate biomaterial structure shaped like the bladder.[7] More recently, in 2006, a 6-year-old patient received the first injections of neural stem cells directly into the brain, the goal being the production of critical enzymes important to healthy brain function.[8] In 2008, the first tissue-engineered trachea was successfully transplanted, using an approach that combined the patient's own stem cells and a biologically compatible material to successfully restore normal function to the patient's airway.[9] In 2009, cardiac stem cell transplantation was performed in a 39-year-old patient, with the donor cells being harvested from his heart tissue.[10] These examples highlight the therapeutic promise and rapidly expanding application of cell-based approaches across tissue types and clinical needs. Significant improvements in reproducibility and precision in cell isolation, cell expansion, and cell differentiation will allow many cell-based tissue engineering strategies to proceed to the clinic (Figure 2).

5.507.2. Cell Sources Used in Tissue Engineering Strategies

5.507.2.1. Overview of Autologous Versus Allogeneic Versus Xenogeneic Sources

Autologous materials are cells/tissues/organs harvested from the patient's own body and returned to SELF. Because autologous cells effectively come from SELF, they are perfectly matched immunologically with a none-to-low risk of antigenicity, and only reported when cells were genetically manipulated. Autologous sources have no risk of disease transmission but cannot be used in cases where the patient's own cells harbor the genetic defect or disease of interest. Common types of autologous sources include blood banking in preparation for a surgery or harvesting bone and vessel autografts from alternative sites in the patient's body. Autologous harvests always yield two sites of surgery with donor-site morbidity and increased risk of infection. Autologous sources are, by necessity, limited in supply and restricted in application, but remain the gold standard in many clinical practices.

Allograft materials are cells/tissues/organs harvested from human donors and transplanted into another human patient. Selected allograft materials can be donated by living donors, such as bone marrow transplants, liver, and kidney. Other allograft materials must be harvested from cadaveric tissue donors, including cornea, heart, and lung. Allograft materials have the possibility of graft rejection or of mounting an autoimmune response against the patient's own tissues because they are not from SELF. When the host mounts an immune attack against the allograft, it is called graft rejection. When transplanted allogeneic cells attack recipient tissue, it is called graft-versus-host disease (GVHD) response. Allografts thus carry the possibility of disease transmission and are also of limited supply.

Xenogeneic materials are cells/tissues/organs harvested from animal donors and transferred into human patients. Although several of the original sheep blood transfusions performed by Dr. Denys in 1667 resulted in patient mortality, novel strategies offer potential solutions for utilizing xenogeneic tissue in the clinic. Specifically, baboons and pigs are favored xenotransplant donors for humans. While baboons are the closest genetic match, pig anatomy is similar to humans in many respects. Typically, xenogeneic grafts result in hyperacute or delayed rejection due to significant major histocompatibility complex (MHC) mismatch. However, new strategies to eliminate mismatched immune recognition components could open possibilities for successful xenogeneic transplantation. For example, recent reports demonstrate elimination of the cell surface α-galactoside epitopes that are the major xenoantigens causing hyperacute rejection in pig-to-human transplantation.[11] These are the first steps to genetically modifying animal tissue by inserting human genes so that the transplanted organ will produce proteins and enzymes that the body recognizes as human and not animal. The first transplant of genetically modified pig liver was in 1995, which was

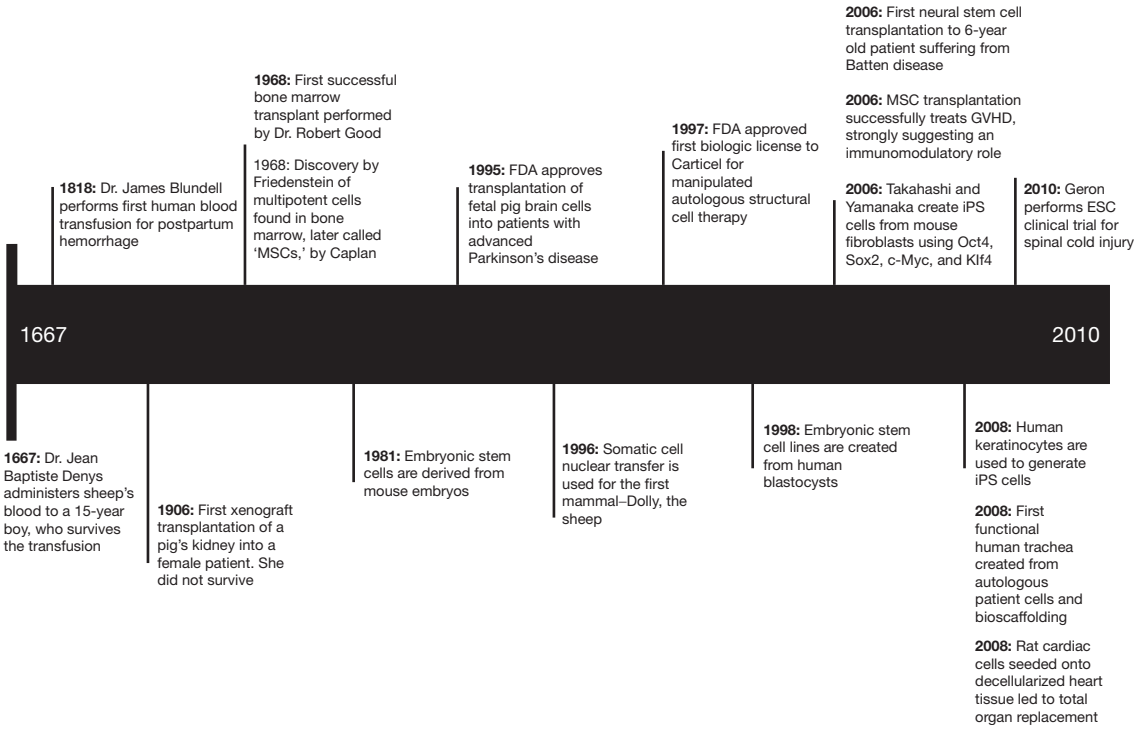

Figure 2 1667–2010: Chronological timeline highlighting significant advances in basic research, clinical application, and product development in the areas of cell-based therapies.

approved by the US Food and Drug Administration (FDA) for patients with end-stage liver disease.[12] The FDA has also approved transplantation of baboon bone marrow in AIDS patients to provide a source of immune cells that are resistant to HIV,[13] and transplantation of fetal pig brain cells into patients with advanced Parkinson's disease.[14] These early studies were conducted primarily to check for safety, not efficacy. Concerns about xenograft applications remain, including the risk of disease transmission and differences in tissue aging properties. Although gene therapies for xenograft transplantation are still in the early stages of development, such avenues could yield promising sources of cells and tissues for future medical applications.

5.507.2.2. Tissue-Specific Cells from SELF

Currently, the predominant cell source used for human application is autologous (SELF) differentiated tissue-specific cells: for example, taking a small biopsy of muscle tissue, isolating individual myoblasts via tissue digestion, expanding this population in culture, and returning this population to a repair site in the body. This choice is important for two reasons: (1) fully differentiated tissue-specific cells are thought to have reduced potential for forming teratomas (i.e., uncontrolled growth/differentiation) compared with less differentiated stem cells sources; and (2) fully differentiated tissue-specific cells are already equipped with tissue-specific function (i.e., osteoblasts secrete mineralized matrix), whereas undifferentiated stem cells require additional information from the surrounding host tissue or from the cotransplanted material to function appropriately as mature differentiated cells. From a clinical standpoint, tissue-specific cells are thought to be less risky and less complicated. However, there are exceptions and challenges to using fully differentiated cells. For example, neurons once fully differentiated do not proliferate. Therefore, generating large numbers of neurons in culture is not possible. Utilization of stem or progenitor cell sources where one could expand progenitors and subsequently induce neuronal maturation may be the best and only option when replacing damaged neurons. Alternatively, clinicians and bioengineers turn to stem cell sources that offer greater flexibility and choice in the tissue type formed.

5.507.2.3. Stem Cells: Defined as a Collective

The term 'stem cell' can be traced back to the late nineteenth century, when it was primarily used to describe what are today called the germline stem cells.[15,16] Later, the term was used to describe stem cells of the hematopoietic system.[17] Now, the identification of stem cells has progressed beyond early embryologic systems and, subsequently, resident niches of adult stem cell 'pools' have been discovered in almost every tissue in the adult body. The current definition according to the *Stem Cell Handbook* of the US National Institutes of Health (http://stemcells.nih.gov/info/basics/), is that stem cells are cells that can self-renew and have the potential to differentiate along more than one lineage. "Stem cells are defined as clonogenic, self-renewing progenitor cells that can generate one or more specialized cell types".[18,19] Originally, these key features were the factors that sparked interest within the biomedical community to develop therapeutic strategies using the various stem cell sources.

5.507.2.4. Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) are the nonhematopoietic fraction of bone marrow that display multipotent characteristics. MSCs were first described by Alexander Friedenstein, who described these 'osteogenic stem cells' as clonal and fibroblastic, and observed that these adherent colonies displayed robust osteogenic potential.[20–22] These cells were first termed 'mesenchymal stem cells' by Arnold Caplan,[23] and their classic multilineage differentiation potential into bone, cartilage, and fat tissue types was demonstrated by Pittenger *et al.*[24] Since the original discovery of MSCs in bone marrow, the reports identifying cells with similar characteristics have significantly expanded across many adult and fetal tissues. Moreover, the literature suggests that MSCs can differentiate into cells of endodermal, ectodermal, and mesodermal origin.[25]

The International Society for Cellular Therapy (ISCT) has established three minimal criteria for defining MSCs, on the basis of current knowledge.[26] MSCs isolated from human bone marrow and other mesenchymal tissues must demonstrate *in vitro* (a) adherence to plastic in standard culture conditions, (b) specific surface antigen expression, and (c) multipotent differentiation potential along the osteogenic, chondrogenic, and adipogenic lineages, as demonstrated by histological staining and other methods. Unlike specific markers or antigens that characterize embryonic[27] and hematopoietic stem cells (HSCs),[28] there have been differing reports on the identities of MSC surface markers. The consensus of the ISCT, which is subject to further modification, is that measurements by flow cytometry must show greater than 95% of the MSC population to express CD73 (ecto-5-nucleotidase), CD90 (Thy-1), and CD105 (endoglin), and no more than 2% of the cells may express CD34 (hematopoietic progenitor and endothelial cell marker), CD45 (pan-leukocyte marker), CD11b or CD14 (monocyte and macrophage markers), CD19 or CD79α (B-cell markers), and HLA-DR (marker of stimulated MSCs) (Figure 3).

