Synthetic biomaterials offer a number of advantages compared to natural biomaterials, including reproducibility due to their defined chemical composition and the ability to control the mechanical properties, degradation rate, and shape independently.[31] The mechanical properties of a scaffold have been shown to play an important role in influencing stem cell differentiation.[32,33] Synthetic scaffolds can also be shaped, allowing for production of scaffolds that conform to specifications of an injury site. Engineering synthetic scaffolds with specific degradation rates can regulate the lifespan of the scaffolds in an *in vivo* setting as well as offer the capacity for controlled release of drugs incorporated into such scaffolds. However, a disadvantage for synthetic biomaterials is their inherent lack of bioactivity, such as sites for cell adhesion. These scaffolds are thus often biofunctionalized to introduce adhesion ligands, growth factors, and other activities. Other challenges include the need to carefully tune the biocompatibility of the material and its potential for inducing an immune response. See **Chapter 4.410, Sterilization of Biomaterials of Synthetic and Biological Origin** for further reading on preparation of scaffolds for implantation.

5.508.2. Biomaterials for Undifferentiated hESC Culture

As mentioned in **Section 5.508.1.3**, the current methods for culturing and expanding undifferentiated hESCs suffer from numerous limitations. The current methods for passaging hESCs are laborious and time consuming. Additionally, the highly complex and undefined nature of Matrigel may result in considerable batch to batch variability in its constituent proteins and polysaccharides.[12] This variability could, for example, introduce challenges in consistently maintaining pluripotency over time. Thus, an increasing focus has been placed on identifying the specific cues necessary to culture undifferentiated hESCs and designing biomaterial surfaces with defined chemical compositions to eliminate the variability encountered when using Matrigel.[34,35] A summary of the studies discussed in this Section is given in **Table 2**.

Table 2 List of biomaterials used for hESC culture

Type of material	*Material*	*References*
Natural	Alginate	[36,37]
	Hyaluronic acid	[38]
	Matrigel	[10,16,39–41]
	Serum	[41,42]
Synthetic	Acrylates	[43]
	Self-assembling monolayers	[44]
	Semi-interpenetrating polymers	[34]

5.508.2.1. Natural Biomaterials for Undifferentiated hESC Culture

This Section will detail the use of natural biomaterials for hESC culture and expansion. Natural biomaterials have been developed from the various proteins and polysaccharides that compose the extracellular matrix. These materials can be classified as heterogeneous biomaterials scaffolds, such as Matrigel and adsorbed human serum, and homogenous scaffolds, which have undergone more rigorous purification processes. See **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**; **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**; and **Chapter 2.221, Decellularized Scaffolds** for further reading on this subject.

5.508.2.1.1. Heterogeneous biomaterial scaffolds

Despite the limitations discussed in **Section 5.508.1.3**, the combination of defined media and Matrigel coated onto a 2D surface remains the current standard for culturing hESCs.[14,15,45] However, even when hESCs are cultured under these specific conditions, some random differentiation occurs due to local variations in the microenvironment. Patterning of Matrigel onto surfaces has been used as a method to help dissect such microenvironmental factors and properties that regulate self-renewal and differentiation. As a key example, Zandstra and colleagues used Matrigel micropatterning on 2D substrates to show that hESC colony size and composition regulated hESC differentiation by controlling local cell–cell signaling.[46] As mentioned in **Section 5.508.1.3**, the signaling activity of TGF-β helps hESCs remain undifferentiated by inhibiting the activity of Smad1. The effect of colony size on both Oct4 (expressed by undifferentiated hESCs) and Smad1 activity (as indicated by phosphoSmad activity) are shown in **Figure 2**. As colony size increases, a corresponding increase in Oct4 staining and decrease in pSmad staining are observed. Additionally they used small interfering RNA to knock down Smad1, which prevented differentiation. This study suggests that a critical hESC colony size is needed to antagonize the effects of Smad1 and thereby prevent hESCs from differentiating when seeded on Matrigel, thereby illustrating the principle that controlling cell–cell interactions may be necessary for maintaining hESC self-renewal.

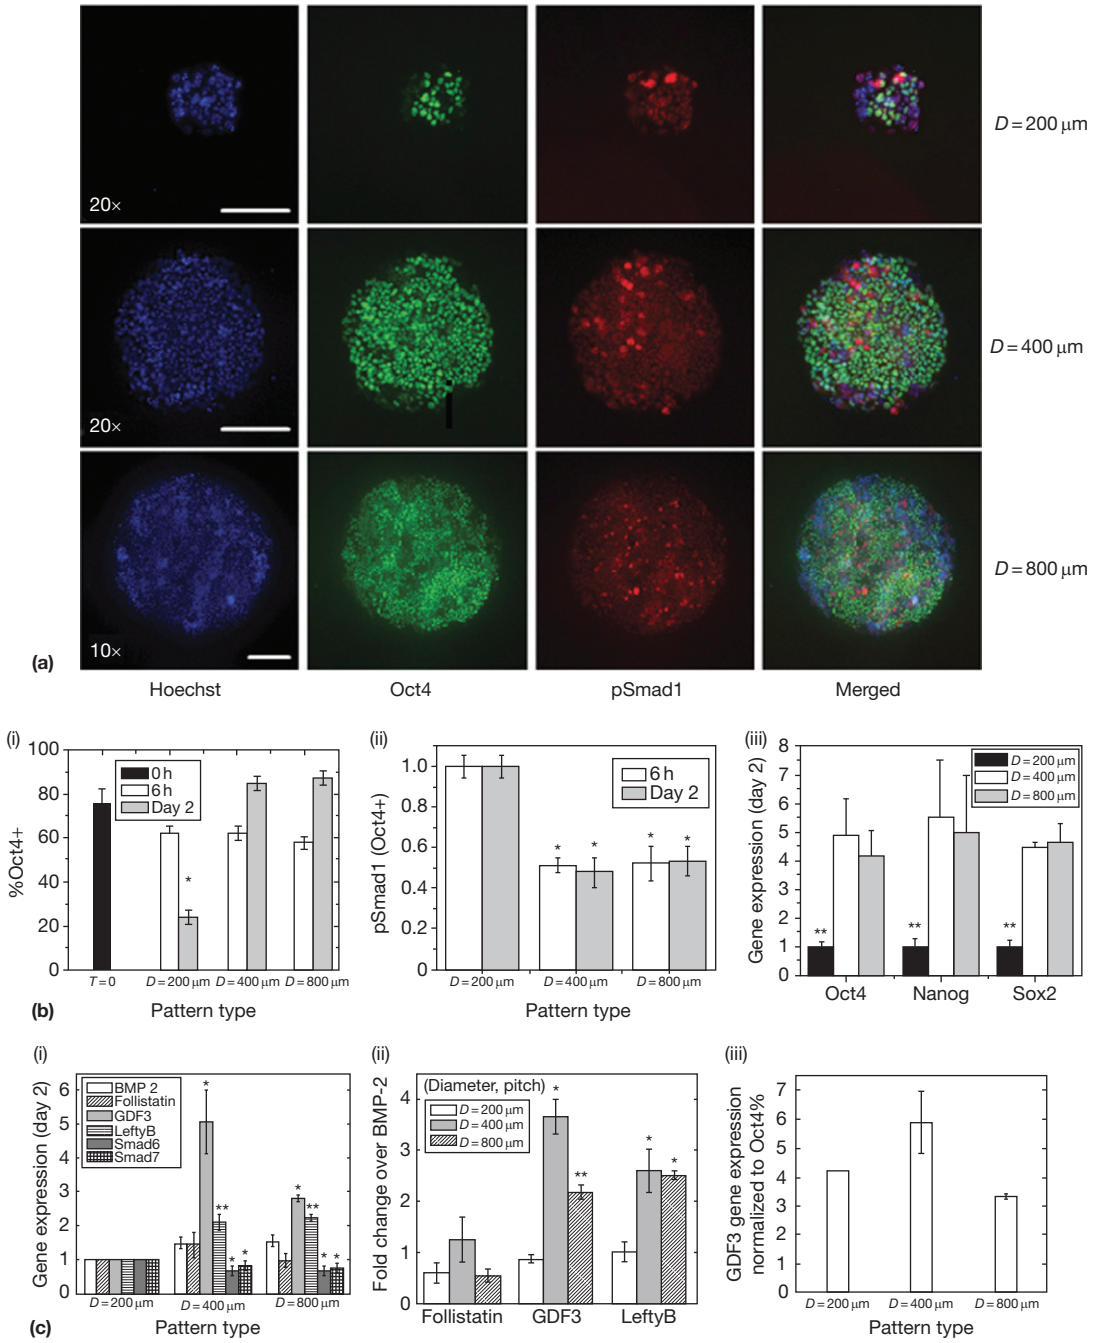

Figure 2 Micropatterning can be used to manipulate the human embryonic stem cell (hESC) microenvironment and control hESC fate. To demonstrate that the hESC microenvironment, and in particular local cell–cell interaction, directly controls hESC fate, H9 hESCs were plated on patterned tissue–culture substrates with Matrigel using microcontact printing. Colony diameters (*D*) ranged from 200 to 800 μm and distance between colonies, pitch (*P*), was fixed at 500 or 1000 μm. (a) Quantitative fluorescent microscopy of patterned H9 cultures in XV media after withdrawal of all growth factors for 48 h and stained for Hoechst, Oct4, and pSmad1. Scale bar is 200 μm. (b) Analysis of micropatterned colonies after 48 h. The percentage of Oct4 cells as a function of colony size (b-i). pSmad1 in the Oct4+ population as a function of colony size (b-ii). Gene expression for Oct4, Sox2, Nanog normalized to β-actin as a function of colony size (b-iii). (c) To elucidate the molecular mechanism for the changes in pSmad1 levels, gene expression was quantified as a function of colony size for Smad1 agonist, BMP2, and antagonists, Follistatin, GDF3 and LeftyB and I-Smads, Smad6, and Smad7. Gene expression after normalization to β-actin and relative to the 200 μm data set (c-i). Ratios of the transcripts of Smad1 antagonists, Follistatin, GDF3 and LeftyB, to the transcripts of Smad1 agonist, BMP2, as a function of colony size (c-ii). GDF3 gene expression as a function of colony size normalized to the percentage of Oct4+ cells present (c-iii). For (c-i), statistical comparisons were made between gene expression for each cytokine in 400 and 800 μm colonies against the expression at 200 μm colonies. For (c-ii), statistical comparisons were made between the ratio of the levels of transcripts of the antagonist to BMP2 between the 400 and 800 μm colonies against the ratio present in the 200 μm. Figure 3 Schematic of microwell fabrication depicting spatial localization of physical and chemical constraints to human embryonic stem cell (hESC) attachment and propagation. Microwells are formed by cross-linking polyurethane (PU) prepolymer. Gold is evaporated on the surfaces surrounding the wells and the sides of the wells at an oblique angle, but the bottoms of the wells are shielded from gold. A triethylene glycol-terminated alkanethiol self-assembled monolayer (EG terminated SAM) is then assembled on the gold surface to repel extracellular matrix (ECM) proteins and cells. The wells are then treated with Matrigel, which adsorbs to the bare PU at the bottoms of the wells. Cells are then cultured in the Matrigel-coated wells. Structures are not to scale. Reprinted from Mohr, J. C.; De Pablo, J. J.; Palecek, S. P. *Biomaterials* **2006**, *27*, 6032–6042, with permission from Elsevier.

hESCs tend to aggregate, thereby forming 3D structures in 2D culture, and another group developed a 3D hESC culture that also involved Matrigel patterning (**Figure 3**).[39] To first generate the microwell structure, photolithography was used to pattern polydimethylsiloxane (PDMS) masters, which were used to mold polyurethane into the desired structures. The resulting microwells were stabilized by UV-induced cross-linking. The resulting microwells were then functionalized with self-assembled monolayers (SAMs) – a monolayer that is formed by self-organizing amphiphilic molecules that possess a polar head group and nonpolar tail, where the polar head group has a specific affinity for the substrate to yield monolayer coverage – which were then coated with Matrigel. The study showed that hESCs could be cultured as colonies inside of these 3D Matrigel-coated scaffolds while maintaining their expression of Oct4. The resulting hESCs maintained their ability to proliferate even when transferred back to traditional 2D Matrigel culture. This system demonstrated that there are beneficial effects to using 3D culture for maintaining the undifferentiated state of hESCs without passaging the cells, and as an additional benefit, it allows for generation of uniform hESC embryoid bodies.

Another group investigated human serum-coated substrates as a 2D biomaterial matrix for the culture of undifferentiated hESCs, as a potential alternative to Matrigel.[42] The use of human serum would avoid the xenogenic pathogens associated with the use of Matrigel, which is derived from a mouse tumor. Tissue culture plates were coated with human serum, and hESCs were then cultured on this biomaterial surface in the presence of conditioned media obtained from human fibroblast-like cells derived from hESCs. This combination of medium and surface maintained the undifferentiated, pluripotent state of the hESCs as well as a normal karotype after 21 passages, suggesting human serum could potentially be used as a Matrigel replacement. That said, although the use of human serum does avoid xenogenic components, it is even more heterogeneous and undefined than Matrigel. A subsequent study directly compared a variety of biomaterials and their suitability for culturing five different hESC lines.[41] Of the materials analyzed, interestingly only surfaces coated with human serum, fetal bovine serum, and Matrigel supported undifferentiated hESC culture for multiple passages. Of these options, Matrigel was the only surface that supported long term (>30 passages) culture of hESCs. On the whole, the materials that could support multiple passages all consisted of heterogeneous, undefined mixtures of extracellular matrix or serum, whereas a fully chemically defined biomaterial surface and medium that can support undifferentiated hESC culture would be ideal.

5.508.2.1.2. Homogeneous biomaterial scaffolds

This section will focus on scaffolds comprising a single natural biomaterial in contrast to the heterogeneous scaffold materials discussed previously in **Section 5.508.2.1.1**. One of the first studies to use a single 3D biomaterial scaffold for hESC culture involved using alginate scaffolds to promote the formation of embryoid bodies.[36] Alginate is a linear polysaccharide derived from algae that can be cross-linked with divalent cations such as calcium to form 3D scaffolds.[47] The alginate scaffolds were produced by cross-linking an alginate solution with calcium, followed by freezing the scaffold and a lyophilization process. The resulting porous scaffold was seeded with hESCs at a low or high density (**Figure 4(b)**). The microenvironments offered by these scaffolds promoted formation of round embryoid bodies and supported hESC proliferation, suggesting a potential method for hESC culture. Such scaffolds were later examined as a method of promoting the differentiation of hESCs after embryoid body formation. Another study also showed the use of alginate hydrogels for extended culture of undifferentiated hESCs.[37] Hydrogels consist of a network of polymer chains that are water insoluble but possess high water content.[48] Siti-Ismail *et al.* used alginate hydrogels to encapsulate the hESCs, which could then be cultured for up to 260 days in chemically defined media while maintaining their undifferentiated state provided the media was changed every 3–4 days. Although the number of hESCs produced was limited by the size of the alginate capsules, this process avoided the use of both animal products and a process of embryoid formation, suggesting the strong potential of hydrogels for hESC culture.

Another study investigated the use of hyaluronic acid (HA) hydrogels for the culture of hESCs.[38] HA is a linear glycosaminoglycan expressed in the extracellular matrix of hESCs as well as in the brain. In this work, the HA was chemically cross-linked to form stable hydrogels for hESC culture. When encapsulated inside of 3D HA scaffolds in the presence of conditioned media obtained from mouse embryonic fibroblasts, hESCs maintained their pluripotent state, whereas hESCs cultured on 2D HA surfaces did not. All of these studies indicate the potential for homogenous natural biomaterial scaffolds to be developed for maintenance of hESC culture. However, more work and rigorous testing will have to be performed before these systems can be coupled with chemically defined media and replace Matrigel as the standard for hESC culture.

5.508.2.2. Synthetic Biomaterials for Undifferentiated hESC Culture

While natural systems such as Matrigel supply the substrate signals needed to support hESC attachment and maintenance, synthetic materials offer the potential for a defined and reproducible system if they can be engineered with the necessary bioactivity. See **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments** for further reading on this subject. To identify numerous synthetic biomaterials to support hESC culture, Anderson *et al*. developed combinatorial microarray to screen potential substrates.[43] Their microarray consisted of 576 combinations of acrylate, diacrylate, dimethacrylate, and triacrylate monomers presented on 2D surfaces consisting of poly (hydroxyethyl methacrylate) (pHEMA) using the mircroarray shown in **Figure 5**. For this study, they cultured the hESCs in knock-out replacement medium containing serum and other defined supplements. This high-throughput screening of potential biomaterials surfaces for hESC culture allowed them to identify several candidate materials, and additional characterization found that several could effectively support hESC differentiation induced by retinoic acid. Future work may analyze whether the materials themselves were bioactive or selectively adsorbed different factors from serum. Regardless, additional characterization may reveal valuable new signals that can regulate cell differentiation.

An analogous approach invovled a SAM array for screening potential peptide substrates for 2D hESC culture.[44] To generate the array, one layer of SAMs consisting of alkanethiols (ATs) was photopatterned onto the surface followed by the spot application of various peptide sequences conjugated to ATs to generate the desired array. These peptide sequences were derived from the sequence of laminin, a significant component of Matrigel. The authors hypothesized that peptide fragments based on laminin would be able to support hESC culture in a manner similar to Matrigel. hESCs were then cultured in mouse embryonic fibroblast (MEF)-conditioned media on the microarray for 6 days and evaluated for their ability to support hESC growth and maintain their undifferentiated state. Their results showed that hESCs prefer to be grown on peptides containing the arginine–glycine–asparatic acid (RGD) sequence when presented at high concentrations.

Earlier work from the Healy Lab investigated the use of semi-interpenetrating polymer networks (sIPNs, **Figure 6**) for the culture of undifferentiated hESCs.[34] For this study, the sIPN was designed to contain cross-links that could be degraded by proteases, to simulate 'natural' remodeling of tissues by cells, and functionalized with an RGD sequence derived from an integrin-binding site of bone sialoprotein to allow for hESC adhesion to the network. These networks were capable of supporting hESC culture for short time periods (~5 days) when used in combination with chemically defined media, representing for the first time a completely synthetic microenvironment used for short-term hESC maintenance. More recent work from the Healy and Schaffer Labs investigated the integrin 'fingerprint' necessary to support hESC attachment and to allow for culture and maintenance of undifferentiated hESC culture in the presence of chemically defined media.[35] They determined that the $\alpha_V\beta_3$, $\alpha_6\beta_1$, and $\alpha_2\beta_1$ integrins mediated hESC adhesion to Matrigel-coated surfaces. Based on these results, they synthesized peptides previously reported to bind these integrins and found that a combination of two integrin-engaging peptides along with an additional peptide designed to bind the heparan sulfate proteoglycan syndecan could support hESC adhesion and propagation for three passages, though the cells eventually lost expression of pluripotency markers. However, this study illustrates the concept that emulating the pattern of adhesion receptor engagement mediated by a natural biomaterial can extend the duration of hESC maintenance in a fully chemically defined culture system, a promising starting point for further work in developing synthetic scaffolds for hESC culture.

Overall, these studies highlight the promise and advantages of using synthetic scaffolds for hESCs. However, significant challenges remain in investigating the mechanisms of interaction between hESCs and natural substrates such as Matrigel, the downstream signaling mechanisms that support hESC

self-renewal, and synthetic ligands that can emulate these engagements. The first two studies described[43,44] demonstrate how such synthetic materials can be screened in a high-throughput manner, allowing for the identification of potential scaffold materials and ligands, and the final study initiates the process of dissecting Matrigel for key signals that activate particular adhesion receptors. As many of the signals that promote hESC survival and proliferation remain unidentified, additional searches aided by high-throughput approaches could potentially be used for identifying novel molecules and peptide sequences for these applications.

5.508.3. Biomaterials for hESC Differentiation

A considerable body of prior work has explored the use of biomaterial scaffolds for engineering various types of tissues (neural, dental, bone, vasculature),[47,49–51] and it is natural to use these biomaterial-based approaches as starting places when investigating methods to promote the differentiation of hESCs into specific lineages for therapeutic applications. As discussed in Section 5.508.2, maintaining hESCs in an undifferentiated state requires a complex combination of signals. Likewise, directing hESC differentiation requires specific cues, such as growth factors and morphogens, combined with biomaterial scaffolds. This section will discuss the current use of both natural and synthetic biomaterial scaffolds for promoting hESC differentiation into specific cell types.

When selecting a material for promoting hESC differentiation, scaffold materials should meet a number of criteria: to be biocompatible, to contain sites for cell adhesion, to promote the desired differentiation, and – if included as part of an implantable graft – to not induce an immune response upon implantation. Furthermore, the degradation rate of the scaffold should also be considered, especially in comparison to the time course required for the desired differentiation. If differentiation-promoting cues are incorporated into the scaffold, this degradation rate can also influence the release rate of these cues. Finally, as previously mentioned in Section 5.508.1.6, it is also important to consider the fact that the mechanical properties of the scaffolds can also influence the resulting differentiation.[32,33] Table 3 summarizes the efforts to engineer materials that investigate a number of these design criteria.

5.508.3.1. Natural Biomaterials for hESC Differentiation

5.508.3.1.1. Alginate

As mentioned in Section 5.508.2.1.1, the biomaterial alginate has been shown to support the hESC cell culture, and in the same study, Gerecht-Nir *et al.*[36] showed that embryoid bodies

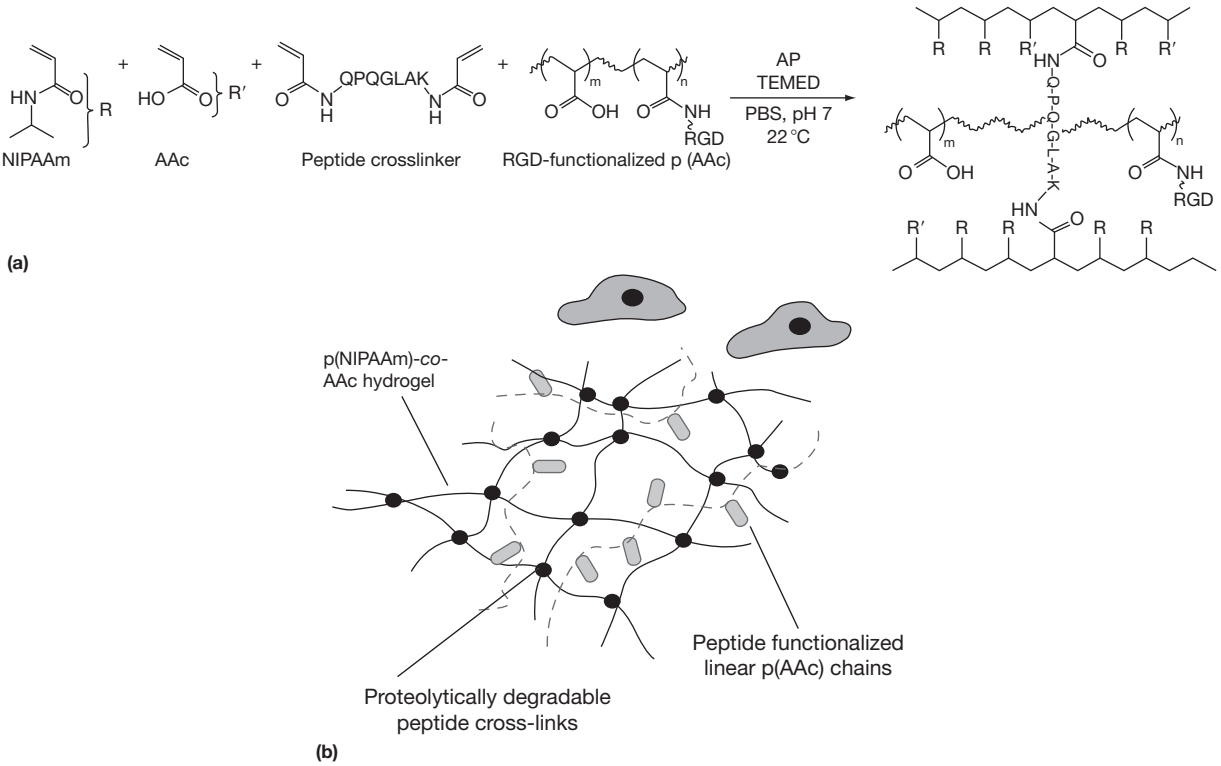

Figure 6 Semi-interpenetrating polymer networks (sIPN) synthesis: poly(*N*-isopropylacrylamide-*co*-acrylic acid) [p(NIPAAm-*co*-AAc)], interpenetrated by polyacrylic acid-graft-Arg-Gly-Asp [p(AAc)-*g*-RGD] linear polymer chains; (a) polymerization scheme and (b) schematic representation of the polymerized sIPN network. Table 3 List of biomaterials used for hESC differentiation

Type of material	*Material*	*References*
Natural	Alginate	[36,52]
	Dextran	[53]
	Fibronectin	[40,54]
	Laminin	[40]
	Matrigel	[40,55]
Synthetic	Carbon nanotubes	[56]
	Poly-D-lysine	[40]
	Poly(ethylene glycol)	[57]
	Poly(lactic-*co*-glycolic acid)	[58–62]
	Poly(tetrafluroethylene)	[63]

made from the hESCs could differentiate into vasculature. The authors hypothesized that the porous nature of their alginate scaffolds helped enhance the differentiation process compared to traditional 2D culture. Another group also investigated that use of alginate to encapsulate hESCs, followed by implantation into mice, and characterized the resulting phenotypes to determine the effects of encapsulation on differentiation.[52] They found that the encapsulated, transplanted cells differentiated primarily into an endoderm lineage. In addition, although it is unlikely that undifferentiated hESCs would be implanted for therapeutic application, this study found that the cells did not form teratomas, benign tumors that can be formed by immature transplanted hESCs, which could enhance the safety of a graft. They also hypothesized that the encapsulation process may help protect the hESCs from immune rejection.

5.508.3.1.2. Dextran

The use of a functionalized dextran scaffold for directing the differentiation of hESCs into vasculature was also investigated.[53] Derived from bacteria, dextran is a complex polysaccharide consisting of glucose subunits, and it resists both cell and protein adsorption.[47] To engineer the capacity for specific interactions with cells, the authors functionalized their dextran hydrogel scaffolds with RGD peptides. Additionally, they incorporated poly(lactic-*co*-glycolic acid) (PLGA, a synthetic polymer) microspheres (Figure 7(a)) that released vascular endothelial growth factor (VEGF) over a 10-day period (Figure 7(b)). Figure 7(c) shows the entire system including the dextran scaffold, the VEGF releasing PLGA microspheres, and hESCs. The hESCs cultured inside the hydrogels exhibited an increase in markers characteristic of differentiation into vasculature, including the VEGF receptor KDF/Flk-1. The authors emphasized that this biomaterial scaffold could potentially generate large numbers of endothelial cells for tissue engineering applications.

5.508.3.1.3. Collagen/laminin/matrigel

Another group explored a wide variety of 2D biomaterial surfaces for directing hESCs into neural phenotypes, that is, neurons, oligodendrocytes, and astrocytes – including Matrigel, type 1 collagen, laminin/poly-D-lysine (PDL) mixture,

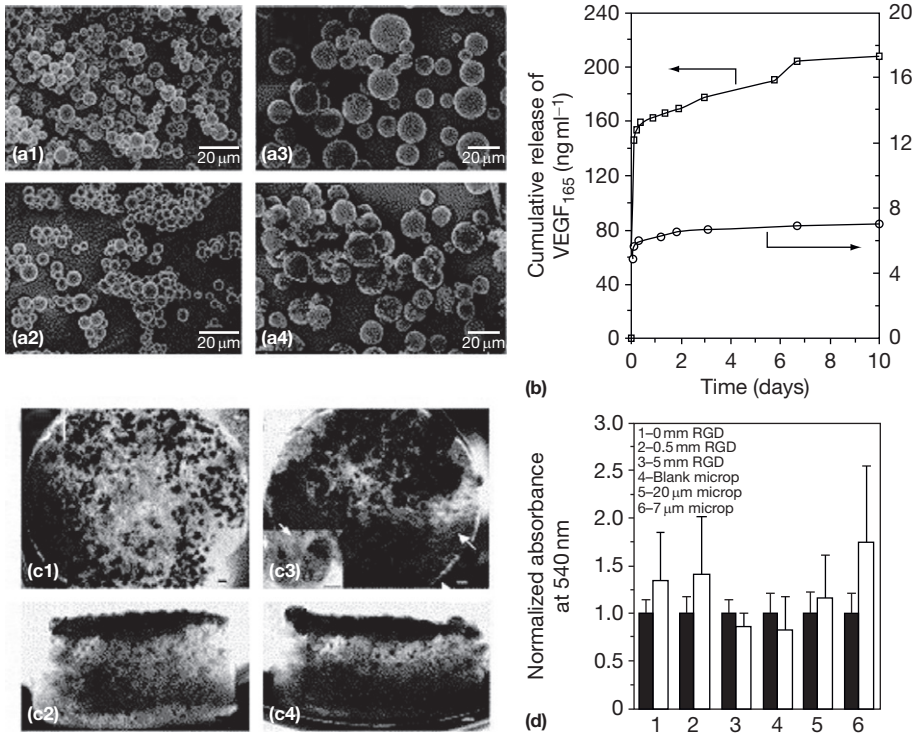

Figure 7 Distribution and viability of human embryonic stem cell (hESC) aggregates encapsulated within bioactive dextran-based hydrogels: (a) scanning electron micrographs of 7 μm (a1, a2) and 20 μm (a3, a4) poly(lactic-*co*-glycolic acid) (PLGA) microparticles at day 0 (a1, a3) and 10 (a2, a4), during the release of vascular endothelial growth factor $(VEGF)_{165}$. (b) Release profile of $VEGF_{165}$ from 7 μm (□) and 20 μm (○) microparticle formulations. (c) Distribution of hESC aggregates on dextran-based hydrogels with 0.5 mm Acr-PEG-RGD and 5 mg ml^{-1} VEGF-loaded 20-μm microparticles, at day 0 (c1, c2) and day 10 (c3, c4). Top (c1, c3) and side (c2, c4) views. Arrows in c3 and c4 indicate a clump of cells proliferating outside the hydrogel. Inset in c3 shows the incorporation of microparticles (arrow) within the hESC aggregates. Scale bar corresponds to 200 μm. (D) Mitochondrial metabolic activity (average ± SD, $n = 6$) of hESC aggregates encapsulated in dextran-based hydrogels with no Acr-PEG-RGD (1), 0.5 mm Acr-PEG-RGD (2), 5 mm Acr-PEG-RGD (3), 0.5 mm Acr-PEG-RGD with 5 mg ml^{-1} of blank microparticles (4), and 0.5 mm Acr-PEG-RGD with 5 mg ml^{-1} of $VEGF_{165}$ loaded 20 μm (5), or 7 μm (6) microparticles. The absorbance at 540 nm was measured after 1 day (black bars) and 10 days (white bars). Both absorbances were normalized to the day 1 absorbance. Reprinted from Ferreira, L. S.; Gerecht, S.; Fuller, J.; *et al*. *Biomaterials* **2007**, *28*, 2706–2717, with permission from Elsevier.

fibronectin/PDL mixture, and PDL alone (whose results will be discussed below in Section 5.508.3.2.[40] This study found that Matrigel and the laminin/PDL mixture promoted an increase in neural progenitor generation as well as subsequent neuronal generation compared to the other substrates (the neuronal subtypes were not analyzed). They also noted a laminin dose-dependency in these responses and thus concluded that laminin is a key molecule for promoting the generation of neural progenitors from hESCs.

Other researchers used a 2D micropatterning approach, with Matrigel in combination with growth factors, to direct hESC differentiation in mesoderm and endoderm lineages.[55] As discussed in Section 5.508.2, the local cellular microenvironment plays an important role in promoting hESC differentiation, and this study restricted the size of hESC colonies using patterns of adsorbed Matrigel. They showed that small, 200 μm colonies promoted hESC differentiation into endoderm, whereas larger, 1200 μm spots promoted mesodermal formation. This study thus illustrates how limiting the size of hESCs cultures can influence the resulting differentiation, which suggest the need to control the uniformity of embryoid body (EB) sizes to tune cell differentiation.

5.508.3.1.4. Fibronectin

Another interesting approach to promoting hESC differentiation involved coating gold nanoparticles with a layer-by-layer deposition of the extracellular matrix (ECM) protein fibronectin to enable cell attachment.[54] Gold is electrically conductive and enables an investigation of the effects of electrical stimulation on hESCs differentiation (Figure 8). They found that electrical stimulation promoted differentiation into osteogenic lineages, as indicated by the expression of collagen type 1 and the transcription factor core-binding factor alpha1 (Cbfa1), while a dramatic decrease in the expression of Oct4 was observed, suggesting that the majority of the hESCs had differentiated. The same effects were not observed in unstimulated cells.

5.508.3.1.5. Other naturally derived materials

Another potential application of hESCs involves periodontal tissue engineering.[64] Inanc *et al*. examined the capacity of tooth root slices, which consist of the soft tissue found in the root canal, as a natural 'microenvironment' to promote the differentiation of hESCs into tooth structures. They examined three different sets of culture conditions for hESCs, including

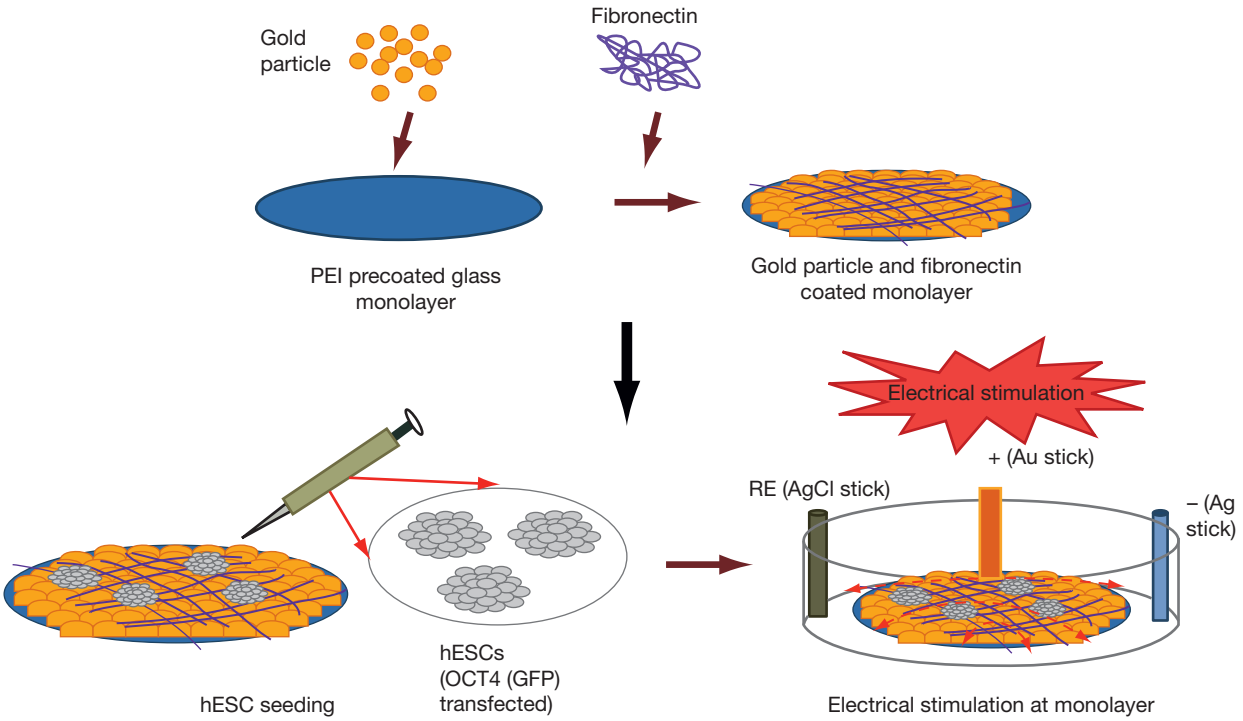

Figure 8 Schematic diagram of a fibronectin-coated gold nanoparticle surface for human embryonic stem cell (hESC) differentiation by alternating electrical stimulation. Reprinted from Woo, D. G.; Shim, M. S.; Park, J. S.; Yang, H. N.; Lee, D. R.; Park, K. H. *Biomaterials* **2009**, *30*, 5631–5638, with permission from Elsevier.

seeding them next to these root slices, seeding them on a feeder layer of periodontal fibroblastic cells with the root slices present in the presence of osteogenic media, and allowing the hESCs to spontaneously differentiate. They found that the presence of the tooth root slices and a feeder layer along with the osteogenic media promoted differentiation into bone tissue, suggesting a potential mechanism for engineering periodontal tissue.

These examples show the variety of natural biomaterials and approaches that can be used for directing hESC differentiation. The cell adhesion ligands naturally present in many of these materials, in conjunction with specific cues such as growth factors or small molecules, can aid in guiding cell differentiation; however, natural materials again suffer from some shortcomings, including reproducibility of composition and properties as well as potential transfer of immunogens or pathogens from the material to the cells.

5.508.3.2. Synthetic Biomaterials for hESC Differentiation

A number of synthetic biomaterial classes have been evaluated for directing hESC differentiation into numerous lineages, and this section will review the current state of the field.

5.508.3.2.1. Poly(lactic-co-glycolic acid)

A key early study examined how to control the differentiation of hESCs seeded inside a 3D scaffold consisting of a 50/50% blend of PLGA and poly(L-lactic acid) (PLLA).[58] hESCs were first mixed with Matrigel to aid survival upon seeding into the scaffolds. To direct hESCs into specific lineages, the following cues were used: retinoic acid (neural), TGF-β (osteogenic), and insulin-like growth factor (vasculature). They observed the ability of these factors to direct hESC differentiation into neural, cartilage, and liver tissue, respectively, through the use of immunohistochemistry, *in vitro*. Additionally, they observed the ability of hESCs to form blood vessels. Based on these promising results, they transplanted these scaffold-containing hESCs after 2 weeks of *in vitro* culture into severe combined immune deficiency (SCID) mice, such that implantation of such scaffolds containing hESCs would not trigger an immune response. Staining results indicate that the hESCs could survive and maintain these individual phenotypes in an *in vivo* setting (Figure 9). This key study demonstrated the potential of synthetic scaffold for promoting hESC differentiation by providing a 3D environment.

Many other studies have used PLGA as a scaffold to promote hESC differentiation. One group encapsulated hESCs in PLGA scaffolds that were coated with laminin, implanted these scaffolds into the livers of SCID mice, and characterized the resulting differentiation.[59] The cells differentiated into all three germ layers, and the scaffolds became highly vascularized. One issue encountered was the formation of teratomas inside these scaffolds due to the presence of undifferentiated hESCs. This issue would have to be addressed before such a strategy could be considered for clinical translation by ensuring that only differentiated hESCs are transplanted. Another group used scaffolds that consisted of PLGA-mixed hydroxyapatite to promote the differentiation of hESCs into bone tissue.[60] To achieve this goal, they first induced the hESCs to differentiate

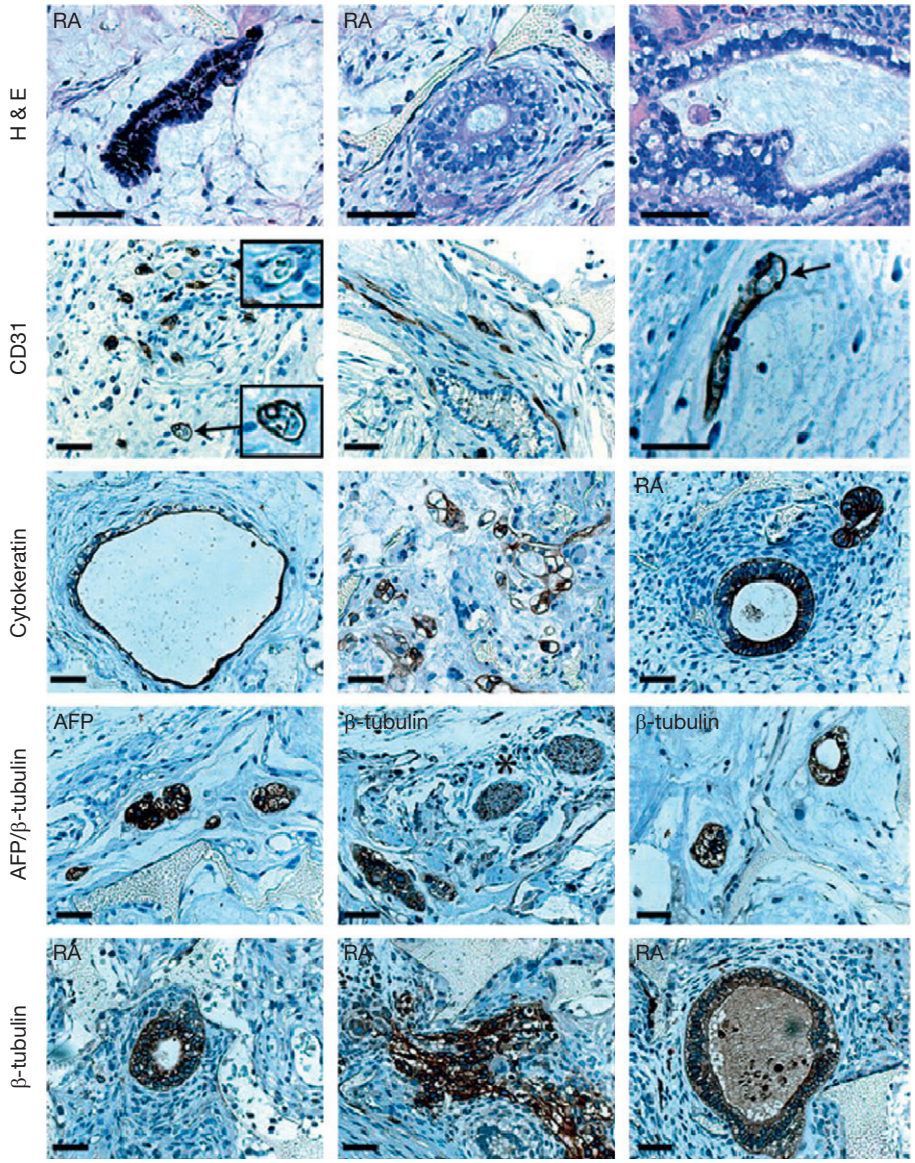

Figure 9 Transplantation of human embryonic stem cell (hESC)–scaffold constructs into severe combined immune deficiency (SCID) mice. Two-week-old constructs (treated with retinoic acid (RA) or control medium) were implanted subcutaneously in the dorsal region of SCID mice. Fourteen-day-old implants were stained with hematoxylin and eosin (H&E) or with antibodies against human CD31, cytokeratin, AFP, or β_{III}-tubulin. Human-specific CD31 staining demonstrated the presence of both immunoreactive (construct-origin, arrows) and nonimmunoreactive (host origin, arrowhead) vessels. In certain instances there appeared to be continued differentiation and organization of constructs postimplantation. After continued construct maturation *in vivo*, RA-conditioned constructs exhibited larger and better organized neural structures than those seen *in vitro* (or with control medium *in vitro* or *in vivo*) including ductular structures lined by tall columnar epithelium invested with long cilia resembling ependymal cells, and rosettes with abundant melanin granules (brown/black in H&E section; confirmed by bleaching with potassium permanganate, data not shown). β_{III}-tubulin antibodies stained neuroectodermal structures within the implant as well as murine peripheral nerve fibers in surrounding connective tissue (asterisk). Scale bar, 50 μm. Reprinted from Levenberg, S.; Huang, N. F.; Lavik, E.; Rogers, A. B.; Itskovitz-Eldor, J.; Langer, R. *Proc. Natl. Acad. Sci. USA* **2003**, *100*, 12741–12746, with permission from the National Academy of Sciences.

into osteogenic lineages through coculture with human bone-derived cells, since the latter secrete the factors necessary for promoting differentiation as previously reported.[65] They seeded the resulting hESC-derived osteogenic progenitor cells inside the aforementioned 3D scaffolds and implanted them subcutaneously in SCID mice. These cell–material scaffolds promoted the regeneration of bone (**Figure 10**), whereas control scaffolds seeded with dermal fibroblasts did not, suggesting that it was the hESC-derived cells that were responsible for the observed effects. This study illustrates the utility of hESC-derived cells for bone tissue engineering applications. To engineer neural tissue, 3D PLGA scaffolds combined with hESCs were treated with a combination of retinoic acid and nerve growth factor (NGF).[61] The researchers made the scaffold

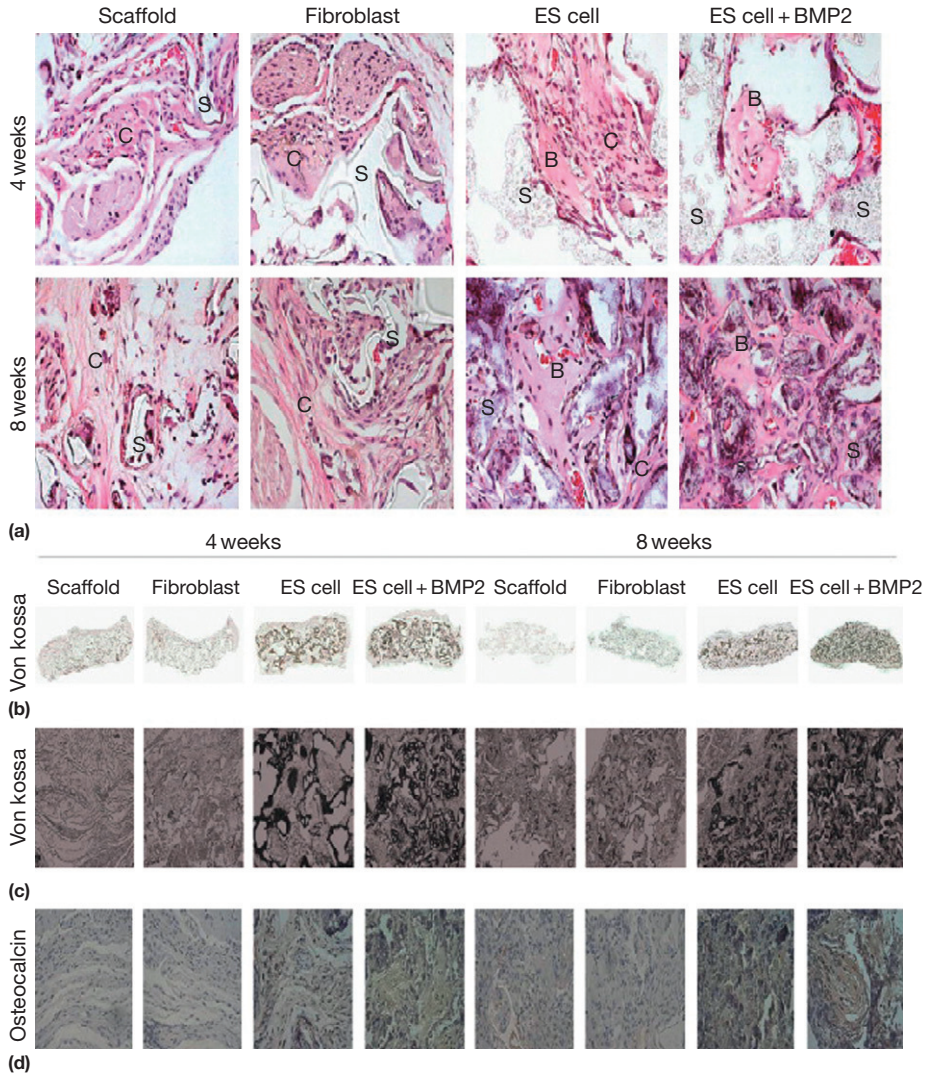

Figure 10 Histochemical evaluation of osteogenic induction 4 and 8 weeks after *in vivo* implantation. *In vivo* bone formations of osteogenic cells derived from human embryonic stem cells (OC-hESCs) were evaluated and compared in four treatment groups: scaffold only, fibroblasts in the scaffold, OC-hESCs in the scaffold, and OC-hESCs in the scaffold with BMP2: (a) H&E staining (B, C, and S represent bone tissue, connective tissue, and scaffold, respectively); (b) von Kossa staining; (c) an enlarged image of (b); and (d) osteocalcin immunostaining (×100). porous to better enable cell proliferation and migration as well as the diffusion of the retinoic acid and NGF. They found that using 3D culture enhanced the expression of nestin and troponin (a skeletal muscle marker) compared to culturing the hESCs in 2D monolayer culture. The authors suggested that it may be beneficial to study hESCs in 3D to better emulate and understand behavior in an *in vivo* setting. A final study used hESCs and 3D PLGA scaffold to generate islet-like cells as a potential treatment for diabetes.[62] In this work, a five-step protocol for generating the islet-like cells *in vitro* that could secrete insulin was adapted. They then encapsulated these islet-like cells inside PLGA scaffolds and transplanted them into diabetic SCID mice. The mice receiving this treatment maintained the presence of the islet-like cells *in vivo* and exhibited a decrease in glucose levels compared to levels in control mice (Figure 11). These studies collectively illustrate the utility of PLGA scaffolds for promoting hESC differentiation for a variety of tissue engineering applications.

5.508.3.2.2. Poly(ethylene glycol)

An early study investigated the use of 3D poly(ethylene glycol) (PEG) hydrogels as a potential scaffold material for hESC differentiation into chondrocytes, resident cells of cartilage.[57] This important work by Elisseeff and colleagues used PEG diacrylate hydrogels chemically modified to present different sites that allow hESCs to bind to the scaffolds. Specifically, they compared the ability of PEG scaffolds conjugated with HA, type I collagen, and the RGD peptide to promote hESC adhesion and found that only RGD allowed hESCs to differentiate into neocartilage, as indicated by both cellular markers and the deposition of basophilic extracellular matrix indicated by glycosaminoglycan content.

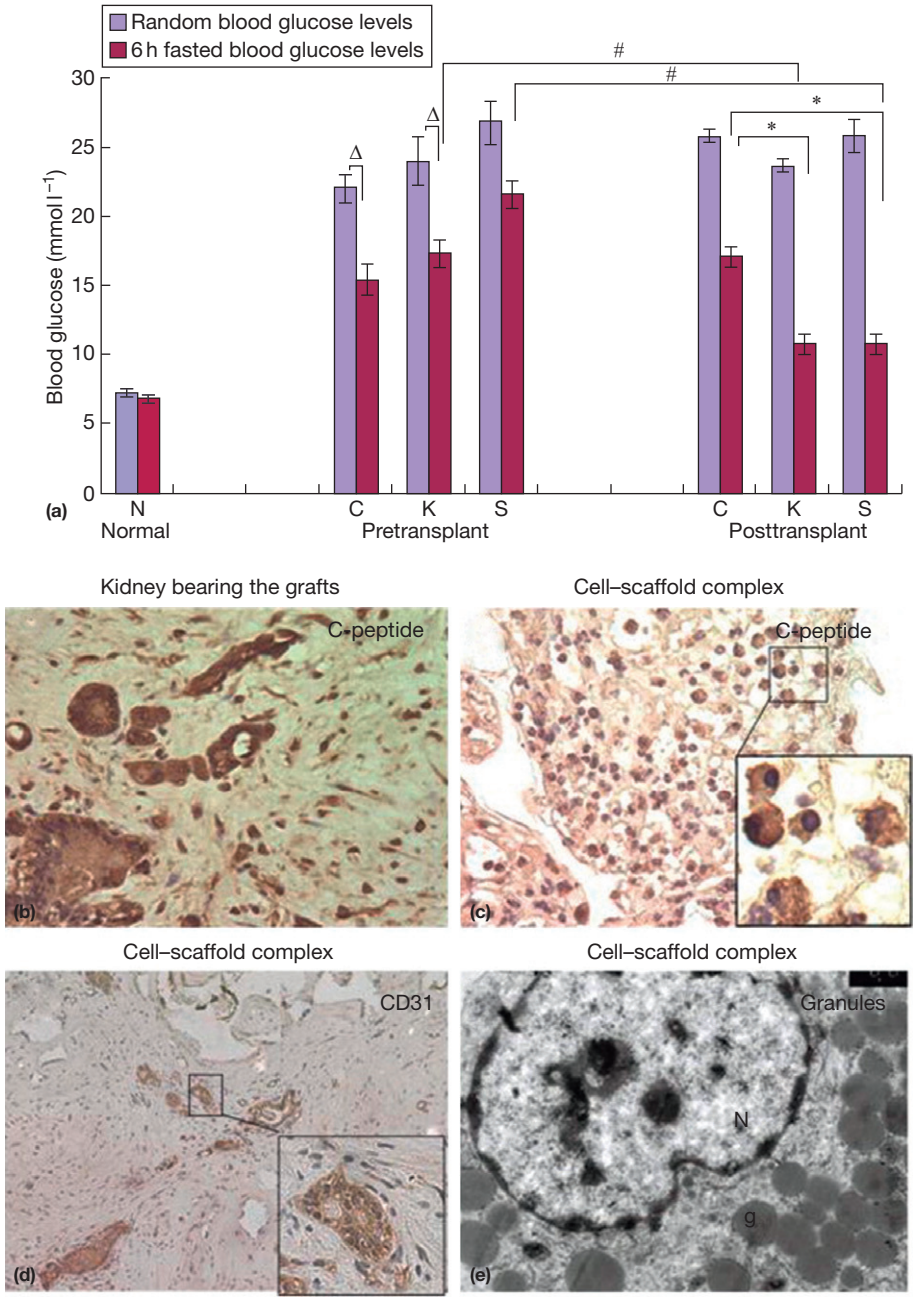

Figure 11 (a) Random-fed and 6 h fasted blood glucose levels in the mice transplanted under the kidney capsules and embedded subcutaneous cell–scaffold complexes. N, normal mice; C, sham-transplanted mice; K, cell transplanted under kidney capsule mice; S, cell–scaffold complex transplanted mice. * $p < 0.05$ versus sham-transplanted mice; Δ $p < 0.05$ versus random blood glucose levels; # $p < 0.05$ versus pretransplant 6 h fasted blood glucose. 5.508.3.2.3. Other synthetic materials

Other synthetic polymers have been studied for their suitability as substrates for hESC differentiation. 2D polytetrafluroethylene (PTFE) surfaces coated with poly-amino-urethane were seeded with hESCs, and a variant of hepatocyte growth factor (HGF) as well as basic fibroblast growth factor (bFGF) were added to the media to induce differentiation into hepatocytes.[63] The resulting cells secreted both albumin and urea, indicating that the hESCs were becoming functional hepatocytes. A study discussed in Section 5.508.3.1,

investigated a number of natural and synthetic materials for the ability to support neural differentiation.[40] The study found that PDL – a synthetic polymer that is often used to enhance the ability of cells to attach to surfaces via ionic interactions between the amine groups and the negatively charged cellular glycocalyx[66] – could modestly support hESC differentiation into neural phenotypes, though the ECM proteins were more effective. A recent study investigated the use of thin films of carbon nanotubes as a 2D substrate for promoting the differentiation of hESCs into neurons,[56] and the nanotube-based surfaces allowed the cells to adhere and differentiate without cytotoxic effects. These are examples of other polymers that could potentially be used as substrates for hESC adhesion and differentiation.

5.508.4. Conclusions and Future Work

Overall, this chapter summarizes the current state of biomaterial scaffolds for the culture and differentiation of hESCs. The use of hESCs in conjunction with bioactive materials holds enormous therapeutic potential that these studies begin to highlight and help harness. This final section will discuss the challenges in current efforts and offer directions for the future of the field.

5.508.4.1. Reflections on the Current State of Biomaterial Scaffolds for hESC Culture and Differentiation

This chapter has discussed the current state of the field, and many valuable studies have shown that hESCs can differentiate into a wide variety of cells types for therapeutic applications, including neurons, bone, and islet-like cells. This work has also demonstrated that hESC behavior is heavily influenced by the culture system, and cues ranging from biochemical signals from matrix, small molecules, and growth factors can support and regulate hESC self-renewal and differentiation. Furthermore, 'geometric' cues such as local cell density and composition, as well as 2D versus 3D culture systems, can profoundly influence cell function. Collectively, this work has highlighted the promise and potential of hESC and biomaterial scaffolds for serving as a culture systems so as to aid cell expansion and differentiation *in vitro*, as well as for supporting the implantation of cells *in vivo*.

5.508.4.2. Future Directions

This section discusses challenges with current approaches, as well as suggests potential novel biomaterial scaffolds for the culture and differentiation of hESCs.

5.508.4.2.1. Issues with hESC culture to be addressed

As discussed in Section 5.508.1.3, progress must still be made in the development of *in vitro* culture systems for hESCs. A major limitation of current hESC culture methods is the use of Matrigel or other poorly defined components such as serum, conditioned medium, or other ECM proteins. The biomaterials described in this chapter have the potential to provide fully chemically defined conditions for cell expansion and differentiation, which would enhance safety, reproducibility, and scaleability. However, considerable progress must be made in identifying biochemical and mechanical cues in the stem cell microenvironment, including both substrate and matrix, to enable the development of defined biomimetic materials and liquid culture systems that can fully substitute for undefined components and support cell function. To address this issue, proteomic analysis of conditioned media was conducted to determine what components are necessary for maintaining undifferentiated hESCs. One hundred seventy-five proteins were found in the media, and a key subset of these factors must aid in maintaining undifferentiated hESCs.[67] Likewise, a recent proteomic study identified hundreds of proteins in Matrigel,[12] which renders the development of a synthetic matrix quite challenging. See **Chapter 4.409, Surfaces and Cell Behavior** and **Chapter 4.427, Cell-Demanded Release of Growth Factors** for further reading on presentation of cues that influence cell behavior.

Bioactive materials along with hESC-derived progeny may aid in overcoming challenges with engraftment, such as low cell viability. In addition, immune responses against the graft may be a challenge. hESCs cultured on Matrigel, in conditioned medium, in serum, or in the presence of animal proteins in general likely internalize and incorporate murine antigens,[13] which could trigger an immune reaction when implanted *in vivo*. This issue would be mitigated by the use of a defined culture system prior to implantation, and the coimplantation of nonimmunogenic biomaterials may to an extent shield cells from immune responses. Cells may well also face immune responses due to challenges in the histocompatibility of donor cells and patient recipients. However, patient-specific pluripotent stem cell lines are theoretically possible with the advent of induced pluripotent stem cells (iPSCs). iPSCs are generated from adult somatic cells, such as fibroblasts, by inducing the expression of specific genes that restore pluripotency.[68] Human iPS cells are similar to ESCs in their self-renewal, pluripotency, and teratoma formation,[69] and it is likely that biomaterials development studies will increasingly involve human iPSC lines.

An additional consideration when developing hESC-based therapies is avoiding teratoma formation *in vivo*. To achieve clinically relevant therapies, it is important to ensure that the cells are sufficiently and uniformly differentiated so as to avoid this hazardous possibility, and Section 5.508.3, details potential scaffold materials that can be used to control and potentially provide uniform hESC differentiation. Furthermore, cell encapsulation inside materials, in some cases, may physically contain cells and thereby inhibit tumor formation.

5.508.4.2.2. Potential new materials for use in combination with hESCs

A number of materials have been successfully investigated for hESC culture and differentiation, though a number of additional materials offer other key advantages that may be explored in future work.

5.508.4.2.2.1. Additional natural biomaterials

Many other natural biomaterials have been used in combination with mouse ESC culture, and these could also potentially be applied to hESCs. For example, fibrin and collagen are two potential protein-based materials that are found in the extracellular matrix, and these materials have been extensively

studied in biomaterial scaffolds.[70,71] Fibrin is a polymer that consists of fibrinogen monomers that are found in blood, which coagulate to form fibrin clots in response to vascular injury. Several groups have shown the feasibility of using fibrin scaffolds for both mouse and mesenchymal stem cell culture.[72–76] Another commonly used biomaterial for scaffolds is collagen, one of the major components in Matrigel, but little work has been conducted using pure collagen scaffolds for the culture and differentiation of hESCs. Previous work has shown that mouse neural stem cells seeded inside collagen scaffolds can form functional neuronal circuits.[77]

The other major group of natural biomaterials that could be investigated is polysaccharides. As mentioned in Section 5.508.3.1, dextran and alginate scaffolds have been successfully used for hESC culture and differentiation, suggesting that other polysaccharide-based biomaterial scaffolds could be used in a similar manner. Dextran is resistant to cell and protein adsorption, but it can be chemically modified to contain sites for cell adhesion, making it a potentially promising substrate for hESC culture. Agarose, a readily available polysaccharide isolated from seaweed, has been used as a scaffold material for differentiating primate ESC lines into cardiomyocytes.[78] The thermoresponsive properties of agarose can be used to regulate scaffold formation, suggesting that such scaffolds could be formulated to produce an injectable version. Another potential scaffold material is chitosan, which consists of glucosamine subunits. Chitosan scaffolds have been used to culture stem cells derived from human cord blood as well as mesenchymal stem cells.[79,80] It can fabricated using a variety of methods, such as encapsulation, spray drying, and gelation, to provide different methods of drug delivery.[81] It would be interesting to study hESC behavior inside scaffolds made from these polysaccharide, based on their suitability for the culture and differentiation of these other stem cell lines.

5.508.4.2.2.2. Additional synthetic biomaterials

Numerous synthetic polymers have been characterized for use as scaffolds in combination with stem cells other than hESCs, including pHEMA and polypyrrole. Scaffolds made from pHEMA do not degrade, and thus, maintain their initial shape after implantation. Such pHEMA scaffolds have been successfully fabricated into hydrogels that support mesenchymal stem culture.[82] Another attractive synthetic material for investigation is polypyrrole, a polymer consisting of connected pyrrole ring structures. It is highly conductive, a potentially interesting property as electrical stimulation has been shown to influence hESC behavior.[54] It has also been used to study mesenchymal stem cell behavior on 2D surfaces, where it was determined that the concentration of polypyrrole used influenced the resulting stem cell differentiation. These studies suggest that both of these synthetic polymers have the potential for use with hESCs.

Recently, several groups have developed novel self-assembling scaffolds based on short synthetic peptide sequences for stem cell culture and differentiation. Stupp and colleagues showed self-assembling scaffolds based on the peptide sequence IKVAV (isoleucine–lysine–valine–alanine–valine) derived from laminin promote the differentiation of fetal neural cells into neurons.[83] More recent studies have examined the use of similar peptide-based self-assembling scaffolds in combination with mesenchymal stem cells for osteogenic differentiation.[4,84,85] Likewise, Zhang and colleagues developed a novel self-assembling material based on a peptide, RADA-16-I, and used scaffolds derived from this peptide and related variants for promoting the differentiation of mesenchymal and neural stem cells.[86,87] These studies illustrate the utility of such novel peptide-based scaffolds, and such a strategy could be applied for hESC culture and differentiation, though precisely controlling the 3D assembly and mechanical properties of these short oligomers can be challenging. Furthermore, successfully implementing such a strategy may require the use of multiple peptide sequences due to the complex requirements of hESC culture.

5.508.5. Summary

This chapter has detailed the current state of the field, including the use of both natural and synthetic scaffolds for hESC culture and differentiation, along with discussing potential trends for future work to help maximize the therapeutic potential of hESCs. In general, hESCs have great therapeutic potential due to their ability to self-renew, which in principle can provide limitless quantities of cells, and their pluripotency, such that a single cell type can be harnessed to address numerous diseases. Many different biomaterial scaffolds have been investigated for hESC culture and differentiation due to their ability to provide the signals and cues, and thereby recreate cellular microenvironments, necessary to regulate and control self-renewal *in vitro* and differentiation *in vitro* and *in vivo*. Therefore, the integrated use of hESCs and engineered biomaterials hold great promise for greatly enhancing the therapeutic potential of tissue engineering and regenerative medicine.

Glossary

Bioartifical liver device (BAL) An artificial device, usually used extracorporeally, consisting of functional hepatocytes for patients suffering from liver failure.

Bioartificial organ Synthetically fabricated tissue replacement consisting of functional cells encapsulated in natural or synthetic polymer materials.

Biocompatibility The ability of a material to integrate with cells and tissue and function as intended when implanted *in vivo*.

Cell encapsulation The confinement of cells within a natural or synthetic polymer network.

Cytocompatability The ability of a material to allow for the viable growth of cells and not to act as a toxic component.

Hydrogel A network of natural or synthetic polymer chains that can absorb a high volume of water.

Immune response The body's reaction to a foreign material including bacteria, viruses, and implanted tissue-engineered constructs.

Macroencapsulation Coating or confinement of larger (>2000 μm) particles or cells within a polymer network.

Membrane permeability The ease at which molecules pass through a specific membrane, which is usually a function of membrane porosity and molecule size.

Microencapsulation Coating of small particles or cells with a thin polymer network, generally <2000 μm in size.

Porosity The measure of void space in a material.

Abbreviations

BAL	Bioartificial liver
BDNF	Brain-derived neurotrophic factor
BMSCs	Bone marrow stromal cells
ECM	Extracellular matrix
ESCs	Embryonic stem cells
GAG	Glycosaminoglycan
HA	Hyaluronic acid
HEMA	Hydroxyethyl methacrylate
HUVECs	Human umbilical cord vein endothelial cells
MI	Myocardial infarction
MMP	Matrix metalloproteinase
MSCs	Mesenchymal stem cells
NIT-1	Mouse insulinoma cells
NPCs	Neural precursor cells
PEG	Poly(ethylene glycol)
PLL	Poly-L-lysine
PMMA	Poly(methyl methacrylate)

RDFs	Rat dermal fibroblasts
RGD	Arginine–glycine–aspartic acid
SCI	Spinal cord injury
Tβ4	Thymosin β4
TGF-β	Transforming growth factor beta
TNF-α	Tumor necrosis factor alpha
VEGF	Vascular endothelial growth factor

5.509.1. Introduction

Cell encapsulation generally involves fabricating three-dimensional (3D) scaffolds, either seeded with cells or with cells directly encapsulated, for use as healthy 'replacement' tissue after injury or for the delivery of cells that can release trophic or stimulatory factors to direct repair. A lack of donor organs and tissues and loss of function after tissue loss or injury motivate the need for cell-encapsulated 'bioartificial organ' therapies and replacement tissue. Important considerations when creating these cell delivery devices are cell source, biocompatibility, graft material, graft stability, and performance. Hydrogels are one group of materials that have promise in these strategies because they often have good membrane permeability, are bioactive, are easy to handle, are hydrated, and in some cases can be formed *in vivo*. Key diseases that are being targeted by cell encapsulation therapies include diabetes, liver failure, neurological disorders, bone and cartilage defects, and cancer.[1–3] In order to obtain the US Federal Drug Administration (FDA) approval for clinical use, it is also critical to use strict standardization protocols and consider practical aspects of design, such as scaling up for manufacturing, marketability, and ease of use for surgeons.

The first major factor for encapsulation systems is selecting the appropriate material. Important aspects to consider are material properties (i.e., mechanics, degradation characteristics, diffusion properties), cytocompatibility (especially if cells are present during gelation), the ability to support 3D cell growth and tissue development, and the ease of use for clinical application.[4] There are two major classifications for materials used in cell encapsulation systems, namely, natural and synthetic systems. Natural materials include collagen, fibrin, chitosan, hyaluronic acid (HA), and alginate. There are several advantages of using natural materials; most importantly, they are cytocompatible and cell tolerable. However, since they are naturally formed, it is more difficult to control the mechanics, degradation, cell adhesion, porosity, and gelation process and time. Synthetic materials offer better control over material properties but require additional modifications in order to allow for cell adhesion and promote cell function.

Without viable functional cells, these constructs will not perform, and therefore, a primary concern in encapsulation systems is cell viability. It is important to first consider the diffusion of nutrients, waste, and oxygen through the material, which are a direct function of material thickness and porosity. Depending on the nature of the material, porosity may be controlled by the chemical structure or cross-linking density. Additionally, several methods have been used to increase the porosity of polymer materials, including photopatterning,[5,6] particulate leaching,[7] and gas foaming[8]; however, these techniques are typically not adaptable for direct encapsulation since processing techniques are toxic to cells. Cell-tolerable techniques to control diffusion include chemical manipulations, such as varying the polymer concentration[9] or modulating the cross-link density.[10]

However, this physical control of diffusion may not be sufficient, and other techniques can be used to increase encapsulated cell survival. Examples of this have been shown with encapsulated islet cells, where nitric oxide scavenger cells were added to encapsulation devices to counteract the diffusion of NO_2 from the implant site,[11] and genetic engineering strategies that have been used to decrease the sensitivity of islet cells to NO_2.[12] Another recent strategy has been to use modifications of poly(ethylene glycol) (PEG) to fabricate a hydrogel conjugated to a peptide antagonist to tumor necrosis factor alpha (TNF-α), a proinflammatory cytokine. Using these TNF-α-antagonizing gels, decreased adhesion of TNF-α to cell surfaces and reduced TNF-α-mediated apoptosis was observed in PC-12 cells, mouse pancreatic islets, and human mesenchymal stem cells (MSCs).[13] A similar approach has been used to create a PEG-based hydrogel network that actively reduces reactive oxygen species damage[14] and can be used to target other inflammatory cytokines.

Control of the immune response may also be critical for effectiveness of cell encapsulation systems (see also **Chapter 4.403, The Innate Response to Biomaterials** and **Chapter 4.404, Adaptive Immune Responses to Biomaterials**).[3] A system with low biocompatibility will elicit a foreign body response, causing the formation of a thick fibrotic layer that encapsulates the scaffold and restricts diffusion and blood supply. An immune response is caused by nonspecific protein adsorption to the surface, which attracts macrophages and other immune cells and can trigger the inflammatory response cascade. Even in the best scenario, some inflammatory response may progress and lead to a thin layer of fibrosis; however, the density and size of the capsule needs to be controlled[15] to avoid immune rejection. Techniques to reduce protein adsorption and inflammatory cell adhesion include using a bioinert hydrogel or anchoring bioinert molecules to the material surface. Since natural materials are inherently biocompatible, they may be considered an ideal encapsulation material, yet they can have a stronger possibility of nonspecific protein absorption than many synthetic alternatives.[3] Materials such as alginate and PEG do not interact with many proteins and are therefore more likely to elicit a reduced immune response.[13] Combinations of these strategies may be important in cell encapsulation systems depending on the encapsulation site and properties of encapsulated cells. Other than material considerations, implant size and implantation methods also play a role in the intensity of host immune response.

5.509.2. Methods

Generally, to encapsulate cells into a polymer scaffold, cells and a liquid precursor (scaffold material) are first combined into a uniform suspension (see **Figure 1**). It is important to

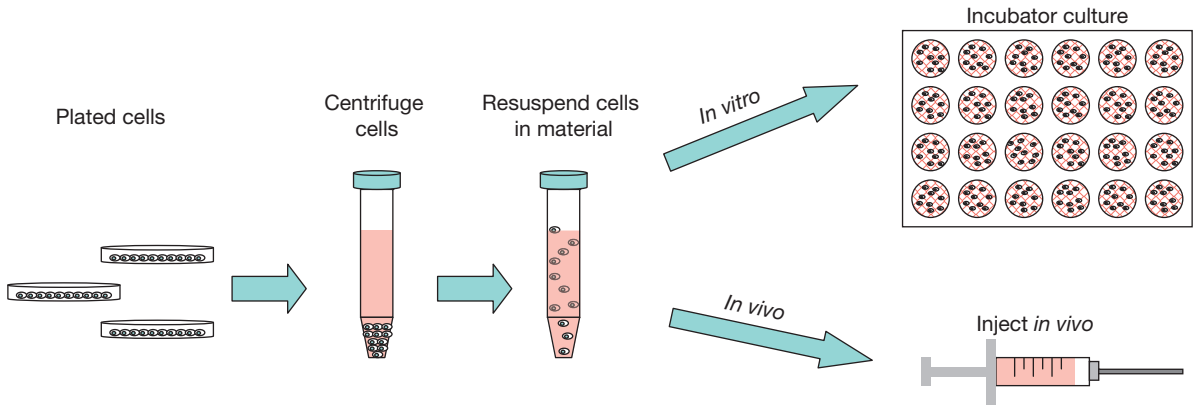

Figure 1 Schematic of cell encapsulation process. Cells are first grown using standard tissue culture procedures. Cells are then removed from the plate, centrifuged, and resuspended in the encapsulation material. After resuspension, cells and materials can be cultured *in vitro* in tissue culture plates or injected *in vivo*, depending on the application.

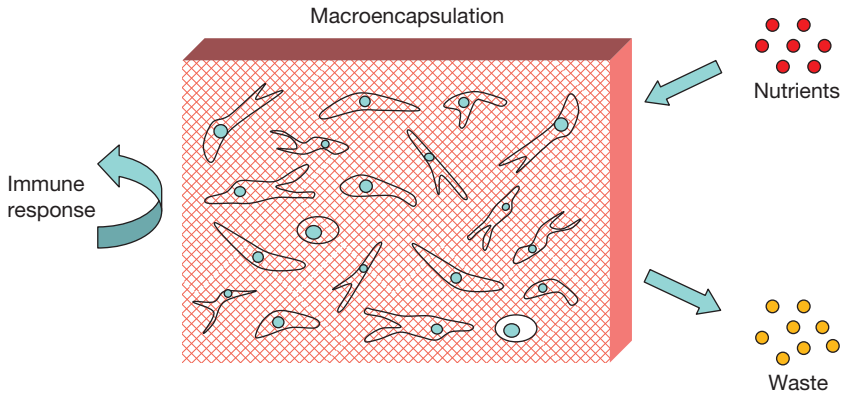

Figure 2 Macroencapsulation strategies involving encapsulation of cells into larger (> 2000 μm) scaffolds, generally used as 'replacement tissue' in various tissue engineering applications.

note the viscosity of the gel precursor solution because a material that is too viscous may produce a shear stress on the cell membrane that can cause cell death. After a uniform mixture of cells and polymer is prepared, the gelation process needs to be activated. Some natural materials, such as collagen, self-assemble with time or temperature. There are several other ways to cross-link materials including photo-cross-linking, redox reactions, thermal cross-linking, chemical cross-linking, and mixtures of the above. Photo-, redox- and thermal-cross-linking systems are controlled by radical-chain polymerization and have the benefit of reacting rapidly but may also produce radicals that can be toxic to cells. Mixed mode reactions take advantage of both methods of cross-linking. Regardless of the cross-linking method, the main considerations in gelation is cytocompatability and gelation time.[4] Depending on the application, cell-encapsulated scaffolds may be cultured *in vitro* prior to implantation or may be directly injected to the injury site *in vivo* as illustrated in Figure 1.

There are two types of common encapsulation systems: macroencapsulation (Figure 2) and microencapsulation (Figure 3). Macroencapsulation is ideal for a defect site where a void in healthy tissue needs to be replaced, such as with skin and neural tissue engineering. In these cases, cell-encapsulated

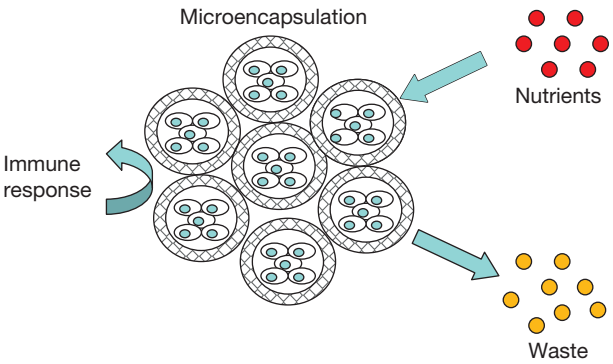

Figure 3 Microencapsulation strategies involving encapsulation of cells into smaller (< 2000 μm) microcapsules that can then be injected *in vivo* and are generally used for cell delivery applications.

devices are used to replace the injured tissue and must therefore be large enough to fill the injury site. For instance, in neural tissue engineering, tissue and encapsulated supporting cells are used to connect severed nerves and must have scaffold cues that span the entire defect. It is important to consider integration of macrocapsules with the surrounding tissue to prevent graft

rejection. Microencapsulation is defined as capsules that are <2000 μm, which generally involve a single cell suspension or a small aggregate of cells in each capsule.[3] This system is ideal for therapies where cell-released trophic factors are needed at a defect site that can be administered through encapsulated cells. In therapies for cancer, for example, cell encapsulation strategies are targeted at injecting genetically engineered encapsulated cells that release tumor reducing factors at the tumor site. Because they are not needed to replace tissue, microencapsulation may be more effective for trophic factor release due to the larger surface area for diffusion and the ability for injection.

Natural materials are commonly used for cell encapsulation processes because of their outstanding biocompatibility. The most commonly used systems are collagen, alginate, chitosan, fibrin, and HA. Collagen has been extensively used as a tissue engineering material and was the main component of an early FDA-approved tissue-engineered product (Apligraf®). It has been used as a base material for several tissue-engineered products including skin,[16] neural,[17] and haptotactic[18] applications. The main benefits of collagen is that it is very biocompatible, allows attachment of a variety of cell types, and self-assembles at 37 °C; however, the mechanics are hard to control and it degrades rapidly as it is replaced by new extracellular matrix (ECM) from interacting cells.

The most popular system for cell microencapsulation is alginate.[1,19] Alginate has been used commercially for years in the food and pharmaceutical industries; has been shown to have superior biocompatibility, long-term stability, and cell viability; and has been used in clinical trials with pancreatic islets as a therapy for diabetes.[20] Alginate encapsulation of islets improves islet cell viability and further improves islet utility by reducing fibrous capsule formation, yet needs rigorous purification steps for effectiveness.[21] Chemically modifying natural materials[22,23] or composites of natural and synthetic materials[24] may offer better control of material properties.

Synthetic materials have the advantage of potential control over gelation time, mechanics, and degradation. PEG,[13,25] polyacrylates (poly(HEMA)),[26] and polyfumarate-based[27] gels and composites[28] have been used for various cell encapsulation strategies. Since synthetic materials do not interact with cells, specific binding sites must be added to promote cell adhesion. This may be advantageous because there is more control over the type of cells that can attach to the material, avoiding problems caused by nonspecific cell adhesion and protein adsorption, which may lead to an increase in immune response. Even with control over mechanics and adhesion, the main disadvantage for synthetic materials is biocompatibility. Whereas natural materials are inherently biocompatible, synthetic materials have to be engineered for this and the biocompatibility of the cross-linker and degradation products must be considered. Commonly used natural and synthetic materials are shown in Table 1.

Beyond material considerations, the other main variable in cell encapsulation systems is the cell source. Cell encapsulation systems serve a function of either replacing damaged tissues at an injury site or providing chemokines released from encapsulated cells. Traditionally, autografts or allografts were used to obtain cells that can then be expanded *in vitro*, encapsulated, and implanted. This is possible in some cases where cells proliferate and expand *in vitro*, such as with skin. However, this is not possible in diseases where sufficient cell sources are not available, such as with liver failure (hepatocytes), diabetes (pancreatic islets), and neurological disorders. In some cases, xenografts are a possible cell source, but there is a concern of cross-species disease contamination. One example where xenografts have been used is with pancreatic islets from swine to treat diabetes.[29] Because of the fear of animal endogenous retrovirus contamination and implant rejection, xenografts have not been used routinely in implantation studies and focus in this field has been in using stem cells as a cell source for 'bioartificial organs' (see also **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**).

Table 1 Examples of natural, synthetic, and composite encapsulation materials

Natural materials	Collagen
	Fibrin
	Chitosan
	Hyaluronic acid
	Alginate
Synthetic materials	PEG
	Polyacrylates
	Polyfumarates
Composites	

Common stem cell sources are MSCs, bone marrow stromal cells (BMSCs), and embryonic stem cells (ESCs). The main advantage of ESCs is that they are pluripotent, meaning they can differentiate into any cell needed for a particular therapy and it is possible to get a large quantity of these cells. However, due to controversy in obtaining ESCs, and difficulty in controlling their fate, some researchers have refocused on more specialized adult stem cells, such as MSCs. MSCs and BMSCs are promising sources for stem cells, which can be obtained from the adult patient's bone marrow. Not only does this make the cell source noncontroversial but it also decreases the chance of immune rejection. However, they have limited pluripotency. MSCs were thought to only differentiate into mesoderm cells such as osteoblasts, adipocytes, and chondrocytes, though they have recently been shown to have more plasticity.[30] Other multipotent stem cells have also been discovered in various tissue sources such as hematopoietic stem cells and neural stem cells, which are capable of differentiating into cells of their respective organ type, though they may have more pluripotent capabilities.[31]

5.509.3. Process

5.509.3.1. Encapsulation Systems

For typical cell encapsulation processes, polymer and cells are mixed when the polymer solution is in a liquid state, and then the polymer is gelled to entrap cells within its structure (Figure 1). Cross-linking of the hydrogel is typically performed with self-assembly, ionic cross-linking, or chemical cross-linking. Self-assembling materials allow for little control over structural properties such as porosity, and gelation time. However, the main advantage is that it is not necessary to add exogenous components to the gel system that may be toxic to cells. Natural materials such as collagen often self-assemble at 37 °C and have physical cross-links, making it convenient

for cell encapsulation applications. Degradation of natural material is not readily controllable and can be too fast for many tissue engineering applications where new matrix has to be formed by cells to fill the defect site once the scaffold degrades. Also, with natural materials, it is difficult to control cell adhesion and the inflammatory response since this is usually inherent to the material.

Synthetic materials are modified to form gel systems and are generally cross-linked chemically,[32] through redox reactions,[33,34] through radical cross-linking, or by photo-cross-linking.[22,35,36] Through these modifications, polymer materials are able to form hydrogels and encapsulation systems. There are two important considerations to ensure cell viability; all materials and cross-linking solutions must be nontoxic to cells in the liquid phase and the material should gel at 37 °C. It is also important to consider how chemical cross-linking may affect the degradation and remodeling of the material. In some cases, it is possible to coordinate degradation rate with tissue formation rate by synthetically introducing degradation sites.[37] The main benefit of using polymer systems is the ability to control mechanics and pore structure as well as cell adhesion to the material, making it possible to have more control over cell adhesion and the inflammatory response.

Composite materials may offer a combination of both natural biocompatibility and synthetic control over material properties and degradation. Composites with biological materials such as collagen and fibrin allow for cell attachment, while the synthetic polymer offers more mechanical stability. For example, composites with PEG offer a possible reduction in immune response due to the bioinert quality of PEG. By using composite materials, scaffold properties can be tailored for each tissue engineering application. Advantages and disadvantages of natural and synthetic materials used in cell encapsulation systems are shown in **Table 2**.

5.509.3.2. Natural Materials

Natural materials have several advantages including support of cellular functions and endogenous factors that are present to promote cell adhesion, proliferation, and migration. However, since these materials are complex, it may be difficult to control any of these cellular functions. Several natural materials are commonly used for cell encapsulation strategies including collagen, fibrin, chitosan, HA, and alginate. These materials are often purified from tissue and therefore may have some batch-to-batch variation, which can cause problems for clinical applications. Also, they are often derived from animal tissue, which may lead to cross-species disease spreading and an immunogenic or allergic response. Although there are several problems with natural materials, to date, it has not been possible to imitate the complexity of natural tissues using synthetic counterparts, and therefore, these materials are still used for a variety of tissue engineering applications (see also **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**).

Table 2 Advantages and disadvantages of natural and synthetic materials

Natural materials	
Advantages	Cytocompatible
	Promotes cell adhesion, migration, proliferation
Disadvantages	Difficult to control material properties, that is, mechanics, degradation rate, adhesion, porosity
	Difficult to control immune response
	Batch-to-batch variations
Synthetic materials	
Advantages	Control over material properties, that is, mechanics, degradation rate, adhesion, porosity
	Better control over immune response
Disadvantages	Not inherently cytocompatible – may need chemical modification
	Difficult to mimic native structure synthetically
	Degradation products may not be cytocompatible

5.509.3.2.1. Collagen

Collagen is a major component of mammalian tissue and is used for a wide variety of tissue-engineered constructs due to its superior biocompatibility and gelation through self-assembly at 37 °C. The main advantage of collagen is that it contains several cell adhesion sites including RGD, which is a ubiquitous cell adhesion peptide shown to promote interactions with a variety of cells. Collagen gels have been used for several tissue engineering applications including skin, tendon, pancreas, and neural. They promote cell viability and function in 3D culture and cells are able to contract these gels and lay their own matrix to form 'tissue equivalents' for *in vitro* analysis and *in vivo* implantation, which is important for implant integration and vascularization (see also **Chapter 2.215, Collagen: Materials Analysis and Implant Uses** and **Chapter 2.216, Collagen–GAG Materials**).

Though collagen has many advantages, the main disadvantage is the difficulty to control cell adhesion and insufficient mechanics for many applications. One method that has been previously investigated to control the bioactivity of collagen is the conjugation of cell-specific peptides to promote adhesion of particular cell types,[38] which offers some control, but inherent adhesion sites in collagen can lead to adhesion of inflammatory cells, which can be problematic. The mechanics of collagen gels have also been previously controlled through chemical cross-linking using aldehydes, enzymes, and natural cross-linkers such as genipin; however, aldehydes cannot be used in cell encapsulation processes since they are toxic to cells.[39] Even with mechanical cross-linking, collagen stiffness may not be sufficient for some 'hard' tissue engineering applications.

Several approaches have been used in cell-encapsulated collagen gels directed at wound healing and skin repair. Enever *et al.* used rat dermal fibrobrasts (RDFs) encapsulated in collagen gels for skin development and wound healing.[16] Because skin is made up primarily of collagen and fibroblasts, collagen is a valuable material for skin tissue engineering. Chida *et al.* also used a collagen model for skin where collagen gels were contracted by kerotinocytes and fibroblasts to form a skin-like sheet,[40] showing the use of fibroblast-contracted collagen gels as a model for dermis. Schechner *et al.*[41] used collagen–fibronectin gels with human umbilical cord vein endothelial cells (HUVECs) *in vivo* and showed the formation of vasculature. This study shows the importance of using 3D constructs encapsulated with cells; these endothelial cells

increased the formation of vasculature in gels, which is important for graft integration and encapsulated cell survival. Subcutaneous implantation in mice showed that constructs were well vascularized after 31 days, which shows the ability to perfuse collagen gel tissue equivalents.

Cell-contracted collagen gels can be manipulated *in vitro* to increase strength and align fibers. MSCs have been encapsulated in collagen gels, contracted, and loaded in tension for 40 h[42] to form tendon-like structures. These constructs were implanted in a rabbit tendon defect model and significantly improved tendon repair when compared with suture alone, where biomaterial and cells were not used. Collagen encapsulation has also been used for protection and immunoisolation of islets from immune cells and enzymes *in vivo* to increase the viability and function of encapsulated islets.[43] Because of the porous structure of collagen, it allowed full diffusion of insulin, and it was shown that collagen constructs enhanced islet cell survival and function by decreasing immune-response-related cell death. Cell constructs also allowed better vascularization and therefore increased cell survival over 'free' implanted islets. Collagen has also been used for several neural applications including differentiation of ESCs to neural lineages, differentiation of neural precursor cells (NPCs),[44] directing neurons in collagen gels,[17] and promoting neuron growth *in vivo*.[45] Because of the inherent weakness of neural tissue, collagen mechanics may be ideal for this application.

5.509.3.2.2. Fibrin

Fibrin is a polymer that is blood-derived and has been shown to be very biocompatible, can be delivered with growth factors, and can form *in vivo* after injection. It consists of two components: fibrinogen and thrombin. When combined, fibrinogen converts to fibrin and polymerizes to a fibrin mesh similar to what is found during blood clotting *in vivo*. It has been used for a variety of tissue engineering applications including myocardium,[46] cartilage,[47] muscle,[48] liver,[49] skin,[50] neural,[51] and ocular[52] applications. The main advantages of fibrin are its biocompatibility, that it can be injected *in vivo*, and that it degrades into biocompatible products; however, it is often too weak and degrades too rapidly for many tissue engineering applications. It is easy to obtain from blood plasma and has been used alone or in combination with other materials with high potential in tissue engineering. Also, since it is derived from blood components, it can be purified from a patient's own blood to decrease the immune response (see also **Chapter 2.217, Fibrin**).

The mechanics of fibrin gels are traditionally controlled by the concentration of the two components of fibrin. Several studies have shown the effect of this control on angiogenesis, which is important to any cell-encapsulated system for graft cell survival.[53] Without the addition of any growth factors or adhesion sites, fibrin has been shown to promote activity of a variety of cell types, and compliance may be ideal for applications such as neural tissue engineering where soft tissue constructs are desired.[54] Cell-specific peptide adhesion domains have been conjugated to fibrin for further activity of specific cell types such as laminin-derived peptides and neurons. Fibrin has also been used as a glue or sealant for the integration of other engineering constructs.[55]

Because of the possibility of an injection delivery, fibrin has been used in applications where surgical implantation may risk increased infection. Martens *et al.*[46] used a fibrin gel system to improve retention of MSCs in the heart after injection. Previous work showed that use of MSCs is promising in heart repair after myocardial infarction, but they were only able to retain 11% of the cells in the heart after injection. Therefore, cell encapsulation in fibrin gels was used, where gel time and solution viscosity were tailored by varying the concentration of both the fibrinogen and thrombin components, and retention increased to 37%. A similar method was used by Bruns *et al.*[49] to study the injection of fibrin-gel-immobilized hepatocytes into the liver. Here, they found once again that fibrin gel was a suitable matrix for cell viability and support and a useful way to inject a healthy bolus of cells to the liver to improve diseased liver function.

Fibrin hydrogels have also been used as a material for directed stem cell differentiation. Willerth *et al.*[51] differentiated mouse ESCs into neural lineages using controlled differentiation in and on fibrin gels. They found that embryoid bodies encapsulated in fibrin gels (rather than 2D cultures) resulted in greater proliferation and differentiation. After 14 days, they were able to differentiate cells into neurons and astrocytes, which could then be used for neural tissue engineering therapies. Recent work with fibrin and MSCs shows the potential of fibrin structure manipulation in differentiation.[56] Here, they looked at variants in fibrin's binding domain to study MSC differentiation toward osteogenic lineages.

Advances in the use of fibrin include several applications where fibrin is combined with polymer materials to increase its effectiveness. By combining fibrin with controllable polymer materials, one can take advantage of fibrin's biocompatibility while improving its structural properties with a stronger material or one whose mechanics can be controlled. Examples of materials combined with fibrin include PEG,[24,57] polyurethane,[58] alginate,[59] HA,[60] and agarose.[61] These composites provide extra strength and controllability to fibrin gels. In one example, a PEG–fibrin hydrogel was fabricated that retained the biofunctionality of fibrin while having tunable permeability and mesh size, through manipulation of the PEG chain. They were able to correlate changes in structural properties with control of cellular morphology in smooth muscle cell-encapsulated gels.[24]

Although fibrin has many favorable properties for cellular interactions, the major disadvantages of using fibrin is that it degrades rapidly (within a few days), which can be improved through composites. In one study, fibrin was combined with HA to increase longevity in the body. These composite gels were encapsulated with chondrocytes and implanted *in vivo* using a rabbit patellar groove cartilage defect model. Results show that composite scaffolds had higher cell viability and implants lasted longer and better filled the defect site.[60] Composite fibrin materials show great promise in the future of tissue engineering as a cell-encapsulating material.

5.509.3.2.3. Chitosan

Chitosan is a material derived from chitin, which is found in the exoskeleton of crustaceans, and has been used in tissue engineering applications for its biocompatiblity[62] and because it can be degraded through enzymes.[63] Chitosan is a linear

polysaccharide of (1–4)-linked D-glucosamine and *N*-acetyl-D-glucosamine derived from chitin, where the degree of *N*-acetylation determines its crystallinity, which generally varies from 40 to 90%.[63,64] Chitosan has been previously used for encapsulation of hepatocytes and neural cells[65] through modifications with sugar residues and proteins. Because chitosan is a glycosaminoglycan (GAG) analog, and it is known that GAGs play an important role in chondrogenesis, chitosan is an ideal material for cartilage tissue engineering and has been used in many therapies.[64,66–68] Additionally, examination of chitosan implants for immune response show little evidence of foreign body reaction and almost no fibrosis. Several other studies show the use of chitosan-based scaffolds for wound healing,[69] orthopedics,[70] and epithelial cell applications (tracheal tissue)[71]; however, processing techniques make it difficult to encapsulate cells. In most cases, scaffolds are fabricated and used directly, eliciting a low immune response. Chitosan can be chemically modified through primary amino acid groups to increase its use in cell encapsulation. For example, chemically modified chitosan has been encapsulated with MSCs and shows promise as an injectable biomaterial (see also **Chapter 2.213, Chitosan**).[72]

Jin *et al.*[73] showed one application where chitosan was made into an injectable hydrogel through modifications that allow gelation at neutral pH and cross-linking with horseradish peroxidase and H_2O_2. Chondrocytes were encapsulated into these gels and were viable *in vitro* and retained a rounded morphology, which is critical for efficient chondrogenic matrix production. These scaffolds are a promising material for cartilage tissue engineering.

During xenotransplantation of insulin-producing cells as a therapy for diabetes, chitosan/gelatin scaffolds have been shown to have immunosuppressive properties and improved viability and function.[74] In this study, mouse insulinoma cells (NIT-1) were encapsulated in agarose microspheres, which were then encapsulated in a chitosan/gelatin solution and injected subcutaneously (toward the rear of each rat) into rats and the nonfasting blood glucose level was recorded from the tail vein puncturing postoperation. Chitosan/gelatin encapsulation was shown to be cytoprotective and prolonged normal blood sugar levels in rats when compared to unencapsulated constructs.

Chitosan has also been used in neural applications where bone marrow stromal-cell-derived Schwann cells were encapsulated in a chitosan sponge and implanted into a rat sciatic nerve defect model.[75] Schwann cells are supporting cells in the peripheral nervous system and have the ability to guide regenerating axons. In this study, Schwann-cell-encapsulated constructs showed significantly higher numbers and length of regenerating axons compared to non-cell-laden scaffolds. Four months postsurgery, chitosan gels were no longer present. The chitosan not only promoted axon growth but has also been shown to prevent fibrosis, which is important for reconnection of axons after nerve injury.[75,76]

5.509.3.2.4. Hyaluronic acid

HA is a naturally found, nonadhesive, biocompatible polysaccharide that comprises alternating D-glucuronic acid and *N*-acetyl-D-glucosamine and is found in most connective tissues. HA is enzymatically degradable and important in many cellular functions including attachment, proliferation, and migration, and has been previously used for cartilage tissue engineering,[77] neural tissue engineering,[78] and drug delivery. HA can be readily modified on its hydroxyl group with methacrylation[22] and photo-cross-linked to form a hydrogel for cell encapsulation. Varying methacrylation can be used to control the mechanical and degradation characteristics of the hydrogels.[22,79] Additionally, by adding hydrolytically degradable ester linkages, degradation characteristics can be further controlled.[23] **Figure 4** shows the chemical structure of HA with both methacryate and ester linkage conjugation as well as the degradation profiles of these gels. **Figure 4(c)** shows an example of MSCs encapsulated into these gels (see also **Chapter 2.214, Hyaluronic Acid**).

Naturally, HA is nonadhesive to cells; however, adhesive peptides, such as RGD, can be incorporated in the gels and concentrations of these peptides can be altered to control adhesivity. Because of the versatility of HA gels, they are a promising material for use in tissue engineering and, specifically, cell encapsulation strategies. HA has potential use in cardiac tissue engineering because it has recently been shown to have an anti-inflammatory effect and enhanced angiogenesis by the recruitment of endothelial cells, particularly in low molecular weight forms by promoting EC migration, proliferation, and sprouting.[80–82] Angiogenesis effects decrease with increasing molecular weight of HA[83] because it is thought to prevent cellular adhesion through interactions with the CD44 receptor.

HA is primarily utilized to encapsulate cells whose native ECM is rich in HA or GAGs. This allows the constructs to mimic the native cellular environment, which has been shown to positively affect cell fate and viability.[77,84–86] Cartilage and epithelial tissues tend to have a relatively high concentration of HA compared to other tissues, making them ideal for HA constructs. Since HA gelation can be controlled chemically, one approach is to develop an injectable hydrogel to fill defects, regardless of shape. In these systems, an HA solution preloaded with cells to be encapsulated can be injected *in situ* into defects and then polymerized into a gel construct. This way, a nonuniform defect can be filled homogenously without inducing further damage.

Chung *et al.*[36,77,87,88] used HA hydrogels to encapsulate chondrocytes from various sources, resulting in the *in vivo* production of ECM and neocartilage formation. They found that cell source directly affects the nature and composition of ECM produced. Specifically, constructs seeded with articular chondrocytes did not exhibit significant neocartilage formation or an increase in compressive modulus. Constructs composed of auricular chondrocytes, however, showed significant neocartilage formation and bulk growth as well as an increase in compressive modulus.[77] The same group found that seeding MSCs in HA matrices induce these cells to differentiate into chondrocytes.[36,88] By measuring gene expression for proteins upregulated in chondrocytes, such as type II collagen and aggrecan, they found that HA hydrogels seeded with MSCs showed significantly greater chondrogenesis than inert materials such as PEG.[36]

HA has also been investigated for use in repairing bone defects. However, Zou *et al.*[89] showed that HA downregulated bone-related gene expression and may have a moduli too weak

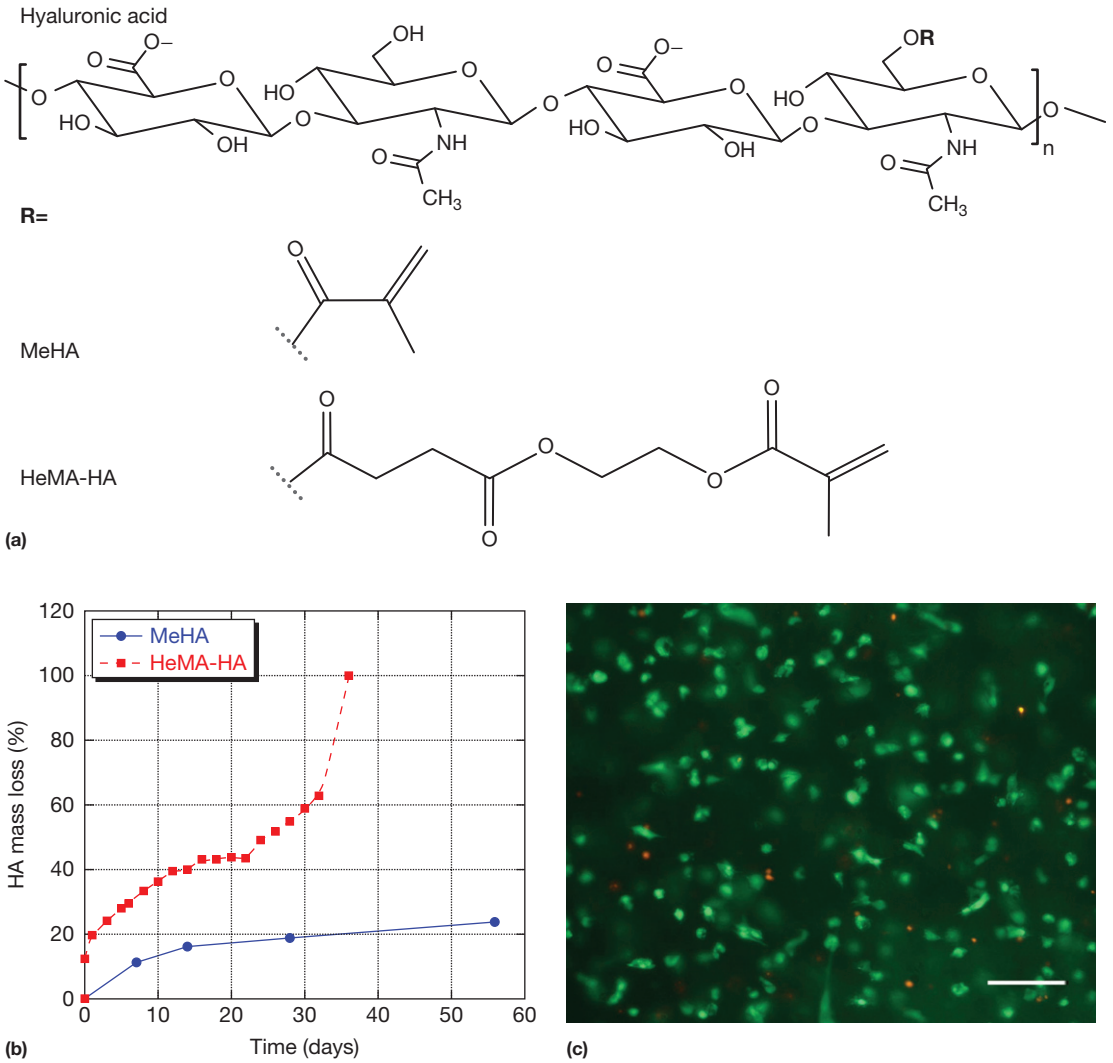

Figure 4 (a) Chemical structure of HA, MeHA, and HeMA-HA. (b) Degradation profile of MeHA and HeMA-HA. HeMA-HA has ester linkages incorporated into the structure allowing for hydrolytic degradation. (c) Live (calcein, green) and dead (ethidium homodimer, red) hMSCs at 1 h post-photo-encapsulation in hyaluronic acid (HA) based hydrogels conjugated with a RGD containing cell-adhesive peptide at a concentration of 1 mM. Scale bar = 100 μm.

for use in bone repair. Due to their compliant nature, HA hydrogels have been investigated for use in neurological disorders. As neurons do not divide or repair themselves, transplantation is an ideal approach. However, transplanted neural cells have low viability *in vivo*. HA has been investigated as a material for neural cell encapsulation constructs to increase viability. For instance, Pan *et al.*[90] found that HA hydrogels allowed NPCs to differentiate into neurons and glial cells for central nervous system repair. Other groups have also attached various differentiation factors to HA hydrogels to increase NPC differentiation and viability. Iwata *et al.* found that hydrogels with ionically attached brain-derived neurotrophic factor (BDNF) increased neuron survival *in vitro*.[91]

5.509.3.2.5. Alginate

Alginate is one of the oldest and most commonly used materials for cell encapsulation strategies due to its superior biocompatibility and bioinert qualities. Alginate is a naturally occurring polysaccharide found in the cell walls of bacteria and plants, most commonly seaweed,[92] and can form a gel in the presence of divalent cations (e.g., calcium or barium) via ionic cross-linking. Though some control of degradation and material mechanics is possible by variations in molecular weight and macromer concentration, as divalent cations are replaced with monovalent cations in the body, alginate will slowly dissolve. Recent chemical advances have afforded more control over mechanics, cross-linking, and degradation of alginate through alginate methacrylation.[4,93] Alginate is very biocompatible but not generally cell adhesive and must be conjugated with cell adhesion peptides[94] or combined with cell adhesive materials such as gelatin[95] to encourage cellular interactions.

Traditionally, alginate is used for immunoisolation of cells that release factors into the body, most commonly insulin-producing cells. This approach has been used as early as 30 years ago for encapsulating xenotransplants of islets[96,97]

to prevent destruction of islet cells by immune response. Though this strategy has had some success, the reverse of insulin dependence has not been able to sustain a long-term effect. Currently used alginate encapsulation systems generally use an alginate–poly-L-lysine (PLL) composite where a final coating of PLL helps control bead strength and diffusion characteristics. The main difficulty with using alginate materials is the need to produce consistent, well-purified, and reproducible gels.[98] Purification is particularly important for the survival of encapsulated cells in alginate microcapsules and current technology leads to a reoccurrence of insulin dependence of ~90% within 5 years of islet transplantation.