Given the prevalence of MSC niches in a variety of adult tissues, these cells are a popular choice of stem cell for bone, cartilage, fat, and tissue-specific replacements strategies. These cells have extensive but finite expansion potential and limited differentiation potential, and thus reduce concerns of teratoma formation. Furthermore, emerging evidence suggests interesting immunomodulatory properties that may be advantageous in treating immune-related disorders or in allograft transplantation strategies, discussed later in this chapter. However, there remains ongoing controversy concerning the significant heterogeneity in this cell population and the lack of consensus in defining appropriate cell surface marker profiles. Complicating this issue is the fact that the expression of cell surface epitopes is highly dependent on the soluble and insoluble components of the extracellular milieu and on their physical properties and spatial orientation. In addition, interactions with supporting cells can functionally modify the cell surface epitope expression of MSCs. Moving forward, comparing information across different laboratories will be critical in the identification, isolation, and clinical application of MSCs for cellular therapies in the future.

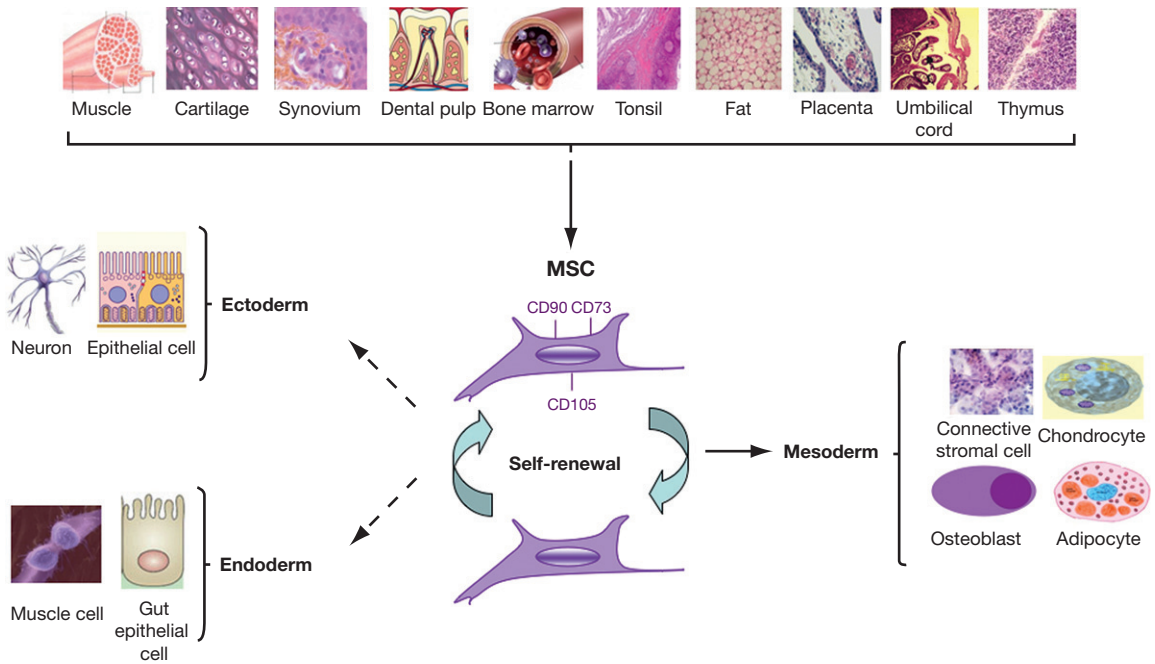

Figure 3 First discovered in bone marrow in 1968, mesenchymal stem cells (MSCs) are a resident multipotent stem cell source isolated from a wide range of adult tissues including muscle fat, and thymus. The most common phenotypic markers used to classify MSCs include CD90, CD73, and CD105. MSCs have the capability to self-renew and exhibit potential to differentiate predominantly along mesodermal lineages. Some studies suggest MSC differentiation along ectodermal and endodermal lineages as well. Reproduced from Kuhn, N. Z.; Tuan, R. S. *J. Cell Physiol.* **2010**, *222*(2), 268–277.

5.507.2.5. Embryonic Stem Cells

Embryonic stem cells (ESCs) are a pluripotent cell source, capable of giving rise to all cell types in the human body, including all three germ layers: mesoderm, endoderm, and ectoderm. ESCs are distinct from multipotent stem cells that have restricted differentiation potential along certain lineages. And, ESCs are not totipotent as they lack placenta and umbilical cord information, and thus cannot independently give rise to a human being. The discovery of ESCs began in 1964 when researchers successfully isolated a single cell type from a teratocarcinoma, a germline-derived tumor.[29] Researchers were able to isolate, culture, and expand these cell populations in culture. These cells, now called embryonic carcinoma (EC) cells, were largely used as an *in vitro* model to study early mouse development, but could never be applied clinically given their tendency for genetic mutation and karotypic instability. Less than 20 years later, in 1981, ESCs were generated from mouse embryos.[30] Seventeen years later, in 1998, the first report describing ESC lines derived from human blastocysts was published.[31] After undifferentiated proliferation over 4–5 months, this cell population still retained the ability to differentiate into multiple tissue types including gut, neuron, bone, cartilage, muscle, and kidney glomeruli (**Figure 4**).

The four fundamental characteristics that define an ESC include (a) pluripotency – potential to give rise to all cell types of all three germ layers (ectoderm, mesoderm, and endoderm); (b) immortality – ability to divide indefinitely under specific conditions; (c) ability to remain undifferentiated; and (d) karyotypic stability – unchanged number and appearance of chromosomes. The current molecular marker signatures used to characterize ESCs include (a) surface markers SSEA-1, SSEA-4, and TRA-1-60; (b) transcriptional factors Oct4, Nanog, and Sox2; and (c) high telomerase activity (http://www.stemgent.com). These cells can be subcultured and maintained in an undifferentiated state *in vitro* for several months by growing them on fibroblastic feeder layers with medium supplementation, including growth factors, leukemia inhibitory factor (LIF), and basic fibroblastic growth factor (bFGF). To initiate differentiation of ESC cultures, embryoid colonies are selectively removed from feeder layers and subcultured alone, thus stimulating embryoid body formation. Subsequently, directed differentiation can be achieved *in vitro* by the addition of growth factors for induction of specific lineage phenotypes, and committed and differentiated cells obtained by transfection with selectable, drug resistant, expression DNA constructs harboring lineage-specific promoters. Finally, terminal differentiation can be achieved by transplantation of progenitor cells into appropriate tissue sites *in vivo*.

Somatic cell nuclear transfer (SCNT) is a technology that has been developed to create a cloned embryo, whereby a nucleus from an adult somatic cell is introduced into an enucleated ovum.[32] This technique has been applied to achieve *reproductive* cloning in which the cloned embryo is subsequently implanted into a pseudopregnant surrogate mother

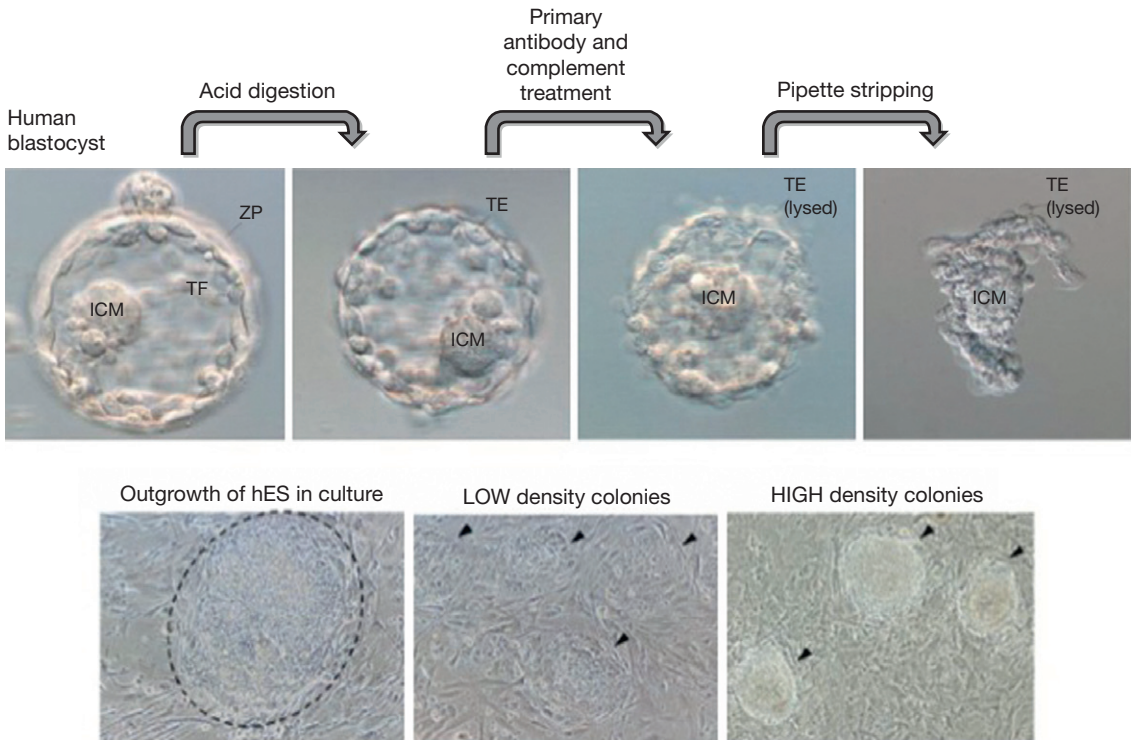

Figure 4 Technical steps to achieve embryonic stem cell isolation. First, acid digestion of zona pellucida (ZP). Second, utilization of a combination of primary antibody and complement-mediated lysis of trophectoderm (TE) cells, termed 'Immunosurgery.' Third, utilization of pipette to strip lysed TE layer away. Finally, collection of inner cell mast (ICM) cells to plate onto feeder layers of mouse embryo fibroblasts (MEFs). Colonies can be passaged to created ES lines. Reproduced from Chen, A. E.; Melton, D. A. *J. Vis. Exp.* **2007**, *10*, 574, with permission from JoVE.