Other than for islet transplantation, alginate encapsulation systems have been used for several systems including stem cell differentiation, chondrocyte encapsulation for cartilage tissue engineering, cardiac tissue engineering, and nervous system disorders.[19,95,99–101] Most of the current focus is on decreasing the immunogenic response created by these systems. In a recent study, genetically modified MSCs were encapsulated in alginate–PLL microspheres and injected adjacent to glioblastoma tumors. Cells were genetically modified to release an angiogenesis inhibitor, and significant tumor volume reduction was observed.[102] Alginate–PLL microencapsulation provided immunoisolation for injected cells, increasing cell viability and allowing injection of cell containing microspheres to the site of the tumor.

Alginate has also been used for macroencapsulation studies specifically in cartilage tissue engineering applications. In a recent study with alginate–gelatin composite hydrogels, chondrocyte-laden hydrogels were implanted in a femoral defect sheep model where they showed that cell-laden scaffolds integrated well with surrounding tissue and showed improved cartilage regeneration at the defect site. Alginate–gelatin composites showed good biocompatibility and potential as an osteochondral regeneration matrix.[95]

Recent work has also shown the utility of alginate material for myocardial defects.[100,103] In one study, isolated fetal cardiac cells were grown in porous 3D alginate scaffolds and transplanted onto an infarcted heart, and echocardiography was performed 65 ± 5 days after implantation with cells or sham-operation control. Alginate scaffolds showed increased neovascularization and attenuated left ventricular (LV) dilatation with improved function compared to controls.[100] Other work with human ESCs injected into 3D implanted alginate scaffolds in a rat model of myocardial infarction (MI) showed attenuation of post-MI scar thinning and LV dysfunction.[103] These studies show the utility of cell-encapsulated alginate scaffolds for cardiac applications.

5.509.3.3. Synthetic Polymer Materials

Polymer materials offer advantages over natural materials such as better control over material properties including mechanics, degradation rate, and porosity, but may need to be engineered to introduce desired biological responses. Several synthetic materials are commonly used in cell encapsulation processes including PEG, polyacrylates, and polyfumarate-based gels. Through chemical modifications, the material properties of these scaffolds can be tailored for specific tissue engineering applications. However, since they may not be inherently biocompatible, cell adhesion needs to be controlled through modification with peptide adhesion sites or ECM proteins. In some cases, this can be advantageous by preventing adhesion of immune cells and thus reducing immune response. Additionally, materials can be customized for adhesion of specific cell types while inhibiting the adhesion of others. However, even with intricate chemistries, the goal of synthetic materials is to mimic the complexity of natural materials and this is difficult to accomplish while keeping materials, cross-linkers, and degradation products cell-tolerable (see also **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)** and **Chapter 1.123, Degradable Polymers**).

5.509.3.3.1. Poly(ethylene) glycol

PEG-based gels are the most widely used synthetic polymer in tissue-engineered systems because they have a history of biocompatibility, are bioinert, and allow for chemical modifications to control material properties. Recently, PEG has been used in several composite systems, and a modified PEG has been used as a nontoxic cross-linker.[104] Additionally, several implant systems use PEG coatings to reduce the immune response. PEG has been used in cell encapsulation systems with various cell types including chondrocytes, vascular cells, neuronal cells, and fibroblasts for a wide range of

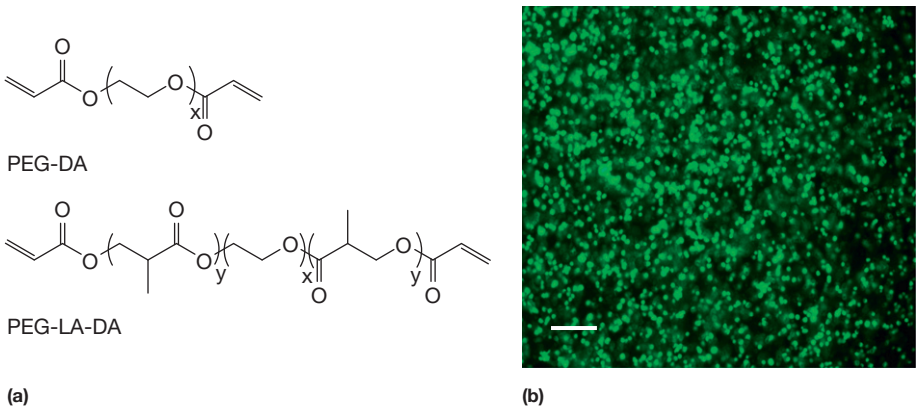

Figure 5 (a) Chemical structure of PEG-DA and PEG-LA-DA. (b) Live (calcein, green) and dead (ethidium homodimer, red) hMSCs at 24 h encapsulation in a PEG hydrogel. Scale bar = 200 μm.

applications.[105–110] Although PEG is naturally nonadhesive, it can be modified with cell-adhesive peptides or used in composite systems with natural bioadhesive materials to provide mechanical and degradation control. Examples of a degradable and a nondegradable PEG used in cell encapsulation systems are shown in Figure 5. Acrylated PEG (PEG-DA) can be conjugated with lactic acid units (PEG-LA-DA) to provide ester linkages for degradation control. MSCs are shown encapsulated in a PEG hydrogel 24 h postencapsulation (Figure 5(b)).

Due to the versatility and ability to modify PEG hydrogels, they are used in many specialized cell-encapsulated hydrogel systems. The simplest modification to increase cell adhesion is the addition of RGD peptide sequences, but various other synthetic peptide sequences have been added to promote specific function. For example, laminin-derived peptides (IKVAV, YIGSR, RGD, IKLLI, LRE, PDSGR) have been conjugated to PEG and were shown to increase viability and functionality of encapsulated β-cells, which are used for insulin production as a treatment for diabetes.[109] In another study, hydrolytically degradable lactide units are conjugated to PEG to allow the hydrogel mesh size to change with time.[105] NPCs were encapsulated in these gels and showed good viability and proliferation with control over degradation and mechanics, which is not possible in natural-based hydrogel systems such as collagen.

Traditionally, immunoisolation strategies rely on the mesh size to reduce the immune response, but proinflammatory cytokines may still diffuse through the barrier because of their small size. Further reduction of mesh size would prevent diffusion of nutrients and waste. A novel study with PEG shows that PEG hydrogels can be conjugated with a peptide sequence that contains a cytokine-antagonizing agent that sequesters TNF-α, a proinflammatory agent, and reduces its effect on encapsulated cells.[13] The diffusion of these cytokines has been shown to cause apoptosis or loss of function of encapsulated cells. Due to the ease of modification of PEG gels, this technique can successfully be adapted to other PEG-based cell encapsulation strategies and can potentially be used in PEG composites.

Another example of specialized hydrogels was recently demonstrated in PEG gels conjugated with matrix metalloproteinase (MMP) and co-encapsulated with HUVECs and a small bioactive peptide, thymosin β4 (Tβ4).[25] In this system, the gel acts as a controlled release device for Tβ4, which is important for HUVEC attachment, and induces vascular-like network formation. Tβ4 increased MMP-2 and MMP-9 secretion in HUVECs, which in turn triggered the release of Tβ4 and increased vascularization and further increased the function of HUVECs. This elegant system is an example of using PEG hydrogels for immunoisolation and cytokine release, which may be important for improved vascularization and can potentially be used with alternate bioactive peptide/cell systems.

Recent chemical advances show the versatility of PEG hydrogels for cell encapsulation and tissue engineering strategies. Additionally, much work has been done with PEG composites, where PEG–gelatin and PEG–fibrinogen composites have shown the utility of natural–synthetic composites which may offer both control and biocompatibility.[24,111] Combinations of these systems may hold the key to future tissue engineering strategies.

5.509.3.3.2. Polyacrylates

Polyacrylates are another form of synthetic polymers that have been used to encapsulate cells for tissue engineering systems and include poly (methyl methacrylate) (PMMA), polyacrylamide, and hydroxyethyl methacrylate (HEMA). Though polyacrylamide and PMMA are used for cell experiments, they are traditionally used in 2D systems, whereas HEMA has been used in several encapsulation studies. Acrylation or methacrylation of polymer materials allows for chemical control of gel formation and mechanics of hydrogels. Due to this increased control of gelation, they are often used in injectable systems to fill irregular-sized defects. One example is the use of goat MSCs encapsulated in an acrylated polymer, acrylated poly(6-aminohexyl propylene phosphate) (PPE-HA-Acrl). Goat MSCs were photoencapsulated and showed good viability and mineralization in the scaffold when grown in osteogenic media, demonstrating the potential for use in bone tissue engineering applications.[112]

HEMA has been used for several encapsulation studies.[26,113–116] In one example, HEMA-methyl methacrylate (HEMA-MMA) was used for immunoisolation of engineered vascular endothelial growth factor (VEGF) producing cells, and enhanced vascularization to improve cell survival *in vivo*.[116] Previous work has shown that HEMA-MMA microcapsules promote encapsulated cell survival only for at most 3 weeks with a significant decrease in cell survival at this time point. When engineered cells were encapsulated, VEGF secretion increased vascularization and therefore cell survival. Such strategies can be used in combination with other cell encapsulation systems to increase encapsulated cell survival through vascularization.

In another study, a collagen–HEMA composite material was used for hepatocyte encapsulation systems targeted for bioartificial liver (BAL) devices.[115] In this case, hepatocytes were encapsulated in microcapsules with a collagen core and HEMA outer shell that controlled mechanical strength and diffusion of nutrients, waste, and chemokines. Bilayer microcapsules were successfully fabricated and showed good viability and functionality of encapsulated hepatocytes. HEMA microcapsules have emerged as an alternative to alginate encapsulation, which traditionally have problems with mechanical strength and purity of alginate.

5.509.3.3.3. Polyfumarates

A more recently developed class of materials is fumarate based, which have the advantage of containing polymerizable vinyl groups and ester linkages that are susceptible to hydrolytic degradation. Since the degradation product is fumarate, which is natural and cytocompatible, this is an attractive material for cell encapsulation strategies.[4] Fumarate-based materials are formed with modifications for injectability, increased degradability, and thermal cross-linking strategies.[33,34,117–119]

In one study, oligo(poly(ethylene glycol) fumarate) (OPF) was used as an injectable, biodegradable cell encapsulation system using a thermal radical cross-linker for orthopedic tissue engineering applications.[33] This material showed good cell viability and differentiation of encapsulated MSCs, with mineralized matrix found throughout the scaffold after 28 days. Additionally, mechanics and degradability can be tailored for other tissue engineering applications through the selection

of cross-linking molecules. In this case, the goal was quick gelation at 37 °C, which was accomplished through a radical-initiation system.

Another example of a fumarate-based material used for cell encapsulation strategies is poly(lactide-*co*-ethylene oxide-*co*-fumarate) (PLEOF), which was used to encapsulate marrow stromal cells.[118] This material was made into an injectable hydrogel where gelation characteristics are controlled by the ratio of MMP-derived peptide cross-linker to methylene bisacrylimide. This material showed osteogenic differentiation of encapsulated cells with mineralized matrix production and has an advantage over natural materials due to the control of mechanics, degradation, and decreased immune response. It is also advantageous over some other synthetic material because it is injectable, which is attractive for irregularly shaped osteochondral defects.

Fumarate-based material composites have also been used for cell macroencapsulation strategies.[119] In one study, OPF hydrogels were combined with TGF-β loaded gelatin microspheres and rabbit marrow MSCs to evaluate the differentiation behavior of MSCs in OPF hydrogels with and without TGF-β and varying swelling ratios controlled by PEG cross-linking. In this study, the authors found that chondrogenic differentiation increased in gels with higher swelling ratios, or increased mesh size, and containing TGF-β microcapsules.

5.509.3.4. Composites

Composites can possess the advantages of several materials, making it possible to tailor tissue-engineered constructs for specific applications. In some cases, combinations of natural materials that are bioactive with polymer materials allow the use of polymer materials without the addition of peptide adhesion sites. In this way, natural materials offer biocompatibility, while synthetic materials can be used to control material properties. Additionally, composite materials may offer better control of mechanics, gelation time, cell adhesion, and porous structure than one material alone.

For example, Liao *et al.* used a composite material of HA and collagen for cartilage tissue engineering because they wanted to take advantage of HA's chondroprotective properties while being able to control gelation and residence time at the defect site through the use of collagen.[120] At optimal HA concentrations, they found an increase in cell proliferation and matrix synthesis compared to collagen alone. If HA is too high, this effect is reduced, which they believe was due to steric hindrance, self-association, and chain entanglement, preventing attachment of chondrocytes and nutrient and waste diffusion. A similar study with fibrin/HA gels showed a significant increase in cartilage-like matrix production and showed that HA was able to delay degradation compared to fibrin alone.[60] HA is a common composite material for cartilage tissue engineering due to its presence in native cartilage tissue.[36,87]

PEG is another material that is often used with composite structures because it reduces nonspecific protein absorption and therefore fibrosis.[121] PEG offers the advantage of being bioinert and having the ability to be chemically modified with various moieties for specific tissue engineering applications. An example of this is a hybrid scaffold of PEG and fibrin where the material retains its bioactivity due to its fibrin backbone, but structural properties such as mechanics and pore size can be chemically controlled. Additionally, a photoinitiated cross-linking mechanism can be incorporated, which is not native to fibrin gel systems.[24] By encapsulating smooth muscle cells, they showed good cell viability in these structures and a high level of physical control. A similar approach was used by Rizzi *et al.*[122] where a genetically engineered protein polymer was synthesized and combined with PEG to form a hybrid material with bioactive properties, as well as chemical control.

Collagen and fibrin are frequently used to make polymer materials bioactive and cell-adhesive.[120,123–127] In one example, fibrin was combined with polyurethane for cartilage tissue engineering. Fibrin (vs. no-fibrin) constructs had higher cell viability, more uniform cell distribution, a threefold increase in retained synthesized GAG, and a two- to sixfold increase in type II collagen and aggrecan gene expression, meaning that chondrocyte phenotype was maintained. However, there is still room for further optimization of fibrin properties in order to prolong chondrocyte phenotype and influence the formation of cartilage-like matrix throughout the constructs.

The future of cell encapsulation technology and the formation of bioartificial organs may be in composite materials that are tailored for each application. Control of adhesion, mechanics, degradation, porosity, and immune response will allow for the creation of materials and cell constructs tailored for each application.[128]

5.509.4. Representative Applications

5.509.4.1. Diabetes Mellitus

Patients suffering from diabetes have deficiencies in producing insulin and therefore cannot control blood glucose levels. Patients suffering from type I diabetes generally rely on exogenous insulin therapy either through injection or by a continuous flow pump. Tissue engineering therapies involve implanting insulin-producing cells to decrease exogenous insulin dependence, and therapies for diabetes are at the forefront of cell encapsulation technologies. The main difficulty in cell injection is rejection or fibrosis that prevents diffusion of insulin, and therefore encapsulation technologies are promising for immunoisolation and overcoming these problems. Several cell sources and materials have been explored. Cell sources include ESCs, tissue progenitor cells, islet cell lines, and xenografts. The most commonly used material for encapsulation is purified alginate, but alginate composites and polysulphones have also been investigated.[129] Initially, the most common cell source was xenografts, which showed a marked reduction in insulin dependence; however, the fear of retrovirus contamination quickly reduced the investigation of this therapy.

The progress of implantation of insulin-producing cells has been slower than initially expected due to the immune response created by implantation and the need for a reproducible immunoprotective barrier for implanted cells.[130] Major concerns for transplantation include hypoxia, biocompatibility of the material, and immunoprotective material properties. In diabetes, the problem is that the immune system destroys original β cells, so immunoprotection is particularly important. The polymer barrier is used to prevent diffusion of large

molecules of the immune system to the encapsulated cells but allow for small molecules such as nutrients and waste to diffuse through.[129] The main advantage of using encapsulated cells is that there is a shortage of donor islets, and using encapsulation methods to reduce immunosuppression will allow for the use of animal islets and engineered insulin-producing cells.[131]

Several materials have been used as a cell encapsulation system for insulin-producing cells, including PEG,[132] chitosan,[74] collagen,[133] and alginate.[134] Cell sources include engineered insulin-producing cells, stem cells, and xenografts, with xenografts being the best at regulating blood glucose levels. Alginate materials have been used in clinical trials, and composite materials of alginate–PEG and alginate–PLL have been investigated to decrease nonspecific protein absorption and increase islet cell survival.[20,135] Alginate provides an immune response suppression barrier that increases the survival rate of islet cells. Several studies have shown the use of alginate-encapsulated islets in various animal models.[98,136–138] The main delay to routine clinical use is the need for a source of highly purified, high-quality alginate. Because alginate is a natural biomaterial, changes in source may cause great variations in material quality. Additionally, specialized purification techniques will be required to decrease the immune response; the amount of purification has a direct effect on islet cell survival.[98] Furthermore, recent work shows the importance of the influence of a specific material on insulin secretion of islet cells, and this could be an important area of further investigation.[139] In a recent study of xenotransplantation of porcine islets into a diabetic dog model, it was found that dogs with implanted porcine islets showed a significant decrease in insulin need,[136] so if the possibility of retrovirus contamination can be reduced, this may be the most direct approach.

5.509.4.2. Liver

Currently, the only treatment for liver failure is a liver transplant, but the shortage of donor livers and risk of immune rejection create a need to find new therapies.[140] Two methods have been proposed for the use of tissue engineering to develop cell-based strategies to target liver failure: extracorporeal BAL devices and implantable tissue engineering constructs. Due to the lack of a proliferative ability of mature hepatocytes, and the anchorage dependency and material sensitivity of hepatocyte and hepatocyte-like cells, cell encapsulation techniques will be important for increased hepatocyte differentiation, to preserve functionality, and for increased cell viability.

For the development of a stable BAL device that can filter a patient's plasma extracorporeally, it is necessary to find a source for metabolically active liver cells. Therefore, the most important goal is to determine the optimal cell source and conditions that would keep these cells metabolically active. The 3D environment is very important for the culture of hepatocytes because they are very sensitive to material and are anchorage dependent.[141] In one example, human fetal hepatocytes were cultured in alginate microcapsules and showed mature hepatocyte properties after 4 weeks. In addition to differentiation and proliferation, cells showed the formation of bile ducts which are typical of the liver. By using alginate microcapsules, cells can easily be released after proliferation for use in therapies[142] or can be used in capsules *in vitro*. In this area of study, the main goal is to develop a large number of functional cells for use in BALs in order to filter plasma for patients with compromised liver function.

Another approach to liver failure is implantable cell therapies that involve cell encapsulation, where cells and materials are injected or implanted onto the compromised liver. Examples of implant material include PEG,[143] alginate,[144,145] collagen,[115] HA,[128] and fibrin.[55] The main advantage of cell encapsulation is that the material can help reduce immune rejection and increase cell survival to promote functionality. The most common material for hepatocyte encapsulation is alginate, which has been used with many cell sources including ESCs, progenitor cells, and mature hepatocytes. In order to maintain hepatocyte function or direct stem cell differentiation into hepatocyte-like cells, it has been shown that it is important for cells to be grown in a natural, liver-like, 3D environment. The first step in liver tissue engineering is developing a system to culture hepatocyte cells *in vitro* in order allow for proliferation to obtain enough cells for *in vivo* use. Since it is known that 3D culture is important, research has been focused on finding the appropriate material system to increase hepatocyte function. In addition to cell source and material, heterotypic implantation or heterotrophic stimulation may be important for hepatocyte function, and several approaches are being investigated.[146–149]

5.509.4.3. Neurological Diseases

The nervous system is one of the most complex systems in the body and requires a multifaceted collaboration between materials, cells, and growth factors for repair after injury or degeneration. The primary cells in the nervous system, neurons, do not proliferate but can grow after injury if provided the right environment. Therefore, tissue engineering strategies may be the key to providing this environment with the inclusion of appropriate materials and supporting cells to direct neurons. Cell encapsulation strategies may include neural precursors, stem cells, neural supportive cells, or genetically engineered cells. It is known that soft materials are important for nerve growth, and several tissue-engineered constructs have been used including collagen,[17] fibrin,[54] HA,[90] and PEG.[150] Cell therapies have been used to target several neurological diseases including multiple sclerosis,[151] Parkinson's disease,[152] Alzheimer's disease,[153] and spinal cord injury (SCI) (see also **Chapter 5.531, Peripheral Nerve Regeneration** and **Chapter 5.532, Nerve Tissue Engineering**).[154]

Though neurons can grow if provided the right environment, supporting cells are important to provide growth factors and myelination and, in some cases, additional neurons are needed for sufficient repair. Hence, cellular encapsulation therapies are a key component of nerve repair strategies including encapsulated Schwann cells, olfactory ensheathing cells, ESCs, and marrow stromal cells.[155] ESCs and NPCs have the potential to differentiate into neurons and glial cells, making them an ideal cell source; however, difficulties in controlling differentiation have limited their use. Encapsulated cells have the important role of providing growth factors and guidance channels for severed neurites and axons and myelinating new growth that was demyelinated due

to injury. Myelination is important for the transmission of electrical signals throughout the nervous system and is necessary for full recovery. Additionally, scaffold cell systems in the nervous system can influence cell alignment; scaffolds should provide a matrix where supporting cells (i.e., Schwann cells, olfactory ensheathing cells) will be aligned and provide guidance to growing axons through the scaffold toward nerve targets. Since an immune response often leads to fibrous tissue formation after nerve injury which blocks the regrowth of neurites, it is important for implant materials to limit this response and provide a matrix for nerve growth.

In encapsulated cell therapies for neurological disorders, it is particularly important to minimize host response because regrowing neurons are unable to cross fibrotic tissue and a decreased immune response increases encapsulated cell survival and function. One example of a cell-encapsulated strategy is for Parkinson's disease, which is characterized by dopamine deficiencies that can cause secondary brain deterioration, loss of motor function, and cognitive issues. In order to treat this, encapsulated dopamine-secreting cells have been implanted to provide a source of dopamine and have shown improved function in rat and primate models, and similar methods have gone into phase 1 clinical trials in Japan[152,153,156] with no immunosupression. Important factors to consider for these therapies are sufficient diffusion of neurotrophic factors through the membrane wall and addressing the lack of the ability of encapsulated cells to integrate with host tissue due to membrane properties.[152]

Several cell encapsulation strategies have been incorporated for central nervous system therapy, mostly targeted at creating cell-encapsulated growth factor-secreting glial cells or neural stem cells to the injury site to promote neurite growth.[150,157–160] In one example, neural progenitor cells were encapsulated in PEG/PLL photopolymerized hydrogels, which form a porous soft hydrogel environment for cell growth. Neural progenitor cells showed high viability and ~55% differentiation into mature neurons with the rest of the cells primarily in the undifferentiated state. These gels have potential in the central nervous system as an environment that supports neuron differentiation and growth potential in combination with other therapies,[150] possibly ones that will include directed differentiation of neural precursors to both neurons and glia. Another recent approach in cell encapsulation therapy for SCI is the implantation of alginate-encapsulated BDNF-producing fibroblasts. Encapsulated cells provided significantly greater functional recovery than unencapsulated cell implant controls. This study shows the functionality of alginate as an environment for neurite growth and the use of encapsulated engineered cells for release of therapeutic factors.[154] In researching cures for neurological disorders, it is expected that a combination of therapies will be necessary to reverse motor and cognitive loss. This therapy will most likely include the use of implanted materials, cells, and growth factors to promote growth of injured and degenerate neurons.

5.509.4.4. Cancer

In the last 10 years, genetically engineered cells that release chemotherapeutic factors targeted at the tumor site have shown promise for use in cancer therapies to avoid toxic effects of systemic administration. Initially, cells were injected into the injury site and this approach showed promise; however, graft rejection is often cited as the biggest concern. To overcome this problem, autologous cells have been used, but this process is time consuming and cannot be scaled up since each patient's cells must be custom-genetically-engineered. An alternative approach is cell-encapsulated constructs. By tailoring the encapsulation material, this strategy can reduce the immune response while implanting cells directly to the tumor site. Manipulating scaffold properties can control diffusion of chemotherapeutic factors. Several studies have shown the use of encapsulated cell technology for tumor suppression through cell release of different factors.[161–164] Novel technologies in cancer therapy involve genetically engineered cells that are programmed to secret molecules specific for tumor suppression.

One example of this is an approach by Cirone *et al.* to engineer nonautologous mouse myoblasts to secrete interleukin-2 while encapsulated in alginate–PLL–alginate microcapsules. Secreted interleukin-2 is targeted toward HER-2/*neu*-expressing tumors in a mouse model and this system has been shown to slow tumor progression and increase animal survival.[161] A similar approach was used in a phase I/II clinical trial where genetically modified allogenic cells that express the cytochrome P450 enzyme which locally activated systemically administered ifosfamide at a tumor site, leading to some success in targeted therapeutics.[163] Additionally, work has been done in encapsulating endostatin-secreting cells in alginate microcapsules and, when implanted proximal to glioblatomas, they were found to decrease tumor growth by >70%.[165–167] These studies illustrate the ability to use angiogenesis inhibitors for cancer treatment.

Hao *et al.*[162] recently investigated the use of genetically engineered alginate-encapsulated cells that release TNF-α. Systemic administration of TNF-α has been shown to regress tumors, but is only tolerated at low doses in human trials. In this approach, the encapsulated genetically engineered J558 cells that release TNF-α were implanted into the tumor and significant tumor cell necrosis and reduction of tumor size were observed.

5.509.4.5. Cartilage

In cartilage tissue engineering, there are important considerations of cell type and materials with the goal to deliver cells and growth factors to the defect site. Several cell types have been investigated, including chondrocytes, fibroblasts, and stem cells. Cartilage is composed of a sparse network of cells distributed in a dense matrix composed of type II collagen and proteoglycans important for specialized mechanics of cartilage tissue. As a result of an increased aging population, obesity, and a more active adult population, damage to cartilage due to osteoarthritis, degenerative joint disease, or injury is increasing, leading to the need for cartilage repair strategies. Due to the low numbers of natural chondrocytes available, other cell sources and materials that promote chondrogenesis and proliferation are being investigated. Various natural and synthetic materials have been used for cell encapsulation strategies in cartilage tissue engineering including collagen, chitosan,

fibrinogen, HA, alginate, PEG-based materials, and fumarate-based materials. Important considerations for cartilage materials are degradation control, cell viability, differentiation, proliferation, ECM production, diffusion of nutrients/waste, the ability to fill the defect site, interaction with surrounding native cartilage, and ability to provide mechanical support at the defect site.[168] Injectable scaffolds may be particularly useful in cartilage tissue engineering due to the irregular defect size (see also **Chapter 5.515, Cartilage Tissue Engineering**).

Natural materials most often used in cartilage tissue engineering strategies are chitosan and HA due to the high content of GAGs. In a recent study with injectable chitosan and sheep chondrocytes, injected chondrocytes encapsulated in temperature-responsive chitosan showed high matrix production *in vivo* and a potential to repair cartilage defects.[169] Though this approach was successful, the main issue is the lack of a sufficient source of chondrocytes for cartilage repair.

PEG is the most widely used synthetic material for cartilage tissue engineering. A recent approach with PEG-encapsulated chondrocytes used dynamic loading to promote cartilage development.[170,171] In this study, a hydrolytically degradable PEG was used and physiological loading conditions were used *in vitro* to evaluate the potential of PEG-based hydrogels for cartilage tissue engineering. Dynamic loading causes an increase in gel degradation behavior.[171] Chondrocyte function, specifically anabolic and catabolic activity, increased in PEG gels for scaffolds with early application of dynamic loading, which may be important for cartilage repair.[170] Due to the ease of tailoring PEG hydrogels, the possibility to control mechanics and degradation can influence chondrocyte function *in vivo*.

Another important approach is the use of HA and MSCs. MSCs have the potential to be a cell source for cartilage tissue engineering because they can proliferate and differentiate into chondrocytes. Mechanical properties of HA can be controlled by increases in methacrylate or acrylate modification, and *in vitro* and *in vivo* studies have shown the viability and functionally of MSCs encapsulated in HA hydrogels.[22,23,36,88,172] HA is naturally found in cartilage and contains cell surface receptors that may be important for chondrogenesis, including CD44, CD54, and CD168. When compared to differentiation in PEG, a bioinert scaffold, MSCs encapsulated in HA showed upregulation of cartilage-specific markers *in vivo*.[172] In a rabbit defect model, MSCs encapsulated in a composite of HA and gelatin were shown to increase defect repair when compared to material-only and cell-only controls. In the experimental group, defects were completely filled with firm, translucent cartilage at 12 weeks and showed superior integration with host tissue.[173]

5.509.5. Summary

It is becoming apparent that the encapsulation of cells in either natural or synthetic materials is a useful technology for a range of applications, including islet cell encapsulation for diabetes or for the delivery of cells for tissue regeneration. The material component is essential and must be designed appropriately from the gelation process to the final material properties that support the functionality of the approach, and considerations of cellular viability and immune response must be taken into account. The material component may be engineered for the appropriate physical properties, such as mechanics and cross-linking, as well as cellular interactions. The cell component may include allogenic transplants, xenogenic sources and may even involve genetic manipulation for enhanced results. Future directions will include advances in material design and processing, as well as in the engineering of cells for desired outcomes.

Glossary

Bioactive Capable of stimulating a biological response, in contrast to biologically inert.

Biomimetic Designed to mimic a naturally occurring biomolecule in structure and/or function.

Biomolecule A molecule consisting of biological components, typically proteins, nucleic acids, lipids, and/or carbohydrates.

Extracellular matrix The complex mixture of biomolecules present between cells in living tissues, largely consisting of secreted proteins, that is primarily responsible for mediating the interaction of a cell with its environment.

Growth factor A molecule, typically a protein produced and secreted by cells, capable of stimulating cell proliferation or differentiation.

Ligand A biomolecule that binds to a cellular receptor and activates cellular signaling. Ligands are typically produced and secreted by cells, after which they can diffuse and act in an autocrine, juxtacrine, or paracrine fashion.

Peptide Short polymers of amino acids, in contrast to proteins, which are generally longer.

Receptor A biomolecule that resides within a cell, typically a protein embedded in the cell membrane. Receptors change conformation after binding a ligand, leading to the transmission of biochemical signals to the cell.

Recombinant Comprised of material derived from multiple sources. For example, recombinant DNA may include a human gene incorporated into a bacterial plasmid for ease of propagation. When describing a protein, recombinant designates production from recombinant DNA.

Transcription factor A molecule, typically a protein, that regulates gene expression by binding directly to DNA sequences and modulating the recruitment of RNA polymerase and/or other cofactors.

Vector A carrier or delivery vehicle, such as a virus that delivers DNA to a cell.

Abbreviations

AAV	Adeno-associated virus
bFGF	Basic fibroblast growth factor
BMP	Bone morphogenetic protein
DNA	Deoxyribonucleic acid
ECM	Extracellular matrix
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
ELP	Elastin-like polypeptide
GAG	Glycosaminoglycan
GAM	Gene-activated matrix
HSV	Herpes simplex virus
mRNA	Messenger ribonucleic acid
NCA	N-carboxyanhydride
PCR	Polymerase chain reaction
PDGF	Platelet-derived growth factor
PEG	Poly(ethylene glycol)
PTH	Parathyroid hormone
RDL	Recursive directional ligation
RGD	Arginine-glycine-aspartic acid peptide
RNA	Ribonucleic acid
S1P	Sphingosine-1-phosphate
siRNA	Small interfering RNA
VEGF	Vascular endothelial growth factor

5.510.1. Introduction

The biomaterials field is undergoing a paradigm change. The early efforts in this area were limited to working with materials that were biocompatible and readily available, including metals, ceramics, and polymers. In this context, biocompatibility was characterized by a minimal biological response. This was largely due to insufficient understanding of the mechanisms that coordinate the cell–material interactions that lead to complex processes such as tissue regeneration, inflammation, and immune response against foreign objects. The work with these biologically inert materials provided the foundation for many of the modern advances in wound repair, implanted devices, and cell culture supports. However, it is now clear that this approach to biomaterial design neglects the tremendous opportunity of incorporating biological cues into the material to guide the biological response. Recent advances in biochemistry have provided important insights into the relationships of the structure and function of biomolecules, including proteins, nucleic acids, carbohydrates, and lipids. Furthermore, progress in cell and molecular biology has led to a more complete understanding of how these biomolecules coordinate the cellular processes that ultimately lead to tissue and organismal function. The biomaterials field is now capitalizing on this new information by building materials that incorporate bioactive molecules into implanted devices, scaffolds for tissue engineering, drug and gene delivery vehicles, and cell culture supports. Typically, the naturally occurring biomolecules are reengineered into forms that are more facile, economical, efficacious, or robust. In fact, the understanding of biological responses to materials has advanced to a level where bioactive molecules are often engineered *de novo*, on the basis of design principles developed from the study of natural molecules. Collectively, this work has established a novel conceptual approach to biomaterial design and created a new concentration in the area of applied molecular engineering. This chapter will review the classes of molecules that are being targeted for this purpose, the methods used for reengineering these molecules, and the applications in biomaterials and tissue engineering that have benefited from this approach (Table 1).

5.510.2. Proteins

Proteins, or polypeptides, are ubiquitous and essential components in a functional tissue environment and participate in nearly every cellular process. Therefore, several classes of proteins are targeted as promising candidates for the engineering of bioactive materials and tissue engineering scaffolds. Proteins are polymer structures composed of 20 distinct types of monomer units (amino acids) linked by amide bonds. The properties of complex protein-containing tissues and organs are exclusively determined by the physicochemical properties of these monomers and their sequence. Therefore, these natural biopolymers present unique opportunities for the engineering

Table 1 Examples of engineered bioactive molecules in various applications of tissue engineering

Tissue type	*Class of molecule(s)*	*Natural molecule*	*References*
Bone	Extracellular matrix	Fibronectin	47
	Biomimetic peptide	Type I collagen	15
	Biomimetic peptide	Fibronectin	39,40
	Biomimetic peptide	RGD	68
	Growth factor	Basic FGF	97
	Growth factor	EGF	105
	Transcription factor	Runx2	111
	DNA, growth factor, and peptide	BMP-4 and PTH1-34	137
	Retrovirus and transcription factor	Runx2	158
	AAV and growth factor	BMP-2	171
	AAV and growth factor	RANKL and VEGF	177
	Adenovirus and growth factor	BMP-7	180
	Lipid	Sphingosine-1-phosphate	207
Cartilage	Extracellular matrix	Type II collagen	16
	Biomimetic peptide	Elastin	24–26
Cardiovascular system	Biomimetic peptide	Fibronectin	35
	Growth factor	Basic FGF	92
	AAV and growth factor	VEGF	175,176
Nervous system	Biomimetic peptide	Elastin	28
	Biomimetic peptide	Laminin	36,84
	Growth factor	Neurotrophin-3	102
	DNA and growth factors	FGF2, BDGF, and NT3	139
	Adeno-associated virus	Capsid proteins	170
Wound healing and angiogenesis	Transcription factor	Hif-1α	113,114
	Transcription factor	Hif-1α/VP16	115
	Transcription factor	Artificial zinc fingers	122
	DNA and growth factor	PDGF	138
	AAV and growth factor	VEGF	173,174
	Lipid	Sphingosine-1-phosphate	204

of a rich complexity of structure and function by controlling sequence, hierarchical organization, and long-range interactions in much the same way as synthetic polymers.[1]

5.510.2.1. Extracellular Matrix Proteins

A large class of molecules relevant to this type of protein engineering is the extracellular matrix (ECM) proteins. The ECM is a tough, elastomeric network composed of various proteinaceous fibrils and fibers interconnected in a hydrated network of glycosaminoglycan (GAG) chains. These components of the ECM provide mechanical stability and structural integrity to tissues and organs by resisting tensile and compressive stresses. The ECM also contains biochemical cues that promote cellular adhesion, motility, and tissue production, and provides mechanical stimuli to cells through its intimate connections with the cellular cytoskeleton via cell surface receptors (**Figure 1**). A significant challenge in the fields of biomaterials and tissue engineering is the recreation of this exact microenvironment at the implantation site to promote favorable tissue anchorage and growth. The most promising approaches rely on engineering scaffold materials that mimic the native ECM proteins that contain functional information for promoting cell adhesion, proliferation, and differentiation.[2,3]

Natural ECM proteins perform a wide array of functions in their native context, including structural integrity, cellular adhesion and communication, storage, and catalysis. Their diverse set of functional properties makes them ideal templates for the engineering of bioactive molecules that closely mimic the native system. Collagen is one of the most promising biomaterials in regenerative medicine and tissue engineering as it is the predominant component of extracellular matrices in mammals, providing mechanical support to various connective tissues, such as skin, bone, tendon, ligament, cartilage, and blood vessels. Collagens, characterized by their unique triple-helical structures, not only provide significant structural integrity to tissues and organs, but also regulate a number of biological events, including cell attachment, migration, survival, proliferation, differentiation, and tissue regeneration. Many of these diverse functions are controlled through collagen-targeted cell surface receptors, such as integrins, discoidin domain receptors (DDR1 and DDR2), and annexin V, which promote cell adhesion and specific cellular functions.[4–6] The rational design of collagen-based biomaterials and tissue engineering scaffolds often incorporates the binding sequences from the native collagen molecule that are recognized by these various cell membrane receptors. In addition, it has been shown that cell adhesion-mediated signaling pathways are affected not only by the recognition sequence bound by the receptor, but also by the collagen molecule's triple-helical structure and assembly in the three-dimensional matrix.[7] For example, studies have demonstrated that fibrillar collagen regulates early integrin signaling differently from monomeric collagen, with the fibrils resulting in the inhibition of smooth muscle cell proliferation.[8] Therefore, the rational engineering of bioactive collagen-based materials often incorporates the specific receptor sequences from the native collagen molecule as well as particular forms, structures, and tertiary configurations of the collagen matrix that are most conducive to the design cell function and tissue performance.

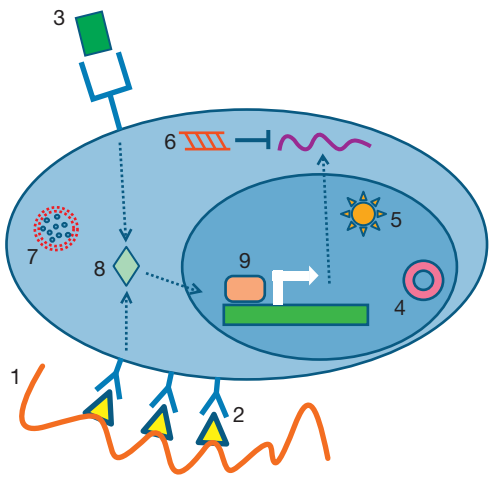

Figure 1 Classes of bioactive molecules that have been engineered for applications in biomaterials, tissue engineering, and regenerative medicine include (1) extracellular matrix proteins on the exterior of the cell, (2) small polypeptides that mimic the epitopes in the extracellular matrix that are involved in receptor binding, (3) soluble or matrix-bound growth factors, (4) plasmid DNA or (5) viral gene carriers that enter the cell and travel to the nucleus to deliver genetic material, (6) small RNAs delivered by polymeric drug carriers into the cytoplasm to disrupt mRNA stability and translation, (7) liposomes that act as drug delivery vehicles, and (8) second messengers that transmit signals from extracellular stimuli to the nucleus to modulate changes in gene expression that are regulated by (9) transcription factors.

Many of collagen's diverse functions are controlled by specific interactions of collagen-binding molecules (cell membrane receptors, soluble factors, and other matrix molecules) with certain structures and/or sequences displayed in the context of the collagen triple helices. Thus, synthetic triple-helical peptides that mimic the structure of native collagens and incorporate receptor-binding sequences have been used to design bioactive surfaces and scaffold substrates. For example, several studies indicate that the $\alpha_2\beta_1$ integrin interaction with type I collagen is a crucial signal for the induction of bone cell (osteoblast) differentiation and matrix mineralization.[9–12] The integrin $\alpha_2\beta_1$ recognizes the Gly–Phe–Hyp–Gly–Glu–Arg (GFOGER) motif in residues 502–507 of the α1[I] chain of type I collagen.[13] Reyes and colleagues demonstrated that an $\alpha_2\beta_1$ integrin-specific GFOGER-peptide triggers the activation of focal adhesion kinase (FAK) and alkaline phosphatase in osteoblast cells – two proteins that have been implicated in the osteoblastic differentiation pathway.[14] In this case, the functional activity of the peptide is entirely dependent on the engineering of the GFOGER recognition sequence in the context of a triple-helical peptide structure. These GFOGER-peptide surfaces also support the expression of multiple osteoblast-specific genes, including osteocalcin and bone sialoprotein, and induce calcification and matrix mineralization in a manner similar to type I collagen, demonstrating that this engineered bioactive peptide is a promising surface modification strategy for the design of collagen-mimetic surfaces that support bone formation. In fact, the GFOGER peptide has been used to dramatically enhance the osseointegration properties of titanium implants in animal models.[15]

Similarly, Ito and colleagues have rationally engineered collagen-like proteins with characteristics tailored specifically for cartilage engineering.[16] They identified the D4 region of human type II collagen as critical for the migration of chondrocytes and genetically engineered a collagen-like protein consisting of tandem repeats of the D4 domain assembled into a triple-helical structure. Scaffolds coated with this protein provided favorable culture conditions for chondrocytes, promoting migration, matrix formation, and maintenance of the chondrocyte phenotype.

Artificial self-polymerizing or self-assembling collagen-like materials have also been designed to mimic collagen suprastructures. Paramonov and colleagues designed collagenous peptide polymers of the form poly(Xaa–Yaa–Gly)$_n$.[17] These triple-helical polymers form nanofiber-like structures and can be engineered with various side-chain functional groups for binding. Cys residues on the polymers allow cross linking and additional functional modification. Koide *et al.* and Kotch and Rain also describe a system for obtaining collagen-like triple-helical supramolecules using a self-assembly process with self-complementary trimers of Pro–Hyp–Gly repeats.[18,19] Peptides are tethered by cysteine knots in a staggered arrangement to form elongated triple helices.

In addition to collagen, several other proteins are commonly found in the ECM and are promising templates for the design of bioactive molecules. The abundant ECM protein elastin, found in arteries, lung, and ligament, has unique elastomeric mechanical properties because of alternating hydrophilic and hydrophobic domains and multiple lysine cross-linking sites that allow for significant extensions and subsequent elastic recoil. Elastin-like polypeptides (ELP) have been derived by engineering repeat hydrophobic motifs from mammalian elastin, the most common being (VPGXG)$_n$, where X is any nonproline amino acid.[20,21] These polypeptides exhibit mechanical properties similar to those of native elastin, but are particularly suited for tissue engineering applications because they are thermally sensitive and undergo a reversible, inverse temperature phase transition. They have been used as thermally responsive injectable hydrogels that are water soluble below their transition temperature and self-aggregating above their transition temperature to form a gel-like, space-filling scaffold. Design principles from the field of polymer science can be applied to adjust the phase transition temperature to the desired *in vivo* application.[21] In addition, highly controlled genetic engineering strategies may be applied to design the precise amino acid sequence at the genetic level, allowing for the introduction of cross-linking sites that affect network modulus and reactive sites that allow the addition of functional ligands to control cell behavior or enzymatic recognition sites to control degradation.[22,23] The combination of polymer design principles and genetic engineering techniques in this system allows for the exquisite control of the physical properties of the scaffold network and the bioactivity and biocompatibility of the material in *in vivo* applications.

To address tissue engineering for cartilage repair, Betre and colleagues demonstrated that chondrocytes encapsulated in an ELP aggregate gel maintain morphology and phenotype *in vitro* for up to 15 days.[24] These cells grew and secreted the characteristic proteins of cartilage matrix, including type II collagen and sulfated GAG. They also demonstrated that ELP gels support the differentiation of human adult stem cells derived from adipose tissue into chondrocytes, as evidenced by the upregulation of genes that control the specific chondrocyte phenotype.[25] Subsequently, these ELP gels have also been used for the controlled release of drugs and other therapeutic agents in the intra-articular[26,27] and perineural[28] environment.

5.510.2.2. Biomimetic Peptides

In addition to bioactive materials that recapitulate the unique and specific structures of large ECM proteins, such as collagen and elastin, the identification of small oligopeptide adhesive and signaling sequences within such proteins has led to the design of ligand-functionalized materials. These materials capitalize on the mechanical properties of a bulk substrate and the specific receptor-binding activity of an attached peptide ligand that promotes cell adhesion and subsequent cellular activity (**Figure 1**). Cell adhesion to ECM proteins controls complex biological processes such as development, wound healing, immune response, and tissue function through specific and dynamic regulation of cell behavior.[29] Cell attachment to the ECM is primarily mediated by integrins, a widely expressed family of heterodimeric cell surface adhesion receptors consisting of noncovalently associated α- and β-subunits.[29] In addition to anchoring cells and providing tissue structure, integrins transmit intracellular signals that direct cell migration, proliferation, cell cycle progression, and differentiation.[30–32] Integrins thus function as the principal mediators of the molecular dialog between a cell and its ECM environment by specifically recognizing and binding to short amino acid motifs, or ligands, present in the ECM.

Engineering small bioactive peptides or ligands for immobilization onto a bulk substrate allows for specific tuning of integrin binding and activity by controlling ligand type, density, and spatial distribution (**Figure 2**). The use of the short peptide over the full-length native ECM protein also results in greater stability during the immobilization or modification process, as well as enhanced steric availability. The RGD (R: arginine; G: glycine; D: aspartic acid) sequence is one of the most effective and widely used peptide motifs for promoting cell adhesion on a synthetic surface. This tripeptide sequence was identified in 1984 by Pierschbacher and Ruoslahti as the minimal essential cell adhesion sequence in the ECM protein fibronectin.[33] Since then, RGD sites have been indentified in several other ECM proteins, such as vitronectin, fibrinogen, collagen, laminin, von Willebrand factor, tenascin, as well as in a variety of membrane proteins.[34] Nearly half of the 24 known integrins have been shown to bind to ECM proteins in some RGD dependent manner.[34] Other peptide sequences, such as Tyr–Ile–Gly–Ser–Arg (YIGSR) and Ile–Lys–Val–Ala–Val (IKVAV) from laminin or Arg–Glu–Asp–Val (REDV) from fibronectin, have also been immobilized onto the surfaces of various biomaterials.[35,36]

The recognition sequence itself is not the only factor in designing a bioactive peptide. Many ligand sequences require certain conformational states or neighboring amino acids for optimal activity. Therefore, the design of the bioactive peptide sequence beyond the simple recognition sequence may allow for greater activity or tunable cell behavior. It has long been recognized that the RGD sequence loses affinity and specificity

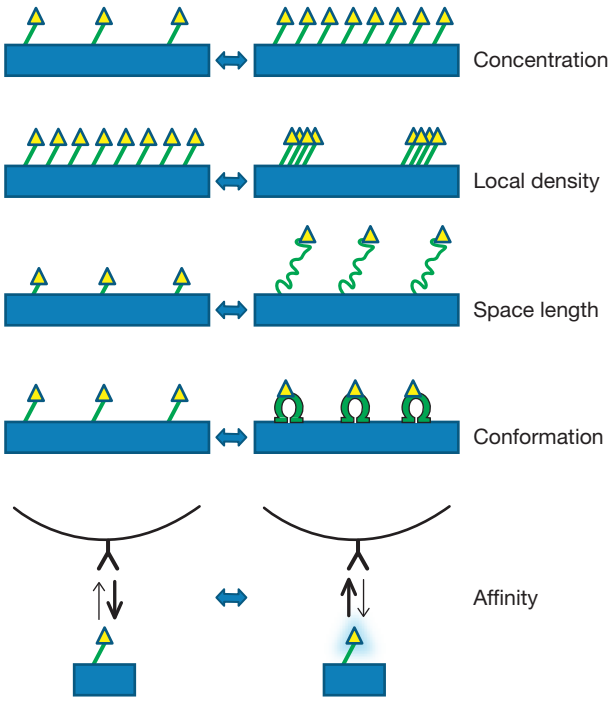

Figure 2 Various design criteria to consider when engineering bioactive molecules into biomaterials for presentation to cells. Each of these parameters can affect the cellular response to the material, including cell differentiation and tissue regeneration.

when presented outside the context of the native protein.[33,37] In fact, the RGD tripeptide alone shows little to no effect in blocking cell attachment.[38] Many efforts have been undertaken to rescue the activity of the RGD ligand by inserting flanking amino acids and adjusting the local conformation of the sequence (Figure 2). The activity of the sequence is improved by blocking the C-terminal carboxyl group on the tripeptide or by adding surrounding amino acids from the native sequence. For example, RGDS has higher activity than RGD and GRGDSP has higher activity that RGDS.[38] Furthermore, Petrie and colleagues have recently published a series of studies demonstrating enhanced bioactivity of a larger fragment of fibronectin encompassing RGD and neighboring epitopes also implicated in integrin binding.[37] This larger fragment has also been more effective in directing osseointegration of titanium implants.[39,40] The conformation and stereochemistry of the RGD sequence has been shown to affect both activity and specificity for particular integrins.[41–47] For example, a kinked RGD conformation favors $\alpha_v\beta_3$ integrin binding and a linear arrangement favors binding to the $\alpha_{IIb}\beta_3$ integrin.[44] The RGD cyclopeptide shows even greater affinity and cell attachment activity compared to linear peptides, which is most likely due to the fact that RGD exists in an exposed loop conformation in ECM proteins such as fibronectin.[48,49] Similarly, the Gly–Phe–Hyp–Gly–Glu–Arg (GFOGER) motif from type I collagen requires a triple-helical conformation to bind to the $\alpha_2\beta_1$ integrin.[50] Engineering the flanking environment and conformation of the recognition sequence in a bioactive peptide may allow precise control over a ligand's affinity and selectivity to various integrin subtypes, which in turn determines the cell types that preferentially interact with the implanted surface (Figure 2).

In the engineering of bioactive materials, there are a number of critical design factors that regulate the cellular interactions with the surface at a molecular level through receptor binding (Figure 2). Receptor binding subsequently determines the strength of cell adhesion,[51–53] the rates of cell migration and tissue infiltration,[54–56] and the extent of cytoskeletal formation and subsequent cell signaling.[57,58] These design parameters include immobilized peptide density and spacer length, receptor-ligand affinity, and spatial distribution or concentration of the bioactive peptide in the biomimetic material, all of which have been shown to affect biological responses. Using immobilized bioactive peptides on model substrates, several investigators have demonstrated a clear dependence of cell adhesion and cellular function on peptide density.[14,59–61] In fact, cell attachment as a function of ligand concentration shows a sigmoidal increase.[50,62,63] Differences in cell adhesion activity using fibroblasts seeded onto RGD-functionalized glass substrates and RGD-functional hydrogels also indicate that the hydrophobic/hydrophilic nature of the substrate affects peptide spacing results.[61,64]

In the engineering of peptide surfaces, cell adhesion is not the only aspect of cell behavior that should be considered. While high concentrations of bioactive peptide may result in greater cell attachment, they may impede cell migration and proliferation, which would adversely affect tissue growth and infiltration. Palacek *et al.* describe the biphasic trend of cell migration in response to ligand density, with cell migration increasing and then decreasing with increasing ligand density.[56] Similarly, Neff *et al.* demonstrate that fibroblast proliferation on RGD-modified polystyrene peaks at an intermediate concentration of RGD and then subsequently decreases with higher concentrations.[65] Hubbell and coworkers have shown that the amount of *in vitro* neurite extension in fibrin gels modified with RGD peptides shows biphasic behavior, with an intermediate concentration of peptide leading to maximal values of extension.[66,67] A similar biphasic response to adhesion peptides adsorbed onto biodegradable polymer scaffolds has also been observed for bone growth *in vivo*, with maximal values of growth at intermediate peptide densities.[68] These and other similar results showing migration, proliferation, and matrix production peaking at intermediate ligand densities suggest that the concentrations of bioactive peptide should be optimized for the particular cell function of interest rather than simply for cell adhesion.[67,69] Additionally, the incorporation of multiple, independent ligands that target unique receptors has been shown to result in synergistic biological activity.[70]

Integrin-mediated cell adhesion depends not only on receptor occupancy but also on receptor clustering (Figure 2). Therefore, peptide-modified surfaces may stimulate different cellular responses not only because of different peptide surface concentrations, as discussed above, but also because of the presentation of those peptides in a manner that allows or triggers integrin clustering or aggregation.[71–74] Maheshwari *et al.* designed surfaces with controlled RGD peptide density and nanoscale spatial distribution and demonstrated that fibroblasts exhibited greater shear resistance, and well-formed stress fibers and focal adhesions when the RGD peptide was presented in a clustered rather than random distribution.[75]

Therefore, designing the precise spatial distribution of a bioactive molecule may contribute to greater control over cell attachment and function.

In addition to peptide density and distribution, biological activity of the peptide recognition sequence must be considered while engineering functionalized surfaces (Figure 2). The immobilized peptide must be flexible enough to interact with the target receptor in the proper orientation and must protrude from the bulk surface sufficiently enough to minimize steric hindrance. To achieve these requirements, nonspecific, flexible peptide chains, such as repeating glycines,[50,76] or hydrophilic polymer chains, such as poly(ethylene glycol) (PEG),[59,77] have been engineered between the substrate or matrix polymer and the bioactive signaling sequence. Hern *et al.* demonstrated that cells adhere to a greater extent to RGD-functionalized surfaces with a PEG spacer than to those without the spacer, even at high surface densities. Similarly, Shin *et al.* showed that the length of PEG peptide spacers affected marrow stromal cells attached to modified hydrogels. Beer *et al.* explained this need for a spacer using an integrin model derived from electron microscopy.[78] The RGD peptide must be long enough to reach inside the globular binding pocket of the integrin. The length of the required RGD spacer varies in the literature, most likely because of differences in surface roughness or microconformations. However, cell attachment markedly decreases if that spacer length is too long because of the increased entropic energy of the long chain and the cell's preference for tight binding and rigid surfaces.[79,80]

Many of the aforementioned studies demonstrate several design principles that should be addressed while engineering bioactive molecules and materials (Figure 2). However, the optimal design parameters, such as peptide concentration and spacer length, vary depending on the cell type of interest, the desired cell function or phenotype, and the intrinsic material properties of the bulk matrix or substrate. The engineer must consider the interplay between all these criteria while designing a specific biomimetic system.

In addition to design factors that affect cell adhesion and functional activity, there are other considerations in the engineering of a bioactive peptide that may improve the ease of production or the long-term stability of the surfaces. In the case of covalent coupling of the ligand, including an accessible N-terminal lysine amino acid or other tethering moiety and avoiding bulky groups that may sterically hinder attachment will enhance coupling yields. Peptide solubility may also be tuned by adjusting the amino acids near the termini, for example, by adding charged side chains.[81] The proteolytic resistance of the peptide may be enhanced by using D-amino acids or cyclic conformations.[43,82]

Finally, the biodegradability of the matrix must be considered (Figure 3). For materials that degrade, surface tethering strategies may be insufficient as the surface can be rapidly removed *in vivo*. In these cases, it may be advantageous to develop polymers that display the bioactive peptide in the bulk material rather than on the surface. New peptide would be displayed continually as the material degraded. This issue has been investigated using the biodegradable material poly (lactic acid). Langer and coworkers synthesized the copolymer poly(lactic acid-*co*-lysine) in which the amino groups on the lysyl comonomer provide sites for peptide tethering.[83] Therefore, the bioactive peptide is presented on the transient surface through the degradation process. This type of bulk matrix incorporation is also relevant in the case of hydrogel scaffolds that undergo cellular infiltration. Migration-stimulating peptides, such as YIGSR and SIKVAV from laminin, have been impregnated in gels for nerve regeneration applications.[84] This allows the infiltrating neuronal cells to encounter the bioactive signal at all times during the infiltration process.

5.510.2.3. Growth Factors

In addition to the adhesion molecules discussed above, the ECM contains another class of morphogenetic molecules known as growth factors. These polypeptides are secreted

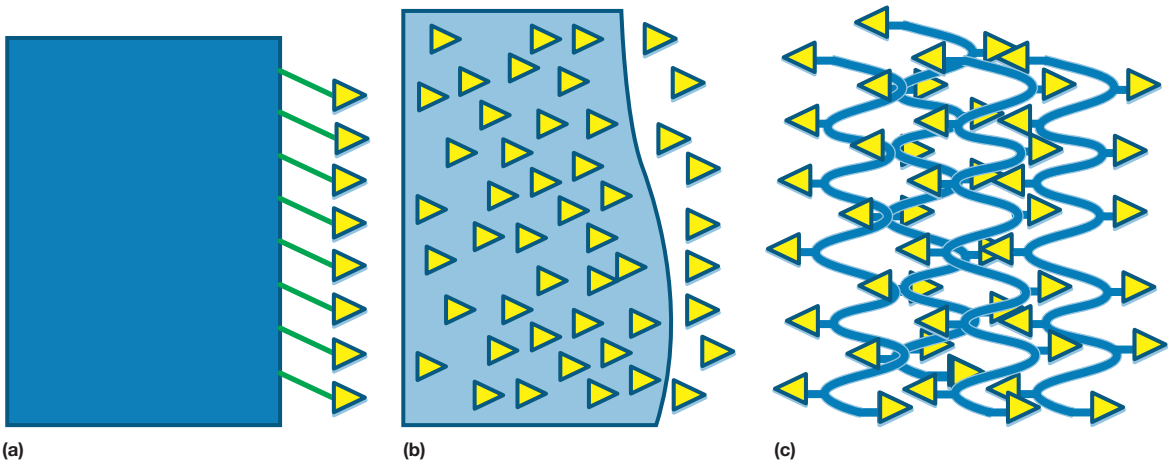

Figure 3 Strategies for incorporating bioactive molecules into biomaterials. (a) The bioactive molecule may be immobilized onto the surface of an implant or device to direct the activity of cells at that interface. This allows for control over the density and geometry of the presentation of the molecule to the cells. (b) The molecule may be incorporated into the bulk of a biodegradable material, such that the molecule is released slowly as the material breaks down and is replaced by host tissue. (c) The advantages of both (a) and (b) can be combined by constructing biodegradable materials that present the bioactive molecules from defined chemical structures.

from cells and subsequently bind to specific receptors on the surface of target cells and transmit signals that modulate cellular activities.[85] In the ECM, growth factors are often bound to proteoglycans, such as heparan sulfate and chondroitin sulfate, which protect them from proteolytic degradation and regulate their bioavailability.[86] These growth factors may be bound in the active state or may require enzymatic cleavage of the matrix or growth factor itself to reach maximal activity.[87]

Biomaterial and tissue engineers have begun to exploit this relationship between the matrix, growth factors, and cells to design systems for tissue repair and remodeling that promote cell growth, tissue production, and cellular invasion. While utilizing growth factors for these applications, it is critical that the functionality and activity of the immobilized growth factor are maintained during the matrix fabrication and release. The simplest approach has been to use an injectable hydrogel scheme in which the growth factor is incorporated into the matrix during the liquid-to-gel transition that occurs under physiological conditions.[88] The aqueous environment inside these hydrogels allows for the diffusion of the growth factor through and from the matrix. These injectable hydrogels may be delivered with minimal invasive surgery and can conform to a variety of complex tissue shapes.

Another approach has been to develop hydrogels or solid-phase biopolymeric materials to mimic the growth factor-binding characteristics of the native ECM. As many growth factors, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), bind to heparan sulfate, several studies have sought to incorporate heparin, a molecule chemically similar to heparan sulfate, onto biomaterial surfaces in order to control the release of growth factors from implants.[89] In this case, the dissociation kinetics of the growth factor from the heparin controls the overall rate of release from the implanted matrix.

Alginate gels are one of the more widely used hydrogels in injury and wound management. Several investigators have sought to heparinize alginate gels to allow growth factor retention and controlled release by covalently conjugating heparin molecules[90] or encapsulating heparin-sepharose in the matrix.[91–93] In one example, sustained release of bFGF from heparinized-alginate pellets resulted in significant improvement of coronary blood flow in a porcine model of myocardial ischemia.[92]

As previously mentioned, collagen matrices are attractive candidates for tissue engineering scaffolds because of their mechanical properties, and cell adhesion and signaling characteristics. However, these scaffolds often display poor growth factor loading and retention. Several techniques have been employed to improve the incorporation and release kinetics of growth factors from collagen, including covalent attachment of heparin or modification of the network to couple growth factor release to the rate of bulk matrix degradation. For example, Tabata *et al.* demonstrated that varying the cross-linking density of collagen by using glutaraldehyde slowed matrix degradation rates and prolonged VEGF retention and release.[94] The same group showed that cross-linked gelatin (denatured collagen) hydrogels with bFGF incorporation by electrostatic interaction implanted into rabbit cranial defects enhanced bone regeneration.[95–97]

One of the more interesting engineered matrices for tissue engineering is fibrin, the provisional matrix formed during tissue repair. Because this matrix functions as a temporary scaffold for tissue repair and regeneration, its physiological role is to promote cellular ingrowth; it is gradually replaced by a more stable ECM upon healing. These are precisely the characteristics that are desired in an implantable tissue engineering scaffold. Sakiyama-Elbert and Hubbell have developed a system in which molecules can be linked onto a fibrin scaffold during the network cross-linking process.[98] They have used this technique to covalently incorporate a heparin-binding peptide into the fibrin matrix. This peptide binds heparin, which in turn immobilizes growth factors to the scaffold.[99,100] With this system, they demonstrated the controlled release of several nerve growth-stimulating growth factors from a fibrin matrix with a high excess of heparin-binding sites. Lee *et al.* and Taylor *et al.* subsequently showed that a fibrin matrix with bound neurotrophin-3 (NT3) enhanced regeneration of the sciatic nerve and the spinal cord.[101,102]

The same investigators also demonstrated that growth factors themselves can be engineered to bind fibrin directly without the heparin intermediate.[103,104] In this case, they developed a fusion protein consisting of factor XIIIa that binds fibrin at one terminus, a central domain containing proteolytic cleavage sites, and the bioactive growth factor at the other terminus. These fusion proteins exploit the proteolytic activity of plasmin and matrix metalloproteinases in the wound site to liberate the bioactive growth factor from the matrix by clipping the central linker.

In some cases, covalent tethering of the growth factors imparts a biological advantage compared to the incorporation of the soluble molecule. Griffith and coworkers demonstrated that surface-tethered epidermic growth factor (EGF) promotes both mesenchymal stem cell spreading and survival more strongly than saturating concentrations of soluble EGF. The same group showed that covalent tethering of EGF reduces epidermic growth factor receptor (EGFR) internalization and restricts signaling to the cell surface, enhancing osteogenic differentiation of bone marrow stromal cells.[105] This group also demonstrated that EGF conjugated to synthetic polymer surfaces is capable of directing hepatocytes to maintain their liver-specific morphology and function.[106]

These studies demonstrate that engineering principles may be applied to both the biomaterial matrix and the growth factor of interest to manipulate and optimize activity, concentration, and release kinetics.

5.510.2.4. Transcription Factors

Growth factors and ECM proteins function by inducing cellular signaling pathways that ultimately lead to changes in gene expression in the nucleus (**Figure 1**). These changes in gene expression are mediated by transcription factors that bind to specific gene sequences and regulate the activation of that locus. Several studies in the area of tissue engineering are now focusing on direct modification of gene regulation by the genetic engineering of cells with transcription factors, rather than by direction of cell activity with extracellular stimuli. For example, García and colleagues have genetically engineered cells to express the transcription factor Runx2 to enhance osteoblastic differentiation and bone formation.[107–110]

Incorporation of this strategy into an inducible gene expression system led to exogenous control of the magnitude and kinetics of cell differentiation and tissue formation *in vitro* and *in vivo*.[111] Furthermore, they have discovered novel mutations of Runx2 that mimic natural posttranslational modifications and lead to bone formation by otherwise recalcitrant cell types.[112]

Transcription factor-based strategies have also been prevalent in approaches for wound healing and therapeutic angiogenesis. In particular, Hif-1α is a transcription factor that regulates genes responsible for angiogenesis, including the growth factors VEGF and platelet-derived growth factor (PDGF). Trentin *et al.* delivered a stabilized form of Hif-1α, in which a natural degradation domain had been removed, to mouse dermal wounds, using a peptide-based gene delivery vector.[113] This led to enhanced angiogenesis relative to direct delivery of VEGF alone, as demonstrated by more stable and mature blood vessels. Similarly, stabilized Hif-1α showed enhanced angiogenesis relative to the VEGF in skeletal muscle.[114] Variants of Hif-1α have also been engineered to incorporate the strong transactivation domain from the herpes simplex virus (HSV) VP16 protein to enhance its transactivation properties. These Hif-1α/VP16 engineered molecules have been successful in treating animal models of limb ischemia[115] and have subsequently moved into clinical trials.[116]

In addition to naturally occurring transcription factors, it is now possible to engineer synthetic transcription factors that target-specific genes within mammalian genomes.[117] For example, artificial zinc finger proteins have been designed to regulate a variety of genes related to tumor development and sensitivity to cancer therapy.[118–121] One particularly successful application of this approach has been in the development of an artificial transcription factor that upregulates the endogenous VEGF gene.[122] This molecule was able to protect against experimental diabetic neuropathy and has now moved into clinical trials for a variety of indications.[123]

5.510.2.5. Methods for Synthesizing Engineered Proteins and Peptides

There are two general strategies for engineering bioactive peptide- and protein-based molecules – recombinant DNA expression and synthetic polymerization. The recombinant DNA approach uses genetically encoded sequences to generate the desired polypeptide. The engineer must first design a recombinant DNA segment that precisely encodes for the therapeutic protein of interest. This segment is then cloned into a suitable DNA plasmid to create a recombinant DNA molecule that can be delivered to cells with the appropriate machinery for expressing the desired protein. This plasmid is transformed into the host cells, which are then grown in culture for a prescribed length of time to allow for protein expression. The protein of interest is then purified from the cells or culture media. A critical step in this process is the generation of the gene of interest. For small polypeptides, short DNA sequences can be directly synthesized using standard solid-phase synthesis. For long proteins with repeating units, including many structural ECM proteins such as elastin, these shorter DNA sequences can be assembled into larger proteins that encode for repetitive structures of the desired molecular weight.[20] This can be accomplished by concatenation of oligonucleotides, recursive directional ligation (RDL), or amplification of gene segments by polymerase chain reaction (PCR).[20] Concatenation is a statistical method in which a distribution of genes encoding the monomer is ligated and the gene inserts are sorted on the basis of size. The desired insert is then ligated into the vector of choice. In RDL, the short DNA segments are linked using recombinant DNA techniques. The resulting larger genes can then be recursively combined until a gene of a desired length is obtained. This approach is modular and can be used to combine genes encoding different polypeptide sequences.[124,125] This method also provides a greater level of control over the size of the insert.

Recombinant protein expression has many advantages over chemical synthesis. It provides well-defined sequences, stereochemistry, and molecular weight based on the engineered genetic template.[20] The resultant transformed cells can be stored to provide an ongoing supply of the protein of interest. Finally, and most important for the generation of structurally complex bioactive peptides and proteins, the intrinsic protein folding machinery of the cell has the ability to form physiologically relevant secondary and tertiary structures. For example, integrin $\alpha_5\beta_1$-binding requires both the PHSRN sequence in the ninth type III repeat and the RGD motif in the tenth type III repeat of the ECM protein fibronectin.[126] Because of the acute sensitivity of $\alpha_5\beta_1$ to small perturbations in the orientation of these domains, the development of proper structural orientation using synthetic peptides remains a challenge. Recombinant molecular techniques have been successfully applied to recapitulate the native secondary and tertiary structure of this important fibronectin domain.[37] The disadvantages of these techniques include the time- and labor-intensive process of assembling the gene and cloning it into the desired vector and then optimizing expression conditions in the host cell line. In addition, these techniques are often limited to the standard 20 amino acids, and the incorporation of unnatural amino acids is a difficult and often inefficient venture. The addition of nonpeptide moieties, such as a synthetic polymer backbone or insert, is also not possible with this approach unless it is done after expression and purification. Finally, in many cases the desired polypeptide is not expressed well in the host cell line, making it difficult to obtain the requisite amounts of purified protein.

Part of the design process of a recombinantly expressed bioactive molecule includes the development of a strategy for protein expression and purification that will optimize the yield and quality of the final product. These conditions will vary according to the sequence, folding structure, and posttranslational modifications of the desired protein. Based on these criteria, different expression hosts are available, including bacteria, insect cells, and mammalian cells. Once a host is selected, the final bulk protein yield can be maximized by optimizing the expression conditions.

Alternatively, the synthetic polymerization approach uses standard techniques such as solid-phase peptide synthesis or α-amino acid *N*-carboxyanhydride (NCA) polymerization to produce the desired protein from individual amino acid monomers. In solid-phase synthesis, small porous beads are functionalized with linkers upon which peptide chains can be built, amino acid by amino acid. The peptide remains

covalently attached to the bead until it is clipped by a reagent such as trifluoroacetic acid. This allows the growing peptide to be retained during several filtration steps, wherein the liquid-phase reagents and reaction by-products are washed away. The general process of solid-phase synthesis includes repeated cycles of coupling and deprotection. The free N-terminal amine of the bead-attached peptide is coupled to a single N-protected amino acid moiety. This amino acid is then deprotected, revealing a new N-terminal amine to which the next amino acid can be linked. The disadvantages of this technique include low yields and an upper size tolerance of around 70–100 amino acids. Beyond this length, this approach is burdened by unavoidable deletions and truncations that result from incomplete deprotection and coupling steps.[127]

The most advantageous process for synthesizing high molecular weight peptide chains with significant yields in large quantities is the polymerization of NCAs.[127] In this technique, a nucleophile or base is used to initiate the polymerization of NCA amino acid monomers. The most common initiators used are primary amines and alkoxide anions.[127] The reagents required are simple and inexpensive; thus NCA polymerization is a very economical and expedient way to generate long polypeptides. The disadvantages of conventional NCA polymerizations include the fact that there is no control over the reactivity of the growing polymer chain end during the polymerization reaction.[127] After initiation, the resulting primary amine, carbamate, or NC anion end group can undergo a host of undesirable side reactions. New developments in the use of transition metal catalysis, however, can lead to products that, in many ways, rival biologically produced counterparts in terms of complexity and purity.[127] Studies have demonstrated the production of block copolypeptides of controlled molecular weight, sequence, composition, and molecular weight distribution with the use of this technique.

Although the recombinant genetic engineering approach may offer greater control over sequence, these synthetic methods allow for the incorporation of artificial or nonstandard amino acids, such as hydroxyproline, and for the creation of alternative stereochemistries, which can prevent protease-mediated degradation. Synthetic techniques also allow for the generation of hybrid molecules that consist of polypeptides fused or merged with other synthetic polymers.

5.510.3. Nucleic Acids

Although proteins are currently the most common biomolecule used in combination with biomaterials, the use of nucleic acids is becoming increasingly popular as a result of advances in genome technologies, genetic engineering, and nanotechnology, and in our understanding of the many varied roles that nucleic acids can play in controlling cell behavior.[128] Nucleic acids can be used to carry the genes that encode various proteins of interest, but this is only one example of their use in combination with biomaterials. For example, biomaterials may be used to deliver small RNAs that modulate cellular pathways. Alternatively, DNA has recently been exploited as a building material for the construction of complicated nanostructures. Nucleic acids are often more economical to produce than proteins, and are sometimes more resistant to decay or denaturation. Additionally, nucleic acids can provide sustained production of gene-encoded proteins over long periods of time, or be used to disrupt cellular pathways in ways that are currently not possible with proteins. Finally, there are a variety of ways by which bioactivity has been engineered into nucleic acids and/or their delivery vehicles. Therefore, nucleic acids are growing in importance in the fields of biomaterials, tissue engineering, and drug delivery.

5.510.3.1. Plasmid DNA

As described above, there are a number of challenges to the delivery of adhesion and growth factors in tissue engineering applications. In some cases, these delivery barriers could be overcome if those growth factors were delivered not as whole recombinant proteins but as DNA. DNA-based therapies for tissue regeneration merge the technologies of tissue engineering with those of gene therapy. In this genetic approach, DNA is delivered to the site of injury via a porous biomaterial scaffold to initiate tissue repair. The scaffold fills the wound and serves as the delivery vehicle for the DNA, allowing endogenous cells to migrate to the site. As these cells encounter the scaffold, they become transfected with the genetic material and function essentially as local *in situ* bioreactors that produce the therapeutic growth factor encoded by the exogenous DNA.[129] The main advantage of such a system is that delivery of genetic material provides sustained low-level expression by the repair cells. This pattern of expression would be more likely to avoid local toxicity associated with uncontrolled delivery of exogenous growth factors. In addition, this technique may result in low levels of system toxicity, given the high efficiency of DNA catabolism in the bloodstream[130] and the low transfection efficiencies observed in normal, non-wound-healing tissue environments.[131] Most of the work in this area focuses on the delivery of naked plasmid DNA. Plasmid DNA is inherently stable, and easy to manufacture and purify in large amounts, unlike the larger and more fragile growth factor proteins.

Bonadio and colleagues developed a local gene delivery system for tissue engineering applications, known as the gene activated matrix (GAM).[129,130] A GAM has two components: plasmid DNA encoding the growth factor of interest and a biodegradable matrix carrier. This system may be adapted as an implantable porous scaffold or sponge, an injectable gel or paste, or a biomedical device coating. Upon delivery of the matrix to the wound site, GAM-mediated plasmid transfer is inextricably linked with physiological events of wound healing. The GAM serves as a reservoir scaffold that holds the DNA in place until the endogenous wound-healing fibroblasts proliferate and migrate from the surrounding viable tissue. Once there, the fibroblasts take up and transiently express the plasmid DNA. This takes advantage of the natural propensity of fibroblast-mediated granulation tissue to grow into a wound-healing site, allowing for the physical targeting of the repair fibroblasts.[129] Therefore, the matrix serves two purposes: it contains the DNA in the wound site and acts as a scaffold to promote fibroblast migration and ingrowth. Once transfected, the fibroblasts express the plasmid-encoded proteins at near-physiological levels, stimulating wound repair.

Bonadio and others have observed substantial levels of transfection *in vivo* with these techniques.[133–135] In one study,

a collagen-sponge GAM resulted in 20–50% transfection of available canine wound-healing cells.[136] Plasmid gene retention and expression by fibroblasts were documented for at least 6 weeks. As the cascade of events associated with wound healing is near universal, this paradigm of matrix-mediated plasmid gene transfer can occur at repair sites in various tissues and organs across species. Investigators have demonstrated direct GAM plasmid gene transfer for wound repair in bone,[133,137] skin,[138] heart and skeletal muscle,[136] and cranial nerve[139] in rat and canine models. These and other studies have used GAM systems with natural biomaterials such as collagen sponges, pastes and gels, hyaluronan, and alginate, as well as synthetic materials such as carboxymethylcellulose, and poly(lactide-*co*-glycolide) (PLG), as the matrix carriers for plasmid DNA.[129] The matrix design must be optimized both for plasmid DNA loading and for the promotion of fibroblast migration and granulation tissue ingrowth.

The earliest GAM studies used the plasmid gene transfer techniques to repair bone in the adult rat. In these studies, GAMs with either bone morphogenetic protein-4 (BMP-4) plasmid or plasmid encoding a fragment of parathyroid hormone (PTH) induced bone filling in a defect.[137] This study also demonstrated the synergistic effects of a GAM encoding for both BMP-4 and the PTH peptide, resulting in faster bone formation than with either factor alone.

The design of the GAM delivery vehicle offers great flexibility in form and application. Mooney and colleagues demonstrated the efficacy of the plasmid gene delivery from a sustained release polymer matrix in rat dermis.[138] In this system, a high-pressure gas foaming process was used to efficiently incorporate supercoiled DNA into a three-dimensional porous matrix of PLG. The polymer was engineered to release the DNA over a period ranging from days to months *in vitro*, leading to the transfection of a large number of cells. *In vivo* delivery of the GAM matrix with plasmid DNA encoding PDGF enhanced granulation tissue deposition and blood vessel formation in the developing tissue of rat dermis. This was in contrast to the direct injection of PDGF plasmid, which showed no significant effect on local tissue formation. These results underscore the importance of the matrix carrier in delivering genetic material.

Berry *et al.* demonstrated that when collagen paste GAMs are placed between the proximal and distal stumps of severed rat optic nerves, DNA is retained within the GAM, promoting sustained transgene expression in the optic nerve, in the GAM itself, and, more importantly, in axotomized retinal ganglion cells (RGC).[139] They showed that plasmids encoding for basic fibroblast growth factor (FGF2), brain-derived neurotrophic factor (BDNF), and NT3 promoted sustained survival of RGC for over 3 months after the initial injury.

Taken together, these studies demonstrate the great potential of direct plasmid gene transfer in the context of tissue engineering. The GAM itself presents a number of opportunities for the application of engineering and design principles to optimize DNA loading and release, and scaffold material properties. Other issues that must be considered include the potential degradation or inactivation of the plasmid upon implantation or cellular uptake,[140–142] poor plasmid binding to cell membranes,[143] nonspecific plasmid internalization, and poor vector nuclear localization.[144–146] These potential barriers to efficient gene delivery and expression represent important areas of research in this growing field. For example, Ogris *et al.* demonstrated that PEGylation, the introduction of PEG chains, of DNA complexes strongly reduces plasma protein binding and erythocyte aggregation.[147] They observed prolonged circulation of these complexes in the blood as well as lower toxicity compared to non-PEGylated DNA complexes. Schaffer and Lauffenburger demonstrated that binding of the DNA complex to the cell surface is a major barrier to efficient gene transfer.[143] They showed that control of charge and optimization of other parameters that affect surface binding could improve efficiency and specificity of gene delivery. To efficiently target exogenous DNA to the nucleus of the cell, several investigators have engineered the construct to include nuclear localization signal peptides.[144–146] Synthetic DNA delivery vectors consisting of DNA and cationic polymers or peptides, or DNA and cationic lipids have also been explored as alternatives to overcome many of the challenges.[148,149] These systems may increase plasmid stability and transfection efficiency, and decrease degradation.[150] Similarly, DNA may be encapsulated in synthetic polymers to spatially and temporally control DNA release. Prior to encapsulation, DNA may be condensed with cationic polymers to decrease complex size and risk of degradation, enhance interaction with cell membranes, and encourage endosomal release.[151] Investigators have encapsulated DNA with either natural or synthetic polymers to form micro- and nanospheres, porous scaffolds, and hydrogels for sustained DNA release.[151] In this case, the physical and chemical properties of the polymer can be engineered to influence transfection efficiency.

In addition to these challenges to delivery and transfection, a potential drawback to the use of plasmid DNAs is their short half-life in the nuclei of the target cells. Many studies have sought to increase the expression of the plasmid-encoded therapeutic genes; however, concerns over oncogenesis from sustained growth factor expression or insertional mutagenesis remain.[152,153] Finally, a major concern with plasmid vectors is that they contain CpG motifs that can activate an immune response through Toll-like receptor action (similar to endotoxin). Studies have shown that plasmid DNA treatment in animals has resulted in pathogenic anti-DNA antibodies that lead to renal failure and premature death.[154] These complications may be addressed by the recent development of minicircle vectors devoid of bacterial DNA sequences.[155] Clearly, the potency, efficiency, and safety of plasmid DNA-based treatments must be addressed in the design process of the tissue engineered construct for human therapy.

5.510.3.2. Viruses

As alternatives to plasmid DNA delivery in GAMs, viral vectors derived from retrovirus, adenovirus, adeno-associated virus (AAV), and HSV may be engineered as part of a tissue engineered scaffold.[156] Viruses are biological agents that infect cells by inserting either DNA or RNA into the host, thereby utilizing the host's cellular machinery to replicate the viral genetic material. Viruses have naturally evolved to maximize their gene transfer efficiency and are, therefore, attractive candidates for the delivery of genetic information to target cells in a tissue engineering application. Each viral vector class has its own

advantages and disadvantages. Tissue engineers will have to address these issues while designing gene delivery vehicles for their particular application.

A retrovirus contains a single-stranded RNA molecule in its genome. Its replication process includes reverse transcription of the viral RNA into linear, double-stranded DNA, and subsequent integration of this DNA into the host cell's genome. Therefore, transcription and translation of the integrated viral DNA occur alongside that of the endogenous genes using the host's translational machinery. The RNA genome is encapsulated by a protein capsid shell and an external envelope of a lipid bilayer. The electrostatic properties of this lipid bilayer can be exploited to module virus interactions with biomaterials, leading to enhanced and controlled virus transduction of cells.[157,158] Retroviral vectors are delivery vehicles that are derived from natural retroviruses and engineered to carry the foreign gene of interest into the target cell. They are designed to be replication defective to avoid budding of new virions. Retroviral modification of target cells has been applied to several orthopaedic regeneration models as well as to wound healing and blood vessel formation.

In many applications, target cells are transduced *ex vivo* and then the cells, expressing the therapeutic of interest, are combined with a scaffold material and implanted into the defect site. Laurencin *et al.* used retroviral gene transfer techniques to develop bone morphogenetic protein-2 (BMP-2) producing murine bone marrow stromal cells.[159] These cells were seeded onto a polymer–ceramic scaffold and implanted into immunocompromised mice. The investigators observed that the scaffold successfully delivered bioactive BMP-2 to the implantation site and induced heterotopic bone formation. Huard and coworkers demonstrated that similar BMP-2 encoding retroviruses could be used to transduce muscle-derived cells, pushing them down an osteogenic lineage and enhancing bone formation.[160] Retroviruses have also been applied to articular cartilage repair. Studies have shown that retrovirally modified bone marrow-derived mesenchymal cells can produce enough transforming growth factor beta 1 (TGF-β1) to undergo chondrogenesis *in vitro*.[161] Analogous *in vivo* studies using fibroblasts have demonstrated the induction of cartilage repair and regeneration at the defect site.[162] Improvements in wound healing have also been observed using retrovirally transduced fibroblasts expressing PDGF alone or in combination with VEGF in poly(glycolic acid) (PGA) matrices.[163,164]

As retroviruses efficiently integrate their genetic material into the host genome, resulting in potentially permanent expression of the delivered therapeutic gene, these vectors are particularly attractive for applications that treat persistent conditions.[165] However, retroviral techniques may not be optimal for cases where transient gene expression is desirable in order to initiate a physiological cascade of events or treat an acute injury. A possible disadvantage of retroviral carriers is their inability to infect nondividing cells. Zang and Godbey note, however, that in tissue engineering applications that utilize *ex vivo* strategies, this may be considered an advantage as somatic cells would be protected from accidental transduction upon implantation of a construct containing transduced cells.[165] A number of safety concerns are also associated with retroviral systems, including the risk of generating replication competent viruses or the possibility of insertional mutations. The random insertions that result from retroviral infection have the potential to knock out an essential housekeeping or tumor-suppressing gene.[166]

AAVs are small DNA viruses with a linear, single-stranded genome. AAV is naturally replication deficient and replication is most often achieved in conjunction with a helper virus or through genotoxic stress, such as carcinogens or ultraviolet irradiation.[165] In addition to its apparent lack of pathogenicity, AAV is particularly attractive for gene therapy and tissue engineering because, unlike retroviruses, it can infect nondividing cells, remains as a stable episome inside the cell for long periods, and has the ability to stably integrate into the genome of the host cell at a specific site. This addresses the concerns regarding random insertional mutagenesis associated with retroviral systems.

The advantages of AAV systems include their ability to infect dividing and nondividing cells and the fact that they do not have the potential for insertional mutagenesis. They have the ability to mediate long-term transgene expression and are replication defective, nonpathogenic, and relatively nonimmunogenic.[165] The major disadvantages to AAV include limitations in transgene size and the requirement of helper viruses. Other challenges to AAV gene therapy include the potential of neutralizing antibodies and infection-resistant cell types. These challenges have recently been addressed in several elegant studies that have used directed molecular evolution to reengineer the properties of the AAV capsid proteins that are responsible for interacting with cellular receptors.[167,168] This has led to AAV vectors with enhanced infection efficiencies for both airway epithelium[169] and glia,[170] two tissues types relevant to regenerative medicine that have so far been resistant to conventional gene transfer technologies.

Unlike the *ex vivo* gene therapy techniques described above in which cells are transduced with virus prior to implantation, much of the AAV work in the tissue engineering field has focused on direct administration of AAV to the wound site. Studies have shown that myoblast cells exhibit osteogenic activity upon transduction with AAV to produce BMP-2 or BMP-4 in vitro.[171,172] These same AAV constructs were injected into rat skeletal muscle, resulting in the formation of new bone. In addition, treatments with AAV-VEGF have also been shown to stimulate angiogenesis and ECM formation through wound-healing mechanisms. This system has been applied to full thickness dermal excisions in rats[173] and partial thickness burn wounds in mice.[174] Similar AAV-VEGF constructs have also been successfully applied to ischemic myocardium.[175,176] AAV is also significantly more stable than retrovirus because it does not have a lipid envelope or RNA genome. As a result AAV can be freeze-dried onto implants and taken up by host cells postimplantation.[177]

Like AAV, adenovirus is a particularly stable viral gene delivery vehicle and can therefore be incorporated into biomaterials *ex vivo* to transduce host cells *in vivo* following implantation. For example, incorporation of adenovirus into hydrogels or protein matrices has led to control over the spatial and temporal delivery to surrounding tissue.[178] This method is also effective in protecting the adenovirus from loss of activity. Subsequently, the design parameters for these systems have been optimized.[179] This approach has been particularly

successful in promoting the healing and integration of dental implants in animal models, suggesting a promising application in oral defects and disease.[180]

Another interesting viral class is HSV. HSV-1 is a naturally neurotopic virus and is extremely efficient at infecting neurons. Therefore, HSV-1 vectors are particularly attractive for the treatment of central nervous system pathologies, such as Parkinson's disease. Restoration of brain function by neural transplants is largely dependent upon the survival of donor neurons. However, in both rodent models and human patients with Parkinson's disease, the survival rate of transplanted neurons has been low. HSV-1-VEGF constructs transduced *ex vivo* into neuronal aggregates have been shown to improve vascularization and implant survival *in vivo*.[181] HSV vectors also have the advantage that they have a large transgene capacity, and may therefore be able to encode for multiple genes of interest.[165]

Collectively, these studies are representative of the field of molecular engineering of virus-based gene delivery vehicles, including bioactive molecules that are delivered by the virus, constitute the virus, or act as a carrier for the virus to an *in vivo* site of tissue repair.

5.510.3.3. RNA

Until recently, incorporation of nucleic acids with biomaterials for tissue engineering and regenerative medicine was almost exclusively limited to delivery of gene-encoding DNA molecules. However, the recent discovery of mechanisms by which small RNAs can be used to inhibit the expression of certain genes through RNA interference has led to a new interest in delivering RNA to cells.[182,183] In particular, there are many applications of this new technology in tissue engineering for coordinating cellular functions that lead to tissue repair and regeneration.[184] Often, these approaches use the same cationic polymers as carriers to deliver RNA as have been previously utilized for DNA delivery.[185] This is a straightforward approach as these carriers are designed to exploit the chemical properties of nucleic acids that are shared between DNA and RNA. However, there are still several limitations to this approach, including significant cytotoxicity and inactivation of RNA/polymer complexes by anionic serum proteins.[186] Additionally, there are important differences in the characteristics and mechanistic action of DNA and small interfering RNAs that lead to different design criteria for RNA carriers. These include differences in molecular topography and size, duration of effect, cellular location of action, and resistance to degradation.[186] Consequently, a new class of drug delivery vehicles is being developed for the transfer of these molecules to cells *in vitro* and *in vivo*. Stayton and colleagues have pioneered the development of 'smart' delivery systems for biomolecular therapeutics that change their functional or structural properties on the basis of environmental stimuli, such as pH.[187] For example, Convertine *et al.* have recently described a novel diblock copolymer that combines siRNA condensing activity with pH sensitivity for enhanced endosomal escape, which is a primary barrier for effective siRNA delivery to the cell.[188] This work is representative of a growing field dedicated to the engineering of bioactive molecules in conjunction with RNA-based therapeutics for regenerative medicine.

5.510.3.4. DNA as a Material

The work described above focuses on the use of nucleic acids specifically for the *genetic* qualities of DNA and RNA. However, new fields are currently developing that use DNA as a building material, rather than as a carrier of genetic information. For example, DNA has been used as a 'smart glue' for programming the self-assembly of nanoparticles.[189,190] Francis and colleagues later functionalized cell surfaces with DNA oligonucleotides and used hybridization to complementary DNA sequences on material surfaces to program cell adhesion.[191] Gartner and Bertozzi then built on this method to program the assembly of cells into microtissues. By mixing different cell types that presented complementary sequences, they were able to direct the assembly of multicellular structures with controllable architecture.[192] This approach to cellular assembly based on the highly specific DNA base pairing may serve as a new approach to the engineering of complex tissues for regenerative medicine.

The field of structural DNA nanotechnology is another example of using DNA as a building material to generate complex structures.[193] This area is based on the use of Watson-Crick base pairing to guide the self-assembly of DNA into complex nanostructures. Initially, this work focused on the engineering of two-dimensional crystalline forms of DNA nanostructures.[194] Later, this idea was extended to 'DNA origami' that described methods for creating nanoscale shapes of any geometry.[195] More recently, Andersen *et al.* have demonstrated a method for assembling DNA into layers of helices arranged in a honeycomb lattice that allows for the construction of three-dimensional nanostructures.[196] In particular, they constructed a nanoscale box with a controllable lid that can be opened by specific 'DNA keys.' These innovative examples of bioactive molecule engineering are providing new ideas for reconstructing the nanoscale architectures within cells and tissues that are essential to the recreation or regeneration of this environment.

5.510.4. Lipids and Liposomes

In addition to proteins and nucleic acids, lipids are emerging as a class of biomolecules with unique chemical properties that may be used to direct cell behavior or serve as drug delivery vehicles. Lipids are a diverse group of organic compounds including fats, oils, hormones, and many components of the cellular membrane. In contrast to proteins, nucleic acids, and carbohydrates, lipids are hydrophobic because of the large hydrocarbon chains that form the majority of the molecule. Amphipathic lipids contain an additional hydrophilic chemical group at one end of the molecule. This structure facilitates the formation of vesicles, liposomes, and membranes in water in which the hydrophobic chains pack together, and the hydrophilic group is exposed to the aqueous environment. This is the basic structure of the cell membrane and many other structures within the cell responsible for trafficking cellular components.

The unique properties of lipids have led to their use in a variety of drug delivery schemes. For example, cationic lipids are routinely used to spontaneously package nucleic acids into nanoparticles, called lipoplexes.[197] The overall positive charge

of these lipoplexes enhances favorable interactions with the cell membrane and increases transfection efficiency over 1000-fold relative to naked nucleic acids.[198,199] Building on these simple systems, many advances have been made in lipid design to engineer liposomes and nanoparticles that enhance transfection efficiency, minimize toxicity, and confer additional functions such as cell-specific targeting and active endosomal escape.[200,201] Consequently, lipid-based gene and drug delivery has advanced to a level that rivals the efficiency of naturally occuring viral vectors.[202]

Lipid molecules also serve several important biological functions in cellular pathways in addition to forming structural membranes. For example, sphingosine-1-phosphate (S1P) is a lipid produced by the metabolism of sphingomyelin, an abundant membrane phospholipid. S1P may act as an intracellular messenger of chemical signals or be secreted to the extracellular compartment where it can access cell surface receptors. S1P is an important mediator of a variety of cellular signals relevant to tissue engineering and regenerative medicine, including immune response, angiogenesis, and vascular permeability.[203] Elbert and colleagues incorporated S1P into hydrogels for controlled release to surrounding cells.[204,205] This led to increased migration of endothelial cells and enhanced angiogenesis in the chorioallantoic membrane assay. The level of S1P released from the biomaterial was particularly important, as they later showed that only a narrow window of S1P concentration was effective in plasma.[206] Sustained release of S1P from a biomaterial scaffold was also shown to enhance microvascular remodeling and bone healing *in vivo*.[207] These studies have established lipids as a class of bioactive molecules that is complementary to proteins and nucleic acids for directing cell activity in applications of tissue engineering and regenerative medicine.

Acknowledgments

The author thanks Dr. Catherine D. Reyes for her critical review of this chapter and valuable discussions.

Glossary

Bioactive Having an effect on or causing a reaction in living tissue.

Fluid drag force Force that opposes the relative motion of an object through a fluid. It acts in a direction opposite to the oncoming flow velocity.

Gravitational buoyancy Upward force caused by fluid pressure that keeps things afloat.

Microcarrier A support matrix usually in spherical shape allowing for the growth of adherent cells in bioreactors. Carrier materials may be composed by degradable synthetic biopolymer, porous glass, collagen, or cellulose, with dimension of 100–500 μm.

Microsphere apparent density The weight per unit volume of microspheres, which takes count of air and pores in the microspheres. For a hollow or porous microsphere, apparent density is lower than the density of a solid microsphere.

Osteopenia A condition where bone mineral density is lower than normal. It commonly occurs among astronauts during space flight.

Rotating frame A special case of a noninertial reference frame that is rotating relative to an inertial reference frame.

Rotating-wall vessel NASA-designed vessels filled with culture medium and rotating about horizontal axis. The fluid media inside the vessels undergo solid body rotation and have very low shear stress. They can simulate microgravity and have been used to study cellular responses to microgravity and 3D cell cultures.

Shear stress A stress which is applied parallel or tangential to a face of a material, as opposed to a normal stress which is applied perpendicularly.

Simulated microgravity A microgravity condition simulated in rotating-wall vessels operated at ground level (unit gravity).

Stem cell Cells have ability to go through mitotic cell division and differentiating into a diverse range of specialized cell types. The two broad types of mammalian stem cells are embryonic stem cells that are isolated from an early stage of embryo, and adult stem cells that are found in adult tissues.

Abbreviations

ALPase	Alkaline phosphatase
BMP	Bone morphogenetic protein
hEBs	Human embryoid bodies
hMSC	Human mesenchymal stem cell
HARV	High aspect ratio vessel
HepG2	Human hepatoblastoma cells
MSCs	Mesenchymal stem cells
PGA	Polyglycolic acid
Pi	Phosphate ion
PLA	Polylactic acid
PLGA	Poly(D,L-lactic-*co*-glycolic acid)
Re_p	Reynolds number
STLV	Slow turning lateral vessel

Symbols

D_{ij}	Diffusion coefficient
F_b	Gravitational buoyancy
F_{cp}	Centripetal force
F_d	Fluid drag force
m_f	Mass of the displaced liquid
m_p	Particle mass
$m_p\omega r^2$	Centrifugal force
μ	Viscosity of the fluid medium
ν_f	Kinematic viscosity of the fluid

5.511.1. Introduction

Conventional bioreactors employed for three-dimensional (3D) cell culture and tissue engineering have many disadvantages that are primarily associated with gravity-induced sedimentation, large fluid shear stresses and turbulence, and inadequate oxygenation. In such bioreactors, sedimentation may be followed by the formation of attachment sites that bind cells to the walls of the bioreactors and distort morphology. To circumvent these disadvantages, NASA-designed rotating-wall vessels (RWVs), such as high aspect ratio vessel (HARV) and the slow turning lateral vessel (STLV), may be used. These vessels are completely filled with the culture medium and rotate about the horizontal axis. The fluid medium inside the RWV undergoes solid body rotation and it eliminates the occurrence of boundary layers, which is inherent to bioreactors in which the medium moves relative to the vessel wall. It is important to ensure that the vessels contain no air bubbles during their operation. Depending on the cell type (e.g., anchorage-dependent cells), microcarrier beads or scaffolds that offer structural support may be conveniently employed in the RWVs. The microcarriers/cells remain suspended during the entire duration of culture, and are provided with an environment that alleviates large shear while ensuring adequate mass transfer. Because the vessel has no agitator or mixing device, the bridges among cells and microcarriers are not easily destroyed. However, mixing and small shear forces do arise in the RWV as a result of the microcarrier's motion relative to the fluid. The relative velocity induces drag. Depending on the material properties (e.g., density) and assembly architectures, the microcarriers/scaffolds experience different levels of shear stresses.

In the RWV, suspension of the microcarrier/cell is maintained by balancing sedimentation induced by gravity with centrifugation caused by the vessel rotation and fluid drag.[1–6] The microcarrier/cell undergoes rotation about its own axis as it moves around in the vessel.[7–9] It results in the rotation of the gravity vector attached to the center of gravity of the carrier/cell. In view of these features, the RWV may be used to simulate some aspects of a microgravity environment in the laboratory. However, there are specific requirements to be satisfied in order to successfully simulate the aspects of microgravity.[10,11]

Tissue structures grown in RWVs often form 3D aggregates with many similarities to the native tissue. In comparison to 2D cell culture flasks, the RWVs not only can support high-density and large-scale 3D cell culture, but also provide adequate and controlled supplies of oxygen and nutrients.[12] In the last 20 years, extensive studies have been carried out to investigate 3D cell culture, tissue engineering, and microgravity effects on cells and tissues with use of the RWV.[13]

A typical RWV unit consists of a culture vessel fully filled with the culture medium, a base on which the vessel is mounted, and a controller that controls the rotational speed of the vessel. A RWV rotates about the horizontal axis. HARV and STLV configurations of RWVs are shown in Figure 1. HARV is a single cylinder vessel with a high diameter-to-thickness ratio, and a flat silicone rubber membrane is mounted on the back side of the cylindrical chamber for oxygenation transport (Figure 1(a) and 1(b)). The small thickness of the chamber enables efficient transport of oxygen throughout the vessel. HARV is commonly used to culture both suspension and anchorage-dependent cells. Different chamber volumes can be achieved by varying the diameter of the vessel. The STLV has concentric inner and outer cylinders which may co- or counter-rotate. It has a central core oxygenator covered by a silicone rubber membrane (Figure 1(c)). The distance between the central core and the wall of the vessel is kept small to ensure efficient gas transport throughout the vessel. STLVs are commonly used for microcarrier cell culture and explant tissue cultures. A variety of chamber volumes is achieved by varying the length of the vessel.

This chapter will explore the factors associated with the fluid mechanics and microcarrier dynamics that affect cell culture in an RWV. The focus will be on factors that affect shear stress, microcarrier trajectory and collisions, and mass transfer in the RWV. On the basis of the fluid flow analysis, the criteria for microcarrier and scaffolds selection will be described. It must be recognized, however, that the irregularity of scaffold shapes, variations in number densities of microcarriers, and the diversity in the material properties of various

Figure 1 Typical rotating-wall vessels. (a) high aspect ratio vessel, (b) high aspect ratio vessel features, and (c) slow turning lateral vessel. Images (a) and (c) from www.Synthecon.com.

supports render such criteria only to serve as a common guide. This chapter also provides a summary of the scaffolds and microcarriers that have been used for different cell cultures and tissue engineering employing RWVs. The advantages and disadvantages of using these carrier materials will be discussed. Because of a lack of detailed information on the microcarriers and scaffolds employed combined with the fact that many different types of cells are being studied, a systematic comparison of the carrier materials is in general difficult, and the performance of support systems in cell culture studies is difficult to evaluate.

Finally, a review on 3D cultures of different cell types, tissue engineering, and space biology research with the use of RWVs is included in the chapter. Although it is difficult to clearly separate 3D cell culture from tissue engineering, a distinction is offered on the basis of close correspondence between the tissues formed and actual functional tissue in man. The tissue engineering section primarily includes the 3D tissue-like assemblies that have many characteristics of the functional tissue, whereas the cell culture section contains 3D cell cultures that have not yet reached the stage of functional tissue formation.

5.511.2. Operating Principles of RWV

The cell cultures (particularly those employing microcarriers and scaffolds) in RWV experience hydrodynamic effects from motion relative to the fluid medium and are exposed to diffusion and flow-induced mass transfer of nutrients, metabolites, and oxygen.

A number of numerical and experimental studies and discussions for cell culture in the HARV have been published,[6,8,10,12,14–16] and will be summarized in the following sections. The numerical modeling has been evolved from considering the microcarrier as a point-mass particle assuming that the flow field is not affected by the presence of the microcarrier[6,12,14] to treating microcarriers as particles of finite size.[8,10]

Although the discussions here pertain to the HARV, similar considerations will apply for the use of STLV.

5.511.2.1. Forces Acting on Microcarrier/Cell

When the HARV or STLV rotates about the horizontal axis, suspension of a microcarrier or a cell in the fluid medium is maintained by balancing sedimentation induced by gravity with centrifugation caused by the vessel rotation and fluid drag.

In Figure 2(a), the various forces acting on a typical microcarrier particle suspended in a HARV are displayed. The forces are weight of the particle $F_W = m_p g$, gravitational buoyancy $F_b = m_f g$, centripetal force $F_{cp} = m_f \omega r^2$, centrifugal force $= m_p \omega r^2$, the fluid drag force F_d, and the lift force experienced by the particle F_l. While m_p is the particle mass and m_f is the mass of the displaced liquid, ω is the specified constant angular velocity of the vessel. The fluid drag force comes into effect when there is relative motion between the microcarrier and the suspending fluid. The forces acting on the particle govern the particle's trajectory. Similar considerations apply for a particle in the STLV. The coordinate system for numerical modeling of HARV culture is shown in Figure 2(b).

5.511.2.2. Modeling of Cell Culture Employing the HARV

5.511.2.2.1. Determination of microcarrier trajectory and velocity

Cell culture employing the HARV may be assisted by numerical modeling. In depth insights into the process may be obtained by a systematic model that accompanies or is carried out simultaneously in a complementary manner with the *in vitro* study. In this section, numerical modeling of solid microcarriers suspended in a HARV is described. Discussions relevant to porous microcarriers are also included.

An incompressible fluid occupying a bounded region $\Omega(t)$ with boundary $\Gamma(t)$ at a given time instant t is considered. There are N solid particles of spherical shape and arbitrary size freely moving in the fluid. The motion of both fluid and individual particles is determined as follows. In an inertial frame (stationary or fixed frame) of reference with its origin coinciding with the center of the cylinder, the fluid motion has to satisfy the conservation of mass,

$$\nabla \cdot \mathbf{u} = 0 \qquad [1]$$

and the conservation of momentum,

$$\rho_f \frac{D\mathbf{u}}{Dt} = \rho_f \boldsymbol{g} + \nabla \cdot \sigma \qquad [2]$$

where $\mathbf{u}$ is the fluid velocity vector observed in an inertial frame, ρ_f is the fluid density, $\boldsymbol{g}$ is the acceleration due to gravity vector, $\boldsymbol{\sigma}$ is the stress tensor, and the material derivative of the velocity $D\mathbf{u}/Dt$ is given by

$$\frac{D\mathbf{u}}{Dt} = \frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla)\mathbf{u} \qquad [3]$$

where the local time derivative $\partial/\partial t$ is with respect to a stationary observer. For a Newtonian fluid, the stress tensor is given by the constitutive relation,

$$\sigma = -P\mathbf{I} + \mu D[\mathbf{u}] \qquad [4]$$

$$D[\mathbf{u}] = \nabla \mathbf{u} + \nabla \mathbf{u}^T \qquad [5]$$

Here, P is the total pressure and μ is the viscosity of the fluid medium.

Next, consider the equations governing the motion of a typical particle (microcarrier).

The particle in the HARV rotates about its own axis while undergoing translation. Let there be a suspension of N particles.

The motion of a particle $(i = 1, 2, \ldots, N)$ in an inertial frame is governed by the following equations:

$$m_i \frac{d\mathbf{V}_i}{dt} = \mathbf{F}_i + \mathbf{G}_i \qquad [6a]$$

$$\frac{d}{dt}(\mathbf{I}_i \omega_i) = \mathbf{T}_i \qquad [6b]$$

$$\frac{d\mathbf{X}_i}{dt} = \mathbf{V}_i, \qquad [7a]$$

$$\frac{d\theta_i}{dt} = \omega_i \qquad [7b]$$

where the eqns [6a] and [7a] describe translation, while the eqns [6b] and [7b] describe the rotational parts of the motion of the ith particle. The rotational part is described in the inertial frame of reference fixed to the center of mass of the spherical particle (a body-fixed frame). Also, m_i is the particle mass, V_i is the translational velocity of the particle as observed in an inertial frame, F_i is the hydrodynamic force exerted by the fluid on the particle, G_i is the gravitational body force, X_i is the position of the centroid of the ith particle, I_i is the moment of inertia tensor (diagonal for a sphere), ω_i is the angular velocity of the ith particle as observed in an inertial frame, T_i is the hydrodynamic moment vector, and θ_i is the angular position of the particle in the body-fixed coordinate system. The forces and the moments imposed on the particle by the fluid are given by

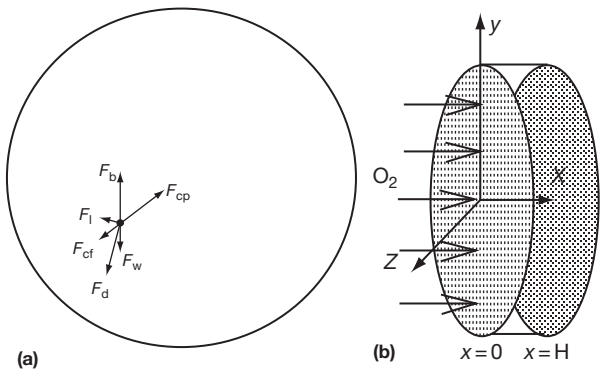

Figure 2 (a) The forces acting on a particle in a high aspect ratio vessel (HARV). (b) The coordinate system for numerical modeling of HARV culture.

$$\mathbf{F}_i = \int \sigma \cdot \hat{\mathbf{n}}\, d\Gamma \quad [8]$$

$$\mathbf{T}_i = \int \mathbf{r} \times (\sigma \cdot \hat{\mathbf{n}}) d\Gamma \quad [9]$$

where the integration is performed over the surface of the particle, $\hat{\mathbf{n}}$ is the unit normal vector on the surface of the particle pointing outward; and $\mathbf{r} = \mathbf{x} - \mathbf{X}_i$ is a vector from the center of the particle to its surface.

The initial conditions ($t = 0$) for the fluid and particle velocities are

$$\mathbf{u} = \boldsymbol{\omega} \times \mathbf{r}, \quad \mathbf{V}_i = \mathbf{u}(\mathbf{X}_i), \quad \boldsymbol{\omega}_i = 0 \quad [10]$$

where ω is the specified constant angular velocity of the vessel because of its rotation. The first condition states that the fluid is in rigid body rotation at $t = 0$. The transient spin-up is not considered here. The second condition states that the particles are released along the streamlines with the same velocity as the fluid; in other words, the initial velocity defect between the particle and the fluid is zero.

The boundary conditions for the rotating flow problem are

$$\mathbf{u} = \boldsymbol{\omega} \times \mathbf{R}_{\text{wall}}, \quad \text{on all boundary sections of the vessel} \quad \Gamma_0 \quad [11]$$

$$\mathbf{u} = \mathbf{V}_i + \boldsymbol{\omega}_i \times (\mathbf{x} - \mathbf{X}_i), \text{ on surface of particle } \Gamma_i, i = 1, 2, \ldots, N \quad [12]$$

Condition [12] represents the no-slip condition on the surface of the particle.

The governing equations together with the initial and boundary conditions are solved to describe the flow field, the trajectory of the particles, and the corresponding forces acting on the particles in an inertial frame of reference. In a rotating bioreactor problem, these results will be useful for evaluating the mass transfer and the net resultant force acting on any biological organism subjected to this type of flow.

The formulation of the problem in a rotating frame has been described in the previous studies.[8,9]

For the solution procedure, a generalized Galerkin finite element formulation, which incorporates both the fluid and particle equations of motion in a single variational equation, is preferable. In that formulation, the spatial domain occupied by the fluid is discretized using the finite element scheme. In the temporal direction, a finite difference method is used. Furthermore, as the spatial domain occupied by the fluid changes with time, a moving finite element mesh is adopted to discretize the fluid domain. To handle the movement of the finite element mesh, an arbitrary Lagrangian–Eulerian (ALE) technique is preferable. The nodes on the particle surface are assumed to move with the particle, and the grid is updated accordingly. The nodes in the interior of the fluid are computed using Laplace's equation. For a given finite element mesh, the ALE Galerkin finite element formulation can be discretized and be reduced to a nonlinear system of algebraic equations, which is solved through a modified Newton's scheme. The corresponding linearized system is solved with an iterative solver using a preconditioned generalized minimal residual (GMRES) algorithm. In this manner, the trajectories and the velocities of the particles are accurately determined.

Consider the situation where the fluid is flowing steadily around the particles beyond the very short duration spin-up stage. The motion of the combined fluid/particle system in that case may be simulated by the procedure developed by Hu *et al.*[17] In this procedure, the positions of the particles and the finite element mesh grid points in the fluid domain are updated explicitly, while the particle velocities and the fluid flow field are determined implicitly to avoid numerical instabilities. The details of the solution procedure are listed as follows:

1. Initialization $t_0 = 0, n = 0$ (index for time step), initialize particle information $\mathbf{X}_i(0)$, $\boldsymbol{\theta}_i(0)$, $\mathbf{V}_i(0)$, $\boldsymbol{\omega}_i(0)$, for $i = 1,2,\ldots,N$ generate an initial mesh $\mathbf{x}_0$
   initialize flow field $\mathbf{u}(\mathbf{x}_0, 0), p(\mathbf{x}_0, 0), \mathbf{u}_m(\mathbf{x}_0, 0)$
2. Explicit update
   select time step $\Delta t_{n+1} : t_{n+1} = t_n + \Delta t_{n+1}$
   update particle position

$$\begin{cases} \mathbf{X}_i(t_{n+1}) = \mathbf{X}_i(t_n) + \Delta t_{n+1}\mathbf{V}_i(t_n) \\ \theta_i(t_{n+1}) = \theta_i(t_n) + \Delta t_{n+1}\boldsymbol{\omega}_i(t_n) \end{cases}$$

$$\begin{cases} \mathbf{X}_i(t_{n+1}) = \mathbf{X}_i(t_n) + \Delta t_{n+1}\mathbf{V}_i(t_n) & \text{update mesh nodes} \\ \theta_i(t_{n+1}) = \theta_i(t_n) + \Delta t_{n+1}\boldsymbol{\omega}_i(t_n) & \hat{\mathbf{x}}(t_{n+1}) = \mathbf{x}(t_n) + \Delta t_{n+1}\mathbf{u}_m(t_n) \end{cases}$$

3. Remeshing and projection (if the updated mesh $\hat{\mathbf{x}}(t_{n+1})$ is too distorted):
   generate a new mesh $\mathbf{x}(t_{n+1})$
   project the flow field from $\hat{\mathbf{x}}(t_{n+1})$ onto $\mathbf{x}(t_{n+1})$
4. Flow solver: iteratively solve the new flow field

$$\mathbf{u}(\mathbf{x}(t_{n+1}), t_{n+1}), p(\mathbf{x}(t_{n+1}), t_{n+1}),$$
$$\mathbf{u}_m(\mathbf{x}(t_{n+1}), t_{n+1}), \mathbf{V}_i(t_{n+1}), \boldsymbol{\omega}_i(t_{n+1})$$

5. If the time t_{n+1} is less than a specified time, go to step (2), otherwise stop.

Using the above procedure, the velocities of the particles and their trajectories in the HARV may be calculated.

5.511.2.2.2. Particle–particle and particle–wall collisions

Particle–particle and particle–wall collisions change the trajectories, the instantaneous relative speed, and the shear stress on the surface of the particles. The collision may affect cell attachment and damage bridges in cell aggregates. Understanding of collision dynamics is needed to alleviate interparticle and particle–wall collisions. Numerical studies and stability analysis have revealed that the density difference between a microcarrier and fluid medium determines if the microcarrier can avoid collision with the wall of HARV.[6,8] Single-particle studies have shown that, if the microcarrier is lighter than the surrounding fluid medium, then it migrates from its initial position in a spiral fashion as viewed in an inertial frame to a final location in the central region of HARV. The trajectories in inertial and rotating frames for a lighter-than-fluid particle are shown in **Figure 3**. If the particle is heavier than the fluid medium, in the inertial frame, it moves spirally outward to reach or collide with the outer wall of the HARV after a period of time (**Figure 4**). These figures are based on the numerical solutions to the modified Maxey–Riley equations that approximately govern the motion of a point-mass particle. With these solutions, it may be shown that a lighter-than-fluid particle migrates to a stable equilibrium radial position in the fluid.

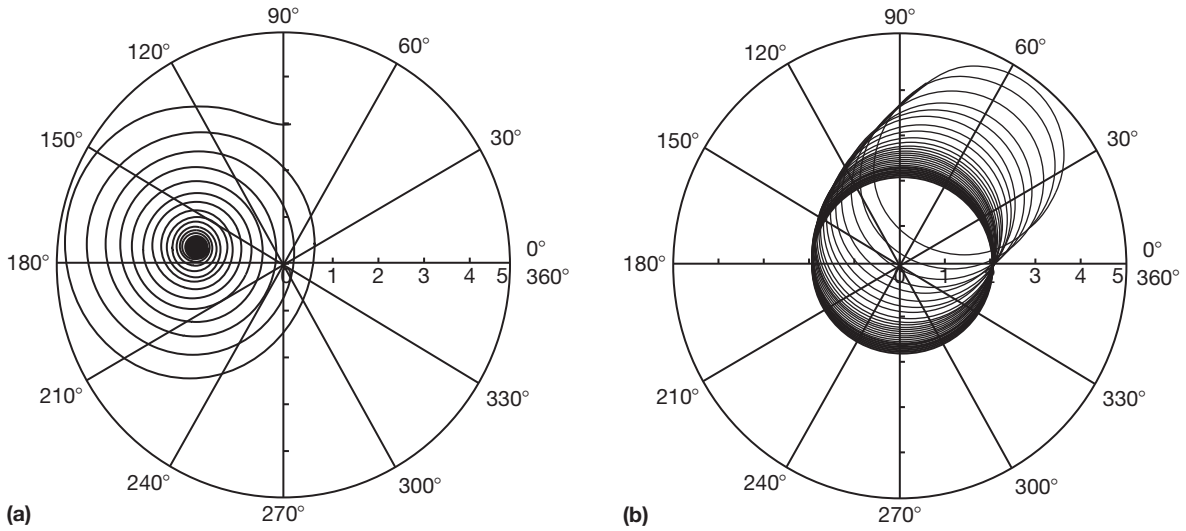

Figure 3 Trajectory of a microsphere particle in the rotating-wall vessel in the (a) inertial frame and (b) rotating frame of reference for ($\rho_p < \rho_l$). $\rho_p = 0.7\ g\ cm^{-3}$, $\rho_l = 1.0\ g\ cm^{-3}$, $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 35$ rpm, $a = 330\ \mu m$, initial position = 3 cm, HARV radius = 5 cm. Reproduced from Gao, H.; Ayyaswamy, P. S.; Ducheyne, P. *Microgravity Sci. Technol. X* **1997**, 154–165.

More detailed studies of single-particle dynamics also show similar behavior.[7,9] When the microcarrier particle density is equal to the density of fluid medium, the microcarrier will stay in any neutrally buoyant position moving along with the fluid, without relative motion. However, this situation is unstable, and with small perturbations, the particle will move away to different locations. For particles, scaffolds, or aggregates that do not have perfect spherical shape, the relative motion has to be carefully evaluated. With a denser microcarrier, it is important to know the migration time (t_w) to reach the outer wall of RWV as the collision with the wall may affect the cell growth and damage the cell/microcarrier aggregate (**Figure 4(c)**). The migration time increases with decrease in the density difference and microcarrier size, and it also increases with increase in fluid viscosity.[6] The migration time decreases as the rotational speed ω increases with other parameters held constant. However, at very low rotational speeds (e.g., <2 rpm with a full-sized HARV), the migration time begins to decrease and eventually it asymptotically approaches the Stokes sedimentation time as $\omega \to 0$ (**Figure 4(c)**).

To account for particle–particle and particle–wall collisions in a numerical study, the collision model described in previous studies[18,19] may be employed. In these models, it is assumed that there is always a very thin liquid film interspersed between the solid objects (particle–particle or particle–wall) even as they get near each other in very close proximity. In the numerical algorithm, a fictitious external short-range contact force on the colliding objects, normal to the contact area between the approaching objects, is introduced. The magnitudes of these contact forces are just large enough to keep objects away from actual touching or geometric overlapping. This contact force is activated when the minimum gap between the approaching objects is less than a prescribed critical distance. The introduction of the fictitious short-range force may itself modify the trajectories of the colliding particles. However, this modification may be minimized by choosing a very small critical gap size when this contact force is activated.[16]

The above analysis is based on a single-particle system. In an actual situation, cell culture is a multiparticle system. Thus, in addition to the factors considered in the single-particle system, the number of microcarriers and cells in the RWV is an important factor in terms of interparticle collisions. To reduce interparticle collisions, the reduction of solid volume fraction by diluting the suspension of particles is an effective approach.

5.511.2.2.3. Microcarrier/cell spin

In the HARV, a spherical particle/cell not only undergoes a circular translatory motion and a radial drift but also a spin about its own axis. A schematic of particle spin about its own axis is shown in **Figure 5(a)**. As a microcarrier rotates, so do the cells embedded within it or attached to its surface. As gravity vector is unidirectional in a laboratory reference frame, an observer sitting on a spinning microcarrier or the cell itself would experience time-varying gravity with a zero mean (vector-averaged gravity) whose frequency is essentially given by the rotation rate of the cell/microcarrier. The general assumption has been that the changes in gravity will appreciably alter the force balance within the cytoskeleton so as to mimic microgravity-like conditions. This assumption or equivalent assumptions have to be validated and the truly prevailing situation must be related to the speed of the microcarrier/cell spin in each study.[10] **Figure 5(b)** shows the numerically evaluated particle rotation rate (it spins about its own axis as a function of the rotation rate of the HARV) and the density of the particle for a 200-μm spherical microcarrier. The rotation speeds are representative of the biological culture conditions. It may be noted that the particle rotates with essentially the same speed as the HARV. It is therefore possible to optimize the rotation rate of the particle by controlling the rotation rate of the HARV in order to better simulate microgravity conditions.

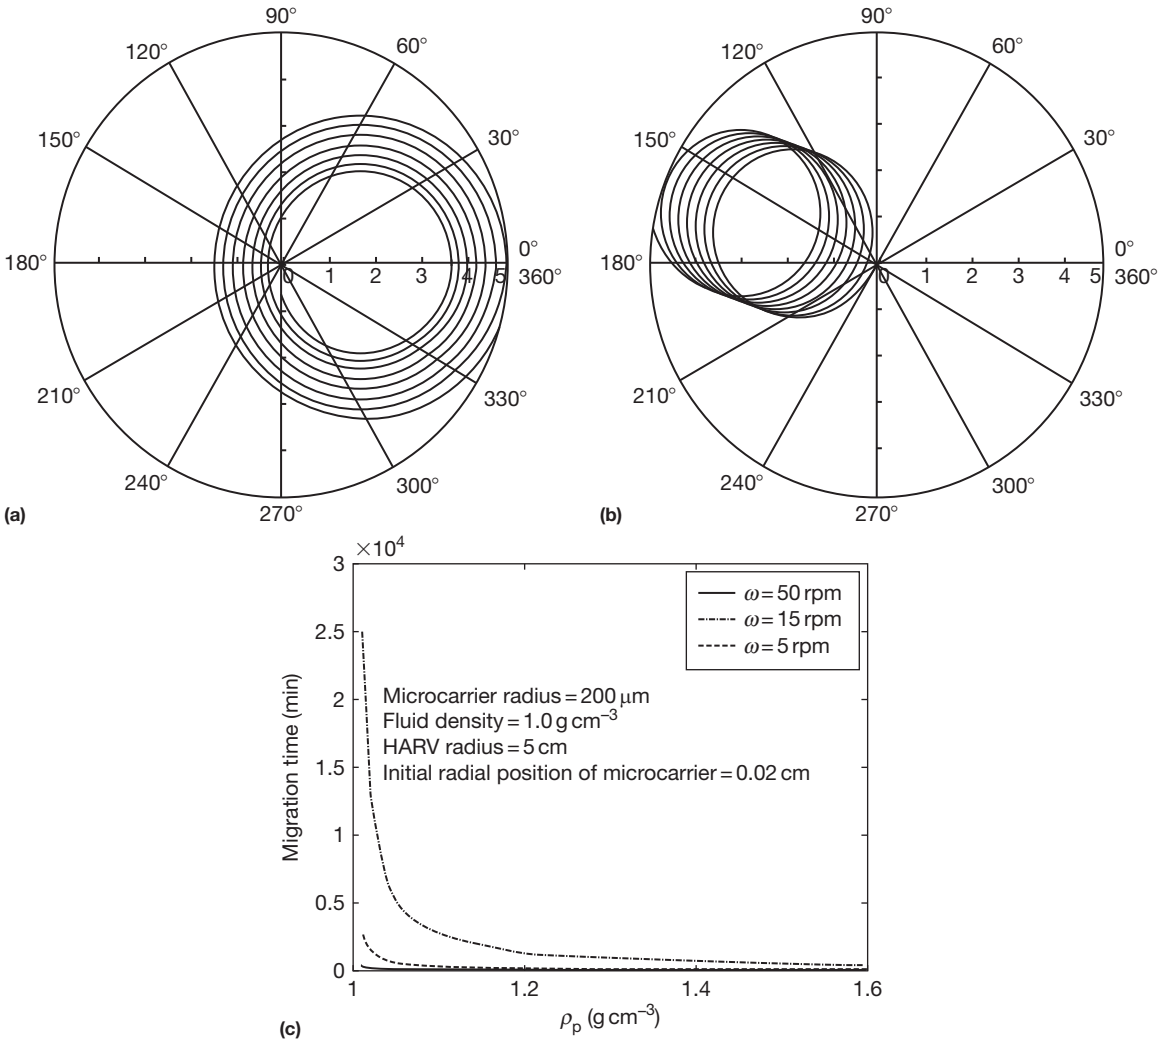

Figure 4 Trajectory of a microsphere particle in the rotating-wall vessel in the (a) inertial frame and (b) rotating frame of reference for ($\rho_p > \rho_l$). $\rho_p = 1.3\,g\,cm^{-3}$, $\rho_l = 1.0\,g\,cm^{-3}$, $\mu = 0.01\,g\,cm^{-1}\,s^{-1}$, $\omega = 25$ rpm, $a = 240\,\mu m$, initial position = 0.5 cm, HARV radius = 5 cm. S.; Mukundakrishnan, K. *Acta Astronaut*. **2007**, *60*(4–7), with permission from Elsevier.

5.511.2.2.4. Shear stress

The shear stresses that act on the microcarrier surfaces are caused by the minute motion of the microcarriers relative to the surrounding medium, and the maximum shear stress on a spherical particle surface, τ_{max}, may be evaluated from the numerical solution as all of the required quantities are available. The shear stress may also be deduced by employing a corotating camera with the HARV during experimentation.[20] For low Reynolds number, the steady-state drag for a single-particle case may be approximated by Stokes drag, and as a convenient estimate, the maximum shear may be calculated from the Stokes solution:

$$\tau_{max} = 3\mu V_{rel}/2a \qquad [13a]$$

where μ is viscosity, V_{rel} is the relative speed (slip velocity) between the particle and the fluid, and a is the radius of the particle. For higher Reynolds number simulations, a rectilinear empirical relation for the drag coefficient for a single-particle case, like the Schiller and Nauman correlation,[21] may be used, and this correlation is given by

$$F_D = C_D(\mathbf{U}_p - \mathbf{U}_f),\ C_D = 6\pi\mu a[1 + 0.15(Re_p)^{0.687}] \quad \text{for } Re_p \text{ up to } 800 \qquad [13b]$$

where $\mathbf{U}_p$ and $\mathbf{U}_f$ are the velocities of the particle and the fluid, respectively; Re_p is the particle Reynolds number given by $2aV_{rel}/\nu_f$; a is the radius of the particle; and ν_f is the kinematic viscosity of the fluid. In the above equation, the transverse lift forces acting on the particle (the transverse direction being perpendicular to the direction of instantaneous slip velocity), and history forces due to the unsteady nature of particle motion are neglected.

The maximum shear stress (τ_{max}) experienced by the surface of a particle is a function of the microcarrier velocity, density difference between microcarrier and fluid, and microcarrier size.[6,15] In Figure 6(a) and 6(b), the numerical results presented are based on the assumption that particles may be

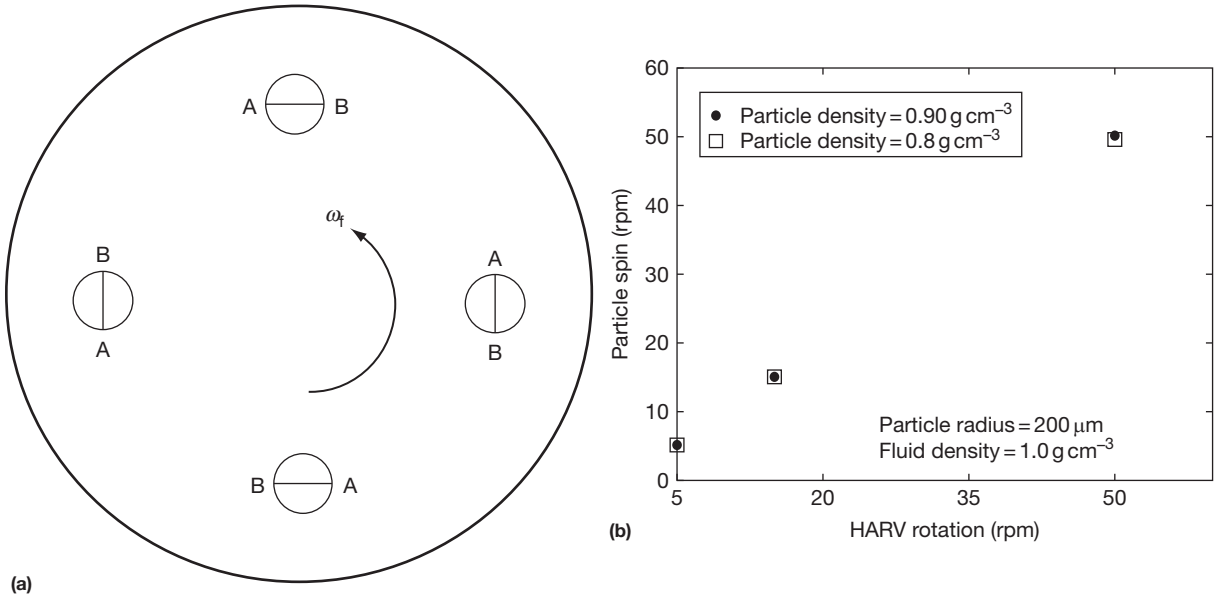

Figure 5 (a) Schematic of particle rotation in a high aspect ratio vessel (HARV). The line A–B is drawn to illustrate the sense of rotation of the particle as it goes around in a circular orbit. Reproduced from Mukundakrishnan, K. Ph.D. Thesis, University of Pennsylvania, 2005. (b) Angular velocity of the particle about its own axis as observed in an inertial frame of reference as a function of the rotation speed of the HARV. $a = 200\ \mu m$ and $\mu_f = 0.01\ g\ cm^{-1}\ s^{-1}$. Reproduced from Ayyaswamy, P. S.; Mukundakrishnan, K. *Acta Astronaut.* **2007**, *60*(4–7), with permission from Elsevier.

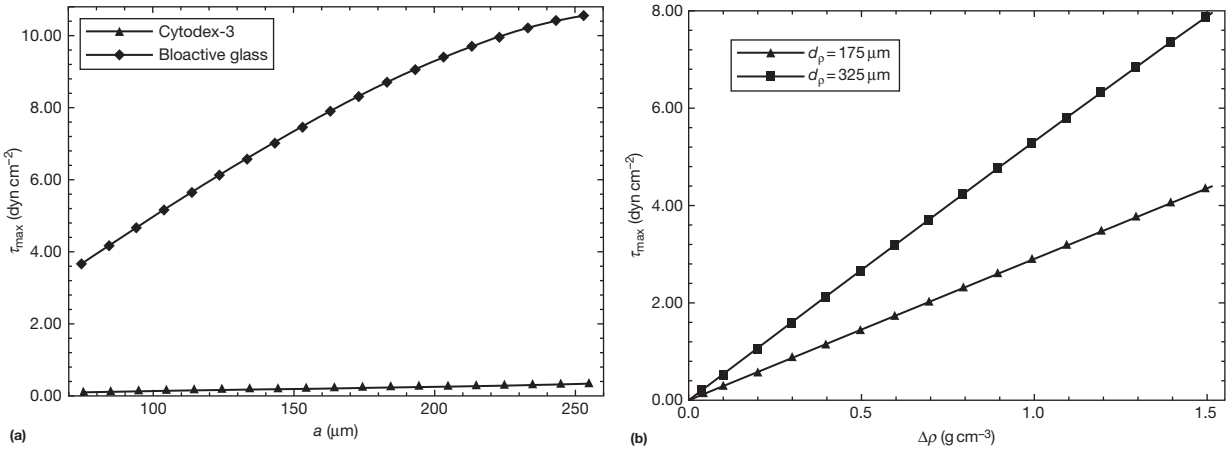

Figure 6 (a) Numerical results. The maximum shear stress on a Cytodex-3 microcarrier and a bioactive glass microcarrier as a function of the microcarrier radius. $\rho_{cy} = 1.04\ g\ cm^{-3}$, $\rho_{bio} = 2.00\ g\ cm^{-3}$, $\rho_f = 1.00\ g\ cm^{-3}$, $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 18$ rpm. (b) Numerical results. The maximum shear stress on a microcarrier as a function of the density difference between microcarrier and fluid, and of microcarrier size. $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 18$ rpm. Reproduced from Qiu, Q.; Ducheyne, P.; Gao, H.; Ayyaswamy, P. *Tissue Eng.* **1998**, *4*(1), 19–34.

regarded as mass points. The maximum shear stress increases linearly with the density difference between the microcarrier and fluid media (Figure 6(b)). When cell aggregates grow in size during suspension culture, the shear stress acting on the aggregate also increases, which may lead to cell damage and inhibit aggregate growth or cause its disruption. However, if the aggregates' density is equal or very close to that of culture medium, the shear stress is extremely low and increases only slightly with the increase in the size of the aggregate. If a microcarrier of high density is used, the maximum shear stress is much larger and increases faster as the size of the microcarrier increases (Figure 6(a) and 6(b)).

Figure 7 shows the variation in shear stress with particle radius for a solid microcarrier as calculated from a numerical computation where the finite size of the particle is taken into account. The density of the particle is less than that of the fluid. As expected, shear stress increases with increasing particle size and the very small values of the shear stress at smaller sizes are noteworthy.

The net acceleration experienced by a typical solid microcarrier as a function of its size is shown in Figure 8. It may be noted that a nearly neutrally buoyant microcarrier experiences some aspects of simulated microgravity while suspended in the HARV during culture.

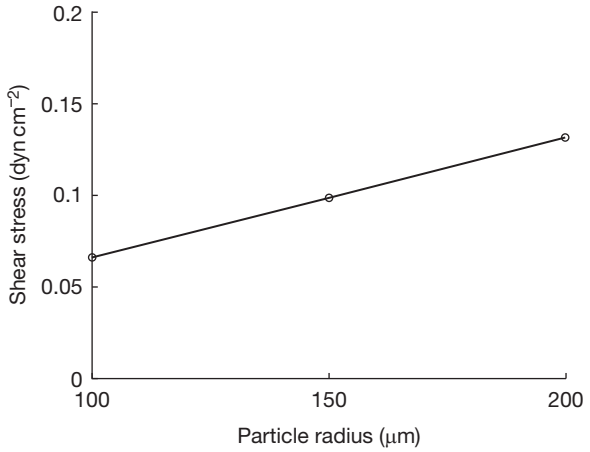

Figure 7 Shear stress variation for a solid microcarrier. $\rho_p = 0.98\ g\ cm^{-3}$, $\rho_l = 1.0\ g\ cm^{-3}$, $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 10$ rpm. Reproduced from Mukundakrishnan, K.; Ayyaswamy, P. S.; Risbud, M.; *et al. Ann. N. Y. Acad. Sci.* **2006**, *1027*(1), 85–98, with permission from Wiley.

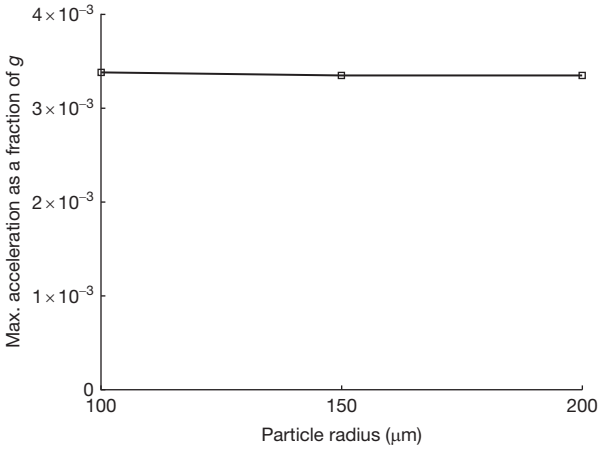

Figure 8 Maximum acceleration experienced by a solid microcarrier as a fraction of *g*. $\rho_p = 0.98\ g\ cm^{-3}$, $\rho_l = 1.0\ g\ cm^{-3}$, $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 10$ rpm. Reproduced from Mukundakrishnan, K.; Ayyaswamy, P. S.; Risbud, M.; *et al. Ann. N. Y. Acad. Sci.* **2006**, *1027*(1), 85–98, with permission from Wiley.

Figure 9 displays the variation in shear stress as a function of the HARV rotation rate for two different densities of a 200-μm spherical carrier. Shear stress significantly increases with increasing density while remaining constant for low to moderate rotation rates of the HARV. The shear stress remains constant for such rotation rates because the gravity-induced buoyancy force dominates over the centrifugal force and shear is largely generated as a result of gravity-induced slip velocity.

Thus a small, nearly neutrally buoyant microcarrier, coupled with moderate rotation rates (~50 rpm), is likely to simulate microgravity-like condition better than other combinations.

It is clear from the above discussions that the density difference plays a crucial role in the successful use of the HARV both for tissue culture and for simulating some aspects of microgravity. Because of the big difference between the densities of air and fluid, air bubbles, if present in a HARV, will experience

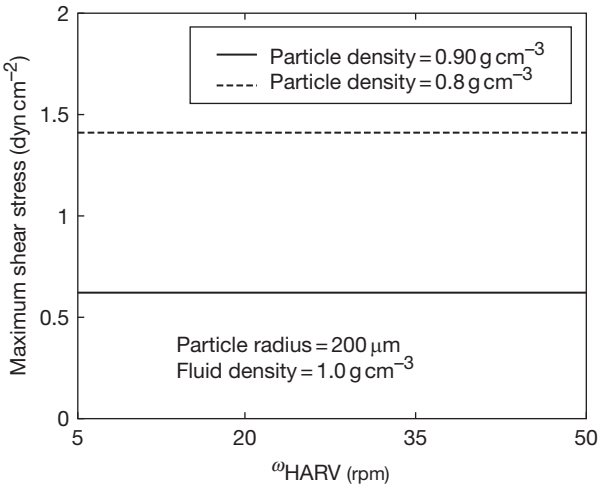

Figure 9 Significance of shear stress. Reproduced from Ayyaswamy, P. S.; Mukundakrishnan, K. *Acta Astronaut.* **2007**, *60*(4–7), with permission from Elsevier.

high shear stresses on their surfaces while in motion. When air bubbles collide with cell aggregates, they may damage the cells and destroy bridges in cell aggregates. Therefore, it is important to completely remove the air bubbles from the RWVs before the start of the study.

Cell cultures in HARV usually employ solid microcarriers with cells attached to their outer surface. One limitation of this system is that the ratio of the number of cells cultured per microcarrier is quite small as the cells are cultured only on the surface and not in the interior. A further disadvantage is that only a limited number of solid microcarriers can be used as a large number density will result in increased particle–particle collisions and damage the cells. To develop 3D tissue structures, porous microcarriers/scaffolds in which cells are immobilized in a 3D polymer network are very useful. In an attempt to quantify the shear stress and acceleration vector experienced by such a porous microcarrier, the modeling described above has to be modified.[8] The essential difference between this and the model for a rigid spherical microcarrier lies with the modification of the effective particle density and the drag coefficient. The effective particle density depends upon the degree of porosity. Also, the drag coefficient here depends on the degree of permeability of the microcarrier.[22] For identical parametric conditions in the HARV, the shear stress at the surface of a porous microcarrier is much smaller compared to the shear stress at the surface of a solid carrier. The time taken for particle migration toward the wall of the HARV is higher for a porous particle compared to that for a solid microcarrier. Furthermore, the net acceleration vector experienced by a porous microcarrier is much less in magnitude compared to that of a solid carrier. These three observations have implications for simulating aspects of microgravity conditions in the laboratory. In cultures without microcarriers, we note that the cell is usually denser than the culture medium. To minimize shear stress, these cells may have to be encapsulated in porous microcarriers made of suitable materials such as alginate hydrogels that do not interfere in any manner with the cell function. Figure 10 shows the variation in shear stress with particle radius for a porous microcarrier. As expected,

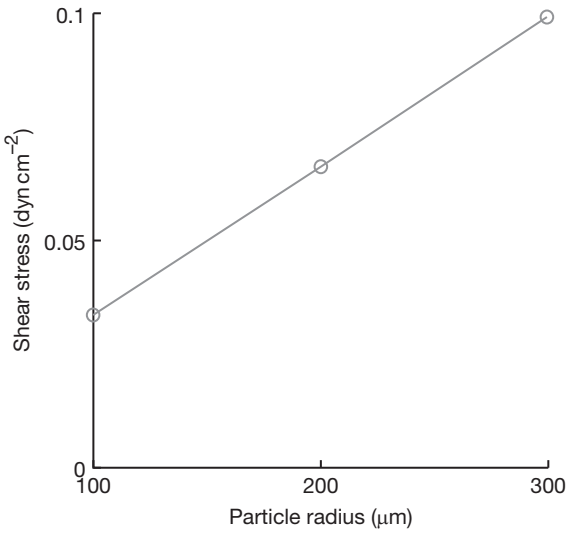

Figure 10 Shear stress variation for a porous microcarrier. $\rho_p = 1.01\ g\ cm^{-3}$, $\rho_l = 1.0\ g\ cm^{-3}$, $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 8$ rpm, $\kappa = 10^{-5}\ cm^2$. Porosity = 97%. Reproduced from Mukundakrishnan, K. Ph.D. Thesis, University of Pennsylvania, 2005.

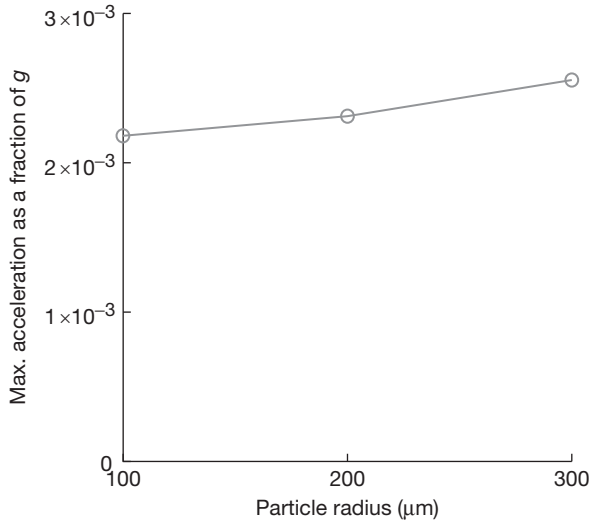

Figure 11 Maximum acceleration experienced by the porous microcarrier as a fraction of *g*. $\rho_p = 1.01\ g\ cm^{-3}$, $\rho_l = 1.0\ g\ cm^{-3}$, $\mu = 0.01\ g\ cm^{-1}\ s^{-1}$, $\omega = 8$ rpm, $\kappa = 10^{-5}\ cm^2$. Porosity = 97%. Reproduced from Mukundakrishnan, K. Ph.D. Thesis, University of Pennsylvania, 2005.

shear stress increases with increasing particle size and the very small value of shear stress is noteworthy. Figure 11 shows the net acceleration experienced by a typical porous particle as a function of its size. It is noted that porous microcarriers may be successfully employed in the HARV to simulate certain aspects of microgravity.

5.511.2.2.5. Mass transfer evaluation

With the fluid velocity evaluated as above, the mass transfer of any given species (glucose, oxygen, or other ions) to a typical

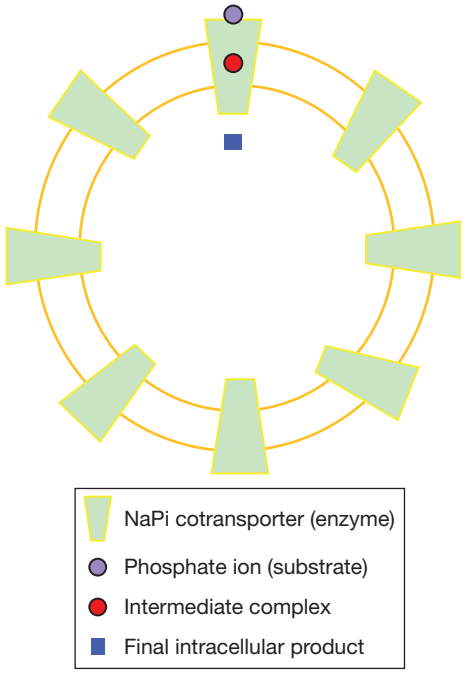

Figure 12 Illustration of extracellular Pi transporting into a cell. Reproduced from Mukundakrishnan, K. Ph.D. Thesis, University of Pennsylvania, 2005.

microcarrier in the HARV may be evaluated using a convection–diffusion–reaction mechanism.

As an example, the mass transfer of a representative ion, phosphate ion (Pi), will be discussed below to illustrate the modeling procedure.

The mass transfer of Pi in osteoblast culture, for example, may be evaluated using a convective–diffusive–reactive model. The consumption of Pi by osteoblasts may be assumed to follow Michaelis–Menten (MM) kinetics aided by NaPi cotransporter system (Figure 12). The MM mechanism approach views the NaPi cotransporter as a system for transporting extracellular Pi into the cell.

Let $C_i(\mathbf{x})$ denote the concentration of species i, which in our case is the Pi. Also let D_{ij} denote the diffusion coefficient of the ith species in the fluid medium. This coefficient is assumed to be a constant. Let $\mathbf{u}(\mathbf{x})$ denote the convective flow velocity (relative velocity obtained by solving the trajectory equations for the particle motion). The Pi consumption of osteoblasts is known to follow saturable kinetics,[23] which can be described by MM equations. Then the steady-state mass transfer equation becomes

$$D_{ij}\nabla\cdot(\nabla C_i(\mathbf{x})) = (\mathbf{u}(\mathbf{x})\cdot\nabla)C_i(\mathbf{x}) \qquad [14]$$

A steady state is assumed because with reference to the particle frame of reference, the fluid flow motion is approximately in the Stokes flow regime and the characteristic time scale of the cell culture is much larger than the convective time scale. In the above equation, it is assumed that there are no volumetric (point) sources or sinks present in the medium. The associated boundary conditions are as follows:

$$C_i = C_{\infty}, |\mathbf{x}| \to \infty \qquad [15]$$

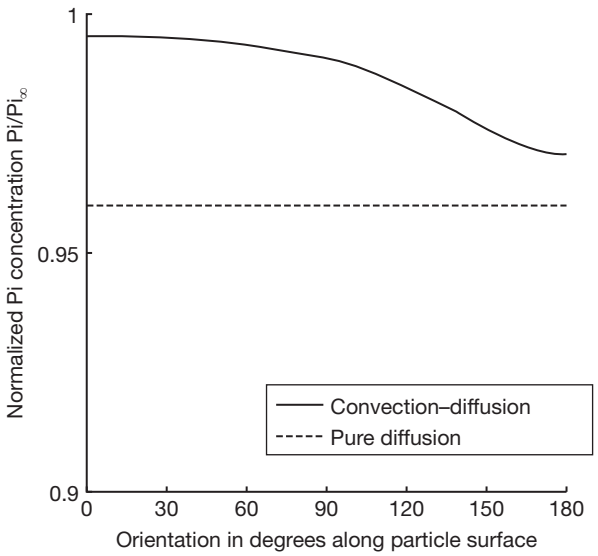

Figure 13 Distribution of Pi concentrations along particle surface in HARV. Reproduced from Ayyaswamy, P. S.; Mukundakrishnan, K. *Acta Astronaut*. **2007**, *60*(4–7), with permission from Elsevier.

$$\nabla C_i \cdot \hat{\mathbf{n}} = \frac{-\gamma V_{\max} C_i}{K_m + C_i} \quad |\mathbf{x}| = a \qquad [16]$$

where C_∞ is the physiological level of Pi concentration (also the serum level Pi concentration), $\hat{\mathbf{n}}$ is the unit normal vector on the surface of the particle, a is the radius of the microcarrier particle, γ is the cell-seeding density, V_{max} is the half-maximal rate of Pi consumption, and K_m is the MM constant. The details of the mass transfer calculations and numerical procedure employed for this purpose are reported by Mukundakrishnan.[8] Figure 13 shows that convection in the HARV enhances the Pi accumulation on the surface of the microcarrier (cell surface). A 4% increase in the accumulation of Pi (normalized concentration) under HARV culture conditions compared to Petri dish conditions is noted.

Similar calculations may be made for other species.

Nutrients and oxygen transport to the cells is critical for cell proliferation and function. Although an accurate prediction of the mass transfer requires detailed knowledge of the fluid field and metabolism reaction of cells, there are some general observations which may be made regarding mass transfer in RWVs. When a cell or a small cell aggregate has very low relative velocity – for example, close to zero – to the fluid medium, the nutrients and oxygen are primarily supplied via diffusion. When a cell aggregate is bigger, the relative velocity usually increases and the nutrients and oxygen are also supplied by convective flow. When the size of a microcarrier/cell aggregate increases, an increase of the rotational speed can help to keep the aggregates in suspension and also increase the mean oxygen concentration in the RWV.[24] In addition, introducing a gradient of fresh media through perfusion of the RWV will also help the transfer of nutrients to the cells.

5.511.2.3. Optimal Conditions of RWV

Optimal conditions for cell culture in RWV have been discussed in detail in a previous publication,[10] and the requirements are summarized as follows:

1. A very low value of shear at the microcarrier/cell surface.
2. An understanding of the role played by the microcarrier/cell spin about its own axis.
3. Adequate mass transport of nutrients and oxygen.
4. Where microcarriers are employed, interparticle and particle–vessel wall collisions must be minimized or eliminated.
5. Shape of the microcarrier or scaffold should be such as to minimize adverse flow effects.
6. Adequate and appropriate controls over cell culture period.
7. Microcarrier and scaffold should be biocompatible, ideally bioactive, and degradable where possible.

5.511.3. Scaffolds and Microcarriers for Cell Culture in RWV

For anchorage-dependent cells, scaffolds, or microcarriers are required for cell culture in RWVs. As discussed in the previous sections, the density and the architectures of the carriers play critical roles on shear stress imparted on carriers, and collisions and motions in RWVs, which may significantly affect cell attachment, proliferation, and differentiation. Therefore, the selection of carriers becomes critical for the success of 3D cell culture in RWVs. In this section, a review of the carriers used in RWVs and their advantages and disadvantages will be discussed. Because of the fact that very limited information on the shear stress and trajectories of carriers and scaffolds used in RWV is available, common knowledge derived from the previous sections will be applied in the discussion on possible shear stress on different types of carriers reviewed in this section.

5.511.3.1. Criteria for Carriers

In order to achieve very low shear stress on the carrier surface and to minimize collisions that can damage cells and cell aggregates, the carrier should meet the following requirements:

1. The apparent density of a microcarrier or the scaffold should be close to that of culture medium, ideally slightly lower than or equal to the density of the culture medium. As the shear stress increases with the increase of density difference between the carrier and culture medium, reducing the density difference will reduce the shear stress on the carrier. In addition, if the carrier is lighter or has the same density as the culture medium, it will avoid moving outward and eventually colliding with the outer wall of the RWV, which may cause cell damage and negatively affect cell attachment and proliferation.
2. The microcarrier size should be big enough for supporting cell attachment and proliferation but should be small enough to avoid inter-microcarrier collisions and allow formation of cell–microcarrier congregates.
3. The shape of the microcarrier should be such as to minimize adverse flow effects. Spherical microcarriers are preferred, although it is acknowledged that their shape will change with cell/aggregate growth and accommodations have to be made to correctly describe such variations.
4. Microcarriers must be biocompatible, ideally bioactive, and degradable where possible.

Table 1 Carriers used in cell cultures in RWVs

	Carrier	*Composition*	*Density (beads)/porosity (scaffolds)*	*Size*	*Surface layer*
Polymers	Cytodex-3 beads	Cross-linked dextran	1.04 g cm^{-3}	133–215 μm (dia.)	Gelatin (type I collagen)
	Biosilon beads	Polystyrene	1.05 g cm^{-3}	160–300 μm (dia.)	Nunclon
	PLGA microspheres	PLGA	0.65 g cm^{-3}	500–860 μm (dia.)	PLGA
	PLGA scaffolds	PLGA	90%	3 × 2 mm (dia. × thick)	PLGA
	PGA scaffolds	13 μm diameter PGA fibers	97%	10 × 2 mm (dia. × thick)	PGA
	HYAFF®	Benzilic ester of hyaluronic acid	–	4 × 4 cm	Hyaluronic acid
	Porous silk scaffold	Natural silk	95.5%	8 × 2 mm (dia. × thick)	Natural silk
	PEG hydrogel	PEG	92%	5 × 3 mm (dia. × thick)	PEG
	Alginate microspheres	Alginate	–	300 μm	Alginate
	Alginate–chitosan microspheres	Alginate–chitosan	–	5 mm (dia.)	Chitosan
Composites	Chitosan–HA microspheres	Chitosan–HA	–	350–450 μm (dia.)	Chitosan–HA
	PLA–BG microspheres	PLA/BG composite	–	100–200 μm (dia.)	Calcium hydroxyapatite
Ceramic	Bioceramic microspheres	Silica and calcium phosphate	0.8–1.0 g cm^{-3}	100–200 μm (dia.)	Calcium phosphate

dia.: diameter; BG: bioactive glass; PGA: polyglycolic acid; HA: hydroxyapatite; PLA: polylactic acid; PEG: poly(ethylene glycol); PLGA: poly(D,L-lactic-*co*-glycolic acid).

5.511.3.2. Microcarriers and Scaffolds Used for Cell Culture in RWV

A variety of scaffolds and microcarriers have been developed and used as carriers for anchorage-dependent cell cultures in RWVs. In general, the carriers can be classified into three categories based on their composition: polymer, polymer–ceramic/glass composite, and bioceramic. In the polymer category, the carriers are in microsphere or scaffold form. For the other two categories, they generally have a microsphere form. Some of the carriers are summarized in Table 1.

5.511.3.2.1. Polymers

5.511.3.2.1.1. Microcarriers

Cytodex-3 beads (133–215 μm diameter) are the most commonly used microspheres for 3D cell culture in RWVs. They are cross-linked dextran microspheres coated with collagen which is covalently linked to dextran. Because their density (1.04 g cm^{-3}) is very close to that of the culture medium, they experience a low shear stress in RWVs.

5.511.3.2.1.2. Scafffolds

Biodegradable polymer scaffolds have unique features: in addition to having defined shape and dimensions, they are biodegradable which allows their replacement by the cells and tissues being formed. As such, biodegradable scaffolds are commonly used for tissue engineering applications that require a specific shape and a high porosity, such as tissue engineering of cartilage tissue. The porous scaffolds made of fibrous polyglycolic acid (PGA) were first used for chondrocyte culture in RWV in the 1990s.[25] PGA scaffold is a nonwoven mesh composed of fine PGA fibers and has a high porosity (97%). Its mass decreases by ~40% or 63% of the initial mass during 4 or 8 weeks of cell culture, respectively.[26]

Because of the high porosity of the scaffold when it is in a RWV filled with culture medium, the apparent density of the scaffold is very close to that of the culture medium. Thus it experiences a low shear stress and can be suspended in the medium during the entire cell culture period without frequent collisions with the outer wall of the RWV.

5.511.3.2.2. Polymer–ceramic/glass composites

In orthopedic and dental applications, calcium phosphate (CaP)-based ceramics and bioactive glasses have been used by virtue of their ability to bond with bone tissues and to promote bone formation.[27] A composite microsphere with low density and a bioactive surface was developed by relying on the low density of polymers and coating polymeric spheres with a CaP film.[28] The composite microsphere has a core that is a mixture of polylactic acid (PLA) and modified bioactive glass powders, and an outer Ca–P-rich layer. As the densities of ceramic and glass are greater than that of culture medium, a composite microsphere needs to have high porosity in order to have an apparent density that is close to that of the culture medium in order to have low shear stress for cell culture in RWVs.

5.511.3.2.3. Ceramics

Because of the fact that ceramic has higher density than culture medium, a microsphere that is made of ceramic has to be hollow inside and/or has high porosity in order to have apparent density that is close to that of culture medium, which is one of the criteria for carriers used in RWVs.

Hollow bioceramic microspheres with a Ca–P surface were developed and used for bone cell cultures in RWVs.[20,29] When a hollow ceramic microsphere with an apparent density of 0.9 g cm^{-3} is placed in HARV at a rotational speed of 18 rpm, a microsphere moves spirally toward to the center and finally remains suspended in the central region of the vessel (Figure 14(a)). In a rotation frame, the microsphere moves in small circles while moving to the center (Figure 14(b)). On the basis of the recorded trajectory in a rotational frame (Figure 14), an empirical maximum shear stress imparted on the hollow

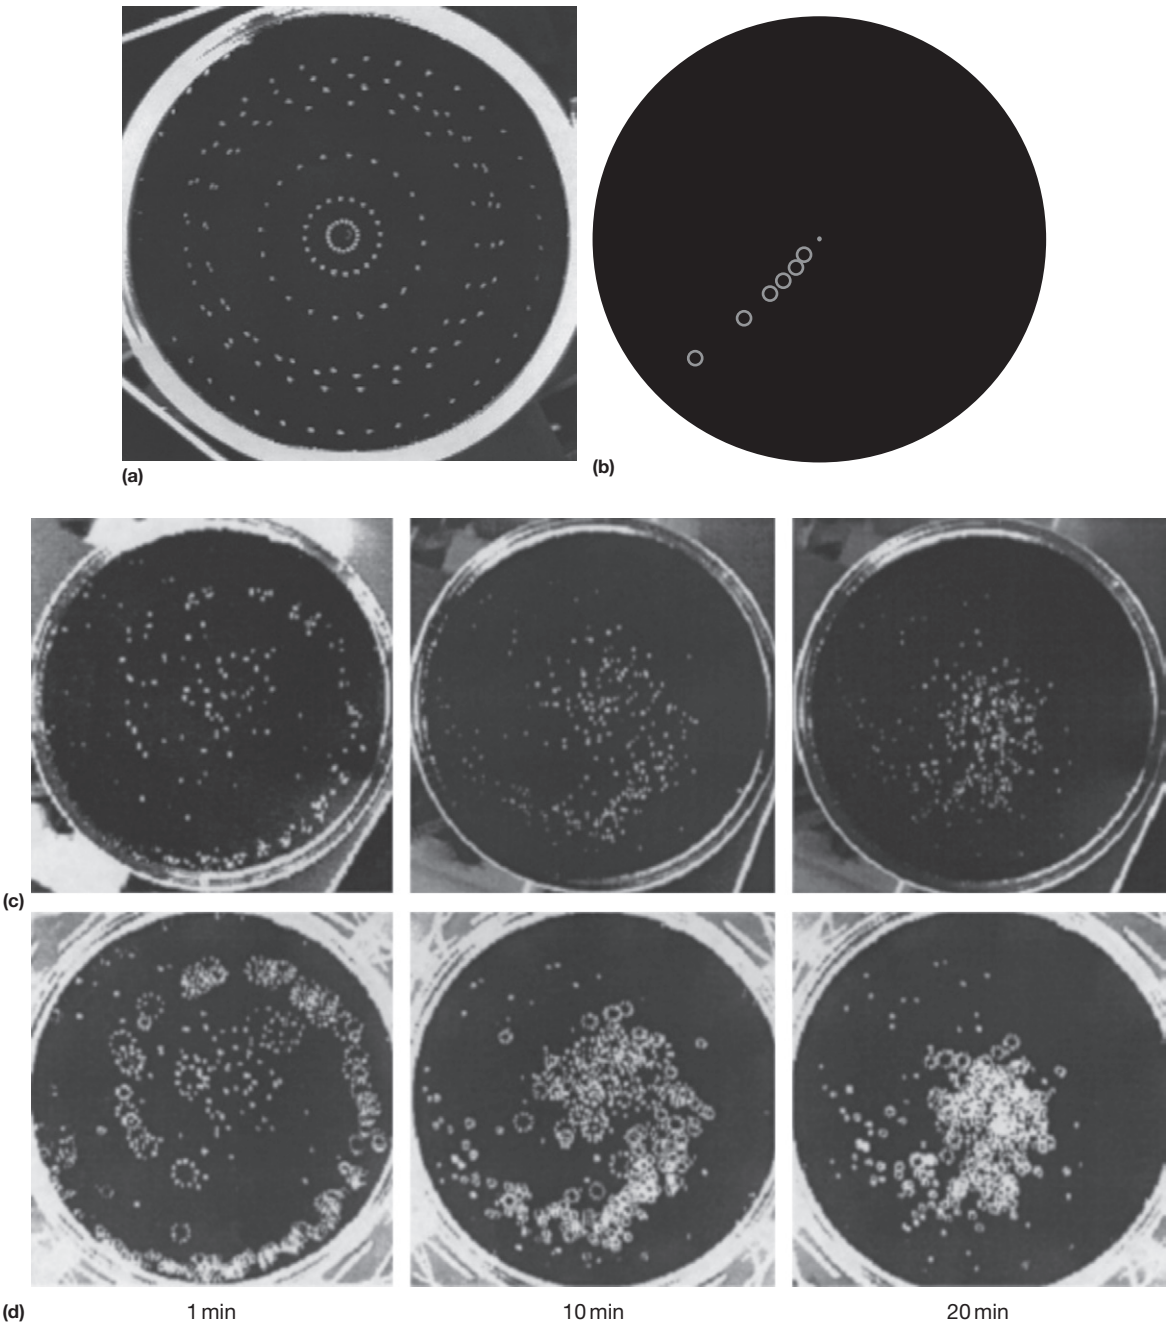

Figure 14 (a–b) Trajectory of a hollow microsphere (100 μm in diameter, density ~0.9 g cm^{-3}) in fluid medium (density 1.0 g cm^{-3}) a high aspect ratio vessel (HARV) from the start of rotation at 18 rpm in an inertial frame (a) and in a rotating frame (b). In the inertial frame, the camera records the locations of the particle while HARV rotates. In a rotating frame, the camera records the location of the particle while it rotates with the HARV at the same speed. The particle locations are displayed at every 1/6 s along the loops that the particle traversed. As the loops tended to overlap each other, a time lapse of 10 min was chosen between each loop displayed beyond the first few loops. (c–d) Trajectories of a large number of hollow microspheres (100–200 μm in diameter) in a RWV. (a) Snap shots of instantaneous locations of microcarriers at 1, 10, and 20 min from the start of rotation at 18 rpm. (b) Picture of closed loop motions of the same microcarriers in a rotating frame at 1-, 10-, and 20-min intervals. One full rotation has been photographed and composed. The particle locations are displayed at every 1/3 s along the loop the particle traversed. Reproduced from Qiu, Q.; Ducheyne, P.; Ayyaswamy, P. S. *Biomaterials* **1999**, *20*, 989–1001, with permission from Elsevier.

microsphere was found to be about 0.6 dyn cm^{-2},[20] which is smaller than the shear stress level that causes cell damage as reported previously, and is comparable to that experienced by polymer microcarriers, for example, Cytodex-3, in an RWV.[30]

5.511.4. Cell Culture in RWV

Cell cultivation in RWVs was pioneered at the NASA Johnson Space Center in the early 1990s.[1–3,31] As shown in the previous

sections, RWVs have advantages of low shear stress, controlled supplies of oxygen and nutrients, and support of 3D cell cultures,[1,3,6,12] and thus have gained great interest in applications of 3D cell culture and tissue engineering. This section will provide a brief review on cell cultures in RWVs.

5.511.4.1. 3D Cell Culture

As illustrated in the previous sections, the carrier materials play a critical role in shear stress and fluid mechanics that cells experience in RWVs. The general review in this section will group the cell culture studies on the basis of the carrier materials employed. A partial list of cell cultures carried out in RWVs is shown in Table 2.

As the model without the use of carrier as cell substrate can eliminate the complexity associated with the carriers, for example, high shear stress due to high density and shape of microcarriers or scaffolds, it is useful for investigating initial cell binding, proliferation, and differentiation processes in a simulated microgravity environment in RWVs and this has also been included in this section.

5.511.4.1.1. Bone cells

The bone loss that accompanies spaceflight is one of the most serious health problems associated with space travel.[88] After extended time in space, a marked reduction in bone mass, a condition known as spaceflight osteopenia, is commonly seen.[89,90] As RWVs can simulate some aspects of microgravity

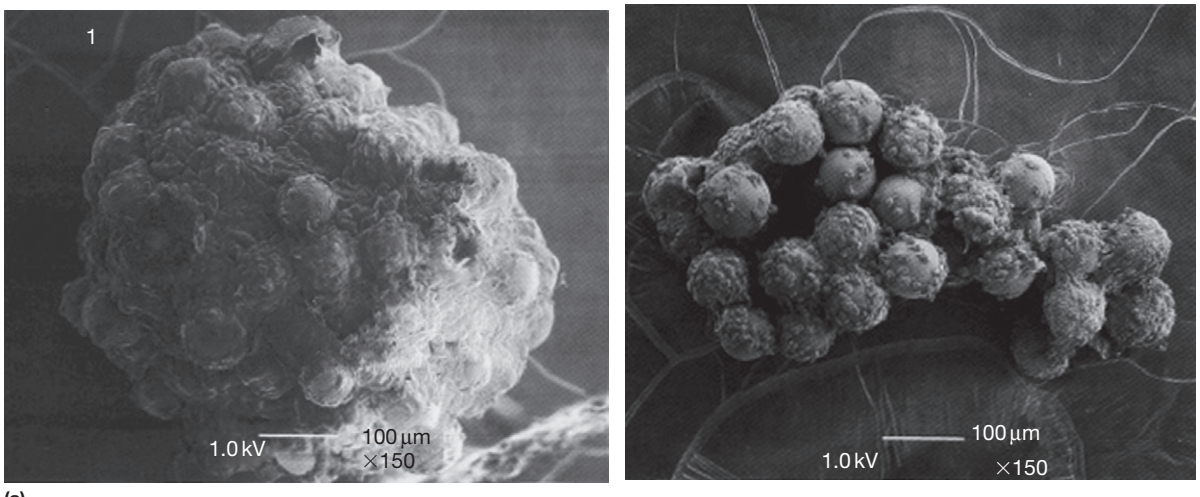
Table 2 Cell cultures and microcarriers used in RWV

Cell culture type	*Scaffolds/microcarriers*	*Culture duration*	*References*
Bone cells			
Human osteoblast-like cells (SaOS-2)	Lighter-than-water PLGA microspheres	7 days	32
Human mesenchymal stem cells (hMSC)	Microcarrier beads	7 days	33
	No carrier		34
Human periodontal ligament fibroblasts (hPDLF)	PLGA scaffolds	3 weeks	35
	Chitosan–hydroxyapatite microspheres with cells encapsulated inside		36
Human bone marrow cells and chondrocytes	Alginate/chitosan with cells encapsulated inside	4 weeks	37,38
Human bone marrow stromal cells	Porous silk scaffold	5 weeks	39
Rabbit bone marrow cells	No carrier	7–21 days	40,41
Rat bone marrow stromal cells	Hollow bioceramic microspheres; bioactive composite microspheres	2 weeks	29
Rat marrow stromal cells	PLGA scaffolds	21 days	42
Rat calvarial osteoblast cells	PLGA scaffolds made with lighter-than-water and heavier-than-water microspheres	7 days	43
Rat calvarial cells	Gelated collagen	3 weeks	44
Rat osteoblast-like cell line (ROS.SMer#14)	No carrier	48 h	45
MC3T3-E1 osteoblast-like cells	Alginate beads with cells encapsulated inside	5, 14 days	46,47
Mouse osteoblast	No carrier	24 h	48
ROS17/2.8 osteoblast cells	Cytodex-3 and Biosilon	8–10 days	49
Chondrocytes			
Human articular chondrocytes	None used	12 weeks	50
Bovine calf articular chondrocytes	PGA scaffold	6 weeks	51,52
Bovine chondrocytes	PLLA nanofibrous scaffolds with cells embedded inside	6 weeks	53
Bovine chondrocytes	PGA scaffolds	8 weeks	54,55
Bovine chondrocytes	PEG hydrogels	5 days	56
Bovine chondrocytes	Cytodex-5 microcarriers	36 days	57
Rat chondrocytes	Cytodex-3 microspheres	41 days	58
Stem cells			
Human embryonic stem cells	None	30 days	59
Murine embryonic stem cells	Alginate beads with cells encapsulated inside	24 days	60
Embryonic limb cells	Cytodex-3 microspheres	65 days	61
Human mesenchymal stem cells (hMSCs)	Silk scaffolds	3 weeks	62
Human mesenchymal stem cells (hMSCs)	None	8 days	63
Murine embryonic stem cells	Alginate hydrogels	14 days	60
Cancer cells			
Human colon carcinoma cells, HT-29, MIP-101	Cytodex-3	17 days	1,64
Coculture of human prostate fibroblasts and human prostate cancer cells	Cytodex-3	10 days	65
Coculture of fibroblast spheroids with PC3 prostate cancer cells	None	4 weeks	66

(*Continued*)

Table 2 (Continued)

Cell culture type	*Scaffolds/microcarriers*	*Culture duration*	*References*
Coculture of human tumor epithelial and umbilical vein endothelial cells	Cytodex-3	10 days	67
LN1 ovarian tumor cell line	Cytodex-3	4.5 weeks	3,68
Coculture of human prostate cancer cell line, LNCaP, and prostate or bone stromal cells	Microcarrier beads	1 week	69
Human MIP-101 colorectal carcinoma cells	Cytodex-3	12 days	70
Human breast carcinoma cells	Cytodex-3	56 days	71
Human endothelial–tumor epithelial cells	Cytodex-3 microcarrier beads	10 days	67
Other			
Human promyelocytic cells	None	7 weeks	72
Human bone marrow CD34+ cells	None	4–6 days	73
Primary human liver cells	Cytodex-3, polystyrene beads, PGA scaffolds	60 days	74
Human hepatoblastoma cells (HepG2)	None	3 days	75
Dendritic cells differentiated from human CD34+ progenitors	None	12 days	76
Adrenal medullary PC12 pheochromocytoma cells	Cytodex-3	20 days	77
Bovine aortic endothelial cells	Cytodex-3	30 days	78
Bovine chondrocytes	Cytodex-3	5 weeks	79
Primary porcine aortic smooth muscle cells (SMC)	Nonwoven benzilic ester of hyaluronic acid	1 week	80
Rat satellite cells	Cytodex-3	5 days	81
Neonatal rat cardiac cells	Polystyrene beads	6 days	82
Neonatal rat heart ventricular cell	Bovine type I collagen matrix	3 weeks	83
Rat hepatocytes		30 days	84
Neonatal rat cardiomyocytes	PGA scaffolds	1 week	85
Mouse splenocytes	None	2 days	86
Mouse myoblasts C2C12	None	1 week	87



(a) (b)

Figure 15 Scanning electron micrographs of rat marrow stromal cells grown on Cytodex-3 microcarriers in a high aspect ratio vessel (a) and cell bag (b) for 14 days. Reproduced from Qiu, Q.; Ducheyne, P.; Gao, H.; Ayyaswamy, P. *Tissue Eng.* **1998**, *4*(1), 19–34.

in bone cell cultures, RWVs have been used to search for answers for loss of bone mass during space flight. Later on, studies were carried out with a goal for 3D bone tissue formation and engineering.[15,91] This section will only provide a brief review on 3D bone cell cultures in RWVs and will include the effect of simulated microgravity on cell cultures in a latter section.

5.511.4.1.1.1. Cells cultured on polymer microcarrier and scaffolds

Osteoblastic cells cultured on polymer microcarriers such as Cytodex-3 beads in RWV were found to be more differentiated than those cultured in 3D petri dish, and mineralization was observed in the 3D aggregates consisting of multiple cell-covered Cytodex-3 microcarriers bridged together[15,49] (**Figure 15**).

When osteoblastic cells were cultured on biopolymer scaffolds, they showed increased expression of ALPase activity, osteopontin, osteocalcin (OC), and cell proliferation in RWV compared with static cell culture.[35,92] It was believed that RWV provides a favorable environment for osteogenic differentiation.[36] However, some studies showed that osteoblastic cells cultured on 3D porous poly(D,L-lactic-*co*-glycolic acid) (PLGA) scaffolds in RWV did not show considerable ALPase activity and OC secretion, but showed reduced life span and increased osteoclast activity.[42,45]

The conflicting observations may be due to the complex fluid flow mechanics in RWVs which are associated with carrier properties (e.g., density and chemical composition) and configurations (e.g., shape and porosity) as well as cell types and culture conditions. For example, cells cultured on heavier-than-water microcarriers or scaffolds that have apparent density greatly different from the density of culture medium will experience higher shear stress and collisions with the outer wall of the vessel than cells cultured on microcarriers or scaffolds that have a density close to or equivalent to that of culture medium. The shear stress and collisions may significantly affect cell proliferation and differentiation.

5.511.4.1.1.2. Cells cultured on carriers lighter than culture medium

As bioceramic material has a density much greater than that of culture medium, it is not suitable to be used directly as a carrier for cell cultures in RWVs. In order to reduce its apparent density to reduce its shear stress and avoid microcarrier–wall collisions, hollow bioceramic microspheres with apparent density between 0.8 and 1.0 g cm^{-3} were developed and used for 3D bone-like tissue engineering in RWV.[20] The osteoblastic cells attached to and formed 3D aggregates with the hollow microspheres, and extracellular matrix and mineralization were observed in the aggregates formed in RWV after a 2-week culture period (**Figure 16**).

In the wake of this work with bioceramic and composite microspheres,[20] PLGA microspheres were also developed. The microspheres were formed into 3D scaffolds and used for osteoblastic cell culture in RWV.[32] Human SaOS-2 cells cultured on lighter-than-water PLGA scaffolds for 7 days retained their osteoblastic phenotype and showed significant increase in alkaline phosphatase expression compared with statically cultured controls.[32] Rat calvarial osteoblast cells were also cultured on 3D scaffolds made with lighter-than-water PLGA microspheres for 7 days in RWV.[43]

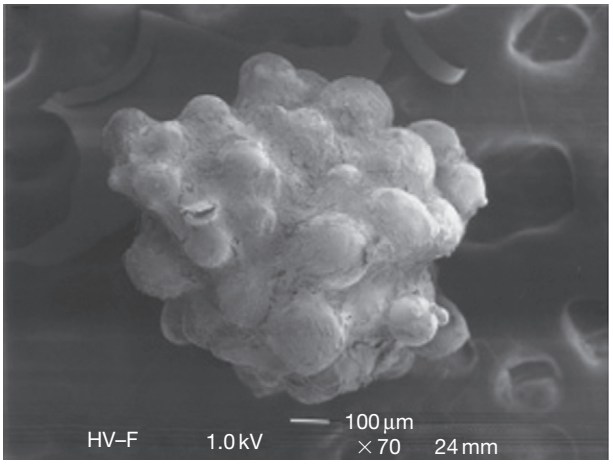


Figure 16 An aggregate of bone marrow stromal cells and hollow bioceramic microspheres in 14-day cell culture in a high aspect ratio vessel. Note the aggregate is in a nearly spherical shape. Reproduced from Qiu, Q.; Ducheyne, P.; Ayyaswamy, P. S. *Biomaterials* **1999**, *20*, 989–1001, with permission from Elsevier.

Previous studies have shown that the shear stress in the range of 3–10 dyn cm^{-2} is sufficient to inflict damage to cells.[93] A shear stress in this range has also been reported to downregulate alkaline phosphatase activity,[94] stimulate release of nitric oxide, and increase prostaglandin E_2 production in osteoblasts.[95,96] As the hollow bioceramic microspheres experience low shear stress ($\sim$0.6 dyn cm^{-2}),[20] they appear to alleviate the damage to cells/cell aggregates from shear stress and collisions.

5.511.4.1.1.3. Cells encapsulated in microcarriers or matrix

Use of microspheres or scaffolds with densities close to that of culture medium does not completely eliminate shear stress on cells in RWVs. For investigations that require no or negligible shear stress, such as studies on the effects of microgravity on cellular functions, further reduction of shear stress is desired. The approaches include encapsulation of cells in hydrogels or inside microcarriers to reduce the cell exposure to shear stress.

Various cell types including embryonic and bone marrow stem cells encapsulated in alginate and chitosan hydrogels, or gelated collagen have been cultured in HARV; 3D constructs formed have displayed morphological, phenotypical, and molecular attributes of the corresponding cell lineage.[38,44,60]

5.511.4.1.1.4. No carrier used

Although bone cells are anchorage-dependent cells, they can be cultured without any carrier in RWVs as they attach to each other to form cell aggregates and differentiate.

When rat or mouse osteoblast cells were cultured in RWV for short time periods, for example, 24–48 h, the cells appeared to be stimulated by regulating osteoblast secretion of crucial regulatory factors,[48] and they showed high levels of alkaline phosphatase activity and elevated expression of osteopontin, OC, and bone morphogenetic protein (BMP-3).[45] However, it was also reported that osteoblastogenesis of human mesenchymal stem cells (hMSC) was severely reduced after 7-day culture in RWV.[33] It was suggested that the cell culture environment in RWV may disrupt collagen I/integrin signaling during osteoblastic differentiation of hMSC.[34]

A regeneration of 3D large and homogenous cartilaginous tissue from rabbit bone marrow cells without a scaffold using RWV was also reported.[41] Bone marrow cells cultured for 4 weeks in the chondrogenic medium in the RWV formed cylindrical cartilaginous tissue with dimensions of 1.25 × 0.6 cm (height × diameter).

5.511.4.1.2. Chondrocytes

Biodegradable and highly porous 3D scaffolds made of PGA, PLGA, or silk fibers are the commonly used carriers for chondrocyte culture in RWVs. Common cell sources for chondrocytes include human and bovine calves.[97]

A high cell-seeding density, for example, 4–10 million cells per scaffold (10 mm diameter × 5 mm thick), plays a

crucial role in the initiation of chondrogenesis *in vitro*; thus it is one of the key parameters for cartilage cell culture and tissue engineering.[55,98] At the start of cell culture (chondrogenesis), cell density is the highest at the construct periphery, and chondrogenesis proceeds from the construct periphery toward its center during the cell culture period in RWVs.[97] It was found that the constructs cultured in RWVs were larger, contained continuous cartilage-like extracellular matrices with higher fractions of glycosaminoglycan and collagen, and better mechanical properties than those cultured in static culture and mixed flasks.[52]

In addition to scaffolds, PEG hydrogels and Cytodex-3 microcarriers have also been used for chondrocyte culture in RWV.[56,79] Chondrocytes can also be cultured without any scaffold in RWV, and form cartilage-specific extracellular matrix.[50]

It was found that major improvements for chondrocyte culture could be achieved using bioreactors that provide efficient mass transfer and controlled shear stress at the cell and implant surfaces over the static cell culture condition.[5]

5.511.4.1.3. Stem cells

Stem cells have the ability to proliferate and differentiate into a diverse range of specialized cell types and regenerate tissues. There are two main types of stem cells, embryonic and nonembryonic. Nonembryonic cells are also known as adult stem cells, usually from bone marrow, which has two types of stem cells: haemopoietic, which will differentiate into blood cells, and the less differentiated mesenchymal stem cells (MSCs). Only nonembryonic cells have been used in clinical therapies so far.[99]

Human stem cells cultured in RWVs showed greater cell proliferation than those in static cell culture,[100] and reduced osteogenic differentiation.[101] It was also found that the type of rotating vessel had a significant impact on the process of human embryoid body (hEB) formation and agglomeration.[59] In the STLV, hEBs were smaller in size and no large necrotic centers were seen, even after 1-month cultivation. In the HARV, hEB agglomeration was massive.

Human hematopoietic bone marrow cells cultured for 4–6 days in RWV exhibited reduced proliferation compared to static cell culture.[73]

5.511.4.1.4. Other

In addition to the cells described in the previous sections, various other cell types including C2C12 mouse myoblasts have also been studied with the use of RWVs.[73,77,81,82,87]

Because the fluid flow and environment experienced by cells in RWVs are influenced by many factors, such as carrier/aggregate density and shape, rotating speed, density of culture medium, cell-seeding density, etc., great caution should be taken when the observations in cell culture studies are interpreted. A better understanding of the fluid mechanics in each cell culture condition would be very helpful to improve cell culture design and studies. In general, major improvements can be achieved by providing efficient mass transfer and controlled shear stress at the surfaces of cells and aggregates.

5.511.4.2. Tissue Engineering

There is a great overlap between 3D cell culture and tissue engineering as cell attachment, proliferation, and differentiation occur at the early stage of tissue formation as well as throughout the entire cell culture and tissue formation period. To avoid extensive overlapping with 3D cell culture, this section will focus on the studies on cell cultures with a goal to form functional tissues and the culture period is at least 1-week long.

For anchorage-dependent cells, biodegradable and porous scaffolds are usually preferred. A biodegradable scaffold allows degradation of the same order of magnitude as the rate of extracellular matrix deposition. A highly porous scaffold could not only allow better mass and oxygen transfer, but also avoid high shear stress and frequent collisions associated with high density of microcarriers or scaffolds.

Among the different types of tissues in the human body, articular cartilage is an avascular tissue known to have a limited capacity for self-repair. Currently the only repair therapy approved by the US Food and Drug Administration is a cell-based method which involves obtaining autologous articular chondrocytes from the patient, expanding them in culture, and then reinjecting them under a periosteal flap at the defect site.[102] As RWVs were invented at NASA, extensive studies on cartilage engineering with the use of 3D biodegradable scaffolds and chondrocytes (or bone marrow stromal cells) have been carried out.[97,103] It was found that the constructs cultured in RWVs were superior to those grown in either static or mixed flasks with respect to GAG and collagen content, equilibrium moduli, and hydraulic permeabilities.[103] Studies on chondrogenesis in constructs of chondrocytes and PGA scaffolds showed that the constructs grown aerobically were superior to those grown anaerobically in wet weight, total cell number, GAG content and total collagen, and rates of cartilaginous matrix biosynthesis.[103,104] This observation indicates that oxygen plays an important role during the cultivation of engineered cartilage in RWVs.

Another source for cartilage tissue engineering is bone marrow stromal cells, which can differentiate into several mesenchymal lineages including osteoblasts, chondrocytes, adipocytes, and myocytes depending on local environments.[105] When human bone marrow stromal cells were cultured on porous silk scaffolds for 5 weeks in STLV, they formed large and homogenous bone-like tissue constructs with mineralization resembling those of the human trabecular bone.[39,62]

After porcine aortic smooth muscle cells (SMC) were cultured on tubular sheets made from benzilic ester of hyaluronic acid for 1 week in RWV, the cell proliferation was higher in RWV than in static control.[80] It was found that the constructs experienced higher maximum stress and lower elastic modulus than the control.

Hepatocyte cells isolated from human livers and cultured on biodegradable scaffolds in RWV formed aggregates which increased up to 3 cm long.[74] Hepatocyte spheroids cultured in a HARV could retain cellular and physiological properties of the intact liver.[84] Morphological evaluation revealed that hepatocyte spheroids cultured for 30 days in the HARV had a compact structure with tight cell–cell junctions, numerous smooth and rough endoplasmic reticulum, intact mitochondria, and bile canaliculi lined with microvilli.

Neonatal rat cardiomyocytes cultured on laminin-coated PGA mesh in RWV showed superior molecular and electrophysiological properties to those of the same cells cultured as

monolayers in terms of cell metabolism, contractile function, and intercellular communication.[85]

Small intestine epithelium and mesenchymal cells cocultivated on Cytodex-3 microcarriers in RWV for up to 40 days were differentiated to form tissue-like masses.[106] Bovine aortic endothelial cells cultured on Cytodex-3 in RWV for 30 days showed enhanced NO production and barrier properties.[78]

Rat and chick cardiac myocytes cultured on PGA scaffolds for 2 weeks showed spontaneously contractile cells. It was believed that high initial cell densities and utilization of RWVs improved structural and functional construct properties.[107]

Other cell types that have also been studied using RWVs include keratinocytes,[108] microvascular endothelial cells,[109] HepG2 cells,[110] hepatocytes,[111] epidermal keratinocytes,[112] and retinal and endothelial cells.[113]

It should emphasized here again that because of the complexity of the fluid mechanics in RWV, the interpretation of the effect on cellular and tissue responses in RWVs remains difficult. The factors include but are not limited to shear stress,[80] mass transfer, and carrier material properties.

5.511.5. Other Applications of RWV

156.5.1. Space Biology

Space flight is known to affect human biological systems including loss of bone mass, muscle strength, and cardiovascular fitness in astronauts.[113–115] It also has a significant negative impact on immune function. As RWVs can simulate some aspects of microgravity environment, they have been used to culture cells on 3D biodegradable scaffolds or microcarriers to investigate cellular responses to simulated microgravity.

It was reported that cartilaginous constructs cultured for 6 weeks in RWVs contained collagen matrix that resembled that of articular collagen with respect to overall organization, fiber diameter, and molecular structure.[51,97] However, the fraction of collagen and dynamic stiffness of constructs cultured in RWVs were significantly lower than those of cartilage explants.[117] In comparison to constructs grown in RWVs on earth, the constructs grown on Mir Space Station floated freely in the bioreactor and were more spherical, smaller, had less weight increase, and were mechanically inferior.[54] The videotapes showed that constructs floated freely in microgravity, but settled and collided with the rotating vessel wall at 1 g. The observation indicated that the collision and the difference in culture conditions might have contributed to the differences. In order to better simulate the microgravity environment on earth, it might be essential to avoid the collision with the vessel wall by choosing the right carriers, such as carriers with density close to and less than that of culture medium.

Embryonic mouse prebone tissues were placed in RWV at one of four different stages of chondrogenesis, ranging from undifferentiated mesenchyme cells to chondrocytes on the verge of undergoing terminal chondrocyte differentiation. The study has found that exposure to the RWV at early stages of chondrogenesis severely limits the ability for cartilage growth and yields abnormal downstream morphogenesis. However, at later stages of chondrogenesis, the RWV environment may be beneficial to enhance growth and development.[118]

A marked reduction in bone mass is common after extended time in space, a condition known as spaceflight osteopenia.[89,90] Osteoblasts cultured in microgravity are generally characterized by a contracted morphology, a decrease in cell number, a reduction in osteoblast-specific gene expression, and a lowered response to anabolic stimuli, relative to unit gravity conditions.[119] A significant problem in ground-based studies is that each system subjects cells to stimuli that could confound the effects of simulated microgravity, most importantly, fluid flow-induced shear stresses, vibration, and convective mixing. The divergent results reported highlight the need to control these extraneous factors. A system was developed that allows control osteoblasts to be cultured in normal (unit) gravity within the same HARV as cells experiencing simulated microgravity (vector-averaged gravity) (**Figure 17**). Two types of alginate bead were fabricated: polar and nonpolar carriers. As the HARV rotates, cells in nonpolar carriers are subjected to vector-averaged gravity while cells in polar carriers remain in normal gravity conditions. It was found that vector-averaged gravity did not reduce osteoblast viability (MC3T3-E1 cells). Furthermore, neither osteoblasts, nor progenitor-like cells were sensitized to apoptogens by exposure to vector-averaged gravity. Some differences in the phenotypic expression were observed in these cells; specifically, there was a decrease in alkaline phosphatase expression in simulated microgravity. These findings suggest that vector-averaged gravity alone is insufficient to induce or modulate the susceptibility of osteoblasts to agents that induce apoptosis.[47]

The studies on human hepatoblastoma cells (HepG2) showed that simulated microgravity in RWVs could modify the expression of several genes and that the RWV in combination with microarray technology might provide insight into the fundamental biological questions of how gravity affects the development and function of individual cells.[75]

Human nonadherent promyelocytic (HL-60) cells cultured in RWV for 7 weeks showed 3.8-fold fewer cells that were able to participate in respiratory burst activity than cells from 1-g cultures. The results demonstrated that simulated microgravity alters an innate cellular function (burst activity). If respiratory burst activity is impaired by true microgravity, then recovery from infections during spaceflight could be delayed.[72]

During spaceflight, astronauts also experience alterations of the immune response.[120,121] Existing evidence suggests that space travelers are immunosuppressed, presumably by microgravity environment stressors. Studies on dendritic cells showed that the cell generation and function were altered in RWV.[76] To prevent immunosuppression during and after space flight, use of dietary nucleotide (NT) supplementation was investigated. It was found that NT supplement could confer immune protection and enhance cytokine responses during space flight.[86]

5.511.5.2. Cancer Research

One of the challenges in cancer research using cell culture is to create conditions that closely simulate the *in vivo* conditions. One of the key features of *in vivo* conditions is 3D growth. As RWVs allow 3D cell cultures and efficient mass transfer, they have been used to culture various cancer cell types, including breast carcinoma cells,[71] ovary tumor cells,[3,68] prostate cancer

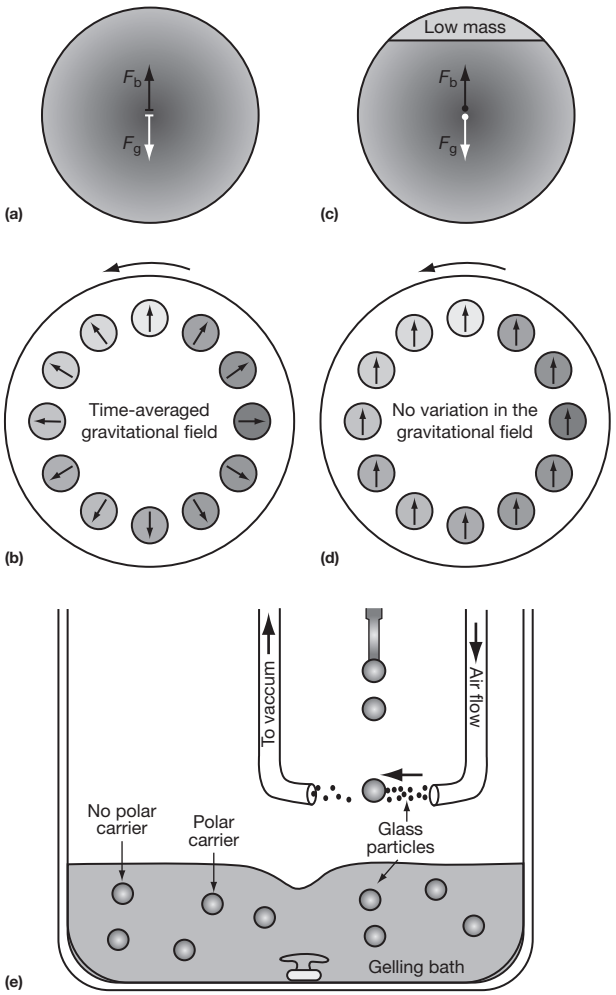

Figure 17 (a–d) Schematic of forces that control the spin of alginate carriers in the rotating high aspect ratio vessel (HARV). The carriers are designed so that the forces of gravity (F_g) and buoyance (F_b) are nearly balanced. As such, the carriers move in near solid body rotation with the fluid in the HARV. In a radially symmetric carrier, the center of buoyance coincides with the center of gravity (a). Such nonpolar carriers have no preferred orientation, and therefore, spin with the HARV rotation. The theoretical spin of a nonpolar carrier over one revolution of the HARV is shown in time lapse (b). The arrow on the carrier indicates its orientation at each phase of the rotation. In the polar carrier, they do not coincide, giving the carrier a preferred orientation (c). There polar carriers resist rotation and therefore resist spinning as the HARV turns. The theoretical stable orientation of a polar carrier over one revolution of the HARV is shown in (d). As the HARV rotates, nonpolar carriers are subjected to vector-averaged gravity while polar carriers remain in normal gravity conditions. (e) Cross-sectional diagram of the system used to encapsulate cells into nonpolar and polar alginate carriers. The alginate–cell suspension (1% alginate, 2×10^6 cells ml^{-1}) was extruded by a syringe pump (100 ml h^{-1}) through an 18-gauge needle. Droplets released from the needle tip polymerized in the $CaCl_2$/NaCl bath forming carriers seeded with cells. The gelling bath was stirred to prevent the carriers from deforming upon entry. The process was used to form nonpolar carriers of uniform size and sphericity. To form polarized carriers, aerosolized hollow glass particles were blown across the drop path. The glass particles were incorporated into the surface of the carriers upon polymerization. Reproduced from Bucaro, M. A.; Zahm, A. M.; Risbud, M.V.; *et al. J. Cell. Biochem.* **2007**, *102*(2), 483–495, with permission from Wiley.

cells,[65,69,121–123] colon adenocarcinoma cell lines,[1] epithelial tumor cells,[67] melanoma cells,[125] and leukemic cells.[126]

When human primary breast carcinoma cells were cultured in RWV for a prolonged time, they formed complex tissue-like constructs, exhibited significantly increased proliferative activity in conjunction with oncogene activation and developed into aggressive aneuploid populations.[71]

To study cellular interactions involved in the growth and differentiation of ovary tumors, a cell line established from ovary tumor was cultured on microcarrier beads in HARV. The tumor cell proliferated and exhibited 3D multicellular aggregates.[3] A cell line derived from a heterologous mixed mullerian tumor cell of the ovary was cultured on Cytodex-3 for 32 days in RWV. The data indicate that the RWV culture system is suitable for generating large quantities of ovarian tumor cells *in vitro* that are amenable to immunocytochemical, oncogenic, and morphologic characteristics demonstrated *in vivo*.[68]

DU 145 human prostate carcinoma cells cultured on Cytodex-3 beads for 2 weeks in RWV showed a lower proliferation rate, but were more differentiated than controls.[122] PC-3 human prostate cancer cells have also been cultured on Cytodex-3 bead in RWV in which glucose, lactate, and glutamine profiles were monitored noninvasively and in real time by near-infrared (NIR) spectroscopy.[123]

Human colon adenocarcinoma cell lines, HT-29 and HT-29kM, were cultivated on Cytodex-3 for up to 17 days.[1]

Human MIP-101 poorly differentiated colorectal carcinoma cells were cultured for 6 days in monolayers or in rotating 3D cultures either in microgravity in low-earth orbit (space shuttle, 3D, μg) or in unit gravity on the ground (3D, 1 g). Over the course of 6 days, static 3D cultures displayed the highest rates of proliferation and lowest apoptosis. Rotated 3D μg displayed significantly less apoptosis than rotated 3D 1 g cultures. Thus rotation appears to increase apoptosis and decrease proliferation.[70]

A novel *in vitro* human prostate cancer model was established by using a coculture technique in which isolated human prostate fibroblasts were observed to grow as a mixed culture with human prostate cancer cells on microcarriers in RWV.[65] Upon coculture of human prostate cancer cell line, LNCaP, with microcarrier beads either in presence or in the absence of prostate or bone stromal cells, 3D prostate organoids were formed after 7 days in RVW.[69]

The multicellular interaction between human tumor epithelial and human umbilical vein endothelial cells grown on Cytodex-3 for 10 days was investigated. It suggests that RWV provides a new model that allows us to investigate the regulatory factors that govern tumor angiogenesis.[67]

Growth patterns of a number of human tumor cell lines that form 3D structures of various architectures when cultured without carrier beads in RWS were also investigated.[66]

5.511.5.3. Other

RWVs have been used to expand human MSCs from isolated bone marrow mononuclear cells.[63] Upon induction, the bioreactor-expanded MSCs were able to differentiate into osteoblasts, chondrocytes, and adipocytes. The rotary bioreactor with the modified Myelocult medium reported in this study may be used to rapidly expand MSCs.

5.512.1. Introduction

The purpose of an *in vivo* bioreactor is to maximize the role of the patient's own body in the regeneration of tissues and organs. The elements traditionally contributing to tissue engineering applications include cells that may be modified to serve specific purposes or stem cells, signal molecules, that is, growth factors and cytokines that exert specific effects on these cells, bioactive scaffolds that may replace or support form or function of impaired tissues or organ systems, and the extracellular environment that maintains protection and nutrition (**Figure 1**).

Many different approaches to combine cells, scaffolds, and signal molecules have been employed in tissue engineering and regenerative medicine, emphasizing either the *in vitro* or the *in vivo* approach to a varying extent.

A bioreactor has thus far been defined as a device or system that supports a biologically active environment and has been extensively used in the past to optimize *in vitro* culture conditions, particularly in the field of liver[1] and bone[2] tissue engineering. On the contrary, the concept of an '*in vivo* bioreactor' is relatively new. To our knowledge, the term was first coined in 2005 by two independent research groups[3,4] in a successful attempt to induce formation of tissue-engineered bone *in vivo*. Even though the animal models and the study design were entirely different from each other, the advantages of an *in vivo* approach toward tissue engineering were similar and continue to be so: availability and chemotaxis of autologous pluripotent stem or progenitor cells, eliminating the need for *ex vivo* cell manipulation and transplantation; autologous supply of growth factors as well as other supportive stimuli; and potential for *in situ* creation of a vascular network supplying the tissue-engineered construct, including a main vessel axis, enabling a later transfer of the vascularized neo-tissue or organoid to the desired site.

Our overview will highlight attempts toward generating *in vivo bioreactors* in different compartments of the body with a broad range of applications which include not only tissue regeneration but also the investigation of tumor and metastasis formation,[5] tolerance induction in tissue and organ transplantation,[6] and substitution of metabolic function.[7,8]

As insufficient oxygen supply has been one of the major obstacles in the generation of bioartificial tissues and organs, we will particularly emphasize vascularization strategies and present the application possibilities of an axially vascularized separation chamber that could be employed not only to create

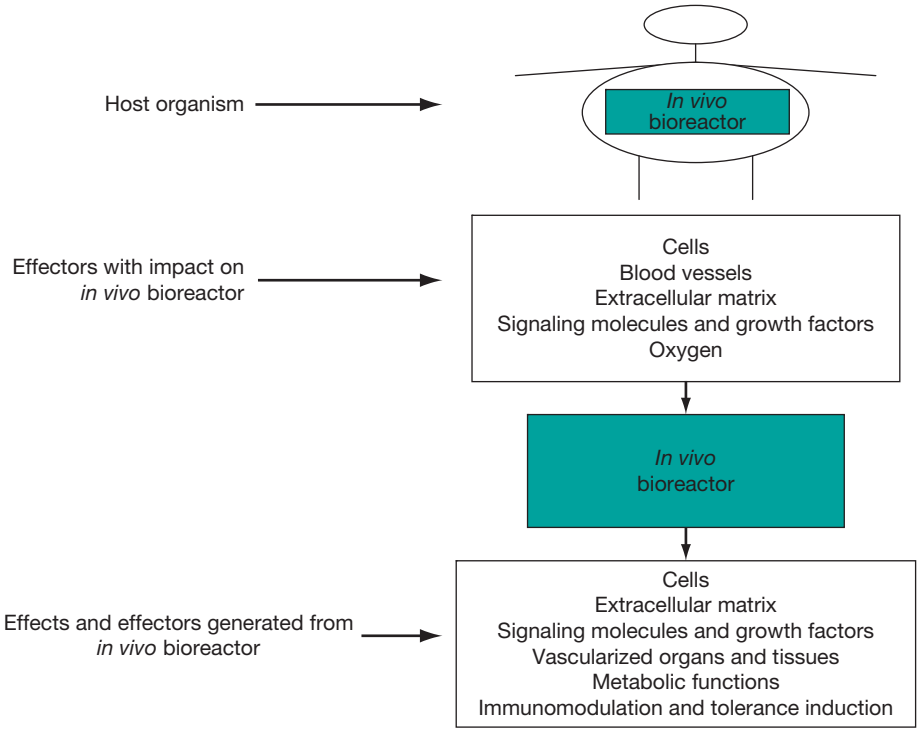

Figure 1 Principles and mechanisms involved in the *in vivo* bioreactor.

transplantable tissues or organoids with their own blood supply, based on a microsurgically created arteriovenous axis (reviewed in Polykandriotis *et al.*[9]) but may also be used as a platform for cancer research (reviewed in Hutmacher *et al.*[5]).

5.512.2. Elements of the *In Vivo* Bioreactor

5.512.2.1. Stem Cells or Progenitor Cells

Stem cells or progenitor cells are considered among the most promising tools today for regenerative medicine applications, but despite extensive research, control over trafficking, survival, proliferation, and differentiation remains extremely challenging and the underlying mechanisms largely unknown (review in Discher *et al.*[10]). The interplay of growth factors, cell–cell contacts, and cell–matrix adhesions taking place *in vivo*, determines the response of these cells to a certain stimulus determining their action and effect, but is very difficult to reproduce under *in vitro* conditions. Drawbacks of this *ex vivo* approach lie in the fact that stem and progenitor cell populations may be very heterogenous, making it difficult to obtain purity of the cell population, thereby limiting reproducibility. In addition, growth in two-dimensional (2D) culture systems may lead to changes in phenotype and differentiation and proliferation status, altering the cells' potential to exert their proper inherent function. Absence of physiological stimuli and factors such as the extracellular matrix, mechanical forces, and signaling molecules may all contribute to undesired changes in the cell's features and capacity for regeneration.

The *in vivo* bioreactor makes use of the fact that potentially useful cell populations already exist in the body and attraction of these cells to a desired anatomic site may provide new therapeutic options. At the same time, complexity of manipulation and cost associated with *in vitro* bioreactors can be reduced. Stevens *et al.* were the first to coin the term '*in vivo* bioreactor' and demonstrated the potential of *de novo* bone growth solely based on the creation of an artificial space between bone and periosteum, which was subsequently filled with a calcium alginate gel that cross-linked *in situ* and provided the scaffold for powerful generation of functional native bone.[3] Recently, an increasing number of studies have been aimed at the mobilization of endothelial progenitor cells (EPC) from bone marrow to ischemic tissues with chemotactic agents such as granulocyte colony-stimulating factor (CSF) or drugs such as statins.[11] *In vivo* vascularization of a given space containing a matrix or a scaffold is gaining increasing attention to prebuild a vascularized structure and deliver either pluripotent or specialized cells to it as the blood vessel tree continues to grow.[12] This approach avoids the typical inevitable problem of hypoxic periods encountered in the primarily *in vitro* approach where cells are combined with a matrix in a bioreactor followed by transplantation into an initially avascular recipient bed where the blood supply has yet to grow into the construct. As mentioned above, EPC have been under intense investigation in the past due to their angiogenic (either directly or via secondary cytokines such as VEGF[13]) and vasculogenic (via direct integration and subsequent *de novo* blood vessel formation).[14] In an attempt to increase homing of transplanted human EPC to a growing prevascularized tissue-engineered organoid in a separation chamber in a nude rat model, Simcock *et al.* administered the chemokine CXC chemokine ligand 12 (CXCL12) and achieved enhanced homing of xenogenic EPC to an angiogenic site developing around an arteriovenous loop inserted in a tissue engineering chamber.[12]

Similar approaches will undoubtedly be developed and optimized to attract vascular progenitor cells and other precursor or stem cells to the *in vivo* tissue engineering site.

5.512.3. Applications and Tissues

5.512.3.1. Skin

The skin is the largest organ in the body and primarily functions as a barrier between the organism and the environment. Major skin loss as a result of trauma and burns has been a major concern to physicians and lead to the development of a multitude of strategies to promote skin wound healing and restore surface integrity. Among them, skin tissue engineering has gained particular attention in recent years and has led to a wide variety of commercially available skin substitutes of different compositions. Significant drawbacks, however, include high costs or the need for extensive *ex vivo* manipulation.

The Eriksson group made the first attempt to use the skin's accessibility and inherent regenerative capacities for healing by creating a standardized and isolated *in vivo* liquid wound environment using a transparent flexible chamber for sealing. This system allowed the delivery of analgesics, antibiotics, growth factors via direct or cell-based gene transfer, growth media, and cells into the chamber, creating an *in vivo* incubator-like environment. The group demonstrated healing of clean wounds as fast as or faster than any other method, with less scarring.[15] The beneficial effects were also demonstrated in a clinical study.[16]

Easy access to the skin has induced interest beyond wound healing and skin regeneration. Keratinocytes secrete a wide variety of proteins that have a role in skin physiology, including proteins and proteinases for matrix remodeling, growth factors, and cytokines.[7] In addition, it has been demonstrated that skin cells, namely keratinocytes, secrete proteins that can reach the bloodstream and gain systemic impact. This effect was initially demonstrated by Teichman and coworkers who grafted human keratinocytes onto athymic mice and rats. Human apolipoprotein E (apoE) was thereafter detected in the systemic circulation of the animals as long as the graft remained on the animals.[17] Human apoE was reduced to undetectable levels within 24 h after graft removal.

The potential of using genetically altered skin cells such as keratinocytes and fibroblasts, given that a skin-derived protein attained systemic distribution, has been exploited in numerous studies since then.[7] Transgene products were not only detected in the serum, but also exhibited physiological effects. A study by Meng *et al.*,[18] in which an interleukin-10 expressing vector was injected into the dorsal skin of rats, demonstrated that the transgene was detected in the bloodstream and led to an inhibition of contact hypersensitivity at distant areas of the skin. A serious drawback of methods of transient gene transfer to exploit the skin's accessibility as a delivery route for systemically effective agents has been the fact that efficiency is low and the effect only transient, likely due to promoter silencing of the transgene and immunological responses.[7]

Therefore, transgenic mouse models have been used for experimental evaluation of the skin as a bioreactor, as gene expression was shown to be higher and more ubiquitous, and simultaneously eliminating a host immune response. Targeting of the therapeutic gene to specific layers of the dermis was achieved by stratum-specific promoters such as keratin 5 and keratin 14.

Gene delivery exploiting the skin's potential as an *in vivo* bioreactor may provide therapeutic options for metabolic diseases, such as growth hormone for dwarfism, coagulation factors for coagulopathies, and insulin for diabetes mellitus.[19]

5.512.3.2. Bone

Treatment of large bone defects still requires autologous transfer of vital bone. Due to the discrepancy between the need on the one hand and limited supply as well as significant donor site morbidity on the other hand, generation of bone by the principles of tissue engineering has become a subject of extensive research efforts.[20,21] Most experimental setups employ traditional principles of tissue engineering where harvested cells are cultured *in vitro*, combined with porous scaffolds, and stimulated with exogenous morphogens and mitogens *in vitro* and/or *in vivo*.

In contrast to this, the Langer group designed a rabbit model where an artificial space between the tibia and the adjacent periosteum was created, which was referred to as an '*in vivo* bioreactor'.[3] Owing to the exposition of this mesenchymal layer which is rich in pluripotent cells, the creation of significant volumes of bone was possible in a predictable manner, without the necessity for delivery of growth factors or cell transplantation. Biological functionality of the newly created bone was demonstrated by successful transplantation to contralateral tibia defects, resulting in complete integration without significant donor site morbidity. This study also showed that inhibition of angiogenesis in this setting and the creation of a more hypoxic environment promoted cartilage formation. A similar model has been described by Miller and coworkers who used a plastic chamber for periosteum-guided bone formation from the rib in a sheep model.[22]

The lack of a defined vascular axis, however, limits the size and potential to transplant ectopically grown neo-bone to the desired location. Therefore, the ideal bone graft would not only include osteoconductive scaffolds, osteoinductive proteins, and osteogenic cells, but also a vascular network based on a main vascular access constituted by an artery and a vein. Prefabrication is defined as 'the process of neovascularization by the implantation of a vascular pedicle into tissues to be transferred later to a distant site either on the pedicle or as a free graft by microvascular anastomosis'.[23] Many attempts focused on using the inferior epigastric pedicle as a vascular axis to supply the *in vivo* bone bioreactor created around a wide variety of scaffolds consisting of hydroxyapatite[24] and coralline,[4] among others, in a separation chamber. A certain degree of bone formation could be demonstrated after addition of BMP-2 and establishment of a vascular network. This *in vivo* bone bioreactor was also shown to be useful as a model of tumor–bone interaction.[25] A clinical application of *in situ*-generated vascularized engineered bone was reported by Terheyden's group to repair an extended mandibular defect. They created a custom-made construct based on a titanium mesh cage filled with bone mineral blocks and infiltrated with recombinant human bone morphogenetic protein-7 (BMP-7) and the patient's bone marrow. Thus prepared, the transplant was implanted into the

latissimus dorsi muscle and 7 weeks later, transplanted as a free bone–muscle flap to repair the mandibular defect. Follow-up by skeletal scintigraphy and CT showed bone remodeling and mineralization inside the mandibular transplant both before and after *in vivo* transplantation, thus providing radiological evidence of new bone formation.[26]

Our laboratory adopted and further developed an arteriovenous loop model based on the femoral vessels, including a venous graft from the contralateral side in a rat separation chamber, which also constitutes an *in vivo* bioreactor. Compared to the previously described model based on the epigastric vessels, it displays superior vascularization potential.[20,21]

5.512.3.3. Small Intestine

The management of patients with short bowel syndrome (SBS) has been unsatisfactory with conventional treatment strategies so far. Various studies from the Vacanti laboratory demonstrated improved recovery after massive small bowel resection (SBR) using tissue-engineered intestine.[27] The tissue-engineered small intestine (TESI) was constructed applying *in vivo bioreactor* principles. First, segments of intestine harvested from neonatal rats were minced and full-thickness plugs of intestine created. These so-called organoid units were then seeded onto a tubular biodegradable scaffold polymer and then wrapped into the omentum of adult rats which served as the *in vivo* bioreactor. These organoid units, arranged on the biodegradable scaffold, became vascularized by the omentum to form a cyst, which histologically resembled the small bowel.[28] Several biochemical features of digestive enterocyte function and polarity have been demonstrated in these cysts in later studies.[29] As a next step, the mature, vascularized TESI cyst was placed in continuity with the gastrointestinal tract at the time of an 85% enterectomy in rats. TESI animals returned to preoperative weight more rapidly when compared with the animals undergoing SBR alone. On histologic analysis, the TESI cysts appeared to resemble normal adjacent intestine. Furthermore, the neointestine had preserved expression of green fluorescent protein that had been introduced into the organoid units prior to implantation. These marker studies strongly suggested that the neointestine was derived primarily from the neonatal-derived intestine, as opposed to ingrowth of adjacent recipient intestine. Additional studies showed lymphangiogenesis as detected by expression of the lymphatic endothelial marker vascular endothelial growth factor receptor (VEGFR)-3 using immunohistochemistry, and the lymphangiogenic growth factor VEGF-C was quantified by ELISA. Moreover, tubular structures, which resembled lymphatics architecturally, developed, and were distinct from CD34-positive blood vessels, and lacked luminal erythrocytes. This was the first demonstration of lymphatic vessels in an engineered tissue.[30] Tissue-engineered intestine also had the capacity to develop a mucosal immune system with an immunocyte population similar to that of native small intestine depending on both exposure to luminal stimuli and the duration of this exposure.[31] These results demonstrate the possibility of ectopic formation of a biologically functional bioartificial organoid with access to blood and lymphatic circulation, which could even be transferred to an orthotopic site with subsequent proof of maintained biological function.