and allowed to develop fully into a complete organism. One of the most famous animals cloned using SCNT technology was Dolly the sheep, by Ian Wilmut and his colleagues.[33] In a similar manner, the technology can also be applied for the purpose of *therapeutic* cloning to expand tissue-specific cell populations for therapeutic gain. Specifically, nuclei derived from patient cells taken from a biopsy are transferred to an enucleated donor oocyte. This exact patient clone is subcultured, expanded, and differentiated to the desired tissue type, and introduced into the patient as a completely immunologically compatible transplant. These SCNT technologies are beginning to enter the clinical arena. For example, Geron Corporation received FDA clearance in January 2009 to conduct the first human clinical trial of ESC-based therapies for acute spinal cord injury (http://www.geron.com/media). Despite the exciting potential of this technique for patient-compatible tissue replacement applications, therapeutic cloning efficiency remains extremely low; there are significant ethical concerns regarding the use of donor embryos, and fears remain of uncontrolled cell growth and differentiation with risk of teratoma formation.

5.507.2.6. Induced Pluripotent Stem Cells

Given the ethical concerns associated with applied ESC strategies, alternative approaches to generate pluripotent cells are currently being investigated. Questions such as "Can 'terminal' differentiation be reversed?" "Can mature adult cells be dedifferentiated?" and "Do committed cells possess plasticity?" and others are the driving force behind the discovery of induced pluripotent stem cells (iPSCs). In 2005, two separate groups reported on a new technique demonstrating cellular reprogramming by fusion with human ESCs.[34,35] These cells reprogrammed by fusion with ESCs had three key characteristics: expression of ESC markers Oct3/4, ESC-specific DNA methylation, and ESC-specific histone modifications. These discoveries, which represented a paradigm shift, opened up the possibility of reactivation of all genes required for normal development in terminally differentiated cells. Furthermore, these exciting findings also suggest that the key epigenetic factors necessary to effect reprogramming are contained within the cytoplasm of the oocyte and ESCs. Shortly after these studies, in 2006, Takahashi and Yamanaka presented the first paper describing the induction of pluripotent stem cells from mature mouse fibroblast cultures utilizing four defined transcription factors: Oct4, Sox2, c-Myc, and Klf4.[36] In 2008, efficient and rapid generation of iPSCs from human keratinocytes was achieved.[37] Here, a single hair bulb, placed in explant culture for 5 days after transduction of the four transcription factors resulted in iPSCs populations. Using this technique on a single hair follicle, researchers could derive cells to give rise to endoderm, mesoderm, and ectoderm tissues. The therapeutic potential behind these newly developed techniques suggested that cells derived from a single hair follicle could, for example, result in the entire replacement of dopaminergic neurons in a patient suffering from Parkinson's disease. Further advancements in iPSCs technology include feeder-free derivation of iPSCs from adult human adipose stem cells, opening up the possibility of liposuction waste being reutilized for cartilage replacement in rheumatoid arthritis damaged tissue.[38] Later in 2009, iPSCs derived from foreskin fibroblasts were differentiated to cardiomyocytes and functional studies measuring beat frequency were carried out following cardiac drug application. Results from such studies suggest that iPSC technology can be translated to toxicity and drug screening arrays (**Figure 5**).[39]

Cell therapy using iPSCs has significant potential. Most importantly, the use of iPSCs will circumvent the ethical issues surrounding ESCs because their creation does not involve destruction of human preimplanted embryos. Furthermore, the ease and reproducibility of generating patient-specific immune-compatible iPSCs in sufficient numbers for regenerative, therapeutic, and research (high-throughput screening) purposes is clearly advantageous. Dermal fibroblasts and bone marrow mesenchymal cells have proven to be reliable starting sources for human iPSC reprogramming.[40,41] However, concerns about continuous passage *in vitro* leading to karyotopic abnormalities remain. Risk of insertional mutagenesis is always associated with retroviral and lentiviral vector techniques. Given the heterogeneous nature of the resultant cell population, selection marker panels need to be developed to better characterize these populations. And again, the low efficiency of reprogramming, possibly due to endogenous anti-reprogramming mechanisms in differentiated cells, will require larger numbers of the starting cell population.

To overcome the poor efficiency of reprogramming and reduce the requirement of large initial populations, recent advances have incorporated the use of chemicals such as valproic acid, a histone deacetylase inhibitor,[42] and small molecule compound, Bix-01294, a TGF-β inhibitor.[43] Other strategies involve reducing the number of programming factors. Hester *et al.*[44] recently reported that the combination of Oct3/4 and either Klf4 or Myc are sufficient to generate iPSC cells from neuronal stem cells. Others have attempted to deliver all four factors in a single polycistronic viral vector, for a single integration site.[45] Still others have designed adenovirus, plasmids, or recombinase to excise reprogramming genes after iPSCs were generated, to increase reprogramming efficiency (http://stemcells.nih.gov). Finally, extensive screens of chemical libraries are currently under way to identify candidate small molecules that may be effective reprogramming agents.[43,46]

5.507.2.7. Endogenous Host Populations

Some tissue-engineered strategies do not involve the transplantation of cell-based therapies. Instead, biomaterials are designed in such a way that endogenous cells will appropriately respond via migration, proliferation, or differentiation. Endogenous cell populations can be recruited from local stem cell niches to proliferate and differentiate within a site of tissue damage. Local vascular beds can be recruited to form newly branched vessel networks within the material implant, and tissue-specific cells can be recruited to line the new material implant. For example, controlled release of small molecule, FTY720 (a target for various S1P receptors) from polymer-coated bone allografts improved bone ingrowth and increased total microvessel density within the defect space.[47] These studies highlight the ability of drug-eluting grafts to successfully recruit host cells to repopulate transplanted materials.

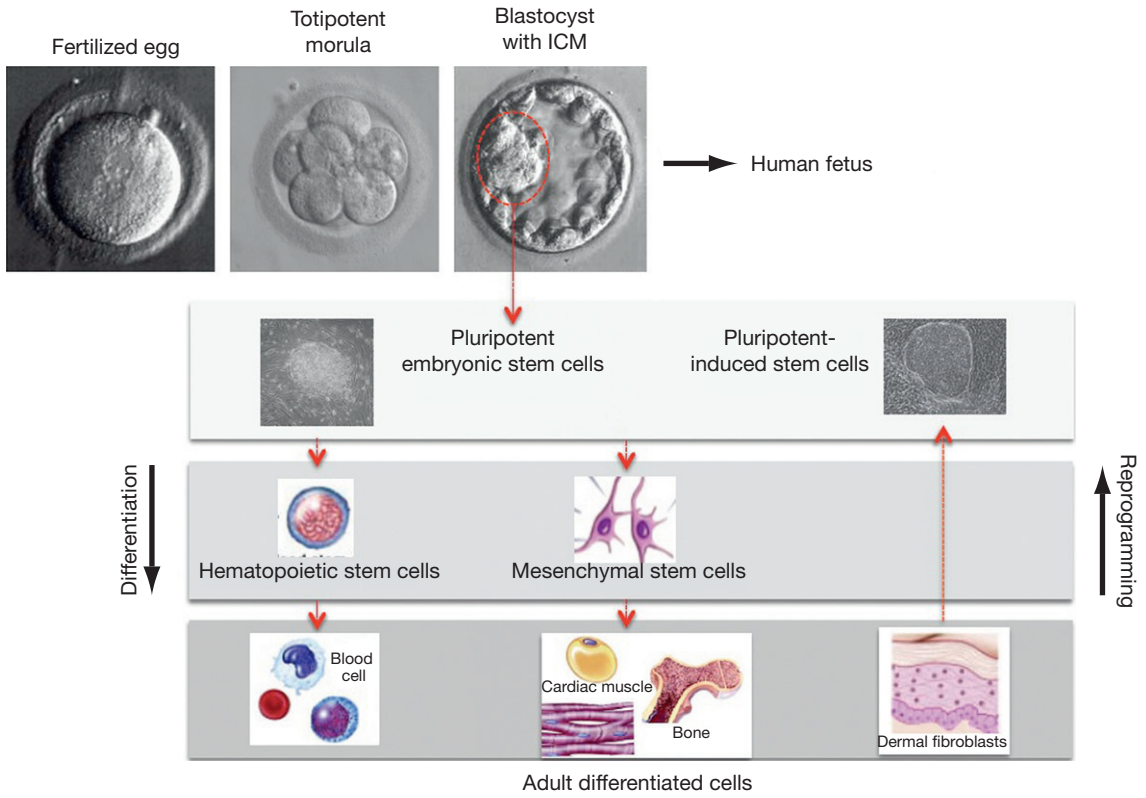

Figure 5 Conceptual flow diagram highlighting the differentiation pathway from fertilized egg to mature differentiated cell types of hematopoietic and mesenchymal lineages. Alternatively, reprogramming or dedifferentiation of mature committed cells can produce iPSCs that exhibit similar characteristics to pluripotent ESCs. These discoveries raise questions about terminal cell differentiation and the new role of plasticity in adult cells.