5.512.3.3.1. Transplant tolerance induction and restoration of metabolic and organ function by cotransplantation of thymus with solid organs

Organ transplantation to restore impaired or lost function is hampered by the short- and long-term complications of immunosuppression and the current worldwide shortage of donor organs.[32] The induction of donor-specific tolerance in allogeneic and xenogeneic transplantation offers a promising solution to these problems. The thymus has been identified as critical for systemic central tolerance to self-antigens in which potentially autoreactive T cells are deleted or anergized by exposure to the appropriate self-antigens presented either by bone marrow-derived cells or thymic stromal cells.[33,34] Based on these findings and their MGH miniature swine model, David Sachs and coworkers have developed composite allografts consisting of vascularized thymic tissue and the kidney as a solid organ to induce tolerance across major histocompatibility complex (MHC)-mismatched barriers.[35]

A new transplantable organ (thymokidney) was generated by autologous thymic grafts under the renal capsule. The thymic grafts exhibited normal macroscopic and microscopic structure, and normal thymocyte composition. To evaluate the thymic function of the graft, a composite thymokidney was transplanted into a recipient who had previously been thymectomized, had few circulating CD4-single positive cells, and had lost MLR reactivity. The number of CD4+/CD45RA+ cells in this animal increased steadily indicating functionality of the thymus within the composite thymokidney. In addition, MLR assays demonstrated that the recipient recovered immunocompetence.[36]

Additional work from the same laboratory demonstrated that transplantation of allogeneic thymic tissue as part of a composite vascularized graft was far more successful in terms of both engraftment and long-term survival than transplantation of thymic tissue or cells alone.[35] This concept of the vascularized composite neo-organ was subsequently extended to transplantation of allogeneic islets, comparing survival of islet cell suspensions to that of vascularized composite islet-kidneys (IK), prepared by injection of autologous islets underneath the renal capsule 2–3 months prior to allogeneic transplantation of the composite organ. Composite IK were transplanted successfully across minor and full MHC mismatch barriers, using treatment regimens previously demonstrated to induce long-term tolerance of kidney allografts across these barriers. IK allografts containing $\geq$5000 islet equivalents (IE) per kilogram recipient body weight were found capable of reversing surgically induced diabetes, while injection of comparable numbers of purified islets via the portal vein or under the renal capsule did not. An additional study was directed toward preparation of autologous 'thymo-islet-kidneys' (TIK), for potential use as xenografts, in which the thymic component was intended to induce tolerance and the islets to reverse diabetic hyperglycemia. To evaluate the function of the transplanted islets, three animals bearing TIK and IK underwent total pancreatectomy 3 months following islet transplantation. All three animals maintained normoglycemia thereafter. In two of these animals, the IKs were removed 2 months after the pancreatectomy, and in both cases normoglycemia was maintained thereafter by the TIK.

The combination of replacement of a lost metabolic function and vascular competence of the grafts, as well as the potential for immune tolerance induction, makes this model a particularly successful example of an unusual application of an *in vivo* bioreactor. Use of both types of composite organ transplants (IK and TIK) may eventually be applicable to the treatment of type I diabetic patients suffering from end-stage diabetic nephropathy.[37]

5.512.3.4. Urinary Tract

Congenital and acquired ureteric defects cause significant morbidity and have been notoriously difficult to regenerate by tissue engineering approaches to create a neoureter in the past. Such attempts to generate a neoureter in animal models failed because of major inflammatory response. Avoidance of such inflammation requires a well-differentiated urothelium. Baumert *et al.* investigated whether omental maturation of a small intestinal submucosa (SIS) matrix seeded with previously cultured urothelial and smooth muscle cells that had been derived from bladder biopsies in a pig model could achieve terminal differentiation of the urothelium to allow construction of a stricture-free neoureter. After 2 weeks of cell growth, the *in vitro* SIS-seeded construct was shaped around a silicone drain and wrapped by the omentum to obtain neoureters. These neoureters were left in the omentum without any contact with urine, and then harvested 3 weeks later for histologic and immunohistochemical studies. Before implantation, the *in vitro* constructs were composed of a mono- or bilayer of undifferentiated urothelium overlying a monolayer of smooth muscle cells. After 3 weeks of omental maturation, these constructs were vascularized and comprised a terminally differentiated multilayered urothelium with umbrella cells over connective tissue and smooth muscle cells, with no evidence of fibrosis or inflammation. This model of *in vivo* maturation using the omentum as an *in vivo* bioreactor enabled for the first time the generation of a mature neoureter composed of a well-differentiated multilayered urothelium.[38]

When looking at other parts of the genitourinary system, bladder regeneration is another challenging goal. One of the main problems is to limit the development of ischemic fibrosis during tissue maturation. Similar to their ureter tissue engineering, Baumert *et al.* described a model using the omentum as an *in vivo* bioreactor for a previously seeded scaffold. A highly vascularized tissue-engineered construct was generated that contracted in response to acetylcholine stimulation. The wall thickness was 4 mm, on average. Histologic and immunostaining analysis of the construct confirmed the presence of a multilayer urothelium on the luminal aspect and deeper fascicles of organized tissue composed of differentiated smooth muscle cells and mature fibroblasts without evidence of inflammation or necrosis. Large- and small-diameter vessels were clearly identified histologically in the tissue obtained. The omentum as an *in vivo* incubator permitted *in vivo* maturation of seeded scaffolds with the development of a dense vascularization that is anticipated to prevent fibrosis and loss of contractility. This *in vivo* maturation into the omentum could be the first step before *in situ* implantation of the construct.[39]

5.512.3.4.1. The arteriovenous loop model: an 'in vivo bioreactor' to generate vascularized tissues and organs

The development of a functional and adequate blood vessel network is a prerequisite for successful application of engineered tissues and organs. When *in vitro*-engineered constructs containing cells are transferred *in vivo*, they lack a defined axial blood supply consisting of a main arterial inflow and a venous outflow, respectively, and therefore rely on blood vessel ingrowth from their surroundings, that is, interstitial fluid diffusion and blood perfusion.[20,21] This limitation in blood supply constitutes the main drawback when transferring *in vitro* tissue engineering approaches to the *in vivo* environment. Cell support via diffusion occurs only up to 200 μm into the matrix,[40] resulting in insufficient nutrition and subsequent loss of cells located in the center of such *in vitro*-engineered constructs.[20,21] For these reasons, induction of vascularization is essential in virtually all successful tissue engineering applications, and a defined vascular axis is desirable whenever the bioengineered tissue or organ is yet to be transplanted to a different site within the host. In order to enable standardized transfer techniques of neo-tissues and organs to a different site, reconstructive surgeons have therefore aimed to generate axially vascularized tissues and organoids that are supplied by a defined arteriovenous axis and could hence be transferred to the desired site using microsurgical techniques of vascular anastomosis. As opposed to other techniques, these tissues are immediately connected to the systemic blood circulation upon implantation as free flaps are.[20,21]

Our laboratory adopted and further developed an arteriovenous loop model based on the femoral vessels, including a venous graft from the contralateral side in a rat separation chamber, which also constitutes an *in vivo* bioreactor. This work is based on the initial description by Erol and Spira[41] who successfully generated a prefabricated skin flap by creating an arteriovenous vessel loop using either arterial or venous grafts in a rat model. They observed the outgrowth of a dense 3D neovessel tree originating from the entire AV loop. This model was later further developed by isolation of the AV loop into isolation chambers and induction of vascularization in polymer matrices.[42–44] Based on these works, we successfully vascularized a custom-made processed bovine cancellous bone matrix by means of the AV loop.[20,21] We established a detailed analysis of the vascularization using invasive techniques such as corrosion casting as well as noninvasive methods such as micro-CT scanning. Using histology-based morphometric analysis, we meticulously quantified vascularization and demonstrated that more than 90% of the scaffold vascularized 8 weeks following implantation. Prevascularization of these matrices significantly improved survival of osteoblasts engrafted into the matrix, emphasizing the importance of an intrinsic blood supply for cell vitality within the construct.[45]

The AV loop model to vascularize tissue-engineered constructs is not limited to hard matrices and the attempt to create bone, but may be extended by using other matrices and cell populations. We have demonstrated that a fibrin gel approved for clinical use can be employed to generate a fibrin matrix, which was successfully vascularized and may be used as a platform to create soft tissues or organoids. The vascularization within this fibrin matrix was shown to respond to proangiogenic

stimuli by accelerating the vascular outgrowth when the recombinant growth factors VEGF and bFGF were suspended in the matrix.[46] We also demonstrated that transplantation of myoblasts into a previously vascularized fibrin matrix containing the AV loop enhanced cell survival and maintenance of the myogenic phenotype compared to fibrin matrices without AV loops, even though no formation of skeletal muscle-like tissue could be observed, possibly due to the lack of potent myogenic stimuli.[47]

The vascularized matrix embedded in the AV loop may also be employed to create organoids or replace organ functions. As a new approach to hepatic tissue engineering, fetal liver cells (FLC) were suspended in the fibrin matrix, resulting in neo-tissue formation containing viable fetal donor cells in the highly vascularized fibrin matrix after 14 days.[1] Previous work demonstrated that continuous hepatotrophic stimulation is necessary in tissue-engineered liver support systems, and it has been demonstrated that cocultivation with pancreatic islets may have stimulatory effects on hepatocytes and that they are mediated by soluble factors, and are dependent on insulin and glucagon.[48,49] Further investigations toward 3D transplantable hepatocyte-islet devices for continuous *in vivo* stimulation were conducted to provide hepatotrophic stimulation. Hepatocyte and pancreatic islets were coseeded into polyvinyl alcohol matrices and supported hepatotrophic stimulation of bioartificial liver equivalents equally well, compared to a protocaval shunt operation. The AV loop model may therefore well serve as a platform for the development of highly vascularized *in vivo* tissue engineering-based liver support systems using these cotransplantation strategies.

Successful engineering of cardiac muscles has been achieved by matrigel-suspended neonatal rat cardiomyocytes implanted inside the AV loop. The presence of gap junctions was shown between the cardiomyocytes at 4 and 10 weeks, and echocardiograms showed spontaneous contraction of the tissue *in vivo*. *In vitro*, positive chronotropy to norepinephrine and positive inotropy in response to calcium demonstrated biological function of the cardiac neo-organ.[50]

The AV loop separation chamber potential is not limited by the availability of local factors in its *in situ* tissue and organ engineering capacity. The regenerative potential of the established chamber construct may be even better exploited by chemotactic recruitment of supportive cells or signaling molecules. It was recently demonstrated that EPC that had been systemically injected before can be recruited from the circulation by CXCL12/stromal cell-derived factor 1,[12] potentially enabling further modulation of the vascularization process.

The isolation chamber setting with its potential to be monitored and manipulated may also be used as an investigation platform to investigate the phenomena and regulation of angiogenesis and antiangiogenesis in cancer research.[5]

Limitations to dimensions in small animal models have always been an argument against successful transfer of tissue engineering applications to clinical relevance. Therefore, our group recently established a large animal model (sheep) where *de novo* formation of axially vascularized tissue was demonstrated for the first time ever by sequential computed tomography angiography (CTA) and magnetic resonance angiography (MRA) *in vivo*, as well as by postexplantational micro-computed tomography (Figure 2) and histology. This constitutes further progress in approaching the first application of tissue engineering vascularized grafts with clinically relevant dimensions.[51,52]

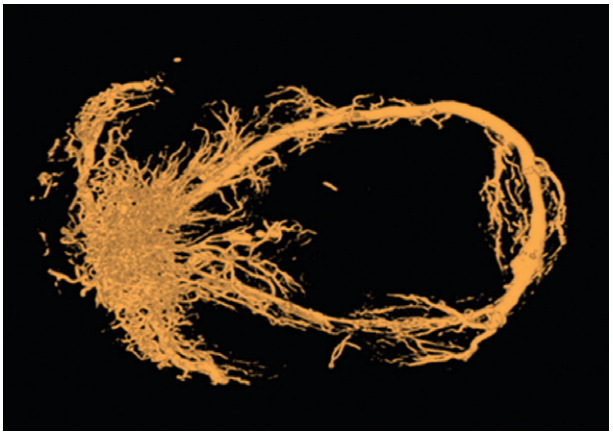

Figure 2 Micro-CT scan from a rat AV-loop following Microfil® – perfusion and explantation, demonstrating vascular sprouting originating from the AV-loop.

In conclusion, the arteriovenous loop model has been investigated mainly as a powerful tool to create bioartificial tissues and organoids, but may also be very useful as a platform to investigate angiogenetic and antiangiogenetic phenomena in general, with particular emphasis on cancer therapy.[5]

uPA	Urokinase-type plasminogen activator
VEGF	Vascular endothelial growth factor

5.513.1. Introduction

Biomaterials research for tissue engineering revolves around various permutations of four fundamental components: biomaterial scaffolds, cells, *in vitro* tissue constructs, and *in vivo* integration into living hosts. Some implantable biomaterials aim at recruiting the native mature or stem cells to the lesion for repair or regeneration; or simply serving as inert prosthesis to replace the functions of the injured or diseased tissues or organs. The choices of biomaterials, cell sources, or design parameters of the tissue constructs have been *ad hoc*, either due to component availability (for certain biomaterials or cell types) or due to the unique constraints of a specific application. This approach has worked well for simpler tissue constructs where the functions are not tightly coupled to the structure, such as extracorporeal devices, prostheses that are self-sufficient to replace the damaged tissues functionally, or cell transplantation that depend entirely on regeneration from the host *in vivo*. In such cases, simply taking available biomaterials and cells, and making a construct that roughly looks like the real tissue, can be reasonably successful. The first section of this chapter describes the discrete approach of working on one material at a time or one cell type at a time, and the discrete approach seems sufficient for these simpler applications. As the field progresses toward repairing and regenerating more complex tissues, the functional demands increase and the structure–function relationships become more tightly coupled. These challenges create a greater need to progress from the discrete approach to a higher throughput, systems-level approach, which typically involves large screens, combinatorial synthesis, or experiments on multiple components. The second section of the chapter summarizes several high-throughput or -omic level projects in tissue engineering, with particular focus on -omics technologies for characterizing cellular responses, and quantitative analytical tools for monitoring tissue integration *in vivo*. Researchers already adopting such systems-level approaches have successfully designed new biomaterials for optimization of complex tissue functions. The second section includes a summary of this progress, followed by a discussion of the limitations of the high-throughput approaches that are still primarily based on individual components (cells, biomaterials, constructs) rather than based on the functional process of interactions and relationships between the components. Quantitative relationships between *in vitro* constructs and *in vivo* responses must be established in order to guide rational biomaterials and tissue engineering efforts to achieve the desired results. High-throughput experiments on individual components may be capable of optimizing a set of parameters, but sometimes this success only highlights the gap of understanding between the optimized parameters and final biomedical goal with integration into a living host. Thus for improving function in tissue engineering, a process-centered approach, described in our third section, will become increasingly important (Figure 1). We have recently explored a process-centered approach to study and facilitate regeneration in a healing defect, liver fibrosis. Our approach, including innovative computational modeling, might be further adopted in the systematic development of biomaterials and tissue engineering applications of the future.

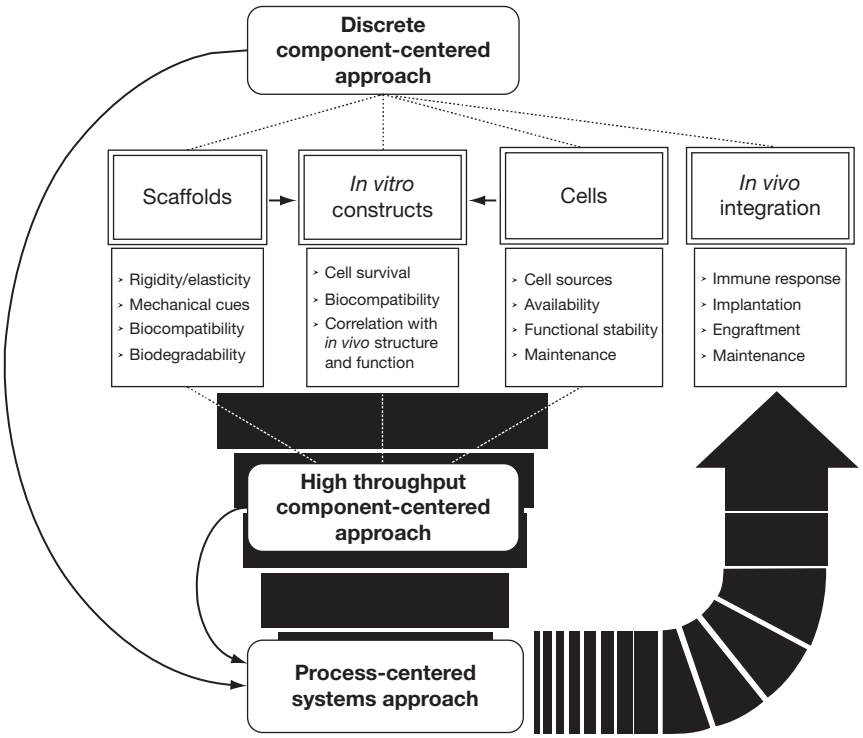

Figure 1 Diagram of the relationship of the four core components and the three tissue engineering approaches.

5.513.2. Discrete Component-Centered Approach

Tissue engineering is an integration of myriad fields, with the ultimate aim of reconstructing a functional tissue or organ for regenerative medicine. In the past decade, engineering tissues with *in vivo* fidelity has found applicability and broad impact in a wide array of additional fields. The chief hindrance to the progress of this field is the complexity of the human body, exemplified by the diversity of cell types; the interplay between the chemical, physical, and topographical factors that regulate cell function; the morphology of tissues; and the astoundingly precise development of organs.[1]

Various approaches have reconstructed living and functional tissue constructs *in vitro*, but over the past two decades, methods based on biomaterial scaffolds have occupied center stage.[2] These methods generally entail seeding cells on scaffolds that serve as centers of tissue regeneration. The scaffolds are tuned specifically for their chemical and biological parameters (e.g., solute diffusivity, porosity, elasticity, and biocompatibility) but are very rarely tuned for their ultimate biological effects or function. Working on one biomaterial or cell type at a time has yielded useful and satisfactory results for reconstructing certain tissues with straightforward structure–function linkage such as bone and ligament,[3] but has failed in areas where there is an intricate interplay between the structure and function such as liver and kidney.[1]

Another context where the focus on specific biomaterials has been successful is in regenerative medicine, where the primary role of the scaffold is simply to help nature take its course in mending lost or damaged tissues, and where control of the scaffold properties occurs on the scale of tens to hundredths of microns.[4,5] The remaining bottleneck in tissue engineering is to develop large *in vitro* models of complex tissues with *in vivo* fidelity, with the facilitation of angiogenesis.[6,7] This phase of research has been arduous, primarily due to poor understanding of the architectural and compositional requirements for creating a large functional tissue, and due to the disparate natures of the fields of biomaterials and biology. Early biomaterial scaffolds did not foster any form of tissue hierarchy and were not tailored for specific *in vitro* purposes, yet the success of these scaffolds *in vivo* fuelled the development of methods that hoped to induce complex tissue architectures.

Although the discrete component approach has been effective in so many different situations,[1–5] it still largely suffers from the narrow focus on either the development of improvised materials to render only a single function or using a construct with a single cell type to mimic multicellular complex tissue functions. A classic example would be the field of skin substitute development. All the commercially available replacements definitely serve the main purpose of rapid wound closure[8] amongst others.[9] But they invariably fall short in creating a complete functional skin (e.g., functions associated with wrinkle and hair follicle) despite the promising developments of new materials[8] and therapeutics for full-thickness skin injuries.[10]

In the perspective of cellular components used in constructs, there is again a growing concern that a single cell type would not be sufficient to emulate the multifaceted functions of any complex tissue. Though there are a few applications where only one type of cells would be deemed sufficient, like in cartilage reconstruction where a construct with chondrocytes and the right substrate[11] would facilitate cartilage repair, tissue engineering with multiple cells types is becoming more relevant with better functions. Interestingly, in urinary bladder replacements there has been a gradual shift from the orthotropic neobladder reconstruction techniques[12] (due to the imminent side effects) to the *ex vivo* engineered bladder constructs,[13,14] in which urothelial cells and smooth muscle cells were both successfully applied on the scaffold. There are other demanding scenarios that require the construct to orchestrate the formation of complex multifunctional structures like in blood vessel generation which can be done only with the appropriate recruitment and organization of different cells in the presence of the right proportions of growth factors.[15] Thus with a more thorough understanding of the inherent mechanisms involved with vascular growth,[16,17] the recent configurations with hydrogel matrices and PLGA scaffolds coupled with VEGF delivery[18,19] have been successful to a great extent in recapitulating various stages of this complex process.

A few methods are drawing attention for tissue engineering. (a) Microfabrication technology – with importance exemplified by its use for maintaining the differentiated phenotypes of primary cells (which had previously proven very difficult to maintain *in vitro*), and its use for probing homotypic and heterotypic cell interactions.[20,21] (b) Microscale flow – fluidic flows in microfluidic channels mimic the interstitial flow in vascularized tissues, and play important roles in mechanical and chemical signaling. The validity of microscale flow models has been demonstrated by microscale fluidic flow bioreactors.[1] (c) Synthetic microenvironments – this field has focused on mimicking the biochemical composition, fibrillar structure, and viscoelastic gel-like character of natural tissue matrices. A good early work has used PEG (polyethylene glycol) scaffolds, which are capable not only of remodeling, but can also be chemically customized to incorporate biological molecules that facilitate signaling, to and from the microenvironment.[22,23]

The explosion in the number of devices that can be implanted into the body includes tissue-engineered constructs, or biomedical implants such as glucose sensors and stents. The implantation of devices *in vivo* can lead to major complications in the body, or other detrimental effects reducing its functionality and longevity in the body. The fact that no single material is biocompatible under all conditions only creates further challenges in designing better biomaterials or tissue-engineered constructs.[24]

Although the diversity of factors governing inflammation and foreign body responses is well-documented,[25] the complexity of the response of the body to different biomaterials is poorly understood. The degree of the biological response is also governed by the (a) morphology and porosity, (b) shape, (c) size, (d) surface chemistry and roughness, (e) design, (f) composition, and (g) degradation.

One disease application where this plays a very important role is the cardiovascular system where stents have long been used with reasonable success, and where longevity has been improved via the use of drug eluting stents.[26,27] Even with technological advances, there has been limited understanding of device/host interactions, which hinders the development of better constructs for *in vivo* applications.[27] One source of the problem is the study and testing of particular constructs in isolation without considering the systemic effects of

biomaterial response and without considering regions beyond the immediate area of the implant.[26] Multiple dimensions of biological response governed by a large number of factors create a process of enormous complexity.[28,29]

5.513.3. High-Throughput Component-Centered Approach

To efficiently search a broad variety of possible cell culture conditions, scaffolds, or other tissue engineering parameters, new experimental platforms offer the possibility of massively parallel experiments, robotic execution of repetitive steps, high-content imaging with automated computational analysis, miniaturization and microfluidics, or lab-on-a-chip platforms that achieve dramatic improvements in experimental throughput. High-throughput measurements can give noisy results, often causing many type I (false positive) errors. Utilization of results from high-throughput experiments is inseparable from computational methods of statistical data analysis and data mining.[30] The availability of free[31,32] and economical general-purpose data analysis software allow data mining needs to be met without customized programming for the tissue engineering context. Meanwhile, a host of experimental tools specific to tissue engineering are necessary to create and assess large-scale multivariate quantitative systems.[33] Microarray and microfluidic technologies, including high-throughput live cell assays, have been developed for performing highly parallelized experimental perturbations, and measurements of the resulting cellular responses.

5.513.3.1. Manufacturing Substrates

In order to increase assay throughput and reduce reagent consumption, and reduce the number of cells required, the substrates being manufactured must be miniaturized. Emerging technologies may ultimately lead to array formats. Current tools include rapid prototyping, the setup of polymer gradients, and spotted microarrays, microwells, as well as microfluidics. Parameters of interest for control include porosity, volume fraction, mechanical properties, oxygen diffusion, degradation rate, tortuosity, permeability, homogeneity of composition, fiber orientation, surface chemistry, biomaterial composition, and protein adsorption.

Nanoliter volumes of different chemicals, biochemicals, and cells, as well as combinatorial combinations of these, can be dispensed in a spatially addressable pattern using automated robotic spotting technologies.[34,35] For example, a library of over 1700 photopolymerizable acrylate-based biomaterials was synthesized and the mechanical properties were measured with nanoindentation.[36] Other applications include toxicology assays,[37] compound screening,[38] gene function screening,[39] cell adhesion assays,[40] and probing embryonic stem cell[41] fate.[42,43] In the work of Flaim *et al.*[42,43], various extracellular matrix (ECM) compounds such as collagen-I, -III, -IV, laminin, and fibronectin were immobilized on hydrogel surfaces. A combination of ECM compounds was identified that most synergistically induced differentiation of ESCs to a hepatic fate. Also some interesting findings were made with regards to the crosstalk between various ECM proteins which culminated in the development of the right substrate for hepatocytes that lead to high levels of albumin synthesis *in vitro*. Combinatorial methods can also be used on the macroscale in well plates, but the miniaturization of such systems would aid in increasing throughput.[44]

For large-scale screening of cell–biomaterial interactions, a continuous polymer gradient can be generated, instead of discrete spots with varying compositions.[11,45] Both 2D and 3D gradients can be generated for exhibiting a gradient of some property along a biomaterial film, hydrogel, or other surfaces. The gradient as presented to cells and cellular response is observed in monolayer (2D)[46] or on cells seeded within porous scaffolds (3D).[47] This way, the optimal point of interaction along a gradually changing surface can be identified.[48,49] Besides being used as a screening tool, scaffolds with a gradation in properties could also serve as a template for the generation of a graded tissue.

Arrays of microwells with defined dimensions can be fabricated using soft lithography, which affords control over the substrate size and cellular aggregates.[34,50] Microwells are attractive because they allow control of parameters such as size, shape, and homogeneity of cellular aggregates, for instance in the expansion of human ES cells. As an example, 3D embryoid bodies (EBs) have been formed within poly(ethylene glycol)[17] microwells.[35,51] Microengineered hydrogel microwells have also been used to regulate ES cell fate in an aggregate size-dependent manner.[52] Similar template-based assembly of cells could also be used to form aggregated tissue sections that contain multiple cell types organized into specific geometries relative to each other.[50] Reproducibility of homogenous cultures has been identified as a potential problem in recreating exactly similar conditions across the board for valid experimental repeats, as in the current difficulty of controlling the homogeneity of EB formation within microwells.[53] Improved reproducibility may occur in the future with improvements in microwell material composition, cell seeding procedures, and handling of aggregates during retrieval.

Microfluidics also presents the opportunity for conducting high-throughput analysis of signals within an array system.[33,34] Microscale channels are formed by casting a polymer, polydimethylsiloxide (PDMS), on a prefabricated mold. Advantages include application and control of laminar flow, shear stress, spatial positioning of soluble factors including concentration gradient generation, and ease of imaging.[35] Systems that can be set up include platforms for drug toxicity studies and multiphenotype cell arrays.[50] By combining microwells and reversibly sealed microfluidic channels, Khademhosseini *et al.* were able to localize multiple cell phenotypes. This work gives an example of the ability to pattern tissues within microfluidics channels in a high-throughput way.[50]

For manufacturing of substrates on the larger scale, rapid prototyping technologies allow fast fabrication of porous biomaterial scaffolds with tunable micro- and macroscale structures.[54] This term generally refers to a computer-controlled manufacturing technique that allows layer-by-layer deposition and processing of materials, resulting in a totally controllable structure.[2,55] Some examples include fused deposition modeling, stereolithography, electron beam melting, and 2D printing.[56] Others include high-throughput laser printing,[57] electropatterning,[58] and solid free-form fabrication.[2]

5.513.3.2. Measuring Substrate Properties

Combinatorial chemistry has made it possible to develop vast assortments of polymers and biomaterials (see **Chapter 4.412, Rational and Combinatorial Methods to Create Designer Protein Interfaces**);[59] however this advance creates a pressing need for equally efficient methods to characterize the different polymers.[60] Because the surface chemistry, topology, and mechanical properties of biomaterials have profound effects on cell behaviors, these properties are crucially important to measure when evaluating their implications for tissue engineering.[61] The current trend in tissue engineering toward developing more customized and tailored biomaterials for specific applications, has amplified the need for fast and easy methods to characterize biomaterials.[62] The following sections describe methods for characterizing certain categories of material properties, with efficient methods highlighted.

5.513.3.2.1. Surface chemistry and techniques

An efficient and scalable method for characterizing the surface chemistry of biomaterials was developed by Kohn *et al.*, who established a correlation between glass transition temperature, hydrophobicity, mechanical properties, and polymer structure. To measure the underlying parameters for these correlation trends, they used differential scanning calorimetry (glass transition temperature, Tg), gel permeation chromatography (molecular weight), thermogravimetric analysis, goniometry, and the sessile drop method (water contact angle).[63] The results of these tests give insight into the structure–property relationship for large quantities of materials developed.

Another important development has been the use of MALDI-TOF (matrix-assisted laser desorption ionization time of flight) mass spectrometry for analysis of macromolecules. Inkjet printing of polymers has been shown to greatly improve the throughput of MALDI-based analysis.[64] Among the characterizations that have been most successfully implemented using high-throughput MALDI platforms are the measurement of molecular weights combined with high-speed columns, and parallelization combined with flow injection analysis.[33] These automation tools provide good predictive power and they vastly improve the speed of material detection, without much loss in resolution.

For high-throughput characterization with less technical complexity than MALDI-TOF methods, new optical methods have been developed, including measurements of absorbance and fluorescence, including the far and near infrared regions.[65] Light scattering and viscometry have also been shown to greatly improve the automated batch characterization of polymer solutions while continuous monitoring of the polymerization of the monomers is done using high-throughput optical techniques like FT-IR (Fourier transform infrared) spectroscopy.[66]

5.513.3.2.2. Mechanical characterization

The mechanical properties of biomaterials (such as tensile properties, modes of deformation and stress–strain behavior) are also of utmost importance for engineering functional constructs. Various studies have shown differential responses of cells when grown on substrates with differing mechanical properties.[67] For example, the mechanical stiffness of a substrate can direct stem cell differentiation into various cell lineages.[67] The mechanical properties are often measured by techniques like nanoindentation, which measures displacement at the nanometer scale. Strain-induced elastomer buckling can also be used for measuring mechanical properties of thin films. Measurement of the surface toughness and pattern formation is performed in a rapid manner using AFM (atomic force microscopy), with the field moving toward nanorobotics to characterize biomaterials with reduced human error (see **Chapter 3.302, Atomic Force Microscopy**).[41] The chemical and mechanical properties of biomaterials have a tremendous impact on cell–material interactions and on tissue engineering outcomes, thus emphasizing the need to characterize materials extensively before they are used for tissue engineering applications. The understanding of the interdependency between chemical and mechanical properties for cells and biomaterials will also play an important role in developing designer biomaterials for future tissue engineering applications.

5.513.3.3. Measuring Cellular Response

Systems-level approaches have afforded great advances at characterizing the responses of cells to different types of biomaterials. The -omics revolution has contributed tremendously to the understanding of biological responses to biomaterials, which aids in understanding which biomaterials and soluble factors achieve phenotypes closest to those observed *in vivo*. Contributions from genomics, proteomics, and metabolomics are helping to elucidate functional and structural aspects of subcellular systems, ultimately helping to engineer better tissues. This section describes how genomics, proteomics, and metabolomics have contributed to tissue engineering.

5.513.3.3.1. Genomics

Genomics, including functional genomics (gene expression analysis), has provided extensive evidence about the diversity of factors responsible for maintaining the function of highly specialized cells, and for determining the levels of mimicry of *in vitro* constructs to *in vivo* tissues.[68] The development of the microarray platform has provided broad insight into understanding the gene expression of *in vitro* constructs (see **Chapter 3.321, Microarrays in Biomaterials Research**). It has led to the large-scale (whole genome) screening of engineered tissue constructs and even to greater understanding of the responses of implants to hosts. Microarray technology has had tremendous impact on the fields of comparative and functional genomics and has improved the understanding of pathways that were perturbed or differentially regulated in culture versus *in vivo*. Gene expression analysis has been used for deriving how various culture configurations modulate pathways required for cell behavior to meet the requirements of bioartificial reactors and drug testing platforms.[69,70] Genomics has also provided insights and a mechanistic understanding on goals such as understanding the divergence of phenotypes in 3D and 2D cultured cardiac cells, and uncovering pathways that contribute to *in vitro* tissue genesis.[71] Culturing cells in a 3D environment has long been known to provide advantages for mimicking the *in vivo* phenotype, compared with 2D environments. 3D culture conditions are more conducive to the formation of multicellular organization, similar to that found *in vivo*.

Primary cells, such as cardiomyocytes for cardiovascular tissue engineering, and hepatocytes for liver tissue engineering,

are the cells of choice for studying tissue genesis, regeneration, and drug-induced toxicity.[72,73] For hepatocytes to maintain proper function, the flow of blood through the liver sinusoids has been hypothesized to induce necessary signals mediated by shear stress. The liver chip developed at MIT[69] demonstrated this by measuring gene expression levels for various important drug metabolism enzymes, comparing them with enzyme activity levels *in vitro*, and with gene expression levels *in vivo*, to confirm the relationship between the culture conditions and the *in vivo* mimicry.[69] This valuable information is obtained in a high-throughput manner, and the consistency of the data obtained makes it a powerful tool to study cell–biomaterial interactions and to determine the phenotypes of various tissue-engineered constructs.

5.513.3.3.2. Proteomics

Proteins are regulated by various mechanisms such as phosphorylation, glycosylation, and other posttranslational modifications (targeted cleavage and degradation) that occur downstream of mRNA that cannot be observed with functional genomics. The field of proteomics involves system-wide analyses at protein levels, sometimes including observations of posttranslational modifications, and often emphasizing differentially expressed proteins. Cellular responses traditionally have been characterized at the proteomic level using methods such as 2D gel electrophoresis and MALDI-TOF mass spectrometry.[74] Additional methods of high-throughput protein analysis such as protein microarrays and antibody microarray[75] are currently being developed. Traditional low-throughput methods of studying proteins have used, for example, antibody methods to detect the release of growth signals, cytokines, or proteins. For tissue engineering, techniques like 2D gel electrophoresis and MALDI-TOF are used to characterize the surface adsorption of proteins to biomaterials and to determine the relationship between the surface and the intracellular signaling pathways affecting cells.[76,77] Used synergistically, they have also helped identify proteins which are secreted into the medium and intracellular proteins which are present in cells cultured on polystyrene and titanium surfaces.[78,79] If similar methods can be pursued with a higher level of spatio-temporal resolution, they will be useful for characterizing cells in their environments *in vitro* or *in vivo*, since the complexity and the lack of reproducibility of this technique has made it difficult to apply it to study all cellular responses.[80,81]

There has been some progress made in utilizing this technology in studying *in vitro* constructs and in measuring protein expression during differentiation and in various cardiovascular diseases, but very little progress has been made in tissue engineering *per se*. Hepatocytes, when cultured *in vitro*, undergo a change in their proteome and many proteins are differentially regulated when compared to cells *in vivo*.[82] A coculture of hepatocytes with nonparenchymal cells like fibroblasts have been shown to increase hepatocyte differentiated functions.[83] In a quest to find out which of the factors is responsible for the improvement in hepatocyte function, we have carried out a proteomic analysis of the culture media of the cells cultured in the coculture configuration. We found that transforming growth factor-beta 1 (TGF-β1) was an important cytokine upregulated in the culture and the substitution of the TGF-β1 in the culture media replaced the need to coculture cells,[84] by maintaining higher order differentiated function of the cells.

Thus the understanding of how cells react when cultured with various cell types and identifying in detail the components responsible for the differential cellular responses could help us identify better biomaterials, supplements to improve and develop better cellular constructs.

5.513.3.3.3. Metabolomics

Another field of great interest today is metabolomics, which involves the measurement of metabolites, in order to create a metabolic map of different tissues or microorganisms. Understanding metabolite flux at a systems level helps provide a direct point of access for normal physiological systems. Metabolomic methods have recently helped identifying markers for cardiovascular diseases,[85] assessing drug toxicity,[86] and characterizing anti-inflammatory compounds.[87] Metabolomics has not been utilized extensively in the field of tissue engineering, but the combination of metabolomics and proteomics could provide a profoundly powerful characterization of *in vitro* constructs.[88]

For example, metabolomics are intricately informative about liver cell function, which meets the demand for robust methods to assess the functionality of liver cells for bioartificial liver devices.[89] Recent work has characterized metabolite profiles using nuclear magnetic resonance (NMR) spectroscopy, leading to the discovery that cells cultured in 2D and 3D bioreactors showed differential consumption of glutamine, lactate, and alanine.[90] The above examples illustrate how the integration of genomics, proteomics, and/or metabolomics can aid in defining culture conditions, media, supplements, or 3D configurations, thus furthering the goals of tissue engineering by allowing us to create constructs that better resemble natural tissues *in vivo*.

5.513.3.4. *In Vivo* Integration into Living Hosts

Over the years, technological advances have provided a wealth of information about how an introduction of foreign stimuli influences various individual molecular species.[91,92] These discoveries, although vitally important for biological progress, have not yet been successfully translated into clinical applications or other success stories *in vivo*.[93,94] For example, synthetic hip prostheses are one of the most widely used implants in the clinic. However, complications often emerge after implantation, which are mainly caused by mechanical failure of the implant material or by the coeffects of chronic inflammation. Revision surgery is often necessarily due to subsequent bone loosening and fracture.[95] Another example is the coronary artery stent, which is widely used in the established therapy of percutaneous coronary intervention for coronary heart diseases. The stent is placed inside the narrowed branch of a coronary artery to keep it open. However, the site with stent bracing up will inevitably become narrowed again gradually after the operation.[96] One of the major reasons is that the exogenous materials of the stent can trigger immune stimulation *in vivo* that creates chronic inflammation *in situ*. At the same time the stent damages the vascular wall by the force it creates inside the artery that will slowly recover by forming tightly

contracted scar. There are various kinds of adjuvant therapeutics to prevent clotting forming again, but still the patient needs another stent intervention when the renarrowing happens.

Observation of *in vivo* response is necessary for the R&D of implantable biomaterials. A typical biomaterials project with *in vivo* implantation might have the following pipeline: after design and fabrication of a construct, researchers will implant it into animal model; then systemic samples like blood are collected at different time points for toxicity analysis; function may be tested to check the phenotypic improvement; and finally the implanted construct is removed again for histological analysis. Interpretation of the above observations, directly or indirectly yields the conclusion about the *in vivo* responses. No single project can measure everything, but too often neglected are the detailed reactions *in situ*, the system-level effects in the body, and a breadth of observations that could identify the underlying mechanisms for positive or negative outcomes.

The *in vivo* integration challenges that remain will require a paradigm shift in the way we identify and associate molecules with specific phenotypes. The multifactorial nature of host/biomaterial interaction makes it crucially important to develop tools and detection methods for studying the entire system simultaneously.[94] This is a divergence from the traditional reductionist approach that is based on studying individual factors associated with complex interactions.[97] Along these lines, the identification of molecules or markers associated with the presence and response of host to biomaterials should rely on a better understanding of the biology at a systems level. To construct a holistic view of systems biology, multiple and different types of endpoints must therefore be combined, including the molecular scale (gene expression, proteomics, lipidomics, metabolomics,), cellular scale, and tissue/organ scale.[98–100] Clinical measurements (e.g., pathology) must also be incorporated when possible. *In vivo* imaging, particularly because of its scalability, is an ideal tool for deeper investigation and integrated pursuit of relationships across components and across scales, at a systems level in the living host.

5.513.3.4.1. Image informatics: Transcending scales with improved speed and resolution

Pursuing a project from molecular manipulations through to clinical endpoints creates difficult problems for integrating information across scales: from nanometers to centimeters, from microseconds to months, and from molecules to tissues. Changes at any scale can affect others, particularly the next higher level of scale.[101] There are no universal recipes for navigating such complexity, but computational modeling can be useful for integrating information derived from traditional bottom up data driven approaches, with top down knowledge, to achieve better predictions in areas of systems medicine and in prognosis of certain conditions (see **Chapter 3.313, Histological Analysis**; **Chapter 3.316, Immunohistochemistry**; **Chapter 3.317, Fluorescence Imaging of CellBiomaterial Interactions** and **Chapter 3.318, Molecular Imaging**).[102]

Imaging techniques, developed over the last century, have greatly advanced our understanding of biological systems and have played an important role in functional understanding of complex organs such as the brain. A great advantage of imaging is that many of the imaging tools are noninvasive and the information obtained is rich in the spatial and temporal dimensions.[103] The need for staining and the possibility of artifacts remain to be disadvantages of imaging techniques.[104] Current imaging systems also suffer from the inherent problems of low throughput of the techniques, which generate images at a high resolution. This has led to development of imaging tools, which can image at higher resolutions with higher throughput.

The working principle of high-throughput imaging-based screening systems is the automation in the imaging of microtiter plates, often in multiples of 96-wells, with images produced via detection of fluorescence.[66] Combined with robotic handling, high-throughput imaging methods result in a large amount of image data and statistically significant information,[105] that can be useful for systems biology analysis. One prominent application of automated microscopic techniques is the use of cell-based assays for screening small-molecule drugs from combinatorial synthesis.[4] Whole body imaging techniques have been developed using epiplanar illumination mechanism and have been useful in neurological detection of cathepsin activity in glioma tumors using MRI coregistered fluorescence tomography.[106] Imaging with infrared light has also improved penetrative power and has enabled the capture of images with higher resolution.[107] The development of new technologies like multifocal multiphoton microscopy hold great promise in imaging 3D tissues with high resolution and improved speed achieved by parallelized illumination.[108,109] Very often, the information obtained in a single measurement is the result of several different mechanisms acting simultaneously, which makes the interpretation challenging. Therefore, a major issue in cell-based imaging is to seek biological relevance from a large pool of collected data and subject them to rigorous statistical analysis.

Integrating, modeling, and understanding the data obtained from different techniques of image acquisition pose a challenge. Sartori *et al.*[110] have combined the use of multi-scale imaging by correlative light microscopy with cryo-electron tomography, to compare images obtained by both of these methods in 2D. Such comparison methods can also be used to correlate the structural information obtained using cryotomogram and the functional information obtained using fluorescent methods.[111] There have also been a few reports of imaging techniques that have been used to study response to a biomaterial. For example, Murata *et al.*[112] studied neointimal coverage after stent implantation, and they found a good correlation between optical coherence tomography and histology-based approaches, for the purposes of observing neointimal area, thickness and luminal area. Thus, by combining the various approaches available by transcending scales and linking data driven approaches with new technologies which provide information at a larger scale we will be able to get a better understanding of life processes and thus predict better integration of engineered constructs with *in vivo* systems.

High-throughput experimental platforms have provided valuable results for diverse applications, and tissue engineering has made significant strides at adapting high-throughput technologies for specific needs. As familiarity and facility with these methods improves, another phase of progress is beginning, where high-throughput or -omic experiments are starting to be used for discovering knowledge, constructing models, and inferring relationships that form the foundation of a system-level understanding and a process-centered approach.

5.513.4. Process-Centered Systems Approach

The transition toward high-throughput platforms may increase efficiency for screening and experimentation, but it does not change the fundamental orientation of most tissue engineering research toward optimizing particular components. In other words, the four core foci; biomaterials, cells, culture configurations *in vitro*, and integration *in vivo*; are most often considered individually and optimized, whether using low-throughput or high-throughput methods. Although we acknowledge that the components are interdependent, we often address them separately for lack of established quantitative relationships between the experimental variables *in vitro* and their ultimate effects *in vivo*. Even for *in vivo* tissue engineering, the choice of biomaterials, cells, and microenvironments must rely heavily on the unpredictable behaviors of cells to proliferate, migrate, and remodel their environments. Therefore, much of what we have accomplished has relied on an empirical, trial-and-error approach.

Future research in tissue engineering and biomaterials has the potential to achieve greater success particularly for functionally ambitious projects, by taking a process-centered approach. The study of components and processes can occur through the use of system-level computational models. With a better understanding of the way cells interact to form tissues in different contexts (e.g., embryonic development or tissue repair); we can identify subsets of parameters that should be covaried simultaneously in subsequent experiments. We can also choose to vary parameters that are mathematically predicted to have highest probability of having the desired impact on the outcome. Achieving fully functional tissues for regenerative medicine involves a huge number of variable dimensions, and performing an exhaustive screen of all simultaneous combinations of all variable parameters is not possible, even with high-throughput platforms. Instead we must understand the larger processes and system-level trends that determine the clinical outcome, and design focused screens that actively manage and quantitatively navigate the landscape of interdependent parameters. In this section on process-centered systems approaches, we discuss example projects that bridge the gap between component-centered approaches and a more holistic quantitative prediction of *in vivo* processes, often through the use of computational modeling and biophysics.

Classical biophysical models use measured parameters in construction of a model that better facilitates the understanding of how certain biomaterials affect or are affected by biological processes. Examples can be seen in the work of Shreiber *et al.*[113] who have modeled the effect of fibroblast cell migration on the compaction of ECM. Other examples of classical biophysical modeling include proliferation of liver cells as a function of the metabolic load on the cells[114] and bone regeneration on scaffolds as a function of substrate porosity.[115] These models are better known for their accuracy and complexity of construction, than for their ability to mimic broad physiological outcomes. These physical models are applicable to biological phenomena but their outlooks are oriented more toward understanding mechanistic issues in tissue engineering, rather than toward simulating clinical outcomes.

For predicting the interplay between complex and simultaneous effects, mathematical modeling has obvious usefulness, but knowledge of the effects is required before a network of multiple effects can be simulated. Initial models have most often been built for extremely well-studied systems, but in general filling this information gap will entail the creation of new knowledge. Better instrumentation is increasing the availability of information, and more biophysical parameters are becoming available for purposes like modeling.[116] A contrasting avenue for assembling information in the future may involve the reuse of high-throughput measurements, due to the following innovation: component-centered measurements become useful for process-centered work when assembled *en masse*, because automated data mining algorithms are increasingly capable of using observed correlations to infer relationships and to reconstruct networks of effects.[117–120] High-throughput studies are widely recognized for having a close interface with statistical data analysis methods, but in addition to data analysis is an opportunity for automated knowledge discovery, to elucidate system-level and process-oriented knowledge from experiments that may have been designed for narrower purposes.

A landmark study[121] reconstructed a genome-wide transcriptional network for mesenchymal transformation of gliomas. Network reconstruction was also used in a study of adipocyte differentiation[82] where correlations between gene expression patterns and transcription factor phosphorylation patterns from large-scale proteomics and phosphoproteomics experiments were sufficient to infer relationships between transcription factors and target genes. Complete biological pathways are too numerous to be fully elucidated by humans and they will increasingly often be pieced together by computational methods. As systems-level approaches become more common in fields such as molecular cell biology, the resulting accumulation of pathway knowledge, regulatory mechanisms, computational models, and other fruits of the research will become available to help advance process-centered system-level research in tissue engineering and regenerative medicine. Few examples of process-centered systems research have been published for biomaterials or regenerative medicine thus far, but among them are projects summarized below on *ex vivo* implants, pathways of cell regulation, and regulation of liver fibrosis.

5.513.4.1. Modeling of Systems in Tissue Constructs

Bridging the gap between more biophysical models and regenerative medicine is the still developing field of *ex vivo* implants.[122] In such implants, cells are seeded on biodegradable scaffolds and after culture for a period of time, are transferred to a region of defect inside the body. An exciting field of tissue engineering research emerges from the possibility of transplanting adult stem cells, such as induced pluripotent stem cells,[97] through engineered constructs. In such systems there is a fusion between basic bioengineering principles and the underlying biology of cells, to create a model that is useful if not exactly accurate for understanding the role of bioengineered substances in tissue engineering. Mathematical models using ordinary differential equations have been constructed by Lemon[123,124] to study the proliferation and adhesion of cells on *ex vivo* implants. The authors used human mesenchymal stem cells (hMSCs) cultured on fibrous PET

(polyethylene-terephthalate) scaffolds, and studied the effect of hypoxia on growth. There are also some detailed models of stem cell attachment on scaffolds which emphasize metabolite diffusion and cell growth kinetics.[125]

Successful survival of an *ex vivo* implant within the host tissue is facilitated by the development of vascular tissue, which can transfer essential nutrients to the stem cells via the capillaries. Lemon *et al.*[123] constructed a highly simplified model of angiogenesis on scaffolds for human embryonic stem cells, and used the chick chorioallantoic membrane[46] as an experimental assay for estimating parameters and validating predictions. Their model predicts that the rate of cell infiltration through the pores of the scaffold to form blood vessels is a limiting factor of angiogenesis. Angiogenesis is increased in VEGF pretreated scaffolds when compared to untreated ones, both in the model as well as the experiments, thereby increasing the success of *ex vivo* transplants. As angiogenesis is a determinant of the success of scaffold integration within tissue, there have been other studies of blood capillary formation in the presence of specific scaffolds.[126] The presence of implants stimulates an inflammatory response by the body. Chang *et al.*[127] have modeled the chain of events from substrate presence to inflammatory stimulation, including increased monocyte adhesion and conversion into foreign body giant cells. These modeling projects use very simplistic representations of how biomaterials affect system processes and might have poor accuracy because they neglect spatio-temporal knowledge. Also these models are coarse-grained and do not contain specific pathway knowledge. In some cases the effects of biomaterials on a system can be better understood when they are studied in relation to more specific pathways rather than the effect on general biological processes.

5.513.4.2. Pathway Modeling for Process-Centered Approaches

With recent advances in systems biology, well-defined and quantitatively calibrated pathway models are now available for apoptosis,[128] the cell cycle,[129] and various growth factor-induced signaling pathways.[130] Sorensen *et al.*[131] *built a* model of platelet activation incorporating the interactions between thrombin, prothrombin, and its inhibitor. Their model predicts the effects on platelet activation from the shear stress of blood flow, and adhesion to biomaterials, which are used as cardiovascular implants. In their subsequent publication[132] the model was validated using a collagen type-I substrate and a parallel-plate flow to show experimental results that agreed with the model predictions. Diverse types of information, about interaction pathways, cell-specific interactions, biophysical characteristics, and substrate–cell interactions, were integrated through modeling to provide guidance for the development of substrates with improved outcome in a physiological context.

5.513.4.3. Pathway Modeling for Activation of TGF-β1 in Liver Fibrosis

Our team undertook a process-centered approach aimed at regenerative therapy for liver fibrosis (Figure 2). Liver fibrosis is driven by high levels of the cytokine TGF-β1 and by the accumulation of fibrotic proteins secreted from activated hepatic stellate cells (HSCs). There are many causal influences in liver fibrosis, but we do not seek simply to perturb the most important cause driving the disease because the mechanisms important to fibrosis are also likely to be important for beneficial wound healing, repair and regeneration. Indeed, elevated TGF-β1 and HSC activation occur normally when the liver regenerates after an injury, and we do not want to impair the pathways of natural regeneration. Rather than considering alternative perturbations individually, we studied the system of TGF-β1 and closely related pathways, seeking to understand the differences in how a healthy system avoids excessive levels of TGF-β1 after a single injury repair event, versus how TGF-β1 activation remains pathologically elevated in the case of chronic injury and fibrosis.

TGF-β1 is secreted in latent form and its bioavailability is regulated by extracellular activation. We studied the regulation of TGF-β1 activation by measuring levels of TGF-β1 activating

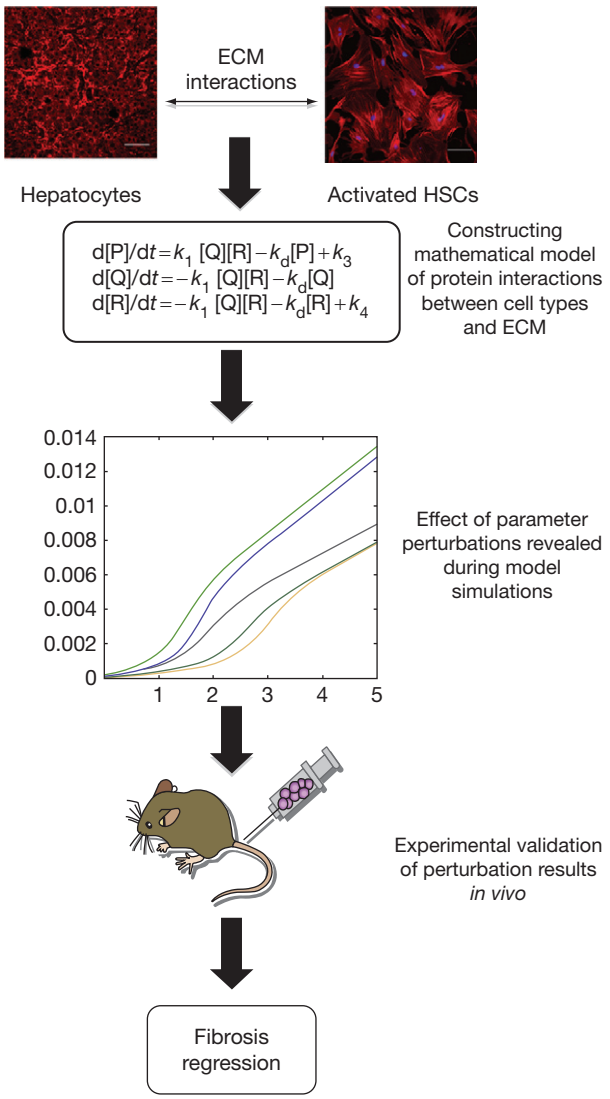

Figure 2 Workflow of systems biology-oriented therapy for liver fibrosis.

proteins in normal liver and at stages of fibrosis progression in rat models of liver fibrosis.[134] Thrombospondin-1, a known activator of TGF-β1, is strongly upregulated during liver fibrosis and has already been implicated as a driver of fibrosis.[133] Plasmin, another activator of TGF-β1, was found at significant levels normally and at dramatically lower levels during liver fibrosis progression.[133] This suggests that plasmin-mediated activation of TGF-β1 occurs in normal liver, and suggests that the thrombospondin-1 pathway becomes a more prominent mode of activation during fibrosis. Toward understanding why normal and fibrotic liver would utilize different pathways of TGF-β1 activation, one notes that TGF-β1 increases expression of plasminogen activator inhibitor-1 (PAI-1), an antagonist of plasmin activation.[135]

The decreased plasmin signaling during fibrosis thus has an explanatory mechanism, but why is the thrombospondin-1 pathway not more active in normal liver, except during injury response? A combination of results *in vitro*, *in silico*, and *in libris* (from data in the published literature) allowed us to establish a system-level model in which plasmin is acting both as a low-potency activator of TGF-β1, and a high-potency antagonist of the thrombspondin-1 pathway. Through its direct cleavage of thrombospondin-1, plasmin antagonizes the thrombospondin-1 pathway of TGF-β1 activation and reduces net TGF-β1 activation.[134] Therefore, plasmin has different downstream effects depending on the level at which it is studied. At a molecular level and in isolation, plasmin functions directly to activate TGF-β1. Meanwhile in a system of extracellular proteins, plasmin functions indirectly to decrease TGF-β1 activation. A process-centered mindset for approaching system-level issues facilitated our discovery of these dual roles of plasmin in the regulation of TGF-β 1 activation.

We next studied how this TGF-β1 activation machinery could be exploited for the therapeutic goal of triggering regeneration. A previous study of plasmin regulation and its upstream activation by uPA (urokinase-type plasminogen activator) revealed that plasmin activation occurs through a bistable switch-like feedback mechanism.[136] Combining this bistability with the previous model of TGF-β1 activation by plasmin and thrombospondin-1 yielded the hypothesis that, changes in the balance between plasmin and thrombospondin-1 might cause a distinct switch-like transition in the regulation of TGF-β1. Using rat models of liver fibrosis, sources of plasmin were added *in vitro* to the culture medium or *in vivo* by transplanting plasmin-secreting hepatocytes into the host.

The results in both experiments showed that TGF-β1 levels decreased and fibrotic disease markers returned to near-normal levels.[134,137] Elevating plasmin as a method to antagonize TGF-β1 is counterintuitive, but it proved to be remarkably effective. Moreover, it mimics the correlations found in the physiological system *in vivo*, and it may prove to be part of the physiological mechanism by which healthy liver tissue naturally switches away from fibrotic pathways during a normal injury response. From an engineering viewpoint, plasmin may also prove to be a relatively safe, robust way to downregulate TGF-β1 because its dual nature allows any overdose of its strong, indirect antagonistic function to be self-corrected via its mild but direct activating function.

Taking a process-centered approach helped us in multiple ways: to integrate knowledge about the various observed effects, to gain mechanistic insight into the switch-like regulation of the system, and to design an effective intervention for regenerative medicine in a rat model of liver fibrosis. However, the system-level nature of the project was only made possible by unusually extensive previous work that elucidated the detailed effects of the individual participants, at the molecular level and the cellular level. For general problems without such resources available, future research will be forced to establish the interactions and molecular relationships explicitly, perhaps one day simply from data mining and knowledge discovery in databases, or for the near term via additional biological experiments *ab initio*.

5.513.5. Future Outlook

Future goals for biomaterials and tissue engineering will require multiple interdependent components (biomaterials, cells, constructs), each with multifaceted optimization and variable parameters. Instead of the discrete or component based approaches studying particular biological outcomes of tissue engineering (**Table 1**) focus should be directed toward a systems-level perspective or process-centered approach.

Biochemical responses need to be assessed, possibly including functional genomics, proteomics, metabolomics, or other

Table 1 Broader perspectives of process-centered implications and approaches to study functional outcomes of tissue engineering

system-wide '-omic' responses. In addition, physical responses such as adhesion, migration, and morphological change need to be assessed. The chemical and physical properties of biomaterials would strongly influence cellular response and these parameters depend on both the underlying biomaterial as well as adsorbed proteins. On top of this are the biochemical and biophysical cues from the culture environment and the host microenvironment. Given this multilayered complexity, the most efficient and useful heuristics for correlating key experimental parameters with *in vivo* outcomes are to focus on biological processes and to define intermediate goals that have systematic and quantitative relationships with respect to the ultimate *in vivo* goal. Meanwhile, high-throughput methods will provide fast, parallel fabrication and measurement of cellular and tissue constructs,[33] and combinatorial synthesis approaches will be increasingly useful for biomaterials development.

Glossary

Articular cartilage A fibrous tissue comprising extracellular matrix proteins (mostly collagen and proteogylcans) produced by the cells (chondrocytes), and functioning to create a viscoelastic tissue with high biomechanical stability and low friction. It has a very limited ability for self-repair, mandating interventional approaches for repair.

Autologous chondrocyte transplantation (ACT) A regenerative medicine and multistep surgical procedure used to treat traumatic cartilage damage or osteochondrosis dissecans, but not degenerative arthritis in adults by harvest of cartilage from the patient, expansion of the chondrocyte progenitor cells, harvest, and transplant of these cells back into the patient's articulating cartilage site.

Chondrocyte Specialized musculoskeletal cell type producing type II collagens and specialized proteoglycans responsible for the structure and unique viscoelastic propeties of cartilage tissue. The only cell found in cartilage.

Chondroprogenitor donor cell-lines Cells representing chondrocyte precursors, capable of harvest and repeated culture to retain chondrocyte phenotypes, self-renewal, and tissue-regenerating properties of mature chondrocytes.

Hyaline cartilage Specialized articular cartilage found in synovial joint surfaces distinct in composition, structure and function from fibrillar cartilage

Osteoarthritis (OA) Cartilage degeneration characterized by cartilage degradation, the formation of osteophytes, and subchondral sclerosis, pain, and joint dysfunction.

Abbreviations

ACI	Autologous chondrocyte implantation
ACT	Autologous chondrocyte transplantation
ATSC	Adipose derived stromal cells
BMP	Bone morphogenetic protein
BMPr1a	Bone morphogenetic protein receptor 1a
BMSC	Bone marrow stromal cell
COMP	Cartilage oligomeric protein
DIO2	Iodothyronine deiodinase enzyme type 2
FGF	Fibroblast growth factor
FRZB	Frizzle related protein B
GDF5	Growth differentiation factor 5
GPR22	G protein coupled receptor protein 22
hES cells	Human embryonic stem cells
HLH	Helix loop helix
HMGB-1	High mobility chromosomal box protein-1
HSC	Hematopoetic stem cell
ID1	Inhibitor of differentiation 1
IL-1	Interleukin 1
MSC	Mesenchymal stem cell
OA	Osteoarthritis
SCN	Stem cell niche
WJCs	Wharton's jelly stem cells

5.514.1. Introduction

Over 250 years ago, the famous anatomist William Hunter stated "ulcerated cartilage is a troublesome thing and once destroyed, is not repaired," a statement that is still valid today.[1] Adult articular cartilage consists mainly of extracellular matrix proteins produced by the cells (chondrocytes), which have the function of creating a visco elastic tissue with high biomechanical stability and low friction (Figure 1). Even though the cartilage is exposed to continuous mechanical wear, the cellular and extracellular matrix turnover is low, which could be a reason for the inability of adult articular cartilage to respond to injuries and subsequently repair lesions.

The damage to cartilage could lead to the end-stage disease osteoarthritis (OA) that is characterized by cartilage degradation, the formation of osteophytes, and subchondral sclerosis. OA is one of the most common forms of musculoskeletal disease throughout the world with millions of affected individuals. The OA disease causes a burden to the society and health care system but despite the increase in knowledge in medical science no drug-based disease-modifying therapy exists basically due to the fact that (i) the disease process stretches over decades, (ii) no surrogate markers exist that can be used to monitor progression of OA, and (iii) no specific drug target and disease mechanism have been identified.[2] The limited repair capacity of articular cartilage defects after trauma is the major contributing factor to early OA with ~5% of the population between 35 and 54 years having radiographic signs of OA.[3,4]

5.514.2. Cell Therapy and Cartilage Regeneration: State of the Art

Articular cartilage has poor ability to self-repair[5] and attempts of replacing the articular joint surface with osteochondral grafts were tested by Eric Lexer in 1908. Following that sporadic attempts were tried (see review by Aichroth[6]) but the variable methodology and clinical outcome did not justify wider clinical applications. Failures have generally been attributed to insufficient bone fixation, and allografts have failed due to immunological rejections and autografts had a better success rate. Over the years treatment of smaller cartilage injuries have been mainly surgically based on the concept of recruiting bone marrow stromal cells (BMSCs) by drilling or microfracturing the subchondral bone, alternatively using osteochondral autografts.

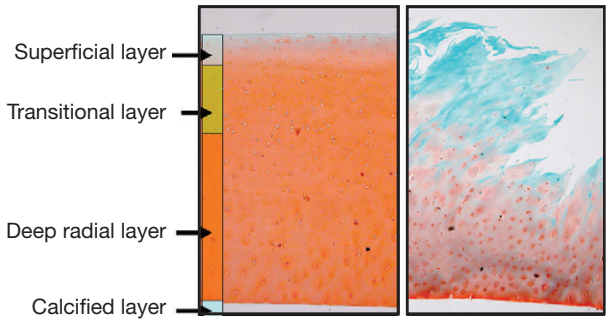

Figure 1 Normal healthy and osteoarthritic cartilage histology. Representive light micrographs of condylar cartilage obtained post mortem from joints with (a) normal healthy cartilage and (b) cartilage obtained at joint replacement surgery. Sections are stained with safranin-O fast green-iron haematoxylin. The different layers are an approximation and the calcified layer is indicated but not present in the sections. Figure modified from *Arthritis Res. Ther.* 2006, *8*(1), R2.

However, the resulting repair tissue is mostly fibrocartilaginous tissue lacking the biomechanical properties of the hyaline cartilage. Cellular attempts to regenerate cartilage were initiated in the 1960s when Green was able to isolate chondrocytes from cartilage and culture the cells.[7] The pioneering work of Bentley in 1971[8] demonstrated the possibility that transplanted and isolated articular chondrocytes as well as epiphyseal chondrocytes taken from very young rabbits (6-weeks old) that were injected into defects drilled in the upper tibial articular surfaces could induce repair. The articular chondrocytes were mostly rejected but the epiphyseal chondrocytes survived in small numbers and laid down normal staining hyaline matrix which filled the defects completely. In subsequent experiments, it was demonstrated that frozen chondrocytes also were able to regenerate an osteochondral defect.

The next step in cellular cartilage repair was taken with the autologous chondrocyte transplantation (ACT) technology developed by our group.[9] ACT or autologous chondrocyte implantation (ACI) has in the last decade emerged as the first disease-modifying treatment with long-term excellent clinical result in patients with isolated cartilage injuries[10,11] and osteochondral lesions in the knee and ankle.[12,13] The good clinical outcome of the ACT technique for the treatment of cartilage injuries has resulted in a worldwide spread of the technology with over 35 000 patients treated, among those, 1500 have been treated by our group over the last 15 years. Four randomized controlled clinical trials have demonstrated treatment superiority for ACT over conventional treatment[14–16] while one showed no difference, although ACT produced a better hyaline repair tissue.[17] However, the latter study does not take into account the fact that inclusion criteria for ACT treatment have repeatedly failed previous conventional treatments as one-third of patients with cartilage injuries diagnosed for the first time improve spontaneously after debridement.[18] Recent reports from our group with 15-year follow-up gives further support for the hypothesis that the ACT technology is a local disease-modifying treatment where the graft has contributed to local cartilage regeneration.[19] Furthermore, long-term follow-up with gadolinium enhancement demonstrated a hyaline repair tissue similar to surrounding cartilage.[20]

5.514.3. Cell Therapy Concepts in Cartilage Disease and Osteoarthritis

We have to accept the fact that OA is a chronic disease where the time between initiation of disease and fully developed OA stretches over decades. The challenge for the development of new OA treatments based on cellular or pharmacological technological base is hampered by the absence of early diagnostic tools. Classical biochemical assays are often based on the leakage of components from damaged cells (compare liver damage and released liver enzymes). The OA assays that are

available detect matrix components like cartilage oligomeric proteins (COMPs) inflammatory cytokines (interleukin-6 (IL-6) or high mobility chromosomal box protein-1 (HMGB-1). However, these markers are not sensitive enough for individual diagnostics at the early stage of the disease. The possibility of a regenerative approach to OA disease which could bridge the gap between the current stage of treatment (with the exception of traumatic defects which is not afflicted by OA disease) has changed given the recent advances in the knowledge of the regenerative capacity of different tissues (e.g., brain and heart) and the tissue ability to regenerate after injury.[21] The paradigm shift has changed the focus toward understanding the mechanisms of the regeneration system within each tissue, that is, identification of specific stem cell niches (SCNs) that harbor and maintain the stem cells through an intricate interaction and control (**Figure 2**). The homeostatic control involves a wide range of secreted soluble and matrix interactive signals. These signals represent a conserved 'developmental toolkit,' which is also important for embryonic development and includes, but is not limited to, bone morphogenetic proteins (BMPs), Fibroblast growth factors (FGFs), Notch, Hedgehog, and Wnt signaling pathways,[22,23] as well as the integrins and the cell surface proteoglycans. Particularly, the syndecans that represent a specific set of signaling molecules are able to modify intracellular events such as transcription. The signals are key players in disease mechanisms; for example, loss and gain of function studies in two Wnt coreceptors (Lrp5 and Lrp6) have drawn considerable attention to the importance of Wnt signaling pathways in skeletal biology.[24] Breakdown of the self-renewal system is a key event in the development of cancer and regeneration in aged muscles can be enhanced by restoration of normal signaling in the Notch pathway.[25] Continuous Wnt activation in the Klotho mice triggers accelerated cellular senescence of stem cells in several organs.[26] Furthermore, increased Wnt signaling during aging alters muscle stem cell fate and increases fibrosis, a process accelerated by Wnt3A while antagonists to the same pathway regain muscle lineage.[27] Future treatment of cartilage defects with cells and/or scaffolds have to adopt this new view of cartilage regeneration.

5.514.4. Molecular Control Mechanisms in the Knee Joint – Implications for Cartilage Repair and OA

In earlier studies, we found that the de- and redifferentiation process of human articular chondrocytes is similar to molecular programs found in fetal cartilage development.[28] Given the fact that there are stem cell markers in the knee joint and a SCN in the surroundings, the Notch signaling pathway has been studied as it is involved in the regulation of joint development and growth[29] and expressed in the surface layer of articular cartilage – *laminae splendance*.[30]

Since OA chondrocytes display an altered differentiation state compared to normal chondrocytes, it is expected that the expression of Notch markers in OA cartilage is altered. In healthy cartilage, Notch1, its ligand, Jagged1, and down stream effector gene *hes*5 (human version of the Drosophila gene, hairy and enhancer of split) are expressed in a few cells localized within the uppermost cell layers of the surface zone *lamina splendence*. This is in sharp contrast to the abundant expression of these markers detected in OA biopsies, where expression was extended to cells in deeper layers of the cartilage.[31] A recent population study added a new susceptible locus on chromosome 7q22 with a strong correlation related to the G protein coupled receptor protein 22 (GPR22).[32] Interestingly, the receptor could not be found in the articular cartilage but was localized to *lamina splendence*, thus colocalizing with the notch receptor in the superficial layer of articular cartilage.

Primary OA has an estimated heritability of 40% for the knee, 60% for the hip, and 65% for the hand.[2] To date, investigations of OA genetics have focused mainly on genome-wide linkage and candidate gene studies with controversial results due to lack of power and replication. Interestingly, two genes have been found to be consistently associated with OA in Caucasians: the growth differentiation factor 5 (GDF5)[33] and iodothyronine deiodinase enzyme type 2 (DIO2),[34] which are associated with SCN growth control.[34,35] Furthermore, hip OA is associated, in females, with the frizzle related protein B (FRZB), which is an inhibitor of the Wnt signaling pathway and is also involved in the stem cell signaling[36] (see **Chapter 5.524,**

Biomaterials for Replacement and Repair of the Meniscus and Annulus Fibrosus).

5.514.5. The Uniqueness of Hyaline Cartilage Chondrocytes

When considering cartilage cell therapies it is necessary to recall the fundamental biology of cartilage and bone formation. Bone develops along two developmental pathways – either intramembraneous or by endochondral bone formation. Both processes are recognized by the process of cellular condensation where the endochondral bone formation has an intermediate cartilage step. Most of the skeletal bones are formed by endochondral formation and most of the skull bones are formed by intramebraneous formation.

The endochondral bone formation is characterized by deposition of matrix into a cartilaginous rod, which is the template for the long bones with cartilaginous tissue in the epiphysis as well as the long bone shaft. Subsequently, the chondrocytes hypertrophy in the long bone area and this process is followed by capillary ingrowth and the start of the process of mineralization. Initially the epiphysis remains cartilaginous but a second ossification zone develops in the central part of the epiphysis. Between the ossification center and the long bone the epiphyseal cartilage is formed that is responsible for the longitudinal bone growth. The proximal cartilage causes endochondral ossification in both distal and proximal directions. Subsequently, the ossification toward the epiphysis ceases and a laminar organization of chondrocytes develops in the distal direction.[37,38] Close to the bony epiphysis there is a uniformly distributed cell layer consisting of rarely dividing cells. This cell layer constitutes the stem cells of the growth plate and is usually called the germinal cell layer. This cartilaginous structure is connected with the articular cartilage and the perichondral ring responsible for the circumferential bone growth.

The articulating joint formation takes place in the cartilaginous rods where the formation of a small condensation zone named the digital ray is the first microscopic sign. This is followed by the formation of a three-layered interzone with two regions of high cell density with a region of lower density in between (Figure 3). The intermediate cell layer disappears through a process of apoptosis and thus forms the cavity of the joint while the surrounding high-density region forms the articulating surfaces.[39] The surrounding joint capsule and the tendons are formed from cellular condensations laterally to the digital ray thus creating the full articulating joint.

Little attention has been attributed to the cellular lineage of this structure since the concept has been that the joint is formed from the cartilage rod and thus similar to the hypertrophic cartilage, although the hypertrophic process is somewhat blocked. Several investigators have studied the factors responsible for cellular growth and structural patterning of the joint and in these studies the BMPs plays an important role. The first BMPs were isolated due to the remarkable capacity of ectopic bone formation. Subsequently many BMPs have been identified and studies of sequence homology have revealed that the BMPs form a subfamily within the TGF-β superfamily. GDF5 belongs to a new subgroup of the BMP family that includes GDFs 5, 6, and 7.

GDF5 has been hypothesized to having multiple functions in the skeletogenesis, since exogenously injected GDF5 protein stimulated cartilage development and inhibited surrounding GDF5 expression and joint formation.[40,41] Further evidence for a unique hyaline cartilage phenotype for articular cartilage was demonstrated in mice where cells expressing a member of the BMP family (GDF5) constitute a distinct cohort of progenitor

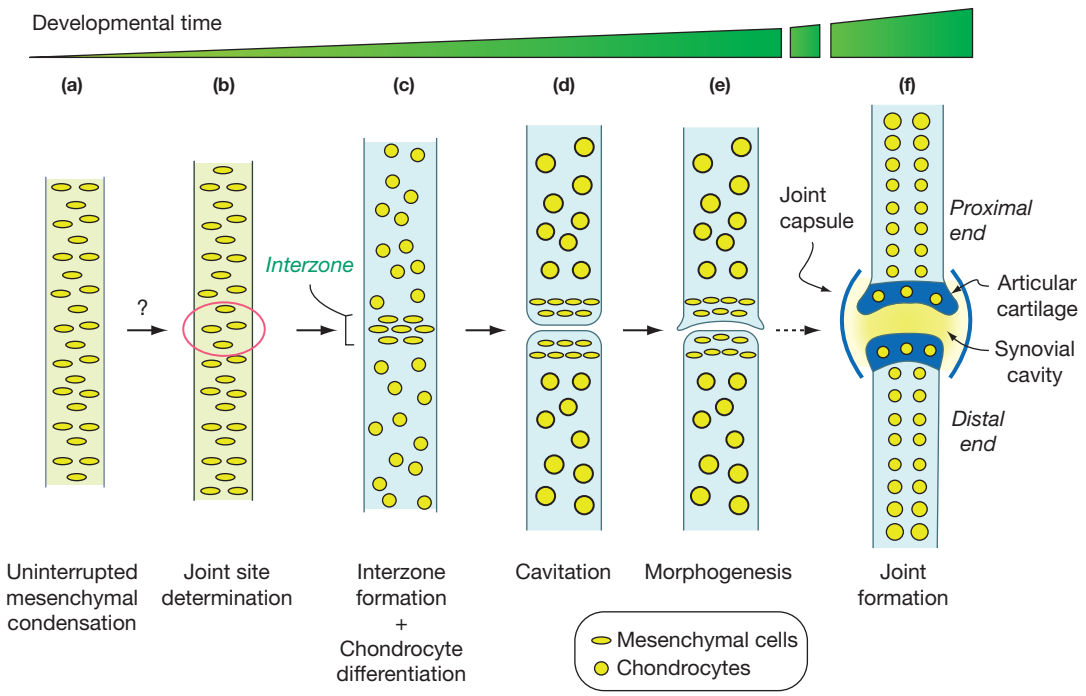

Figure 3 Schematic overview of the localization of the BrdU-positive cells in the knee. Reproduced from *J. Anat.* **2009**, *215*(3), 355–363.

cells responsible for limb joint formation including articular cartilage, ligaments, synovial lining, with limited contribution to the adjacent long bone cartilaginous shaft and growth plate formation.[42] Congenital mutations in the GDF5 gene cause defects in digits, wrist, and ankle[43] while deletion of antichondrogenic factors like *Wnt9a* causes limb and joint deformation.[44] This gives an additional support for a lineage specificity for articular cartilage that has to be taken into account when discussing cell therapy models in the joint (see **Chapter 5.538, Finger**).

5.514.6. Adult Stem Cells and Stem Cell Niches

The joint is a complex entity and it is still an important question if the joint and cartilage is a regenerating tissue with some repair capacity and in such case there has to exist a potential chondrogenic stem cell population within the joint. However, the poor capacity for self-repair of articular cartilage has been explained by cell senescence and the lack of chondroprogenitor cells. In contrast, human articular chondrocytes cultured *in vitro* display phenotypic plasticity with chondrogenic, adipogenic, and osteogenic potential[28,45,46] although whether this is due to dedifferentiation of the cells or selection of a progenitor cell population is debatable.

The anatomical location of the potential stem cells as well as the existence in a specific tissue *in vivo* is not well explored, particularly not in the joint. In recent years, it is becoming evident that stem cells are located in a special microenvironment termed stem cell niches (SCNs). The location and nature of these niches can vary depending on the tissue type but one common entity is that the signaling pathways are conserved.[23]

The bulge area of hair follicles where epithelial stem cells are resident and the intestinal SCN located near the crypt base has been extensively studied.[47,48] An area of potential interest with regard to progenitor cells in the joint is the circumferential anatomical structure first described by Ranvier in 1873 and formerly named the perichondrial groove of Ranvier. This area is located at the periphery of the epiphyseal growth plate and has been demonstrated to contain proliferating cells.[49] It has also been suggested that perichondrial cells from the ring of LaCroix, which is a fibrous band that surrounds the groove of Ranvier and is continuous with the periosteum of the metaphysis, serve as a reservoir for precartilaginous cells in the germinal layer of the epiphyseal growth plate.[50] The important role of an intact epiphyseal growth plate, and perichondrial zone, for longitudinal bone growth is well documented. Salter–Harris type VI fractures within the groove of Ranvier has demonstrated severe growth disturbances.[51]

An established method to identify stem cells within different tissues is the labeling of slow cycling cells corresponding to the stem cell population with bromodeoxyuridine (BrdU). Progenitor cells/stem cells can be identified and characterized due to expression of specific proteins, although no unique marker for these types of cells exists today. However, there are markers associated with stem cells in the literature, for example, Stro-1, bone morphogenetic protein receptor 1a (BMPr1a), Patched, Notch1, Integrin β1, and N-cadherin. Indeed a SCN in the zone of Ranvier close to the knee joint has been demonstrated with the technique of long-term labeling with BrdU. The SCN expressed similar immunohistochemical markers as other SCNs, that is, β-catenin, Notch1, Noggin, and c-kit[52] (**Figure 4**) and proliferating cells were present in the deeper areas of the articular cartilage. Although a significant decrease in the number of BrdU positive cells were detected at the later time points, some cells were still detected suggesting that progenitor cells might be present in the deeper layers of the cartilage. A similar SCN has also been identified in the intervertebral disk region[53] The interesting question is, if these niches could potentially be involved in human joint and disk regeneration and disease – a positive answer would mean a paradigm shift for the concept of cellular treatment for cartilage defects and the OA disease mechanism as well as disk degeneration.

5.514.7. Improvements in ACT Cell Technology – Alternative Cell Sources

OA patients and younger patients with small injuries are not subjected to ACT treatments due to the limited source of 'normal'

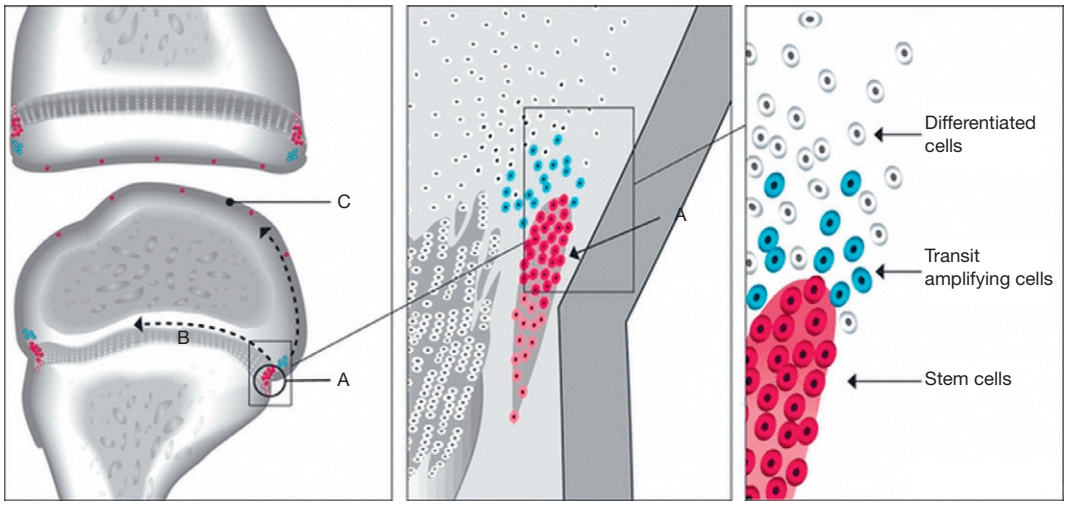

Figure 4 Development of bone and joint cartilage.

cartilage in an OA joint and the high costs of GMP-produced cells or grafts. This has raised the question if other cell types could replace the autologous chondrocytes (i.e., mesenchymal stem cells (MSCs), OA chondrocytes, human embryonic stem cells (hES cells), and umbilical cord or cord blood cells). When discussing different cell sources, there are requirements to be considered although some sources seem to be more easily accessible than others. Requirements for cells intended for hyaline cartilage repair is that they (i) are of the correct lineage and are able to differentiate toward hyaline cartilage. They should also be (ii) accessible and harvested with minimal (iii) morbidity for the patients. The requirement of multipotency and telomerase activity should be considered but more important is the (iv) capacity of cell expansion without loss of differentiation potential. Currently, the chondrocytes isolated from human articular cartilage are pluripotent with a unique differentiation capacity toward cartilage, bone and fat cells, and the cells are derived from the GDF5 lineage as earlier described. Alternative cell sources to consider would depend on the intended use. These could be divided into two distinct groups of treatments where one is *autologous* use and the second is *universal donor* use. The cell sources are discussed based upon these aspects as well as lineage specificity and expandability.

5.514.8. Autologous Use of Cells

5.514.8.1. Osteoarthritic Cells

The use of osteoarthritic cells could seem like a tempting source of cells which would mean that the doctor is able to harvest cells from a damaged knee for subsequent culture and expansion. Currently, autologous chondrocyte transplantation (ACT) is used to treat traumatic cartilage damage or osteochondrosis dissecans, but not degenerative arthritis.

The original ACT technology is based on culture-expanded chondrocytes transplanted under a cover of periosteum. The main indication was treatment of small isolated lesions but gradually over the last decade the indication has been expanded to include lesions up to 20 cm^2 in size. The implantation method has been followed by culture-expanded cells loaded on a membrane or into a biodegradable scaffold before implantation. Advantages of using scaffolds as cell carriers is that the cells can be positioned in the lesion arthroscopically and could potentially treat larger defects. This is especially interesting for young (under 60-years old) and active patients with developed OA, who at present lack an appropriate treatment alternative. Different scaffold materials have been used for this purpose, for example, different combinations of poly-L-lactic acid and poly(lactic-*co*-glycolic acid)[54] or materials obtained by esterification of hyaluronic acid.[55]

The etiology of OA has been suggested to contain a phenotypic alteration of the chondrocytes[56] due to systematic, mechanical, or unknown reasons. Chondrocytes isolated from OA cartilage have been shown to be more metabolically active than cells isolated from non-OA regions in the same joint[57] and proteoglycan synthesis in OA cells have been demonstrated in comparable amounts to normal cartilage from ACT donors although collagen synthesis is significantly lower.[58] Furthermore, chondrocytes isolated from less-severe grades of OA cartilage synthesize normal matrix components.[59]

When OA cells were cultured in a hyaluronan scaffold (Hyaff 11) only few genes were differentially expressed between OA and normal hyaline cartilage as determined by genome-wide oligonucleotide microarrays and the risk of differentiation into hypertrophic cartilage was not increased.[60] In such systems the OA cells could fulfill the requirements for matrix-associated cartilage implantation and OA patients could likely benefit from the treatment. In another study the gene expression patterns of osteoarthritic (OA) chondrocytes after primary culture and subculture were compared to these with healthy chondrocytes and with articular chondrocytes expanded for treatment of patients by ACT. In those studies OA chondrocytes showed highly elevated levels of interleukine 1β (IL-1β) mRNA, but type I and II collagen levels were comparable to those of healthy chondrocytes. After primary culture, IL-1 β levels decreased to baseline levels, while the type II and type I collagen mRNA levels matched those found in chondrocytes used for ACT. OA chondrocytes generated type II collagen and proteoglycan-rich cartilage when transplanted in a SCID mice model.[61] One conclusion from these studies could be that after expansion under suitable conditions, the cartilage of OA patients contains cells that are not significantly different from those from healthy donors prepared for ACT. OA chondrocytes supported by hyaluronan or collagen-based scaffolds could potentially be used for regenerating cartilage in humans although cells in single cell suspension are less suitable. Whether other types of scaffolds have similar capacity remains to be demonstrated.

5.514.8.2. Bone Marrow Stromal Cells or Mesenchymal Stem Cells

In the human bone marrow, a rare population of clonogenic nonhematopoietic stem cells (~1/100 000 of the bone marrow mononuclear cells) resides and the cells were earlier denoted as bone marrow stromal cells (BMSCs). The function of these cells is to support hematopoetic stem cell (HSC) function. Furthermore, these cells have the capacity to differentiate into cells of various connective tissue cells such as bone,[62,63] muscle,[64] adipose tissue,[65] cartilage,[66] and tendon.[67] Within the scientific literature, the acronym MSC has been used to represent (bone) marrow stromal cells,[68] MSC, and multipotent mesenchymal stromal cells, and this sometimes causes confusion since MSCs can be found in various tissues. It is more correct to give the MSCs a prefix depending on the source of harvest although the cells have similar capacity; for example, MSC derived from bone marrow aspiration would therefore be described and termed BMSC. Other MSCs that are candidate for replacing chondrocytes in cell-based repair of cartilage lesions could be derived from many other sources besides the bone marrow, that is, from adipose tissue, where the cells are termed adipose derived stromal cells (ATSCs), from Wharton's jelly in the umbilical cord (Wharton's jelly stem cells, WJCs), from umbilical cord blood (umbilical cord blood stem cells), or from synovial tissues, which also have the capacity to differentiate into specialized cells *in vitro* (see **Chapter 5.537, Adipose Tissue Engineering**).

However, it has not been clarified if MSCs can acquire the hyaline phenotype, and whether chondrocytes and MSCs show the same expression patterns of critical control genes in development. Several attempts have been made to achieve

regeneration of cartilage defects using MSC.[66,69] One major drawback of using these cells in cartilage or intervertebral disk tissue engineering is that human MSCs express type X collagen, a marker of chondrocyte hypertrophy associated with endochondral ossification.[70]

In high-density culture systems the gene expression patterns were compared between articular chondrocytes and iliac crest-derived MSCs. For articular cartilage, a significant decrease in expression of collagen type I was timed with increased expression of collagen types IIA and IIB during differentiation, thus indicating differentiation toward a hyaline phenotype. Chondrogenesis in MSCs on the other hand resulted in up-regulation of collagen types I, IIA, IIB, and X, demonstrating differentiation toward cartilage of a mixed phenotype. Expression of the helix loop helix (HLH) transcription factor 1 (HES1) increased significantly during chondrogenesis in chondrocytes while expression in MSCs was maintained at a low level. The HLH gene HES5 on the other hand was exclusively detected in chondrocytes. Expression of the HLH gene ID1 (inhibitor of differentiation 1) decreased significantly in chondrocytes while the opposite was seen in MSCs.[71] These findings suggest that chondrocytes and MSCs formed different subtypes of cartilage, the hyaline and a mixed cartilage phenotype, respectively. These results are important when considering the use of MSCs in cartilage repair.

The migration capacity of chondrocytes and mesenchymal stem cells (MSCs) is also important in cartilage regeneration and tissue engineering approach. A study analyzed growth factors and cytokines for their ability to induce migration of human articular chondrocytes and bone marrow-derived MSC in Boyden chamber assays. The platelet-derived growth factor was the most potent migrating agent but no differences between the two cell types could be detected.[72] When stimulated with GDF5 (formerly named cartilage-derived morphogenetic protein-1 (CDMP-1))[73] cartilaginous differentiation was demonstrated.

In conclusion, the MSC are easily accessible from the iliac crest but the harvest causes some morbidity to the patients; it is possible for the cells to expand in monolayer cultures and have multipotency but the default pathway demonstrated is not hyaline cartilage but hypertrophic cartilage and bone formation. This could be due to the fact that the cells are not in the GDF5 lineage although MSCs are able to differentiate into chondrocytes but the tissue represents an unmineralized hypertrophic cartilage.

5.514.8.3. Fat Stromal Cells and Cartilage Regeneration

Isolation procedure of adipose cells is well described and basically the liposuction material is thoroughly washed and digested by collagenase type I. The isolated cells are subsequently separated from adipose cells by centrifugation where superficial cells are the fat cells and the pellet contains the ATSCs. The differentiation capacities of these cells are similar to MSCs. The cell fraction has been evaluated in horses with cartilage defects and compared to treatment with MSC. Small differences were found although MSCs where more effective as treatment.[74] The human ATSCs were examined regarding phenotypes and gene expression profile in the undifferentiated states and compared with that of BMSC. Flow cytometric analysis showed that ATSCs have a marker expression that is similar to that of BMSC. ATSCs were superior to BMSC in respect to functionality in maintenance of proliferating ability, and microarray analysis of gene expression revealed differentially expressed genes between ATSCs and BMSCs. The proliferating ability and differentiation potential of ATSCs were variable according to the culture condition[75] including cartilage differentiation.[76] ATSCs are abundantly available as source for differentiation for cartilage repair but the differentiation pathway is similar to MSCs and thus end in mineralized bone. Furthermore, the harvest of cells is connected to an additional operative procedure with risk of patient morbidity.

5.514.9. Universal Donor Cell Lines for Cartilage Repair

Although widely used, there are some inherent problems with the use of autologous chondrocytes. They show restricted proliferative capacity in culture and rapidly lose their functional properties in culture. Harvesting these cells is itself an additional injury to the joint surface, and even if the harvest site is located some distance from the lesion, this cartilage might be affected by the injury as well. An alternative method is the use of adult MSC. One drawback with these cells is that they tend to differentiate toward hypertrophic cartilage instead of hyaline cartilage, resulting in a tissue that is not adapted to the pressure and shear force that the joint is subjected to.[66,69,70] Furthermore, the number of MSC, their proliferative capacity, as well as their synthetic abilities declines with age.[77] The ultimate goal for human cartilage cell-based repair would be an off-the-shelf arthroscopic product based on a universal donor cell line combined with a suitable scaffold. For such cells their ethical aspects have to be acceptable and the immunogenic properties low as well as chondrogenic properties high. For this purpose cells have to be cultured in an industrial scale or within a hospital setting. For this type of cells, ATCS, umbilical cord stromal cells, and cell derived from hES cells fulfill the requirements to various extents.

5.514.9.1. Derivation of Chondrocytes from Human Embryonic Stem Cells

Human embryonic stem (hES) cells, derived from the inner cell mass of the human blastocyst, may have significant potential to be used in cartilage tissue engineering. The most prominent advantage of using hES cells in cartilage regeneration is that they are immortal and could potentially provide unlimited numbers of chondrocytes or chondro-progenitors for transplantation.

The majority of the published research concerning *in vitro* differentiation of embryonic stem (ES) cells into chondrocytes has been conducted on murine cells, using medium supplementation with members of the transforming growth factor-beta family (TGF-β) or bone morphogenic protein-2 and -4 (BMP-2, -4),[78] or by coculturing with embryonic limb buds.[79] The microenvironment of the culture has the capacity to influence cellular differentiation, and the ability to drive differentiation toward specific lineages in various coculture systems of embryonic tissues with stem/progenitor cells has been evaluated.[80–82] These efforts have provided important knowledge and contribute to a better understanding of the mechanisms underlying chondrogenic differentiation, even though the use of differentiated cells for cartilage tissue engineering still remains a challenge.

Conditioned media from cartilage progenitor cells did not induce increased chondrogenesis instead it supported the growth of a hES cell line that could be cultured without feeders (MFG-hESCs).[83] When subjected to bone differentiation the cell line has high similarities with MSCs and has a higher expansion capacity and also retains its differentiation capacity at higher passages[83] although with limited chondrogenic potential.

In order to increase the chondrogenic differentiation of hES cell lines the cells have been cocultured with mitotically inactivated human articular chondrocytes *in vitro*. These cocultured progenitors demonstrated the best chondrogenic differentiation capacity so far from progenitors derived from hES cells.[84] The system allows intimate contact between different cell types, thus resulting in more efficient transduction of molecular signals that induce chondrogenesis. The surface receptors of cocultured cells come into direct physical contact, and the autocrine and paracrine factors secreted by one cell type readily interact with the other cell type. In contrast to hES cells prior to the coculture and likewise chondrocytes, the cocultured hES cells were able to form and grow as pellets when cultured in 3D pellet mass

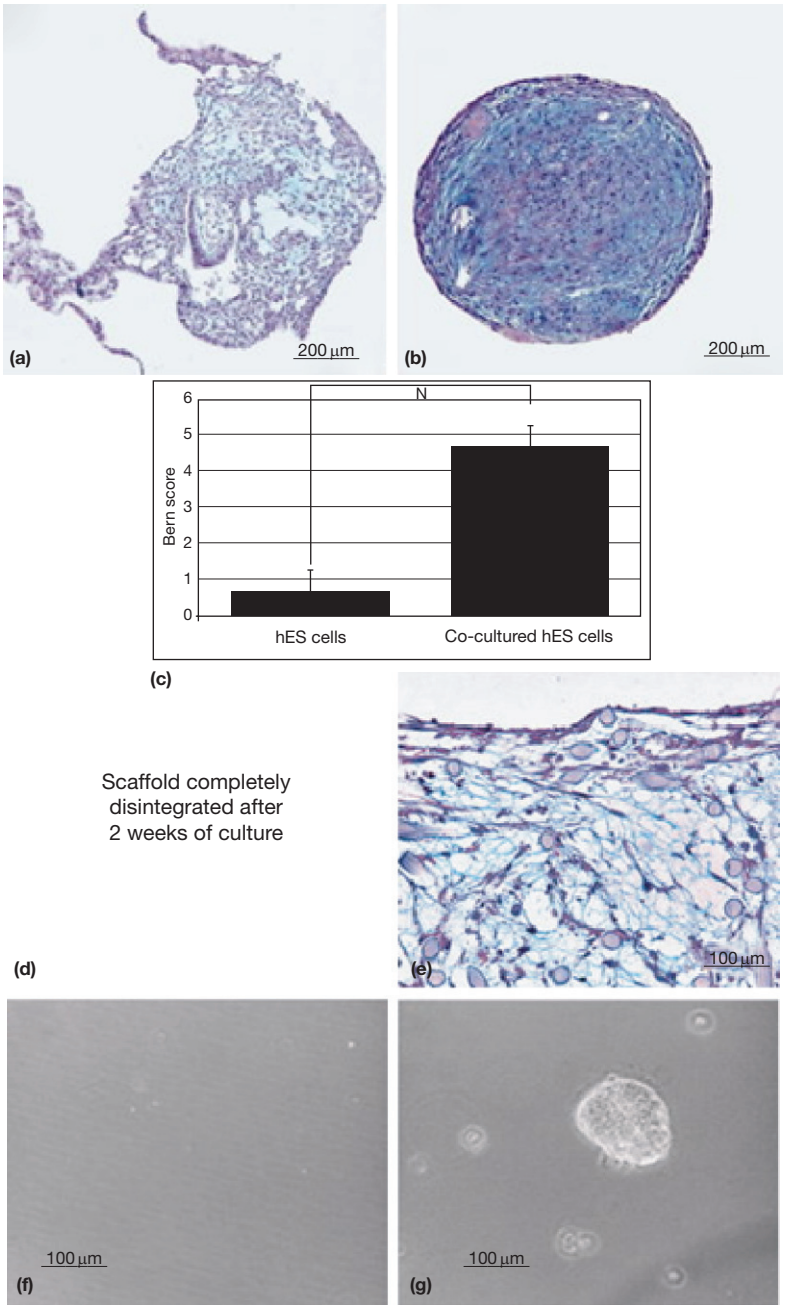

Figure 5 Chondrogenic differentiation. Pellet mass cultures stained with Alcian blue van Gieson of hES cells prior to (a) and after (b) coculture. Chondrogenesis of the pellets evaluated according to the Bern scale (c). Alcian blue van Gieson staining of hES cells prior to (d) and after (e) coculture in scaffold. Colony formation in agarose suspension culture of hES cells prior to (f) and after (g) coculture. hES cell, human embryonic stem cells. Reproduced from *Stem Cell*. **2009,** *27*(8), 1812–1821.

culture system. Interestingly, a number of studies have reported that coculture with chondrocytes has a positive effect on the osteogenic differentiation of MSC while coculture of chondrocytes and embryonic stem cells direct the cells into the chondrogenic lineage or significantly decreases the osteogenic potential of the cells.[81,85] MSC and hES cells thus respond differently to coculture with chondrocytes.

The cellular morphology of the cocultured cells in pellet cultures were similar to that of articular chondrocytes cultured in pellet mass cultures (Figure 5). Significantly improved differentiation toward the chondrogenic lineage of the cocultured cells was demonstrated both by their ability to form colonies in agarose-suspension culture with a morphology very similar to that of chondrocytes cultured under the same conditions as well as significantly increased accumulation of a cartilaginous matrix in pellet masses.[86] The only cell types with the ability to survive in agarose suspension culture are chondrocytes and tumor cells.[87,88] However, the cells had low expression of stem cell markers (CD117, CD133, SSEA-4), indicating a poor capacity of tumor formation of these cells.

Vats *et al*. recently demonstrated that coculture with chondrocytes from patients undergoing otorhinolaryngological–head and neck surgery and hES cells using well inserts for separating the cells displayed an increased accumulation of sulphated GAGs as well as expression of Sox9 and collagen type II.[89] In this study, differentiation was assessed after 28 days of coculture. Furthermore, mouse ES cells can be programmed to differentiate into chondrocyte-like cells by coculture with progenitor cells from the limb buds of the developing embryo.[79] In both of these studies, chondrocytes were present during the differentiation of the hES cells, either separated from the hES cells using a membrane or present in the micromass culture and eliminated after 4 days of culture.

In high-density pellet mass cultures it is difficult to direct the differentiation of the hES cells into only one specific lineage. Human ES cells cultured as pellets did not produce any cartilage-like matrix and the only hES pellet staining positive for Alcian blue van Gieson also resembled embryoid bodies with structures of cells differentiating into other tissues than cartilage. After coculture, a more homogenous, likely lineage restricted, population of cells have been formed with an increased potential for chondrogenic differentiation. In accordance, no teratoma formation could be detected in the cocultured cells after injection under the kidney capsule in SCID mice model confirming phenotypical alteration of the cells and lack of pluripotency. In conclusion, derivation of chondrocytes progenitors from human ES cells could be possible but a lot of work remains. Derivation of xeno-free culture systems has to be combined with better differentiation protocol since the cartilage formed has more similarities with fetal cartilage than with adult, a finding also demonstrated in keratinocytes derived from hES cells.[90]

5.514.9.2. Derivation of Chondrocytes from Umbilical Cord Cells and Umbilical Cord Blood Cells

The umbilical cord consists of umbilical veins and arteries and the supporting mesenchyme called Wharton's jelly (Figure 6) where MSC-like cells can be isolated. These cells are denoted WJCs and are derived from the surrounding matrix between the umbilical blood vessels.[91] The cells meet the criteria for stem cells as they have inherent self-renewal capacity and can be induced to differentiate into various cell types. The advantage of cells derived from the umbilical cord matrix is (i) the isolation of large numbers of cells without subsequent expansion in culture and (ii) that the cells are derived from fetal structures and could, like umbilical cord blood cells, thus have a better immunotolerance in the recipient patient.

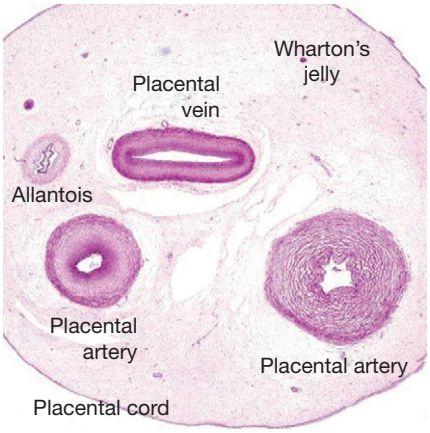

Figure 6 Wharton's jelly.

The question whether the different compartments of the umbilical cord have different MSCs has been addressed in experiments with cells isolated from umbilical cord blood, umbilical vein subendothelium, and the Wharton's jelly. Within Wharton's jelly, MSCs can been isolated from three indistinct regions: the perivascular zone, the intervascular zone, and the subamnion. It is not clear whether cells isolated from these different compartments of the umbilical cord represent distinctly different populations of MSCs. The WJCs express MSC surface markers, thus suggesting that they are of the MSC family; however, in experimental settings, WJCs differ from BMSCs because WJCs are slower in differentiating into adipocytes.[92] Since many features are shared with MSCs such as poor ability to differentiate to adipocytes, shorter doubling times than BMSCs, and greater numbers of passages to senescence, it not clear whether the MSCs derived from umbilical cord blood are different from those found in Wharton's jelly. For an extensive review, see Troyer and Weiss.[93]

However, the potential use of MSCs derived from umbilical cord or cord blood in the treatment of cartilage defects in humans remains to be established. Although the availability and immunogenicity could be of advantage, no scientific data today exist that support the notion that the cells are of lineage other than the bone default pathway.

5.514.10. Conclusion

The development of human cell therapy for cartilage repair over the last decades has both changed the stage and the view of cartilage as a nonregenerating tissue. We have only started to understand the cartilage tissue regeneration and repair and the potential use of cells for curing patients suffering from cartilage defects and OA. The autologous chondrocytes harvest is so far the best cell source for cartilage repair although other potential sources for a more universal treatment might be around the corner.

Glossary

Articular cartilage The cartilage covering the articular surfaces of the bones participating in a synovial joint.
Compartmental model A mathematical model that simplifies the description of the behavior of spatially distributed physical systems into a topology consisting of discrete entities that approximate the behavior of the distributed system under certain assumptions.
Mechanobiology The study of how cells sense and respond to mechanical stimuli.
Modulus The physical measurement of stiffness in a material, equaling the ratio of applied load (stress) to the

resultant deformation of the material, such as compression, tension, or shear.

Osteoarthritis Arthritis characterized by erosion of articular cartilage, either primary or secondary to trauma or other conditions, which becomes soft, frayed, and thinned with eburnation of subchondral bone and outgrowths of marginal osteophytes; pain and loss of function result; mainly affects weight-bearing joints, is more common in old people and animals.

Rheology The study of the flow or deformation of materials.

Synovial fluid A clear thixotropic fluid, the main function of which is to serve as a lubricant in a joint, tendon sheath, or bursa; consists mainly of mucin with some albumin, fat, epithelium, and leukocytes; also helps to nourish the avascular articular cartilage.

Synovial joint A joint in which the opposing bony surfaces are covered with a layer of hyaline cartilage or fibrocartilage; there is a joint cavity containing synovial fluid, lined with synovial membrane and reinforced by a fibrous capsule and ligaments, and there is some degree of free movement possible.

Tribology The study of friction and its effects in biologic systems, especially in regard to articulated surfaces of the skeleton.

Viscosupplementation Intraarticular injection of a viscous agent, often hyaluronan-based compounds.

Abbreviations

ACL	Anterior cruciate ligament
BF	Bioengineered fluid
COL	Collagen
CPM	Continuous passive motion
ECM	Extracellular matrix
(s)GAG	(sulfated) Glycosaminoglycan
HA	Hyaluronic acid
IGF	Insulin growth factor
IL	Interleukin
LIF	Leukemia inhibitory factor
MMP	Matrix metalloproteinase
MW	Molecular weight
OA	Osteoarthritis
PG	Proteoglycan
PRG4	Proteoglycan 4
RA	Rheumatoid arthrtitis
SF	Synovial fluid
SZCs	Superficial zone chondrocytes
TGF	Transforming growth factor
TNF	Tumor necrosis factor

5.515.1. Introduction

Synovial joints are the most numerous type of joint in the body and allow for movement between long bones. Synovial joints, including the knees, hips, shoulders, elbows, and phalangeals, are characterized by articular cartilage, a connective tissue at the ends of the articulating bones, which is bathed in synovial fluid (SF), a viscous, lubricating fluid that is constrained within the joint by a fibrous joint capsule. Articular cartilage grows and matures through adulthood in response to physiological cues, including mechanical forces, while SF is an ultrafiltrate of blood plasma, filtered through the joint capsule with additional lubricant molecules secreted by local cell populations. The mechanical properties of these tissues allow for their physiological function. The extracellular matrix (ECM) of cartilage resists compression and tension, allowing for load-bearing during joint motion, while the viscous and lubricating properties of SF reduce cartilage wear due to articulation. The homeostasis of these tissues is dependent on mechanobiology – cell populations receiving mechanical cues to guide biosynthesis and thereby alter their microenvironment and tissue-scale mechanical properties.

Synovial joints are susceptible to damage from injury and disease, including osteoarthritis (OA). OA is an age-related degenerative joint disease characterized by erosion of articular cartilage, leading to joint pain and restricted motion. In addition to generalized cartilage erosion in OA, focal regions of degenerated or eroded cartilage are commonly seen during arthroscopy of non-OA joints. Treatment options for OA are limited, including injectible analgesics and total knee arthroplasty, while options for focal defects are more numerous, including auto- and allografts, and tissue-engineered cells and/or scaffolds, including autologous chondrocytes implantation and matrix-induced chondrocytes implantation, and a variety of other natural and synthetic, cellular and acellular scaffolds. Tissue engineering approaches to the treatment of cartilage degeneration are evolving toward more complex, biomimetic, and shaped constructs that can be used for even larger regions of cartilage damage and biological SF replacements.[1]

Advances in tissue engineering approaches to the *in vitro* development of articular cartilage and SF for the treatment and study of damaged synovial joints are covered in this chapter. Tissue engineering approaches are based on an understanding of human and animal joint physiology in health, injury, and disease, and data from and relating to those different states interpreted through analytical models (**Figure 1**). First, the composition, structure, and function of cartilage and SF, including the natural growth and development of cartilage and formation of SF, are discussed, followed by the mechanical properties of these tissues and the theoretical models that have been used to describe them, including a compartmental model for integrating different synovial joint tissue types. Next, the effects of mechanical stimuli on cartilage chondrocyte biosynthesis and pathological changes in SF composition and function are covered. Finally, advances in the tissue engineering of cartilaginous tissue and SF are reviewed, focusing on the mechanobiology of chondrocytes embedded in tissue-engineered constructs.

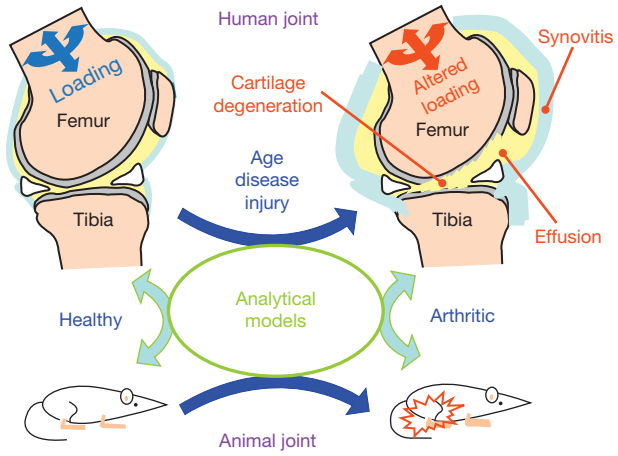

Figure 1 Schematic view of how data from the human system and animal models in normal and diseased states can be integrated and analyzed using models of the joint.

5.515.2. Articular Cartilage Maturation and Synovial Fluid Formation

5.515.2.1. Articular Cartilage Structure and Maturation

5.515.2.1.1. Overview

Articular cartilage is a connective tissue that covers the ends of long bones and functions as a load-bearing, low-friction, and wear-resistant surface to facilitate joint movement. Articular cartilage is composed of chondrocytes embedded in a hydrated and specialized ECM that consists mostly of collagen (COL) type II and proteoglycan (PG) (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses** and **Chapter 2.216, Collagen–GAG Materials**).[2] PG provides cartilage with compressive strength due to the fixed charge density of these molecules that create an osmotic swelling pressure. The COL network resists the swelling tendency of PG molecules and provides cartilage functional integrity, tensile and shear stiffness, and strength. Cell and matrix contents, as well as mechanical properties of cartilage, vary with depth from the superficial surface. During growth and maturation of articular cartilage, there are significant changes in cellular distribution, cartilage composition, structure, and mechanical function.

5.515.2.1.2. Composition

Chondrocytes, the main cell type of articular cartilage, contribute 1–10% of the total volume of cartilage and are responsible for maintenance of COL and PG by balancing synthesis and degradation. Cellular content and organization in articular cartilage vary with depth. Cell density is relatively high in the superficial zone (0–10% of total thickness)[3] and decreases by 59–67% in the deep zone (40–100% of total thickness).[4] The ECM of articular cartilage provides a suitable microenvironment to maintain chondrocytes' phenotype and biosynthetic homeostasis.[5] PG content ranges from 1 to 10% of total wet weight and increases with depth.[6,7] COL accounts for 10–20% of the wet weight of adult articular cartilage, is rich in the superficial layer, and is distributed evenly from middle to deep layer.[2,6–8]

5.515.2.1.3. Structure

Chondrocytes are arranged distinctly in the different zones of articular cartilage. In the superficial zone, cells are arranged in clusters parallel to the articular surface with a flattened morphology and smaller nuclei with similar shape. Cells in the middle region appear more rounded with some nuclei arranged in pairs. Cells in the deeper region of adult cartilage are organized into columns.[4,9]

The size and organization of collagen fibrils in articular cartilage varies with depth. Collagen in the superficial zone of adult cartilage consists of thin fibrils oriented parallel to the articular surface, while middle and deeper zones contain fibrils that are thicker and increasingly oriented in the vertical direction.[10] The depth-varying collagen structure contributes to the depth-dependent tensile and shear properties of cartilage.

5.515.2.1.4. Function

The PG content in cartilage, together with the COL network, is the major determinant of the tissue's compressive properties.[11,12] PG aggregates are large molecules formed as aggrecan monomers noncovalently associated with hyaluronan and stabilized by link protein. Each aggrecan monomer has a large number of sulfated glycosaminoglycan (sGAG) chains of chondroitin sulfate and keratan sulfate. The polyanionic sGAG moieties of aggrecan molecules, when restrained by the COL network, provide cartilage with a high osmotic pressure, a high tendency to retain water, and a high resistance to fluid flow. The swelling pressure exerted by the PG contributes to a high resistance to compression and the tensile stress of COL network.[13]

The COL network composition and organization, in part modulated by PG, appears to be the major determinant of cartilage tensile properties. The COL to PG ratio as well as COL network organization within the tissue correlates strongly with equilibrium tensile modulus of cartilage.[14,15] The balance of the swelling propensity of PG molecules and the restraining function of COL network influences tissue hydration, load-bearing, and tensile properties. *In vitro* inhibition of functional assembly of the COL network causes marked decrease in tensile strength of cartilage explants after 13 days in culture.[16,17] In immature cartilage, PG indirectly affects the tensile properties of cartilage. Depolymerization of chondroitin and dermatan sulfate glycosaminoglycan (GAG) chains of PG molecules by chondroitinase ABC[18] resulted in an increase in overall tensile modulus.[19–21] In addition, PG depletion in immature cartilage with guanidine markedly increases tissue tensile integrity.[16,17]

5.515.2.1.5. Cartilage maturation

Cellular density and organization in articular cartilage change markedly with growth and maturation. In bovine cartilage, cellular density undergoes minor changes from fetal to calf, but decreases significantly (~50%) from calf to adult. In the deep zone, chondrocytes of mature cartilage are arranged in columns, whereas those of immature cartilage do not exhibit zonal organization and appear similar to cells in the middle zone.[22]

The biochemical properties of articular cartilage change with growth and maturation. There are gradual alterations in COL network as well as COL and PG contents. At early developmental stages of cartilage, the COL network does not appear to organize in a zonal manner and orients parallel to the cartilage surface throughout the tissue.[23,24] As cartilage matures, its water content decreases markedly, COL and

pyridinoline crosslink densities increase, while PG density stays relatively constant.[12,15,25] At the young adult stage, the fibrils of the deep zone run predominantly perpendicular to the cartilage surface.[24] In adult tissue, COL fibers are arranged parallel to the articular surface in superficial zone, isotropic and random in the middle zone, and perpendicular in the deep zone.[10]

During growth and maturation of articular cartilage, the mechanical properties evolve toward that of the adult. In bovine articular cartilage, from the fetal stage, through the new born calf, and to the skeletally mature adult, cartilage becomes stiffer both in compression and tension as indicated by increases in equilibrium aggregate modulus (89 kPa in fetal, 197 kPa in newborn to 890 kPa in young adult bovine), equilibrium tensile modulus (2 MPa in calf to 5–6 MPa in young adult bovine), and tensile strength (4 MPa in calf to 15 MPa in young adult bovine).[5,16,17,26] The remarkable changes in biochemical and mechanical properties of cartilage with maturation may be due to regulation by mechanical and chemical factors. Once tissue reaches maturity, articular cartilage homeostasis in terms of composition and function is desirable.

5.515.2.2. Synovial Fluid Composition and Formation

5.515.2.2.1. Overview

SF is normally a clear, viscous liquid found inside synovial joints that functions as a biomechanical lubricant and as a medium for metabolites and soluble signaling factors. In the normal human knee joint, the volume of SF is on the order of 1 ml.[27] In their typical proportions and concentrations, the molecular constituents comprising normal SF give rise to its unique properties and functions in maintaining joint homeostasis. SF is composed of a blood plasma dialysate and molecules secreted by cells lining the synovial joint (**Figure 2**), including hyaluronic acid (HA) (see **Chapter 2.214, Hyaluronic Acid**) and proteoglycan 4 (PRG4, also known as lubricin and superficial zone protein). One main function of SF is to lubricate articulating joints, facilitating the low-friction and low-wear properties of cartilage. Additionally, it serves metabolic functions, facilitating the transport of nutrients, waste products, and other metabolites to and from synovial tissues. Finally, it mediates molecular communication by soluble factors between disparate cell populations in the joint.

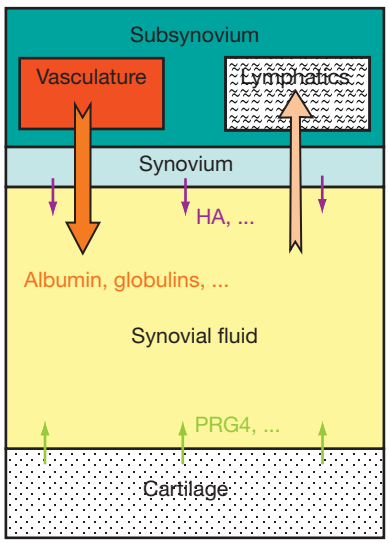

Figure 2 Schematic view of synovial fluid formation as an ultrafiltrate of blood plasma with additional lubricant molecules secreted by synoviocytes and chondrocytes.

5.515.2.2.2. Composition

5.515.2.2.2.1. Plasma proteins

The composition of SF reflects its origin as a plasma ultrafiltrate. The protein composition of SF is similar to that of plasma,[28,29] though synovium selectively retains most large plasma proteins in the vasculature and limits their entry into the synovial joint space. In normal human SF, the total protein content is 25–28 mg ml^{-1}, which is approximately one-third of the total protein concentration in plasma.[27,30] Large molecular weight (MW) plasma proteins, such as β_2 macroglobulin (1000 kDa), fibrinogen (340 kDa), β_1 lipoprotein (3200 kDa), α_2 macroglobulin (820 kDa), and α_2 glycoprotein (1000 kDa), are low or undetectable in normal SF as determined by immunoelectrophoresis, while small MW plasma proteins, such as albumin (69 kDa), α_1 glycoproteins, transferrin (90 kDa), and γ globulin (160 kDa), are found in high quantities in plasma and SF.[31,32] The most abundant macromolecule in SF is albumin (~10 mg ml^{-1}), which is found in SF at 40–45% of its plasma concentration, and is a major contributor to SF colloidal osmotic pressure and a minor contributor to SF viscosity.[33] Globulins are also present at ~0.5 mg ml^{-1}. SF does not contain fibrinogen.

5.515.2.2.2.2. Lubricant macromolecules

The main lubricating macromolecules present in SF are HA[34] and PRG4.[35,36] HA is a GAG consisting of repeating disaccharide units of D-glucuronic acid and D-*N*-acetylglucosamine. It exists in SF as a polydisperse population with 60–70% of the HA having a MW greater than 4 MDa and a weight average MW of 6–7 MDa.[37] The concentration of HA plays a major role in determining the viscosity of SF. In addition, HA provides outflow buffering, a phenomenon which decreases trans-SF loss under raised intraarticular pressures.[38] PRG4 is a mucinous glycoprotein with multiple O-linked β(1-3)Gal-GalNAc oligosaccharides, which mediate the molecule's function as a boundary lubricant,[39,40] and has a MW of ~300 kDa.[41] The PRG4 gene encodes a lubricating glycoprotein known as SZP, lubricin, or PRG4 found in SF, articular cartilage, synovium, and other synovial tissues.[42,43]

5.515.2.2.2.3. Cytokines and growth factors

Although a minor component of SF by mass, cytokines and growth factors, which include members of the transforming growth factor (TGF), interleukin (IL), and tumor necrosis factor (TNF) families, exert regulatory control over cell populations in the synovial joint (see **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**). These signaling factors may be derived from plasma through ultrafiltration or may be secreted by cells lining the synovial joint into SF. They can participate in intercell signaling, influencing cellular metabolism such as lubricant secretion rates. Proinflammatory cytokines, which have catabolic action in general, that are found in SF include IL-1α, IL-1β, TNF-α, leukemia inhibitory factor (LIF), IL-6, IL-8, IL-17, and IL-18.[44–46] Anti-inflammatory cytokines include IL-4, IL-10, and IL-13. Growth factors such as TGF-β1

and insulin growth factor 1 (IGF-1) have anabolic effects on tissues. Chondrocytes and synovial fibroblasts are the target of many of these biochemical signals.[47,48] By nature of its physical contact with all synovial joint tissues, SF serves as a medium through which these tissues, including cartilage, synovium, meniscus, and ligament, can interact.

5.515.2.2.2.4. Cells

Normal SF contains relatively few cells compared to whole blood. Monocytes and lymphocytes are the predominant nucleated cells present, with SF averaging ~63 nucleated cells per mm^3,[27] while erythrocytes are largely absent. Reference ranges for blood tests include $4.0–5.6 \times 10^6$ erythrocytes and $3.54–9.06 \times 10^3$ white blood cells per mm^3.[49]

5.515.2.2.3. Formation, molecular transport, and mechanobiology

5.515.2.2.3.1. Formation

SF is an ultrafiltrate of blood plasma with additional molecules secreted by cells lining synovial joints. The synovium functions as a semipermeable membrane that selectively retains and permits specific molecules based on size. The biosynthetic sources of SF lubricant molecules are the cell populations lining the synovial cavity, with synoviocytes mainly secreting HA and superficial zone chondrocytes (SZCs),[41] synoviocytes,[39,40,50,51] and meniscal cells[52] secreting PRG4. High MW species, such as the lubricant molecules HA and PRG4, are selectively retained within the synovial joint, while low MW species, such as most metabolic substrates and byproducts, cytokines, and growth factors, are not. Molecular sieving by the synovial membrane matrix is size dependent.[53] An active filtration process, together with secretory contributions from the cell populations lining the synovial joint, results in fluid with typical steady-state concentrations of 1–4 mg ml^{-1} HA[54] and 0.05–0.35 mg ml^{-1} PRG4.

5.515.2.2.3.2. Transport characteristics of synovium

Synovium, a highly cellular intimal tissue layer adjacent to the intraarticular space, is composed of ECM molecules, including HA, collagen, and PGs. It is the main barrier to the transport of molecules, such as lubricants, into and out of SF. Fluid flow through synovium occurs through the ~2 μm[55] wide intercellular regions of ECM, which has a hydraulic conductivity of $\sim 10^{-11}$ $cm^4(s^{-1}\,dyne^{-1})$ in rabbits.[33] Diffusive and convective passive transport of molecules occurs through pores in the ECM (~20–90 nm in diameter)[53,56] at these intercellular openings, making synovium permeability inversely related to molecule size. High MW lubricant molecules are retained in the joint, as the reflection coefficient of synovium to high MW HA has been reported as ~57–75%.[57]

5.515.2.2.3.3. Mechanobiology of lubricant-secreting cells

The secretion rates of the main lubricant molecules HA and PRG4 by synoviocytes and SZCs, respectively, are mechanosensitive. At the cellular level, HA secretion by isolated synoviocytes grown to confluence increased by 57% over 3 h when stretched by 10% for as little as 10 min.[58] At the joint scale, passive flexion of anesthetized rabbit knees resulted in a 100% increase in HA secretion over 5 h, decreasing the HA turnover time estimates from 17–30 to 8–15 h.[59] Dynamic mechanical shear of calf cartilage explants increased PRG4 expression to 300–400% of free-swelling and static compression controls.[60,61] In an experiment applying continuous passive motion (CPM) to *en bloc* calf knee joints, increased local cartilage superficial zone secretion rates of PRG4 correlated with areas in continuous or intermittent sliding contact with apposing surfaces.[62]

5.515.3. Mechanical Properties and Models of Articular Cartilage and Synovial Fluid

5.515.3.1. Biomechanics of Articular Cartilage

5.515.3.1.1. Types of mechanical loading during joint articulation

During normal joint articulation, cartilage is subjected to compression, shear, and sliding. When cartilage is compressed,[5] interstitial fluid pressurizes resulting in the load being mainly supported by hydrostatic pressure. As compression continues, fluid begins to exude out of the matrix, transferring load from interstitial fluid to the solid matrix and causing the cartilage to deform. Once equilibrium is reached, fluid flow out of the tissue ceases, and total load support is provided by the solid matrix.

5.515.3.1.2. Physiological loading of articular cartilage during gait

Articular cartilage deforms in response to joint loading. During normal activities such as walking or running, articular joint surfaces come into contact, roll, and slide past each other, subjecting cartilage tissue to both compression and shear. Knee cartilage is compressed by ~3–10% of its overall thickness following various physical activities, such as walking, cycling, running, and knee bending.[63,64] Under normal loading, talar cartilage appears to be compressed by 5–35%, with 42% of the contact area having compressive strain higher than 15%.[65] Cartilage also deforms in shear when subjected to combined compression and shear loads. For normal adult human femoral cartilage tested with normal SF, shear strain reached 5.6% near the articular surface and 2.8% overall, increasing markedly with degeneration to 28% and 4.1%, respectively.[66,67] After reaching a peak shear strain, with increasing lateral motion, cartilage surfaces slide relative to each other while peak shear is maintained.[66,67]

5.515.3.2. Rheology and Tribology of Synovial Fluid

5.515.3.2.1. Rheological properties

The rheological properties of SF have been characterized using measurements of viscosity and viscoelasticity. The viscosity of SF strongly correlates with the concentration of HA present.[68] SF exhibits non-Newtonian viscous behavior, acting as a shear-thinning fluid over a wide range of shear rates, with higher viscosities reported at higher HA concentrations.[69] Viscoelastic models of SF have demonstrated an elastic-like response from 'normal' SF at high frequencies of oscillation, with dynamic storage and loss moduli on the order of ~10 Pa, depending on shear rate.[70]

5.515.3.2.2. Tribological properties

Studies using a cartilage-on-cartilage friction test have identified HA and PRG4 as primary boundary lubricants in SF,[71,72] lowering friction in a dose-dependent manner, both alone and in combination.[73,74] Normal bovine SF values of boundary-mode kinetic friction coefficient in this setup were ~0.025. Cartilage on glass friction testing has shown that recombinant human lubricin lubricates cartilage in a dose-dependent manner and involves both lubricin bound to the surface and lubricin in solution.[75]

In addition to friction, the wear-reducing properties of SF have been measured in tissue- and joint-scale setups. Using a cartilage-on-cartilage system, the contributions of various SF lubricants to reducing wear have been determined.[6,7] Other counter surfaces have also been used to investigate cartilage wear, including stainless steel[76,77] and polymers.[78,79] At the joint scale, SF lubrication has been assessed using pendulum instruments on intact joints.[80]

5.515.3.3. Modeling Joint Tissue Biology

Tissue-level tissue engineering analyses rely on kinetic and physicochemical properties of the tissue components to develop models that are mechanistic, which are used to deduce the functional behavior of the system. Early models of the synovial joint focused on specific joint tissues. More recently, integrated models of the synovial joint have been developed and interactions between two or more joint tissues examined.

5.515.3.3.1. Models of individual joint tissues

Various models of SF have been constructed to explain its rheological properties and mechanical functions in synovial joints. The rheological properties of SF have been described as viscometric,[81] viscoelastic,[82,83] and as a Bingham plastic,[84] whose properties are primarily determined by the concentration and MW of HA, and recently as a micromorphic fluid containing deformable particles.[85] Several different mechanisms of SF lubrication of cartilage–cartilage contact have been suggested, including hydrodynamic and boundary modes as well as 'weeping' and 'boosted' lubrication. Hydrodynamic lubrication is generated by hydrostatic pressure in the SF because of cartilage loading and sliding.[86] Boundary mode lubrication occurs through direct cartilage–cartilage contact via monomolecular films that are chemically adherent to the cartilage surface.[87] 'Weeping' lubrication is a description of the flow of SF into and out of porous cartilage during compression and relaxation,[87] while 'boosted' lubrication describes pools of entrapped SF due to apposing cartilage surface irregularities where the lubricant concentrations are elevated as water is squeezed out.[88]

Cartilage has frequently been studied, with compartmental and continuous models at different scale levels detailing fluid and molecular transport in the tissue and mechanics under various conditions. Ion-exchange modeling revealed that the hydraulic permeability[89] and molecular transport[90] in cartilage are primarily determined by fixed charge density, which is proportional to the concentration of sGAG. Transport during cartilage loading has also been addressed using continuum-mixture theory[91,92] and, combined with solute-binding, porous media theory.[93] The transport and binding of molecules secreted by chondrocytes through the tissue have also been investigated in both compartmental[94] and continuous models.[95,96] The importance of cartilage interstitial fluid pressurization to support joint loading and reduce the effective friction coefficient was shown using a boundary friction model.[97] Poroviscoelastic models of cartilage have also been developed,[98] where the mechanical properties of the tissue are coupled to tissue composition, enabling study of the effects of changes in tissue composition, as might occur in certain disease states.

Fluid and mass transport through synovium play a major role in determining the composition of SF. Models of synovium compliance and hydraulic conductivity, based on pressure–volume measurements,[99,100] albumin[101] and macromolecular[102–104] transport through synovium, and the glucose transport through SF to cartilage,[102,104] have been described. In addition, the microvasculature physiology and exchange,[105] synovial perfusion measurement techniques,[106] and mass transport through synovium[102,104] have been reviewed previously.

5.515.3.3.2. Multicomponent models of the synovial joint

A few models have been developed to combine several joint tissues, allowing for computation and prediction of phenomena derived from multitissue interactions in the joint. Blewis *et al.*[107] constructed a compartmental model of the synovial joint to predict the dynamic recovery of steady-state SF lubricant concentrations. The model describes transport of lubricant molecules in four tissues: (i) SF surrounded by (ii) articular cartilage and (iii) synovium, which provides the outflow resistance and filtration of SF to the (iv) subsynovium. A mass balance is applied to the lubricant concentrations of HA and PRG4 resulting in a system of linear, first-order differential equations with three state variables that take into account rates of secretion, degradation, and flux across the synovial membrane. The behavior of the model can be analyzed under normal conditions and after specific perturbations, such as elevated cytokine levels, after joint lavage with saline, or after therapeutic injection of HA.

The Entelos PhysioLab® platform has been used to construct a mathematical model of rheumatoid arthritis (RA).[108] The model integrates inflammatory cells, endothelium, synovial fibroblasts, and chondrocytes within a synovial joint compartment, as well as cytokines and growth factors including IL-1β, TGF-β, IL-6, and TNF-α. Model predictions include synovial hyperplasia, cartilage degradation rate, bone erosion index, and soluble factor concentrations. The model can be used to predict different patient phenotypes in RA and determine the critical pathways that produce the observed phenotype *in silico*.

5.515.3.3.3. Extending current models of the synovial joint

5.515.3.3.3.1. Overview

An engineering framework for modeling of transport in the synovial joint is needed in order to utilize and interpret the wealth of molecular to tissue-scale information available (**Figure 3**). The transport of molecules within the synovial joint allows for the interactions between different joint tissues, making consideration of molecular transport an important

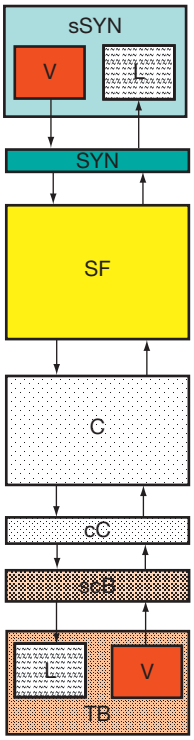

Figure 3 Generalized compartmental model schematic showing possible compartments, including the vasculature (V), lymphatics (L), subsynovium (sSYN), synovium (SYN), synovial fluid (SF), cartilage (C), calcified cartilage (cC), subchondral bone (scB), and trabecular bone (TB).

part of an integrated joint model (see **Chapter 3.309, Fluid Mechanics: Transport and Diffusion Analyses as Applied in Biomaterials Studies**). One possible approach is to generalize the molecular transport equations to allow for interactions between all molecules in the joint within a physiological framework, using experimental data to fill in the molecular concentration and secretion rates for different tissue states.

5.515.3.3.3.2. A generalized compartmental model of transport in the joint

Building upon the tissue-specific and partially integrated models discussed above, a generalized compartmental approach to modeling transport in the synovial joint[94,95,107] is described in this section. A schematic with possible compartments is shown in **Figure 3**, and the model variables and parameters are defined in **Table 1**. The equations can be grouped by purpose as the mass balance, transport, and physical coupling equations.

5.515.3.3.3.2.1. Mass balance equations For each compartment, the mass balance of each molecule considered is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[V^{\alpha}c_x^{\alpha}\right] = \left(\sum_{n=\beta}^{\varepsilon} J_x^{\alpha/n}\right) - \left(d_x^{\alpha}\right) - \left(b_x^{\alpha}\right) + \left(r_x^{\alpha}\right) \qquad [1]$$

where α represents the compartment under consideration, x each molecule, V the compartment volume, c the concentration of x in α, J the total mass flux directly to or from every other compartment, d the degeneration rate, b the binding of x in α, and r the secretion rate of x in α. Thus, to consider three compartments and 20 molecules, there would be 60 mass balance equations of this type to account for. The degradation, binding, and secretion rates are given as generic functions f of the relevant variables as their specific form will depend on which molecules and compartment are being considered. The degeneration rate of x in α

$$d_x^{\alpha} = c_x^{\alpha}V^{\alpha}f\left(\sum_{k=1}^{n_k} c_k^{\alpha}\right) \qquad [2]$$

is a function of the mass of x in α and the sum of the action by all catabolic mediators c_k, such as proteases, in the compartment. The binding rate of x in α

$$b_x^{\alpha} = f\left(c_x^{\alpha}, c_x^{*,\alpha}, c_l^{\alpha}\right) \qquad [3]$$

is a function of the concentration of x, the concentration of binding proteins c_l in the compartment, and c^* the concentration of x already bound

$$c_x^{*,\alpha} = f\left(b_x^{\alpha}t, c_x^{\alpha}\right) \qquad [4]$$

The secretion rate of x in α

$$r_x^{\alpha} = \chi^{\alpha}f\left(c_j^{\alpha}, F, \theta\right) \qquad [5]$$

is a function of the cell density, the concentration of cytokines c_j, and mechanobiology factors including loading F and articulation θ of the joint.

5.515.3.3.3.2.2. Diffusive and convective transport equations The diffusive and convective transport of mass J between each compartment is defined as

$$J_x^{\alpha/\beta} = p_x^{\alpha/\beta}\left[c_x^{\beta} - c_x^{\alpha}\right] + v_{\mathrm{H_2O}}^{\alpha/\beta}\left(1 - \sigma_x^{\alpha/\beta}\right)c_x^{\alpha} \qquad [6]$$

where v is the velocity of fluid from α to β, σ is the reflection coefficient of the boundary between α and β to x, and p is the permeability of x from α to β,

Table 1 List of variable units and descriptions for the generalized transport model

Variable	*Description*
c_i^{α} (mg cm^{-3})	Concentration of free i in α
$c_i^{*,\alpha}$ (mg cm^{-3})	Concentration of bound i in α
χ_i^{α} (cells cm^{-3})	Cell density of type i in α
$J_i^{\alpha/\beta}$ (mg s^{-1})	Mass of flux i from α' to β
d_i^{α} (mg s^{-1})	Degradation rate of i in α
b_i^{α} (mg s^{-1})	Binding rate of i in α
r_i^{α} (mg s^{-1})	Secretion rate of i in α
$v_{\mathrm{H_2O}}^{\alpha/\beta}$ (cm s^{-1})	Linear velocity of fluid from α to β
$p_i^{\alpha/\beta}$ (cm s^{-1})	Permeability of α to i
$k^{\alpha/\beta}$ (cm s^{-1} Pa^{-1})	Hydraulic conductance from α to β
$\sigma_i^{\alpha/\beta}$	Reflection coefficient of i from α to β
V^{α} (cm^3)	Volume of α
$A^{\alpha/\beta}$ (cm^2)	Surface area of α exposed to SF
P^{α} (Pa)	Hydrostatic pressure in α
Π^{α} (Pa)	Osmotic pressure in α
F (N)	Loading of joint
θ ($^{\circ}$ s^{-1})	Articulation of joint
t (s)	Time

$$p_x^{\alpha/\beta} = f\left(c_m^{\alpha}, c_m^{\beta}, \sigma_x^{\alpha/\beta}\right) \quad [7]$$

which depends on the concentration of structural molecules m in α and β and σ the reflection coefficient of the boundary between α and β to x.

$$\sigma_{x,\,H_2O}^{\alpha/\beta} = f\left(\sum c_x^{*,\,\alpha/\beta}, c_m^{\alpha,\beta}\right) \quad [8]$$

5.515.3.3.3.2.3. Physical coupling of the compartments

The compartments are coupled by the fluid flow and volume, which depend on the hydrostatic and osmotic pressures. The volume can be described by

$$V^{\alpha} = V_0^{\alpha} + \sum_{n=\beta}^{\gamma}\left(v_{H_2O}^{\alpha/n} A^{\alpha/n} t\right) + V_{Cells}^{\alpha}(t) \quad [9]$$

where V_0 is the initial volume, A is the area between compartments α and n, and V_{Cells} is the volume of additional cells in the compartment, such as red blood cells entering due to injury. The velocity of fluid moving between compartments can be described by

$$v_{H_2O}^{\alpha/\beta} = k^{\alpha/\beta}\left[\left(P^{\beta} - P^{\alpha}\right) - \sigma_{H_2O}^{\alpha/\beta}\left(\Pi^{\beta} - \Pi^{\alpha}\right)\right] \quad [10]$$

where the hydrostatic pressure P, osmotic pressure Π, and hydraulic conductance k are given as generic functions whose explicit form would depend on the compartment under consideration.

$$P^{\alpha} = f(V^{\alpha}, F, \theta) \quad [11]$$

$$\Pi^{\alpha} = RT\left(\sum c_x^{\alpha}\right) \quad [12]$$

$$k^{\alpha} = f\left(c_m^{\alpha}, V^{\alpha}, P^{\alpha}\right) \quad [13]$$

5.515.3.3.3.3. Example of model setup

There are a large number of interactions, concentrations, and secretion rates to define in order to implement a model based on this generic description. However, both protein- and genomic-level experimental data can suggest values for many of these variables from a single tissue source and tissue state, as well as how those values are altered during disease or injury (see **Chapter 5.513, Systems Biology in Biomaterials and Tissue Engineering**).

One example would be to focus on concentrations and secretion rates for lubricant molecules HA and PRG4 in SF. The most important compartments for this example are the synovium, SF, cartilage, and subchondral bone, especially if a disease state such as OA is to be considered. After defining initial values and rates, the system of equations would be solved numerically. Analysis of the system could include the effects of different perturbation stimuli relevant to the clinical situation: hemarthrosis by influx of blood and cells into the SF compartment, inflammation by increasing specific cytokine levels, OA by degeneration of cartilage structural molecules, and focal defects in cartilage by allowing fluid flow from the subchondral bone directly to SF.

Integration of the large amounts of experimental data with a model based on classical transport analysis will allow for the description of emergent system properties and molecular interactions with the goal of discovering novel clinical diagnostic, intervention, and treatment strategies.

5.515.4. Mechanical Effects on Cartilage Maturation and Synovial Fluid Pathology

5.515.4.1. Effect of Mechanical Stimuli on Cartilage Maturation

5.515.4.1.1. Overview

Mechanical cues resulting from joint loading and tissue deformation modulate chondrocyte and cartilage metabolism and cause coordinated changes in biochemical and mechanical properties of articular cartilage.[109–111] Hydrostatic pressure can modulate cartilage biosynthesis to various degrees depending on the magnitude, frequency, and duration of pressurization. Application of static compression inhibits collagen and PG biosynthesis in cartilage explants, whereas dynamic compression or dynamic shear superimposed on static compression offset at certain magnitudes and frequencies stimulates matrix metabolism (see **Chapter 5.502, Engineering Scaffold Mechanical and Mass Transport Properties**; **Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation**; and **Chapter 5.506, Effects of Mechanical Stress on Cells**).

5.515.4.1.2. Effects of mechanical loads on cartilage metabolism

5.515.4.1.2.1. Hydrostatic pressure

Hydrostatic pressure is a physiological factor that regulates cartilage biosynthesis independently of other factors such as cell/matrix deformation, fluid flow, or electrokinetic effects. Continuous or intermittent pressures of <3 MPa may[112–114] or may not[115] affect PG synthesis in normal articular cartilage. Higher pressures (5–50 MPa) modulate cartilage biosynthesis to various degrees depending on the magnitude, frequency, and duration of pressurization. Hydrostatic pressure in the presumably physiological range (~5–15 MPa) in the short term (up to 2 h) increased aggrecan and collagen biosynthesis, but higher pressures (20–50 MPa) had no effect.[113] Cartilage biosynthesis was inhibited with longer exposure (2 h) to pressures of 30–50 MPa. PG synthesis was upregulated in a subsequent 2 h following a single application of 5–15 MPa pressure for 20s or for 5 min, but was not altered with a single application of higher pressures (20–50 MPa).[113] The frequency of the applied pressure is also important as a 0.5 Hz cyclic 5 MPa pressure was shown to stimulate biosynthesis, while the application of the pressure with same magnitude at 0.0167–0.25 Hz did not have any effect on synthesis.[116]

5.515.4.1.2.2. Static compression

Static compression inhibits collagen and PG biosynthesis in cartilage explants. The inhibition of biosynthesis depends on the stress (or strain) magnitude as well as the duration of the applied load. At low level of compressive stress (<0.06 MPa), the protein synthesis rate was not significantly altered, whereas at higher levels of stress (0.06–3 MPa) or strain (10–50%), aggrecan synthesis was reduced 20–80% compared to that in unloaded cartilage explants.[117–121] Different zones of articular cartilage appear to respond similarly to static compressive

loading.[120] Inhibition of collagen and PG synthesis occurs within 1–2 h of load application and is increased under prolonged static compression (~24 h).[60,61,122,123] In contrast to the inhibition of protein synthesis, static compression causes a transient increase in transcripts of genes encoding for matrix proteins such as aggrecan and type II collagen within 1–8 h after loading,[124,125] followed by decreased expression to control levels while upregulating the expression of matrix proteases (MMP-3 and MMP-13), ADAMTS-5, and TGF-β.[125,126] The gene-expression patterns during 24 h of subsequent static compression are time-dependent and depend on intracellular calcium and activation of cyclic AMP.[125]

5.515.4.1.2.3. Dynamic compression

Dynamic compression superimposed on static compression offset at certain magnitudes and frequencies can regulate matrix metabolism.[60,61,111,119,127–130] In the radially unconfined compression configuration with a nonporous counter-surface, oscillatory strains of 1–5% at >0.01 Hz significantly stimulated collagen and aggrecan synthesis, whereas the same strain magnitude at lower frequencies <0.001 Hz had no effect on biosynthesis.[119,127,128] Other studies reported that unconfined dynamic compression in high frequency range (0.5 Hz) with a porous counter-surface had inhibitory effects on PG synthesis.[131] The inhibition was proportional to the applied stress, but not dependent on loading time. However, this loading protocol reversed the catabolic effect of IL-1 on mature bovine cartilage.[132] During 24 h of oscillatory compressive loading, the expressions of genes encoding for matrix proteins such as aggrecan and type II collagen, matrix metalloproteinases (MMP-3 and MMP-13), and ADAMTS-5 were upregulated,[133] indicating an increase in matrix metabolism. The gene-expression patterns depend on intracellular calcium and activation of cyclic AMP, as well as ERK1/2 and p38 activation,[134] suggesting that MAPK pathway is a central conduit for transducing mechanical forces into biological responses in cartilage.

5.515.4.1.2.4. Dynamic shear

Dynamic shear stimulation of cartilage explants markedly increased biosynthesis and expression of PG, collagen,[133–136] and PRG4.[137,138] Dynamic shear loading at 1–3% strain amplitude at frequencies between 0.01 and 1.0 Hz stimulated the synthesis of protein by approximately 50% and PGs by approximately 25%.[136] The stimulatory effect was relatively uniform in the radial and vertical directions, which was likely associated with uniform deformation of cells and pericellular matrix caused by simple shear loading. Levels of PRG4 expression and accumulation were increased by applying shear stress, depending on location within the knee, and decreased to control levels with the use of a specific inhibitor of TGF-β receptor type I kinase. CPM applied to whole joints in a way dependent on the duty cycle of cartilage sliding against opposing tissues also modulates PRG4 synthesis. In regions that were continuously or intermittently sliding against meniscus and tibial cartilage, PRG4 synthesis was higher with CPM than without.[62]

5.515.4.1.3. Effects of mechanical loads on cartilage composition, structure, and function

Both short- and long-term applications of compression and/or shear loads *in vitro* and *in vivo* modulate cartilage composition,[62,120,139] structure,[140,141] and function.[138,142] Cartilage regions that are continuously or intermittently sliding against meniscus and tibial cartilage expressed more PRG4 than noncontact regions.[62] In animal studies for extensive times (3–4 months), *in vivo* cyclical joint loading by repetitive flexion did not alter collagen content or cartilage thickness, but appeared to increase PG (normalized to collagen) content in mature articular cartilage by ~60%.[139] Mechanical loads have also been shown to induce age- and zone-dependent alteration in collagen structure of articular cartilage. The birefringence of collagen increased in the superficial zone cartilage, but decreased in the deep zone when cartilage was subjected to *in vitro* dynamic compression.[140] Running exercise increased cartilage collagen birefringence, indicating either a higher degree of fibril assembly and organization or increased amount of collagen, or both, in young pigs, but decreased birefringence in older pigs.[141] A short application of cyclic compressive load to cartilage explants *in vitro* induced a transient increase in denatured collagen and hydraulic permeability, and weakening of the collagen network compared to unloaded controls while it did not alter total collagen and sGAG contents.[120,142]

5.515.4.2. Synovial Fluid Pathology

5.515.4.2.1. Overview

The composition and function of SF are altered in injury and disease, because of inherent changes in both SF and other joint structures. SF is in direct contact with cartilage, synovium, meniscus, and ligament, which are themselves altered in injury and disease. Changes in cellular metabolism and structure in these tissues may be reflected by changes in SF composition and function. Such changes in SF, in particular reduced ability to lubricate joint articulation and an altered cytokine environment (**Figure 4**), are believed to contribute to joint pathologies including OA and RA. Thus, the disease-associated changes observed in SF likely contribute to and are exacerbated by the effects of pathology on other tissues.

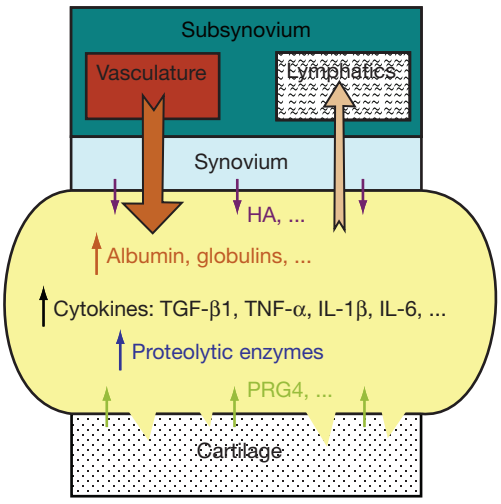

Figure 4 Schematic view of synovial fluid pathology including effusion, synovial hyperplasia, and altered protein, cytokine, and enzyme composition.

5.515.4.2.2. Changes in composition

5.515.4.2.2.1. Plasma proteins

Inflammation of the synovium, likely increasing synovium permeability, as occurs in RA, is associated with an increased protein content in SF. RA SF has an increased content of globulin and glycoproteins compared to normal SF, and the globulin content increases more than the increase in albumin such that the distribution of proteins in SF approaches that of proteins in serum. Similarly, a relative increase in α_2 glycoproteins in SF is observed in patients with RA, resulting in the distribution of glycoproteins in RA SF to approach that of serum.[31] Serum proteins can be detected in RA SF by immunoelectrophoresis, and in particular, large MW proteins such as β_2 macroglobulin, fibrinogen, β_1 lipoprotein, and α_2 macroglobulin which are low or absent in normal SF are significantly elevated in RA SF.[32]

5.515.4.2.2.2. Lubricant macromolecules

The concentration and quality of lubricant molecules are altered in different ways in OA, RA, and injury. Changes in SF HA in OA and RA have been reviewed elsewhere.[68] Briefly, the concentration of HA in SF is decreased in RA samples and, to a lesser extent, in OA samples. The MW of HA in OA is much lower than is found in normal SF, while the MW of HA in RA is only slightly smaller than that found in normal SF. In patients undergoing total knee arthroplasty, those requiring revision surgery for prosthetic failure have lower concentrations of HA.[54] Following acute injury, there is an increase in elastase activity and decrease in lubricin concentration and lubricating ability in SF, as well as an increase in cartilage degradation.[143] Sheep meniscectomy models of early OA show cartilage degeneration associated with a downregulation in PRG4 expression by SZCs.[144] In patients with the genetic disease camptodactyly-arthropathy-coxa vara-pericarditis syndrome (CACP), an autosomal recessive disease with loss-of-function mutations in the PRG4 gene, precocious cartilage degeneration and joint failure are observed.[145] PRG4 gene knockout mice develop fibrillation in the cartilage surface, loss of SZCs, and synovial hyperplasia, indicating the importance of PRG4 in maintaining joint homeostasis.[146]

5.515.4.2.2.3. Cytokines and growth factors

Alterations in cytokine levels in SF occur in joint disease and after injury.[45,46,147] In SF of ACL deficient knees, levels of IL-1β, IL-6, IL-8, and TNF-α are increased and level of IL-1RA is decreased compared to that in SF of uninjured knees.[148] Increased cartilage degeneration is also associated with higher levels of IL-1β and lower levels of IL-1RA.[149] Modulation of cytokine activity has been explored as a therapeutic approach. In a rat ACL injury model, inhibition of TNF-α with etanercept resulted in higher levels of lubricin in SF and on the cartilage surface, lower PG release from cartilage, and lower whole joint coefficient of friction values compared to untreated groups.[150]

5.515.4.2.2.4. Proteolytic enzyme activity

Proteolytic enzyme concentrations and activities are altered in the SF of joints in disease states that involve deranged cartilage matrix metabolism. Alterations in proteolytic activity are often inferred by measurements of degradation product levels. In a study of SF from patients with ACL rupture, measures of aggrecan fragments, stromelysin-1, and tissue inhibitor of metalloproteinases-1, all markers of cartilage matrix metabolism, first increased acutely and then decreased with time. In addition, symptomatic patients during the chronic phase had higher levels of degradation marker concentrations compared to asymptomatic patients.[151]

5.515.4.2.3. Changes in formation and molecular transport

Synovium in pathological joints displays altered transport characteristics and rheological properties, directly affecting the composition of SF. The permeability of synovium from joints with RA to proteins is increased,[152,153] with proportionately larger increases in permeability for larger proteins.[154] Increased Starling pressure due to the reduced oncotic gradient as protein accumulates in SF and increased permeability of capillaries during inflammation contribute to the buildup of fluid and protein in RA SF. The transport characteristics of synovium in OA are less affected than in RA, with significantly lower permeabilities to proteins measured over a range of MW.[155]

5.515.4.2.4. Changes in rheology and tribology

Pathological SF displays altered rheological properties. Lower viscosity and lower MW of HA have been reported in SF from OA joints, and much lower viscosity and low concentrations of HA in SF from joints with inflammatory disease, such as RA. In a rabbit knee injury model, SF boundary lubricating ability, determined by an artificial bearing system under load, and lubricin concentrations were decreased at weeks 2 and 3 after injury.[143]

5.515.5. Engineering Cartilaginous Tissue and Synovial Fluid

5.515.5.1. Engineered Cartilaginous Tissue

5.515.5.1.1. General overview

Engineered cartilaginous tissues can be formed by chondrocytes embedded in a hydrogel or seeded onto a scaffold (see **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**; **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design** and **Chapter 5.502, Engineering Scaffold Mechanical and Mass Transport Properties**). Hydrogels include polyethylene glycol (PEG),[156,157] agarose,[158,159] and others.[160] Scaffolds include polyglycolic acid.[129,130,161–163] Substrates include polyurethane[164,165] and calcium phosphate.[166] Alternatively, constructs can be formed scaffold-free.[167–169] Constructs may be subjected to different biological or mechanical stimuli to elicit particular responses that enhance composition (determined by ECM analysis or gene expression), structure (determined by histology or microscopy), and function (determined by biomechanical measurements).

5.515.5.1.2. Bioreactors

As mechanical forces play an important role during development and maturation, engineered tissues may be formed *in vitro* under controlled situations by application of

biophysical stimuli such as hydrostatic pressure, compression, tension, perfusion, and shear in a bioreactor. The combination of such mechanobiological stimuli with anabolic growth factors modulates the biosynthetic response (structure, composition, expression) and resulting tissue's functional biomechanical properties. The use of a bioreactor to deliver forces and flows to chondrocytes requires knowledge of how cells react to a particular stimulus, and the amount of stimuli needed to elicit a response. Such information may be gathered from *in vivo* kinematic studies and *in vitro* studies on whole joints or explants.

5.515.5.1.3. Effects of physical stimuli on cartilaginous tissue growth and maturation

5.515.5.1.3.1. Hydrostatic pressure

Static and dynamic hydrostatic pressures have been used as physical factors in cartilage tissue engineering. Continuous[169–173] or intermittent[168,169,174,175] pressures ranging from 3.4 to 10 MPa increased chondrocytes PG and collagen synthesis and construct compressive biomechanical properties.

PG biosynthesis by chondrocytes in 3D culture appears to respond differently on the basis of the magnitude of static hydrostatic pressure. In scaffold-free constructs, at low hydrostatic pressure (1 MPa), PG content did not appear to be elevated; however, at higher pressures (5 and 10 MPa), PG content increased.[169] At this same level, anabolic PG synthesis and mRNA expression for aggrecan and collagen II were markedly elevated.[171,172] Whether the effect of even higher hydrostatic pressure regimes on engineered cartilage has an anabolic or catabolic effect on chondrocyte biosynthesis remains to be determined.

The composition and functional response of chondrocytes in 3D culture to dynamic hydrostatic pressure is markedly different from that of static pressure. Dynamic pressure amplitude and frequency, and duty cycle play a role in affecting the mechanobiological response. At low dynamic hydrostatic pressure (3.4 MPa), and low frequency (0.25 Hz), little or no change in PG content was evident.[174,175] However, at higher pressure amplitudes and frequencies (5–10 MPa, 1 Hz), PG and collagen II content increased.[169,174,175] The exact duty cycle remains to be determined. The equilibrium Young's modulus of scaffold-free, chondrocytes-derived constructs increased when cultured under static or dynamic pressure compared to free-swelling conditions. Addition of growth factors, such as TGF-β1, during static culture also resulted in an increased modulus.[169]

5.515.5.1.3.2. Perfusion

Perfusion bioreactors are often used in cartilage tissue engineering.[161–163,176,177] One objective of such a bioreactor is to develop dynamic laminar flow conditions which may enhance cellular biosynthesis. Engineered constructs in perfusion bioreactors have been maintained for up to 7 months, with functional properties reaching similar values to that of native calf articular cartilage, and with matrix content, synthesis rates, and structural changes (COL, crosslink formation) increasing during the culture duration. Supplementation with IGF-1 during culture in the perfusion bioreactor can result in improved GAG, but not COL.[178] Constructs cultured in TGF-β1 during culture showed increases in type II collagen gene expression. Gene expression for type II collagen increased further when constructs were cultured in TGF-β1 and IGF-1.[177] Construct biomechanical properties are typically improved during dynamic perfusion culture, with increases in confined compression modulus (from ~0.2 to 0.4 MPa), and in Young's modulus (0.075–0.125 kPa).

5.515.5.1.3.3. Static compression

Static compression modulates the metabolism of chondrocytes in PGA and agarose-based cartilaginous constructs by inhibiting PG and COL biosynthesis.[129,130,158,179] *In vitro*, free-swelling cartilaginous constructs appear to be PG rich, but with reduced collagen content, and with biomechanical properties that are inferior to (~25% of) that of native articular cartilage.[180] Compressive loading (up to 50% for 24 h) suppresses PG and COL by 35 and 57%, respectively. Uniaxial static compression of up to 50% inhibits the expression of COL type I and II mRNA in chondrocyte-seeded COL I gels.[179] Static compression also reduces thymidine uptake by chondrocytes in agarose, suggesting decreased cell proliferation.[158]

5.515.5.1.3.4. Dynamic compression

Similar to its effect on native articular cartilage, dynamic compression modulates the composition, structure, and function of tissue-engineered cartilage. Dynamic compression at amplitudes of 3–5% has stimulatory effects on synthesis that are dependent on the static offset compression amplitude (10–50%) and dynamic compression frequency (0.001–3 Hz).[129,130,158,159,181–183] PG synthesis increases at 1 Hz compared to 0.3 Hz. However, collagen synthesis appears to be inverse of PG synthesis, being higher at 0.3 Hz compared to 3 Hz. The construct compressive modulus also increases for samples subjected to dynamic loading during culture when compared to free-swelling controls.[166,181,183,184] Nitrite production also appears to be suppressed when under dynamic loading compared to free-swelling controls. Cyclic loading can also increase catabolic MMP-3 and MMP-13 gene expression, in association with MAPkinase pathway signaling.[185]

The composition and function of engineered constructs can also be modulated by growth factors TGF-β1 and IGF-1 during dynamic loading.[159] PG and collagen content are stimulated by such cytokines and increase as culture duration increases, with even greater increases for samples subjected to dynamic loading. The construct compressive modulus in one study increased threefold over static cultures.[159]

The duty cycle of the dynamic compression protocol is likely important in determining the effects of the mechanical stimulation. Accounting for duty cycle, whether intermittent or continuous over experimental duration, is important for interpretation and comparisons of experimental data.

5.515.5.1.3.5. Dynamic shear

Dynamic shear generally increases chondrocytes matrix synthesis, leading to increased construct modulus. Application of 2% cyclic shear strain amplitude at 1 Hz to chondrocytes cultures stimulated PG and COL synthesis compared to free-swelling controls, with threefold increases in compressive modulus.[186] Such results demonstrate that intermittent application of dynamic shearing forces over a culture period improves the quality of cartilaginous tissue formed *in vitro*.

Fluid shear stress has also been shown to increase matrix composition and tensile biomechanical properties of engineered cartilaginous tissues.[129,130,187] In a stress-dependent manner, type II collagen was the highest in the high shear-stress group (0.1 Pa) when compared to lower shear-stress groups (0.001 Pa) and free-swelling controls. Type I and II collagen gene expression also increased after shear-stress stimulation. However, less PG was retained in the samples under high shear. Tensile Young's modulus (5 MPa) and failure strength (1.3 MPa) were also increased for samples under high shear.

5.515.5.1.3.6. Sliding

Engineered cartilaginous constructs may also be subjected to sliding to elicit a response in mRNA levels of anabolic or catabolic ECM genes, as well as PRG4.[164,165] A combination of static (10%) and dynamic compression (0–10%, 0.1 Hz) and shear ($\pm 25^{\circ}$) of chondrocytes seeded into a polyurethane scaffold stimulated PRG4 and cartilage oligomeric matrix, as well as increased collagen II mRNA expression. Aggrecan and TIMP-3 were also upregulated, suggesting that the mechanical effects applied by the surface motion can contribute to the maintenance of the chondrocyte phenotype of the seeded cells.

5.515.5.2. Tissue Engineering Synovial Fluid

5.515.5.2.1. Overview

The fabrication of synthetic or tissue-derived SF could be useful for a number of applications, including clinical treatment of OA joints and experimental use as a lubricant for cartilage friction, as well as wear testing at the tissue and joint scales. SF is altered in pathology, as described above, with changes to the protein content, lubricant composition, cytokine and growth factor environment, and proteolytic enzyme activity. Clinically replacing or supplementing such diseased SF with a lubricating and cartilage wear-reducing substitute fluid may provide pain relief and reduce the abnormal friction and wear that leads to further cartilage degeneration. Experimentally, SF is needed to replicate the *in vivo* environment during cartilage friction, wear, and biomechanical testing. Such testing has been done on cartilage explants and osteochondral cores at the tissue scale, as well at the joint-scale using pendulum testing and with a CPM device.

5.515.5.2.2. Viscosupplementation

Viscosupplementation of SF with exogenous preparations, typically HA-derived molecules, is used for intra-articular injection as an analgesic treatment for OA knees, though the mechanism of effect is not well defined. Several different preparations of HA-derived molecules are available clinically, including Euflexxa, Hyalgan, Synvisc, Supartz, and Orthovisc. Injection timing varies with preparation, ranging from one injection per 6 months to a program of weekly injections for several weeks. The clinical effects of such treatment typically show reduction in pain and modest improvement in function scores in the 5–13 week range postinjection. Several meta-analyses have been prepared summarizing the clinical data on such viscosupplements.[188,189]

5.515.5.2.3. Biomimetic approaches

Tissue engineering and tissue culture methods have also been used to generate a synoviocyte-derived lubricious fluid with viscosity and friction-reducing qualities approaching those of SF. On the basis of a model description of the biosynthesis, clearance, and degradation of lubricant molecules under specific cytokine conditions,[107,190,191] a bioreactor coculture system was designed and tested. The bioreactor contained two compartments separated by a semipermeable membrane. The first compartment contained synoviocytes in cell culture and cartilage explants, separated from the second compartment by the membrane, allowing for selective retention of high MW lubricant molecules on the basis of the pore size. The second compartment contained culture medium, providing nutrients to the cells and explants by diffusion through the membrane. The transport rates of HA and PRG4, as well as the biosynthesis rates of these molecules in the bioreactor were assessed in the bioreactor.[190,191] After 12 days in culture, the bioengineered fluid (BF) in the first compartment contained lubricant molecules HA and PRG4 in similar concentrations to normal SF, and the friction coefficient of the fluid in a cartilage-on-cartilage friction assay approached that of normal SF. The friction coefficients were negatively correlated with lubricant concentration. This biomimetic, tissue engineering approach created a BF biomaterial with similar lubricant composition and function as native SF. This type of bioreactor system may have application in generating BF for identifying molecules involved in lubricant regulations, experimental use in cartilage and joint friction and wear testing, and in developing viscosupplementation products.

5.516.1. Introduction

Articular cartilage is an avascular, aneural tissue lining the surface of diarthrodial joints. This anisotropic tissue is composed of a superficial, middle, and deep zone. The articular cartilage zonal structure is generally consistent between species; however, considerable differences exist in thickness, cell distribution, and matrix properties.[1,2] The zonal architecture consists of variance in the organization of the collagen network which plays a significant role in the tensile and compressive properties of the tissue.[3] Specifically, the collagen fibrils are responsible for the anisotropic nature of the articular cartilage tissue. For instance, in the superficial zone, collagen fibrils are aligned parallel to the articular surface, thereby providing high tensile strength to endure the joint loading stresses. The middle zone consists of randomly oriented collagen fibers which allow the progression to the deep zone in which the fibers are aligned perpendicularly to the subchondral bone.[4]

While collagen is the most abundant component of cartilage, large aggregating proteoglycans are a large constituent as well. In fact, the proteglycan aggregates increase from the articular surface to the deep zone, even in fetal cartilage.[5] The aggregates comprise a hyaluronic acid backbone that has aggrecan monomers attached. The monomers consist of a core protein that is extensively glycosylated with negatively charged chondroitin sulfate (CS) and keratan sulfate glycosaminoglycans (GAGs). One contribution to the zonal variation in GAG content is the significant differences in the metabolic properties of the chondrocytes from different zones.[6,7] Chondrocytes from each zone have unique growth rates, gene expression, and levels of biosynthesis.[8] For example, chondrocytes from the superficial layer show enhanced superficial zonal protein (SZP) expression, while chondrocytes from middle and deep zones exhibit increased type II collagen expression.[9] The increase in collagen and GAG provides the mechanical properties for efficient distribution and transmission of loads across the joint surface to the subchondral bone.[10] This subject matter is treated at much greater length in the previous chapter.

Because of its avascularity, articular cartilage is considered hypoxic in comparison to other tissue types.[11] Levels of oxygen (O_2) are estimated between 5% and 7%, which is perhaps the reason as to why articular chondrocytes have few mitochondria.[12] Consequently, metabolism is largely anaerobic with little capacity for oxidative phosphorylation.[11,13,14] Recent evidence shows that O_2 tension is a critical parameter affecting chondrocyte phenotype, gene expression, and morphology.[15] For example, studies have shown a shift in energy metabolism, following chondrocyte introduction to a monolayer culture environment, from a characteristically glycolytic to an oxidative metabolism.[16] As a result, there is an increase in reactive oxygen species (ROS), and therefore 5% of oxygen consumption in the electron transport chain is diverted into superoxide production.[17] In turn, the enhanced ROS generation presents detrimental implications for long-term cell expansion especially in the case of articular chondrocyte transplantation, a technique expanding chondrocytes in monolayer under atmospheric oxygen tension.[18]

Tissue engineering has emerged as a promising potential for treating tissue damage and tissue loss to millions of people each year.[19] The fundamental approach is the use of cells, scaffolds, and signaling molecules, separately or in combination. Cartilage's limited ability to self-repair makes it an ideal

candidate for tissue engineering. This chapter will discuss approaches in articular cartilage repair with an emphasis on cell sources, biomaterials, and growth factors.

5.516.2. Cell Sources

First-generation autologous chondrocyte implantation (ACI) introduced autologous chondrocytes into the clinical setting after *in vitro* culture expansion.[20] As mentioned previously, monolayer expansion of chondrocytes alters phenotype, gene expression, and morphology. As a result, this early technique led to spindle-shaped fibroblast-like cells that secreted fibrous tissue or fibrocartilage when implanted *in vivo*. Later generation ACI techniques are in development and are an attempt to preserve the chondrogenic phenotype through the use of three-dimensional implants. Understanding the importance of the cell population has embarked efforts into selecting a chondrocyte subpopulation that possesses a specific marker profile predictive of the capability to form stable hyaline cartilage.[21]

Mesenchymal stem cells have also been investigated because of the limited proliferative capacity of the chondrocytes as well as their propensity to dedifferentiate *in vitro*. Numerous studies comparing the chondrogenic ability of various MSC sources show exceptional results with bone marrow-derived mesenchymal stem cells (BM-MSCs).[22,23] BM-MSCs are available in large quantities, and are able to differentiate into chondrocytes in response to chondrogenic signals.[24] These attractive characteristics lead to the introduction of culture-expanded BM-MSC implantation in the clinical setting to treat cartilage defects.[25] Thereafter, autologous matrix-induced chondrogenesis (AMIC) became a technique using local, unprocessed BM-MSCs recruited from the microfracture site onto a scaffold implanted *in situ*.[26] More recently, minimally processed BM-MSCs have been introduced in the clinical setting via the bone marrow aspirate concentrate (BMAC) technique. BMAC uses laboratory procedures within the operating room to isolate and concentrate the MSCs resident in the nucleated cell portion of the bone marrow for reimplantation.[27]

5.516.3. Scaffolds

A wide range of natural and synthetic materials are currently under investigation for cartilage tissue engineering. An ideal scaffold provides a three-dimensional environment that will enable the production of cartilaginous tissue. The scaffold should be biocompatible, resorbable, and mechanically stable to supply temporal support for the implanted cells, and allow diffusion of nutrients and waste products. Scaffolds are designed to degrade overtime while permitting sufficient time for extracellular matrix (ECM) tissue production, usually through hydrolytic or enzymatic degradation. Determining the balance of degradation is a pertinent factor as investigations have shown that slow degradation may impede new cartilaginous ECM production, while fast degradation may compromise structural support and shape retention.[28] Another important parameter when designing a scaffold is cell seeding density and seeding method. Many approaches show high seeding densities to facilitate greater ECM synthesis, most likely because of cell–cell interactions.[29,30]

Natural polymers explored frequently in tissue engineering include agarose, alginate, cellulose, chitosan, CS, collagen, fibrin, gelatin, and hyaluronic acid (HyA). Natural polymers exhibit bioactivity with cells via cell surface receptors thereby allowing regulation of cell function. As a result, this interaction may stimulate an immune response limiting the control of the materials degradation kinetics. In contrast, synthetic polymers do not exhibit cellular interaction unless it is a hydrophobic material or specific chemical functional groups are incorporated. Current synthetic polymers investigated for cartilage engineering include poly(α-hydroxy esters), poly(ethylene glycol/oxide), poly(NiPAAm), poly(propylene fumarate), poly(urethane), poly(vinyl alcohol), and self-assembling peptides. Unlike the case of natural polymers, *in vivo* synthetic polymer degradation and diffusion kinetics can be readily modified; but there are disadvantages with synthetic polymers such as toxic degradation by products causing inflammation and cell death.[31] Thus, each specific application will dictate scaffold of choice. One pertinent factor is the scaffold architecture, as it has been observed to play a significant role in determining cellular behavior. Scaffold architecture can be divided into hydrogels, sponges, and fibers. The following sections will describe scaffolds investigated for cartilage engineering.

5.516.3.1. Hydrogels

Hydrogels are three-dimensional hydrophilic polymer networks. Recently, injectable hydrogels have become appealing scaffolds because of the structural resemblance to extracellular matrix of many tissues and their minimally invasive delivery manner. Hydrogels support cell viability within a three-dimensional environment where encapsulated cells retain a rounded morphology, an essential parameter for chondrogenesis. In addition, the injectable nature of hydrogels provides a facile method to fill defects of any size and shape.

Hydrogels are formed through either physical or chemical cross-linking. Physical cross-linked gels are prepared through molecular entanglements and/or ionic or hydrogen bonding, or hydrophobic interactions, while chemically cross-linked gels are covalently bonded. Photopolymerization is one of the most common chemical cross-linking methods using ultraviolet or visible light.[32] Several factors including cross-linking method and density, macromer concentration, and molecular weight determine the physical and chemical properties of hydrogels.

Poly(ethylene glycol) (PEG) is currently FDA-approved for several medical applications.[33,34] PEG's relatively inert nature and resistance to protein adsorption make it an attractive candidate for cartilage engineering. An extensively studied PEG hydrogel system employs ultraviolet irradiation to generate radicals from appropriate photoinitiators.[35,36] The free radicals will react with modified PEG functionalized with acrylate groups to form a covalently cross-linked bond. Further modifications to PEG include copolymerization with degradable polymers such as poly(lactic acid), poly(glycolic acid), and poly(propylene fumarate) for improved cartilage tissue growth.[37] In addition, bioactive peptides such as collagen mimetic peptide (CMP) have been incorporated into PEG hydrogels. Lee and colleagues showed that PEG hydrogels conjugated with CMP increased ECM production of encapsulated chondrocytes by providing cell-manipulated

cross-links and collagen binding sites that simulate natural extracellular matrix.[38]

Another polymer commonly used in cartilage engineering is hyaluronic acid (HyA), a nonsulfated GAG found natively in cartilage. HyA plays an integral role in cell proliferation, morphogenesis, inflammation, and wound repair.[39] As a natural polymer, it can also interact with cell surface receptors for HyA enabling cell–scaffold interactions. HyA hydrogels can be formed by covalent cross-linking with hyrazide derivatives, esterification, and annealing and by functionalizing HyA with methacrylate groups for photopolymerization.[40–42] Varying HyA scaffold properties have shown to affect neocartilage formation by auricular chondrocytes *in vivo*.[43]

CS, another natural polymer and component of cartilage, can be photopolymerized with similar modifications as HyA and even more commonly can be incorporated with a synthetic polymer such as PEG. Varghese and colleagues showed that bone marrow-derived MSCs encapsulated in a PEG/CS hydrogel had enhancement of both chondrogenic gene expressions and cartilage-specific matrix production as compared to control PEG hydrogels containing no CS-moieties.[44]

Fibrin glue has also been used as a scaffold for chondrocytes in numerous clinical studies.[45] Fibrin is an appealing candidate because it can be made from autologous blood, and a gel can be polymerized with the presence of thrombin. Furthermore, the excellent adhesive properties, ease of application via injection, biocompatibility, and biodegradability make it an attractive candidate for ACI techniques. However, some drawbacks are its poor mechanical properties as well as its potential immunogenicity.[46,47]

Collagen is another attractive material as it is the main component of natural ECM. The basic structure of collagen composes of a tri-helical protein that contains ligands which enable cell adhesion, migration, and differentiation.[48] Chondrocytes encapsulated within a type I collagen gel regenerated cartilage tissue in rabbit defects.[49] Gelatin, a partial derivative of collagen, is formed by breaking the natural triple-helix structure of collagen into single-stranded molecules via hydrolysis.[50] Gelatin is less immunogenic compared to collagen and when incorporated with alginate encapsulated chondrocytes, expression of type II collagen increased in addition to having a rounded morphology.[51]

Alginate is a hydrophilic, linear polysaccharide, commonly used in biomedical applications because of its biocompatibility, low toxicity, and relatively low cost.[52] Alginate is a block copolymer with a linear structure composed of homopolymeric blocks of β-D-mannuronate (M) and α-L-guluronate (G) monomers. The G-blocks of alginate chains can be cross-linked with divalent cations through ionic interactions with carboxylic groups in alginate, which induces gelation. Alginate can also form hydrogels via cell-cross-linking, instead of ionic cross-linking.[52] Park and colleagues found that gels cross-linked by combining both cross-linking methods were effective to engineer cartilage tissues *in vivo*.[52]

Agarose is another linear polysaccharide derived from seaweed that solidifies when cooled. Ng and colleagues investigated agarose gels of various concentrations seeded with chondrocytes as a model for depth-dependent mechanical properties of articular cartilage.[53] Their results showed potential tissue engineering of inhomogeneous articular cartilage constructs.

Chitosan is composed of polyglucosamine, is liquid at room temperature, and gels at physiological temperatures. Its high positive charge allows water-insoluble complexes to be formed with a variety of negatively charged substances. Therefore, negatively charged growth factors can be loaded and released from this scaffold making it a promising potential to treat cartilage defects.[54] Degradation products of chitosan include CS, dermatan sulfate, HyA, keratin sulfate, and glycosylated type II collagen, all of which are nontoxic molecules involved in articular cartilage synthesis.[27]

Hydrogel composites such as p(NiPAAm-*co*-AAc) and HyA have been investigated for potential use as an injectable cell and growth factor carrier for cartilage tissue engineering applications.[55] The blended hydrogel loaded with transforming growth factorβ-3 (TGFβ-3) seeded with chondrocytes were injected subcutaneously into the nude mice. An increase in expression and synthesis of cartilage-specific ECM proteoglycans was found at the end of the study.[55]

Another group of synthetic polymers hydrogels are self-assembling peptides. They are formed by amino acid sequences of alternating ionic hydrophobic and uncharged hydrophilic side groups. Exposure to electrolyte solution enables self-assembling peptide hydrogels to form stable β-sheets of interwoven nanofibers. Kisiday and colleagues showed that articular chondrocytes maintain their phenotype and produce cartilage-like ECM when encapsulated in self-assembling peptide KLD-12 hydrogels *in vitro*.[56]

5.516.3.2. Sponges

Scaffold porosity affects cell infiltration and migration, matrix deposition and distribution, and nutrient and waste exchange. Many scaffold applications require a sponge-like architecture where tissue formation is dependent upon pore size and interconnectivity. Several methods have been employed to prepare three-dimensional biodegradable scaffolds including phase separation, emulsion freeze-drying, gas foaming, fiber bonding, and porogen leaching.[57] Phase separation methods cannot obtain large pores nor can the pore structure be easily controlled and fiber bonding techniques will often construct scaffolds lacking structural stability. The most established method providing simple control of pore structure is porogen leaching. This technique involves casting a mixture of polymer solution and porogen in a mold and drying the mixture, followed by leaching out the porogen with water to generate the pores. As porogen materials can be salts and carbohydrates, the pore structures can easily be manipulated by controlling the property and fraction of the porogen material. Chitosan can be formed into sponges via freeze-drying and lyophilization.[58] Kuo and colleagues investigated ECM production of chondrocytes in chitosan and chitin hybrid scaffolds.[59] They found that increase in weight percentage of chitin resulted in smaller pore diameters, increased surface area, a higher Young's modulus, and lower extensibility, all of which lead to an increase in cell number and ECM production.

Sponges can also be formed from silk fibroin through a solvent casting/salt leaching method. Silk fibroin is made up of a filament core protein, fibroin, along with a glue-like coat of sericin proteins. Wang and colleagues evaluated this method's support of both chondrocytes and stem cells.[60]

Type II collagen–GAG scaffolds have also been shown to mediate cell behavior. Vickers and colleagues seeded chondrocytes on type II collagen–GAG scaffolds with varying cross-linking densities and found that scaffolds with low cross-link densities experienced cell-mediated contraction, increased cell number densities, a greater degree of chondrogenesis, and an apparent increase in the rate of degradation of the scaffold compared to more highly cross-linked scaffolds that resisted cellular contraction.[61]

5.516.3.3. Fibers

Fiber networks can be woven or nonwoven. Variations in void volume, fiber diameter, and direction can dictate cell behavior. Nonwoven fiber networks tend to have higher void volumes and surface area, while, woven fiber networks are mechanically stronger and can be designed with a wide range of porosities. Fiber networks can be fabricated *in vitro* with cells and then later implanted *in vivo* for tissue repair. Moroni and colleagues developed a fiber scaffold using poly(ethylene oxide) terephthalate/poly(butylene) terephthalate (PEOT/PBT) having mechanical properties comparable to bovine articular cartilage.[62] Recently, electrospinning has become a popular technique for fabricating polymers that mimic structural similarity to natural ECM.[63] In this technique, polymer solution is drawn from a capillary forming a suspended droplet at the tip of the capillary by force of gravity or mechanical pumping combined with electrostatic charge. Nanofibers are formed by the narrowing of the ejected jet stream as it is subject to increasing surface charge density due to evaporation of the solvent. The nanofibrous structure produced by the electrospinning process has a high surface area-to-volume ratio, providing more substrate for cell attachment compared to other structures. Li and colleagues demonstrated that chondrocytes seeded on poly(ε-caprolactone) (PCL) nanofibrous scaffolds efficiently maintained their differentiated phenotype supporting nanofibrous structures as a suitable scaffold biomaterial for cartilage tissue engineering applications.[63]

Several natural materials such as cellulose and HyA have also been fabricated into fibrous scaffolds.[64,65] For instance, nonwoven HyA esters (HYAFF® derivatives) semisynthetic, resorbable fibrous networks have been shown to support cell adhesion, proliferation, and ECM production *in vitro* and *in vivo*.[66,67] Radice and colleagues conducted a pilot study with HYAFF®11 and even after complete degradation after 4 months of implantation, there was no inflammatory response.[67] Later clinical studies using Hyalograft® C (a graft of autologous chondrocytes cultured on HYAFF®11 scaffolds) to treat human articular cartilage defects showed considerable improvements even in joints with progressed osteoarthritis.[68]

5.516.4. Growth Factors

A number of different growth factors have an impact on articular cartilage repair, but the key for tissue engineering is combining these factors with cells and scaffolds. Members of the transforming growth factor (TGF) superfamily play a significant role in cartilage development. TGF-β is secreted in an inactive form, bound to a latency-associated peptide from which it dissociates before becoming active and binding to its target receptor.[69] Of the three isoforms, TGF-β1 is responsible for initial cell–cell interactions between condensing progenitor cells and as a result is the most widely investigated.[70] *In vitro* studies show TGF-β1 to induce chondrogenesis of MSCs, promote cell proliferation and proteoglycan synthesis, and inhibit the actions of matrix metalloproteinases.[71–74] However, there are negative effects observed with high doses leading to fibrosis and osteophytosis.[74,75]

A number of *in vitro* studies using rabbits have produced positive results with locally applied TGF-β1. Fan and colleagues demonstrated enhanced cartilage repair in a study applying a porous gelatin-chondroitin-hyaluronate tri-copolymer scaffold containing microspheres loaded with TGF-β1 to an osteochondral defect.[76] Similarly to *in vitro* studies, some *in vivo* studies have shown that higher doses of TGF-β1 lead toward osteophytosis.[77]

Bone morphogenetic proteins (BMPs) are also members of the TGF superfamily of growth factors and are of particular interest because of the clinical availability of both BMP-2 (Infuse, Medtronic, Minneapolis, Minnesota) and BMP-7 (Osteogenic Protein-1 (OP-1) Stryker Biotech, Hopkinton, Massachusetts).[31] BMPs enhance chondrogenesis and osteogenesis, and in particular can assist in osteochondral integration at implant site. BMP-2 and -7 improve ECM production in chondrocytes and progenitor cells. Specifically, BMP-2 upregulates TIMP-1, Sox 9, type II collagen, and aggrecan expression levels.[78,79] BMP-7 increases production of GAGs and suppresses fibroblast migration in the scaffold.[80] Mason and colleagues transfected BMP-7 into periosteal-derived MSCs and observed complete or near-complete bone and cartilage regeneration in an osteochondral rabbit defect model with a PGA scaffold after 8 weeks.[81]

Insulin-like growth factor-1 (IGF-1), the main anabolic growth factor of articular cartilage, is used to increase production of proteoglycans and type II collagen.[82,83] IGF-1's activity is likely regulated via the interaction between itself and binding proteins. As a result, the increase in catabolic activity causes proteolysis of these proteins, thereby modulating its release. Nixon *et al.*[84] coupled IFG-1 with fibrin composites in an equine osteochondral model. They found that the growth factor-treated defects showed improved histologic appearance over controls along with a significant increase in type II collagen. Elisseeff *et al.*[85] used a PEG hydrogel scaffold along with PLA microspheres containing both TGF-β1 and IGF-1 to culture bovine chondrocytes. Their results indicated an increase in ECM synthesis and cell content. While Worster *et al.*[86] found similar results *in vitro*, later *in vivo* studies showed contradicting results. Holland *et al.*[87] used a PEG hydrogel scaffold containing gelatin microparticles of TGF-β1 and IGF-1 and found no improvement in the cartilage defects of adult rabbits, but instead found that IGF-1 alone was better than TGF-β1, either alone or in combination, in terms of improving tissue composition.

Currently, there are a total of 22 different members of the FGF family identified, of which FGF-2 is the most widely investigated in articular cartilage repair.[88] FGF-2 is an important mitogen for cells of mesodermal origin and is a chemo-attractant for endothelial cells.[89] Kato and Iwamato[90] showed that FGF-2 inhibits terminal differentiation of chondrocytes. Their results provided future promise for inhibiting terminal differentiation

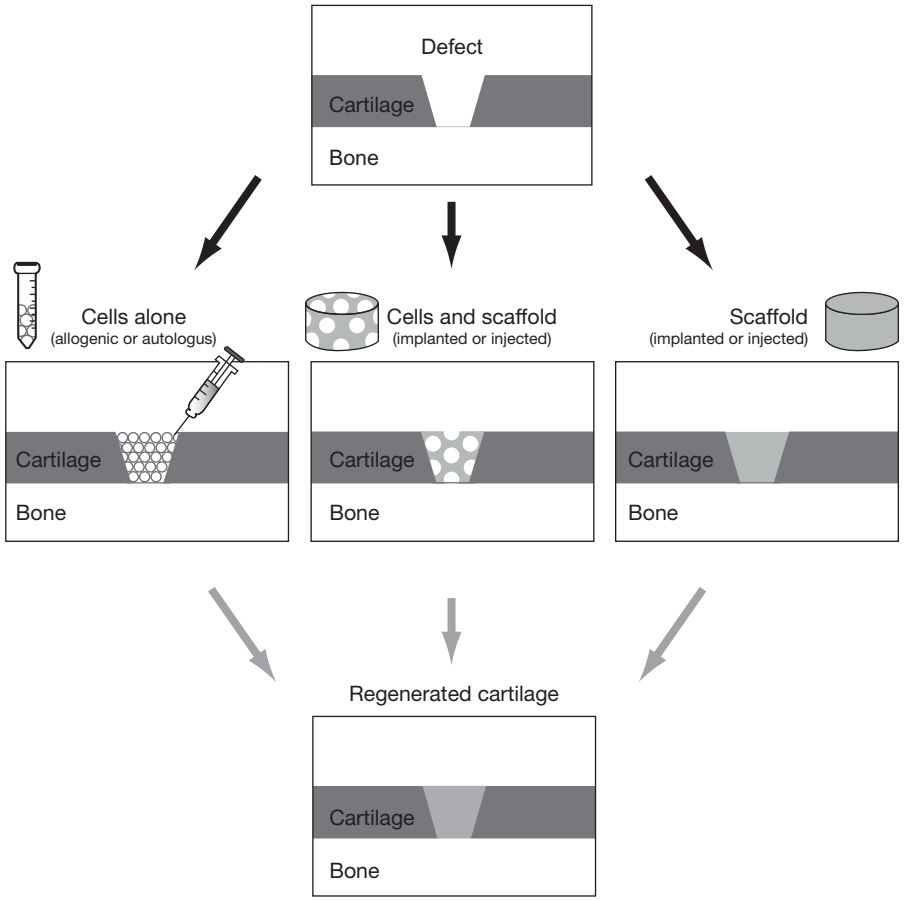

Figure 1 General schematic of approaches used in cartilage regeneration strategies, ranging from cell-only repair, cell–scaffold repair, and scaffold-only repair.

of MSCs undergoing chondrogenesis. Stewart *et al.*[91] demonstrated enhanced chondrogenic differentiation and stabilized phenotypic expression of bone marrow-derived mesenchymal stem cells cultured in a 3D pellet in the presence of FGF-2. Weisser *et al.*[92] found that FGF-2 cultured with chondrocytes in an agarose gel stabilize the chondrocyte-differentiated state while implanted into rabbit osteochondral defects. Weisser *et al.*[92] implanted FGF-2 incorporated within a triaxial 3D woven structure of ultra-high molecular weight polyethylene into a rabbit osteochondral defect. They found improved biomechanical properties nearly matching native tissue at 26 weeks post implantation. While FGF-2 is the most commonly investigated mitogen in its family, FGF-18 also has great potential in articular cartilage tissue engineering, with a number of recent studies showing its potential to stimulate cell proliferation and differentiation, and matrix production both *in vitro* and *in vivo*.[93,94]

Platelet-derived growth factors (PDGFs) are a chemoattractant stimulating macrophages and fibroblasts during healing.[89] As a result, it has become recognized as the key growth factor in microfracture techniques.[95] Several *in vitro* studies indicate PDGFs to contribute in roles other than as chemo-attractants, but also influencing mesenchymal stem cell differentiation, enhancing matrix production, as well as preventing the progression of chondrocytes down the endochondral maturation pathway.[71,96]

5.516.5. Clinical Repair Techniques

In any cartilage repair system, preparation of the defect site is necessary prior to receiving the implant. First, the defect area is debrided with a ring curette or a low-profile drill removing abnormal cartilage and fibrous tissue. Then the defect can be measured using an arthroscopic-graded probe and templated using sterile paper or aluminum for preparation of the implant if it is not in an injectable form.[27]

First-generation ACI injected a cell-suspension of chondrocytes under a sutured periosteal flap or collagen membrane sealed with fibrin glue. Drawbacks of this procedure were morbidity to donor cartilage, long recovery, graft failure, and periosteal flap hypertrophy.[97] In order to circumvent some of these complications, second-generation ACI emerged. This technique cultured chondrocytes on various membranes (matrices) that could be fixed with fibrin glue without sutures. Collagen became the most common matrix used and the technique was named matrix-induced autologous chondrocyte implantation (MACI). Autologous cartilage is harvested arthroscopically using a gauge or ring curette from healthy, nonweight-bearing areas of the knee. *In vitro* expansion usually achieves nearly 2 million cells per cm^2 of defect.[98] Once, the defect is prepared and measured and the knee is drained, the collagen matrix encapsulated with cells 3–4 days prior

implantation is cut to fit the defect size. Mini anchors with absorbable sutures are placed on opposite sides of the defect site. The suture is passed through the MACI matrix and the matrix is guided down the sutures to the defect by an inserter. Fibrin glue is applied within the defect, giving the matrix further support.

Another second-generation ACI scaffold is Hyalograft C. The hyaluronic acid patch is seeded with chondrocytes 3 weeks prior to implantation. The patch is then attached to a delivery device with a sharp edge which is introduced through the arthroscopic portal to overlie the defect. Then the graft is pushed out of the delivery device and adhered to the subchondral bone within the defect. If necessary, fibrin glue is applied to the defect to improve implant stability.

Bioseed C, another second-generation ACI scaffold is composed of poly(glycolic) acid, poly(lactic acid), and a polydioxanone fleece with fibrin gel to evenly distribute cells 3 weeks prior to implantation. Arthroscopic implantation of this technique requires the defect to be debrided to a rectangular shape. The four corners of the defects are drilled with guide wires through the cannula in an inside-out technique. Then the scaffold is placed within the corners with resorbable sutures and mounted on the corresponding guide wires. Finally the threads are pulled into the joint by the guide wires acting as a pulley leading the implant into the joint.

Eventually, several studies indicated the possibility of *in vitro* expanded chondrocytes cultured on three-dimensional matrices regaining their chondrogenic phenotype after *in vivo* implantation.[99,100] It was also found that mechanical stimulation of chondrocytes in three-dimensional culture can promote maintenance of the chondrogenic phenotype and produce stable mature hyaline matrix.[101,102] Therefore, to preserve chondrocyte phenotype, third-generation ACI evolved with new three-dimensional cartilage constructs. Techniques were developed to improve cell and/or scaffold implant by mechanically conditioning the three-dimensional constructs *in vitro* prior to implantation. In addition, third-generation ACI techniques utilized phenotypically stable characterized chondrocytes selected on the basis of quantitative gene expression markers predicting ability to form hyaline cartilage *in vivo*.[21]

For example, NeoCart, a third-generation ACI technique, is comprised of a three-dimensional bovine collagen type I matrix encapsulated with autologous chondrocytes and treated in a hydrostatic bioreactor for at least 7 days. After designing the construct to match the defect, it is then sandwiched with a collagen–poly(ethylene glycol) adhesive and fixed within the defect.[103]

Another third-generation ACI technique, alginate-cultured three-dimensional grafts (Cartipatch), is an agarose/alginate hydrogel scaffold seeded with autologous chondrocytes. This polysaccharide material can be manipulated at 37°C into complex shapes that solidify at about room temperature, thereby providing manageable handling properties. Once the defect is debrided, the cell-loaded agarose–alginate gel can be delivered to the site and simply press fitted with forceps.[104]

Alginate beads are also used for ACI techniques. Allogeneic chondrocytes harvested from donors' knees within 24 h of death are expanded and then mixed with alginate to form beads over a 2-week period. A mini-arthrotomy is performed to allow access to the defect. After the chondrocyte-cultured alginate beads are packed under the periosteal flap, fibrin glue is injected into the defect to fill empty spaces.[105] Even after cryopreservation and long-term storage, alginate-cultured allogeneic chondrocytes retained viability, thereby potentially providing 'chondrocyte banks' in the future.[106]

A current modification to third-generation ACI is minced articular cartilage. After harvest, articular cartilage is 'minced' into small fragments and encapsulated into a scaffold without any culture expansion. Chondrocytes from the fragments are capable of migrating into the surrounding scaffold or fibrin glue to produce ECM. A minimal amount of tissue (one-tenth the size of the original defect) is needed to produce enough chondrocytes for treatment of a relatively large defect.[107]

The cartilage autograft implantation system (CAIS) consists of minced cartilage and a resorbable copolymer foam scaffold of polycaprolactone (PCL) and PGA reinforced with a polydioxanone (PDS) mesh. The system utilizes a harvester made of a stainless steel tube with a controlled cutting tip and a disperser that directs the minced cartilage into the PCL/PGA scaffold. Fibrin glue is used to stabilize the fragments in the scaffold. After a mini-arthrotomy and designing of the scaffold, the implant is placed into the defect and fixed with resorbable PDS staples.[108]

Another similar application for cartilage regeneration and repair is DeNovo Natural Tissue (NT) graft. The implant consists of allogeneic minced juvenile cartilage treated under specific biological conditions. The graft is implanted in a single-stage arthroscopic procedure where the chondral defect is measured and the NT graft is trimmed accordingly, and then implanted in the defect. Fibrin glue adhesive is again used to fill areas between implant and subchondral bone.[108]

Wakitani *et al*.[25] introduced a method similar to ACI using BM-MSCs because of their abundance and chondrogenic potential as well as their potential to decrease donor site morbidity from chondrocyte harvest. First-generation techniques embedded culture-expanded BM-MSCs in acid-soluble bovine or porcine type-1 collagen 1–2 days prior to implantation and then placed the cell-laden collagen gel on a collagen sheet for additional support. After mini-arthrotomy, the implant was inserted into the defect and the periosteal patch was sutured without the need of fibrin glue. A later second-generation BM-MSC implantation method mixed BM-MSCs with platelet-rich fibrin glue and allowed them to gel. The addition of platelet-rich plasma decreased the adhesive properties of fibrin glue and as a result the implant had to be covered with a sutured periosteal flap.[27]

A modification to microfracture surgery is autologous matrix-induced chondrogenesis (AMIC). It is a relatively simple single-stage procedure that uses a collagen membrane to cover the microfracture defect for 5 min. Following bone marrow saturation, the matrix is measured and trimmed to fit defect along with fibrin glue for stability.[26]

Finally, BST-CarGel, a chitosan/glycerol hydrogel, provides another modification method to microfracture surgery. The gel is dispersed throughout uncoagulated whole blood, and then delivered to a surgically prepared lesion. BST-CarGel allows normal clot formation, reinforces the clot, impedes retraction, increases adhesiveness, and ensures prolonged residency of both the clot and critical tissue repair factors from

blood. Animal studies have shown BST-CarGel to increase the volume and hyaline character of repair tissue along with GAG and collagen content compared with microfracture controls.[109]

5.516.6. Conclusion

All current approaches to engineering articular cartilage have their advantages and limitations. The major concern facing these technologies is finding a method having vast superiority over general surgery technologies. Thus far, results of various studies have been both similar and controversial and do not show any method with clear superiority.[110] One of the biggest challenges is cell source. Current work on alternatives to chondrocytes is expanding, and the potential and limitations of stem cells are being explored. Novel biomaterials are continuously being developed and are progressing toward unique cell–scaffold interactions. Ultimately, the ideal tissue engineering solution for cartilage repair must be simple and cost-efficient if a successful product is to proceed from bench to bedside.

Glossary

Ankylosis Hypertrophic bone growth from the mandible and/or the fossa resulting in fusion of the joint.

Arthrocentesis A minimally invasive procedure where a needle and syringe are used to flush and drain fluid from the joint.

Arthroplasty A surgical procedure that involves reshaping of the articular surfaces of the joint.

Etiology The study of disease causation.

Fibrocartilage A tissue that contains properties of both hyaline cartilage and fibrous tissue such as tendon. This is typically characterized by the presence of both collagens I and II.

Glycosaminoglycan Long chains of repeating disaccharides, which typically contain a negative charge.

Internal derangement An abnormal position of the TMJ disc relative to the mandibular condyle and glenoid fossa.

Occlusal splint Removable acrylic molds that cover the upper and lower teeth. Typically used to protect the teeth from grinding or clenching.

Orthognathic surgery A surgical procedure involving the cutting and repositioning of bones in the mandible or maxilla.

Proteoglycan A molecule composed of protein core with at least one, but often many glycosaminoglycan side chains.

Stress relaxation Testing modality to measure the viscoelastic properties of a material. A constant strain is applied to the tissue and the decaying stress is measured over time.

Abbreviations

bFGF	Basic fibroblast growth factor
BMP-2	Bone morphogenic protein-2
C-ABC	Chondroitinase-ABC
CS	Chondroitin sulfate
DS	Dermatan sulfate
ECM	Extracellular matrix
ePTFE	Expanded polytetrafluoroethlyene
FDA	Food and Drug Administration
GAG	Glycosaminoglycan
HA	Hydroxyapatite
IGF-I	Insulin-like growth factor-I
IL-1	Interleukin-1
MMP	Matrix metalloproteinase
PCL	Polycaprolactone
PDGF	Platelet-derived growth factor
PEG	Poly(ethylene glycol)
PGA	Polyglycolic acid
PLA	Polylactic acid
PLLA	Poly-L-lactic acid
TGF-β1	Transforming growth factor-β1
TMD	Temporomandibular joint disorder
TMJ	Temporomandibular joint
UHMWPE	Ultra-high-molecular-weight polyethylene
VEGF	Vascular endothelial growth factor

5.517.1. Introduction

Tissue engineering of the temporomandibular joint (TMJ), or jaw joint, is still in its early development. While a large body of knowledge exists for the characterization and tissue engineering of other synovial joints, only recently has the TMJ received significant attention. Tissue engineering of the functional TMJ tissues is a promising technology for the treatment of TMJ disorders (TMDs), potentially improving the lives of millions of people. Because of the complex loading patterns that engineered tissues will experience in the TMJ, complete design parameters from native tissue are critical. Unfortunately, neither the normal nor the diseased states of the TMJ are fully understood at present, hindering tissue engineering efforts. Within the TMJ, the fibrocartilaginous disc has received the most attention thus far, but efforts are underway to engineer the mandibular condyle cartilage and bone as well. Implantation of engineered tissues may help alleviate pain, restore range of motion, and return the patient to normal jaw function. The potential impact of a biological TMJ replacement is even greater considering the significant lack of long-term treatment options for TMD patients. This chapter provides a survey of the literature related to the rapidly expanding field of TMJ tissue engineering.

5.517.2. Gross Anatomy and Physiology of the TMJ

The anatomy and physiology of the TMJ have been reviewed in detail in the literature.[1–4] This section provides a summary of the pertinent anatomy and physiology for engineers. The TMJ is composed of the condyle of the mandible articulating against the glenoid fossa and articular eminence of the temporal bone with an interposed disc (Figure 1). The mandibular condyle is the moving component of the articulation, while the fossa-eminence remains stationary relative to the cranium. Both of the articulating surfaces of the TMJ are covered by fibrocartilage, unlike the knee, where the articulating surfaces are covered by hyaline cartilage. Positioned between the condyle and fossa-eminence is a fibrocartilaginous disc that is attached to the periphery of the joint and is free to move over both the superior and inferior articulating surfaces. The TMJ disc serves to increase congruity between these surfaces, distribute load, and aid in joint lubrication.[5] The TMJ is surrounded by a capsule, which encloses the intra-articular environment and attaches to the disc near the condylar head.

Movement of the TMJ is unique because it includes both rotation relative to the transcranial axis and translation forward relative to the skull base. During normal mastication, the joint movement is mainly rotational, allowing vertical opening and closing of the mouth. It is only during wide mouth opening (to around 40 mm) that translation becomes a major component of the movement.[4] Under normal rotational movements, a complex pattern of compression and shear loading occurs between the anterior side of the condyle and posterior slope of the eminence.[6] A healthy TMJ disc and synovial fluid act to dissipate these loads across the joint. If the disc becomes displaced, the lack of force dissipation results in abnormal loading patterns and can cause degradation of the joint.

The attachments of the TMJ disc with the surrounding tissues are extremely important for the coordinated movements of the TMJ. Anteriorly, the disc attaches inferiorly to the anterior condyle and superiorly to the eminence by bending with the joint capsule. Posteriorly, it attaches to the bilaminar zone, which is in turn attached superiorly to the temporal bone and inferiorly to the posterior condyle. Laterally and medially, the disc attachments blend into the joint capsule near its attachment to the condylar head. This complex attachment pattern allows the condyle to rotate relative to the disc but still allows the disc and condyle to translate as a single unit during wide mouth opening.[1] Additionally, the disc and

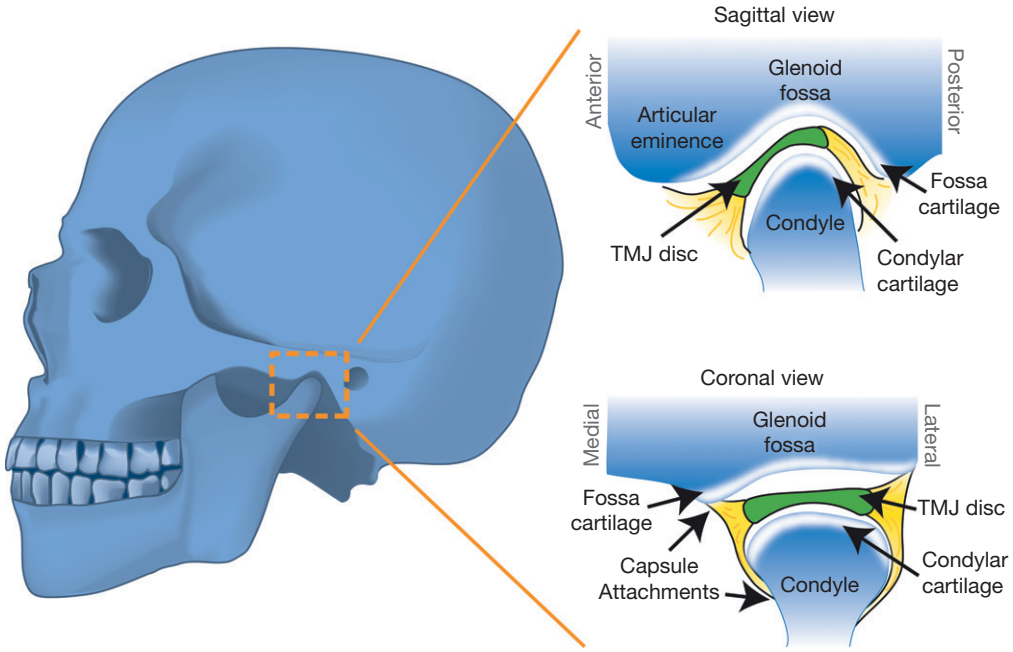

Figure 1 Location and anatomy of the temporomandibular joint (TMJ) in the sagittal and coronal planes. The TMJ is capable of both rotational and translational movement and is composed of three articulating structures: the mandibular condyle, TMJ disc, and the glenoid fossa. The mandibular condyle and glenoid fossa are both covered by fibrocartilage and the TMJ disc is positioned between these two structures.

its attachments separate the joint space into distinct inferior and superior regions. It has been proposed that the TMJ is mainly a translatory joint in the superior space and primarily a rotational joint in the inferior space.[7] This means that the loading patterns experienced by the two surfaces of the disc during normal motion are considerably different.

Like other diarthrodial joints, the TMJ is surrounded by a capsule, the inner surface of which is lined by synovium, a layer of cells that specialize in the production of synovial fluid. Synovial fluid serves two main functions within the TMJ. First, it acts as a lubricating fluid with a coefficient of friction of approximately 0.001.[8] Second, synovial fluid acts as a transmission medium for nutrients to the fibrocartilages within the joint and also serves to remove waste products. The volumes of synovial fluid in the inferior and superior joint spaces of the TMJ are about 0.5 and 1.0 ml, respectively.[2] As it nourishes all the tissues of the joint, the importance of a healthy synovium should not be overlooked by tissue engineers.

5.517.3. Characterization of TMJ Tissues

TMJ tissue engineering requires finely tuned design criteria in order for constructs to effectively handle the complex loading environment of the TMJ. These design criteria are determined through the characterization of the tissue in three major categories: cells contained in the tissue, its biochemical makeup, and its biomechanical properties. An understanding these components of TMJ tissues is critical for the development of mechanically functional engineered constructs, though the number of characterization studies of TMJ tissues remains relatively small in comparison to that of other synovial joints, such as the knee. Fortunately, recent characterization studies, particularly for the TMJ disc, have significantly increased our understanding of these complex tissues. Reviewing this information can greatly improve tissue engineering efforts by illuminating the TMJs structure–function relationships and providing gold standard specifications.

5.517.3.1. TMJ Disc

The TMJ disc is a biconcave fibrocartilaginous tissue that sits atop the mandibular condyle and articulates against the glenoid fossa of the temporal bone. It allows for smooth jaw movement during normal daily activities such as eating and talking. Because of its unique shape, the disc is commonly thought of consisting of three regions in the anteroposterior direction: the anterior band, intermediate zone, and posterior band (Figure 2). The intermediate zone also exhibits mediolateral variation and it is thus divided into the medial, central, and lateral regions. Finally, the two surfaces of the TMJ disc have varying properties, so the disc can also be classified into inferior and superior regions. The cellular, biochemical, and biomechanical properties that accompany this unique architecture provide the appropriate lubricating and cushioning functions for the joint. This section provides a summary of the salient TMJ disc properties for tissue engineers. Further information about the cellular, biochemical, and biomechanical properties of the disc has been reviewed in the literature.[7,9–12]

5.517.3.1.1. Cells

Similar to other fibrocartilages such as the knee meniscus, the TMJ disc contains a heterogeneous population of cells.

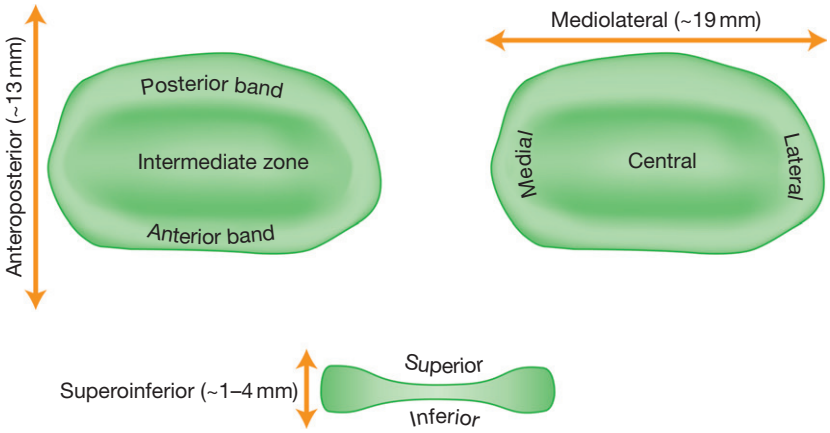

Figure 2 Regional variations and approximate dimensions of the temporomandibular joint (TMJ) disc. The TMJ disc is commonly classified into the posterior band, intermediate zone, and anterior band in the anteroposterior direction. In the mediolateral direction, the disc can be separated into the medial, central, and lateral regions. The disc exhibits a biconcave shape in the superoinferior direction, with each surface having distinct properties.

These cells possess characteristics of both fibroblasts and chondrocytes and are therefore termed fibrochondrocytes.[13] The overall cellularity of the disc is reported to be between 20 and 50 million cells per gram of tissue.[13,14] Although the TMJ disc contains multiple cell types, the overall population appears to be more fibroblastic than chondrocytic. Histological investigations have shown that approximately 70% of the disc cells are fibroblast-like, with the remaining 30% being chondrocyte-like.[15] The chondrocyte-like cells lack a pericellular matrix found around hyaline chondrocytes, and are mostly located in the intermediate zone.[15–17] Regional variations in cell number appear to vary with species. The anterior band was seen to contain the smallest number of cells in the porcine disc,[14,15] while the intermediate zone was found to have the fewest cells in primate discs.[17] Regardless of distribution, the heterogeneous fibrochondrocyte cell population has been seen in all species, and the difficulty involved in recreating this cellular environment should be appreciated by tissue engineers.

5.517.3.1.2. Collagen

The main extracellular matrix (ECM) component of the TMJ disc is collagen, which largely controls the functional properties of the tissue. Collagen makes up about 37% of the wet weight,[18] 50% of the wet volume,[19] or 69–85% of the dry weight.[14,20] Regional distribution of total collagen has been seen to vary depending on the animal model tested. The anterior and posterior bands were seen to contain most of the collagen in the rat disc,[17] while the intermediate zone was reported to contain more collagen in the porcine disc.[14] Although there are several types of collagen in the TMJ disc, collagen type I is by far the most prevalent.[13,17] Collagen type II, the primary component in hyaline cartilage, can be found in small amounts in the intermediate zone, surrounding chondrocyte-like cells.[13,17,21] Trace amounts of other fibrillar (type III) and nonfibrillar (types VI, IX, XII) collagens have also been found in the TMJ disc.[22–24] Collagen type I is by far the most prevalent component of the TMJ disc's ECM and will need to be recreated in a tissue replacement.