5.507.3. Patient Delivery Challenges: Controlling Cells in the Body

5.507.3.1. How Do We Control Cells to Survive *In Vivo* After Transplantation?

Delivery of cells *in vivo* exposes these populations to a host of survival challenges. Immune issues related to autoimmunity and inflammation are among the first pathways of assault and destruction of delivered cells. Degranulating neutrophil populations recruited to sites of tissue injury can release chemokines that can cause plasma leakage, recruitment/activation of phagocytic macrophage and mast cells that can lead to a hostile environment, and increased risk of cellular apoptosis and inflammation. Besides surviving the initial innate immune responses, transplanted colonies must also interact with the adaptive immune cascade or otherwise be targeted for elimination.

Apart from immunity, cells have basic metabolic requirements, including oxygen availability and waste exchange. It is now recognized that incorporation of functional mature vessel networks is required for all cell maintenance and tissue survival, save avascular sites such as cartilage. Proximity to existing vascular beds and the ability to establish and maintain new vascular networks are critical in maintaining this delicate balance of oxygen and nutrient requirements and waste removal. Material properties such as pore size and degradation can influence this balance.

5.507.3.2. How Do We Control Cells to Maintain Appropriate Phenotype *In Vivo*?

A significant challenge with all cell-based therapies is to ensure maintenance of appropriate phenotype *in vivo*, following transplantation. The challenge with transplanting tissue-specific cells is to *maintain* phenotype, following *ex vivo* expansion and reimplantation. The challenge with transplanting undifferentiated cells, including iPS cells, MSCs, and ESCs is to achieve appropriate *differentiation* and functional end-stage phenotype without leading to uncontrolled growth or inappropriate differentiation (Figure 6).

For undifferentiated cells, the intended end-stage phenotype may either be conferred before transplantation or posttransplantation. Thus soluble factors, mechanical or shear stimuli, can be applied in culture prior to implantation to establish appropriate differentiation. Alternatively, such factors or topographical surface features or chemistry can be applied to elicit similar differentiation pathways *in vivo* posttransplantation. Furthermore, interactions with the local milieu, including endogenous cells types, local matrix structures, and soluble chemokine gradients, can provide

Cell source	Donor type	*Ex vivo* expansion potential	Stemness	Tissue source	FDA approved for human use
Tissue-specific committed cells	Autologous or allogeneic	Low	Committed	Various	Yes, carticel for cartilage defects
Mesenchymal stem cells (MSCs)	Autologous or allogeneic	Mid	Multipotent	Bone marrow, fat, dental pulp, cord blood, placenta, muscle, cartilage, tonsil	Yes, Lou Gehrig's disease, heart disease, GVHD
Induced pluripotent stem cells (iPS)	Autologous	High	Pluripotent	Dermal fibroblasts, hair follicles	No
Embryonic stem cells (ESCs)	Allogeneic	High	Pluripotent	Fertilized egg	Yes, Geron for spinal cord injury
Endogenous host populations	Autologous	N/A	Committed	Various	Yes, i.e., devitalized bone grafts

Figure 6 The range of different cell sources utilized in cell-based therapies. Donor type, *ex vivo* expansion potential, tissue source, and examples of current FDA approval are highlighted for each cell source.

important instructional cues for appropriate differentiation and phenotypic maintenance.

5.507.3.3. How Do We Control Cells to Migrate . . . NOT to Migrate *In Vivo*?

Depending on the application, the desired motility of delivered cells could range from *stationary* (i.e., replace missing tissue) to *disseminating* (e.g., repopulate entire hematopoietic system). Sites of delivery can certainly influence these parameters. Subcutaneous injections provide initial point sources of cell entry, whereas intravenous injections immediately disseminate cells throughout the blood stream. Beyond this, biomaterials are expected to play an important role. For example, several cell-based vaccination approaches utilize alginate beads to physically encapsulate antigen-presenting cells (APCs) to act as a local hub for T-cell priming.[48] Coating delivery materials with extracellular matrix proteins or locally releasing growth factors can encourage host cell retention within the local regions. Other material properties such as stiffness,[49] pore size,[50] protease-control,[51] and integrin–ligand relationships[52] can all play a role in cell migration behaviors *in vivo*.

5.507.4. Donor Versus Host Immune Issues

The primary role of the immune system is to protect the individual against uncontrolled tissue damage and disease by appropriately identifying and destroying non-SELF pathogens and tumor cells. The ability of the immune system to effectively distinguish between SELF and non-SELF is critical in maintaining human health. Loss in this self-tolerance can lead to autoimmunity, a condition in which the immune system attacks healthy SELF cells misidentified as foreign. Autoimmune-mediated tissue destruction can result via two distinct pathways: (a) autoimmune disorders that arise from errors in self-regulating machinery and (b) immune responses triggered by delivering poorly matched allogeneic or xenogeneic materials into SELF. Cell-based transplantation therapies fall into the second category of autoimmune responses, where donor-derived T-cells can recognize recipient tissues as foreign, resulting in tissue attack and a 30–60% mortality rate.[53] Thus, all clinical therapies utilizing cell sources to replace damaged and diseased tissues must also address issues of immune surveillance.

Typically, autologous cells isolated from SELF, expanded, and reintroduced into SELF do not trigger foreign body responses because the cell source is identically matched to each patient. However, cell harvest from adult tissue is limited, associated with donor-site morbidity, and success rates in deriving multipotent cell lines from adult tissues are poor. Furthermore, there are various *ex vivo* treatments, including genetic modifications, that may significantly alter cellular properties so as to induce an immune response.[54] Thus, finding strategies to circumvent locally or alter immune surveillance systemically would enable wider applicability of allogeneic (cell sources from other human donors) and xenogeneic (cell sources from animal donors) cell-based therapies.

Cell transplantation from non-SELF sources triggers the immune system via mismatch in major histocompatibility molecules (MHC I and II). Professional APCs, including dendritic cells (DCs), macrophages, and B cells use these two classes of molecules as presentation platforms on the cell surface to display peptide fragments from both SELF and foreign

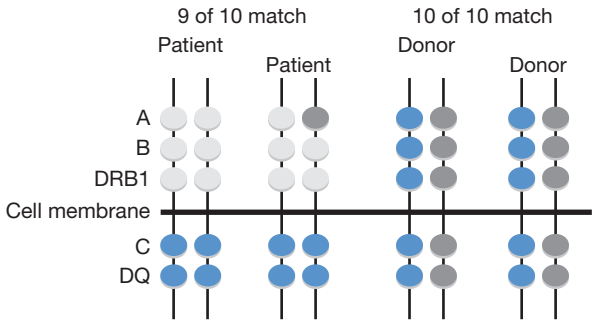

Figure 7 Major histocompatibility complex molecules come in two classes: I and II. These molecules are found on the surface of antigen-presenting cells (APCs), which include dendritic cells, macrophages, and B-cells. APCs use their MHC molecules as a platform to present antigen to local T-cells. Reorganization of an antigen signature by a T-cell initiates the adaptive immune cascade. In the case of cell transplantation, this can led to either graft rejection or autoimmunity. Half of one's HLA markers are inherited from one'smother. The other half are inherited from one's father. So identical donor matches from siblings is 25%. The National Marrow Donor Program sets a minimal requirement that five of six HLA markers must match to be used for transplant.

antigens to T-cells. One set of alleles (haplotype) is inherited from each parent, and thus haplotypes must be closely matched for successful allogeneic transplantation. Therefore, hyperacute (within hours) or delayed rejection (within days) of xenografts occurs primarily because of a severe mismatch in MHC and complement molecules (Figure 7).

Because haplotypes are inherited, immediate family members are typically the best match for a bone marrow transplant or a kidney donation. However, new strategies are emerging to combat this strict requirement for MHC matching. For example, the MHC locus may be targeted by homologous recombination (a type of genetic recombination to exchange nucleotide sequences between similar DNA molecules) to remove or replace donor-derived HLA molecules in donor ESCs.[55] Chromosomal-elimination cassettes can also be engineered to jettison the entire chromosome 6, which contains MHC haplotypes, during S phase and effectively replace donor chromosomes with recipient copies.[56] Conceptually, these strategies could eliminate mismatched MHC issues, but they are highly inefficient and potentially hazardous if karyotypic stability is affected. Alternatively, creation of a mixed chimera has also been attempted to induce donor-specific tolerance.[57] For example, a mixed chimera is created by irradiating SELF bone marrow and subsequently repopulating bone marrow with both SELF and donor bone marrow isolate. In this way, there is coexistence of SELF and donor HSCs, resulting in coengraftment of SELF and donor immune cells within the recipient thymus.

Fortuitously, allogeneic *cell* transplants have significantly reduced immunogenic issues compared with *whole-organ* transplants. For example, by selectively removing APCs (i.e., DCs, macrophages, and B cells) from the transplant pool, the potential of the newly transplanted cells to recognize SELF as foreign is reduced. Furthermore, immune surveillance can be minimized by delivering allogeneic cells to regions distal from vessel structures and/or encapsulated within delivery materials to prevent access from the host immune system via blood. Selecting allogeneic cell populations with reduced MHC expression will also help reduce host rejection of transplanted cells.