The orientation of collagen fibers in the TMJ disc is anisotropic, but there is a basic symmetry. Collagen fibers near the periphery of the disc align in a ring-like structure, while the collagen fibers in the intermediate zone run predominately in an anteroposterior direction.[21,25,26] In the center of the disc, transition regions are observed where the anteroposterior directed fibers of the intermediate zone meet the mediolateral directed fibers of the anterior and posterior bands.[26] It has been speculated that the outer ring of fibers serves to maintain the disc shape under both tensile and compressive loads.[27] The average collagen fiber diameter in the disc is $18 \pm 9\,\mu m$.[21] Finally, collagen fibers in the disc exhibit a wavy or crimped appearance throughout the full thickness of the tissue.[28] The unique ring-like collagen fiber orientation of the TMJ disc has important ramifications for the mechanical properties of the tissue, as described subsequently.

5.517.3.1.3. Glycosaminoglycans and proteoglycans

Together glycosaminoglycans (GAGs) and proteoglycans can contribute to the compressive and tensile properties of a tissue. GAGs are long repeating disaccharide chains with or without branching that possess at least one negatively charged side group. Proteoglycans are composed of a central protein core with one or many GAG side chains. There is little agreement in the literature about the total quantity and regional variation of GAGs in the TMJ disc. The total sulfated GAG content has been reported to be between 1 and 10% of the dry weight.[29,30] This is a large range, but most studies indicate that disc GAG content is below 5%.[14,20,21,29,31] Regionally, studies of the porcine TMJ disc have indicated that the posterior band has the least sulfated GAG.[14,21] Similar results have been seen in the bovine disc, where the bands were shown to have less GAG content than the intermediate zone.[31] The exact opposite distribution of GAGs has been seen in the primate disc, with the anterior and posterior bands having the highest content.[17] Regardless of conflicting results, it is clear that the GAG content of the disc is much lower than hyaline cartilage.[10]

The main proteoglycans in the TMJ disc are chondroitin sulfate (CS) and dermatan sulfate (DS). The GAG chains associated with these two proteoglycans make up 75–93% of the total GAG content of the disc.[20,21,31] Other proteoglycans including keratan sulfate and heparin sulfate have been found

in trace amounts.[20,21,29,31] As in the case of GAGs, there are conflicting reports about the regional proteoglycan distribution in the TMJ disc. In the rat disc, the highest concentrations of CS proteoglycans were found in the bands and the greatest concentration of DS proteoglycans was found in the intermediate zone.[32] The exact opposite trends in CS and DS proteoglycan distributions were seen in the porcine disc.[21] Unfortunately, the studies that have investigated regional distribution of proteoglycans and GAGs have all used different assays. As a result, it is difficult to determine whether the regional disparities seen are a result of interspecies variations or a byproduct of the different assays used.

5.517.3.1.4. Tissue mechanics

It is important to understand the mechanical properties of the TMJ, as engineered constructs will need to support the same loads imparted on the native tissue. The compressive properties of the disc have been studied fairly extensively, but the measured mechanical properties have varied widely between studies. Under unconfined compression, the porcine disc displays an instantaneous and a relaxed moduli of 500 and 30 kPa, respectively.[33,34] These results match well with those of other porcine and human disc studies.[35,36] The canine and bovine discs demonstrate a much larger compressive resistance, with instantaneous moduli of 31 and 15 MPa under unconfined compression and stress relaxation, respectively.[37,38] It is unclear whether these drastic differences are due to interspecies variations or the different testing modalities used. Regionally, the greatest instantaneous moduli have been seen in the anterior and medial portions of the disc from porcine and bovine samples.[33,34,38] Additionally, a large instantaneous modulus has been observed in the posterior band of the porcine disc, but this was not observed in bovine samples. The central portion of the disc is reported to have a modulus equal to or less than that of the anterior and posterior bands.[33,34,36,38] This is an interesting finding, as the center of the disc is generally reported to have more sulfated GAGs, which often correlates to compressive stiffness.[11] From these data, it appears that compressive properties are more closely related to total collagen content than GAG content, probably because of the exceedingly low GAG content in the TMJ disc.

Tensile testing of the TMJ disc has also resulted in large variations in reported mechanical properties. Reported tensile moduli for the TMJ disc range from 0.5 to 100 MPa.[37,39–41] This large range of recorded properties is related to dramatic variations in regional tensile properties, which are fairly consistent across studies. The tensile modulus of the porcine disc is higher in the anteroposterior direction than in the mediolateral direction.[40,41] Regionally in the mediolateral direction, the relaxation moduli of the posterior band, anterior band, and intermediate zone in the porcine disc are 23.4, 9.5, and 0.58 MPa, respectively.[41] Similar results have been seen in the canine disc.[39] The dramatic twofold decrease in tensile modulus between the posterior band and intermediate zone is interesting because it does not correspond to a dramatic difference in biochemical content. Instead, it is due to the fact that the collagen fibers in the intermediate zone are aligned in the anteroposterior direction, perpendicular to loading.[41] Tensile variation in the anteroposterior direction is not as substantial, but the central region is the stiffest followed by the medial, and then lateral sections.[37,41] It is clear that collagen alignment is important for the tensile properties of the tissue and should be considered in all engineering efforts.

5.517.3.2. Condylar and Fossa Cartilages

While characterization of the TMJ disc is not fully complete, it is far more comprehensive than the current characterization of condylar cartilage. This cartilage lines the articulating surface of the mandibular condyle and moves against the inferior surface of the TMJ disc. Like the disc, condylar cartilage is a fibrocartilaginous tissue with noted amounts of collagen types I and II. This tissue exhibits a zonal architecture and is commonly divided into four zones in a superior to inferior fashion: fibrous, proliferative, mature, and hypertrophic (**Figure 3**). The articulating fibrous zone is a fibrocartilaginous region that sits on top of a highly cellular proliferative zone. The mature and hypertrophic zones, which border the subchondral bone, are considered to be like hyaline cartilage. This section provides an overview of the salient properties of condylar and fossa cartilages. It should be noted, however, that scant information exists on fossa cartilage. More detailed reviews of structure and composition can be found in the literature.[12,42,43]

5.517.3.2.1. Cells

Similar to other fibrocartilages, the cells of condylar cartilage are a heterogeneous fibrochondrocyte population, but unlike the TMJ disc, true chondrocytes can be found in some regions.

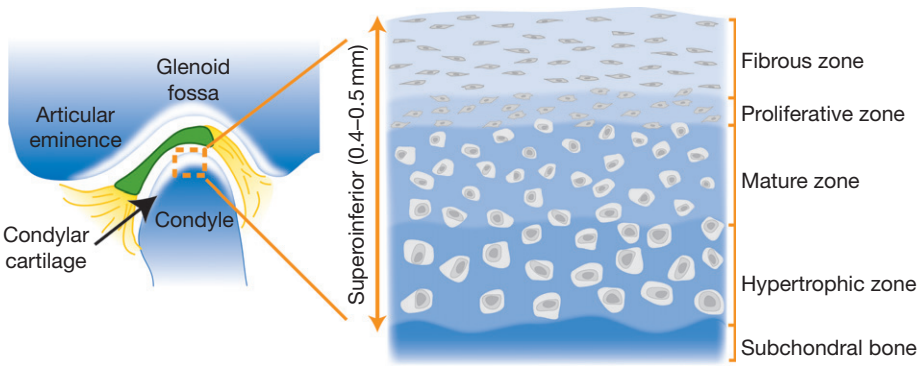

Figure 3 Zonal architecture and approximate dimensions of condylar cartilage. Condylar cartilage is commonly divided into four zones in the superoinferior direction: fibrous, proliferative, mature, and hypertrophic.

The articulating surface of mandibular cartilage contains flat fibroblast-like cells, which is indicative of this region being called the fibrous zone.[44,45] The proliferative zone is a highly cellular region that appears to play a role as a cell reservoir for the other zones. It produces cells for the overlying fibrous zone,[46,47] as well as chondrocyte precursors for the underlying mature zone.[48–50] Terminally differentiated chondrocytes are the main cell type in the mature and hypertrophic zones, although hypertrophic chondrocytes can be found near the junction with the subchondral bone.[51] The fact that the proliferative zone produces cells for all other zones should be noted by tissue engineers. If this layer can be purified, the cells it contains may be a potent cell source for engineering condylar cartilage.

5.517.3.2.2. Extracellular matrix

Although collagen appears to be the main constituent in condylar cartilage, there is little known about the exact quantity of collagen present. A value of 165 nmol of hydroxyproline/mg of dry weight has been reported,[52] as well as 2.2 $\mu g\,mg^{-1}$ of wet weight.[12] In contrast, the types of collagen present in condylar cartilage have been studied quite thoroughly using immunohistochemistry. Collagen type I can be found throughout the cartilage but is primarily located in the fibrous and proliferative zones.[16,53,54] Collagen type II is the primary collagen of the mature and hypertrophic zones,[16,53] although type X can also be found in these regions.[55] The fibrous zone contains collagen type III in addition to type I, which is representative of its fibrous nature.[54] More studies need to be completed on the quantitative distribution of collagens in condylar cartilage.

Collagen orientation in condylar cartilage has also been seen to have zonal heterogeneity. Microscopic investigations on the fibrous zone have indicated a transversely isotropic collagen fiber alignment, with sheets of fibers stacked on top of each other.[51,56,57] More recently, a macroscopic study of the fibrous zone showed anisotropic fiber orientation.[58] The proliferative zone is mostly cellular and contains few collagen fibrils.[59] The mature and hypertrophic zones exhibit randomly oriented collagen fiber bundles, indicating that there is an isotropic arrangement of collagen in these zones.[56,59] Overall, collagen organization results indicate the presence of a bilayered fiber structure with an anisotropic layer near the articular surface and an isotropic layer near the underlying bone.[43]

The total GAG content in mandibular cartilage is reported to be 6.4 $\mu g\,mg^{-1}$ wet weight in the rat,[54] or about 0.19 mg in the rabbit.[52] Keratin and chondroitin sulfates are the only GAGs that have been studied in mandibular cartilage, and there is contradictory evidence about their distribution. A primate study found these GAGs only in the mature and hypertrophic regions,[16] while they were found in the fibrous and proliferative zones of porcine and rat cartilage.[60,61] Regionally, cartilages from the anterior and posterosuperior portions of the condyle have been found to contain more CS than the superior region.[62] There is a zonal distribution of proteoglycans as well, with aggrecan located primarily on the mature and hypertrophic zones.[60,61] Decorin, on the other hand, is distributed fairly evenly throughout the cartilage.[63] Even though condylar cartilage contains chondrocytes, its GAG and proteoglycan content are significantly different from that of articular cartilage.

5.517.3.2.3. Tissue mechanics

Tensile testing of condylar cartilage has revealed a dramatic anisotropy in tensile stiffness, which matches the collagen fiber organization discussed earlier. The Young's moduli of condylar cartilage in the anteroposterior and mediolateral directions have been reported to be 9.0 and 6.6 MPa, respectively, when the cartilage is connected to subchondral bone.[64] When the cartilage is tested independent of bone, the moduli range from 8.0 to 11.0 MPa in the mediolateral direction, and 22 to 29 MPa in the anteroposterior direction.[58] This anisotropy has also been seen under dynamic shear testing, where the storage moduli of condylar cartilage were found to range from 1.50 to 2.03 MPa in the anteroposterior direction and 0.33 to 0.55 MPa in the mediolateral direction.[65,66] Overall, condylar cartilage is stiffer under tension and shear in the anteroposterior direction, which is also true for the TMJ disc.

Compressive testing of condylar cartilage has been conducted using numerous methodologies, but unfortunately there is no consensus about the anteroposterior variation in compressive properties. Studies using nanoindentation and dynamic compression have found that cartilage from the anterior region of the condyle was stiffer than that from the posterior region.[67,68] In contrast, studies using creep indentation and unconfined compression reported that the posterior cartilage was the stiffest.[69,70] With regard to mediolateral variation, multiple studies have agreed that cartilage from the medial region of the condyle is the stiffest.[67,70] In general, the aggregate modulus of condylar cartilage has been reported to be in the range of 45–75 kPa.[70] Unfortunately, there is no consensus about the regional variation in compressive properties of condylar cartilage, and more data are required to provide exact design requirements for tissue engineering.

Although little characterization of the fossa cartilage has occurred, the compressive properties have been tested using creep indentation. The average aggregate modulus of fossa cartilage was reported to be around 36 kPa, with cartilage from the posterior fossa being the stiffest and anterior fossa cartilage being the most compliant.[36] Overall, the fossa cartilage was found to be 57% thinner and 50% stiffer than the TMJ disc. Although this study provides a start for fossa characterization, a significant amount of further research is needed.

5.517.3.3. Mandibular Condyle and Temporal Fossa

The mandibular condyle, covered by a thin layer of fibrocartilage, is the major moving structure in the TMJ. It articulates against the glenoid fossa, also called mandibular fossa, which is a part of the upper temporal bone.[12] Looking at the structural organization of bones, they are typically composed of two microarchitectures: woven and lamellar bones, which are organized into dense cortical bone (compact bone) and porous cancellous bone (spongy or trabecular bone), as reviewed.[71] For example, underneath the condylar cartilage, a compact bone plate covers cancellous bone in the mandibular condyle.[42] From the viewpoint of chemical composition, bone is a well-organized composite matrix that is composed of a protein-based soft hydrogel template (e.g., collagens, noncollagenous proteins, and water) and hard inorganic components (such as hydroxyapatite, HA), as reviewed.[72] Specifically, a large amount of nanocrystalline HA, typically 20–80 nm long

and 2–5-nm thick, is found in the bone matrix.[71] Additionally, 90% of the organic phase in bone is made of type I collagen, which contributes to the elastic properties of bone. Other noncollagenous proteins, including various adhesive proteins (such as laminin, fibronectin, and vitronectin), bone-inductive proteins (such as osteopontin, osteonectin, and osteocalcin), growth factors, and cytokines, are found in the bone matrix to mediate cell–bone functions.[71,73] Unlike cartilage, bone has strong self-repairing potential. Various bone cells, including osteoblasts (bone-forming cells), osteoclasts (bone resorbing cells), and osteocytes (mature osteoblasts), are actively involved in normal bone functions, including ECM mineralization and new bone synthesis.

Clearly, the mandibular condyle's unique structure and composition must support a variety of mechanical loads during daily activities. To date, there have been several studies investigating the mechanical properties (such as stiffness and strength) of the cortical or cancellous bones in the TMJ.[74–78] For instance, it was reported that the cancellous bone of human mandibular condyle has anisotropic mechanical properties: the compressive elastic modulus and ultimate stress of axial specimens in mandibular condylar bones were 431 and 4.5 MPa when compared to 127 and 1.6 MPa of respective transverse specimens.[74] Cortical bone throughout the human mandibular condyle has been shown to posses significantly more stiffness than cancellous bone, exhibiting elastic moduli of roughly 12.2–26.6 GPa varying with different axes and locations.[76] It was also observed that the cortical plate on the lateral side was much thicker than the medial side. These anisotropic properties should be kept in mind when trying to engineer condylar bone. Unlike mandibular bone, little information exists about the bone of the glenoid fossa, and therefore, further characterization is needed.

5.517.4. Pathology of the TMJ

TMDs include a wide variety of conditions for which the etiology is not fully understood. Signs and symptoms of TMDs include limited mouth opening, deviation of the jaw during opening, dislocation, clicking, locking, and muscle pain during jaw movements.[79] Epidemiological studies report that about a quarter of the population has symptoms of TMD,[80] but after reviewing patient records, it appears that only 3–4% of the population seek treatment.[81] Three common pathologies of the TMJ which end up requiring clinical treatment are internal derangement, degenerative joint disease, and ankylosis. The first two mainly affect the soft tissues of the joint and the third affects the bony structures.

Internal derangement of the TMJ is defined as an abnormal relationship of the articular disc to the mandibular condyle and articular eminence.[2] It is believed to be the result of multiple pathological processes, including softening of the tissues, perforation of the disc, alterations in synovial fluid lubrication, and overactive musculature.[4] Disc displacement typically occurs on the anterior medial side of the condyle. The result of TMJ disc derangement depends largely on the extent and duration of the displacement. Long-term internal derangement typically results in altered loading patterns in the joint, reduced mobility, and increasing degradation of the soft tissues.[4] These long-term degenerative effects are thought to be caused by a direct mechanical injury and/or a hypoxia–reperfusion injury.[82] A progression of five stages of internal derangement has been described involving increasing joint degradation over time.[83] Most TMD patients with intermediate stage internal derangement progress into the later stages. An understanding of the internal derangement is particularly important, because a prior study has indicated that 70% of patients with TMD have disc displacement.[84]

Degenerative joint disease involves a catabolic loss of articular tissue and is a common form of degeneration in synovial joints. The main form of degenerative joint disease in the TMJ is osteoarthritis caused by excessive loading, but rheumatoid arthritis caused by autoimmune responses can also occur. Osteoarthritis of the TMJ is characterized by degradation and abrasion of the articular cartilage surfaces, which are accompanied by secondary inflammation.[85] The exact etiology of osteoarthritis in the TMJ is unknown, but it likely involves trauma to the joint, excessive loading, immobility, and increasing age.[86] During TMJ osteoarthritis, expression of matrix metalloproteinases (MMPs) and vascular endothelial growth factor (VEGF) in the joint is elevated, resulting in increased inflammation and degradation of the soft tissues.[87] The result is abnormal remodeling and breakdown of the TMJ cartilages. TMJ degenerative joint disease can result from internal defragment, or it can develop independently.

The next TMJ pathology differs from the preceding conditions, because it involves a disorder of bone metabolism, rather than of soft tissue. TMJ ankylosis involves hypertrophic bone formation in the condyle or temporal bones. This excessive bone growth reshapes the articulating surfaces, and if given time to grow, can completely bridge the joint space. This results in immobilization of the mandible and a complete lack of joint function. Trauma to the joint cavity in young children, or repetitive trauma from surgeries is connected to the development of ankylosis.[88] Removal of the hypertrophic bone is typically not a long-term solution for ankylosis, as the bone will commonly regenerate.

Engineers must appreciate the complex pathologies of the TMJ. Without understanding the factors responsible for destruction of the native joint, it will not be possible to produce a permanent biological replacement. For example, if the joint degradation is initially caused by a displaced disc, not only must the disc be repositioned or replaced, but the catabolic and inflammatory environment of the joint must also be addressed. Because of the joint disease, the synovial fluid will be saturated with inflammatory factors that, if left unchecked, will likely lead to destruction of the newly implanted disc. An understanding of TMJ pathology will significantly increase the likelihood of success for future tissue-engineered TMJ replacements.

5.517.5. Current Therapies

As TMJ pathology progresses, an increase in symptoms often causes patients to seek clinical care. The most common reason for TMD patients to request medical care is pain.[5] Current clinical treatment options can be divided into four categories: noninvasive, minimally invasive, invasive, and alloplastic

replacement. As detailed elsewhere,[89] the goals for treatment of TMD patients should include (1) decreased joint pain, swelling, and reflex masticatory pain; (2) increased joint function; (3) prevention of further damage; and (4) prevention of disability and disease-related morbidity. This section provides an overview of the common clinical treatments for TMD. More detailed information can be found in the literature.[4,89]

The first stage of clinical treatments for TMD is noninvasive and generally includes occlusal splints and physical, myofunctional, and behavioral therapy as well as medications. Occlusal splints provide physical separation of the teeth. The goal of occlusal splints is to eliminate occlusal factors which trigger parafunctional habits and masticatory muscle hyperactivity, thereby reducing the involuntary overloading of the joint. Mandibular repositioning splints are used in order to achieve a repositioning of a dislocated TMJ disc. Because of the multifactorial nature of TMDs and the numerous types and concepts for occlusal splints, there are mixed reports on the effectiveness of this treatment.[90] Physical therapy, including active and passive joint movement and myofunctional therapy, is another important component of noninvasive therapy which has been seen to reduce pain in TMD patients.[91] Occlusal splints and physical therapy are commonly combined with behavioral therapy such as biofeedback and techniques for stress management, which has emerged as an extremely important component of TMD therapy. Nonsteroidal anti-inflammatory agents, such as ibuprofen, are the most common medications given for TMJ pain.

Following or in conjunction with noninvasive treatments, minimally invasive therapies include injections, arthrocentesis, and arthroscopy. Corticosteroid injections are used occasionally for severe inflammation, but repeated injections can lead to cartilage destruction.[92] Intra-articular injections of hyaluronic acid to increase lubricity of the joint have been suggested,[93] but have not yet been approved for clinical practice. During arthrocentesis, a needle is used to flush and drain the joint space, with the goal of removing inflammatory mediators and enhancing lubrication. Arthroscopy of the TMJ is mainly used for the diagnosis of early stage arthritis,[94] although some manipulation can be done such as removing fibrotic tissue.

Even though a majority of TMD patients can be managed with minimally invasive treatment, there is a subset of patients (~20%) who will require surgical intervention.[95] TMJ arthroplasty is a relatively common surgical procedure that requires the replacement of the disc with, for example, an autogenic material. Typically, the local temporalis muscle flap is used for disc replacement,[96] although a tissue-engineered disc would be of great utility in this situation. Hemiarthroplasty, reshaping the fossa or replacing it with an alloplastic implant, became popular in the 1960s, but is rarely used today because of concerns about degradation of the remaining joint tissues.[4] Although orthognathic surgery is an option for TMD patients, it is not frequently used, as the outcomes are poor for patients with preexisting TMJ degradation.[97] Instead, orthognathic surgery is now used in conjunction with total joint replacement to enhance facial symmetry.

When advanced degenerative disease is present in the TMJ, currently, the only clinical option is an alloplastic total joint replacement. Replacing all or part of the TMJ with an alloplastic material will always come under intense scrutiny on the basis of the poor history of these procedures. In the late 1980s, a Teflon–Proplast implant was approved for TMJ disc replacement by the Food and Drug Administration (FDA). These implants ended up fragmenting under normal loading conditions, leading to a large foreign body giant cell inflammatory response and causing immense resorption of the condyle and fossa.[98] In spite of this failure, alloplastic total joint replacements for the TMJ have been researched intensely for the last 20 years (**Chapter 6.621, Biomaterials and Their Application in Craniomaxillofacial Surgery**). Currently, there are three total joint replacement systems approved by the FDA, manufactured by Christensen, Biomet, and TMJ Concepts. TMJ total joint replacements generally consist of a chromium–cobalt–molybdenum condylar head articulating against an ultra-high-molecular-weight polyethylene (UHMWPE) fossa. The total alloplastic TMJ reconstruction is considered an appropriate treatment of advanced-stage degenerative TMJ disease, although the lifetime of the device and the long-term implications for the surrounding tissues have not been known yet.[89] Tissue engineering may provide a functional and permanent biological replacement for the TMJ, eliminating the need for alloplastic regeneration.

5.517.6. Tissue Engineering

While many tissues in the body when injured have an innate capacity to self-repair, there are some tissues that have little to no self-repairing capacity. The tissues of the TMJ fall into the latter category. Additionally, because of the complex interplay of tissues within the joint, a deficiency in one area can detrimentally affect the surrounding tissues, causing pathology of the joint as a whole. Widespread injury of the TMJ, combined with its limited reparative capacity, necessitates some form of clinical intervention in order to maintain normal function and eliminate pain for the patient. Presently, clinical therapies fall short of addressing the full spectrum of issues and are only semipermanent. Tissue engineering may address these deficits by providing permanent, biomimetic, replacement tissue systems for the TMJ. To achieve this, scientists use the tissue engineering paradigm (**Figure 4**). In this paradigm, native tissue is first characterized to create design parameters for tissue engineering (**Chapter 5.519, Biomaterials Selection for Dental Pulp Regeneration**; **Chapter 5.524, Biomaterials for Replacement and Repair of the Meniscus and Annulus Fibrosus**; and **Chapter 5.535, Cartilage Regeneration in Reconstructive Surgery**). These design parameters are then used to inform the selection of an appropriate cell source, bioactive factors, biomechanical stimulation, and/or scaffold for the creation of an implantable biomimetic tissue. In this section, current tissue engineering efforts for the disc, condylar cartilage, and condyle will be reviewed.

5.517.6.1. TMJ Disc

Characterization data for the TMJ disc have determined certain specifications that should be considered when tissue engineering a suitable replacement. It is known that this tissue houses a distinct cell population and has unique geometry and mechanical properties, brought on by the anisotropic behavior of its biochemical components. Tissue engineering of the disc,

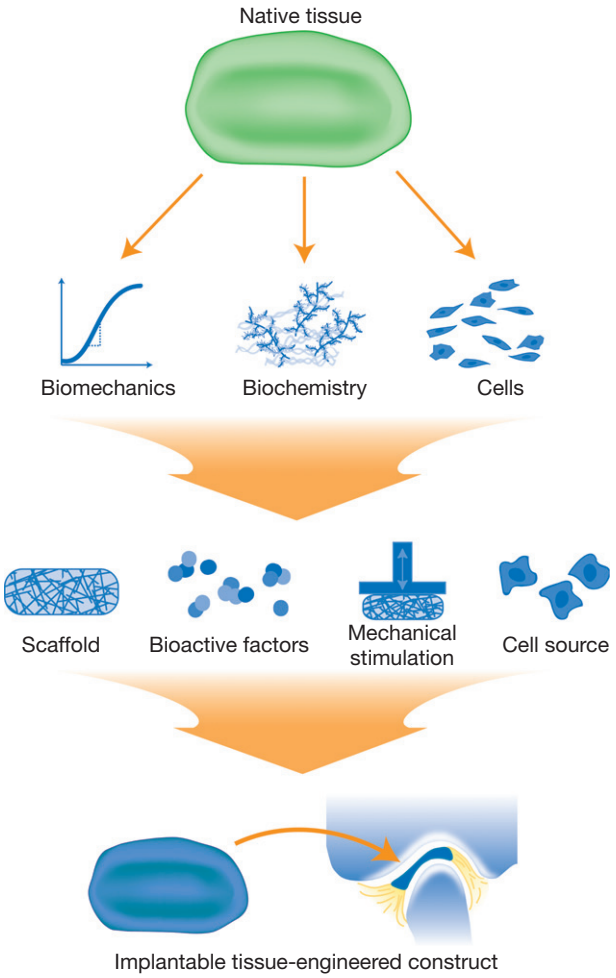

Figure 4 Tissue engineering paradigm for engineering temporomandibular joint (TMJ) tissues. The tissue engineering process is initiated by characterizing the biomechanical, biochemical, and cellular properties of the native tissue to create design parameters for tissue engineering. Next, cells are combined with scaffolds, bioactive agents, and mechanical stimuli to produce a tissue-engineered TMJ tissue that can be implanted *in vivo*.

therefore, must recapitulate these characteristics of the disc in order to preserve its function within the joint. Unlike other tissues of the TMJ, a considerable number of studies have investigated engineering of the disc. Although the first report of TMJ disc tissue engineering appeared in 1994, a majority of the tissue engineering efforts have been conducted recently. This section reviews important advances in cell and scaffold selection, as well as the role of bioactive factors and mechanical stimulation used in the field of TMJ disc tissue engineering.

5.517.6.1.1. Cell sources

Selection of a cell source is likely the most important aspect of any tissue engineering strategy (**Chapter 5.507, Tissue Engineering and Selection of Cells**). These cells are responsible for ECM production and maintenance, resulting in a functional replacement tissue. The most commonly used cells for engineering the TMJ disc have been primary disc cells.[99–109] Although primary TMJ disc cells have been studied extensively, there are two main problems with this cell source: (1) lack of donor cells and (2) donor site morbidity. It is possible to passage cells in monolayer to increase cell numbers, but unfortunately, TMJ disc cells dedifferentiate rapidly in culture and their phenotype is difficult to recover.[110–112] Because of concerns about donor site morbidity, costal chondrocytes have recently been investigated as an alternative cell source for TMJ disc engineering.[113–116] This research was prompted by the fact that oral surgeons already use costal rib grafts for the replacement of the mandibular condyle, and donor site morbidity is minimal.

To completely eliminate concerns about primary cell sources, progenitor cells will likely need to be used for future TMJ tissue engineering efforts. Recently, a series of self-renewing and highly potent human stem cells, such as multipotent mesenchymal stem cells (MSCs), umbilical cord matrix stem cells, and pluripotent embryonic stem cells (ESCs), have emerged and have shown promise for TMJ tissue regeneration. These stem cells, as shown in **Figure 5**, have a large proliferation capacity enabling them to expand without losing their phenotype. Even after expansion, they are able to differentiate into cartilage, bone, and tendon/ligament. Both adult and embryonic stem cells have been shown to be capable of differentiating into fibrochondrocytes that can be used for TMJ disc engineering.[117–120] Additionally, progenitor cells from the skin have been shown capable of differentiating down a chondrogenic lineage in response to ECM molecules.[121,122] Future studies will need to further investigate the differentiation of progenitor cells and their application in TMJ tissue engineering.

5.517.6.1.2. Scaffolds

Scaffolds are an important consideration in tissue engineering as they provide the constructs' initial mechanical integrity and allow for cell attachment. The first TMJ disc tissue engineering study used a porous collagen scaffold and produced constructs with appreciable size and ECM.[99] Similar success was seen with porous polyglycolic acid (PGA) and polylactic acid (PLA) scaffolds. Both materials were shown to support cell attachment and matrix production for up to 12 weeks.[123] Another early study compared PGA, polyamide filaments, expanded polytetrafluoroethylene (ePTFE), and bone blocks for disc engineering.[100] While all scaffolding materials supported cell attachment, there was poor ECM production in all groups. The majority of more recent TMJ disc engineering efforts have used PGA nonwoven mesh scaffolds.[101–103,105–107] While PGA scaffolds do support cell attachment and biosynthesis, PGA fibers degrade too rapidly, producing constructs of very small size. As a result, Allen and Athanasiou[109] compared the use of PGA to that of poly-L-lactic acid (PLLA) nonwoven meshes. PLLA scaffolds produced constructs with enhanced dimensions and mechanical integrity compared to PGA.[109] Additionally, encapsulation of TMJ disc cells in alginate hydrogels has been investigated, but cell viability and ECM production were quite low after 4 weeks.[101] Overall, significantly better results have been observed when culturing TMJ disc cells on natural and synthetic mesh scaffolds than encapsulating the cells in hydrogels.

Although scaffolds are typically an integral part of tissue engineering, it is also possible to produce scaffold-less constructs. Recent efforts to engineer the TMJ disc using costal chondrocytes have produced large functional constructs using a scaffold-less 'self-assembly' technique.[113–116] In this

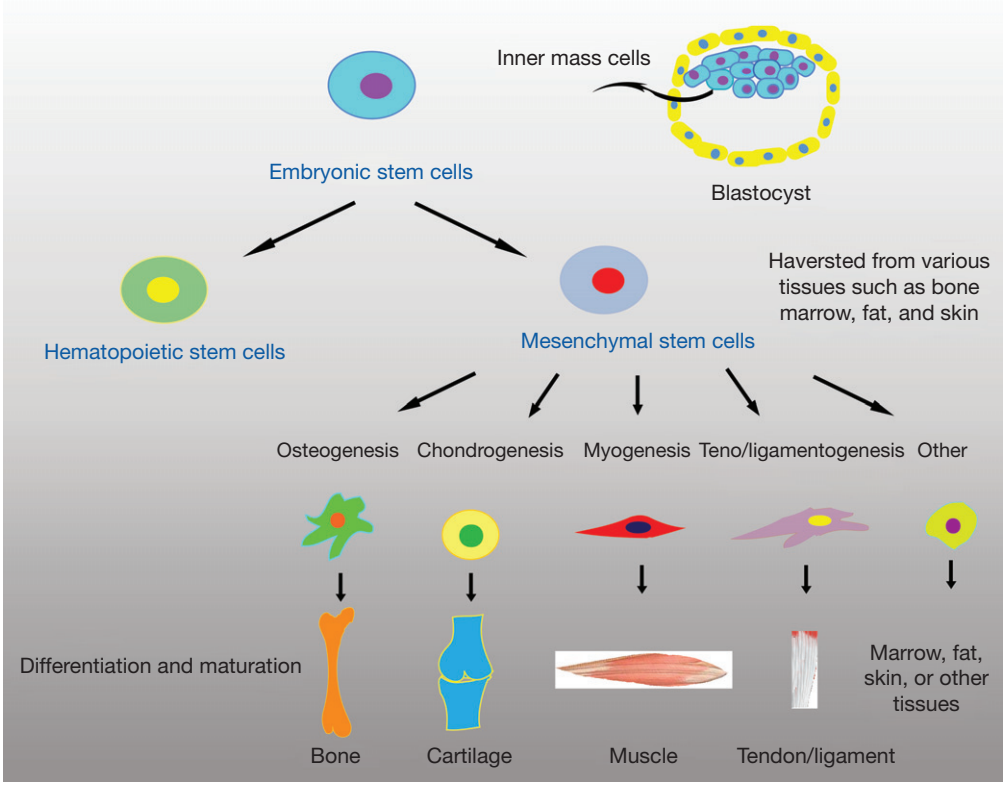

Figure 5 The hierarchal structure of human embryonic and mesenchymal stem cells. Embryonic stem cells are derived from the inner cell mass of the blastocyst and can differentiate down any of the three germ lineages. Mesenchymal stem cells are multipotent and can differentiate into any mesenchymal tissue, including cartilage and bone.

procedure, cells are seeded at very high density into a nonadherent well, which forces the cells to bind to one another.[124] The cells then secrete their own ECM scaffolding over time. Ultimately, both scaffold-less and scaffold-based approaches have seen beneficial results for tissue engineering the TMJ disc, and both techniques should be further investigated.

5.517.6.1.3. Bioactive agents

Growth factors are commonly used in tissue engineering because of their ability to enhance cellular proliferation and/or biosynthesis (**Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**). So far, five different growth factors have been investigated for TMJ disc tissue engineering: platelet-derived growth factor (PDGF); basic fibroblast growth factor (bFGF); transforming growth factor-β1 (TGF-β1); transforming growth factor-β3 (TGF-β3); and insulin-like growth factor-I (IGF-I). In monolayer culture, TGF-β1, IGF-I, and bFGF have all been shown to increase TMJ disc cell proliferation and biosynthesis.[13,125] It was noted that high concentration of growth factors favored cell proliferation, while low concentrations of growth factors favored biosynthesis.[125] In three-dimensional culture, the effects of growth factors in TMJ disc tissue engineering have been investigated with both PGA and PLLA mesh scaffolds. On PGA scaffolds, both IGF-I and TGF-β1 were shown an increase in the collagen synthesis of porcine TMJ disc cells.[103] In contrast, with PLLA constructs, only TGF-β1 showed a significant increase in biochemical and biomechanical properties.[109] This differential effect may be related to the fact that PGA degrades much faster than PLLA. Growth factors have also been used to enhance TMJ disc tissue engineering using costal chondrocytes. IGF-I enhanced the cellular and biochemical properties of scaffold-less costal chondrocyte constructs.[114]

Although growth factors have received the most attention, other bioactive agents can have a significant impact on TMJ disc tissue engineering as well. TMJ disc cells cultured in media with 25 $\mu g\,ml^{-1}$ of ascorbic acid produced constructs with higher collagen content than cells cultured under concentrations of 0 or 50 $\mu g\,ml^{-1}$.[107] Molecules such as ascorbic acid are important to ECM protein synthesis and should be considered when choosing a media for tissue engineering. Recent evidence from articular cartilage engineering suggests that using catabolic agents can improve construct properties. Natoli *et al.*[126] recently demonstrated that applying chondroitinase-ABC (C-ABC, a GAG removing enzyme) during the midpoint of culture can improve the tensile properties of engineered cartilage. The GAGs that were depleted by C-ABC return by the end of culture and there is no loss in compressive properties.[126] Nontraditional bioactive agents such as this deserve future investigation for TMJ disc tissue engineering.

5.517.6.1.4. Mechanical stimulation

The native TMJ disc experiences significant loading which encompasses compression, tension, and shear components (**Chapter 5.506, Effects of Mechanical Stress on Cells**).[127] As the disc is such a mechanically important tissue, it makes

sense that mechanical stimuli may be required to produce an optimal tissue engineering construct. The first study to investigate mechanical cues on TMJ tissue engineering used a rotating wall bioreactor to create a low-shear fluid environment. Constructs grown in the rotating wall bioreactor ended up being statistically the same as culture controls, and no benefit of the low-shear environment was observed.[104] Continuous hydrostatic pressure of 10 MPa has been shown to increase ECM synthesis of TMJ disc cells both in monolayer and in PGA scaffolds.[105] In contrast, intermittent hydrostatic pressure of 10 MPa applied at 1 Hz was seen to be detrimental to TMJ disc cell biosynthesis. In two-dimensional culture, TMJ disc cells exposed to dynamic tensile strain significantly reduced production of MMPs in response to the proinflammatory cytokine interleukin-1β (IL-1β).[128] While it is clear that mechanical cues have an impact on TMJ disc tissue engineering, more research is needed to determine whether other stimuli used in articular cartilage engineering, such as compression and shear, are beneficial.

5.517.6.2. Condylar Cartilage

Of the three TMJ tissues for which tissue engineering has been attempted, condylar cartilage has received the least amount of attention. The first report of three-dimensional condylar cartilage engineering did not appear in the literature until 2007. Similar to the disc, condylar cartilage has limited repair capabilities and is an excellent candidate for tissue engineering. To this point, disc and condylar cartilage engineering have been conducted independent of each other, although tissue engineering results from one tissue will likely benefit the other. As engineering of condylar cartilage is a new field, efforts thus far have focused on the issues of cell source and application of bioactive agents.

5.517.6.2.1. Cell sources

The majority of condylar cartilage tissue engineering efforts thus far have used primary cells from the tissue.[129–134] Currently, two methods have been used for harvesting primary condylar chondrocytes. The first uses collagenase to digest the cartilage,[129] and the second allows the cells to migrate out of tissue explants.[130] The collagenase method isolates cells from all four cartilage zones, whereas the tissue explant method isolates only cells from the fibrous zone. While condylar chondrocytes do grow in culture and respond to growth factors, they show relatively low ECM production *in vitro*.[42] Because of the low matrix production, chondrocytes from other parts of the body have been used for condylar cartilage engineering. Articular chondrocytes from the ankle have been compared to condylar chondrocytes during both monolayer and three-dimensional culture. In monolayer, condylar chondrocytes showed greater proliferation but ankle chondrocytes produced tremendously more matrix.[135] On PGA scaffolds, ankle chondrocytes again produced an order of magnitude more ECM than condylar chondrocytes.[136] Future studies using primary cells will likely use a chondrocyte source from somewhere other than the condyle.

Because of the standard concerns about primary cell sources (insufficient cell number and donor site morbidity), progenitor cells have begun to be investigated for condylar cartilage engineering. Recently, human umbilical cord mesenchymal stromal cells (hUCMSCs) have been identified as an attractive cell source for condylar engineering. hUCMSCs are multipotent stem cells that develop from the extraembryonic mesoderm of the umbilical cord. When hUCMSCs were compared to condylar chondrocytes for tissue engineering, hUCMSCs were seen to proliferate more rapidly and produce significantly more matrix.[134] External stimuli have been shown to increase the matrix production of hUCMSCs even further.[119,120] Capitalizing on the deficiencies of primary cells, multipotent stem cells appear to have a bright future in condylar cartilage engineering.

5.517.6.2.2. Scaffolds

While there are many potential scaffolds for condylar cartilage engineering, at this point, only two scaffolding materials have been used. The most common scaffold choice has been a PGA mesh.[119,120,134,136] The choice of PGA has likely been influenced by TMJ disc engineering where it had previously been used. As mentioned earlier, PGA supports good cell attachment and matrix production, but degrades too rapidly in culture. Other than PGA, one study has investigated encapsulation of condylar chondrocytes in alginate gel beads.[137] After 4 weeks, the cells maintained a chondrogenic phenotype based on immunostaining. As the field of condylar cartilage expands, it is clear that attention will need to be paid to scaffold choice.

5.517.6.2.3. Bioactive agents

To date, the use of bioactive agents in condylar cartilage engineering has focused on the application of growth factors to condylar chondrocytes and hUCMSCs. The growth factors investigated are similar to those used for TMJ disc engineering, including bFGF, IGF-I, TGF-β1, and epidermal growth factor (EGF). A high concentration of bFGF appears to have the greatest effect on condylar chondrocyte proliferation, although it may inhibit ECM biosynthesis of the cells.[131–133] IGF-I has been shown to be a potent promoter of both cell proliferation and matrix synthesis, particularly GAG production.[133,138,139] Condylar chondrocyte biosynthesis has also been shown to increase with TGF-β1 application, but it is unclear whether it exhibits positive effects on cell proliferation.[133] Cells from the fibrous zone of condylar cartilage have been show to be stimulated by EGF, but the remaining zones have not been investigated.[130] Finally, IGF-I has also been shown to enhance the fibrochondrogenesis and matrix synthesis of hUCMSCs.[119,135] These results provide the basis for further investigations into using external stimuli to enhance condylar cartilage engineering.

5.517.6.3. Mandibular Condyle

Unlike tissue engineering the TMJ disc which began in the early 1990s, condylar engineering did not appear in the literature until 2000. Fortunately, bone tissue engineering in general has been studied extensively. Although still lagging behind the TMJ disc, there has been more effort to engineer the mandibular condyle than the condylar cartilage. The current field of mandibular condylar tissue engineering combines a variety of cell types (i.e., osteoblasts, chondrocytes), mandibular-condyle-shaped scaffolds (i.e., polymers, ceramics), and bioactive factors (i.e., TGF-β, IGF-I, bFGF), to

restore the functionality of damaged tissues. A majority of the efforts thus far have been focused on creating a condyle-shaped scaffold as this is a nontrivial shape.

5.517.6.3.1. Cell sources

Mature osteoblasts and chondrocytes are the most commonly used cell types to regenerate new bone and cartilage tissues. Specifically, osteoblasts have been investigated as one of the main cell sources for subchondral bone repair.[140] They can actively interact with proteins and minerals to adhere, proliferate, and develop a mineralized ECM and differentiate into mature bone. Weng *et al.*[141] created a tissue-engineered mandibular condylar construct via a combination of osteoblasts, chondrocytes, and scaffolds. They seeded osteoblasts into a PGA/PLA scaffold and then painted chondrocytes onto the surface of the scaffold.[141] This study showed that the formation of a bone/cartilage composite *in vivo* is promising for future mandibular condylar reconstructions.

The lack of clinical translatability for primary cells has also been recognized in mandibular condyle engineering. A recent push has been made to investigate the use of stem cells in condylar engineering. Many studies have revealed promising results of bone marrow-derived MSCs for repairing condylar defects.[142–145] Alhadlaq and colleagues[146] once encapsulated the chondrogenically and osteogenically differentiated bone marrow MSCs into biphasic poly(ethylene glycol) (PEG)-based hydrogels in order to create a human-shaped mandibular condyle. After 8 weeks of *in vivo* implantation, it was demonstrated histologically that cartilaginous and osseous phenotypes were present in two stratified layers.[143] In summary, stem cells are emerging as a promising cell source for mandibular condyle tissue regeneration, although they require more investigations to fully explore their medical potentials.

5.517.6.3.2. Scaffolds

Scaffolds play an important role in mandibular condylar tissue engineering through providing structural and mechanical supports for cell growth and tissue formation. Because of the ease of fabrication, good biocompatibility, suitable mechanical properties, and controllable biodegradability, natural or synthetic polymers have been extensively used as bone, and osteochondral tissue engineering scaffolds. Popular polymers for tissue engineering the mandibular condyle have been PEG, polycaprolactone (PCL), PLA, PGA, and poly-lactic-*co*-glycolic acid (PLGA). Ueki *et al.*[147] implanted PLA/PGA/gelatin sponges (PGS) with or without recombinant human bone morphogenic protein-2 (BMP-2) into condylar defects of rabbit TMJs. After 4 weeks, it was observed that the PGS scaffolds with or without BMP-2 induced new bone and cartilage-like tissues in the TMJ.[147] In another study, a tissue-engineered bone construct with a mandibular condyle shape was obtained by combining osteogenically differentiated MSCs and PLGA scaffolds.[148]

Calcium phosphate ceramics such as HA and tricalcium phosphate (α- or β-crystalline TCP) share a similar crystal structure and chemical composition with natural bone. As a result, they have good osteoconductive and osteoinductive properties and have been considered as popular bone substitutes, filler materials, and bone tissue engineering scaffolds.[72] For mandibular condylar tissue engineering, calcium phosphates are usually fabricated with polymers into a composite. The Hollister group has generated various load bearing tissue-engineered scaffolds with appropriate bulk geometry and microarchitecture through image-based design and solid free-form fabrication methods from polymers (PLA, PGA, PLGA, PPF, etc.), ceramics (HA or TCP), or their composites (PLA/HA, PPF/TCP, and HA/TCP).[149–153] For instance, a biphasic PLA/HA composite scaffold was made and fibroblasts with BMP-7 and chondrocytes were separately seeded into the HA and PLA phases.[150] The results showed simultaneous growth of bone, cartilage, and a mineralized interface tissue in the tissue-engineered scaffold. Thus, this technology holds the potential for repairing osteochondral defects in the TMJ.

Natural tissues or organs have numerous nano features and cells directly interacting with nanostructured ECM. Therefore, biomimetic nanomaterials, which have basic structural units, grains, particles fibers, or other constituent components smaller than 100 nm in at least one dimension, have been investigated for TMJ implants, bone, and cartilage regenerations.[72,154] For example, by using chemical vapor deposition technology, a nanostructured diamond film with high hardness and enhanced toughness was deposited on articulating surfaces of TMJ implants and exhibited excellent biocompatibility and mechanical properties.[155] In addition, some *in vitro* studies showed that nanophase HA significantly enhanced osteoblast adhesion and inhibited undesirable fibroblast adhesion compared to conventional HA.[71] Venugopal and colleagues[156] demonstrated that osteoblast proliferation, alkaline phosphatase activity, and mineralization were significantly improved on the electrospun fibrous PCL/HA/gelatin nanocomposite when compared to PCL alone. It was also reported that the electrospun PCL nanofibrous scaffolds effectively induced chondrogenic differentiation of MSCs *in vitro*,[157] and bone formation *in vivo*.[158] Even though few results of nanostructured scaffolds for mandibular condylar tissue engineering are available, it is a promising research field because of its use of biomimetic surface topography, increased wettability, and better mechanical properties.

5.517.6.3.3. Bioactive agents

Even though condylar engineering is a new field, one recent study has investigated the effects of growth factors on tissue development. Srouji *et al.*[159] evaluated *in vivo* mandibular defect repair by hydrogel scaffolds with IGF-I and TGF-β1. After 6 weeks, significant bone formation was observed in the mandibular defects implanted with TGF-β1, IGF-I, and TGF-β1 + IGF-I incorporated hydrogels.[159] Although this study provides a preliminary insight, more research needs to be performed to determine the full potential of bioactive agents for condylar engineering.

5.517.7. Future Directions for TMJ Tissue Engineering

TMJ tissue engineering has progressed quite dramatically over the last 10 years. Now, there are investigators actively working on biological replacements for the disc as well as

the cartilage and bone of the condyle. The current literature provides a reference point for tissue engineering challenges such as cell source and scaffold selection, although the amount of prior work varies between tissues. There is still a significant amount of work that needs to be completed to produce functional replacements for TMJ tissues. Clear directions for the future of TMJ tissue engineering include progenitor cells, enhanced external stimulation, and engineering of the remaining TMJ tissues.

5.517.7.1. Progenitor Cells

Previous work using primary TMJ cells has allowed the characterization of these cells *in vitro*, but a clinically relevant tissue-engineered construct will likely not contain these cells. Problems with primary cells have been discussed earlier and include a lack of donor tissue and high donor site morbidity. A practical cell source for TMJ engineering should originate from healthy tissues which, when removed, should not result in significant morbidity.[12] The likely choice is progenitor cells, whether adult or embryonic. Direct comparison has shown that multipotent progenitor cells outperform TMJ cells.[134] Both MSCs and embryonic stem cells have shown the ability to differentiate down fibrocartilaginous and osteogenic lineages.[118,120,143,160] Although stem cells have been used for TMJ tissue engineering, different cell types have been used for each tissue in an investigator dependent manner. Additionally, the differentiation of these progenitor cells into TMJ-like cells is not fully understood. In the future, there should be coordinated efforts to determine the appropriate progenitor cells for all TMJ tissues, as a total biological joint replacement must be the ultimate goal.

5.517.7.2. Mechanical Stimuli

Even though a significant number of TMJ tissue engineering studies have been completed, only three have investigated the effects of external mechanical stimuli. As TMJ is a frequently loaded joint, it makes sense that mechanical stimulation would enhance TMJ engineering. Biomechanical stimuli have been used extensively in articular cartilage engineering with great success.[161] Stimuli that may be beneficial for TMJ tissue engineering include compression, tension, shear, and hydrostatic pressure. All of these mechanical loads are present in the TMJ.[12] Hydrostatic pressure[105] and tensile loading[128] have both shown promise for disc engineering and should now be carried forward toward tissue engineering of other TMJ tissues. Compression and shear have not yet been evaluated for TMJ engineering, but should certainly be incorporated into future studies.

5.517.7.3. Other TMJ Tissues

While current tissue engineering efforts have focused on engineering the disc and condyle, other tissues of the joint, including the fossa cartilage, disc attachments, and capsule, should also be considered. Each of these tissues plays an important role in the joint, and needs to be considered toward engineering a total biological TMJ replacement. Although the fossa-eminence is not well characterized, fossa cartilage and bone engineering are likely to benefit directly from condylar cartilage and bone engineering studies. The disc attachments and joint capsule on the other hand are distinct tissues that will require independent characterization and tissue engineering efforts.

5.517.7.3.1. Disc attachments

Although significant attention has been paid to characterization and engineering of the disc, very little focus has been placed on the disc attachments. These attachments connect the disc to the capsule and bony structures of the joint. The discal attachments are important for keeping the position of the disc in the joint relative to the condyle and fossa.[1] Maintaining disc position is critical for preserving normal loading patterns, and a breakdown in the discal attachments will result in joint degradation. Characterization of the native disc attachments will provide important information about how a tissue-engineered disc should be implanted in the joint. It is possible to anchor an engineered disc directly to the condylar head, but this will prevent movement of the disc relative to the condyle and alter the loading pattern in the joint. A more likely solution would be to engineer a disc with its attachments so that the attachments could be anchored to the condyle and sutured to the capsule. This would allow a natural movement of the disc within the joint. Future studies will need to investigate the properties and the tissue engineering potential of the disc attachments.

5.517.7.3.2. Joint capsule

Like the discal attachments, the capsule is a critically important but poorly understood component of the TMJ. Globally, the capsule provides a barrier which isolates the intra-articular joint spaces. Unlike the fibrocartilages of the joint, the TMJ capsule is innervated with various groups of nerve endings, including Pacinian corpuscles.[4] Inclusion of these nerve endings may be necessary for a physiologically normal joint replacement. Additionally, the capsule is lined with synovium, which produces the lubricating and nourishing synovial fluid for the joint. Lubrication is critically important for maintaining normal TMJ loading and must be incorporated into an engineered replacement. The exact difficulties involved in recreating the TMJ capsule will need to be investigated in the future. Ultimately, all of the TMJ tissues, including the fossa, disc attachments, and capsule, will need to be tissue engineered to produce a total biological replacement for the TMJ.

5.517.8. Conclusions

Although it has only recently received attention, the field of TMJ tissue engineering is growing rapidly. The pathology of the TMJ is complex, but it is important to address these diseases for the millions of people suffering from TMD. Even though characterization of native TMJ tissues has not been completed yet, the available literature has provided a rough set of design and validation criteria on which tissue engineering efforts can be based. Current tissue engineering efforts provide a basis for selecting a cell source, scaffold, and external stimuli, although technological advancements provide new options regularly. The rapid increase in TMJ disc characterization and engineering studies over the last 10 years provides

optimism for the remaining TMJ tissues that are not as well studied. It is clear that significant effort must be put forth before the ultimate goal of creating a functional biological replacement for the TMJ can be reached, but the future looks bright for this technology.

Glossary

Computer-aided design (CAD) In this context to duplicate both bone form and function for molded in situ cultivated autologous bone grafts.

Critical sized defect A bone defect incapable of healing or regenerating sufficient new bone to close the defect without surgical intervention and grafting.

Endocultivation Use of autologous mesenchymal stem cells loaded within a preformed titanium mesh cage and implanted into a surgically created pouch within the right or left latissimus dorsi muscle. The pouch serves as *in vivo* bioreactor to produce vascularized bone for autologous transplant to a critical defect.

Latissimus dorsi A flat, fan-like muscle that arises directly from the spinal processes of the lower six thoracic vertebrae, the lumbar and sacral vertebrae and the dorsal iliac crest via the thoracolumbar fascia. The muscle inserts between the teres and pectoralis muscles at the humerus and together with the teres major, forms the posterior axillary fold.

5.518.1. Introduction

The repair of critical size skeletal defects from trauma, congenital malformations, infection or tumor resection remains a challenge in modern Orthopedic, Maxillofacial and Plastic-Reconstructive surgery.[1] Besides function and mechanical integrity the reconstruction of the skeleton must also meet high aesthetic demands of the prevailing patient especially when recreating the skull and mandible. For example: the mandible has a complex function and shape. It is involved in mastication with high mechanical loading which imposes requirements of high compressive and torsional stability. The ability to speak and articulate properly requires a comprehensive interaction of adjacent muscles and two evenly balanced temporomandibular joints. The size and shape of the mandible is important for the proper occlusion of teeth (or dental implants) with those of the opposite maxilla. And at least the aesthetic appearance of the individual is highly dependent on the position of the chin and the mandibular angles. However, many patients require to be 'made up' as they had been prior to their impairing disease. Thus, the perfect reconstruction of the mandible or the facial bones is an ambitious goal.

Today, major bone defects that create a discontinuity in the bone extending over more than 5 cm are usually repaired with an autologous vascularized graft such as a fibula, scapula, iliac crest, or rib transplant. However, a major disadvantage of these techniques is that harvesting the required bone grafts creates another skeletal defect which is associated with significant morbidity (Figure 1).[2]

Recent advances in the emerging field of regenerative medicine may offer new solutions for Orthopedic and Plastic-Reconstructive surgeons. 'Regeneration' implies repairing the damaged tissue by growing it anew by means of tissue engineering.[3] This circumvents the issue of immunological rejection, as the patient's own cells are used to cultivate the required tissue.

In vitro tissue engineering has been a focus of many research groups; however, *in vivo* techniques such as endocultivation may offer even greater potential today.[3,4] *In vitro* techniques often focus on an optimized combination of three factors: cells, signaling molecules, and scaffolds. This is known as the classical 'Triangle or Tissue Engineering' (Figure 2). These three factors are already part of endocultivation, as shown in Figure 2. However, there is also an ongoing discussion about

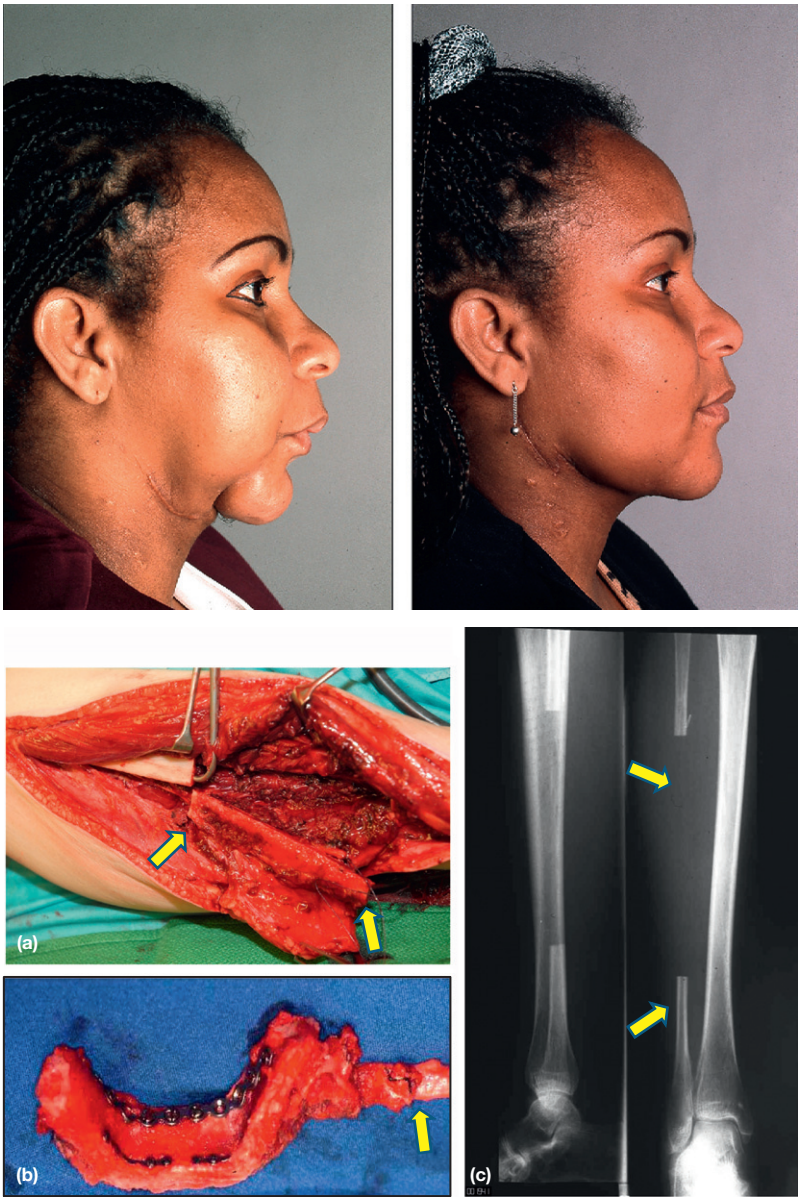

Figure 1 Autologous vascularized fibula grafts. Top left: Female with loss of mandible due to osteomyelitis. Impaired function and unsatisfactory aesthetic appearance (drop chin). Top right: After reconstruction with autologous vascularized fibula graft. Bottom: (a) When harvesting a fibula graft (between arrows) another reasonable skeletal and muscular defect is created. (b) The previously straight fibula being contoured into a mandibular shape and fixed with osteosynthesis plates. The arrow shows the vessel pedicle. (c) X-ray: The critical size defect along the fibula after harvest (arrows). Further complications such as instable ankle joint may occur at this site (Surgeons: Terheyden, Wiltfang, Springer, Warnke; Kiel, Germany).

the way as to how to best apply *in vitro* synthesized tissue and how to insert a vessel pedicle. Thereby, a hexagonal shaped model as shown in Figure 2 may be more appropriate for the future of tissue engineering.

There are additional factors that are especially important when focusing on the cultivation of entire organs with multiple different cell types. For example, a multifaceted organ such as the kidney cannot be engineered without the ability to synthesize and coordinate the orchestra of different cell pathways at the same time, same place and in the same milieu. In short, an organ is a coexistence of different cell types with different desires at the same place. So, how do we grow this? At least understanding how to grow and to control the minimum of two tissue types simultaneously together will be one key step forward. But many *in vitro* cultivation recipes for different cell types such as osteoblasts or chondrocytes for example require different competing environmental or bioreactor conditions to be cultivated. The hypothesis that is pursued here is that a more elegant solution can be found in endocultivation, where living bioreactors are applied.

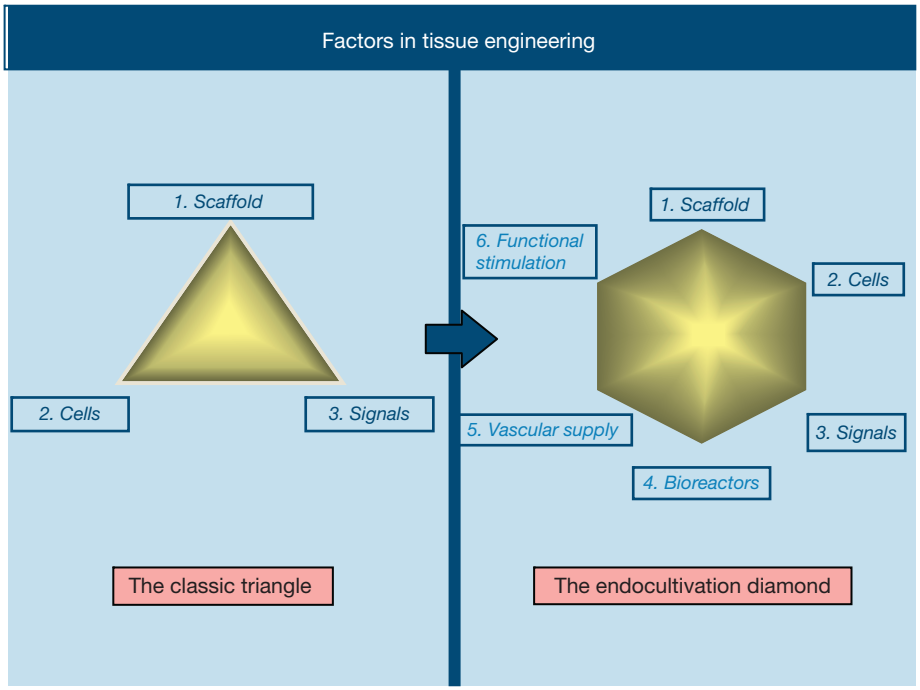

Figure 2 The classic triangle of three factors influencing tissue engineering changes into a diamond of six factors, when applying endocultivation. Many more factors may be identified in the future.

5.518.2. Endocultivation of Autologous Vascularized Bone Grafts

Endocultivation is a pioneering technique used to grow individually shaped bone replacements within the latissimus dorsi muscle of patients with severe skeletal defects. The goal is to use the patients as their own living bioreactors to avoid the common problems associated with engineering tissue *in vitro* (in the laboratory). The replacement scaffolds are individually designed prior to surgery using computer-assisted design (CAD) to enable for an excellent fit. The major advantages of the endocultivation technique are related to achieving an optimal three-dimensional esthetic outcome, and to preventing the creation of a secondary skeletal defect. In addition, good vascularization can be achieved using endocultivation, which remains a major challenge in the engineering of thick tissues *in vitro*.[13] However, as only autologous cells are applied, immune reactions problems caused by foreign tissue, as is known to occur in other disciplines of organ transplant surgery will not occur.[6]

5.518.2.1. The Living Bioreactor (Musculus Latissimus Dorsi)

The latissimus dorsi is a flat, fanlike muscle that arises directly from the spinal processes of the lower six thoracic vertebrae, the lumbar and sacral vertebrae and the dorsal iliac crest via the thoracolumbar fascia. The muscle inserts between the teres and pectoralis muscles at the humerus and, together with the teres major, it forms the posterior axillary fold.[7,16]

Parts of the latissimus dorsi muscle also sometimes serve as an autologous vascularized flap used in Plastic and Reconstructive surgery. Thus, the latissimus dorsi flap has accrued a broad spectrum of clinical applications. This is due to the large area of tissue available, thereby allowing flexibility in flap design. For example, the muscular flap can be combined with a skin pedicle or bone segment of the scapula, thus being one of the favorite autologous vascularized osteomyocutaneous flaps in Plastic and Reconstructive surgery.[16]

The main nutrient vessel of the muscle is the thoracodorsal artery, which regularly gives off a strong branch to the serratus anterior muscle. The length of the extramuscular part of the vessel course varies from 6 to 16 cm and is about 9 cm on average.[8] The extramuscular part gives off several minor branches.[7] At the point of origin from the subscapularis vessels, the thoracodorsal vessels have diameters of 1.5–4 mm (artery) and 3–5 mm (vein after unification of the two concomitant veins).[7,8]

This long and high-capacity vascular pedicle permits a relatively easy surgical procedure to achieve tissue transfer and microvascular anastamoses at the recipient site.[7,8]

Animal studies and initial clinical data demonstrate that the choice of a prepared muscle pouch inside the latissimus dorsi can be a highly successful site to function as a bioreactor. In fact, there is substantial evidence of heterotopic bone growth and remodeling within the graft.[5,9,12] The muscular bioreactor allows for neovascularisation of the bone replacement thanks to the thoracodorsal artery and vein, thereby allowing subsequent transfer of perfused and living cultivated tissue into the desired recipient region (**Figure 3**). The dimensions of the replacement determine the size of the pouch. It should be located near the lateral rim of the muscle due to the anatomical location of the thoracodorsal artery. Thus the

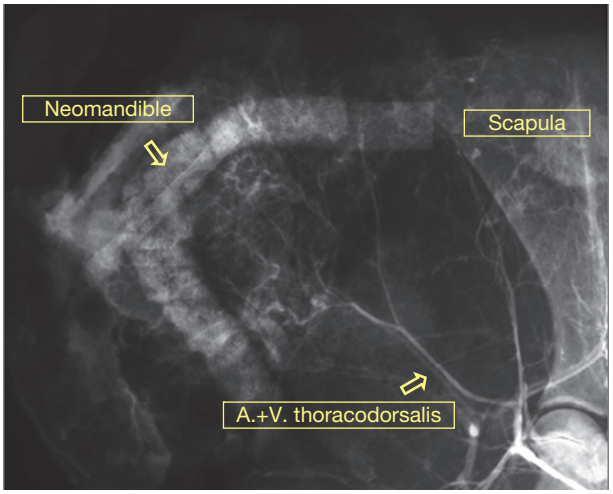

Figure 3 Angiography of an endocultivated new mandible inside the latissimus dorsi muscle of a pig 6 weeks after implantation of hydroxyapatite scaffolds and bone morphogenetic protein-7. The thoracodorsal artery and vein perfuse the neomandible entirely. Thus, transplantation and subsequent microsurgical anastomosis is possible. Note: The horseshoe-shaped neomandible was cultivated with a resorbable external scaffold and not titanium mesh in this case.

cultivated bone replacement will have sufficient blood supply after both transplantation and microsurgical anastomosis of the vessel pedicle.

This independent vascular supply makes it possible to grow constructs of the size of a mandible or in the future, possibly of a joint or even a complex organ.

5.518.3. Clinical Applications of Endocultivation: Tissue Engineering of Autologous Customized Vascularized Bone Replacements *In Vivo*

In 2004, we started using endocultivation techniques to grow customized computer-designed vascularized jaw replacements in the latissimus dorsi muscles of patients for subsequent transplantation to reconstruct their previously resected jaws[4,5] (Figure 4). These types of jaw replacements allowed for immediate masticatory function after transplantation into the recipient region. Besides this, patients are provided with a significantly superior quality of life given their improved esthetic appearance and enhanced ability to speak.

5.518.3.1. Operative Technique

The endocultivation procedure has one presurgical step (Step 1) for custom scaffold design and two different surgical steps (Steps 2 and 3).[16] There is also a subsequent phase for remodeling and integration of the graft into the recipient region (Step 4). These will be described for the cultivation of a mandible replacement in the following sections.

5.518.3.1.1. Step 1: Preoperative planning and CAD design

The aim is to grow a subtotal replacement mandible inside the latissimus dorsi muscle with an adequate vascular pedicle to allow for subsequent transplantation of a viable graft into the defect. Furthermore, the replacement should be individually shaped to fit the defect perfectly, thus improving the chances of adequate postoperative function and a satisfactory esthetic result.

Initially a three-dimensional computed tomography (CT) scan of the head must be performed to identify the mandibular defect and to design an ideal virtual replacement of the missing part(s) using computer-aided design (CAD)-planning techniques (Figure 4). The data describing the mandible replacement is then directed to a CAD-operated 3-axes-milling machine and a Teflon mandible model is created exactly matching the virtual dimensions of the replacement mandible.

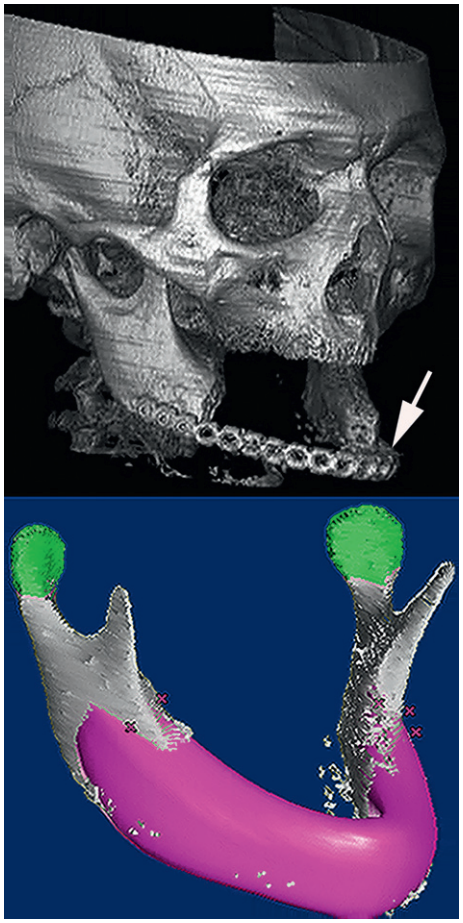

Figure 4 Top: Three-dimensional CT-scan of a 56-year-old male patient after ablative surgery for squamous cell cancer 8 years ago. The mandible was resected from paramedian left region to the retromolar right region. This critical size defect of over 7 cm had been bridged with a titanium reconstruction plate since the initial surgery. Lower image: The CT data of the mandible with defect region is separated. Using computer-aided design (CAD)-planning techniques, an ideal virtual mandibular transplant (pink) is designed that would fit exactly into the defect. The data of this virtual transplant is forwarded to a CAD operated 3-axes-milling-machine to form an identical Teflon model (compare with **Figure 2**). Reproduced from Warnke, P. H.; Springer, I. N.; Wiltfang, J.; *et al. Lancet* **2004**, *364*(9436), 766–770.

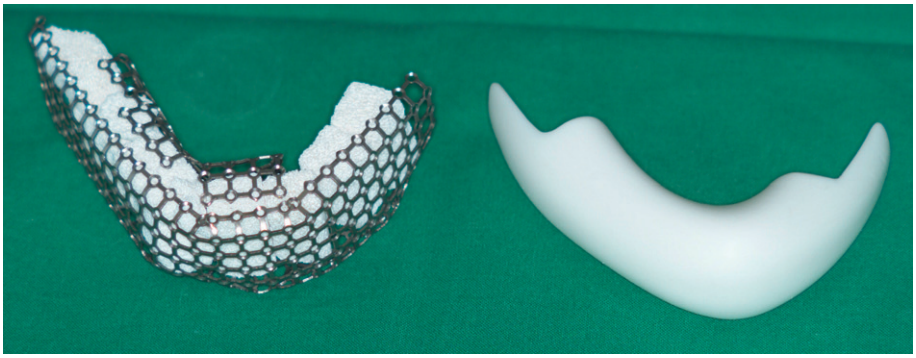

Figure 5 A Teflon mandible model (right) was prepared with a CAD-operated a 3-axes-milling machine. The model has identical dimensions as the virtually designed transplant (compare with **Figure 4**). A titanium mesh scaffold was then formed onto the Teflon model. After removing the Teflon model the remaining titanium mesh cage (left) has similar dimensions as the ideal virtual transplant. The cage is loaded with hydroxyapatite blocks serving as internal scaffold. The blocks will be later coated with bone morphogenetic protein-7 and autologous bone marrow. Reproduced from Warnke, P. H.; Springer, I. N.; Wiltfang, J.; *et al*. *Lancet* **2004**, *364*(9436), 766–770.

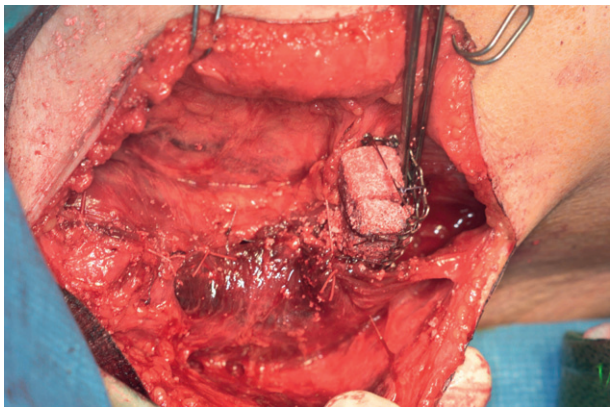

Figure 6 The loaded titanium mesh cage is implanted into a pouch of the right latissimus dorsi muscle of the patient. The surrounding muscle tissue is fixed on the cage with resorbable sutures to allow for maximum soft tissue contact for neovascularisation inside the graft. Reproduced from Warnke, P. H.; Springer, I. N.; Wiltfang, J.; *et al*. *Lancet* **2004**, *364*(9436), 766–770.

5.518.3.1.2. Step 2: Scaffold preparation and implantation

The Teflon mandible is then used as a mold from which a titanium mesh scaffold is created (**Figure 5**). The Teflon mandible is subsequently set aside and the titanium mesh cage (now serving as an external scaffold) is filled with an internal scaffold–bovine hydroxyapatite matrix. This internal scaffold is then coated with recombinant human bone morphogenetic protein-7 (BMP-7). Subsequently, 10–20 ml bone marrow are aspirated from the iliac crest and added to the hydroxyapatite matrix with the intention of providing undifferentiated precursor cells as a target for BMP-7. However, future developments with sterile GMP facilities available may allow for application of high numbers of autologous mesenchymal stem cells in patients at this stage.

The loaded titanium mesh cage (**Figure 6**) is then implanted into a surgically created pouch of the right or left latissimus dorsi muscle. The pouch serves as *in vivo* bioreactor. A 7–10 week cultivation phase is required to allow for both the growth of heterotopic bone and for ingrowth of new vessels from the thoracodorsal artery (**Figure 7**). The use of external titanium meshes is required as long as there are no shapable stable biodegradable scaffolds of the size of a mandible available.

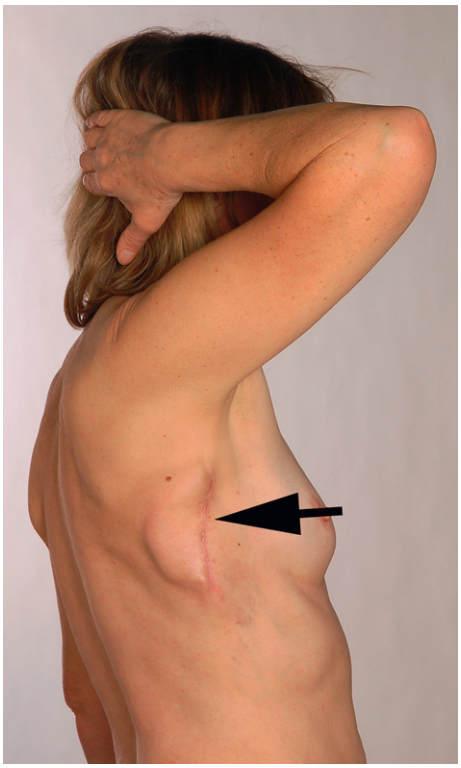

Figure 7 View on the lateral side of another female patient, where a mandibular replacement (arrow) is growing inside her lateral right latissimus dorsi muscle. The shoulder range of motion is not significantly reduced. Reproduced from Warnke, P. H. In *Grabbs Encyclopaedia of Flaps: Head and Neck*, 3rd ed.; Wolters Kluwer/Lippincott Williams & Wilkins: Philadelphia, 2007; Vol. 1.

CT after implantation and prior to transplantation is helpful to detect heterotopic bone growth or any increase in mineralization (**Figure 8**). In addition, bone scintigraphy (600 MBq technetium-99m-oxydronate-tracer) may be used to demonstrate extraskeletal osteoblast activity inside the

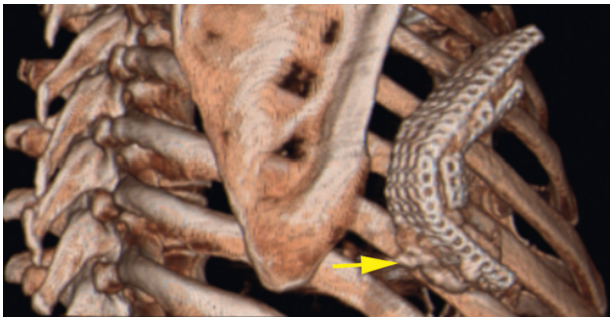

Figure 8 Three-dimensional (3D) CT scanning of the thorax. The mandible replacement is cultivated without contact to the skeleton laterally anterior of the tip of the scapula. New bone formation is even seen to be occurring through the titanium scaffold around the mandibular replacement. Reproduced from Warnke, P. H.; Springer, I. N.; Wiltfang, J.; *et al*. *Lancet* **2004**, *364*(9436), 766–770.

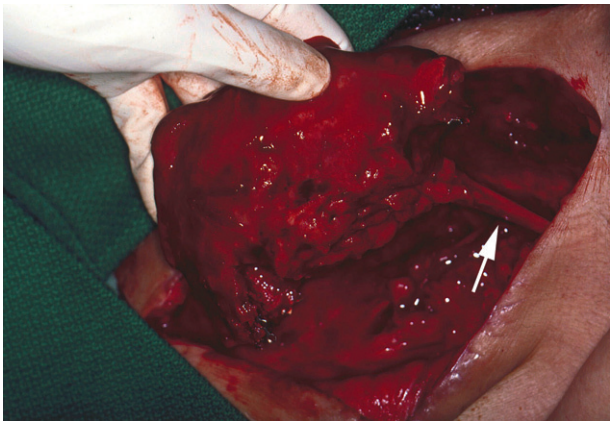

Figure 9 The mandible replacement is harvested with the surrounding muscle tissue and the adjacent thoracodorsal vessel pedicle (arrow). Reproduced from Warnke, P. H.; Springer, I. N.; Wiltfang, J.; *et al*. *Lancet* **2004**, *364*(9436), 766–770; Warnke, P. H. In *Grabbs Encyclopaedia of Flaps: Head and Neck*, 3rd ed.; Wolters Kluwer/Lippincott Williams & Wilkins: Philadelphia, 2007; Vol. 1.

replacement. This is useful to demonstrate the successful induction of new bone formation.

5.518.3.1.3. Step 3: Transplantation

After a cultivation period of a minimum of 7 weeks the mandible replacement is transplanted to repair a significant mandibular defect. The replacement is harvested with the surrounding muscular tissue and the adjacent vessel pedicle from the A. and V. thoracodorsalis (Figure 9). Transplantation into the defect region is performed via an extraoral approach. Minor bone overgrowth on the ends of the replacement can be curetted in order that the transplant fits easily into the defect. As the replacement has been customized using CAD design no further correction of the shape or form of the graft should be required. When a titanium mesh cage is being used as the external scaffold it is helpful to have overlapping edges at the docking points to the original mandible stumps. Thus, the replacement can be easily fixed onto the stumps with miniscrews (Figure 10). The transplant's vascular pedicle is then anastomosed onto the neck vessels utilizing standard microsurgical techniques.

Figure 10 3D CT scan of the male patient after transplantation of the endocultivated mandible replacement. The overlapping titanium-mesh wings of the replacement are fixed in the correct position thus returning the contour of the patient's jaw-line to approximately that present pre-morbidly. Reproduced from Warnke, P. H.; Springer, I. N.; Wiltfang, J.; *et al*. *Lancet* **2004**, *364*(9436), 766–770; Warnke, P. H. In *Grabbs Encyclopaedia of Flaps: Head and Neck*, 3rd ed.; Wolters Kluwer/Lippincott Williams & Wilkins: Philadelphia, 2007; Vol. 1.

5.518.3.1.4. Step 4: Mechanical loading and functional integration

After transplantation the bone graft will receive immediate mechanical loading. This will allow for integration of the graft into the recipient region. Thus, the cultivation of the graft is not over at this point. From now on the patient's body again will allow for remodeling and the graft will undergo an adaption process according to the requirements of the recipient site. This is especially the case after the external titanium scaffolds are removed. However, current studies focus on the prevention of such nonresorbable titanium scaffolds for providing shape.

5.518.4. Clinical Results

Experience in humans with this computer-assisted endocultivation technique is currently limited. The method is still experimental and at the time of publication of this chapter, still requires ethics approval as the use of BMPs at this anatomical site is an off-label use. As such, mandibular reconstructions using vascularized fibula, scapula, or iliac crest grafts remain the gold standard. The preoperative planning requires experience in CAD planning and rapid prototype development to allow for the exact fit of the replacement.

To date, patients who underwent this procedure have not complained of pain or sleep disturbance and relayed only minor concerns regarding the range of motion of their affected shoulder.

Wound closure can be a problem after transplantation of a massive replacement, particularly if the skin is nonelastic in the defect region given previous irradiation therapy and fibrosis. Although not ideal, a split-skin graft covering the adjacent muscle tissue of the graft may be employed if this proves to be particularly problematic.[4]

This type of mandible replacement allows for masticatory function when the external scaffold is properly fixed onto the mandible stumps. Patients are provided with a significantly superior quality of life given their improved esthetic appearance and enhanced ability to speak. To date, there has been no experience in the insertion of dental implants into such neomandibles.

The amount of bone that can be induced with BMP is limited. Follow-up computed tomographies have shown that bone density inside the replacements subsequently enhanced, probably as a result of masticatory functional loading.[5] We see this as a strong foundation for our hypothesis that the grafts undergo a process of functional integration into the recipient, as we describe here as Step 4. This phase might be underestimated in contemporary tissue engineering approaches. The human body seems to be capable to change the tissue engineered grafts according to its needs. Thus, it is an attractive idea to grow premature grafts inside the muscular bioreactor and then to transplant these for subsequent maturization. This could be important for *in vitro* tissue engineers as there seems not to be the absolute need for a 100% ready-to-go graft, when being applied in humans later. The human body may add the missing parts by itself.

A detailed 5 year follow-up for the first patients is currently in preparation.

5.518.5. Future Improvements

It is likely that with the endocultivation technique described above, it may not exceed the density of regular cancellous bone until transplantation at this current stage.[5,12] A firm cortical layer is expected to form only after functional loading of the graft. Thus a mechanically stable and formable external scaffold with sufficient size such as titanium mesh is still necessary to allow for mechanical loading after transplantation.

We are currently in the phase of designing CAD designable and individually formable resorbable hydroxyapatite matrices. A print and sintering processing has been proven to manufacture porous hydroxyapatite matrices. These can already be shape in the size of a simple joint-like-structure. Mechanical tests and *in vitro* plus *in vivo* biocompatibility tests are promising.[14,15] These matrices can also be combined with additional features such as vessel and nerve canals.

Future studies are also focusing on improvement of bone induction inside these matrices. Integrated canals inside the scaffolds may allow for further vascular ingrowth and may also serve as spaces for growth factor delivery to enhance bone formation. These spaces would offer the possibility to administer cell preparations such as autologous stem cells directly into the center of the scaffold. Also a periosteal cover is in preparation to direct cortical bone growth and outer shape of the graft. Thus, mechanically stable grafts might be produced inside the muscular bioreactor without the need for nonresorbable titanium.

The endocultivation method could be advantageous to couple the growth of different tissue types such as bone and cartilage as the cultivation potentials of the human organism are employed. Growth of bone and cartilage *in vitro* requires different culture environments. Whereas the living organism is able to grow even multifaceted organs and also to contol growth in one homogenous environment at the same time. Before we can grow an entire organ we should focus on only two different tissues such as bone and cartilage. Thus, the growth of a biological joint replacement using the endocultivation technique is the next major milestone. The European Union funded tissue engineering network is working toward achieving this goal (see www.myjoint.org) (**Figure 11**).

Figure 11 The concept of intramuscular endocultivation is addressed in growing a biological joint replacement by the research network 'MyJoint'.

5.518.6. Summary

Endocultivation is a pioneering technique used to grow individually shaped bone replacements within the latissimus dorsi muscle of patients with severe skeletal defects. The goal is to use the patient as his own bioreactor to prevent the common problems of engineering tissue *in vitro*.

Replacement scaffolds are designed prior to surgery using CAD to enable a perfect fit. The site of cultivation is a surgically created pouch in the lateral latissimus dorsi which allows for neovascularization, courtesy of the thoracodorsal artery and vein, thereby allowing subsequent free-flap transfer into the desired recipient region. This independent vascular supply makes it possible to grow constructs of the size of a mandible, or in the future, possibly even a complex organ.[10,11]

Glossary

Dental pulp The only vascularized connective tissue comprising collagen and elastic fibers in the tooth; maintains tooth homeostasis as a viable organ, and is embedded in highly mineralized structures including dentin, enamel, and cementum.

Pulpectomy The most common endodontic treatment involving extirpation of dental pulp, leaving no dental pulp stem cells in the same tooth for pulp regeneration following the surgical procedure. Due to pulp devitalization from surgical procedures, endodontically treated teeth become devitalized and brittle, susceptible to postoperative fracture and other complications including reinfections due to coronal leakage or microleakage.

Tissue engineering A biomedical engineering strategy that aims to achieve functional restoration of tissue structure and physiology to repair and regenerate impaired or damaged tissues due to congenital anomalies, cancers, infectious diseases or trauma, conventionally believed to require three key elements: cells, scaffolds, and signals.

Abbreviations

ALP	Alkaline phosphatase
β-TCP	β-tricalcium phosphate
bFGF	Basic fibroblast growth factor
BMP-2	Bone morphogenetic protein-2
BMP-7	Bone morphogenetic protein-7
BSP	Bone sialoprotein
DSPP	Dentin sialophosphoprotein
ECM	Extracellular matrix
HA	Hyaluronic acid
HAp	Hydroxyapatite
hMSCs	Human mesenchymal stem cells
NGF	Nerve growth factor
PCL	Poly(ε-caprolactone)
PDGF	Platelet-derived growth factor
PEG	Poly(ethylene glycol)
PGA	Polyglycolic acid
PLGA	Poly(D,L-lactide-*co*-glycode)
POC	Poly(1,8-octanediol-*co*-citrate)
SCID mouse	Mouse with severe combined immunodeficiency
VEGF	Vascular endothelial growth factor

5.519.1. Introduction

Dental pulp is the only vascularized tissue in the tooth and is embedded in highly mineralized structures, including dentin, enamel, and cementum. Dental pulp maintains the homeostasis of the tooth as a viable organ. The overall health of the tooth is compromised upon dental pulp trauma or infections, frequently manifested as dental pulp infections named pulpitis.[1] A typical endodontic treatment or root canal therapy for irreversible pulpitis is pulpectomy, involving pulp extirpation followed by root canal enlargement and obturation of root canal with gutta percha, a bioinert thermoplastic material.[1] Despite reported clinical success, endodontically treated teeth become devitalized and brittle, susceptible to postoperative fracture and other complications including reinfections due to coronal leakage or microleakage.[1,2] A substantial amount of tooth structures including enamel and dentin is removed during endodontic treatment, potentially leading to posttreatment tooth fracture and trauma.[1–3] Moreover, endodontically treated teeth have lost pulpal sensation, and are deprived of the ability to detect secondary infections.[1,2,4] As a result, the complications of current endodontic treatment are inevitable because of pulp devitalization or the loss of the tooth's innate homeostasis and defense mechanisms once dental pulp is replaced with bioinert materials.

Tissue engineering aims to achieve functional restoration of tissue structure and physiology to repair and regenerate impaired or damaged tissues due to congenital anomalies,

cancers, infectious diseases, or trauma.[5,6] Tissue engineering is conventionally believed to require three key elements as shown in Figure 1[7]: cells, scaffolds, and signals.

Existing effort in dental pulp regeneration has focused primarily on cell transplantation.[8–10] Several reports have documented regeneration of dental-pulp-like tissue *in vitro* or ectopically by transplantation of dental pulp stem cells.[11–13] Deciduous and adult dental pulp stem cells seeded in a self-assembling peptide-amphiphile (PA) hydrogel showed distinctive behavior: greater proliferative rate for deciduous cells but greater osteogenic differentiation potential for adult cells.[9,10] Delivery of collagen scaffolds with dental pulp stem cells and dentin matrix protein-1 in dentin slices in mice led to ectopic formation of pulp-like tissue.[14] Deciduous dental pulp stem/progenitor cells seeded in Matrigel in 1.5-mm cross-sectional tooth slices regenerated vascular pulp-like tissue following ectopic implantation in severe combined immunodeficiency (SCID) mice.[15] Similarly, stem/progenitor cells from apical papilla and dental pulp in root fragments yielded vascularized pulp-like tissue following ectopic implantation also in SCID mice.[14] Despite its scientific validity, dental pulp regeneration by stem cells encounters clinical and commercialization hurdles. Pulpectomy, the most common endodontic treatment, involves extirpation of dental pulp, and therefore leaves no dental pulp stem cells in the same tooth for pulp regeneration. For a patient who requires endodontic treatment in a given tooth but has intact dentition otherwise, no healthy tooth is to be sacrificed for isolation of dental pulp stem cells. Even in patients whose autologous dental pulp stem cells can be harvested, for example, from extracted wisdom teeth, clinical therapy of dental pulp regeneration is difficult to develop due to excessive costs including cell isolation, handling, storage, and shipping, *ex vivo* manipulation, immune rejection (for allogeneic cells), not to mention liabilities of potential contamination, pathogen transmission and tumorigenesis that may be associated with *ex vivo* cell manipulation.[16,17]

Therefore, the key challenges to dental pulp regeneration include the following:

1. Cells of dental pulp that are widely believed to be the regenerative cells for dental pulp regeneration are no longer available after pulpectomy in the same tooth.
2. Alternative cell sources for dental pulp regeneration, including dental pulp stem/progenitor cells, can rarely be harvested without sacrifice of healthy teeth.
3. Even when dental pulp stem/progenitor cells can be harvested without undue surgical trauma, the cost and hurdle for commercialization appear to be insurmountable.
4. Biological signals that may be important or critical for dental pulp regeneration have not been investigated until a recent report.[56]

This review focuses on biomaterial needs for dental pulp regeneration, with reference to both cell delivery and cell-homing approaches. Given that biological signals are rarely investigated in dental pulp regeneration, this review specifically explores delivery of bioactive cues in biomaterials for dental pulp regeneration.

5.519.2. Biomaterial Selections

The native extracellular matrix of dental pulp provides a scaffold for adhesion, proliferation, and differentiation of resident cells including odontoblasts, fibroblasts, vascular cells, and neural endings. In principle, ideal biomaterial scaffolds for dental pulp regeneration should allow the key functions of the native dental pulp. At a minimum, biomaterial scaffolds for dental pulp regeneration should be biocompatible, nontoxic, and promote regeneration of vascularized soft tissue that is analogous to the native dental pulp.

5.519.2.1. Polymer Choices

Biomaterial choices can be natural or synthetic polymers or a hybrid. The natural polymers, such as collagen and fibronectin, have advantages of good cytocompatibility and bioactivity,

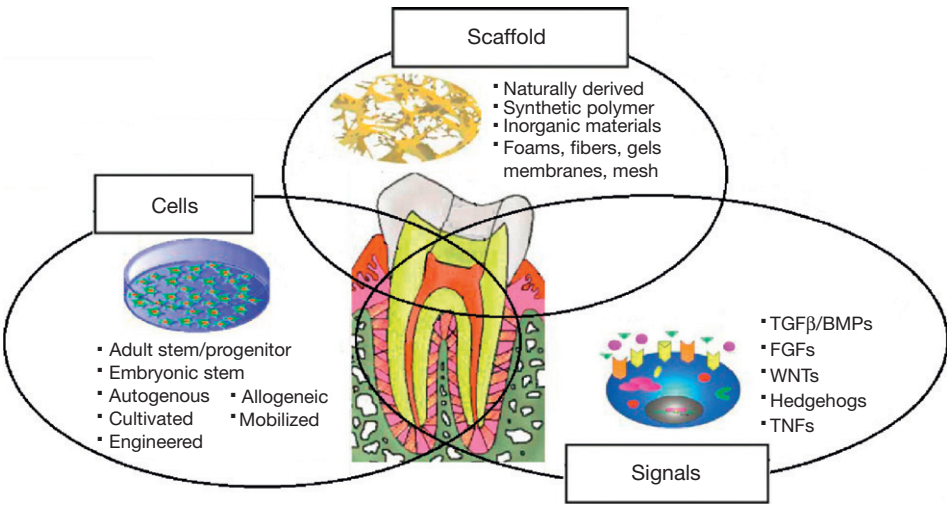

Figure 1 The key elements of tissue engineering and dental regenerations. The triad consists of stem cells, a scaffold of extracellular matrix, and bioactive cues. The figure is adapted from Nakashima, M. *Cytokine Growth Factor Rev.* **2005**, *16*, 369–376 with permission. Modified with permission from Dr. Nakashima, with permission from Elsevier.

while synthetic polymers allow precise control of the physicochemical properties such as mechanical properties, degradation rate, porosity, and microstructures.[18] For instance, dental pulp cells grown in collagenous, ceramic, or metal (titanium) matrices may develop differential expression of dental matrix markers such as dentin sialophosphoprotein (DSPP).[19] These cells initially express STRO-1, a marker for multipotent cells such as bone marrow-derived mesenchymal stem cells.

Extracellular matrix components such as fibronectin have been shown to mediate the binding of signaling molecules and regulate cell attachment, which aids in regulating the interactions between cells and extracellular matrix resulting in the reorganization of cytoskeleton in preodontoblasts during pulp wound healing.[20,21] Particularly, collagens regulate preodontoblast rearrangement and aid in the attachment of new odontoblasts to pulp tissue.[22] Bone sialoprotein (BSP) is a component of mineralized tissues such as bone, dentin, cementum, and calcified cartilage. As a noncollagenous protein, BSP used for the restoration of pulp defects appears to stimulate the differentiation of cells which secrete an organized extracellular matrix more efficiently than other capping materials such as calcium hydroxide.[23] Thus, the choice of composite materials for pulp regeneration must take into account the individual contribution of the biomaterials themselves during the regeneration process.

A number of synthetic materials have been fabricated into nanometer-scale structures in attempts to simulate the matrix environment for proliferation and differentiation of seeded cells toward desirable lineages.[24–27] Nanofibers formed by electrospinning have been shown to mimic the extracellular matrix environment to various degrees when cultured with several cell types.[28–32] Specifically, poly(D,L-lactide-*co*-glycolide) (PLGA) is widely used as scaffolding material in tissue engineering and has been approved for several biomedical applications in humans.[33–35] The porosity and tensile properties of electrospun PLGA nanofibers are favorable for medical applications,[36] and osteoblast adhesion were shown to occur when seeded in PLGA nanofibers.[36] Nanofibers made of another widely investigated polymer, namely poly(ε-caprolactone) (PCL), accommodated the differentiation of human mesenchymal stem cells (hMSCs) into adipogenic, osteogenic, and chondrogenic cells.[37] We have previously shown that hMSCs proliferate and maintain differentiation characteristics toward osteoblasts and chondrocytes when seeded in PLGA nanofibers.[38] In the study, PLGA of 85:15 ratio was electrospun into nonwoven fibers and cells attached them well (**Figure 2**).[38] After a 2-week culture on PLGA nanofiber scaffold, hMSCs remained as precursors upon

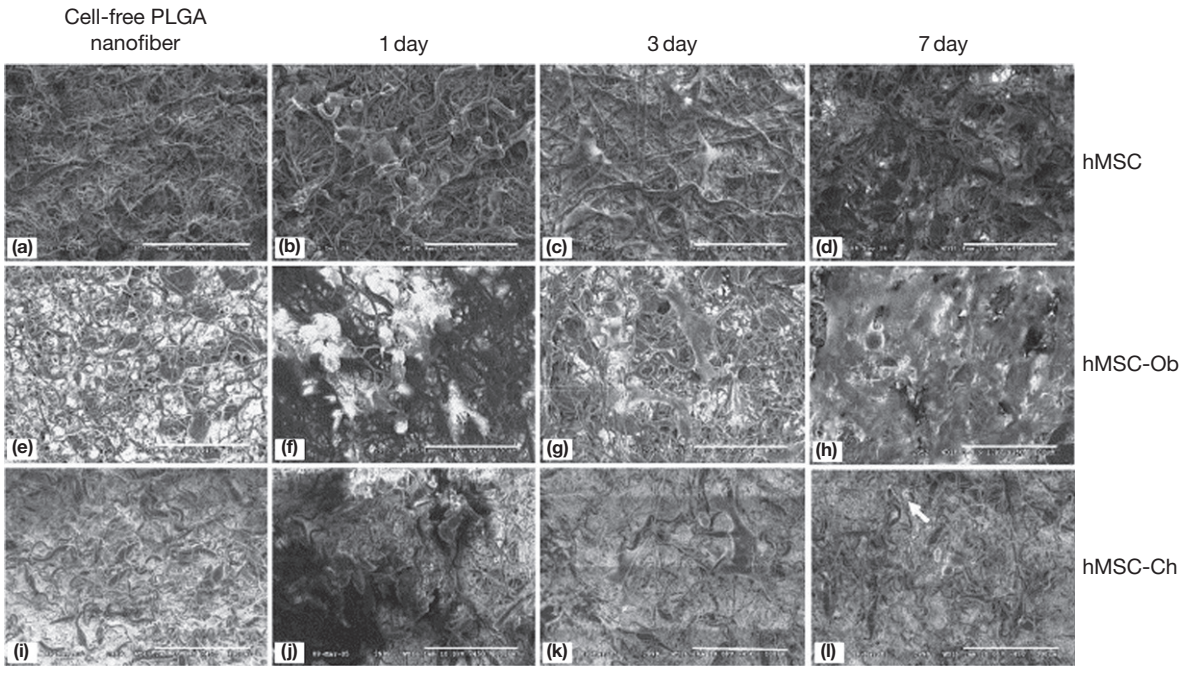

Figure 2 Electrospun poly(D,L-lactide-*co*-glycolide) (PLGA) nanofibers and the seeding of human mesenchymal stem cells (hMSCs), as well as hMSC-derived osteoblasts and hMSC-derived chondrocytes. (a), (e), (i) Prior to cell seeding, three randomly selected PLGA nanofiber scaffolds showed similar characteristics. Upon seeding of hMSCs (b, c, d), various extracellular matrices were apparently synthesized among PLGA nanofibers over time. By 7 days following hMSC seeding, the seeded cells apparently have attached to nanofiber surface and penetrated into the pores of PLGA nanofiber scaffolds (d), in comparison with 1 and 3 days after cell seeding (b and c, respectively). The morphology of hMSC-derived osteoblasts seeded in PLGA nanofibers also varied between 1, 3, and 7 days following cell seeding (f, g, and h, respectively). By 7 days following cell seeding, hMSC-Ob apparently synthesized a substantial amount of extracellular matrices (h), in comparison with 1 and 3 days after cell seeding (f and g, respectively). Human MSC-derived osteoblasts apparently attached to nanofiber substrates. Human MSC-derived chondrocytes revealed characteristic features after seeding in PLGA nanofibers (j, k, and l). Most PLGA nanofibers were still visible at 7 days following the seeding of hMSC-Ch (l), in comparison with the characteristics of hMSC-Ob seeded in PLGA nanofiber scaffolds after 7 days (h). A number of seeded hMSC-Ch apparently were located in lacunae-like structures, seen arrow (l) (scale bar = 100 mm). Reproduced from Xin, X.; Hussain, M.; Mao, J. J. *Biomaterials* **2007**, *28*, 316–325, with permission from Elsevier.

immunoblotting with hKL12 antibody. The overwhelming majority of hMSCs was viable and proliferated in PLGA nanofiber scaffolds up to the 14 days tested. In a separate experiment, hMSCs seeded in PLGA nanofiber scaffolds were differentiated into chondrogenic (hMSC-Ch) and osteogenic (hMSC-Ob) cells. Scanning electron micrograph (SEM) taken up to 7 days after cell seeding revealed that hMSCs, hMSC-Ob, and hMSC-Ch apparently attached to PLGA nanofibers. Moreover, histological assays revealed that hMSCs continuously differentiated into chondrogenic cells and osteogenic cells after a 2-week incubation on PLGA nanofibers.[38]

Dental pulp is a loose connective tissue with collagen and elastic fibers.[39] In the fibrous matrix, collagen fibers, type I and III, are present in an unbundled and randomly dispersed fashion, higher in density around blood vessels and nerves, and provide sufficient toughness and tensile strength to the matrix. Elastic fibers with high elasticity are interconnected with collagen fibers.[40] A collagen I-collagen III-elastic polymer composite scaffold may promote dental pulp regeneration. For example, poly(1,8-octanediol-*co*-citrate) (POC) is a soft scaffold and yet can recover from deformation. *In vitro* and *in vivo* evaluation using cell culture and subcutaneous implantation, respectively, confirmed cell and tissue compatibility.[39,41] POC has been used in regeneration of blood vessels, tendons, and ligaments, and may find its application in dental pulp regeneration.

The degree of polymerization is relevant to dental pulp regeneration. Chitosan is a naturally occurring substance that is chemically similar to cellulose and is derived from chitin. Chitosan increases the cross-linking efficiency of glutaraldehyde due to the longer chain of amino groups.[42–45] Chitomonosaccharide (chitosan monomer) has been attempted in dental pulp regeneration[46] with both *in vitro* and *in vivo* experiments to study cell metabolism and wound healing. After 3 days of osteoblast culture, alkaline phosphatase (ALP) activity significantly increased in the chitosan monomer group. Reverse-transcription polymerase chain reaction analysis revealed that chitosan monomer induced an increase in the expression of ALP mRNA after 3 days and bone morphogenetic protein-2 mRNA after 7 days of osteoblast incubation. Inflammatory cytokine, interleukin (IL)-8, synthesis in fibroblasts was strongly suppressed in the medium supplemented with chitosan monomer. After 1 day, inflammatory cell infiltration was weak when compared with chitosan polymer. After 3 days, remarkable proliferation of fibroblasts occurred near chitosan monomer, and the inflammatory cell infiltration virtually disappeared. After 5 days, fibroblastic proliferation progressed, and some odontoblastic cells appeared at the periphery of the proliferated fibroblasts.[46] These findings indicate that chitosan monomer may function as a scaffold at the initial stage of wound healing in comparison with chitosan polymer in view of its advantageous biocompatibility.

5.519.2.2. Scaffolding

Selection of a polymer for dental pulp regeneration is only half of the battle. Polymers must be fabricated and delivered as a scaffold for clinical utility. For dental pulp regeneration, the ideal scaffold should support the functions of multiple cell types, as well as vascularization and innervation. The successful utilization of fibrous scaffolds as synthetic matrices for pulp regeneration can be traced back to 1996, when dental pulp fibroblasts were found to adhere and proliferate in fibrous matrices fabricated from polyglycolic acid (PGA).[47] New tissues resembling dental pulp can be engineered by culturing human pulp-derived fibroblasts on these biodegradable scaffolds.[47] The cells proliferated on the scaffolds over time, and ultimately occupied the spaces between the polymer fibers (**Figure 3**). During the same time, the cells contracted the polymer matrix as it degraded, leading to decreased matrix volume over 60 days. A self-assembling PA hydrogel encapsulated with dental pulp stem cells in adult teeth, cultured *in vitro* in osteogenic medium, expressed osteoblast markers, and deposit mineral, while deciduous dental pulp stem cells showed little hard tissue formation.[11]

Porous hydroxyapatite/β-tricalcium phosphate (HAp/β-TCP), powdered HAp/β-TCP, and PGA fiber mesh were used as scaffolds and transplanted with cultured porcine dental-pulp-derived cells into the dorsum of nude mice.[48] Samples were harvested after 6 weeks, and newly formed hard tissue was observed in all transplants. When porous HAp/β-TCP was used, dentin-like hard tissue was observed on the inner wall with minimum cell inclusions and odontoblast-like cells were aligned adjacent to the hard tissue. When HAp/β-TCP powders or PGA were used, bone-like hard tissues showed cell inclusions and cell alignment was not observed. Hard tissue from the HAp/β-TCP block group was positive for type I collagen, osteonectin, BSP, and dentin sialoprotein (DSP). This result was confirmed by *in situ* hybridization with a DSP probe. Only the aligned cells were positive with an antisense probe. On the other hand, hard tissue from other scaffolds showed incomplete expression of both bone and dentin markers and they were negative for osteonectin and DSP. These results suggest that not only materials themselves, but also scaffold shapes affect the type of tissue regenerated by dental-pulp-derived cells.[48]

Another study investigated the *in vitro* and *in vivo* behavior of human dental pulp stem cells isolated from impacted third molars, when seeded onto different three-dimensional

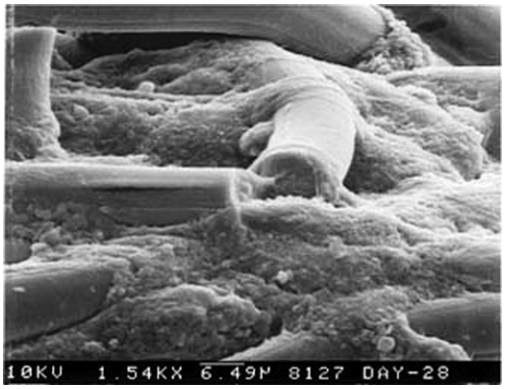

Figure 3 Photomicrograph of pulp-derived fibroblast filling the interstices between polymer fibers after 28 days in culture. S.; Shon, J.; Rutherford, B.; Mooney, D. J. *J. Biomater. Sci. Polym. Ed.* **1998**, *9*, 749–764, with permission from Brill.

scaffolds: that is, a spongeous collagen, a porous ceramic, and a fibrous titanium mesh (Figure 4).[19] Scaffolds were loaded with dental pulp stem cells and divided into two groups. The first group was cultured in osteogenic differentiation medium *in vitro* for 4 weeks. The second group was implanted subcutaneously in nude mice for 6 or 12 weeks. *In vitro*, cells developed abundant deposition of mineralized extracellular matrix with expression of DSPP in all 3D scaffolds. *In vivo* implantation led to formation of DSPP positive tissue in all three scaffolds materials immediately. However, tissues in all *in vivo* implanted scaffolds resembled soft connective tissue rather than a dentin-like tissue. There was somewhat limited calcification only in ceramic scaffold.

Hydrogels are also widely investigated scaffolding materials for tissue regeneration, but its application in dental pulp regeneration is quite limited.[49] An injectable hydrogel is likely to be clinically preferable because pulp chamber and root canal have irregular shape. The effects of hyaluronic acid (HA) sponge on responses of the odontoblastic cell line (KN-3 cells) *in vitro*, as well as responses of amputated dental pulp of rat molar *in vivo* was investigated by Inuyama *et al.* *In vitro*, KN-3 cells adhered to the stable structure of HA sponge and that of collagen sponge (Figure 5). Expression of IL-6 and TNF-α in KN-3 cells seeded in HA sponge were nearly the same with those in the cells seeded in collagen sponge, while the numbers of granulated leukocytes invaded into HA sponge from amputated dental pulp was significantly lower than in collagen sponge, leading to a conclusion that HA sponge has an appropriate structure, biocompatibility, and biodegradation for use as a scaffold for dental pulp regeneration.[49]

The performance of different scaffold characteristics on dental pulp regeneration was further compared.[50] Human dental pulp fibroblasts were seeded onto three different synthetic matrices: PGA fibers, type I collagen hydrogel, and alginate. Culturing cells on PGA resulted in high cell density, whereas collagen underwent significant degradation. Alginate allowed little cell proliferation, whereas collagen gel only allowed moderate cellular growth after 45 days.[50]

Scaffold fabrication is critical not only for soft tissue regeneration, but also vascularization. In an *in vivo* investigation, biophysical and/or biochemical approaches were employed to induce neovascularization in soft tissue.[51] Hydrogel cylinders were fabricated from poly(ethylene glycol) diacrylate (PEG) in four configurations: PEG alone, PEG with basic fibroblast growth factor (bFGF), microchanneled PEG alone, or both bFGF-adsorbed and microchanneled PEG (Figure 6). *In vivo* implantation revealed no neovascularization in PEG, but substantial angiogenesis in bFGF-adsorbed and/or microchanneled PEG. It was unexpected that substantial angiogenesis was detected in microchanneled PEG without bFGF incorporation. The dramatic

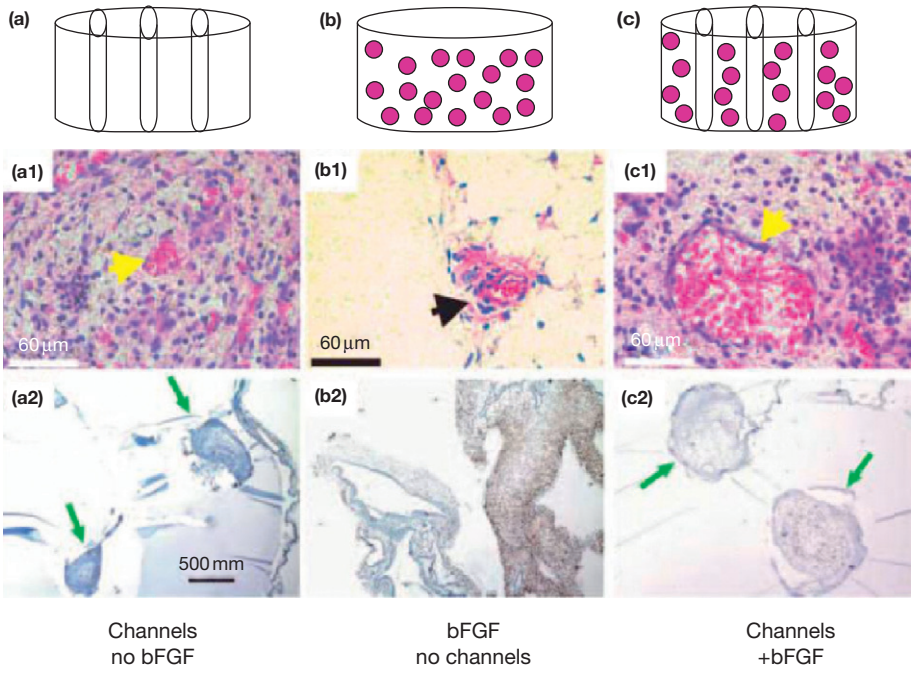

Figure 6 *In vivo* implantation of poly(ethylene glycol) (PEG) hydrogel. PEG hydrogel was fabricated in four configurations: PEG alone, PEG with basic fibroblast growth factor (bFGF), microchanneled PEG, or both bFGF-adsorbed and microchanneled PEG. (a) PEG hydrogel molded into 6 × 4 mm (diameter × height) cylinder (without either bFGF or microchannels). (b) PEG hydrogel with three microchannels. (c) PEG hydrogel cylinder with microchannels and adsorbed with both 0.5 μg μl^{-1} bFGF and three microchannels. Following *in vivo* implantation subcutaneously in the dorsum of immunodeficient mice, the harvested PEG hydrogel samples showed distinct histological features. (a1) PEG hydrogel with microchannels but without bFGF showed host tissue infiltration primarily in the lumen of microchannels, and scarcely in the rest of PEG hydrogel. The infiltrating host tissue includes erythrocyte-filled blood vessels that are lined by endothelial cells (arrow). (a2) Vascular endothelial growth factor (VEGF) was immunolocalized only to host-derived tissue within the lumen of microchannels, indicating the vascular nature of the infiltrating host tissue. Arrows point to microchannels and the infiltrating host tissue. (b1) PEG hydrogel with bFGF but without microchannels showed apparently random and isolated islands of infiltrating host tissue (arrow). There is random infiltration of host tissue into bFGF-adsorbed PEG hydrogel. The infiltrating host tissue includes vascular structures with erythrocyte-filled blood vessels that are lined by endothelial cells (arrow). (b2) VEGF was immunolocalized to host-derived tissue within PEG hydrogel (without microchannels). (c1) PEG hydrogel with both microchannels and bFGF showed host tissue infiltration only in the lumen of microchannels, but scarcely in the rest of the PEG hydrogel. The infiltrating host tissue includes vascular structures with erythrocyte-filled blood vessels that are lined by endothelial cells (arrow). (c2) VEGF was immunolocalized only to host-derived tissue within the lumen of microchannels. Since no cells were delivered in any of the PEG hydrogel samples in this experiment, tissue infiltration following *in vivo* implantation must be derived from the host. Arrows point to microchannels. Reproduced from Stosich, M. S.; Bastian, B.; Marion, N. W.; Clark, P. A.; Reilly, G.; Mao, J. J. *Tissue Eng.* **2007**, *13*, 2881–2890.

difference of neovascularization between PEG and microchanneled PEG suggests that microchannels promote the genesis of vascularized tissue phenotypes, and thus channeled or porous structures may be preferred for vascularized tissues. Especially, engineered microchannels may provide a generic approach for modifying existing scaffolds by providing conduits for vascularization and/or diffusion.

Controlled release approaches affect scaffold fabrication and the efficacy of tissue regeneration. Bioactive cues are usually expensive and when delivered without protection, lead to premature denature and diffusion. In order to achieve controlled and sustained release of BMP-2, Nie and colleagues[35,52] developed a PLGA-based fibrous scaffold releasing BMP-2 in a linear mode over a period of ~4 weeks and the scaffold performed well in repairing bone defects. In consideration of the lower cost of BMP-2 plasmid, the research group further developed a series of BMP-2 plasmid-delivery scaffolds, with shapes of fiber sheet (Figure 7)[53] and foam,[43,54] which presented different release patterns for different applications. Subsequent *in vivo* experiment demonstrated that DNA nanoparticles-loaded fibrous scaffold are advantageous over the traditional scaffolds prepared by protein adsorption or DNA adsorption.[24]

5.519.3. *In Vivo* Dental Pulp Regeneration: State of the Art

In vivo dental pulp regeneration represents translational approaches for ultimate applications of dental pulp regeneration in patients. All *in vitro* biomaterials and scaffolding experiments should eventually lead to *in vivo* dental pulp regeneration (Table 1).

A tooth slice model has been developed by cutting ~1 mm coronal slices for testing dentin–pulp regeneration.[57,58] This model has recently been modified to study dental pulp regeneration.[13,15] The basic approach for this model is to fill the center void of the 1-mm tooth slice with a biomaterial scaffold, followed by subsequent seeding with dental stem cells. When

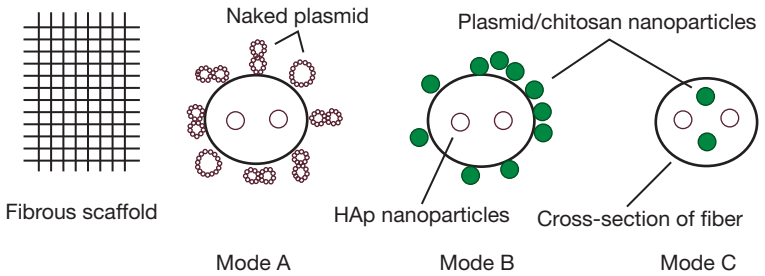

Figure 7 Schematic illustration of three loading modes of plasmid in fibrous scaffolds. Mode A: coating of naked plasmid on scaffolds after fiber fabrication by dripping; Mode B: coating of plasmid/chitosan nanoparticles on scaffolds after fiber fabrication by dripping; Mode C: encapsulation of plasmid/chitosan nanoparticles into scaffold by mixing them with poly(D,L-lactide-*co*-glycolide)/Hydroxyapatite (HAp) solution before fiber fabrication. HAp nanoparticles, as a biocompatible material, was employed in the study in order to enhance the release of plasmid or plasmid/chitosan nanoparticles from scaffolds. Reproduced from Nie, H.; Ho, M. L.; Wang, C. K.; Wang, C. H.; Fu, Y. C. *Biomaterials* **2009**, *30*, 892–901, with permission from Elsevier.

Table 1 Representative examples of *in vivo* dental pulp regeneration

Authors	*Cell sources*	*Biomaterials*	*Delivered bioactive factors*	In vivo *model*

implanted *in vivo*, the seeded dental stem cells were able to differentiate into odontoblast-like cells and endothelial-like cells. However, it is not clear whether this thin tooth slice model can be successfully adapted to regenerate real-size, fully vascularized dental pulp tissue for clinical applications. Limited blood supply is a major concern for de novo pulp regeneration. Along the same direction, a human tooth root fragment (6–7 mm) was developed with an enlarged root canal (1–1.25 mm wide), with one end sealed to mimic a natural tooth root.[14] Dental pulp stem cells were seeded onto a PLGA scaffold fabricated using a gas foaming/particulate leaching process, and inserted into the fragmented tooth root. The cell-seeded tooth fragments were transplanted subcutaneously for 3–4 months. The results showed that the root canal space was filled with soft tissue. The cells in regenerated soft tissue reacted positively to antihuman mitochondria antibodies, indicating their human origin; however, host cell ingrowth was not ascertained. It is further unclear what kind of cells have infiltrated the fragmented root canal.

Dental pulp regeneration by transplantation of cells, including stem/progenitor cells, suffers from a number of shortcomings including a lack of clinically available cell source, excessive cost, and difficult and lengthy regulatory approval. Cell transplantation may well be justified for life-threatening diseases such as Parkinson's disease, cardiac infarcts, or spinal cord injuries. However, cell transplantation for dental pulp regeneration appears to lack clinical justification and commercial viability.

We recently attempted to regenerate dental-pulp-like tissue without cell transplantation, but rather by cell homing.[56] Clinically extracted, real-size human teeth were treated endodontically as in patients, with the exception of filling with gutta percha. Collagen scaffolds loaded with a series of growth factors were implanted in endodontically treated root canals. Upon *in vivo* implantation of endodontically treated real-size human teeth in mouse dorsum for the 3 weeks tested, delivery of bFGF and/or vascular endothelial growth factor (bFGF and/or VEGF) yielded recellularized and revascularized connective tissue that integrated to native dentinal wall in root canals. Furthermore, combined delivery of bFGF, VEGF, or platelet derived growth factor (PDGF) with a basal set of nerve growth factor (NGF) and bone morphogenetic protein-7 (BMP-7) generated cellularized and vascularized tissues positive of VEGF antibody staining and neo-dentin formation over the surface of native dentinal wall in some, although not all, endodontically treated teeth. Newly formed dental-pulp-like tissue appeared dense with disconnected cells surrounded by extracellular matrix. Erythrocyte-filled blood vessels were present with endothelial-like cell lining. Reconstructed, multiple microscopic images showed complete fill of dental-pulp-like tissue in the entire root canal from root apex to pulp chamber with tissue integration to dentinal wall upon delivery of bFGF, VEGF, or PDGF with a basal set of NGF and BMP-7. These findings demonstrate for the first time regeneration of

dental-pulp-like tissue in real, endodontically treated human teeth without the need for cell transplantation. Dental-pulp-like tissues were regenerated entirely by host endogenous cells that were recruited chemotactically by signaling molecules and migrated into the collagenous scaffold enclosed by endodontically treated tooth. Regeneration of dental pulp by cell homing, rather than cell delivery, may accelerate clinical translation.

Given the initial positive data with delivery of bFGF and/or VEGF, two potent angiogenic cytokines, Kim and colleagues followed up with an exploration of the efficacy of additional cytokines, with or without bFGF or VEGF, in pulp regeneration. A basal combination consisted of NGF and BMP-7 due to its potency on induction of odontoblast/osteoblast differentiation. Combined delivery of bFGF with basal cytokines (NGF and BMP-7) also yielded recellularization in the entire endodontically treated root canal of real-size human tooth as shown by reconstructed, multiple microscopic images (Figure 8(a1)). A representative close-up image shows abundant cells in the endodontically treated root canal and apparent integration of regenerated tissues with dentinal wall in root canal (Figure 8(a2)). A representative higher magnification image further shows the presence of erythrocyte-filled, blood vessel-like structures (arrows in Figure 8(a3)). Scattered islands of positive VEGF antibody staining were found in association with combined bFGF + basal cytokine delivery (Figure 8(a4)). Furthermore, combined delivery of VEGF with basal cytokines (NGF and BMP-7) induced recellularization in endodontically treated root canal as shown by reconstructed, multiple microscopic images (Figure 8(b1)). Abundant cells were present in the endodontically treated root canal and showed apparent integration with dentinal wall (Figure 8(b2)). Remarkably, a layer of amorphous dentin-like tissue was present on the surface of native dentinal wall (arrows in Figure 2(b2)), resembling newly formed secondary dentin. Multiple blood vessel-like structures were present in regenerated soft tissue in root canal (arrows in Figure 8(b3)). Areas of positive VEGF antibody staining were readily identified in association with VEGF + basal cytokine

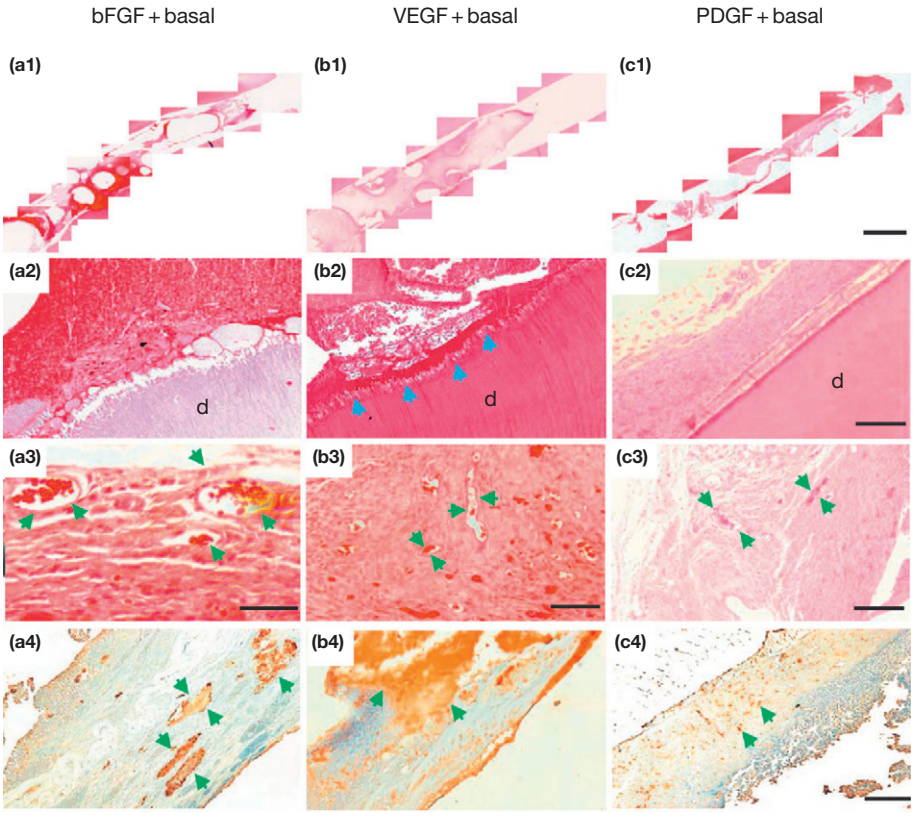

Figure 8 Combinatory cytokine delivery and chemotactic effects on pulp regeneration from host endogenous cells. (a1) Combined delivery of basic fibroblast growth factor with basal cytokines of nerve growth factor (NGF) and bone morphogenetic protein-7 (BMP-7) yielded recellularization in the entire endodontically treated root canal as shown by reconstructed, multiple microscopic images from root apex to pulp chamber. (a2) Close-up image showing abundant cells and integration with native dentin (d) in endodontically treated root canal. (a3) Higher magnification showing erythrocyte-filled blood vessels (arrows) in connective tissue. (a4) Scattered islands of positive vascular endothelial growth factor (VEGF) antibody staining (arrows). (b1) Combined delivery of VEGF with basal cytokines of NGF and BMP-7 induced recellularization in the entire endodontically treated root canal. (b2) Connective tissue with abundant cells integrated with native dentin (d), including a layer of dentin-like tissue between abundant cells and dentinal wall (arrows). (b3) Multiple blood vessel-like structures in regenerated connective tissue (arrows). (b4) Positive VEGF antibody staining. (c1) Combined delivery of platelet derived growth factor with basal cytokines of NGF and BMP-7 yielded fully regenerated tissues in the entire endodontically treated root canal. (c2) Abundant cells in connective tissue that integrated to native dentin (d). (c3) Blood vessel-like structures (arrows) in connective tissue. (c4) VEGF antibody staining. Scale bars = a1, b1, c1: 1 mm; a2, b2, c2: 100 μm; a3: 100 μm; b3, c3: 300 μm; a4, b4, c4: 300 μm. Reproduced from Kim, J. Y.; Xin, X.; Moioli, E. K.; *et al*. *Tissue Eng. A* **2010**.

delivery (Figure 8(b4)). Combined delivery of PDGF with basal cytokines (NGF and BMP-7) in an endodontically treated root canal resulted in recellularization along the entire root canal as shown by reconstructed, multiple microscopic images (Figure 8(c1)). A representative close-up image shows abundant cells and integration of regenerated tissue with dentinal wall in root canal (Figure 8(c2)). A representative higher magnification image further shows the presence of blood vessel-like structures (arrows in Figure 8(c3)) with abundant cells and some extracellular matrix. VEGF antibody staining revealed scattered positive locations in association with PDGF + basal delivery (Figure 8(c4)). Given that all human teeth utilized in the present work were endodontically treated and autoclaved to remove any biological tissue, all regenerated tissues, including vasculature, in the root canal are derived from host endogenous cells.

5.519.4. Conclusions

The doctrine of cells, biomaterial scaffolds, and biological signals has been the guiding principle for tissue engineering. Given the vast diversity of tissues that are being regenerated, it is difficult to conceive that one doctrine would govern all. In dental pulp regeneration, the triad of the doctrine is considered below:

Cells

- Fewer cells are needed for dental pulp regeneration due to its small scale than for regeneration of most other tissues such as skin, oral mucosa, or liver.
- Clinical treatment of pulpectomy removes all dental pulp cells in the very tooth that needs regeneration. Transplantation of dental or other stem cells may not be economically viable, given root canal treatment is far from a life-threatening disease.
- Cells are indeed required for dental pulp regeneration; however, cells do not necessarily need to be transplanted.

Scaffolds

- Biomaterial scaffolds are likely to be indispensable for dental pulp regeneration.
- Ideal scaffolds for dental pulp regeneration should allow functionality of multiple cell types including odontoblasts, pulp fibroblasts, vascular cells, and/or neural endings.
- Ideal scaffolds for dental pulp regeneration must be clinically viable, that is, easy to handle up to the point of a turn-key approach, must be possible to be readily sterilized, and with shelf life.
- Ideal scaffolds for dental pulp regeneration should be biocompatible, nontoxic, and may need to undergo biologically safe degradation.
- Either native or synthetic polymers, or a hybrid, are valid choices as scaffolding materials for dental pulp regeneration.

Bioactive cues

- Several angiogenic growth factors, including VEGF, bFGF, and PDGF, are effective in inducing revascularization and recellularization for dental pulp regeneration.
- Growth factors including BMP-2 and BMP-7 are capable of elaborating mineralization and probably odontoblast-like cells for dental pulp regeneration.
- Neuronal sprouting cues such as NGF are likely to be effective in elaborating neuronal sprouts for dental pulp regeneration.

In summary, the goal for dental pulp regeneration is clear: to regenerate revascularized and recellularized tissues in dental pulp that support the vitality and homeostasis of the teeth. Progress has been made to regenerate dental-pulp-like tissues with both cell delivery and cell-homing approaches. Biomaterials are critical if not indispensible for either cell delivery or cell-homing approach. Due to its small scale, dental pulp regeneration represents one of the lower hanging fruits in the regeneration of all tissues and organs.

Glossary

Bioceramics Ceramic materials that are specifically developed for use as medical and dental implants.

Biodegradable Capable of being broken down especially into innocuous products by the action of living things (as microorganisms).

Biomineralization Process by which living organisms produce minerals, often to harden or stiffen existing tissues.

Bone resorption Process by which osteoclasts break down bone and release the minerals, resulting in a transfer of calcium from bone fluid to the blood.

Composite materials Often shortened to composites, are engineered or naturally occurring materials made from two or more constituent materials with significantly different physical or chemical properties which remain separate and distinct at the macroscopic or microscopic scale within the finished structure.

Osteoconduction Process by which fibrovascular tissue and osteoprogenitor cells invade a porous structure, often acting as a temporary scaffold, and replace it with newly formed bone.

Osteoinduction Process that promotes mitogenesis of undifferentiated mesenchymalcells, leading to formation of osteoprogenitor cells that have osteogenic capacity.

Stress-shielding Reduction in bone density (osteopenia) as a result of removal of normal stress from the bone by an implant.

Abbreviations

ACP	Amorphous calcium phosphate	**ECM**	Extracellularmatrix
ALP	Alkaline phosphatase	**FDA**	Food and Drug Administration
bFGF	Basic fibroblast growth factor	**FN**	Fibronectin
BCP	Biphasic calcium phosphate	**HA**	Hydroxyapatite
BGs	Bioactive glasses	**HCA**	Hydroxylcarbonate apatite
BMP-2	Bone morphogenetic protein-2	**PCL**	Poly-ε-caprolactone
CA	Carbonated apatite	**PDLLA**	Poly-DL-lactic acid
CaP	Calcium phosphates	**PEG**	Polyethylene glycol
CDHA	Calcium-deficient hydroxyapatite	**PGA**	Polyglycolic acid
		PLA	Polylactic acid

PLGA	Polylactic-*co*-glycolic acid	**SCPC**	Silica–calcium phosphate nanocomposite
PLLA	Poly-L-lactic acid	**TCP**	Tetracalcium phosphate
poly(3HB)	Poly(3-hydroxybutyrate)	**TGF-β**	Transforming growth factor-β
poly(3HB-*co*-3HV)	Poly(3-hydroxybutyrate-*co*-hydroxyhexaoate)	**VEGF**	Vascular endothelial growth factor
PPF	Polypropylene fumarate	**β-TCP**	β-Tricalcium phosphate

5.520.1. Introduction

The holy grail in bone tissue engineering is the pursuit of scaffolds that act as a temporary support for cells to facilitate the regeneration of bone, as the requirements of scaffold materials are extremely challenging. Scaffolds provide cell anchorage sites, mechanical stability, and structural guidance, and *in vivo*, provide the interface to respond to physiologic and biologic changes as well. In addition, they serve to facilitate the remodeling of the extracellular matrix (ECM) in order to achieve the integration with the surrounding native tissue. As such, ideal scaffold materials need to be biocompatible, osteoinductive, osteoconductive, integrative, porous, and mechanically compatible with native tissue. To fulfill such a desired role, many biomaterials have been tested.[1]

Bioactive ceramics, such as calcium phosphates and bioactive glasses (BG), have been used for many years in dentistry, oral and maxillofacial surgery, and orthopedic trauma and joint replacement surgery. These materials bond to bone and enhance bone tissue formation (osteoconduction). They typically have chemical and physical characteristics mimicking the composition and structure of the mineral phase of the bone, or as a result of reacting with physiologic fluids, develop such a surface.

Ceramics are relatively stiff, brittle, and difficult to form into complex shapes. Conversely, polymers are more easily fabricated into complex structures, but they are typically too weak to meet the demands of surgery and the *in vivo* physiologic environment. Thus, composite scaffold comprising bioceramics and polymers are studied because the limited fracture toughness of the ceramic can be mitigated by a polymer matrix, all while the composite displays the osteoconductivity and delayed/sustained release characteristics typical for the ceramic component.

This chapter reviews recent development of bioactive ceramic and bioactive ceramic composite scaffolds in terms of material constituents, structural and bioactive properties, as well as *in vitro* and *in vivo* characteristics especially for applications in bone tissue engineering and tissue regeneration. In our analysis, we include only a short description of some critical aspects of composition and mechanism of biological activity, as these topics are discussed at much greater length elsewhere in this comprehensive (see **Chapter 1.109, Bioactive Ceramics** and **Chapter 1.114, Bioactivity: Mechanisms**).

5.520.1.1. Limitations of Natural Bone Grafts

The current gold standard for bone grafting is autografting using cancellous bone or vascularized grafts of the fibula or iliac crest.[2] This is because autografts provide osteogenic cells as well as essential osteoinductive factors needed for bone healing and regeneration. Unfortunately, however, harvesting autografts, typically from the iliac crest, adds cost to the surgery, is constrained by anatomic limitations, and is associated with significant donor-site morbidity.[1,3–5] Furthermore, the amount of graft needed clinically often makes autografting impossible. The conventional alternative to autograft has been allogenic bone obtained from cadaveric donors. Although it provides a natural bony scaffold, there is the potential risk of inducing an immunologic response due to genetic differences and the risk of both bacterial and viral transmission from the donor material to the host.[3,4,6,7] Moreover, the current supply of cadaveric bone is tight.[7]

5.520.1.2. Synthetic Bone Grafts and Materials Used

The limitations of biologic grafts have prompted the use of synthetic biomaterials as bone grafts. There is evidence suggesting that synthetic scaffolds merit consideration as the grafting material of the fracture for many indications. Presently, the application in which synthetic scaffolds show the most immediate promise is in treating large-defect fractures.[7] In this area, existing bone graft substitutes such as calcium phosphates[8–10] and BGs[11] have been found to yield results equal to those attained with autograft. The excellent results with these bioactive ceramics are primarily due to their bioactive property, which is a surface layer that is the equivalent of the bone mineral phase. When implanted in bone, bioactive materials enhance bone cell growth and direct bone deposition on their surfaces. Therefore, bioactive ceramics have been used as a bone-filling material to provide a scaffold for cell migration and rapid bone formation.

Polymeric materials, including naturally occurring[12,13] and synthetic polymers,[14] are widely considered materials for bone tissue-engineering applications. In particular, polyesters such as polylactic acid (PLA), polyglycolic acid (PGA) and their copolymers polylactic-*co*-glycolic acid (PLGA),[15–17] polydioxane and their copolymers are synthetic and biodegradable polymers with an extensive history of use in products that have been cleared by the US Food and Drug Administration (FDA).[18]

Ceramic/polymer composites have been considered for use as bone tissue-engineering scaffolds due to their combined advantages of improved physicochemical, biological, and mechanical properties, and in particular, the capacity they offer in tailoring their structure and degradation rate to the specific need at the implant site.[19–22] Typical examples of these composites are described by various authors.[23–25] Overall, as the engineering technology continues to evolve, future synthetic scaffolds can only be expected to perform better.

5.520.2. Scaffold Requirements

For successful treatment of bone defects, scaffolds for bone tissue engineering must fulfill three primary functions. First, the scaffold must be mechanically competent to withstand *in vivo* stresses and loading during tissue ingrowth. Second, the scaffold must degrade in a predictable rate without interfering into the tissue ingrowth and regeneration process. Third, the internal micostructure and surface properties of the scaffold must be able to guide cells to grow into the desired physical form, and it must be permeable to nutrients and neovascularization. The requirement of fulfilling the above-mentioned primary functions often poses conflicting design requirements. For example, in order to achieve the equivalent mechanical strength of bone, one needs minimally porous scaffolds. However, a high degree of porosity is essential to ensure cell migration, vascularization, and well-connected tissue formation within the scaffold. The issue of optimal design and fabrication of a scaffold which can fulfill the primary functions is still under extensive research.[26]

5.520.2.1. Load-Bearing Properties

In critical size bone defects, the goal of using bone scaffolds is primarily to implant these in bone defects that will not heal spontaneously. As sustained mechanical loading is needed in most cases, an ideal load-bearing scaffold must provide sufficient initial mechanical support to substitute for the mechanical function until the tissue-engineered transplant is fully remodeled by the host tissue.[27] It must also match as closely as possible bone mechanical behavior as issues arose with most materials by virtue of their higher stiffness than that of either trabecular or cortical bone. This inability to match stiffness results in the phenomenon called 'stress-shielding,' in that bone is insufficiently loaded compared to the scaffold, leading to the interruption of desired bone remodeling. While maximum mechanical properties can be obtained with a control of microarchitecture of the scaffolds, the materials choice is still one of the most important aspects in designing scaffolds. This is because, depending on the material properties, some biomaterials are either too weak or too stiff to be arranged into the desired architecture. Both the tissue and architectural levels must be designed to achieve both spatial distribution and a material that provide sufficient strength to sustain loading.[28]

5.520.2.2. Degradation and Resorption Kinetics

Biodegradation of ceramic implants used for bone regeneration is governed not only by material characteristics, but also by conditions of the biological environment. Either physicochemical dissolution or degradation by cellular, that is, osteoclastic activity, or by a combination of both are the major mechanisms for biodegradation. Tricalcium phosphate[29,30] and BG[31] degrade mainly by physicochemical dissolution; their degradation by osteoclasts was shown to be minor. Other ceramics, such as a dense hydroxyapatite (HA), however, appear to degrade mainly by osteoclastic activity.[11]

Biodegradable scaffolds are the best alternative for the temporary fixation for many different types of bone defects for various reasons. During the early stages of tissue healing, the biodegradable scaffold holds the healing tissue in place.[32] It is crucial that the rate of degradation of the scaffold parallels the rate of bone growth in order to maintain the required mechanical properties of the construct. If resorption occurs too quickly, pseudoarthrosis might occur. Conversely, if resorption occurs too slowly, this will interfere with bone ingrowth, also leading to pseudoarthrosis or, alternatively, to weakening of the newly formed bone.[1] At the optimal rate, resorption leads to the gradual transfer of stresses to the healing tissue, avoiding the stress-shielding effects. At the same time, such resorption does not require a removal operation of the surgical devices, which is a substantial benefit both economically and to the patient being treated.[32] Finally, it also would be advantageous to utilize this degradation property for any growth factor delivery intended to enhance bone formation and integration.

5.520.2.3. Scaffold Architecture for Bone Ingrowth and Permeability of Nutrients and Neovascularization

In the case of scaffold-based tissue-engineering approaches, it is important to focus on both the architecture and the material of the scaffold as they influence bone regeneration in combination. In particular, it is related to the effect of pore size and porosity. The scaffold microstructure must ensure cell migration as well as attachment and differentiation at the pore surfaces. Moreover, for easy migration of cells within the scaffolds, the pores must be large enough.[33] The optimal porosities higher than 80% and pore sizes in the range 100–500 μm are suitable for applications in bone tissue engineering, as a larger pore size results in fibrous tissue growth.[34] The precise pore dimension depends on the specific application.[35–40] In order to allow bone growth and functions, once cells are attached to the material surface, there must be enough space and channels to allow the key metabolic functions such as transportation of nutrients to cells that migrate through the scaffolds, waste evacuation,[27,40] protein transport, and vascularization upon implantation, which are obtainable with an interconnected network of pores. The degree of pore interconnectivity determines the permeability of scaffolds; this is thus another key factor influencing the scaffolds' ability to enhance tissue regeneration. Studies have found a direct correlation between the cell growth and permeation of nutrients through the porous structure during the cell culture process in a scaffold.[33,41–43]

5.520.3. Fundamentals of Ceramic Bioactivity

5.520.3.1. Surface Transformation

The nature of the biomaterial and its surface characteristics play important roles in determining bone adaptation to the implant material. Surface reactivity is one of the common characteristics of bone bioactive ceramics, and this attributes to biomineralization of a thin layer of calcium phosphate at the interface between the ceramics and host bony tissue that provides the bonding interface with tissues. Time-dependent assessments in animal models imply that after implantation the biologically equivalent carbonate apatite layer is formed on the bioactive surface at an early period, and thereafter mediates

integration of bone matrix to metabolize as a part of tissue.[44–46] BG with its surface turned into a calcium phosphate was the first material for which this property was described.[47]

The calcium phosphate formed on the bioactive ceramics is nanocrystalline calcium-deficient HA ($Ca_{10}(PO_4)_6(OH)_2$) (CDHA), containing sodium, magnesium, chlorine, and carbonate, and hybridized with biomacromolecules.[48] This hydroxyl carbonated apatite (HCA) phase that forms on bioactive implants is akin to the mineral phase in bone and is different from synthetic HA. The calcium phosphate, with its bone mineral-like characteristics recruits bone cells and leads them to proliferate in preference to fibroblasts, differentiating and producing an ECM composed of biological calcium phosphate and collagen.[46,49]

The interstitial body fluid is the very first medium that a bioactive ceramic interfaces with after being inserted in a bony defect. The development of a biologically equivalent CA layer is initiated through solution-mediated surface reactions that take place after immersion of bioactive ceramics in biological fluids.[46] The sequence of reactions leading to such layer includes dissolution, precipitation, and ion-exchange phenomena, concurrent adsorption of Ca-P in combination with protein adsorption events occurring at the bioactive ceramic surface.[49–54] In previous review papers, we summarized these events that were reported to occur at the bioactive ceramic–tissue interface.[49,50,55] The following list does not imply a ranking in terms of time sequence or importance: (1) dissolution from the ceramic[50,52,56–59]; (2) precipitation from solution onto the ceramic[50,52,58–60]; (3) ion exchange and structural rearrangement at the ceramic–tissue interface[50,52,58,59]; (4) interdiffusion from the surface boundary layer into the ceramic[61]; (5) solution-mediated effects on cellular activity[62,63]; (6) deposition of either the mineral phase (a) or the organic phase (b) without integration into the ceramic surface[56,64]; (7) deposition with integration into the ceramic[56]; and (8) chemotaxis to the ceramic surface.[11]

5.520.3.2. Protein Adsorption onto the Biomineralized Surface and Selective Binding of Integrins

It is also an important aspect that the transformed bioceramic surface composition and structure influences FN adsorption. There is support for the view that the enhanced cellular and tissue responses to bioactive ceramics are related to enhanced FN adsorption at their surfaces.[49,65]

FN is one of the major components of ECM and it is also secreted by osteoblasts. When adsorbed onto biomaterials, FN plays a crucial role in bone cell attachment, proliferation, and differentiation. It has been documented by Garcia *et al.*[66] that the formation on bioactive ceramics of a calcium phosphate surface layer with characteristics similar to those of the calcium phosphate mineral phase in bone resulted in enhanced FN-mediated cell adhesion in comparison to what transpires on control materials and an unreactive form of HA. This effect was not due to differences in adsorbed fibronectin (FN) concentration, but arose from differences in FN conformation. In fact, surface chemistry of the biomaterial surface was reported to modulate the structure and activity of adsorbed FN.[67] These differences in FN structure, in turn, influence integrin binding, membrane-associated adhesion receptors that mediate the cellular interactions between osteoblasts and the biomaterial surface,[68–71] and thus can result in selective binding of the different types and/or combinations of integrins (e.g., $\alpha_5\beta_1$ or $\alpha_v\beta_3$).[67] Recent findings suggest that selective binding of the $\alpha_5\beta_1$ integrin leads to upregulation of osteoblastic differentiation and matrix mineralization.[72] In addition to their role as adhesion receptors, integrins are also involved in transducing signals from the ECM to the interior of the cell,[73,74] resulting in the activation of signaling molecules and regulation of gene expression, thus modulating cellular migration, proliferation, differentiation, and apoptosis.[75–80] However, little is known about the intracellular events that follow osteoblast attachment to these bioactive ceramics, leading to differences in osteoblast activity. To obtain a fundamental understanding of the mechanisms by which bone tissue formation is stimulated, the atomic and molecular phenomena induced by osteoblast–implant materials interactions and their effects on signaling pathways of cells and tissues should be further investigated.[55]

5.520.4. Characteristics of Bioactive Ceramics and Bioactive Ceramic Composite-Based Scaffolds for Bone Tissue-Engineering Scaffold

5.520.4.1. Bioceramics and Bioactive Glasses

5.520.4.1.1. Bioactive glasses and glass ceramics

Bioactive glasses (BG) are a group of surface-reactive glass-ceramic biomaterials and include the original bioactive glass, Bioglass. It has excellent biocompatibility as well as the ability to bind to bone and other tissues, as was first described by Hench in the early 1970s.[47] It can be synthesized like conventional glass but with components SiO_2, Na_2O, CaO, and P_2O_5. BG possesses an excellent stimulatory effect on bone cell function.[11,49,66,81,82,83] It has been demonstrated that BG accelerates bone growth significantly more than a low reactivity HA when implanted in bone.[84,85] Excellent bioactivity of these materials resulted in their successful application as bone-substitute material for non-load-bearing applications in orthopedic and dental surgery.[7,82,86–88]

The reason behind the bonding ability of BG is the chemical reactivity of the BG through interfacial and cell-mediated reactions in which silicon bonds are broken and a CaP-rich layer is formed on top of the glass which crystallizes to HCA. BGs also support many other bioactivity such as enzyme activity[89,90]; vascularization[91,92]; foster osteoblast adhesion, growth, differentiation; and induce the differentiation of mesenchymal cells into osteoblasts.[11,93–96] Bioactivity, however, is not an exclusive property of BGs. Various forms of HA and related CaP also show an excellent osteoconductivity, which is critical in elimination of scaffold loosening.[96]

In order to have application in tissue engineering, along with the bioactivity, the BG should be degradable and porous. The porous BG can be prepared in a method similar to porous CaP ceramics. Yuan *et al.*[97] used a H_2O_2-foaming method to obtain a macroporous BG with pore sizes ranging from 100 to 600 μm. Chen *et al.*[85] were able to prepare a 86–93% porous BG by use of a polyurethane template which was immersed in a glass slurry, and the polymer was burned out after which the scaffold was sintered. Kaufmann *et al.*[98] used polyethylene

glycol (PEG)–glycol particles of different sizes and amounts to retrieve a porous BG substrate after sintering.[81]

It has been found that reactions on BG surfaces can release soluble Si, Ca, P, and Na ions, depending on the processing route and particle size, inducing intracellular and extracellular responses.[99,100] In recent investigations, 45S5 BG has also been shown to increase secretion of vascular endothelial growth factor (VEGF) *in vitro* and to enhance vascularization *in vivo*, which is critical to large tissue-engineered constructs.[30]

5.520.4.1.1.1. Compositions and bioactivity

The basic constituents of most BGs are SiO_2, Na_2O, CaO, and P_2O_5. 45S5 BG contains 45% SiO_2, 24.5% Na_2O, 24.4% CaO, and 6% P_2O_5, in weight percent. In spite of using a somewhat unsophisticated rat model and testing methodology, Hench and coworkers were able to describe the effect of compositional variation in the four-component glass systems with a constant 6 wt% P_2O_5 content. They summarized these data in review papers.[101,102] They divided the compositions into three regions according to their bioactivity. BGs (e.g., 45S5 Bioglass®) with compositions in the system SiO_2–Na_2O–CaO–P_2O_5, having <55% SiO_2, exhibit a high bioactivity index (in region A) and bond to both soft and hard connective tissues. Glasses of compositions in region B exhibit only osteoconductivity. Compositions in region C are resorbed within 10–30 days in tissue (**Figure 1**).[103]

Ease of control over the range of chemical properties and thus the rate of bioresorption makes BGs a very attractive scaffold material. Moreover, by varying either composition, or thermal or environmental processing history, the structure and chemistry of glasses can be controlled at a molecular level. This flexibility in synthesis process makes it possible to design glasses with degradation properties specific to a particular application of bone tissue engineering.[104,105]

However, it was also reported that the level of bioactivity decreases with the increase in crystallinity of BGs[105] and even turned into an inert material.[106] This is the main drawback that limits the application of BGs as scaffold materials, as full crystallization happens prior to densification by sintering[107] and extensive sintering is necessary to densify the struts of a scaffold to achieve the required mechanical stability.

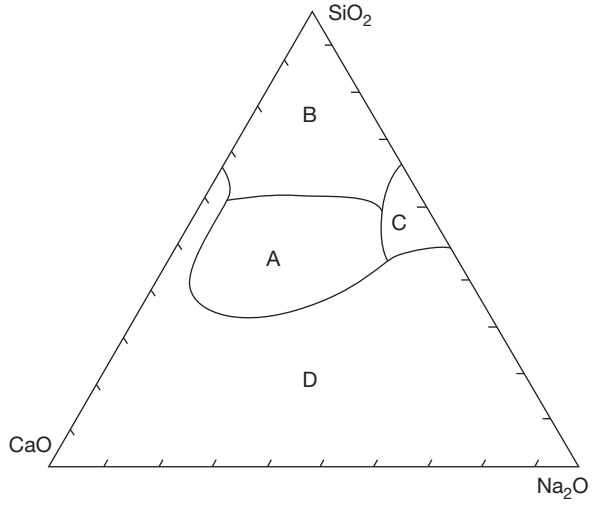

Figure 1 Behavior of BG of different compositions. Region (A), bone bonding, (B) fibrous tissue encapsulation, (C) dissolution, and (D) nonglass forming. All compositions have a constant 6% P_2O_5 by weight. Reproduced from Hench, L. L.; Wilson, J. *Science* **1984**, *226*(4675), 630–636, with permission.

5.520.4.1.1.2. Mechanical properties

Two key properties of the BG, ion release into physiologic solutions and the subsequent bioactivity reactions, are facilitated by its amorphous structure.[108] On the other hand, the amorphous structure of BG impairs the mechanical strength of the material and lowers its fracture toughness, especially in a porous form. Tensile strength of most of the BG compositions is in the range of 40–60 MPa and cannot be used alone in load-bearing situations. **Table 1** elaborates the compressive strength, elastic modulus, and some fracture toughness values for dense and porous bioactive ceramics.[103–117] It can be seen that particularly porous scaffolds which are essential for tissue engineering exhibit very low mechanical properties compared to cortical and cancellous bone. However, for some applications, low strength is offset by the glass's low modulus of elasticity of 30–35 GPa which is close to that of cortical bone (7–25 GPa).

Recently, it has been demonstrated that 45S5 BG can partially crystallize when heated to high temperatures (>950 °C) during scaffold fabrication and the mechanically strong crystalline phase can transform to a biodegradable, amorphous calcium phosphate (ACP) at body temperature in a biological environment.[85,118] This transformation enables the preparation of biodegradable mechanically competent BG scaffold. This discovery promises to go some way toward the scaffold optimization and its clinical application. In addition, bioactive glass-ceramic materials exhibit better mechanical properties than amorphous do glass and calcium phosphate ceramics (**Table 1**). For this reason, other ceramic components are sometimes added to the BG for reinforcement, referred to as glass-ceramic composites.[119,120]

5.520.4.1.2. Calcium phosphates

5.520.4.1.2.1. Calcium phosphates composition and bioactivity

Owing to the high abundance of $Ca_{10}(PO_4)_6(OH)_2$ and HA in bone, both HA and related calcium phosphates (CaP) have been looked at as the major component of scaffold materials for bone tissue engineering. Among different types of CaP-ceramics materials are mainly HA, β-TCP, biphasic calcium phosphate (BCP), ACP, or CDHA, and they are classified as useful for bone tissue growth.

On account of their close chemical and crystal structure resemblance to the mineral phase of bone, calcium phosphate exhibits excellent biocompatibility.[121] Calcium phosphates possess osteoconductive properties; however, they have not shown osteoinductivity.[122–124] Many *in vivo* and *in vitro* studies demonstrated that calcium phosphates, regardless of the form (bulk, coating, powder, or porous) and phase (crystalline or amorphous), always support the attachment, proliferation, and differentiation. However, the poor mechanical strength of this material limits their application in tissue engineering, especially at load-bearing sites.

Table 1 Mechanical properties of dense and highly porous HA, 45S5 BG, A/W glass-ceramic, and human cortical bone

Ceramics	*Compressive strength (MPa)*	*Tensile strength (MPa)*	*Elastic modulus (GPa)*	*Fracture toughness (MPa √m)*	*References*
HA	>400	~40	~100	~0.1	107,112
45S5 BG	~500	42	35	0.5–1	107,108,200
Glass-ceramic A/W	1080	215	118	2.0	111
Porous BG 70S30C (82%)	2.25	–	–	–	109
Porous HA (82–86%)	0.21–0.41	–	$0.83–1.6 \times 10^{-3}$	–	110
Cortical bone	130–180	50–151	12–18	6–8	114,201,202

5.520.4.1.2.2. Mechanical properties

Mechanical properties of synthetic calcium phosphates are highly dependent on their crystallinity, grain size, porosity, and composition. In general, the mechanical properties of synthetic calcium phosphates decrease with increasing amorphous phase, microporosity, and grain size. High crystallinity, low porosity, and small grain size result in high stiffness, compressive and tensile strengths, and greater fracture toughness.

In comparison, cortical bone has better compressive strength than HA and related calcium phosphates, although it is less dense than most HAs. Also, bone has higher fracture toughness than most dense HA. The mechanical properties are lower for porous HA structures. The unique composite structures, high tensile strength, and fracture toughness of bone come from the presence of tough and flexible collagen fibers reinforced by HA. Hence, calcium phosphates alone cannot be used for load-bearing scaffolds despite their excellent biocompatibility and osteoconductivity.[96]

5.520.4.2. Ceramic/Polymer Composite Materials

Today, composite materials composed of organic and inorganic phase are studied extensively because the combination of the tailored degradability and controlled release of the polymer with the osteoconductivity and delayed/sustained release characteristics of the ceramic material can fulfill the necessary requirements of an ideal scaffold (Table 2).[81] In addition, mechanical properties of ceramic materials can be enhanced with the presence of polymer. Ceramics and ceramic/organic composites are summarized in the following paragraphs. The use of this material for bone tissue engineering with conjoint biomolecules release is discussed in view of the previously formulated ideal scaffold characteristics.

5.520.4.2.1. Composite materials strategy

Inclusion of bioceramics and glasses in polymers provides the mechanical stability to constructs, prior to synthesis of new bone matrix by cells, as these materials have greater mechanical strength than polymer. However, ceramics and glasses are characterized by flaw sensitivity and inherent brittleness.[81] This puts ceramics at a disadvantage as scaffold materials. Conversely, polymers are easily fabricated to form complex shapes and structures yet, in general, they lack bioactivity (as defined above) and are too flexible and weak to meet the mechanical demands in surgery and in the physiologic environment. Thus, the formation of composites capitalizes on the advantages of both material types and minimizes their shortcomings. The combination of polymers and inorganic phases leads to composite materials with improved mechanical properties, exploiting the well-known composites approach by incorporation of stiffer particles into the softer matrix.[125] Moreover, as previously mentioned, addition of bioactive phases to bioresorbable polymers can alter the polymer degradation behavior, by allowing rapid exchange of protons in the aqueous phase for alkali in the glass or ceramic.[18] While release of acidic degradation from polymers can cause inflammatory reactions,[126,127] this mechanism provides the basic degradation of calcium phosphate or BGs that could buffer the acidic by-products of polymers, thus contributing to avoid the formation of an unfavorable environment for cells due to low pH values.[20] Development of composite materials is also attractive since their properties can be engineered to suit the mechanical and physiologic demands of the host tissue by controlling the structure of the polymer and volume fraction, and arrangement of the reinforcing phase.[94] Recently, inclusion of BGs has been shown to modify surface and bulk properties of composite scaffolds by increasing the hydrophilicity and water absorption of the hydrophobic polymer matrix,[128] thus altering the scaffold degradation kinetics.[129] In addition, composites are able to absorb water due to the internal interfaces formed between the polymer and more hydrophilic bioactive phases. It has been reported that polymer composites filled with HA particles hydrolyzed homogeneously due to water penetrating the interfacial regions.[130] In general, the degradation and resorption kinetics of composite scaffolds are designed to allow cells to proliferate and secrete their own ECM while the scaffolds gradually vanish, leaving space for new cell and tissue growth. The physical support provided by the 3D scaffold should therefore be maintained until the engineered tissue has sufficient mechanical integrity to support itself.[18]

5.520.4.2.2. PLA/PGA-based polymer/ceramic composites

The most often utilized biodegradable synthetic polymers for 3D scaffolds in tissue engineering is the family of poly (α-hydroxy ester)s and copolyesters of the lactic acid and glycolic acid. Members of this ester-backbone polymer group are poly(lactic acid) (PLA, PLLA) and PGA, as well as PLGA copolymers and poly(caprolactone) (PCL). The PLA/PGA group is interesting because a wide range of physical properties and degradation times can be achieved by varying the monomer ratios in lactide/glycolide copolymers. The basic chemical structure of all aliphatic polyester materials is the same and

Table 2 Selection of scaffold composites designed for bone tissue engineering and their properties

Scaffold composite		*Percentage of ceramic*	*Porosity (%)*	*Pore size (μm)*	*Compressive (C), tensile (T), flexural (F) strength (MPa)*	*Modulus (MPa)*	*Reference*
Ceramic	Polymer						203

the only difference is the pendent groups. The degradation mechanism is a hydrolysis reaction in which the glycolic acid residue degrades faster than the PLA while the cleavage site of PLA is sterically hindered.

A combination of calcium-based ceramics and biodegradable polymers yields composites with desirable properties such as controlled degradation, improved osteoblast integration, and tailored mechanical properties. This is considered as a viable approach to make tissue scaffold for bone growth. These scaffolds can be either a porous or dense structure using BG, HA, ACP, and BCP as a ceramic component in a PLLA, PLGA, or PCL matrix. Navarro *et al.*[131] synthesized a glass-ceramic particle/PLA scaffold by homogeneous mixing of the glass-ceramic into a PLA solution and they used H_2O-solvable NaCl particles to create macroporosity in the scaffold. It is demonstrated that the mechanical properties of the PLA increased after adding up to 40% of glass-ceramic particles, but compressive strength was very low. On the contrary, Niemela *et al.*[132] observed that when BG was added to a poly-L,DL-lactide (70/30) bending strength/modulus as well as shear, compression, and torsion strength significantly decreased. BG renders the polymer carrier bioactive, as was observed by Yao *et al.*[63,133,134] These authors reported that the addition of BG particles promoted osteoblastic differentiation of marrow stromal cells.

In the case of PCL, a porous composite produced by a 3D printing method containing 10/20% CaP particles, the compressive strength increased dramatically compared to pure PCL.[135] *In vivo* studies of these composites with human embryonic palatal mesenchymal cells showed an increased proliferation in the 20% CaP composites. Along with the usual ceramic particles/polymer matrix, other ceramic/polylactic composites have also been formulated.[136,137]

On the other hand, porous composites of slow degrading PCL or PLLA with ceramic particles pose no difficulties to the addition of cells, but faster degrading polymers, such as low molecular weight PLGA or PLA, can elicit cytotoxic reaction due to the production of acidic degradation products. This is clearly evident when cells are implanted as well as in the *in vivo* studies with these polymer/ceramic composites without the addition of cells. Strong inflammatory response was observed by Ignatius *et al.*[138] after 24 months in sheep when

composites of PLA and α-TCP or a glass ceramic were implanted. This inflammatory response was accompanied by a strong reduction of the PLA and mechanical strength.

The possibility of incorporating drugs in PLA/PGA–ceramic implants and using them as scaffolds is intriguing. The drug is either incorporated into the polymer[139] or is absorbed onto the composite.[140] Gentamycin was incorporated in calcium phosphate/PLA blends and release kinetics showed a burst release followed by a slower sustained release, which is typical for PLA.[139] However after coating the implants with these composites, the burst release was reduced and a sustained release over a period of 10 weeks was observed. The aspects of incorporating growth factors within these composites[140] are discussed in detail in ceramics paragraph.

PLA/PGA microspheres can be utilized to synthesize PLA/PGA–CaP cement. In such a case, CaP-cements are processed at room temperature, while polymer microspheres are added as a porogen forming pores after *in vivo*/*in vitro* degradation as well as a possible carrier of growth factors.[96]

These composites showed a small sustained *in vitro* release (5–10%) of rhBMP-2 after 4 weeks[141] in medium. However, in the case of composites with low and high molecular weight, PLGA microspheres showed higher release efficiencies (25–50%) *in vivo*.[142] The highest release was observed for the low molecular weight PLGA microsphere composites, indicating that the drug in this formulation exhibited less interaction with the surrounding cement. The discrepancy between *in vitro* and *in vivo* results could be due to a more dynamic flow and the occurrence of high amounts of salts and proteins like albumin *in vivo* that positively influenced the release properties (**Figure 2**).[96]

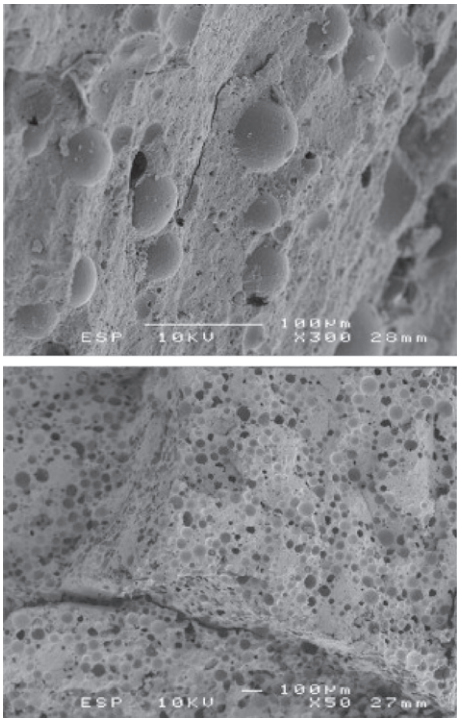

Figure 2 PLGA microsphere/CaP cement composites; close-up PLGA microspheres inside cement scaffold (above, original magnification 300×), 20% PLGA microsphere/CaP cement scaffold after 12 weeks *in vitro* degradation (below, original magnification 50×). 5.520.4.2.3. Protein-based polymer/ceramic composites

Because of excellent biocompatibility and biological characteristics that are similar to the human bone, protein-based polymers and CaP-ceramics composites are investigated extensively. Well-known examples of this group of biopolymers are collagen and gelatin.

Collagen has been widely used for the regeneration of tissues, mostly for the repair of soft tissues. Collagen favors the cell adhesion and provides cellular recognition for regulating cell attachment and function. There are many collagen types and forms that are usually obtained by processing different animal tissues. Gelatin is a natural material derived from collagen by hydrolysis and has almost identical composition as that of collagen. Gelatin is a processed form of collagen that is usually derived from pig skin using an acidic process (type A) or from bovine origin with a basic (lime cured) process (type B). Both gelatin and collagen undergo enzymatic degradation which occurs in the body via enzymes, such as collagenases, gelatinase, and metalloproteinases, to yield the corresponding amino acids. The degradation rates can be altered by chemical cross-linking of the proteins. A combination of these biopolymers and ceramics can produce a composite scaffold with tailored degradation rates, and have the biological and mechanical/physical properties of both materials.

Porous gelatin/collagen scaffolds with ceramic particles have already synthesized,[143–145] especially the so-called gelatin sponges that are prepared by freeze-drying a gelatin/calcium phosphate mixture. Often times, the gelatin/collagen is highly cross-linked for a better mechanical stability, though this can also decrease biocompatibility, since cross-linking agents like glutaraldehyde can produce a cytotoxic reaction.[146] To avoid this drawback, Shibata *et al.*[144] prepared a colloidal β-TCP/collagen composite that does not need any extra treatment. Collagen type I was also used as a matrix for CaP mineralization to obtain a collagen/CaP composite.[147] In this study, the biomimetic properties of the collagen were exploited and 60–70% CaP composites were produced with a high tensile strength. In another study, a 10% gelatin composite was formed by soaking a macroporous HA ceramic in which the gelatin penetrated the bulk of the ceramic.[148] To ensure the biocompatibility, a low concentration of cross-linker was used to slow down diffusion of gelatin out of the scaffold.

CaP particle/biopolymer composites have not been widely investigated for the release of growth factors; even the release properties of gelatin, especially, is well investigated and relies on an electrostatic interaction between a positively/negatively charged gelatin and a drug of the opposite charge.[149] Takahashi *et al.*[145] synthesized the gelatin sponges by chemical cross-linking of the gelatin in the presence of different amounts of β-TCP granules. Bone morphogenetic protein-2 (BMP-2) was loaded by simply dropping a solution of the growth factor to freeze-dried sponges. *In vivo* release study of BMP-2 labeled with ^{125}I from these composites revealed a high initial release followed by a more sustained release. For all types of composites, the evidence of bone formation was observed, though high amounts of β-TCP granules made the sponge collapse during degradation, leading to denser structures and less bone

formation. Kim *et al.*[143] synthesized the gentamycin-loaded HA-particle/gelatin composite sponge and investigated the *in vitro* drug entrapment and release as a function of cross-linking density of the gelatin, amount of HA in the sponge, and drug loading. They have found that increasing the cross-linking density leads to a higher drug entrapment, a decreasing initial drug release, and a more sustained release pattern. An increase in the percentage of HA particles decreased the percentage drug entrapment, though release here is also more sustained. Because in this study no gelatin degrading enzyme was added, the degradation and release is due to the degradation of the cross-linker used (1-ethyl-(3,3-dimethyl-aminopropyl carbodiimide hydrochloride), EDC).

A collagen scaffold with HA nanoparticles and rhBMP-2 was studied *in vivo* and a positive influence of the added drug was observed in a loaded implant model in dogs.[150,151]

Composites of gelatin/collagen with calcium phosphate cements are formulated to obtain better handling properties and to improve biological response. A handful of studies have been done on the biological response as well as on the properties of the gelatin and calcium phosphate cement (α-TCP) composites.[152–154] An acceleration of the cement setting reaction as well as an increase in compression strength due to the high density of the gelatin was observed. Furthermore, an excellent biological response was observed with an improvement of osteoblast activity and differentiation. Fujishiro *et al.*[155] prepared a porous composite of a 5% and 20% gelatin-containing α-TCP-based cement. Pores of 20–100 μm were prepared by mixing a gelatin gel with α-TCP powder. Results showed an increase in mechanical properties over time with the 5% composites when compared to the original cement, though with 20% gelatin, the compressive strength was lower. The biomimetic abilities of gelatin that acts as a nucleation point of CaP-crystal growth are behind the good biological response and increase in mechanical strength of these composites.[156] Rammelt *et al.*[157] investigated the properties of collagen/CaP-cement composites. They have added 3% of collagen I to nanocrystalline HA cement which led to an increased bone remodeling in rat tibia defects. Another research group[158] added 1.0–2.5% collagen I to a commercial apatite cement and also observed mechanical and physical changes of the cement especially when osteocalcin was added. The behavior of osteoblasts cultured on the same 2.5% collagen-containing cement was investigated.[159] They observed that changes in the local microenvironment like the pH greatly influenced cell differentiation and proliferation on these composites.

Lode *et al.* investigated the release of VEGF from a collagen-containing apatite cement and compared it to the release pattern and VEGF activity of the normal cement.[160] Both the cumulative release (25%) and burst release were higher from the collagen cement composites, indicating a looser binding of the VEGF to the collagen. Furthermore, they analyzed the proliferation of endothelial cells after exposing them to the diluted release medium. They found that the introduction of phospherine and sodium citrate to the collagen-containing cement has a positive impact on VEGF activity.

Besides the gelatin and collagen, other protein-based polymers were explored to make composite material with CaP-ceramics and cements. Fibrin and especially fibrin glue was applied for the introduction of ceramic particles[161,162] or mixed together with calcium phosphate cement.[163]

Studies have been performed introducing alumina and TCP-particles in a casein and soybean protein scaffold,[164] and polypeptides into CaP-cement.[165] Again, main reasons for the use of these proteins were biodegradability, biomimetic properties, and mechanical reinforcement.

5.520.5. Modifications of Bioactive Ceramics and Bioactive Ceramic Composite-Based Scaffolds

5.520.5.1. Localized Delivery of Biomolecules and Cells

The additional function of scaffolds is to enable a controlled release of molecules as a carrier at the treatment site for a sufficient duration to aid therapeutic efficacy of those molecules released. The scaffold as a carrier material in bone tissue engineering should be biocompatible and should not physically interfere with the normal processes of osteogenesis or elicit any inflammatory or immunogenic response in the body. An ideal biomaterial carrier must maintain the activity of molecules and also allow initial cellular infiltration and subsequent integration with native tissue.

BMP-2, transforming growth factor-β (TGF-β), basic fibroblast growth factor (bFGF), and VEGF are common but vital growth factors that are introduced into the scaffolds due to their osteoinductive properties and vascularization.[166–168]

BMP delivery to localized sites has been explored for repair of bone defects and nonunions in several different experimental models.[169–182] Many delivery systems have been explored, such as demineralized bone matrix, collagen composites, fibrin, calcium phosphate, polylactide, poly(lactide-*co*-glycolide), polylactide–PEG, HA, dental plaster, and titanium.[183–188] It is worth mentioning here that none of these materials meet all of the demands for an ideal delivery system.

Ceramics like HA are known for their positive interaction with BMPs due to strong binding affinity to the growth factors/proteins. Owing to this phenomenon, high amounts of these growth factors are added in *in vivo* studies to guarantee a positive tissue response, which results in an increased level of BMPs compared to the clinical relevant values inside the human body and increases the cost of a single implant substantially, therefore decreasing a possible use of the material.

It has been observed by many researchers that incorporation of BMP in HA,[178,187] HA/collagen,[169] and HA/TCP composites[189,190] greatly accelerates bone formation. However, these systems suffer from a high degree of bioresorption and poor mechanical strength, which limits the effective application of these synthetic bone substitutes. Moreover, acute inflammatory and immunologic reactions are observed with the collagen composite, when calcium phosphate ceramics were used as carriers for osteoinductive factors.[191,192] Alam and colleagues impregnated different doses of recombinant human (rh)BMP-2 into BCP ceramic with varying ratios of HA to a TCP(HA/TCP ratios: 100/0 (pure HA, 75/25, 50/50, 25/75, and 0/100 (pure TCP)).[193] The samples were implanted under the pericranium in adult wistar male rats and were harvested 8 weeks after implantation. The extent of bone and bone marrow formation and the degree of resorption of the ceramic particles were significantly higher in the samples composed of 25% HA and 75% TCP.[193] The enhancement in the bioactivity of the composite 25HA/75TCP corresponds very well

with the high quantity of preadsorbed rhBMP-2 on the material surface. There is a possibility that the high rate of dissolution of the TCP-rich composite provides empty space to grow new bone. From this study, it is not possible to conclude whether the enhanced-rhBMP-2 adsorption was due to the variations in the chemical composition or the variations in the surface area of the substrate, as there is no quantification of the surface area and porosity of the material. Collagen type IV was also explored to effectively adsorb BMP to the ceramic.[173] They grafted TCP cylinders loaded with partially purified sheep BMP and Type IV collagen in the diaphyseal segmented defects in the tibia of sheep.[173] It is demonstrated that the TCP loaded with a high dosage (100 mg) of partially purified BMP has superior healing capacity for the segmental bone defects.

Silica-based porous glass xerogel was also explored for the delivery of growth factor such as TGF-β1 *in vitro*.[194] It is shown that the release of TGF-β1 can be facilitated by modifying the scaffold properties such as the degree of drying and surface area.[194] The same research group evaluated the silica xerogel composites for the release of BMP-2 *in vitro*.[192] They found that when rat stromal marrow cells were seeded onto the surface of xerogel discs with rhBMP-2, incorporated in the glass, adsorbed onto the surface of the glass, or added to the culture media,[195] cell differentiation was increased most when the BMP-2 was incorporated or adsorbed onto the xerogel glass.[195] Recent studies reported on a novel resorbable bioactive cyclo silicate (silica–calcium phosphate nanocomposite, SCPC) nanocomposite as a potential tissue-engineering scaffold for cells and biologic molecule delivery.[196,197] When the SCPC material was loaded with rhBMP-2, it provided an excellent release profile of biologically active rhBMP-2 compared with porous HA ceramic (HA-200). In addition, bone marrow cells attached to the SCPC-rhBMP-2 hybrid produced mineralized ECM and bone-like tissue that covered the material surface and filled the pores over the entire thickness of the template after 3 weeks in culture. Conversely, cells attached to the HA-rhBMP-2 produced a limited amount of unmineralized ECM after the same time period. From the results of these studies, it can be concluded that the silica-based materials have very high potential to be used as a scaffold for BMP delivery.

Certain bioceramics, such as BG, which have specific bone affinity, may affect cell behavior by regulating the expression of BMPs.[173] Northern hybridizations demonstrated similar trends in the mRNA levels of collagen Type I, alkaline phosphatase (ALP), and BMP-2 in Saos-2cells grown on the dishes and plates. However, the relative levels of mRNAs, BMP-2, collagen I, and ALP in cells cultured on BG plates were 9-, 6-, and 1.2-times higher than that on BG dishes, respectively. However, in this study, the prepared BGs were not characterized, and it is difficult to understand why there were differences on the cellular activity of cells cultured on the plates versus dishes when both are made of BG.[198]

5.520.6. Conclusion and Future Directions

The treatment to reconstruct and repair major bone loss due to injury or disease is one of the major problems in orthopedic and maxillofacial surgery. The development of new scaffolds to deliver cells and molecules has made remarkable progress to addressing these clinical issues. There are numerous composite systems comprising synthetic biodegradable polymers and bioactive phases, such as HA and BGs.

Outstanding mechanical properties and osteoconductivity of highly porous polymer/ceramic composite scaffold make them a promising substrate for bone tissue engineering. Biodegradable polymer scaffold may provide a number of benefits for bone tissue engineering; enhanced environment for cell seeding; survival, growth, and differentiate function because of the osteoconductive function imparted by HA, which increases mechanical properties that are essential for load bearing. High porosity also increases the resorption rates; however, it can decrease mechanical properties. A challenge is the brittleness of the ceramic, which makes implantation for load-bearing applications complex.

CaP cements/ceramics can be applied as promising carrier materials for drugs in which release patterns and efficiencies strongly depend on the type of ceramic/cement used. In general, ceramics suffer from initial burst release compared to cements that have a more sustained release pattern. Also, BG prepared by sol–gel can be used as a carrier for drugs.

The totally synthetic biodegradable polymer/inorganic bioactive phase composites reviewed here are particularly attractive as tissue-engineering scaffolds due to the flexibility in tailoring structural properties, bioactive behavior, and biodegradation kinetics. From the materials science perspective, the present challenge in tissue engineering is to design and fabricate reproducible bioactive and bioresorbable 3D scaffolds of tailored porosity and pore structure, which are able to maintain their structure and integrity for predictable times, even under load-bearing conditions. Poor compression strength and biological activity of the added polymers often undermine the advantages of the polymer/ceramic composites.

To enhance the *in vivo* cohesion and injection properties of the cement, biopolymers like chitosan, gelatin, and collagen are frequently added to calcium phosphate cement. Occasionally, the goal is to reinforce the cement, which is a result of the compact microstructure that is formed after mixing both inorganic and organic materials. The porosity and degradation rate of cement can also be altered with the addition of polymer microspheres/particles that degrade *in vivo*, as it was observed with PLGA microspheres. Furthermore, PLGA microsphere and collagen-containing cements have shown to be promising materials for drug release/entrapment.

Ceramic particles can also be added to a polymeric carrier to improve the mechanical properties and incorporate the nanotopographic features that mimic the nanostructure of natural bone. In general, scaffolds comprised of a ceramic in a polylactic, protein, or carbohydrate carrier show higher degradation rates than do pure ceramics. Furthermore, by changing the synthesis parameters such as molecular weight or cross-linking density of the polymer, degradation rates can be controlled. A compression strength of 100% ceramic composites is much higher than these scaffolds, but the addition of the polymer reduces the brittleness of the ceramic and makes it applicable for the purposes of tissue engineering. In general, release patterns from drug-loaded protein-based polymer/ceramic scaffolds show an initial burst release. This problem can be reduced by adding higher amounts of

ceramic particles to the composites or by increasing the cross-linking of polymer, which can provide a more sustained release of drugs/growth factors.

The possibility of incorporating growth factors into composites formed with the aim to accelerate local bone healing and vascularization is promising and has started to be explored. Inducing rapid vascular ingrowth during tissue development will continue to be of major importance in tissue engineering. The incorporation of biomolecules during scaffold processing, however, is not simple because it does not allow extreme temperature ranges (470 °C) or extremely aggressive chemical conditions during processing, this being a challenge to the scaffold fabrication process. Immobilization of proteins and growth factors via the surface functionalization of the scaffold can be a promising strategy.

With methods like protein adsorption or plasma treatment, there is ample scope in the application of surface modification to provide more cues to cell attachment and response, thus making the scaffold more biocompatible. Adsorption of proteins such as FN and collagen should cause improvements in wettability of highly hydrophobic polymers such as poly-DL-lactic acid (PDLLA). Further research should focus on understanding cell–material interactions at a molecular biology level, coupled with the design of a new generation of bioactive materials that activate proliferation and differentiation of cells to enhance rapid formation of ECM and tissue growth *in situ*. Successful tissue development may be achieved by chemical modifications including the incorporation of functional groups, chemotactic factors, matrix protein, or peptides.

The unique properties of nanomaterials can be exploited to enhance the properties of the scaffold for tissue engineering. For example, use of ceramic nanoparticles and carbon nanotubes (CNTs) may also improve the environment to enhance cell attachment and proliferation as well as adding extra functionalities to the base scaffold; however, critical issues like toxicity associated with nanoparticles and CNTs must be well addressed beforehand. Nanotechnology can provide an alternative way of processing bioceramics with high mechanical strength and enhanced bioactivity and resorbability. The nanometer grain sizes and high surface fraction of grain boundaries in nanoceramics increase osteoblast functions (such as adhesion, proliferation, and differentiation). The decrease in the grain size results in a significant increase in the grain boundaries, which modifies the overall physicochemical characteristics and, in particular, those related to the surface. Moreover, key properties like dissolution and protein adsorption, which are dependent on surface chemistry, energy, and roughness, can be optimized to enhance cell adhesion, proliferation, and differentiation. Other composite systems of interest are those combining nanostructured inorganic phases (e.g., nanoparticles and nanofibers) and biodegradable polymers, recently discussed in this series,[109] in order to influence cell response in contact with scaffold by mimicking the surface nanotopography of living tissues.

There is a lack of current understanding in the literature regarding the long-term *in vitro* characterization of the composites discussed here, specifically regarding the long-term effect of the incorporation of inorganic bioactive phases on the degradation and ion release kinetics of these highly porous systems. In this regard, the development of appropriate characterization techniques coupled with predictive analytical models is an important avenue of research in order to comprehensively assess the degradation of these systems with respect to pore structure, scaffolds geometry, fluid flow, and the influence of the bioactive additions. Here, the use of X-ray microtomography as a reliable tool for quantifying 3D pore structure parameters is likely to gain increased importance.[110]

Additionally, the properties of interfaces between the polymer matrix and inorganic inclusions need to be further investigated and characterized, since interfacial properties have a huge influence on degradation kinetics, ion concentration, and release profiles, as well as the effective composite mechanical properties. The use of improved cell seeding mechanisms and perfusion bioreactors should enable improved optimization of the scaffolds, especially with respect to the influence of ion concentration and release kinetics on cellular response. Moreover, improved cell biology assessment models are related to better understand the influence of media composition and volume, which can significantly influence the ion release kinetics and cell response.

In conclusion, it can be said that ceramics have been widely used in the biomedical engineering and bone substitution/regeneration field, whether it comprises a 100% ceramic composite, a composite of polymer with ceramic particles, or addition of polymeric additives/porogens to calcium phosphate. But still, significant improvements in the design and structure of porous bioactive ceramics are needed to overcome major drawbacks, such as their unpredictable osteoclastic activity and degradation/dissolution rates, as well as to facilitate controlled graft material resorption and tissue regeneration.[99]

Glossary

Osteoinductive material A synthetic material that gives rise to bone formation in nonosseous sites (i.e., in muscle or subcutis) without additional growth factors (such as bone morphogenetic proteins) or osteogenic cells.

Abbreviations

ACS	Absorbable collagen sponge
AIO	Alumina ceramic
ALP	Alkaline phosphatase
BCP	Biphasic calcium phosphate
BMPs	Bone morphogenetic proteins
BMP-2	Recombinant bone morphogenetic protein 2
BMP-7	Recombinant bone morphogenetic protein 7
BSEM	Backscattered electron microscope
β-TCP	Beta tri-calcium phosphate
CaP	Calcium phosphate materials
DBM	Demineralized bone matrix
HA	Hydroxyapatite
mRNA	Messenger ribonucleic acid
OCP	Octacalcium phosphate
OP-1	Recombinant bone morphogenetic protein 7

PGE2	Prostaglandin E2
PRP	Platelet-rich plasma
rhBMPs	Recombinant bone morphogenetic proteins
SEM	Scanning electron microscope
TCP	Tri-calcium phosphate
TCP-a	Pure tri-calcium phosphate ceramic particles
TCP-b	Pure tri-calcium phosphate ceramic particles
TCP-c	Tri-calcium phosphate ceramic containing traces of hydroxyapatite
TCP-B	Tri-calcium phosphate ceramic with large grains and large micropores
TCP-S	Tri-calcium phosphate ceramic with small grains and small micropores
TRAP	Tartrate resistant acid phosphatase

5.521.1. Bone and Its Biology

Bone is as vital to life as any other organ system. It provides the internal support of the body and is the framework for the attachment of the muscles and tendons essential for locomotion. It not only protects the vital organs of the heart, lungs, brain, and spinal cord but also encloses the blood-forming elements of the bone marrow. In addition, it contains 99% of the body's calcium, 85% of the body's phosphorous, and 65% of the body's sodium and magnesium. It plays important roles in the homeostatic regulation of the concentration of calcium and phosphorous in the blood and in other body fluids.[1,2]

The shape of bone in different parts of the body varies with their specific functions, but the structure of bones of different shape is basically similar. It is one of the unique connective tissues that are normally mineralized. Biochemically, bone is defined by its special blend of organic matrix (35%) and inorganic elements (65%).[1,2]

The inorganic matter of bone consists mainly of calcium and phosphate, a significant amount of citrate and carbonate ions, and traces of fluoride, magnesium, and sodium. Through a process of biomineralization, calcium phosphate in bone deposits vary similarly, but not identically, to mineral hydroxyapatite (HA) on collagen matrix. The mixture of calcium phosphate and collagen matrix gives bone strength and toughness.[1,2]

Despite its strength and hardness, bone is a dynamic living tissue with its own biology. In development, bone occurs by direct replacement of primitive connective tissues (intramembranous ossification) or by replacement of preexisting cartilage (endochondral ossification). In addition to embryonic bone development, bone is also renewed throughout the lifetime of the individual through a process of bone remodeling: existing bone is resorbed and new bone is formed in the resorbed bone bed (this bone formation is called secondary bone formation).[1–3]

Bone is also one of the few tissues that can fully repair itself. For instance, the fracture of bone activates osteogenesis and, eventually, the fracture heals without any scar formation.[1]

Sometimes, but not frequently, normal bone is formed in nonosseous sites.[1]

5.521.2. Bone Grafting and the Strategies

Although bone has the ability to repair itself, the ability decreases with the age, is affected by diseases (e.g., osteoporosis) and other factors, and is limited to small bone defects. When bone loss is too large (e.g., in case of excision of bone tumors or other bone diseases, in case of bone loss due to accidents, and in fractured bones that cannot repair themselves), surgery is necessary to repair the bone defects.

Several strategies are taken into consideration for cases of difficult bone repair. New surgical techniques and novel tools could allow mini-invasive or noninvasive surgery,[4,5] and novel instruments could improve the bone healing.[6] In any case, bone grafts are necessary and bone grafting materials with high bone regeneration ability are an important strategy for the achievement of the clinical outcome of bone repair.[7,8]

5.521.2.1. Bone Grafts

Several bone grafts are chosen for bone repair: autografts, allografts (including demineralized bone matrix, DBM), and synthetic materials.[9–12] Autogenous bone graft typically taken from the iliac crest has long been the gold standard, although it is associated with donor site morbidity. Although the non- or mini-invasive surgical techniques to harvest iliac crest autograft can minimize the donor site morbidity and pain, the amount of autograft that can be harvested is limited for bone defects where a large volume of grafting material is needed. Owing to the growth factors, osteogenic cells (i.e., osteoblasts and osteogenic progenitor cells), scaffolding substances and to the fact that it is obtained from the patient itself, autograft is biocompatible, osteoconductive, and osteoinductive. Biologically active substances intended to extend, enhance, or even replace autologous graft include allograft and DBM. However, these biologically active substances do not have the potency of autografts and promote less bone formation. Moreover, they can be associated with disease transmission. Various synthetic materials exist that are available in large quantities, and are biocompatible and bioactive (osteoconductive). Additionally, they do not carry the risk of disease transmission. Their effect on bone tissue formation varies widely as is described at length in other chapters of this publication.

5.521.2.2. Synthetic Bone

Synthetic bone that mimics one or more components of bone is under consideration, with the goal of achieving the degree of repair typically resulting from the use of autograft.

5.521.2.2.1. Biomaterials

Although the goal has been to make biomaterials that mimic bone chemically, physically, and mechanically, this is not simple to accomplish. Biomaterials can vary with chemistry, forms, and shapes for different applications. They can be

biocompatible and osteoconductive. Some metals are strong enough for bone augmentation in load-bearing sites. Calcium phosphate materials chemically mimic bone. The combination of polymeric materials and calcium phosphate could mimic bone both chemically and mechanically. Applying porous structures similar to cancellous bone to biomaterials enables them to mimic bone physically and thus, the resulting materials can become scaffolding substances for bone regeneration.

5.521.2.2.2. Growth factors

Loading growth factors to materials is a way to mimic autograft for bone repair. Among the growth factors, bone morphogenetic proteins (BMPs) and platelet-rich plasma (PRP) are of interest. BMPs are proteins having the potency to differentiate inducible cells to osteogenic cells that can form bone. Once BMPs are introduced to materials, the hybrid scaffold becomes osteoinductive and makes it possible to repair large bone defects.[13] BMPs have been introduced to patient care first with highly purified BMPs[14] and later on with recombinant BMPs (rhBMPs). Among the rhBMPs, BMP-2 and BMP-7 (also called OP-1) are currently used. However, the high dose of rhBMPs currently administered has led not only to high costs, but also to clinical issues.[15,16] PRP is a concentrated source of autologous platelets, which contains and releases (through degranulation) different growth factors (cytokines) that stimulate bone and soft tissue healing.[17,18] PRP may enhance bone formation but does not induce bone formation as BMPs do. Applying PRP to materials may therefore not be a good choice in mimicking autologous bone, and the variation of the quality with the processes of preparation is another shortcoming of PRP that makes it unsuitable for clinical uses.

5.521.2.2.3. Bone tissue engineering

Bone tissue engineering, an approach in which osteogenic cells are loaded onto materials, is another way to achieve repair similar to that achieved with autologous bone. This principle has been studied extensively, as is described elsewhere in this publication. Two studies, for example, are studies in rodents with relatively small defects.[19,20] The osteogenic cells can be obtained from *in vitro* expanded bone marrow stromal cells and from bone marrow aspiration. Mesenchymal stem cells from other tissues like adipose tissue can also be used. It is possible to fabricate tissue-engineered bone for large bone defects by using large-size scaffold materials. For large tissue-engineered bone, perfusion represents a limitation.

5.521.3. Biomaterials for Bone Substitution

5.521.3.1. From Bioinert Materials to Bioactive (Osteoconductive) Materials

Many materials have been used in bone repair procedures. First, select non-bone–bioactive materials (mainly metals and polymers), which do not give rise to any adverse tissue responses, were used to physically and/or mechanically repair bone. Later on, it was found that better bone repair could be achieved with bioactive calcium phosphate (CaP) materials (calcium phosphate ceramics and glasses in bulk, cement, composite, and coating form). These materials are not only biocompatible but also guide bone formation on their surface and bond to the newly formed bone.[21–26]

5.521.3.2. From Bioactive (Osteoconductive) Materials to Materials Associated with Osteoinduction

Bioactive materials support osteogenic cells to form bone on their surface and integrate with the newly formed bone. As bone formation on bioactive materials needs osteogenic cells and the migration of such cells from the surrounding tissues is limited with respect to distance, bioactive materials are not sufficient to repair large bone defects (e.g., critical-sized defects). To repair critical-sized defects, materials that are associated with events of osteoinduction are valuable to get full bone formation throughout large defects.

5.521.4. Bone Induction Associated with Materials

5.521.4.1. Bone Induction Study Models

When bone is observed in a nonosseous site, such bone formation is described by the terms heterotopic bone formation, heterotopic ossification, or ectopic bone formation.

Pathophysiological heterotopic bone formation is an uncommon but well-recognized complication of spinal injury, closed head injury, total hip arthroplasty, burns, and other trauma.[27] Controllable and reproducible bone induction was postulated to be very useful in musculoskeletal repair,[28] and efforts have been made to obtain osteoinductive bone substitutes. Introduction of growth factors (e.g., BMPs) to carriers[13] is one approach to the synthesis of osteoinductive bone substitutes, while induction of osteogenic progenitor cells to scaffolding materials is another (bone tissue engineering).[19,20]

Soft tissue implantation is the model to evaluate osteoinduction of bone substitutes. For example, subcutaneous implantation or intramuscular implantation in mouse or rat is quite often used to evaluate osteoinduction of bone substitutes bearing growth factors or osteogenic progenitor cells.[28,29]

The calcium phosphate literature of the 1980s and before described the properties of these materials as osteoconductive.[30]

Starting with the studies by Ripamonti,[31,32] and later by Schepers *et al.*,[33] data were published that showed an induction effect associated with various calcium phosphate ceramics, that is, bone formation in soft tissue sites, or bone formation by upregulation of precursor cells without osteoconduction taking place. Animals other than rodents were used to evaluate osteoinduction associated with materials and since then events of induction associated with specific materials have been shown in different animal species. The quite often used models to evaluate bone induction of materials are the intramuscular implantation and the subcutaneous implantation. It has been shown that, following intramuscular implantation, materials could give rise to better bone formation than following subcutaneous implantation, possibly because of the better vascularization of the implants in muscle.[34,35]

Bone induction with materials is identified by bone morphogenesis. Osteoinduction of growth factors can be evaluated *in vitro* with special cell types and the osteoinductive property of tissue-engineered bone (with osteogenic cells or osteogenic progenitor cells) can be partially tested *in vitro* as well, while there

is no *in vitro* evaluation system available so far for evaluating the osteoinductivity of materials alone. Although some materials enhance bone marker expression of osteogenic cells or osteogenic progenitor cells cultured on them,[36] the materials may fail to give rise to bone formation when implanted in soft tissue. Thus, it is then imprudent to use *in vitro* cell cultures to predict the osteoinduction associated with a material. For example, microstructures have shown to have an important role in bone induction associated with calcium phosphate materials,[37,38] while an *in vitro* study has reported an adverse role of microporosity in the behavior of human osteoprogenitor cells.[39] However, it would be useful to find *in vitro* markers for cells cultured on materials that are associated with the osteoinduction *in vivo*.

5.521.4.2. Bone Induction in the Presence of Calcium Phosphate-Based Ceramic Materials

5.521.4.2.1. Phenomenon

As the main inorganic component of bone, calcium phosphate has been developed as a material in different forms for bone regeneration. It has been demonstrated that calcium phosphate materials in their various forms are biocompatible, osteoconductive (i.e., they form a chemical bond with the newly formed bone), and resorbable.[21–26] Osteoconductive calcium phosphate materials are considered as alternatives to autograft for bone repair.

Osteoinduction associated with calcium phosphate materials was ruled out based on the results from rodents,[30] but ectopic bone formation associated with calcium phosphates was first found in specific HA ceramics following subcutaneous or intramuscular implantation in dogs and baboons by Yamasaki,[40] Zhang.[41] Since then, ectopic bone formation by other calcium phosphate materials has been found in different animal species (**Table 1**).

So far, bone formation of calcium phosphate materials has been observed in HA ceramics, biphasic calcium phosphate (BCP) ceramics, tricalcium phosphate (TCP) ceramics, calcium phosphate cements, and glass ceramic in nonosseous sites.

5.521.4.2.2. Animal dependence

Animal dependence of bone induction associated with materials has been shown by evaluating ectopic bone formation of calcium phosphate materials in different animal species.[35,48,68] The ectopic bone formation with calcium phosphate materials has been tested directly in various animal models (i.e., mouse, rat, rabbit, goat, sheep, pig, dog, monkey, and baboon) and indirectly in humans (**Table 1**). Although the ability of calcium phosphate materials to give rise to ectopic bone formation varies with the animal species, bone induction with calcium phosphate materials has been seen in all the aforementioned animal models except in rats till date.

Among the animal species, bone induction with calcium phosphate materials appears to occur in various models using baboons, dogs, and sheep. This is not the case among models that use rabbits, goat, and mice. In fact, variations occur in terms of the bone incidence, if any, the amount of bone formed, and the time for bone formation to occur intramuscularly or subcutaneously. In goats, the amount of the formed bone in calcium phosphate materials following intramuscular implantation is limited (±1% in the available space)[61,64] and variations between individual animals are often observed.[74] In some studies, no bone induction was seen.[35,80]

Although bone induction with calcium phosphate materials does not occur in all the animal species tested, it takes place in nonhuman primates (monkey and baboon) and also in nonosseous sites of humans. This prompts the concept of clinical significance for bone repair if such materials were capable of enhancing bone regeneration in large bone defects.

5.521.4.2.3. Bone formation and osteoinduction in the presence of materials

The process of bone induction associated with calcium phosphate materials was evaluated in animals for periods from 7 days up to 2.5 years.

Four patterns of structural tissue organization were found in HA ceramic following intramuscular implantation in baboons at 3, 6, and 9 months: first, fibrous connective tissue with pronounced cellular and vascular components was formed in the implants, then collagen fibers condensed in fibrous connective tissue at the interface of the HA, followed by morphogenesis of bone, remodeling of bone, formation of lamellar bone, and differentiation of bone marrow.[32]

A complex process, involving clot formation, vascular invasion, granulation-like tissue formation, polymorphic cell aggregation, osteoblast differentiation, and bone formation, was observed in BCP ceramic implanted in muscle of dogs at an early period of 7–45 days. Before bone formation started, alkaline phosphatase (ALP)-positive polymorphic cells aggregated on the inner surface of the implants and near the invading capillaries or small venules, followed by osteoblast differentiation of the polymorphic cells and bone formation on the pore surface.[50]

The chronological bone formation in the specific forms of BCP and HA (with their unique chemical and physical properties) was observed from 7 to 360 days following intramuscular implantation in dogs. Although bone formation started earlier and more bone formed inside BCP than in HA, the process of bone formation was the same, including cell attachment, proliferation and differentiation, formation of bone matrix by osteoblast-like cells, and mineralization of bone matrix on the material surface, followed by bone remodeling, bone marrow formation, and formation of mature bone. However, each step took place earlier in the BCP used than in the HA used. For instance, bone matrix formation, which is the indicator of early bone formation, was found in the BCP at day 30 and in the HA at day 45.[70]

Similar bone formation was observed chronologically with a specific form of β-TCP with unique chemical and physical properties implanted in dog dorsal muscles from 14 to 112 days. New bone was observed after 56 days, and α1 chain of type I procollagen mRNA-positive osteoblasts lined the newly formed bone.[67]

The time needed for bone induction varied with materials, while bone always started to form on the inner surface of the materials and was observed inside the implants, which were surrounded by a layer of connective tissue. The amount of the formed bone increased with time and stayed stable at longer time (up to 2.5 years).[32,56,57]

Bone formed in the presence of calcium phosphate materials is biologically and biochemically similar to normal bone: in fact, the cellular events observed in normal bone formation

and bone remodeling occurred in inductive bone formation as well. The matrix fibers of the induced bone were mainly composed of type I collagen.[75] The pattern of crystal deposition in bone tissue induced in the presence of calcium phosphate materials and the structure of osteoblasts, osteocytes, bone lining cells, and osteoclast-like cells were similar to those of normal bone tissue.[75] The bone-forming cells are ALP-positive[50] and produce OP-1 and collagen IV.[72,79]

Unlike bone formation induced by BMPs, bone formation induced in the presence of calcium phosphate materials started directly with bone and no cartilage was observed along the induced bone formation. It appeared that bone formation induced in the presence of calcium phosphate materials follows intramembranous ossification.[32,50] However, it was noticed that multinucleated cells were present on the surface of the materials before bone formation started.[50,67] Meanwhile, the multinucleated cells yielded a positive result to osteoclast markers (TRAP and cathepsin K).[67] Moreover, EP4 agonist, which stimulated osteoclastogenesis, enhanced bone formation in TCP implanted in muscle of dogs.[78] The data indicate that bone formation induced in the presence of calcium phosphate materials likely resembles the pattern of bone formation during bone remodeling rather than during intramembranous formation.

5.521.4.3. Bone Induction by Non-CaP Materials

In addition to bone induction associated with calcium phosphate materials, ectopic bone formation was also found in materials other than calcium phosphates. As early as 1969, Winter and Simpson found that heterotopic bone formed in a synthetic sponge of polyhydroxyethylmethacrylate under the skin of young pigs.[81] Okumura *et al.*[82] observed bone tissue formation in titanium fiber mats implanted with osteogenic cells, albeit in a different pattern than in the HA implanted by Ohgushi *et al.*[83] in prior studies with the same model. Fujiibayashi and Takemoto found bone formation in physicochemically treated titanium metal following intramuscular implantation in dogs.[84,85]

Moreover, it was found that an alumina ceramic, which is normally considered as a bioinert material, was associated with osteoinduction when its surface was microstructured (Figure 1(a)). When cylindrical alumina ceramics (ø5 × 6 mm^3) made from Al_2O_3 powder with diluted H_2O_2, sintered at 1300 °C for 10 h, were implanted in back muscle of dogs for 3 months, bone was observed inside all the harvested implants. Bone formation started from the inner pore surface of alumina ceramic near plenty of blood vessels (Figure 1(c)), while mineralization of the bone matrix did not start directly on the alumina surface, leaving an unmineralized zone between the alumina surface and the mineralized bone (Figure 1(b)).

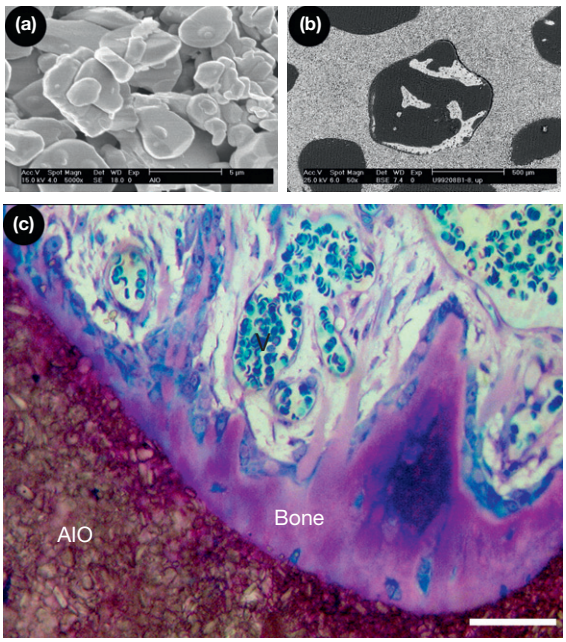

Figure 1 Bone induction in porous alumina ceramic following intramuscular implantation in dogs for 3 months. (a) SEM image showing the microstructured surface of the porous alumina ceramic. (b) BSEM image showing bone (white color) in pores of alumina ceramic (dark grey color). (c) Histology of porous alumina ceramic harvested from muscle of dog showing bone matrix (BONE) on inner pore surface of alumina ceramic (AlO), blood vessels can be seen near the bone (V) (undecalcified section, methylene blue and basic fuchsin staining, scale bar = 50 μm).

5.521.5. Role of Calcium Phosphate in Bone Induction

Bone induction is quite often observed in calcium phosphate materials. It appears that bone induction is a unique property associated with calcium phosphate materials at first sight. However, bone induction is also associated with non-CaP materials, suggesting that calcium phosphate may not be necessary for bone induction to take place.

However, the presence of calcium phosphates is a contributing factor to bone induction. Porous tantalum is not associated with bone induction, while it has been observed that after octacalcium phosphate (OCP) coating was applied on its porous surface, osteoinduction occurred.[54] The same findings were obtained with titanium alloy implants.[62] Non-CaP materials may form a CaP layer on their surface through *in vivo* calcification. This phenomenon was seen during bone induction in a synthetic sponge[81] and in physicochemically modified titanium implants.[84,85] As observed by Winter and Simpson, the surface of the materials was calcified before bone formation started in the synthetic sponge. It is noticeable that only the physicochemically treated titanium implants, whose surface allowed biological calcium phosphate layer to form, were associated with bone induction, while the untreated ones, where no calcium phosphate layer could form, were not.[84,85]

Calcium phosphates present in the materials may cause bone induction through their high ability to bind proteins (including growth factors), or through their specific architectures, or through an *in vivo* surface calcification. The same may happen to some non-CaP materials with microstructured surfaces, which can incorporate growth factors and thus attract osteogenic precursor cells to induce bone formation.

5.521.6. Material Factors

It has been observed that the osteoinductive potential in the presence of materials can vary with the type of material. Some materials induce bone formation as early as 30 days,[70] others after 3 months, and some do not induce bone formation even after 12 months.[79,84] In addition to the various times for the occurrence of bone formation in soft tissue implantation, it was found that the amount of the bone induced by a certain time varied with the materials.[70,85] Moreover, only the materials having a higher osteoinductive potential could induce bone formation in rodents.[68]

The chemistry, the microstructure, and the macrostructure have shown their influence on the osteoinductive potential associated with materials.

5.521.6.1. Chemistry

Calcium phosphate materials varying with chemistry have different dissolution rates and degradation rates. Generally speaking, dense HA is nondegradable or slowly degradable, TCP is fast degradable or degradable, and BCPs containing both HA and TCP are in between.[26] A study proved that too high a content of TCP is not good for bone induction. When compared in muscle of rabbits, BCPs having 70%HA/30%TCP induced bone formation, while BCPs having 20%HA/80%TCP

and pure TCP (0%HA/100%TCP) did not induce bone formation.[59] It was also noted that, in rabbits, the implants of BCP having 20%HA/80%TCP and pure TCP collapsed and lost their macroporous structures. The reason for the absence of bone induction may be the fact that the materials degraded too fast and a stable surface to support bone induction was not available anymore.[34,59]

5.521.6.2. Microstructures

The microstructure plays an important role in bone induction. HA with micropores on its macroporous surface induced bone formation, while HA without micropores on its surface did not induce any bone formation in dogs following soft tissue implantation, either under skin[37] or in muscle.[38] The influence of micropores on bone induction was also seen in BCP. BCP having higher microporosity (17%) induced bone formation in muscle of goats, while BCP having lower microporosity (4%) did not.[34]

Not only the presence of micropores, but also the dimension of the micropores has recently shown to influence bone induction as well. Two kinds of β-TCP ceramics (TCP-B and TCP-S, where TCP-B was TCP ceramic having large grains and large micropores, while TCP-S was TCP ceramic with small grains and small micropores) were prepared in particle form (1–2 mm) and implanted in muscle of dogs for 12 weeks. Large grains (±2 μm) and large micropores were present on the macroporous surface of TCP-B (**Figure 2(a)**) while small grains (±1 μm) and small micropores were present on the surface of TCP-S (**Figure 2(b)**). Mercury intrusion test showed that TCP-B had large micropores (the majority of the micropores were 2–5 μm), while TCP-S had small micropores (most of the micropores were 0.5–1.0 μm) (**Figure 2(c)**). Histology of the implants showed that only TCP-S gave rise to inductive bone formation in muscle of dogs in 3 months (**Figure 2(d)**, TCP-S), while no bone induction occurred in TCP-B (**Figure 4(d)**, TCP-B).

Small micropores was shown to favor bone induction; however, the ideal size of the small micropores for bone induction is not yet clear. How the microstructures affect bone induction is not clear either. The micropores may, in one hand, increase the surface area of the implants allowing the adsorption of higher amounts of growth factors, which have osteogenic potency, and then induce bone formation as secondary response or, on the other hand, if with the proper dimensions, the microstructures may directly initiate osteogenic differentiation of inducible cells able to form bone. There is no evidence either way at this time.

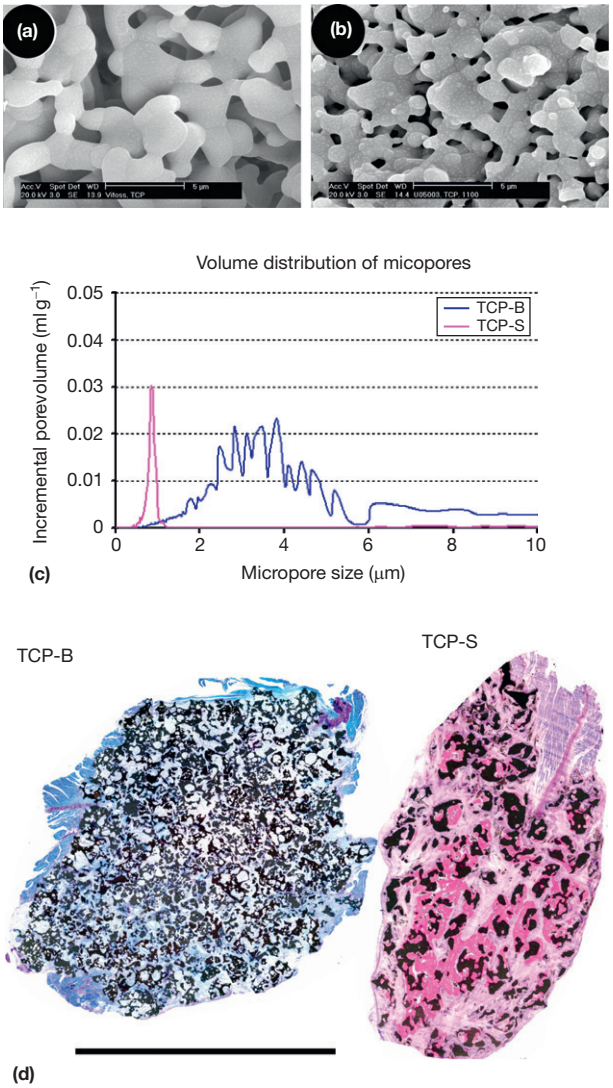

Figure 2 Influence of the microstructure dimension on bone induction of calcium phosphate ceramics. (a) SEM image of TCP-B showing large grains and large micropores. (b) SEM image of TCP-S showing small grains and small micropores. (c) Mercury intrusion data showing the micropores size distribution in the two considered tricalcium phosphates. (d) Histological overview of implants showing bone formation in TCP-S, while no bone formed in TCP-B 12 weeks after intramuscular implantation in dogs (red color; bone, black color: tricalcium phosphate ceramics, undecalcified section, methylene blue, and basic fuchsin staining, scale bar = 10 mm).

5.521.6.3. Macrostructures

Bone induction occurring inside the implants also indicated the importance of the macroporous structure of materials. A tridimensional environment[52,53] was suggested as necessary for the phenomenon of bone induction, as was also the case in transformed excavated bioactive glass granules reported by Schepers *et al.*[33] Cylinders (blocks) and particles of materials have been evaluated regarding their association with bone induction. It turned out that cylinders or blocks lead to more osteoinduction than particles.[46] In addition to the form of the implants, the size of the implants has shown its influence on bone induction: bone induction may not occur in small implants.[34]

With respect to the particles, the particle size of calcium phosphate materials plays a role. BCP particles with two different particle sizes (1–2 mm vs. 212–300 μm) were compared in dogs. One milliliter of each particle size was implanted in back muscle of eight dogs for 6 weeks. Histological analysis showed limited bone formation (2 ± 2%) in seven out of eight implants for the bigger particle size (**Figure 3(a)**), while more extensive bone formation (21 ± 15%) occurred in eight out of eight implants when smaller particles were used (**Figure 3(b)**).