5.507.4.1. Immunomodulatory Role of MSC Populations

In 2002, emerging evidence began to suggest an interesting immunoregulatory role for adult MSCs. Specifically, this stem cell population has low antigenicity with no expression of MHC II and low expression of MHC I and costimulatory molecules. Furthermore, studies demonstrated that MSCs are capable of suppressing both T-cell proliferation and activation in response to allogeneic antigens. These immunomodulatory properties are not limited to bone marrow-derived MSCs alone, but have also been shown in MSCs derived from other tissues.[58] Also, T-cells are not the only cell type within the immune system upon which MSCs have been shown to exert their modulating effects. MSCs also play an influential role in DC differentiation, maturation, and phenotype maintenance. Specifically, coculture with both human and murine MSCs *in vitro* prohibits differentiation of monocytes and $CD34^+$ progenitor cells into antigen-presenting DCs.[59] Furthermore, MSCs can reduce expression of MHC II, CD40, and CD86 on DCs following maturation induction[60,61] and have also been shown to alter B-cell proliferation,[62,63] activation, IgG secretion,[64] differentiation, antibody production, and chemotactic behaviors (Figure 8).[65]

Perhaps the most exciting data supporting the immunomodulatory role of MSCs are from *in vivo* studies conducted in humans, which demonstrate successful treatment of GVHD, a condition where donor cells recognize SELF as foreign and attack recipient tissues. Specifically, treatment with *ex vivo* expanded allogeneic MSCs successfully resolved severe grade IV acute GVHD.[66] Thus, a growing body of *in vivo* evidence now supports the hypothesis that MSCs have immunosuppressive properties, including (*murine*) prevention of GVHD,[67] decreased graft rejection,[68] prevention of experimental acute encephalomyelitis,[69] (*baboon*) prolonged skin graft survival,[70] (*rat*) protection against renal ischemia/reperfusion injury,[71] (*human*) HSC engraftment with no GVHD,[72] platelet engraftment with low incidence of GVHD,[66] and resolution of severe acute GVHD.[73] Furthermore, new studies suggest that MSCs can retain these immunosuppressive properties even after manipulation, such as phenotypic differentiation and genetic engineering. Specifically, allogeneic MSCs that were differentiated toward a chondrogenic phenotype continued to suppress antigen-specific T-cell proliferation in rheumatoid arthritis[74] and locally transplanted MSCs genetically engineered to produce bone morphogenetic protein-2 (BMP-2) escaped immune rejection and induced ectopic bone formation *in vivo*.[75]

However, in 2005 Djouad *et al.* reported the first indication that immunomodulatory properties were not universal and unconditional. Specifically, allogeneic MSCs delivered to a murine collagen-induced arthritis model did not confer any benefit, and paw swelling worsened compared with control groups. Furthermore, coincubation with tumor necrosis factor-alpha (TNF-α) was sufficient to reverse the immunosuppressive effects of MSCs on T-cell proliferation.[76] Others reported similar

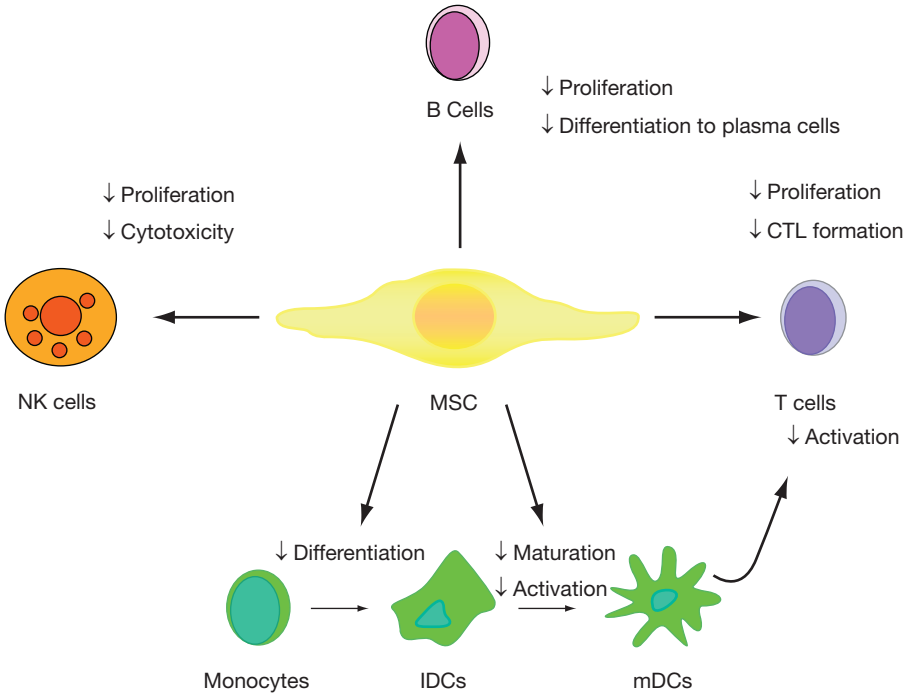

Figure 8 Signaling pathway map highlighting MSC immunomodulation properties on various cell types within the immune system. Overall, MSCs have been shown to decrease T-cell, B-cell, and NK cell proliferation and prevent maturation and differentiation along the monocyte/DC lineage. Reproduced from Nauta, A. J.; Fibbe, W. E. *Blood*, **2007**, *110*(10), 3499–3506.

results where MSC transplantation failed to alleviate GVHD in a murine model, even though *in vitro* assays confirmed suppression of T-lymphocyte proliferation.[77] More recently, repeated intravenous injections of MSCs failed to reduce GVHD-related recipient mortality. Most interestingly, local implantation of MSCs derived from bone marrow, placenta, or umbilical cord prompted ectopic bone formation in syngeneic recipients and ultimately led to transplant rejection by allogeneic mice.[78] Taken together, these results suggest that MSC phenotype is transient and context dependent.

That MSC phenotype and function may be particularly susceptible to the microenvironmental context suggests that, in terms of their trophic and phenotypic characteristics, MSCs may not have an entirely autonomous program, but instead may be influenced by the surrounding microenvironment. In this way, isolation from resident niches, subsequent expansion *ex vivo*, and redelivery to a remote inflamed or injured site where inflammatory chemokines and bioactive extracellular matrix fragments are abundantly present may heavily influence MSC behavior and function. Therefore, issues related to appropriate delivery mechanisms, timing of delivery, and manipulation of the injury site microenvironment are of utmost importance in the study and application of MSCs.

5.507.5. Donor Versus Host: Cell/Tissue Integration

To overcome the failure of organs and tissues is the goal of tissue engineering, and in this lies the expectation that the injected cells or the grafted cell-laden tissue construct will be well-integrated with the host tissue. Many levels of integration must occur, including physical, metabolic, and functional, which in turn determine the ultimate success of the cell-based therapy. For example, for musculoskeletal tissues, it has been well established that, unlike during musculoskeletal tissue development, postinjury regeneration between soft tissue and bone does not occur.[79] Interfaces that often challenge tissue engineers are cartilage-to-bone, ligament-to-bone, and tendon-to-bone integrations. Specific examples of advances in the cartilage-to-bone (osteochondral) integration are provided in this section to illustrate the importance of this issue.

Physical integration is particularly important when the interface is between such distinct tissue types. Specifically, it is desirable to engineer a functional gradient of mechanical properties that approximates that of the native interface. For example, at the osteochondral interface, which barriers articular cartilage and subchondral bone, there is a precisely controlled heterogeneity in the ultrastructure that is important for the load bearing and force distribution.[80] Directly interfacing the bone is the deep zone of articular cartilage that contains hypertrophic chondrocytes within a densely mineralized extracellular matrix.[81,82] Recently, scaffolds have been designed with multiple phases and seeded with phase-relevant cell populations to engineer the osteochondral interface.[83]

One early example of a biphasic scaffold approach was to take two separate scaffold—one a hyaluronan sponge seeded with MSCs stimulated with TGF-β1 for chondrogenic differentiation and the second a porous calcium phosphate scaffold seeded with MSCs stimulated with osteogenic media—and to join them by a fibrin sealant. In this study, Gao *et al.*[84] implanted the scaffold into rats and observed the presence of continuous collagen fibers between the two scaffolds at

6 weeks postimplantation. Continuous biphasic scaffolds have been developed, for example, by utilizing a sequential photopolymerization technique to form an osteochondral construct with a polyethylene glycol-diacrylate hydrogel. The top and bottom hydrogel layers contained MSC-derived chondrocytes and osteoblasts, respectively.[85] Histological examination 12 weeks postimplantation into a subcutaneous SCID mouse model revealed distinct cartilaginous and osseous regions with integration between the two scaffold layers. A number of other studies have confirmed these observations with MSCs cultured on biphasic scaffolds.[86–90]

With an increase in complexity, a triphasic scaffold was designed that had an agarose hydrogel-based cartilage region, a polymer–ceramic composite microsphere bone region, and an interfacial region consisting of a hybrid of the hydrogel and polymer–ceramic composite.[91,92] The hydrogel was seeded with chondrocytes and the composite with osteoblasts. Although *in vivo* validation has not yet occurred for triphasic scaffolds, they are intended to provide superior integration compared with other more simplified tissue-engineered constructs.

Important attributes to consider and evaluate for successful tissue integration *in vivo* are the host environment plus the precise effects of biochemical and physical stimulation on the interface. There is also the need for physiologically relevant *in vivo* models to determine the clinical potential of the designed scaffolds. It is also necessary to determine how existing tissues will attach to stratified scaffolds to direct tissue growth and reestablish the native interfacial organization. Additionally, the selection of multiple cell sources is typically necessary to ensure or enhance heterogeneous tissue formation. In addition to optimization of methods for sterilization and potentially long-term shelf storage of the scaffolds, the identification of an optimal cell source that is readily available (i.e., quickly isolated and expanded), such as an adult stem cell source, will be required for the clinical implementation of these scaffolds.

5.507.6. Safety and Stability

It is imperative to ensure the clinical safety and stability of stem cell-based products for their success in the clinic. The FDA is responsible for evaluating the safety profile of stem cell-based products that are intended for clinical studies. Because stem cells have an extensive ability to proliferate and differentiate, the FDA has put into place a gamut of safety concerns relating to each stem cell-based product.[93] With respect to the use of iPS and ESCs in particular, the FDA requires preclinical testing due to the characteristic ability of these pluripotent stem cells to form teratomas after injection into adult, immunodeficient mice. An example of a cell-based product approved by the FDA is Carticell, an autologous cartilage tissue replacement therapy (**Figure 9**).

Several additional safety concerns exist pertaining to the use of stem cell-based products, including the mobility of stem cells to a site other than where injected, spontaneous malignant transformation due to prolonged *ex vivo* expansion, the expression of cell/tissue donor human leukocyte antigen molecules that causes immunogenicity, and the possibility of cellular impurities in the differentiated cell product.

The *in vitro* culture of human ES and iPS cells has traditionally involved the use of irradiated mouse embryonic fibroblast feeder cells to maintain the cells in a stem state (i.e., proliferating and undifferentiated, yet maintaining pluripotency). The use of organs, tissues, and cells derived from animals to treat human disease, or xenotransplantation, raises concerns

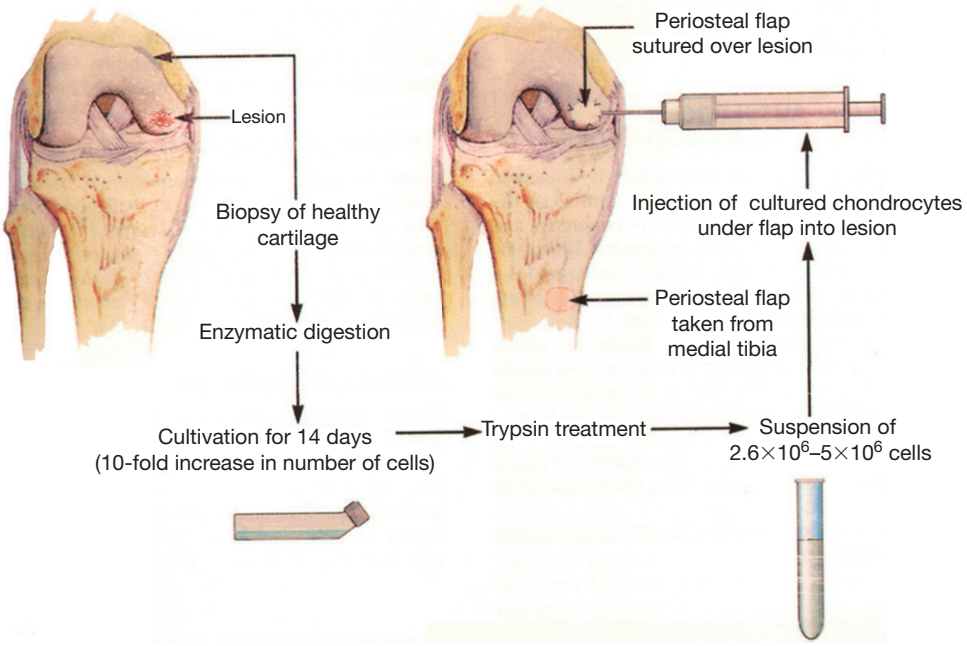

Figure 9 In 1997, FDA approves first biologic license to Carticel for manipulated autologous structural cell therapy. Here, biopsy of healthy cartilage is taken from the patient, expanded *ex vivo*, and reimplanted at the lesion site. Figure from http://www.drmendbone.com/swedish.htm

about the unintended transfer of animal viruses into humans. In turn, researchers have considered alternatives to the use of mouse feeder cells. For example, human foreskin fibroblasts have been shown to be comparable in their ability to maintain human ES and iPS cells in a stem state.[94,95] Furthermore, it has been shown that the stem state of these cells can be maintained by seeding them onto a commercially available basement membrane matrix and culturing them in medium conditioned by feeder cells.[96]

The FDA has suggested comprehensive characterization of stem cell-based products by using a multiparametric testing approach. The recommended tests that target cell types within a stem cell-based product include comprehensive examination of cellular morphology, phenotype-specific cell surface antigens, unique biochemical markers, and the genome and/or proteome profile. To test for safety against the possibility of spontaneous malignant transformation, the stem cells can be karyotyped and their *in vitro* growth kinetics can be routinely measured, along with their differentiation potential. Additionally, stem cell cultures should be tested to ensure that they are free of microbial (bacterial/fungal) and mycoplasma contamination.

Most stem cell cultures require the use of serum-containing medium for their growth and survival. The use of serum in clinical studies has long been under contention, especially due to the outbreak of bovine spongiform encephalopathy (BSE) in cattle herds (mostly those raised in the United Kingdom). The FDA has indicated that use of bovine serum is acceptable provided demonstration that the source of serum is from herds reared for the entirety of their lives in certified, BSE-free countries. Furthermore, the use of clinical-grade serum sourced from humans is also accepted. Alternatively, a serum-free, chemically defined medium can be developed that obviates risks associated with serum supplementation from either bovine or human sources.

In the design of preclinical animal studies, there are further toxicological assessments that need to be performed. Specifically, comprehensive histological examination should be performed to provide evidence for implant site reaction, inflammatory response in target and nontarget tissue, host immune response, cellular fate plasticity, morphologic alterations in target or nontarget tissues, cell survival posttransplantation, cell migration, tissue integration, and tumorigenicity (hyperplasia or uncontrolled growth). Moreover, the stem cells should be shown to have the desired biological activity. Relevant bioassays that measure the potency of stem cell preparations are important for showing that the cells are not inert.

In summary, the assessment of human stem cell safety requires a comprehensive multiparametric analysis. This analysis must begin from the initial isolation of the stem cells, and continue through the characterization and assessment of their safety and stability in culture and in preclinical animal studies. The strategies should be routine, systematic, and carefully scrutinized at every step of the process, for consideration by the FDA for approval of a cell-based therapy.

5.507.7. Conclusion

Cell-based therapies have expanded the possibilities in the clinic such that genetically faulty, dying, injured, or damaged cells can be effectively replaced. Adult tissue-derived MSCs, though limited in differentiation/expansion potential, are immune-privileged cells that are currently being used in a large number of clinical trials and applications. Better understanding of MSC immunomodulatory mechanisms may reduce rejection issues and expand applicability of allografts and xenografts and cells derived from these sources. ESCs represent an excellent platform for studying developmental and pathogenic processes, but their clinical application continues to encounter significant ethical complications. With the recently discovered cell reprogramming technology, iPSCs may be directly derived from adult somatic cells. However, their potential tumorigenicity and uncertain long-term functional stability must be overcome to realize the clinical therapeutic potential of this cell source. Xenogeneic cells offer new possibilities, provided immune rejection issues can be effectively overcome. Finally, the use of appropriate 'smart' biomaterials is critical for cell-based therapy to enhance cell delivery, host integration, range of function, and long-term recovery.

Glossary

Biomaterial A material that can be either natural or synthetic and that comprises either the whole or a part of a living structure or biomedical device that performs, supplements, or replaces a natural function.

Conditioned media Media taken from cell culture that contains growth factors and other molecules that have been secreted by the cells.

Ectoderm One of the three germ layers formed during embryogenesis that gives rise to the nervous system and the epidermis.

Embryoid body Aggregates of embryonic stem cells usually grown in suspension culture.

Embryonic stem cell Pluripotent cells derived from embryos or fetal tissue with the capacity for self-renewal.

Endoderm One of the three germ layers formed during embryogenesis that gives rise to the gastrointestinal and respiratory tracts along with the organs of the endocrine system.

Extracellular matrix The matrix that surrounds cells and consists of a complex mixture of proteins, proteoglycans, and other molecules.

Feeder layer A layer of cells that secrete specific factors into the media to allow for the culture of the desired cell line in coculture.

Hydrogel A network of polymer chains that are water insoluble but possess a high water content.

Karotype Characterization of the chromosomal content of a eukaryotic cell that can be used to evaluate if a gross genomic aberrations or abnormalities are present in a cell line.

Matrigel A commercially available mixture of basement membrane proteins, including laminin and collagen, and proteoglycans that are secreted by Engelbreth–Holm–Swarm (EHS) mouse sarcoma cells as their extracellular matrix.
Mesoderm One of the three germ layers formed during embryogenesis that gives rise to muscle, bone, connective tissues, and the dermis layer of skin.
Niche Term used to describe the microenvironment that encompasses stem cells, composed of matrix, growth factors, small molecules, and adjacent cells.
Passage The process of maintaining a cell culture that has neared or reached confluence by diluting the number of cells present and replating to allow for continuous culture.
Self-assembled monolayer A monolayer that is formed by self-organizing amphipilic molecules that possess a polar head group and nonpolar tail where the polar head group shows a specific affinity for the substrate for monolayer formation.
Vasculature The network of blood vessels found in tissues.

Abbreviations

AT	Alkanethiols
bFGF	Basic fibroblast growth factor
Cbfa1	Core binding factor alpha1
EBs	Embryoid bodies
ECM	Extracellular matrix
EHS	Engelbreth-Holm-Swarm
ELISAs	Enzyme linked immunosorption assays
GABA	γ-aminobutyric acid
HA	Hyaluronic acid
hESC	Human embryonic stem cell
HGF	Hepatocyte growth factor
IKVAV	Isoleucine–lysine–valine–alanine–valine
IPSCs	Induced pluripotent stem cells
LIF	Leukemia inhibitory factor
MEF	Mouse embryonic fibroblast
NGF	Nerve growth factor
PCR	Polymerase chain reaction
PDL	Poly-(D-lysine)
PDMS	Polydimethylsiloxane
PEG	Poly-(ethylene glycol)
pHEMA	Poly-(hydroxyethyl methacrylate)
PLGA	Poly-(lactic-*co*-glycolic acid)
PLLA	Poly-(L-lactic acid)
PTFE	Poly-tetrafluroethylene
qPCR	Quantitative polymerase chain reaction
RGD	Arginine–glycine–aspartic acid
SAMs	Self-assembled monolayers
SCID	Severe combined immune deficiency
sIPNs	Semi-interpenetrating polymer networks
SSEA-3	Stage-specific antigen 3
SSEA-4	Stage-specific antigen 4
TGF-β	Transforming growth factor β
TRA-1-60	Tumor recognition antigen 1-60
TRA-1-81	Tumor recognition antigen 1-81
VEGF	Vascular endothelial growth factor
2D	Two dimensional
3D	Three dimensional

5.508.1. Introduction

This chapter will discuss the use of biomaterial scaffolds for the culture and differentiation of human embryonic stem cells (hESCs). The first section will provide definitions of stem cells and biomaterials and associated terminology, as well as describe the experimental techniques needed to study these cells. Section 5.508.2 will describe the research that has been conducted using biomaterials for culturing undifferentiated hESCs, while Section 5.508.3 will discuss the use of such materials for promoting hESC differentiation into specific phenotypes. Finally, Section 5.508.4 summarizes this field along with a discussion of future trends and directions.

5.508.1.1. Defining Stem Cells and Potency

Stem cells possess two defining characteristics: (1) the ability to self-renew, or proliferate and maintain themselves in an undifferentiated state, and (2) the ability to differentiate into one or more cell phenotypes. A variety of different stem cell types exist – including embryonic, fetal, and adult – and each has different properties such as varying degrees of potency, that is, the ability to differentiate into multiple cell types. Cells with the ability to differentiate into all of the cell types found in an organism along with the associated extraembryonic structures, such as the placenta, are referred to as totipotent. Pluripotent cells can differentiate into any cells in the different germ layers of an organism, and thereby give rise to all cell types in an adult organism, but lack the initial ability to generate the extraembryonic structures. Other classes of stem cells include unipotent (possessing the abilities to self-renew, but only to differentiate into one cell type) and multipotent (the ability to give rise to a subset of cell types). These final two typically include tissue-specific stem cells, such as muscle stem cells and neural stem cells, that typically differentiate into cells associated with that tissue.

5.508.1.2. Derivation of hESCs

hESCs are pluripotent cells derived from human embryos. The first hESC lines were generated in 1998 from the inner cell mass of human blastocysts (Figure 1),[1] which were obtained by culturing cleavage stage human embryos generated via *in vitro* fertilization. To confirm that viable and stable hESC lines are produced, the cells were continuously cultured for 4–5 months to demonstrate their ability to continuously proliferate,

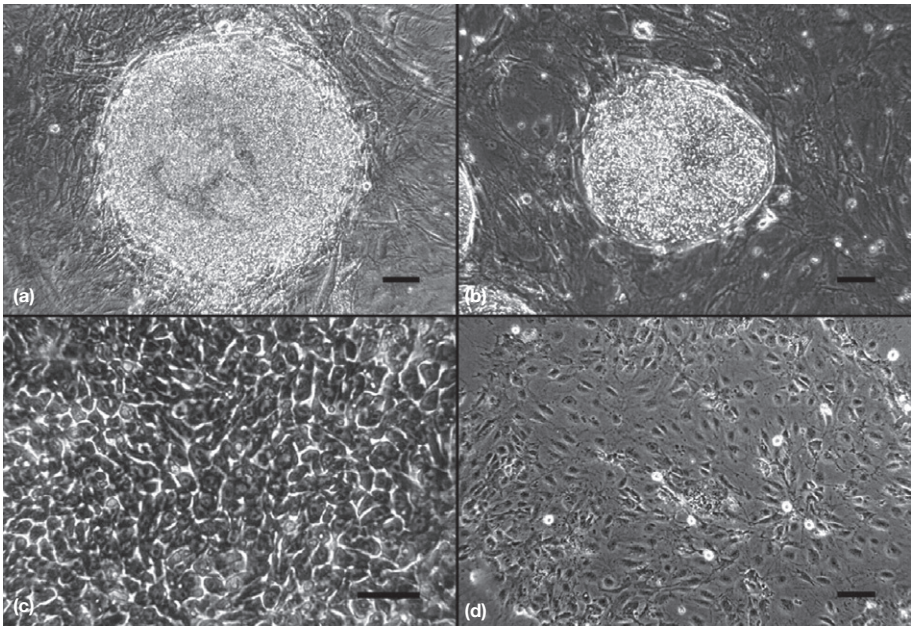

Figure 1 Derivation of the H9 cell line. (a) Inner cell mass-derived cells attached to a mouse embryonic fibroblast feeder layer after 8 days of culture, 24 h before their first dissociation. Scale bar, 100 μm. (b) H9 colony. Scale bar, 100 μm. (c) H9 cells at higher magnification. Scale bar, 50 μm. (d) Differentiated H9 cells, cultured for 5 days in the absence of mouse embryonic fibroblasts, but in the presence of human leukemia inhibitory factor (LIF) (20 ng ml^{-1}; Sigma). Scale bar, 100 μm. Reprinted from Thomson, J. A.; Itskovitz-Eldor, J.; Shapiro, S. S.; *et al*. *Science* **1998**, *282*, 1145–1147, with permission from The American Association for the Advancement of Science.

differentiate into cells from all three germ layers (endoderm, ectoderm, and mesoderm), and maintain a stable karyotype. Additionally, undifferentiated hESCs express a number of markers – including stage-specific antigens 3 and 4 (SSEA-3 and SSEA-4) and the transcription factors Oct4, Sox2, and Nanog – that can be used to confirm the successful generation of a new hESC line and confirm the maintenance of a hESC state for existing lines. Further studies have confirmed the ability of hESCs to differentiate into numerous cell types from various tissues, including neuronal, glial, endothelial, cardiomyocytes, beta cells, muscle cells, and osteogenic lineages.[2–5] Their pluripotency makes hESCs highly desirable for tissue engineering applications, as this single cell type provides the means to produce any cell present in the adult body, and their ability to self-renew yields a way to continually generate cells for these therapeutic purposes.

5.508.1.3. Standard Culture Methods for hESCs

The first hESC lines were isolated and cultured on feeder layers of irradiated mouse embryonic fibroblasts.[1,6] In general, feeder layers are a cellular monolayer that is cocultured with the desired cell type (in this case hESCs) and provides nutrients and growth factors necessary for the latter's survival and proliferation. A variety of cell types have since been used as feeder layers to support hESC culture, including human fetal, foreskin, and adult fibroblasts as well as adult human marrow cells.[7–9] In the interest of avoiding the use of feeder layers and thereby moving toward more defined and reproducible culture systems, hESC were then propagated on the substrate Matrigel in the presence of conditioned media derived from mouse embryonic fibroblast cultures.[10] Matrigel consists primarily of a mixture of basement membrane proteins, including laminin and collagen as well as proteoglycans that are secreted by the Engelbreth–Holm–Swarm (EHS) mouse sarcoma cell line as their extracellular matrix.[11] The highly complex and heterogeneous nature of Matrigel[12] means that its exact composition varies from batch to batch, making it less than ideal for hESC culture. Furthermore, the animal proteins present in Matrigel as well as from feeder layers could potentially transfer immunogens to hESCs, which could elicit a downstream immune response against transplanted stem cells.[13]

To generate hESC lines for clinical applications, the cells should ideally be cultured in fully defined conditions. To this end, many groups have worked toward developing defined hESC culture conditions, a challenging problem since the factors known to support mouse ESC culture did not directly translate to hESC culture. In 2006, Ludwig *et al*.[14] described the derivation of new hESC lines in defined media that did not require the use of a feeder layer. Their methodology involved using chemically defined media referred to as TeSR1 that contained basic fibroblast growth factor (bFGF), lithium chloride, γ-aminobutyric acid (GABA), pipecolic acid, and transforming growth factor-β (TGF-β), though the system still utilized Matrigel as a substrate for hESC adhesion. The Geron Corporation, a leading company advancing human stem cell therapies, has developed an alternative system composed of X-VIVO 10 medium (Cambrex Corporation) supplemented with bFGF and TGF-β1 for culturing their hESC lines on Matrigel.[15] More recent work has suggested that the use of Noggin in combination with the Matrigel culture system can help hESCs remain undifferentiated.[16] However, each of these

systems utilized Matrigel as a substrate, and there are considerable efforts underway to replace Matrigel with a defined substrate.

5.508.1.4. Techniques for Evaluating the Differentiation State of hESCs

Some of the most important considerations when working with hESCs are how to evaluate and characterize their differentiation potential and state. This section will discuss the different experimental techniques that are used for such purposes, including both analysis of marker expression and functional validation of pluripotency. It is important to have markers that can be used to identify hESCs to validate that such a line has been produced and confirm that the cells have remained undifferentiated after extended periods of culture. Similarly, it is necessary to identify specific markers of differentiation states when trying to generate specific cellular phenotypes from hESCs or confirm the pluripotency of a hESC line. Finally, these marker expression analyses should be combined with functional assays to confirm cell potency. See **Chapter 3.314, Materials to Control and Measure Cell Function** for further reading on analyzing cell behavior.

5.508.1.4.1. Markers for observing the differentiation state of hESCs

To take advantage of the potential of hESCs for therapeutic applications, it is important to analyze biological markers that can be used to assess their differentiation state. Previously identified markers that could be used for studying mouse ESCs do not always directly translate to hESCs, and this section will discuss the specific markers that can be used to study hESCs (summarized in **Table 1**).

Numerous markers are specifically or selectively expressed by undifferentiated hESCs,[25] including the glycolipids SSEA-3 and SSEA-4[17,26] that can be detected with antigen-specific antibodies. Another set of hESC markers includes the tumor rejection or tumor recognition antigens, TRA-1-60 and TRA-1-81, which are keratan sulfate derivatives.[1] Other very commonly used ones are transcription factors that are critical in maintaining hESCs pluripotency: Oct4, Sox2, and Nanog.[18–20]

In addition to analyzing self-renewal markers, the capacity for pluripotent differentiation, which can be characterized by the ability to differentiate into cells of the three germ layers found during human embryogenesis, must often be assessed. Markers used to identify the ectoderm lineage include nestin and β_{III}-tubulin.[21,22] Smooth muscle actin is often employed to detect cells from the mesoderm,[24] and α-fetoprotein is frequently utilized to identify the endodermal germ layer cells.[23] In addition to these commonly used markers, there are many alternatives used to detect cells from these germ layers. Finally, numerous downstream lineage- and cell-specific markers are utilized to monitor the process of hESC differentiation into a final desired differentiated phenotype.

Table 1 List of biological markers indicating differentiation state

Differentiation state	*Marker*	*References*
Undifferentiated hESCs	SSEA-3	[1]
	SSEA-4	[17]
	TRA-1-60	[1]
	TRA-1-81	[1]
	Nanog	[18]
	Oct4	[19]
	Sox2	[20]
Differentiated hESCs		
Ectoderm	Nestin	[21]
	β-tubulin	[22]
Endoderm	α-fetoprotein	[23]
Mesoderm	Smooth muscle actin	[24]

5.508.1.4.2. Experimental techniques for observing the differentiation state of hESCs

Numerous experimental methods exist to confirm the expression of the aforementioned markers, and this section will discuss the most frequently used techniques along with their relative advantages and disadvantages. Furthermore, in addition to marker expression, it is always important and often critical to utilize functional assays to confirm differentiation into specific cell phenotypes. While a variety of methods are employed to validate specific cellular phenotypes (such as electrophysiology for neuronal or cardiac differentiation, or enzyme and albumin synthesis for hepatocytes),[27,28] the commonly used functional assays for confirming hESC identity will be discussed in **Section 5.508.1.4.2.3**.

5.508.1.4.2.1. Immunostaining

Immunostaining is a standard technique that employs antibodies to detect and quantify antigen levels. This process involves using an antibody targeted against a specific molecule, referred to as the primary antibody, to detect its presence. A secondary antibody conjugated with either a fluorescent or enzymatic tag is used to bind to the primary antibody, and the presence of the marker can thereby be visualized and/or quantified through the use of a fluorescence microscope or by the addition of a colored substrate. While this process is extremely useful in allowing observation of proteins, it is important to perform proper controls to ensure that the desired antigen as opposed to background staining is being observed. Additionally, the quality of the staining is dependent on the specificity and quality of the primary antibody, and thus, different primary antibodies directed against the same target may yield different staining results. Nonspecific binding can often be reduced through enhancing blocking steps, often requiring the use of serum or other proteins, and through the use of wash steps that remove nonspecifically bound antibody.

Immunohistochemistry is a variant of immunostaining where the cells or tissue to be stained is preserved through fixation prior to the staining process. This method has the advantage of showing the various structures formed by cells in culture and in tissue. Other ways of performing immunostaining include the use of flow cytometry where the resulting mixture from the cells stained in solution is analyzed quantitatively using a flow cytometer instrument, allowing for the determination of the fraction of cells expressing a specific marker and at what levels. In addition to measuring fluorescence, the flow cytometer characterizes cells based on their size and granularity, which allows for the exclusion of dead cellular

matter as well as for the analysis of the composition of a specific cellular population based on size. Another commonly used immunostaining method is Western blotting. In this process, the cells to be analyzed are lysed, and the resulting protein mixture is electrophoresed on a gel to separate the proteins by size. The separated proteins are then transferred to a membrane that can be immunostained. The separation of proteins by size allows for a second confirmation of the antibody specificity by confirming that the protein being identified is the correct weight. Western blotting can also be used to compare the expression levels of target proteins in a semiquantitative manner. A more effective method for quantitatively comparing protein expression levels using immunostaining is enzyme-linked immunosorption assays (ELISAs). In this assay, the protein mixture to be analyzed is adsorped to a plate either through nonspecific binding or through the use of a capture antibody. A detection antibody conjugated with an enzyme is then used to detect the presence of the protein and the levels of protein are detected based on the enzymatic activity using either a colorimetric or chemiluminescence based substrate. One issue is the presence of background activity, which can be reduced through the use of blocking steps and washing. Overall, a variety of immunostaining techniques exist, and specific techniques should be chosen based on the desired information, such as protein location versus protein expression levels.

5.508.1.4.2.2. Polymerase chain reaction

Another means to assess the expression of the various differentiation markers is polymerase chain reaction (PCR). The process of PCR involves amplifying small quantities of DNA to generate detectable levels of DNA using a preset number of cycles that heat and cool the reaction containing the target DNA, gene-specific primers (short specific DNA sequences that bind to the target gene) and a thermostable polymerase, the enzyme that synthesizes new copies of the target gene. Thus, this method can be used to study the mRNA expression levels of target genes by first performing a reverse transcription reaction that converts mRNA isolated from hESCs into DNA. The PCR reaction can then be performed and the resulting products electrophoresed on an agarose gel to confirm that the target genes were expressed. While examining these products on a gel will allow for semiquantitative comparison of gene expression, numerous methods for quantifying DNA amplified in a PCR reaction, that is, quantitative PCR (qPCR), have been developed. One uses a fluorescently labeled dye that binds to double-stranded DNA, such that the amount of PCR product at each cycle can be quantified in real time using a qPCR cycler. Other methods involve the use of gene-specific DNA probes that fluoresce when they bind to a complimentary piece of DNA, or upon degradation of the probe by the polymerase during the amplification. These fluorescence-based detection methods require the use of a thermocycler (the instrument that cycles the temperatures during the PCR reactions) that is specially equipped to detect fluorescence. The additional use of a standard curve of known concentrations of the target gene can be used to calculate the number of copies of mRNA present in a sample. It is also possible to examine relative gene expression between two samples by normalizing the data for the samples obtained from a housekeeping gene such as β-actin that is constitutively expressed by the cells, though caution should be applied since the expression of housekeeping genes can sometimes vary with cell state. Additional caveats with using qPCR to analyze differentiation are that mRNA levels do not necessarily translate directly to protein expression, and that glycoproteins and polysaccharides cannot be detected by this method.

5.508.1.4.2.3. Functional assays for confirming hESC identity

In addition to these methods for analyzing the expression of characteristic markers by hESCs and their differentiated progeny, there are several standard assays conducted to confirm the integrity and functionality of hESC cells. These assays should also be performed periodically to confirm that an established hESC line is maintaining its properties. One of these methods is karotyping, a method used for characterizing the chromosomal content of a eukaryotic cell and evaluating whether aberrations or abnormalities such as chromosomal duplications or translocations are present in a cell line.[29] This process is important to ensure that cells with no gross genomic abnormalities are used for basic biological studies or downstream translational efforts, though modern methods such as next generation sequencing may aid in higher resolution analysis of genomic integrity. Another important assay for confirming hESC identity is to validate that the cells can undergo self-renewal – or be continuously cultured while maintaining pluripotency marker expression and normal karyotype – for an extended period of time, such as between 4 and 6 months. Another key assay is teratoma analysis, the injection of hESCs into immunodeficient mice to determine if they have the capacity to form teratomas, benign tumors that express tissues similar to those found in the three embryonic germ layers.[30] To confirm the presence of all three layers (ectoderm, endoderm, and mesoderm), histology followed by immunostaining for the aforementioned germ layer markers is performed.

5.508.1.5. Using Biomaterials for the Culture and Differentiation of hESCs

As described in Section 5.508.1.3, the use of chemically defined media in combination with Matrigel has been shown to support undifferentiated hESC culture. Matrigel is considered a biomaterial, and its success as a substrate for hESC culture suggests that other, more defined and controlled biomaterial surfaces could be used for this application. In general, a biomaterial can be defined as a material, either natural or synthetic, that comprises either the whole or a part of a living structure or biomedical device that performs, supplements, or replaces a natural function. In addition to coating two-dimensional (2D) surfaces for the culture and differentiation of hESCs, biomaterials can also be used as 3D scaffolds for these applications. This chapter will detail the various studies that have used biomaterials in combination with hESCs in both 2D and 3D culture, along with the relative advantages and disadvantages of such scaffolds. The first part of this chapter focuses on biomaterials used to culture and expand undifferentiated hESCs, and the latter discusses the use of scaffolds to direct hESC differentiation into specific phenotypes. These parts are further subdivided into natural materials, obtained from animals or plants, and synthetic biomaterials, of artificial origins.

5.508.1.6. Comparison of Natural Versus Synthetic Biomaterials

It is important to first consider the advantages and disadvantages of both natural and synthetic biomaterials. Natural materials have been developed from the different components that make up the extracellular matrix, such as proteins and polysaccharides, including, for example, Matrigel.[31] These components perform many roles *in vivo*, making the resulting materials attractive for tissue engineering applications since they typically contain sites for cellular adhesion and are biocompatible, meaning that the material does not typically induce an immune response upon implantation. However, some disadvantages include potentially large variability of the material depending on the source and the method of isolation, the need for robust purification of the protein or polysaccharide to both reduce variability and avoid triggering an immune response *in vivo*, potential challenges with supply in the case of human materials, and concerns with the transfer of pathogens from the animal or human materials into stem cells. Furthermore, as discussed below, scaffolds made from natural biomaterials tend to possess a limited range of mechanical properties compared to synthetic biomaterials, and it is very difficult to independently tune mechanics and the presentation of biochemical signals.