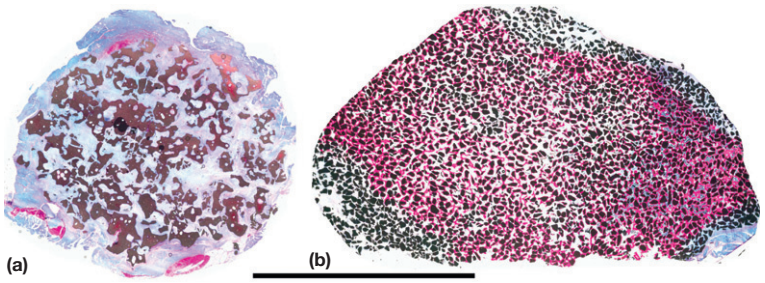

Figure 3 Influence of particle size on bone induction in biphasic calcium phosphate particles following intramuscular implantation in dogs for 6 weeks (undecalcified sections, methylene blue and basic fuchsin staining, black color: biphasic calcium phosphate ceramic, red color: bone, scale bar = 10 mm). (a) 1–2 mm particles and (b) 212–300 μm particles.

It is not yet known how macrostructures affect bone induction, although it has been mentioned that it is related to angiogenesis. The formation of blood vessels inside the implants may bring pericytes into the implants, and thereafter, the pericytes may differentiate into osteogenic cells able to form bone.[86] This hypothesis is supported by the fact that bone formation typically occurs nearby blood vessels.

5.521.7. Mechanism of Bone Induction

The sporadic bone formation observed in nonosseous sites indicates the presence of inducible cells in nonbony sites.[87] Once osteogenic signals are available, the inducible cells are differentiated into osteogenic cells to form bone. The inducible cells are present in many nonosseous tissues, including bone marrow, muscle, skin, adipose tissue, synovium, intestine, deciduous teeth, and nerve tissue.[88] It was found that the inducible cells isolated from the muscle have the ability to form bone.[89]

It is therefore possible to achieve bone induction in any of the nonosseous tissues having inducible cells if the osteogenic signals are present. What the osteogenic signals within materials in which osteoinduction has been observed are, is not known, but some hypotheses have been proposed.

5.521.7.1. Protein Adsorption

The first hypothesized cause of bone induction from materials is the protein adsorption. Calcium phosphate materials showed to have high affinity to BMPs.[90] It was thus suggested that calcium phosphate materials can concentrate growth factors, including osteogenic proteins (i.e., BMPs), and bone induction happens as a secondary response. Credence for this hypothesis also derives from the work on bioactive glasses, which develop a calcium phosphate surface layer. Protein absorption is one of the key steps leading to their extensive effect on bone tissue formation.[91–94] In addition to calcium phosphate materials, alumina is a strong absorbent for proteins.[95,96] As described earlier, with increased surface area thanks to the surface microstructure, microstructured alumina ceramic may concentrate growth factors as well and thereafter give rise to bone induction. Furthermore, protein adsorption is one of the explanations for bone induction by materials having high microporosity: by increasing the microporosity, the surface area of the implants increases; thus, more proteins can be concentrated, and consequently, bone induction happens. However, no direct evidence is available so far to support the role of protein adsorption in osteogenesis associated with materials, except with bioactive glasses.[91–93]

5.521.7.2. Topography

Microstructures play an important role. Although the protein adsorption effect is putative, they offer higher surface area available for protein adsorption. The effect may also be related to topography. As recently shown, highly controlled microstructures or nanoscaled disorders can differentiate mesenchymal stem cells into osteogenic cells. Rat bone marrow stromal cells not only proliferate, but also differentiate into mature osteoblasts on microstructured poly(methyl methacrylate) substrates.[97] Nanoscaled disorders stimulate human mesenchymal stem cells to produce bone mineral *in vitro* in the absence of osteogenic supplements.[98] It could then well be that the materials' microstructures, when in the range of proper dimensions (in the means of shapes and sizes) act as direct signals to differentiate inducible cells to osteogenic cells to form bone.

5.521.7.3. Surface Calcification

The role of surface calcification was seen in the case of bone induction occurring in synthetic polymeric sponges[81] and in treated titanium implants.[84,85] It is observed, or assumed, that before the onset of bone formation, the surface of the implants is a calcium phosphate surface. It has been proposed that *in vivo* surface calcification prepares a suitable environment for inducible cells to form bone, while osteogenic growth factors are trapped during calcification.[77] It is generally accepted that calcium phosphate materials have calcified surfaces,[25,26] a finding that actually underlays their osteoconduction. This is discussed at length in other chapters of this publication.

5.521.7.4. Inflammation

Inflammatory reactions occur upon the implantation of materials. It has been hypothesized that the initial inflammatory responses bring in and provide factors that attract and differentiate inducible cells.[99] One such factor is

prostaglandin E2 (PGE2), which is produced by macrophages during the inflammatory phase.[100,101] It was found that macrophages produce higher quantities of PGE2 in response to microstructured calcium phosphate ceramic as compared to calcium phosphate ceramic having smooth surfaces.[77] It is also an interesting observation that macrophages were present in the implants at early implantation times,[50,67] although this is not a proof for an association in and by itself.

5.521.8. Clinical Significance of Osteoinductive Materials

Although the causation and specific events associated with bone induction in materials have not yet been elucidated, and the current materials that show the effect may not be the best ones, materials associated with the event of osteoinduction do show their significance in bone repair not only in small or critical-sized bone defects, but also in spinal fusion procedures.

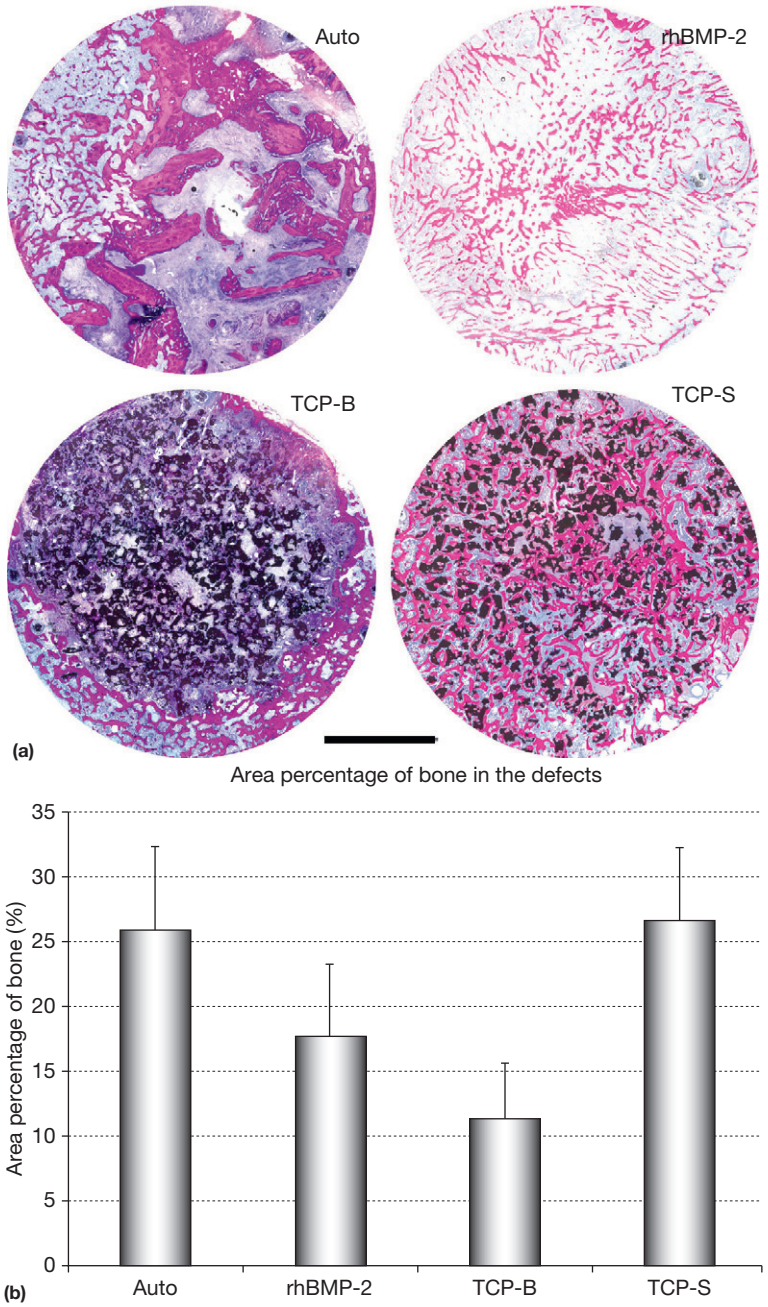

Figure 4 Comparison of autologous bone, rhBMP-2, and two forms of tricalcium phosphate. The sites were critical-sized defects in iliac crest of dogs for 12 weeks (auto: defect filled with autologous bone, rhBMP-2: defect filled with Infuse, TCP-B and TCP-S: defects filled with two forms of tricalcium phosphate). (a) Histological overviews of the defects (undecalcified sections, methylene blue and basic fuchsin staining, red color: bone, black color: tricalcium phosphate ceramic, scale bar = 5.0 mm). (b) Area percentage of bone in the defects.

5.521.8.1. Repairing Small Bone Defects

The usefulness of materials associated with osteoinduction for bone repair was first evaluated in small bone defects in femoral bone of dogs.[70] Two calcium phosphate ceramics (BCP and HA) were compared at different time periods from 7 to 360 days and it was found that the BCP used repaired bone defects faster than the HA.

5.521.8.2. Critical-Sized Defects

The possibility to repair critical-sized defects was evaluated in critical-sized defects in the iliac crest of goats using various forms of BCP.[69] Depending on the physicochemical characteristics of the BCP, 17-mm diameter (ø17 mm) bone defects were repaired or not at 12 weeks.

A subsequent study demonstrated that specific calcium phosphate materials could not only repair critical-sized bone defects, but also be better than rhBMP-2 and be comparable to autologous bone (Figure 4). TCP with small microstructures (TCP-S, 1–2 mm) and TCP with large microstructures (TCP-B, 1–2 mm), rhBMP-2 (Infuse, 400 µg rhBMP-2 on 1 ml ACS), and autologous bone chips (auto, 1–2 mm) were compared in critical-sized bone defects (ø17 mm) in iliac crest of dogs for 12 weeks. Bone was observed throughout the defects with autologous bone (Figure 4(a), auto), Infuse (Figure 4(a), rhBMP-2), and TCP-S (Figure 4(a), TCP-S), while no bone was observed in the center of the defects filled with TCP-B (Figure 4(a), TCP-B). Although bone formed in the center of the defects with Infuse, areas without bone tissue were noticed and the bone was thinner as compared to the bone in the defects containing the other implants (Figure 4(a), rhBMP-2). As a result, bone in the defects with rhBMP-2 was higher in terms of percentage area than the bone in the defects with TCP-B but it was not comparable to the bone formed in the defects with autologous bone (Figure 4(b)), while the bone formed in the defects with TCP-S was more than the bone in the defects with rhBMP-2 and comparable to the bone in the defects with autologous bone (Figure 4(b)).

5.521.8.3. Spinal Fusion

To study the potential of spinal fusion with calcium phosphate materials, three TCP ceramics (TCP-a: pure TCP, particle size 0.5–2.0 mm; TCP-b: pure TCP, particle size 0.5–2.0 mm and TCP-c: TCP with traces of HA, particle size 1–2 mm) and one HA ceramic (HA: pure HA, particle size 1–2 mm) were compared in muscle and in a noninstrumented spinal fusion model (L3–L4) in 16 dogs for 12 weeks. Histological analysis showed no bone formation in TCP-a and TCP-b, limited bone formation in HA, and extensive bone formation in TCP-c following intramuscular implantation. Extensive bone was formed between the two spinous processes with TCP-c (Figure 5(a), TCP-c), but bone was hardly formed with HA (Figure 5(a), HA), TCP-a (Figure 5(a), TCP-a), and TCP-b (Figure 5(a), TCP-b). In the region of interest (the region between the two spinous processes), a high percentage of bone was formed with TCP-c, while bone was limited in

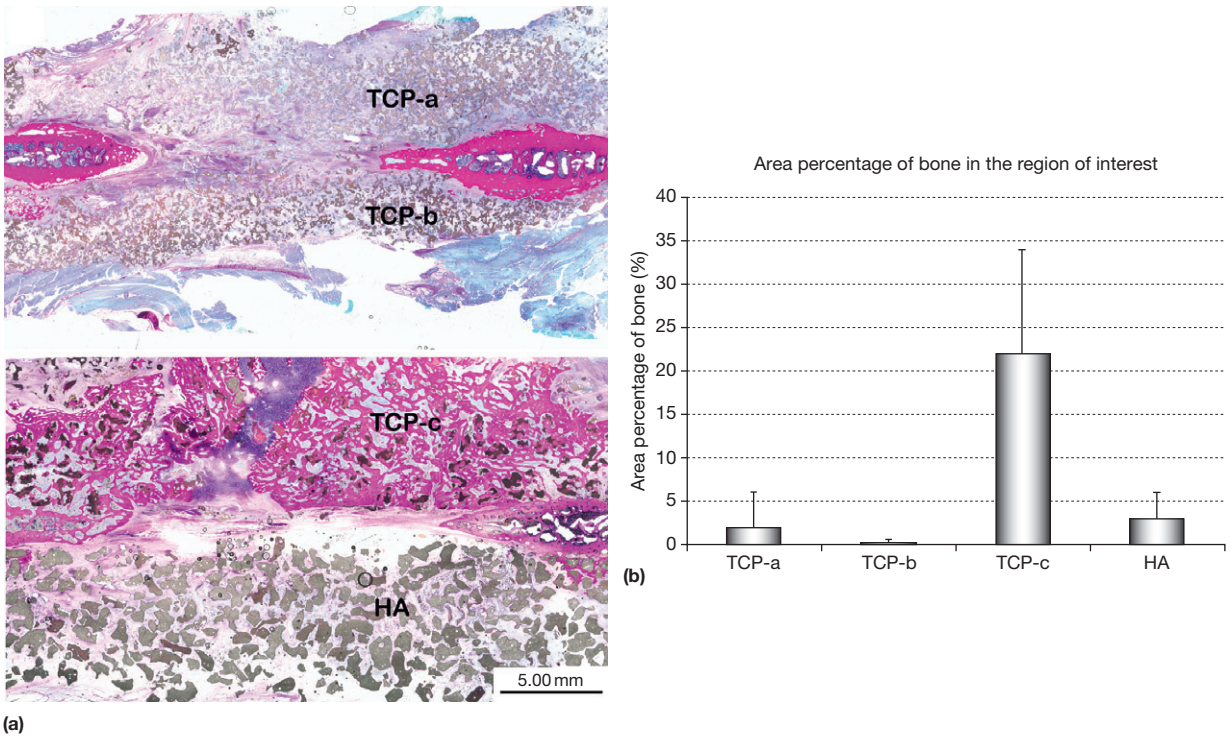

Figure 5 Spinal fusion in dogs with various calcium phosphate materials in a noninstrumented spinal fusion model in dogs for 12 weeks (HA: HA ceramic, 1–2 mm; TCP-a: tricalcium phosphate, 0.5–2.0 mm; TCP-b: tricalcium phosphate, 0.5–2.0 mm; TCP-c: 1–2 mm). (a) Histological overview of spinal fusion with calcium phosphate ceramics (undecalcified sections, methylene blue and basic fuchsin staining, scale bar = 5.0 mm). (b) Histomorphometry showing area percentage of bone in the region of the interest.

amount with HA, TCP-a, and TCP-b (Figure 5(b)). The results clearly indicated that spinal fusion could be obtained with calcium phosphate materials.

5.521.9. Future Directions

The progress made in the last two decades has paved the way for the development of materials that are associated with osteoinduction in various animal models for use in bone regeneration. This notwithstanding, the critical parameters associated with bone induction in calcium phosphates need to be further addressed.

Besides the mechanism of bone induction and developing more osteoinductive materials, other properties may be taken into account in order to improve bone regeneration with more powerful bone grafting materials. These properties include handling in surgery and improved mechanical properties.

TRAP	Tartrate-resistant acid phosphatase
VEGFR	Vascular endothelial growth factor receptor
VEGFs	Vascular endothelial growth factors
Wnt	Wingless-type MMTV integration site

5.522.1. Bone Biology

5.522.1.1. Introduction

The focus of this chapter is the translational application of growth factors and cytokines for bone tissue engineering with the goal of regeneration. The outcome of regeneration is the restoration of form and function to tissues and organs to make them indistinguishable from their original state. The process of regeneration is highly complex, and involves spatially and temporally dynamic interactions among biological signaling molecules, cells, extracellular matrix (ECM) products, and mechanobiology. Assembling and harnessing in time, space, and dose the elements that drive the process of achieving a regenerative outcome is the quest for bone tissue engineers.

Many aspects of the regenerative process are unclear. However, there are some aspects that have been elucidated and may be exploited through tissue engineering. The authors emphasize what is currently known about the process of bone regeneration and the potential of tissue engineering to exploit this knowledge for clinical applications.

5.522.1.2. Fundamental Process

Growth factors and cytokines either directly or indirectly influence bone embryogenesis, homeostasis, modeling and remodeling, pathology and disease, as well as bone regeneration. Therefore, antecedent to the discussion of the bone regenerative process, fundamentals are described and the implications of regeneration are underscored.

The assembly and dynamic integration of component parts, the highly complex architecture of the resulting physiological structure, and the maintenance and enduring features of the vital tissue product (e.g., bone) are fundamental to tissue engineering. It is therefore reasonable to begin with morphogenesis: a road map that yields a three-dimensional structure.

5.522.1.3. Bone Morphogenesis

A consummate series of instructional cues bring mesenchymal cells together into a patterned, three-dimensional array as the vertebrate embryo forms.[1] The outcome of cell–matrix aggregate interactions in limb bud locales, spine and ribs, is the formation of a chondrogenic anlage that calcifies and is resorbed while being populated by osteogenic cell phenotypes (osteoclasts, osteoblasts, osteocytes); the product is a unique blend of collagenous and carbonated-hydroxyapatite matrices. The process is called endochondral ossification. In distinction to endochondral ossification is intramembranous ossification, which occurs in the cranium, mid-face and mandible where collections of mesenchymal cells divert directly to the

osteogenic phenotype without an intervening cartilaginous precursor. The outcome of both processes is bone formation.

Morphogenesis involves a highly complex dynamic process among cells, matrices and soluble signaling factors. The signaling factors are proteins encoded by conserved multigene families, including the bone morphogenetic proteins (BMPs), epidermal growth factors (EGFs), fibroblast growth factors (FGFs), hedgehogs, homeobox gene products, and Wingless-type MMTV integration sites (Wnts).[2] Though they are as yet partially described mechanisms, an assembly of biological parts exist that produce endochondrally and intramembranously derived bones. The assembly process is a marvelous consortium of movements honed by a molecular tool kit that determines the locations of occurrence of congregations of cells, the interactions among the cells, and the shape, size and positions of structures derived from that congregation, as well as the death of cells. During osteogenesis, controlling gates either stop or redirect events. The extracellular stopping mechanism may include cell contact and extracellular inhibitory signals. For example, BMPs are powerful inducers, and, left unbalanced, they will induce an aberrant outcome; consequently, BMPs are modulated by anti-BMPs, for example, noggin, fetuin, chordin, cerebrus, and deadenylating nuclease (DAN).[3]

5.522.1.4. Bone

Bone is an organ system.[4] We must appreciate the clever organization and function of this organ system if we are to be stewards of its engineering and regeneration. An organ is a part of the body that is arranged according to a characteristic structural plan and performs a special function or functions; it is composed of various tissues, one of which is primary in function.[5] Bone consists of two specialized tissues: vascular and calcified.

The vascular tissue of bone is positioned in the marrow as well as in the periosteal–diaphyseal–metaphyseal and epiphyseal–physeal vascular tapestries for metabolic exchange and trafficking of molecular signals to sustain osseous physiological dynamics and homeostasis. A lush web of vascular highways populate Haversian systems and Volkmann's canals in bone, thus underscoring a profound vascular dependency that begins during embryogenesis, continues through mineral homeostasis, modeling and remodeling and is pivotal to the regenerative osseous wound healing cascade. The vascular architecture of bone ensures that bone cells will neither perish nor be without a tributary for cell renewal. A partnership between osteoblasts and vascularity ensures that a vascular tributary enriches each cubic millimeter of bone volume. Consequently, engineering vascular tissue is a requisite for engineering bone.

The calcified tissue component of bone includes several cell phenotypes (e.g., hematopoietic and osteogenic), biological factors (e.g., proteins such as the transforming growth factors (TGFs) and platelet-derived growth factors (PDGFs), and many others that are discussed in subsequent sections of this chapter), and the inorganic (predominantly calcium-phosphate ions organized as carbonated hydroxyapatite) and organic (mostly type I collagen) matrices. The organizational hierarchy produces a macrostructural form that directly correlates with the functional properties of bone: protection, locomotion, and homeostasis. The macrostructural format consists of cortical and trabecular bone.

Cortical bone looks dense and compact; it constitutes 80% of the skeleton, forming the outer and inner layers of appendicular bone, inner and outer tables of the flat bones, and the inner and outer surfaces of vertebral bodies and pelvic structures.[4] On microscopic inspection, cortical bone is built from a series of melded plates, lamellae, that are crafted through resorption and formation drifts into transverse tubular structures in the appendicular skeleton: the Haversian systems (osteons) (Figure 1). The Haversian system consists of 4–20 circumferential rings with a central Haversian canal ~22–110 μm in diameter that houses blood vessels, lymphatics and, sometimes, nerves.[6] The average Haversian system in man is about 200 μm in diameter, a targeted dimensional parameter advocated for optimizing osteoconductive tissue-engineered scaffolds. Osteoconduction may be defined as follows: A tissue renewal process integrating angiogenesis and osteoprogenitor cells from the recipient site into a three-dimensional implanted material and graft. However, the budding tissue engineer must be mindful that defining osteoconductive properties according to pore-size dimension, range and distribution remains nonstandardized; the parameters have not been awarded universal concurrence, and therefore controversy may arise when we dogmatically insist upon strict

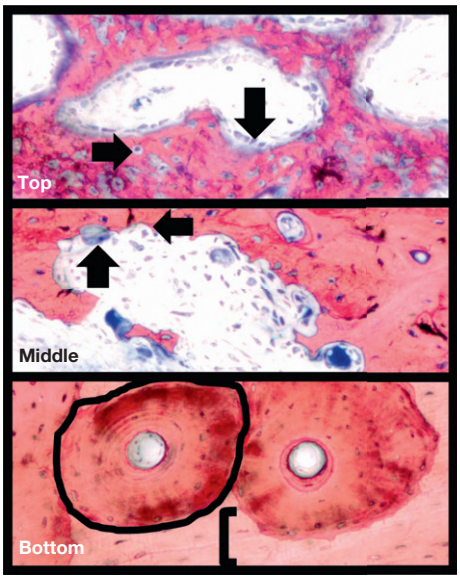

Figure 1 (Top) Osteoblasts (down arrow) produce osteoid (subjacent to the osteoblasts) that mineralizes and these elements comprise the woven bone depicted in the top panel. Rounded osteocytes (side arrow) reside in the woven bone. (Middle) Osteoclasts (up arrow) are bone-resorbing cells that form scalloped bays in the woven bone; these areas are called Howship's lacunae (side arrow). Osteoclasts are necessary for bone remodeling and structural adaptation of bone. (Bottom) Woven bone is remodeled into lamellar bone (black bracket). Osteonal (Haversian) systems form as the lamellar bone matures. An osteon is identified by the circumscribing black line. Each osteon consists of a central canal containing a vein, artery, and lymphatic with radially arranged concentric layers of bone populated by osteocytes that interconnect through a cytoplasmic network. Kindly provided by Stefan Tangl.

adherence to pore-size parameters. Features to underscore that temper the decisions on pore-size dimension, range and distribution (and interconnectivity) are the anatomical location to be implanted, patient physiology, biomechanical dynamics, and physicochemical properties of the implanted materials.[7] The important point to note is that by examining the structure and function of bone, we receive key instructional engineering guidance. Despite the assiduous study of form and function in bone for many decades, it is still unclear why Haversian systems are consistently in the ~200-μm-diameter size range.

The architectural design of the Haversian systems is built on concentrically layered lamellae, with each lamella populated by a variable number of osteocytes (**Figure 1**) and each osteocyte linked to siblings in the same and contiguous lamellae through a gossamery meshwork of cell-cytoplasmic process traversing 8-μm-diameter caverns: canaliculi. In addition to this integrated network are the Volkmann canals, which penetrate cortical bone obliquely, anastomosing with the Haversian systems to provide transit for metabolic exchange and trafficking of soluble signals. Highly noteworthy is the vascular dependency of bone that ensures that neither osteocyte nor osteoblast (see below) is more than 300 μm from a blood vessel.[8]

Sandwiched between cortical bone is spongy-looking trabecular or cancellous bone. Unlike cortical bone, which is designed for load bearing, cancellous bone is designed to respond to physiologic requirements. Roughly 20 times greater surface area and concomitant cell density per unit volume is associated with cancellous bone as compared to cortical bone.[9]

5.522.1.5. Modeling and Remodeling

Bone is a vascularized, dynamic organ that is constantly in motion, biomechanically stressed and continuously sculpted to address homeostasis, microfracture repairs and mechanical loading. Consequently, twenty-first century tissue engineers must address the dynamic nature of bone as an organ, and recognize and anticipate modeling and remodeling. Modeling may be viewed as the cellular, functional and biochemical events that shape maturing bone until epiphyseal plate closure.[2] Remodeling consists of similar events responsible for bone repair following epiphyseal closure, and results in the restoration of form and function.[10,11] Cortical bone remodels at a rate of about 2–10% per year; this metric is site-dependent and remodeling rates of up to 20% may occur around loaded endosseous implants.[12] Packets of bone-forming osteoblasts, bone-resorbing osteoclasts, and mechanosensory osteocytes function as a basic multicellular unit (BMU) during the remodeling process. The dynamics of bone resorption and formation are especial elements for tissue engineers who aim at regeneration of deficient bone through the implantation of a scaffold that will localize, protect and release biological cues; this scaffold will synchronously resorb to be replaced by a functional quantum of new bone. Bone forms at the rate of about 1–2 $\mu m\,day^{-1}$, but during the osseous wound healing cascade, the acceleration of the regenerative process accentuates bone deposition to a rate approaching 15–20 $\mu m\,day^{-1}$, an outcome referred to as the regional acceleratory phenomenon (RAP).[2] Therefore, bone tissue engineered scaffolds must be tuned synchronously to the dynamics of the bone architecture that is to be regenerated. If the scaffold is not resorbed in register with bone formation, but resorbs too slowly, formation is hindered. Moreover, if the scaffold resorbs too rapidly, fibrous tissue invades the void space, scar formation occurs, or soft tissue subsidence and prolapse of the soft tissue envelopes around the bone preclude osseous regeneration.

Bone regeneration is the culmination of multiple, interactive, complex cellular, matrix, and molecular events that will not occur without angiogenesis. Consequently, as we develop the discussion and subsequent appreciation for the process of regeneration, we highlight angiogenesis following it up with an overview of the recruitment and morphodifferentiation of the cellular craftsmen that enable bone regeneration and ensure its maintenance.

5.522.1.6. Angiogenesis

Angiogenesis is a physiological process involving the growth of new blood vessels from preexisting vessels. Angiogenesis is a normal and vital process in growth and development. It is additionally a necessary component of wound healing and of the transition of tumors from a dormant state to a malignant one. Though terminology related to it differs, angiogenesis occurs in two forms; sprouting angiogenesis and splitting angiogenesis, otherwise known as intussusceptive angiogenesis. *Angiogenesis* is the term used for spontaneous blood vessel formation, and *intussusception* is the term for new blood vessel formation by the splitting off of existing vessels.[13]

Angiogenesis occurs in several stages. Initially, angiogenic growth factors (e.g., vascular endothelial growth factor, VEGF) activate receptors present on endothelial cells in existing blood vessels. Activated endothelial cells release proteases that degrade the basement membrane to allow the endothelial cells to escape from the vessel walls (i.e., move through the vessel walls: *margination*) and proliferate into the surrounding matrix, forming a vessel lumen for the new blood vessels. The vasculature can result in several millimeters of new growth per day. In distinction to the process of intussusception just described, is the process of angiogenesis, where new vessels form independently of existing ones.[14]

With intussusception, the capillary wall extends into the lumen to split a single vessel into two. This occurs as two opposing capillary walls come into contact. The endothelial cell junctions reorganize and the vessel is perforated to allow growth factors and cells to penetrate into the lumen. At the zone of contact, a core is formed that is filled with pericytes and myofibroblasts. These cells begin laying collagen fibers into the core, providing an ECM for the growth of the vessel lumen. Intussusception is a reorganization of existing cells.[15]

Angiogenesis may be a target for treatment of diseases characterized by either poor or abnormal vasculature. Application of specific compounds that may inhibit or induce vasculature may control vascular-dependent pathologies, such as solid state tumors.

5.522.1.7. Osteoblasts

Osteoblasts are mononucleate cells that are responsible for bone formation and are derived from osteoprogenitor cells in the periosteum and the bone marrow. However, contemporary data have validated that several cell phenotypes, including

adipogenic and myogenic lineages, can be cued into an osteogenic lineage, and, thus, osteoprogenitor pathways are possible outside the classical pathway associated with bone.

Osteoprogenitors may be induced to differentiate under the influence of growth factors, such as BMPs, FGF, PDGF, and TGF-β. These growth factors promote the division (mitogenesis) of osteoprogenitors and may increase osteoblast populations, thereby boosting osteogenesis.[16] Once osteoprogenitors start to differentiate into osteoblasts, they begin to express a range of genetic markers including osterix (Osx), monocyte-colony-stimulating factor (M-CSF), osteocalcin, osteopontin, and osteonectin.

Osteoblasts are located on the surface of bone and are responsible for synthesizing the organic components of the bone matrix. The organic components include primarily type I collagen (90% of bone protein), proteoglycans and glycoproteins; however, other proteins may be identified. Osteoblasts synthesize the enzyme alkaline phosphatase, which is needed locally for the mineralization of osteoid, as well as zinc, copper, and sodium.[17]

5.522.1.8. Osteocytes

As the bone matrix calcifies under the influence of alkaline phosphatase, osteoblasts become trapped in the bone matrix and eventually change into osteocytes. The osteocytes cease to generate osteoid and mineralized matrix and, instead, act in a paracrine manner on active osteoblasts. Osteocyctes purportedly act in a mechanosensory manner, sensing mechanical forces on bone, and send signals to regulate bone turnover at the bone surface.[18–20]

Osteocytes reside in lacunae in the mineralized bone and are interconnected by their cytoplasmic processes within canaliculi. The processes of adjacent cells make contact at gap junctions and are responsible for the maintenance of osteocyte vitality by passing nutrients and metabolites between blood vessels and osteocytes, regulating ion homeostasis and transmitting electrical signals in bone.[21]

5.522.1.9. Osteoclasts

Osteoclasts are multinucleated giant cells that are derived from the monocytic-macrophage system and are responsible for bone resorption. Osteoclasts have fine, fingerlike cytoplasmic processes and are rich in lysosomes that are characterized by expression of tartrate-resistant acid phosphatase (TRAP) and cathepsin K.[22] Osteoclast formation requires the presence of the RANKL (receptor activator of nuclear factor κβ ligand) and M-CSF (macrophage colony-stimulating factor). These membrane-bound proteins are produced by neighboring osteoblasts and stromal cells, thus requiring direct contact between osteoblasts and osteoclast precursors.[23] There is a complex, highly interactive and exciting relationship between cytokines and osteoclasts that will be established later in this chapter.

Osteoclasts inhabit cavities in bone called Howship's lacunae. Mature osteoclasts are restricted to the resorbing surfaces of bone. However, upon activation, osteoclasts migrate to bone microfractures, attach via adhesion structures called podosomes and release hydrogen ions through the action of carbonic anhydrase, thus forming a resorptive cavity, acidifying and dissolving the mineralized bone matrix. In addition, hydrolytic enzymes such as cathepsin are secreted into the resorptive pit by lysosomes to digest the organic components of the matrix.[24]

Osteoclasts have a significantly shorter life span than osteoblasts and are seen infrequently in routine histological sections of normal bone. An increased number of osteoclasts on histological sections is characteristic of diseases with increased bone turnover.[25]

In conclusion, the didactic argument to emphasize bone biology is that it provides an instructional biological road map that must be navigated. A fundamental knowledge, appreciation and understanding of basic bone biology are epochal. Bone embryogenesis, homeostasis, modeling and remodeling are pillars upon which regenerative engineering therapeutics is constructed; the organizational synchrony must be masterfully integrated and the constitutive elements recognized. Spatial, temporal and mechanobiological directors are maestros, mysteriously assembling elements in a hierarchal cascade that is unclear and that contemporary tissue engineering science has not duplicated. Nevertheless, attention to the details of the biological road map that define bone as a dynamic organ capable of regeneration can be exploited for the rational development of regenerative therapeutics.

5.522.2. Growth Factors, Cytokines, Nomenclature, Mechanism of Action

Growth factors and cytokines are a group of endogenously produced mediators that characteristically act as signaling molecules between cells. The mode of action can be autocrine, paracrine, juxtacrine, and endocrine – meaning that local and systemic effects are possible.

Growth factors and cytokines bind to the respective receptors on the surface of target cells, causing activation of the intracellular signaling cascade. This ultimately changes the cellular function, which can be suppression or enhancement. Cellular function involves, but is not restricted to, proliferation, motility, synthesis of ECM, differentiation and even cell death. Activation of the intracellular signaling cascades further causes the expression of growth factors and cytokines that amplify or reduce the overall cellular response by positive or negative feedback loops, respectively. Growth factors and cytokines, however, also drive local and systemic pathological processes of inflammation, tumor-induced bone loss and osteoporosis.

An international nomenclature of growth factors and cytokines could provide a basis for communication. However, there is no consensus on the nomenclature. Growth factors and cytokines may be classified on the basis of the cell(s) of origin or target cell(s), genetic homologies and major activities. Moreover, there is no consensus recognition of the distinction between growth factors and cytokines and, therefore, both terms are often used interchangeably, leading to confusion.

The term *signaling molecules* was considered an umbrella term for growth factors and cytokines; however, this tactic also caused confusion. Intracellular signaling molecules are neither growth

factors nor cytokines. Consequently, in this chapter, we stay with the definition of the Human Genome Organization (HUGO) Gene Nomenclature Committee (www.genenames.org).

5.522.3. Bone Tissue Engineering: Growth Factors and Cytokines

5.522.3.1. Transforming Growth Factor β

The TGF-β family of proteins regulates cell proliferation and differentiation. TGF-β proteins, along with activins, growth differentiation factors (GDFs) and BMPs, are members of the TGF-β superfamily.[26] There are three isoforms of TGF-β in mammals: TGF-β_1, TGF-β_2, and TGF-β_3.

The TGF-βs are homodimeric proteins that are ~25 kDa[27] and are synthesized as inactive latent precursors, which are cleaved outside of the cell that expressed them and thus, extracellularly, form an active protein. There are three TGF-β receptors; the TGF-β ligand binds to the TGF-β receptor II and dimerizes with TGF-β receptor I. After phosphorylation, TGF-β activates a group of mothers against decapentaplegic homolog (SMAD) proteins via serine–threonine kinase and tyrosine kinase activity.[28] TGF-β further promotes the production of Runt-related transcription factor 2 (Runx2), which forms a complex with SMAD proteins, leading to osteoblast differentiation.

TGF-βs are present in cartilage, bone, and skin, and are produced by platelets, osteoblasts, and chondrocytes.[29] TGF-β s regulate bone cell metabolism and are important regulatory molecules in wound healing cascades.[30] The use of TGF-β in bone fracture repair and reconstructive surgery has been evaluated in numerous experimental models and the outcome is ambiguous: sometimes the protein may work, and bone may be formed; at other times, it does not work; and dosing issues are highly problematic.

5.522.3.2. Bone Morphogenetic Proteins

BMPs belong to the TGF-β superfamily. There are over 40 known BMP-like molecules.[31,32] BMP-2–BMP-17 and GDF2–GDF10 also belong to the BMP family.

BMPs are dimeric proteins of ~30 kDa with the two identical strands linked by a cysteine-binding group. Signaling begins with the binding of the BMP to its transmembrane receptor, type II (serine–threonine kinase: bone morphogenetic protein receptor 2 (BMPR2)). (Noggin and chordin are extracellular binding proteins that alter the binding of BMP molecules with their receptors.) Binding of BMPs causes the recruitment of a bone morphogenetic protein receptor 1, type A (BMPR1A) or type B (BMPR1B). The type I receptor phosphorylates receptor-regulated SMADs (I-SMADs; SMAD1, SMAD2, SMAD3, SMAD5, and SMAD8/9). Common-mediator SMAD (SMAD4) interacts with the R-SMADs during signaling, while inhibitory SMADs (SMAD6 and SMAD7) block this process. Phosphorylated I-SMADs, together with SMAD4, enter the nucleus and target BMP-response genes (e.g., alkaline phosphatase and osteocalcin). Thus, BMPs stimulate differentiation of mesenchymal progenitors into the osteo-chondrogenic lineage. This process of differentiation partially explains the unique capacity of BMPs to induce *de novo* bone formation by recapitulating the embryonic ossification. The Food and Drug Administration (FDA) has approved two recombinant BMP-containing products for clinical applications: Infuse BMP-2 and BMP-7 (the latter also termed osteogenic protein 1: OP-1; Figure 2).

5.522.3.3. Insulin-Like Growth Factors

Insulin-like growth factors (IGFs) are polypeptides that have a sequence similarity to insulin, and as such, have similar molecular structures. The IGFs exist in two isoforms (IGF-1

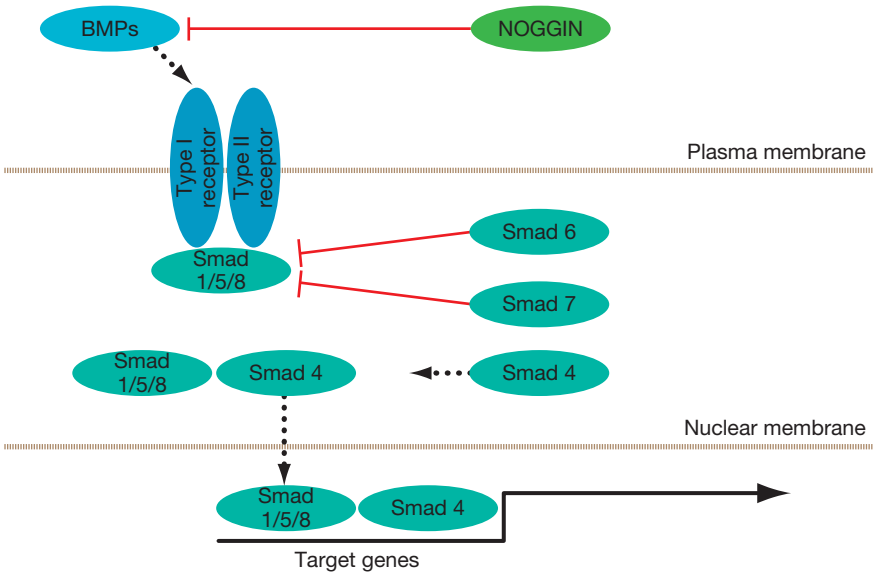

Figure 2 Bone morphogenetic proteins (BMPs) signal by binding to BMP receptor, type II (BMPR2). BMPR1A or BMPR1B are recruited and phosphorylate intracellular receptor-regulated mothers against decapentaplegic homologs (SMADs). SMAD4 supports signaling and activates responsive genes, while inhibitory SMADs (SMAD6 and SMAD7) block this process. Noggin and chordin are extracellular binding proteins that also inhibit this process at the extracellular level.

and IGF-2), and both bind to six different binding proteins. The IGF binding proteins (IGFBP1–6) regulate IGF concentration and modulate bioactivity by enhancing IGF activity and prolonging half-life.

The liver secretes IGF-1, the main IGF involved in muscle, cartilage and bone cells. IGF-1 binds primarily to IGF-1 receptor (IGF1R), which is a tyrosine kinase receptor. Binding initiates intracellular signaling and stimulates cell proliferation and differentiation.[33] Moreover, IGF-1 upregulates protein kinase D (PKD) and c-jun N-terminal kinase (JNK), which in turn have a significant impact on Osx expression.[34] Furthermore, Runx2 expression may be increased by IGF-1.[34] In addition, IGF-1 upregulates type I collagen and alkaline phosphatase gene expression in mesenchymal stem cells, all of which are key markers for osteoblast differentiation.[35]

5.522.3.4. Platelet-Derived Growth Factor

PDGF has four isoforms that cause cellular responses through two different receptors. The isoforms are PDGF α- and β-polypeptides (PDGFA; PDGFB), and PDGF C and D (PDGFC, PDGFD). PDGFA and PDGFB can form homo- and heterodimers, while PDGFC and PDGFD form homodynes only. Optimal concentrations of PDGF-AB (1 ng ml^{-1}) was shown to upregulate BMPR-1B messenger ribonucleic acid (mRNA) by 2.4-fold.[36] Two types of PDGF receptors (R) have been identified: PDGF receptor, α-polypeptide PDGFRA and PDGF receptor, β-polypeptide PDGFRB. The receptors form homo- and heterodimers.

PDGF-BB homodimer can activate all three combinations of receptors and is thus the most potent ligand. Ligand binding causes the receptors to dimerize and activate tyrosine kinase. Phosphorylated cytosolic domains provide binding sites for signaling proteins that initiate signal cascades, such as the phosphoinositide 3-kinase (PI3K) and mitogen-activated protein kinase (MAPK) family pathways.

Mesenchymal cells respond to PDGF-signaling by proliferation, motility and synthesis of ECM. The osteogenic differentiation of the cells is transiently suppressed.

The FDA has approved recombinant human PDGF-BB in a carboxy methyl cellulose delivery system (Regranex, Ortho-McNeil) in clinical applications for the treatment of diabetic patients and in combination with tricalcium phosphate (GEM-OS, OsteoHealth) for periodontal regeneration in dentistry (Figure 3).

5.522.3.5. Vascular Endothelial Growth Factor

VEGFs are a subfamily related to the PDGF family. VEGFA was first described and originally termed VEGF before related members were discovered, such as VEGFB, VEGFC, and V-fos FBJ murine osteosarcoma viral oncogene homolog (c-fos) induced growth factors (FIGF; VEGFD). VEGFA has characteristic splice variants ($VEGF_{121}$, $VEGF_{121}b$, $VEGF_{145}$, $VEGF_{165}$, $VEGF_{165}b$, $VEGF_{189}$, $VEGF_{206}$).

VEGF ligands bind to receptors that dimerize and activate tyrosine kinase. The phosphorylated signaling proteins, in turn, activate the downstream signaling cascades. VEGFA binds to Fms-related tyrosine kinase 1 (vascular endothelial growth factor/vascular permeability factor receptor; FLT1, VEGFR1), and kinase insert domain receptor (KDR, fetal liver kinase 1 (FLK1), VEGFR2). VEGFC and FIGF bind to a third

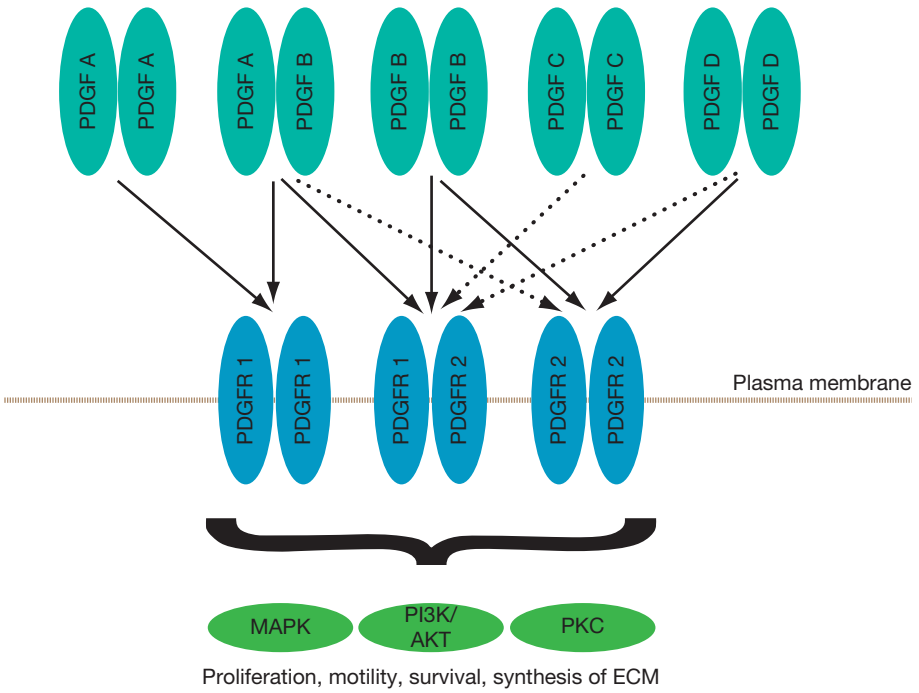

Figure 3 Platelet-derived growth factor (PDGF) isoforms signal via two different receptors. PDGFA and PDGFB can form homo- and heterodimers, while PDGFC and PDGFD form homodynes only. The receptors also form homo- and heterodimers. PDGF-BB can activate all three combinations of receptors and is thus the most potent ligand. Intracellular tyrosine kinases phosphorylation activates signaling proteins such as phosphoinositide 3-kinase and members of the mitogen-activated protein kinase family.

receptor (FLT4, VEGFR3). While FLT1 and KDR mediate vascular angiogenesis, FLT4 mediates lymphangiogenesis.

VEGF has been shown to promote angiogenic differentiation and enhance bone formation.[37] During endochondral ossification, VEGFA is produced by chondrocytes and osteoblasts, and it has a profound impact on the vascular invasion of cartilaginous tissue.[38] Further, VEGF increases endothelial progenitor cell mitogenesis and chemotaxis, which can lead to the formation of new blood vessels.[39,40] By inducing angiogenesis, VEGF increases the amount of oxygen and other nutrients required for osteogenesis.[38] Moreover, osteoblasts secrete VEGF, and osteoblasts and osteoclasts have been shown to secrete VEGF receptors.[41,42]

While VEGF may not have a direct osteogenic differentiation effect, it may promote bone formation by complementing and potentiating the osteogenic effect of other growth factors.[43] In addition, the homodimeric glycoprotein VEGFA has an affinity to VEGFR2, which is secreted by chondrocytes, and induces angiogenesis from the perichondrium, thereby leading to the recruitment of bone cells, osteoclasts and osteoblasts, and hematopoietic stem cells.[44] The therapeutic application of recombinant VEGFA to enhance bone regeneration is restricted to preclinical studies. However, in tumor therapy and macular degeneration, monoclonal antibodies that neutralize VEGFA (e.g., bevacizumab) and tyrosine kinase inhibitors (e.g., lapatinib) are undergoing clinical evaluation (Figure 4).

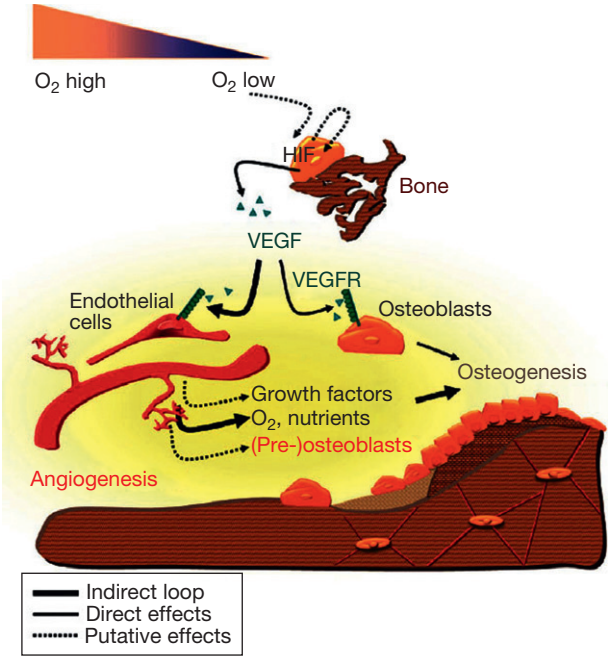

Figure 4 Regulation of osteogenic–angiogenic coupling by hypoxia inducing factor (HIF) and vascular endothelial growth factor (VEGF). Mature osteoblasts located on the bone surface express HIFs and respond to HIF activation, which may be induced in response to low oxygen tensions in the bone and marrow environment. Cell-autonomous effects of HIF may affect bone formation (osteogenesis), but a critical effect of HIF stabilization in mature osteoblasts is the increased accumulation of VEGF. VEGF can act through its receptors (VEGFR) on endothelial cells to induce angiogenesis and thereby indirectly increase the supply of oxygen and nutrients required for osteogenesis. Increased vascularization may also lead to a higher input of putative skeletal stem cells and/or (pre-)osteoblasts and to elevated levels of endothelium-derived osteogenic growth factors or anabolic signals. In addition, VEGF can affect osteogenesis through direct interactions with osteoblasts that also express VEGF receptors. Altogether, the HIF–VEGF pathway is likely to be critically important in coupling the processes of angiogenesis and osteogenesis.

5.522.3.6. Fibroblast Growth Factors

FGFs are a family of proteins, with 23 identified members, some of which promote bone formation through an anabolic effect.[45,46] FGF-1 and FGF-2 (the most abundant ligands) promote osteoblastic and angiogenic activity in addition to inducing VEGF.[45]

FGF-2 is an important mitogen in bone for precursor cells, such as mesenchymal stromal cells as well as for calvarial and mature osteoblasts.[47–49] However, the effects of FGF-2 in bone formation are controversial. While FGF-2 contributes to the proliferation of osteoblast cells, it also inhibits late stages of osteoblast differentiation and bone formation.[50,51]

FGF-2 and FGF-9 stimulate proliferation of mature osteoblasts, but can inhibit osteoblast marker genes and mineralization.[48] FGF-2 expression levels are elevated during fracture healing and this has been shown to accelerate wound healing in critical-sized bone defects.[52,53] Recent publications have shown that FGF-8 may cue bone marrow cells to differentiate into osteoblasts.[54] In addition, FGF-8 and FGF-18 stimulate the proliferation of osteoblasts *in vitro*.[55] FGF-8b and FGF-8e have been reported to induce osteoclastic differentiation, which is possibly dependent on the RANKL/osteoprotegerin (OPG) pathway.[54,56] A complex relationship exists between bone and the FGF family of growth factors, the precise biological details of which have not been suitably elucidated.

5.522.3.7. Sclerostin

Sclerostin (SOST) is a 22.5 kDa secreted glycoprotein almost exclusively expressed by osteocytes. It is released to the bone surface via the osteocyte canalicului system and binds to low density lipoprotein receptor-related protein 4 (LRP4) LRP5 and LRP6, which are coreceptors for frizzled homolog 1 (Drosophila; FZD1), alias Wnt receptor. SOST prevents Wnt-signaling, which requires FZD1 and the LRP-coreceptors to be activated by soluble Wnt-ligands. When activated, intracellular β-catenin is protected from degradation and can function as a transcription factor. In the presence of SOST or other inhibitors of Wnt-signaling such as dickkopf homolog 1 (*Xenopus laevis*; DKK1), β-catenin is targeted for proteosomal degradation. SOST has gained attention as a potential therapeutic target because mutations of the gene are associated with a high bone mass phenotype. Preclinical studies and clinical trials provided first evidence that blocking SOST by neutralizing antibodies stimulates an anabolic activity.

There are numerous additional biological molecules, for example, growth factors that have an impact on bone formation and resorption. The chapter focuses on the factors commonly recognized as being most significant and whose functional relationships are least controversial (Figure 5, Table 1).

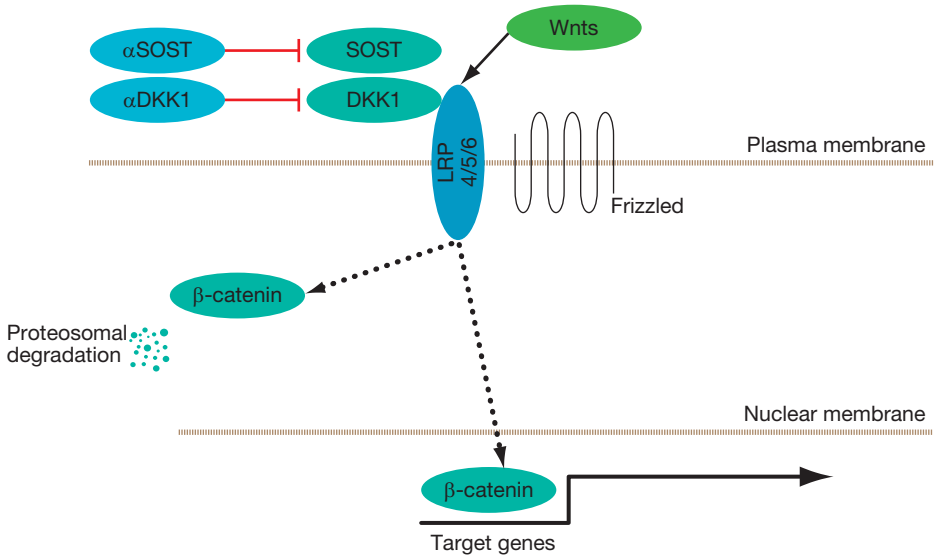

Figure 5 Wingless-type MMTV integration site signaling requires the receptor frizzled homolog 1 (Drosophila; FZD1) and the low density lipoprotein receptor-related protein (LRP)-coreceptors to be activated. Intracellular β-catenin is protected from degradation and can function as a transcription factor. Sclerostin (SOST), alias SOST binds to low density LRP4, LRP5, and LRP6, which are coreceptors for FZD1. SOST thus prevents canonical signaling and β-catenin is targeted for proteosomal degradation.

Table 1 Selected bone growth factors

Growth factors	*Source*	*Biological response*	*Action on bone*
BMP-2, -4, -7	Mesenchymal Osteoblast Endothelial Chondrocyte	Chondrogenic Osteogenic Osteoinductive	Chemotactic Maturation Differentiation
FGF-1 and -2	Mesenchymal Osteoblast Chondrocyte Inflammatory cells Endothelial	Angiogenesis Connective tissue cell proliferation	Chemotactic Proliferation
IGF-I and -II	Osteoblast Chondrocyte Hepatocyte Endothelial	Anabolic and catabolic effect on osteogenesis	Chemotactic Proliferation Maturation Differentiation Resorption
PDGF-BB	Platelet Osteoblast Inflammatory cells Endothelial	Angiogenesis Connective tissue cell proliferation	Chemotalic Proliferation
TGF-β	Platelet Osteoblast Chondrocyte Endothelial Inflammatory cells Fibroblast	Immunosuppression Angiogenesis Cell growth and differentiation	Proliferation Osteogenic ECM production
VEGF	Platelet Osteoblast Chondrocyte	Chemotactic Angiogenesis	Conversion of cartilage to bone, Chemotactic Proliferation

5.522.4. Cytokines and Bone

Cytokines are primarily involved in the inflammatory response and provide integration between immune and endocrine systems. The interconnected network between the skeletal and immune systems has led to the emergence of a new discipline referred to as osteoimmunology.[57] Cytokines comprise a group of regulatory factors with the following attributes: having a molecular weight of <80 kDa and biological activity in the 10^{-10}–10^{-13} M range, generally occurring as glycosylated

peptides, produced transiently by most nucleated cells, having pleiotropic properties, being autocrine or paracrine, and possessing overlapping biological activities.

In general, cytokines exert regulatory control over bone remodeling by serving as intermediaries for the indirect effects of hormones while also mediating the complex cell–cell communications between osteoblasts and osteoclasts. The principal cytokines involved in physiologic bone remodeling are RANKL, RANK, OPG, M-CSF, IGF-I, IGF-II, TGF-β, interleukin 1 (IL1), IL6, tumor necrosis factor α (TNF-α).[57] We emphasize a select few of the many cytokines associated with bone. There are, in fact, many cytokines; however, we want to focus on those cytokines that have been the most documented relative to bone formation and resorption.

5.522.4.1. Receptor Activator of Nuclear Factor κβ Ligand

RANKL is a transmembrane molecule expressed by mesenchymal cell and lymphocytes. The soluble form of RANKL is a consequence of proteolytic cleavage. RANKL binds to RANK on hematopoietic cells and activates cytoplasmic adaptor proteins (e.g., tumor necrosis factor receptor-associated factor 6, TRAF6). These events activate downstream signaling pathways involving nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), MAPK family and nuclear factor of activated T cells, cytoplasmic 1 (NFATc1). However, RANKL is neutralized by its soluble decoy receptor OPG. It is consequently the ratio between RANKL and OPG that regulates the process of bone resorption. Based on this physiological principle, the monoclonal antibody that neutralizes RANKL (denosumab) may have efficacy in preventing fractures in osteoporotic patients. As a consequence of the importance of RANK/RANKL, this topic is discussed further under bone resorption (Figure 6).

5.522.4.2. IL1β and TNF (Superfamily Member 2, TNF Alias TNF-α)

IL1β and TNF-α are central mediators of inflammation and are produced by lymphocytes and mesenchymal cells. Interleukin 1 receptor, type I (IL1R1) is responsible for mediating the signaling response; IL1R2 has inhibitory action. The tumor necrosis factor receptor superfamily member 1A (TNFRSF1A alias TNFR1) is widely expressed, whereas, TNFRSF1B alias TNFR2 is expressed mainly by hematopoietic and immune cells. Both receptors activate adaptor proteins and downstream signaling molecules such as NF-κB and the MAPK family.

It is not surprising, given the hematopoietic lineage of osteoclasts, that many of the cytokines typically associated with the immune system influence bone modeling and remodeling. What is surprising is the complexity of this system given that there are only two primary cell types, the osteoblasts and osteoclasts, involved in the processes. At least 19 cytokines play some role in the regulation of these processes: IL-1, 3, 7, 10, 13, TNF-α and interferon-γ in the regulation of osteoblasts, and IL-1, 3, 4, 6–8, 10–13, 15, 17, 18, 23, TNF-α, OPG, leukocyte inhibition factor (LIF), M-CSF, and interferon-γ in the regulation of osteoclasts.

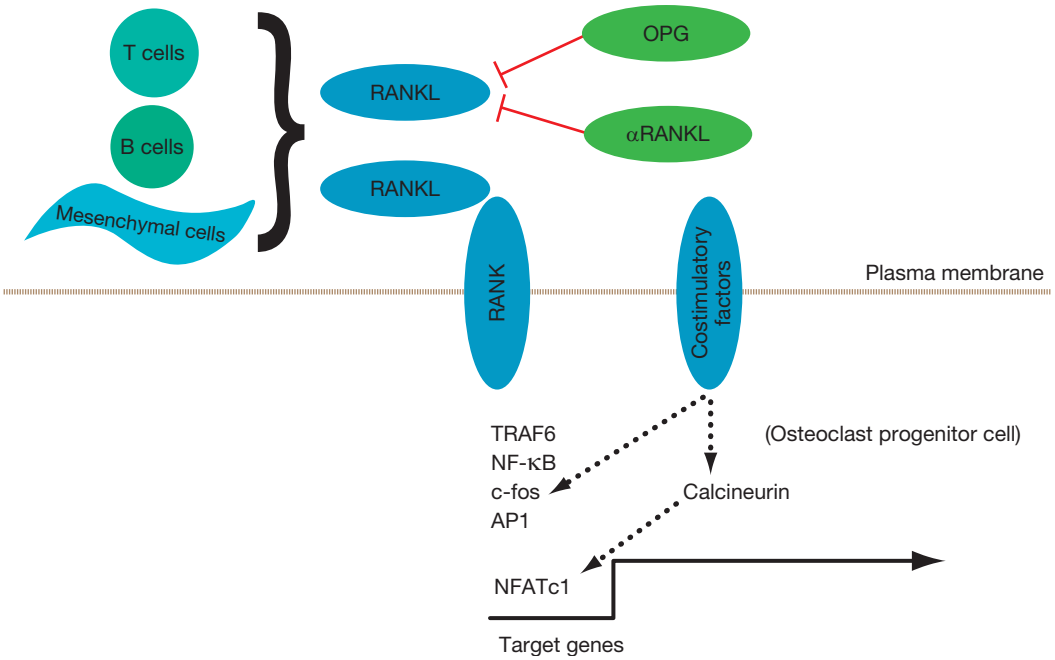

Figure 6 Receptor activator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) ligand (RANKL), RANK and osteoprotegerin (OPG) build a triumvirate of molecules that control the formation, activity and the survival of osteoclasts. RANKL binds to RANK and activates cytoplasmic adaptor proteins (e.g., tumor necrosis factor receptor-associated factor 6). Downstream signaling pathways include NF-κB, mitogen-activated protein kinase family, and nuclear factor of activated T cells, cytoplasmic 1. RANKL is neutralized by its soluble decoy receptor OPG. Thus, the ratio between RANKL and OPG regulates the process of bone resorption.

5.522.4.3. Bone Resorption

After the implantation of a biomaterial in bone, events including hemorrhage, hemostasis, complement activation, inflammation, and bone resorption ensue. For the focus of this chapter, we underscore *resorption of bone*, where osteoclasts are the hallmark cells recruited to the implant site with macrophages as a requisite antecedent event prior to bone apposition and formation.

5.522.4.3.1. Osteoclast precursor signaling

IL-3 and -7 participate in osteoclast precursor signaling. IL-3, produced by mesenchymal stem cells, promotes osteoclast precursor formation.[58] IL-7 is produced by T cells. Systemically, IL-7 increases osteoclast precursor formation while local administration of IL-7 to hematopoietic stem cells decreases formation.[59]

5.522.4.3.2. Osteoclastogenesis

Osteoclastogenesis involves differentiation of osteoclast precursors to mononuclear osteoclasts via RANK/RANKL interaction. RANK is a membrane-bound receptor found on osteoclast precursors. RANKL is a membrane-bound molecule found on osteoblasts. (RANKL belongs to the TNF family of cytokines and is also called TRANCE, OPGL, and ODF.) The interaction is optimized[57] when three RANKs contact three RANKLs, usually when the RANKL-associated osteoblast is attached to the surface of bone.[60] While there have been reports of RANKL on T cells being able to induce osteoclastogenesis,[61] a more recent study concluded that this source of RANKL was insufficient to induce osteoclastogenesis.[60]

It has been shown that M-CSF and RANKL are necessary to achieve the differentiation of osteoclast precursors to mononuclear osteoclasts.[62] A number of cytokines are involved in the regulation of RANK and RANKL expression. These mechanisms are discussed one at a time.

5.522.4.3.2.1. RANKL upregulation

Upregulation of RANKL on osteoblasts is controlled by IL-1, 6, 7, 8, 17, LIF, TNF-α, and interferon gamma (IFN-γ). IL-1 influences RANKL expression indirectly by upregulating the production of IL-7.[63] When administered systemically, IL-7 promotes RANKL expression.[59] IL-6, produced by osteoblasts and bone marrow stromal cells (BMSCs), stimulates RANKL mRNA expression.[64] Likewise, IL-8, produced by macrophages, neutrophils, and endothelial cells, upregulates RANKL mRNA expression.[65] Cytokines are also produced by osteoclasts themselves, resulting in a paracrine feed-forward mechanism to promote osteoclastogenesis. IL-17 is a six member family of cytokines (IL-18A–F)[58] produced by the T helper cell 17 (TH17) subset of the CD4+ T cells.[66] It upregulates RANKL in osteoblasts[66] and T cells.[63] However, knockout mice deficient in IL-17 show normal bone formation, so this cytokine participates in, but is not essential to, healthy bone formation.[66] In T cells, it also stimulates production of IL-1 and TNF-α, acting as a feed-forward mechanism to promote osteoclastogenesis. LIF (part of the IL-6 or gp130 cytokine family)[67] stimulates both RANKL and Osteoprotegrin (OPG) expression.[58] OPG is secreted by marrow stromal cells and osteoblasts,[68] as well as B cells, after CD-40 binding T cells, and dendritic cells.[66] OPG plays a minor role in osteoclastogenesis by upregulating RANKL mRNA expression in T cells.[63] The main role of OPG is to act as a decoy protein by competitively binding to RANKL, thus frustrating osteoclastogenesis.[57,66]

5.522.4.3.2.2. RANKL downregulation

Downregulation of RANKL on osteoblasts is controlled by IL-4 and IL-13. IL-4, produced by activated T cells, decreases RANKL expression in osteoblast precursors.[69] IL-13, produced by TH2 cells[60] also decreases RANKL expression.[58] Both IL-4 and IL-13 are locally acting cytokines.

5.522.4.3.2.3. RANK expression

There are far fewer known controlling cytokines for RANK compared to RANKL. Takahashi *et al.*[70] reported that macrophage colony-stimulating factor (M-CSF) may cause monocyte/macrophage lineage cells to express RANK. Balancing this, Palmqvist *et al.*[69] reported that IL-4 decreases RANK mRNA expression in cultured rat calvaria.

5.522.4.3.2.4. Upregulation of osteoclastogenesis

The cytokines IL-1, 6, 7, 8, TNF-α, and M-CSF promote the formation of osteoclasts. IL-1 upregulates osteoclastogenesis by stimulating the production of IL-7. IL-6 participates in the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway, and turns on osteoclast genes after RANK/RANKL binding.[71,72] IL-7, when administered systemically, increases the number of osteoclast precursor cells.[59] IL-8 is involved in G-receptor coupled signaling, which causes mononuclear cells to differentiate into osteoclasts.[19] TNF-α augments the response of osteoclasts to RANKL[66]; this mechanism is M-CSF dependent.[58] TNF-α may induce osteoclastic genes via the canonical (involving translocation to the nucleus of P50 and P65 dimers) and noncanonical (involving translocation of P52 and Re1B dimers to the nucleus) pathways.[68] Finally, M-CSF produced by osteoblasts works with RANKL to initiate and maintain osteoclast differentiation.[57]

5.522.4.3.2.5. Downregulation of osteoclastogenesis

The cytokines IL-3, 4, 7, 10, 12, 18, and interferon-γ decrease the formation of osteoclasts after the RANK/RANKL production. IL-3, produced by mesenchymal stem cells, inhibits RANKL-mediated osteoclastogenesis.[73] IL-4 suppresses RANKL-mediated osteoclastogenesis by upregulating OPG expression.[69] When administered locally to hematopoietic stem cells, IL-7 influences the stem cell commitment toward the B cell pathway, thus decreasing the population of osteoclast precursors. This is not a strictly post-RANK/RANKL binding mechanism. IL-10 disrupts Ca^{2+} mobilization, which interferes with NFATc1 activity, needed to upregulate osteoclast genes downstream of the RANK/RANKL binding event.[74] In addition, IL-10 upregulates M-CSF which may promote more macrophages rather than more osteoclasts to differentiate from hematopoietic precursors.[75] IL-12, produced by dendritic cells, macrophages and B cells also disrupts NFATc1 activity. IL-18 increases expression of OPG, thus blocking RANK/RANKL binding.[76] Further, IL-12 increases expression of IFN-γ, which

results in the downregulation of osteoclastogenesis.[77] IFN-γ also decreases osteoclast formation by inhibiting vitamin D (25D3), parathyroid hormone (PTH), and IL-1 activity.[78]

5.522.4.4. Bone Formation

Following localized osteoclastic action in the bone repair cascade, bone-forming units arrive. Cytokine control over this process may be coupled with growth factors such as the BMPs to regulate differentiation, proliferation, motility, attachment, and anabolic ECM activities.

During bone formation and repair, *osteoblastogenesis* is upregulated by TNF-α, which induces the TAK1/TAB1/NIK signaling cascade in mesenchymal stem cells.[79] TNF-α aids in osteoblast differentiation as well as in downregulation of osteoblast proliferation. IL-3, on the other end, inhibits osteoblast differentiation.[73] IL-13 stimulates osteoblast migration.[58] In general, bone formation is suppressed by IL-7,[80] and IL-10 inhibits type I collagen, osteocalcin and the onset of mineralization (Table 2).[82]

5.522.5. Translational Applications of Growth Factors and Cytokines in Bone Tissue Engineering

This chapter has reviewed the growth factors and cytokines involved either indirectly or directly with the dynamics of bone embryology, homeostasis, modeling–remodeling and regeneration. Moreover, as the authors of this chapter have underscored, there is an astonishingly lush symphony of activities choreographed for each contributing element involved in the process of bone regeneration. It is, consequently, remarkably counter-intuitive to presume that, through tissue engineering, a scientist could engineer a single biological element that will produce a complex outcome: regeneration. Yet, single growth factors such as BMP-2 and PDGF discussed earlier in this chapter, have been used therapeutically in patients to regenerate bone. How can this outcome occur? Why does this outcome occur? Can we do better? (Figure 7)

The focus of the last section of the chapter showcases the growth factors and cytokines that have demonstrated a clear clinical benefit and produced a regenerative outcome. Especial emphasis is given to the factors that have achieved FDA approval.

5.522.5.1. Dental

Dentistry offers a large spectrum of possible applications of growth factors in bone tissue engineering. One therapeutic target is the periodontium, a complex structure that anchors the tooth in the alveolar bone of the mandible and the maxilla.[83] As a consequence of a multifactorial etiology, periodontal disease destroys the periodontium. Moreover, it is noteworthy that periodontal disease is the most prevalent disease in the United States and Western Europe, with more than two-thirds of the elderly population being afflicted.[84] Consequently, regeneration of the periodontium has become a serious clinical challenge (Figures 8 and 9).

The combination of recombinant human (rh) PDGF-BB and β-tricalcium phosphate (Growth-factor Enhanced Matrix®; OsteoHealth Company: GEM 21S) has been approved by the FDA for periodontal regeneration. Recently, gene therapeutic approaches based on PDGF-BB were successful in preclinical models of periodontal defects.[85] These observations may be a consequence of the mitogenic and chemotactic activity of PDGF-BB for mesenchymal cells. Moreover, PDGF-BB is a pro-angiogenic molecule, which stimulates angiogenesis.[86]

Recombinant BMP-2 is an osteoinductive growth factor that, in combination with type I bovine collagen (known as INFUSE® Bone Graft: Medtronic Sofamor Danek), has been approved by the FDA as an alternative to an autogenous bone graft for maxillary sinus augmentation. Moreover, approval was obtained for localized alveolar ridge augmentations for defects associated with extraction sockets.

Other growth factors and cytokines have been linked with dentistry but remain mostly at the preclinical level. For example, recombinant VEGFA and gene therapeutic approaches combined with BMP have been suggested for bone regeneration procedures.[87,88] Local and systemic application of PTH has been mentioned for osseointegration of dental implants.[89,90] Neutralizing antibodies against SOST might promote osseointegration.[91] Blocking bone resorption either directly by neutralizing RANKL[92] or by an anti-inflammatory strategy that blocks IL-1 or TNF[93] might reverse periodontal disease.[94]

5.522.5.1.1. Therapeutic bone regeneration in dentistry

Therapeutic bone regeneration may be required when there is impaired angiogenesis. Other limiting factors are insufficient mesenchymal cells that can become chondrocytes or osteoblasts during endochondral or intramembranous ossification, respectively. Thus, a compelling indication for a growth factor-based therapy is a situation of compromised bone healing, typically observed with the elderly patient.[95] Additional patients at risk for poor bone healing are diabetics and those with osteoporosis.

5.522.5.2. Orthopedic and Craniomaxillofacial

5.522.5.2.1. Contextualizing the discussion

The gold standard for bone regenerative purposes is a vascularized bone-like tissue. Unfortunately, the attendant morbidity and mortality with autografting procedures inspires the profoundly compelling need for alternatives that will not involve multiple invasive procedures. Consequently, recombinant genetically engineered molecules that induce bone regeneration and supportive angiogenesis have been assiduously studied and are being brought into the clinic.[96,97]

5.522.5.2.2. Interpreting preclinical data

Studies have shown that growth factors in combination with any number of carriers or vehicles can stimulate robust new bone growth in just about every aspect of the skeleton.[96,98–101] This is promising in itself but data has also suggested that there are significant differences in bone biology between humans and animal models. Consequently, clinicians have to be mindful about extrapolating results from animal data to the clinical setting. This might be because the timing of bone healing in humans is different than in animals and the duration of growth factor expression during healing processes across species also differs. In this context, it has become apparent that the strategy for growth factor delivery and the release kinetics are critical to clinical success. This is made more complex by the fact that different skeletal sites have unique characteristics,

Table 2 Cytokines in bone cell metabolism

Cytokine	*Produced by*	*Cell it signals to*	*Mechanism of action*	*Additional information*
IL-1	Osteoclasts and osteoclast precursors (OCP's) can secrete TNF leading to feed forward for resorption. This happens when OCP's contact bone matrix[68]	Promotes MSC to blast by inhibiting MSC to adipocyte[79]	IL-1-induced TAK1/TAB1/NIK signaling cascade attenuates PPAR-gamma-mediated adipogenesis by inhibiting the binding of PPAR-gamma to the DNA response element[79]	
			First cytokine (along with IL-6) involved in bone loss due to estrogen deficiency[80]	
		T cells[63]	Increases RANKL mRNA expression[63]	
		Stromal marrow cells and osteoblasts[63]	Enhance osteoclastogenesis via RANK/RANKL mechanisms by upregulating IL-7 production[63]	
	Osteoblast			
		Osteoclast precursor	Enhances RANKL expression[62]	
		Osteoclasts[58]		
IL-3	Mesenchymal stems	T-lymphocytes	Inhibits osteoblast formation[73]	
		Osteoclast precursors[58]	Inhibits RANKL-mediated osteoclastogenesis but otherwise promote osteoclast precursor formation (along with GM-CSF)[58]	
IL-4/IL-13	Activated T-cells	Osteoblast precursors	Suppress RANKL-induced osteoclast differentiation (IL-4)[69]	IL-4 and IL-13 bind to IL-4Rα and IL-13α1 activating JAK/STAT6 pathway of tyrosine kinase phosphorylation. This in turn effects NF-κB, peroxisome proliferator-activated receptor-γ1, MAPK and Ca^{2+} signaling, NFATc1 and c-Fos[129]
		Osteoclasts	Increase OPG and decrease RANKL and RANK expression, thereby inhibiting osteoclast differentiation (IL-4 and IL-13)[69]	
IL-5	Eosinophil in asthma and rhinitis and nothing directly on bone			
IL-6	Osteoblasts, BMSC	Osteoclast progenitor cells	Induce osteoclastogenesis and bone resorption	Differentiate into mature osteoclasts[72] Stimulates RANKL and OPG mRNA production in bone[64] Enhances production of prostaglandins[130] Specific IL-6 binding protein binds IL-6, this then activates cells that contain the gp 130 signal peptide, signal transduction occurs through JAK/STAT pathway of tyrosine kinase phosphorylation[71]
IL-7	T cells[59]		Suppresses bone formation[80] (no mechanism given). Promotes RANKL expression and upregulates osteoclastogenesis when administered systemically. Upregulates the number of osteoclast precursor cells.[59] When administered locally to HSCs, decreases OCP population by influencing lineage commitment toward B cell development pathway	
IL-8	Macrophages, neutrophils, endothelial cells, osteoclasts	Osteoblasts	Induce osteoclastogenesis[65]	Stimulate RANKL mRNA expression[65]
		Human bone marrow-derived osteoclast-like cells[131] (osteoclast progenitor cells)		Directly stimulates differentiation of mononuclear cells into osteoclasts

(*Continued*)

Table 2 (Continued)

Cytokine	*Produced by*	*Cell it signals to*	*Mechanism of action*	*Additional information*
				IL-8 binds to CXCR1 receptor which, is a G-protein-coupled receptor, triggers a flux of intracellular Ca^{2+} ions for cell response[19]
IL-10	Activated T and B lymphocytes	Mononuclear cells (osteoclast progenitor cells)[132]	Inhibits osteoclastogenesis	Increases M-CSF gene expression in bone marrow (thereby increasing macrophage production disproportionately)[75]
		Mesenchymal osteoblastic precursors		Increased tyrosine phosphorylation of a variety of proteins in osteoclast precursor cells[133]
				Suppreses RANKL-induced NFATc1 activity via disruption of Ca^{2+} mobilization[74]
				Inhibit ALP, collagen type 1 and osteocalcin (bone proteins) and inhibit onset of mineralization at early osteogenic differentiation stages[82]
IL-11 (part of the IL-6 or gp130 cytokine family)[67]		T cells[63]	Enhances bone resorption[63]	
			Increases RANKL mRNA expression[63]	
		Osteoblasts	Downregulates type II glucocorticoid receptors	
			Has no effect on isolated osteoclasts *in vitro*[58]	
IL-12	Dendritic cells, macrophages, B cells	Osteoclast precursors	Inhibits osteoclastogenesis	Inhibits RANKL-induced NFATc1 expression for osteoclast differentiation[134]
				IL-12 binds to IL-12R-beta2 receptor, IL-12R-beta2 becomes tyrosine phosphorylated and signal transduction occurs through JAK/STAT pathway[135]
IL-13 (a locally acting cytokine along with IL-4)[58]	TH2[60]		Inhibits IL-1 stimulated bone resorption by decreasing prostaglandin levels and cyclooxygenase-2 activity[58]	
		Osteoblast	Stimulates osteoblast migration and regulates osteoclast formation and activity by increasing OPG and decreasing RANKL production	
IL-15 (a member of the IL-2 superfamily)[58]	T-lymphocytes[58]	Osteoclast precursors	Involved in maintenance of stromal cell population but no direct link to blasts or clasts.[66] Leads to increased osteoclastogenesis in RA patients[58]	
			Increases osteoclast precursor cell numbers in culture[58]	
IL-17 (a 6 member family IL-17A-F)[58]	TH17 subset of the CD4+ T-cells	Osteoblasts	Stimulates bone resorption by upregulation of RANKL[66]	
	IL-17A[58]			
			However, mice deficient in IL-17 showed normal bone so it doesn't seem essential to bone formation[66]	
		Osteoclast precursors	Stimulate osteoclastogenesis in mixed hematopoietic cell/osteoblasts cultures via prostaglandin synthesis and RANKL expression[58]	
		T cells[63]		
			Increases RANKL mRNA expression[63]	
			Stimulates production of IL-1, IL-6, and TNF[60]	

IL-18	Osteoblasts, macrophages	Osteoclasts	Inhibits osteoclastogenesis	1. T cell production of GM-CSF[136] 2. Increased expression of IFN-γ[77] 3. Synergistically increases IFN-γ production with IL-12[137] 4. Increased expression of OPG[76] IL-18 signals through the IRAK receptor to induce translocation of NF-κB complex[136]
TNF	Osteoclasts and osteoclast precursors can secrete TNF leading to feedforward for resorption[68]	Osteoclast precursor	Regulates expression of SDF-1 by marrow stromal cells which promotes osteoclast precursor egression from marrow to blood.[68] Also causes expression of osteoclastic genes via two pathways (1) Canonical: phosphorylation and degradation of in inhibitory kappa kinase b $\rightarrow$ free NF-κB P65 and P50 dimers which translocates to the nucleus, inducing expression of osteoclastogenic genes (2) Noncanonical: Phosphorylation and degradation of p100 (p100 normally attached to Re1B, an inhibitory NF-κB protein), a P52 fragment of P100 binds to Re1B and the dimmer translocates to the nucleus to turn on osteoclastogenic genes[68] TNF upregulates expression of NF-κB p100 in OCP's[68]	
TNF-α		Osteoclast	Directly stimulates them and augments their response to RANKL.[66] Ability to do this is M-CSF dependent[58]	
		T-cells[63]	Increases RANKL mRNA expression[63]	
		Stromal marrow cells and osteoblasts[63]	Enhance osteoclastogenesis via RANK/RANKL mechanisms by upregulating IL-7 production.[63] Ability to do this is IL-1 dependent and can be accomplished in the absence of RANK although the effect is substantially weakened in this case[58]	
		Mesenchymal stem cells[79]	Promotes osteoblastogenesis by inducing TAK1/TAB1/NIK signaling cascade that attenuates PPAR-gamma-mediated adipogenesis by inhibiting the binding of PPAR-gamma to the DNA response element.[79] In contrast to the summary of Takada, Lee summarizes that TNF-α inhibits osteoblast differentiation and Type 1 collagen production and is even proapoptotic for osteoblasts. However, mice without TNF receptors produce normal bone suggesting that the cytokine's effects are only seen during inflammation and not during normal bone formation[58]	
OPG (osteoprotegrin)	Osteoblast produce in response to other cytokines, hormones, and mechanical stress.[68] Also secreted by osteoblastic stromal cells.[68] Produced by B cells after CD-40 binding with T cell.[66] Also produced by T cells and dendritic cells	Osteoclast precursor	Inhibits RANK thus inhibiting osteoclastogenesis.[57] Inhibition is by binding to RANKL to act as a decoy receptor[66] Decreases production of IL-6, IL-11 in response to dendritic cell stimulation by RANKL, also decreases IL-12 and IL-15 from T cells[63]	
	On surface of dendritic cells[63]	T cells[63]	Increases RANKL mRNA expression[63]	

(*Continued*)

Table 2 (Continued)

Cytokine	*Produced by*	*Cell it signals to*	*Mechanism of action*	*Additional information*
RANKL receptor activator of NF-κB ligand (a TNF family protein also called TRANCE, OPGL, ODF)	Osteoblast produce in response to other cytokines, hormones, and mechanical stress[68] and activated CD4 and CD8 T cells[66] also produced by Th17 cells and B cells.[138] Also found on TH1 and TH2 cells[60]	Osteoclast precursor	Principal mediator between blasts and clasts. With M-CSF initiates osteoclastogenesis.[57] Sequentially activates NF-κB, c-Fos, and NFATc1 to result in osteoclastogenesis but does not upregulate NF-κB p100 as TNF does.[68] Requires 3:3 dimers of RANK/RANKL to be formed for optimal stimulation.[139] Only a few papers prove a direct contribution of RANKL on T cells to osteoclastogenesis as even tH17 cells could not induce osteoclastogenesis in the absence of osteoclastogenesis-supporting cells, it was tentatively concluded that the expression of RANKL on T cells was not sufficient for the induction of osteoclastogenesis[60]	
M-CSF (macrophage colony-stimulating factor)	Osteoblast	Osteoclast precursor	Works with RANKL to initiate and maintain osteoclasts[57]	
Interferon-γ	TH1[60]	It is a species specific cytokine[60]	Inhibits bone formation.[66] Enhances RANKL and TNF-α production[58] Inhibits osteoclastogenesis by interfering with the RANK-RANK system[80] by interfering with TNF receptor-associated factor 6 (TRAF-6) expression there by inhibiting transcription pathways stimulated by RANKL[63] but does not directly affect resorption by mature osteoclasts[58] Inhibits the abilities of 1,25-dihydroxyvitamin D3, PTH, and IL-1 to stimulate OCL formation in bone marrow cultures[58] Inhibits osteoblast proliferation[58] All above effects are *in vitro*. *In vivo* the results are different. Intraperitoneal injections in rats induced osteopenia and partially reversed the effects of osteopetrosis in humans[58]	
IFN-γ	Th1 cells, Tc cells, dendritic cells, NK cells	Osteoclast progenitor cells	Inhibits osteoclasts	Inhibits formation multinucleated cells by inhibiting 1, 25D3, PTH, and IL-1 thereby inhibiting osteoclast formation[78] Production of IFN-γ by T cells suppresses osteoclastogenesis by interfering with RANKL signaling by inducing rapid degradation of the RANK adapter protein TRAF6 that in turn inhibits NF-kB[81] IFN-γ binds to IFNGR1 and IFNGR2 activating JAK/STAT pathway
T helper cytokines				
Th1	IFN-γ		Inhibit osteoclastogenesis	
Th2	IL-4, IL-6, IL-10[82]		Inhibit/induce osteoclastogenesis	
Th17	IL-17[19]		Induce osteoclastogenesis	

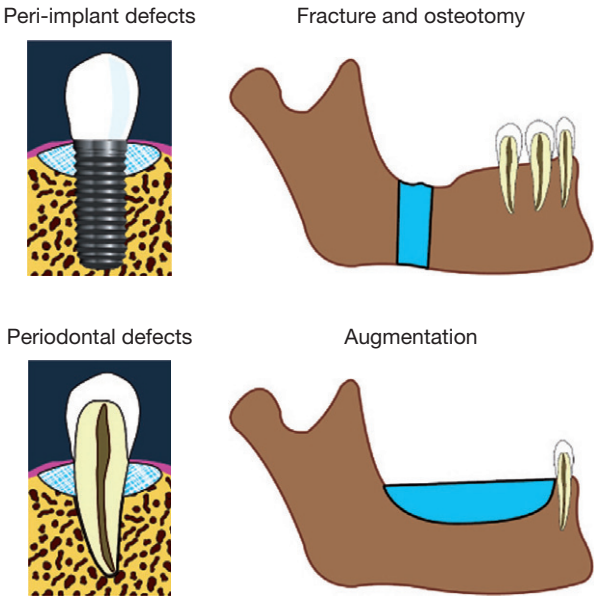

Figure 7 Dentistry offers a large spectrum of possible applications related to tissue engineering. Therapeutic targets for local treatment include, but are not restricted to, peri-implant and periodontal defects, as well as segmental defects and augmentation sites. Even though all sites are in the same anatomical region, they have their unique requirements to a therapeutic concept. For example, a therapeutic concept that solely causes bone formation might not be suitable to support the regeneration of the complex structure of the periodontal ligament.

making some growth factors (and carriers) appropriate for some sites but not for others. Consideration of these host and site specific factors has regulatory implications as well.

5.522.5.2.3. Host factors

The characteristics that are specific to defect type and host factors in general can have a profound impact on the clinical response to growth factor administration, for example, when reconstructing a bone defect in a field previously exposed to radiation or in massive orthopedic trauma where blood supply has been compromised.

5.522.5.2.3.1. Strategies for growth factor delivery

Many strategies have been described for delivering growth factors. The primary objective of growth factor delivery is provision of sustained biologically relevant concentrations at the site of administration. The simplest technique would be direct injection. The problem with this approach is that growth factors are rapidly metabolized in the body, resulting in short half lives.

A sustained local concentration can be achieved by one of two methods:

1. Gene therapy that will be sequestered locally and thus result in local expression or
2. Packaging the growth factor protein in a carrier with release kinetics matched to the localized wound healing cascade.

Gene therapy (whether by transduction or transfection) has potential, but there are issues of safety that have to be resolved before full clinical implementation. Consequently, the method currently being used clinically involves growth factors plus a

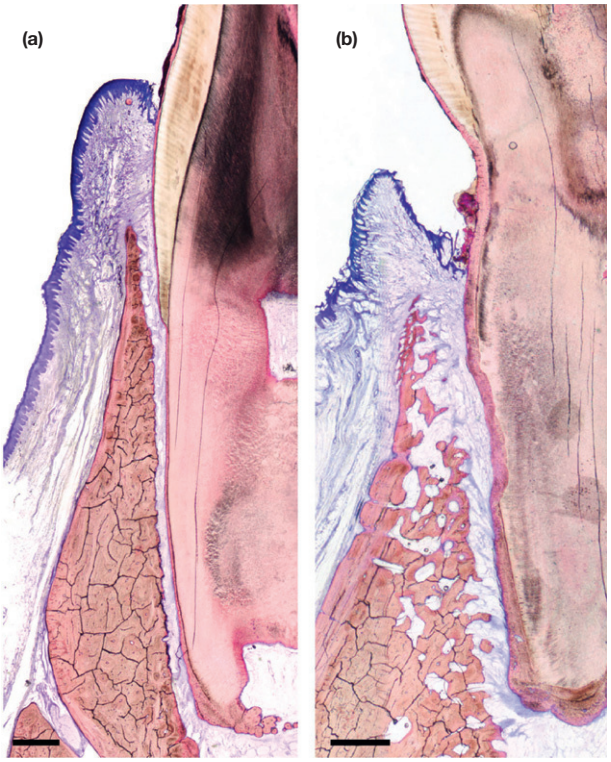

Figure 8 Histologic section through a premolar showing the alveolar bone crest, periodontal ligament and the dentogingival region in a healthy sheep (a) compared to a diseased sheep from the test group (b). In the elderly osteoporotic animals, there is alveolar bone resorption and the concomitant attachment loss. Undecalcified ground sections, Levai–Laczko stain, bars equal 1 min. Adapted from Dvorak, G.; Reich, K.; Tangl, S.; *et al*. *Arch. Oral Biol*. **2009**, *54*, 857–863 and kindly provided by Karoline Reich.

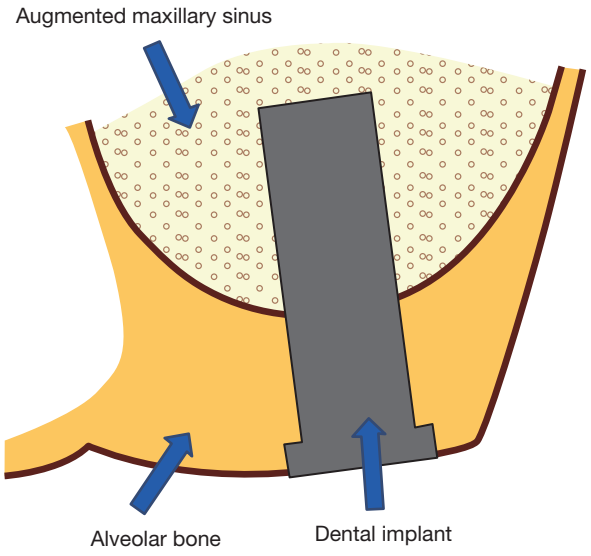

Figure 9 This surgical procedure creates an artificial space beneath the sinus mucosa and the atrophic local bone that is filled with grafting material. Implants can be inserted into the augmented area in a one-stage or two-stage approach.

delivery system. The delivery system, as mentioned previously in this chapter, must be biocompatible, the pharmacokinetics of the factor released must match the local healing cascade, and the delivery system must be calibrated to biodegrade in register with new bone formation.

From a practical, clinical standpoint, surgeons administering therapeutics to patients often emphasize the need to have something that is simple to use. Therefore, a delivery system for a complex biological that is complicated to use, will likely not be used by the surgeon. From a surgical perspective, the surgeon wants a biomaterial that is easy to handle, is fully resorbable and has robust mechanical properties.

In addition, the three-dimensional architecture of a carrier (i.e., biological delivery system) can dramatically affect the release kinetics and, therefore, the biological activity. The carrier must allow vascular ingrowth throughout its structure. This means finding ways of improving surface area to volume ratios in the scaffold. When constructing a material intended for load-bearing applications out of a resorbable material (whether the substrate is biologically derived or not), a balance must be struck between the biological activity of the scaffold itself and the biomechanical properties of the material.

5.522.5.2.4. Growth factors and cytokines in clinical use

5.522.5.2.4.1. Nonrecombinant sources of growth factor and cytokines

A discussion of growth factors and cytokines in clinical use should include platelet gel and demineralized bone matrix (DBM); both are used clinically in many of the same applications. Platelet gel is prepared by isolating a patient's platelet concentrate from blood and activating the release mechanism of α-granules by adding calcium and thrombin. Platelet gel is attractive to clinicians for several key reasons: it is autogenous, inexpensive and fairly easy to process. However, it has variable concentrations of relevant growth factors and consequently, is subject to high variability among individuals. Platelet gel by itself has not been shown to add significant benefit when used for spinal fusion[102] though it has shown some positive effects in some dental applications.[103] Dallari *et al.*[104] showed in a prospective, randomized and controlled study that platelet gel, alone or combined with BMSCs, on lyophilized bone chips causes increased bony healing in high tibial osteotomies.

DBM is processed allogeneic bone and contains multiple growth factors and cytokines. DBM is regulated by the FDA as a reprocessed human tissue and as an off-the-shelf product. DBM has, in the past, been widely used either alone or in combination with autogenous bone as a bone substitute in non-load-bearing sites. However, there are studies that indicate its ineffectiveness in many applications.[105,106] Issues with allograft material include limited supply, erratic performance, perhaps due to varying processing techniques and donor age,[106–109] and the risk, albeit small, of disease transmission. The clinical use of DBM has declined as recombinant human growth factors have become available to surgeons and dentists.

5.522.5.2.4.2. Recombinant sources of growth factor and cytokines

The most commonly used growth factors for bone regeneration in the clinical setting are rhBMP-2 and -7 OP-1. PDGF has also

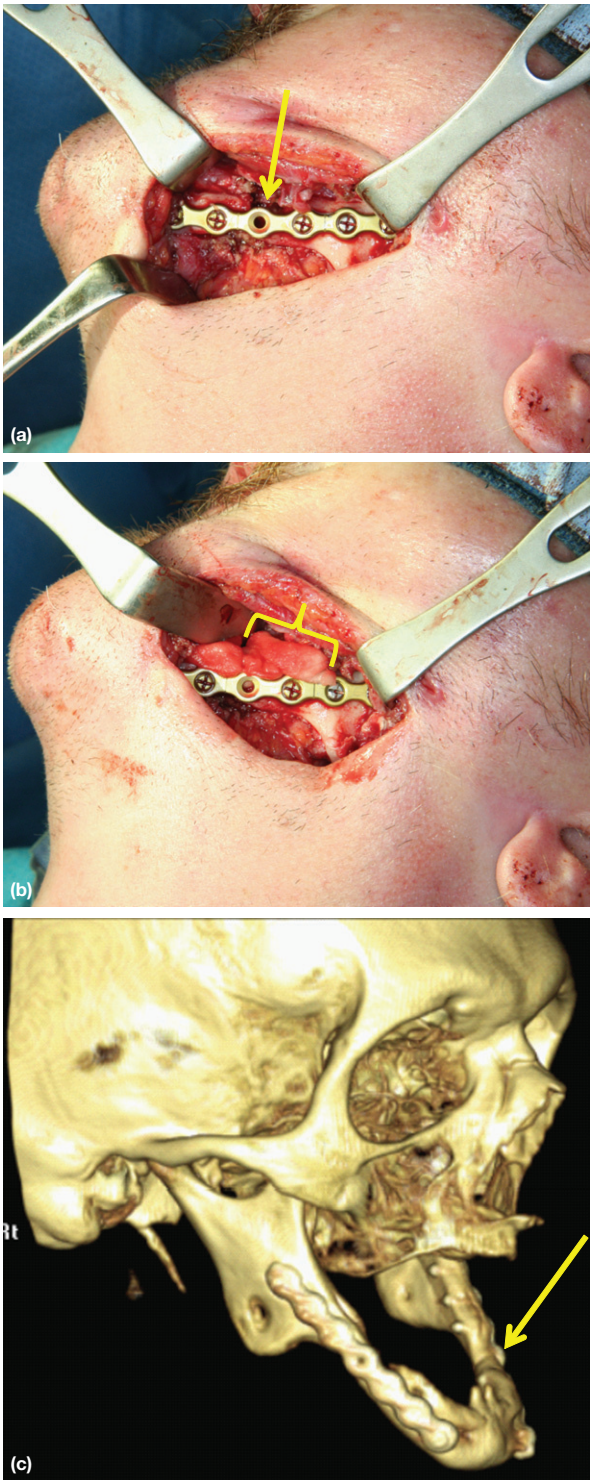

Figure 10 This patient suffered from traumatic bone loss in the left body of the mandible, with a 3 cm defect in an atrophic mandible. (a) A titanium reconstruction plate was used to stabilize the fracture (the arrow points to the missing bone). (b) Following stabilization, the defect was packed with BMP-2/ACS (bracket). (c) After 10 weeks, there has been complete spanning of the defect with bone that radiographically appears normal (arrow in (c)). The patient has regained function. Note: patient had a right side body fracture as well.

been gaining clinical attention. The BMP-2 in the INFUSE® Bone Graft product comes in a kit containing 12 mg dibotermin-α (1.5 mg BMP-2/ml after reconstitution), which is applied to an absorbable collagen sponge (ACS). BMP-7 comes in 1-g lyophilized powder form with 3.5 mg eptotermin-α that is combined with type I bovine collagen for a maximum dosage of 2 g. The BMP dosages that have been found to be effective in humans are quite high. For instance, the amount of BMP-7 in a package intended for one human application is roughly equivalent to the total BMP-7 quantity in two full grown people.[110] A large quantity of the exogenous rhBMP is released after implantation, resulting in supraphysiologic dosages. The supraphysiologic dose is needed to produce a therapeutic effect: bone regeneration. Complications from this approach have included inflammation, hematomas, and ectopic bone formation in the spinal canal.[111–116] These complications could be related to the release kinetics associated with the ACS (collagen) carrier for rhBMP-2 and -7.

5.522.5.2.4.2.1. Clinical applications: Recombinant human BMP-2 The FDA approval for rhBMP-2-containing INFUSE® Bone Graft product was for anterior lumbar interbody fusion. This approval was based on a prospective, randomized, multicenter clinical trial that compared rhBMP-2/ACS to autogenous iliac bone (**Figure 10**).[100,117] Surgeons have also evaluated rhBMP-2 in posterior lumbar and transforaminal lumbar interbody fusion and found the fusion rates comparable to those of autogenous grafting.[118,119] Outcome from a randomized controlled study that evaluated rhBMP-2 in an ACS in open tibial fractures suggested reduced healing time, with a decrease in the number of revisional procedures for delayed fracture healing and infection.[120] However, there are concerns reported with the clinical use of rhBMP-2; specifically, rhBMP-2 used in the cervical spine has caused sequelae of edema and dysphagia (inability to swallow), causing airway compromise.[115,121] Purportedly, these complications are attributable to an initial bolus release of unbound rhBMP-2 from the collagen delivery sponge that is a component of the INFUSE® Bone Graft. The outcome of a rapid bolus release produces inflammation. Moreover, rhBMP-2-containing InFuse® Bone Graft has been reported to produce ectopic bone formation (foraminal), which leads to neurologic impairment.[116,122] Consequently, complications from rhBMP-2 for cervical fusions contraindicate its use in the cervical spine.[115]

Clinical applications of rhBMP-2-containing INFUSE® Bone Graft have been reported throughout the craniofacial skeleton despite the fact that the FDA approval is only for localized alveolar ridge defects and maxillary sinus augmentation (**Figure 11**).

In a review conducted on 14 patients for mandibular defect reconstruction with INFUSE® Bone Graft, the results were positive.[123] The clinical outcome suggested successful restoration of bony continuity and at least some dental function in all patients. However, in another series of five patients, the same degree of success was not reported.[124]

5.522.5.2.4.2.2. Recombinant human BMP-7 In the United States, rhBMP-7 received FDA approval under a Humanitarian Device Exemption (HDE) in 2001 for recalcitrant nonunions in the long bones. In 2004, the FDA extended approval under an HDE for revision of posterolateral (intertransverse) lumbar spinal fusions. The significance of the HDE is that rhBMP-7 cannot be used in more than 4000 applications a year. However, rhBMP-7 has received full regulatory approval in several other countries. In several UK medical centers, reports of BMP-7 in 653 patients was associated with successful bony union in over 80% of cases.[99] In a prospective,

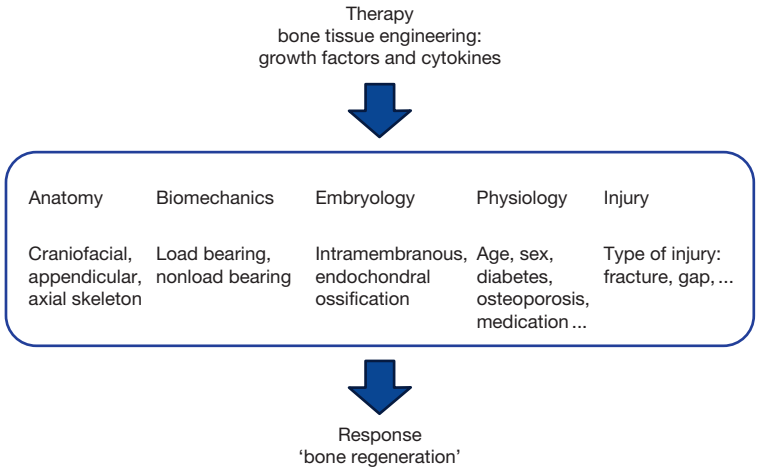

Figure 11 The sequential process of bone regeneration runs with the robustness of clockwork. However, while 'clockworks' are based on mechanical movement, subtle changes may influence the regenerative capacity of bone. Moreover, systemic diseases and their pharmacologic therapy can influence the regenerative capacity of bone. Compromised bone regeneration therefore has an impact on the clinical success of a therapy. Thus, the response of a patient to a therapy, and thus to a bone tissue engineering concept, is complex and involves various aspects, for example, the defect site, the biomechanical conditions, the embryologic origin of the bones, the numerous physiological and pharmacological variables, and the type of injury. These variables should be considered in the planning phase of bone tissue engineering strategies. Modified with permission from Hollinger, J. O.; Hart, C. E.; Gruber, R.; Doll, B. A. In *Tissue Engineering: Applications in Oral and Maxillofacial Surgery Periodontics*, 2nd ed.; Lynch, S., Marx, R. E., Nevins, M., Wisner-Lynch, L. A., Eds.; Quintessence Publishing Co, Inc.: 2008; pp 3–25.

randomized, double blinded clinical study, it was reported that rhBMP-7 promoted osteogenic activity in critical size fibular defects.[125] Other studies have underscored efficacy of rhBMP-7 compared to autogenous bone in posterolateral spine fusion[101,126,127] and anterior cervical fusion procedures.[128]

5.522.5.3. Future Clinical Directions

5.522.5.3.1. Defining the clinical performance criteria

The future for clinical applications of growth factors and cytokines is highly promising, provided researchers and clinicians pay attention to fundamental bone biology, modeling and remodeling, and bone healing cascades.

Moreover, as release kinetics and clinical performance properties are improved for delivery systems so that they are more tightly matched to biology, the therapeutic effectiveness of growth factors and cytokines will also be profoundly improved and the adverse effects significantly diminished. Furthermore, multiple factors dynamically interact in a rigorously defined temporal, spatial and dose-dependent cascade during wound healing. Those complex and complicated interrelationships have not been sufficiently defined; nor have performance properties of materials been satisfactorily matched to the biological and biomechanical needs.

All these aspects must be blended to produce a therapeutic package that will predictably and safely promote a regenerative tissue outcome.

Glossary

Biosensing The use of devices to determine or sense a biological event.
Carbon nanotubes A helical arrangement of carbon creating a tube diameter with nanodimensions.
Cyclic voltammetry (CV) A type of potentiodynamic electrochemical measurement that can be used to determine events surrounding an implant.
Dexamethasone An anti-inflammatory steriod.
Multiwalled carbon nanotubes Carbon nanotubes which have greater than two walls, or layers of helical carbon.
Nanomaterials Traditionally defined as a material with at least one dimension (like a grain, fiber, or particle) <100 nm in at least one direction.
Nanomedicine The use of nanotechnology in medicine.
Nanotechnology The use of nanomaterials to improve a particular property of a material.
Osteoblasts Bone-forming cells.
Penicillin An antibiotic.
Poly-lactic-*co*-glycolic acid An FDA-approved polymer commonly used in tissue engineering.
Polypyrrole An electrically conductive polymer.
Single-walled carbon nanotubes Carbon nanotubes with only one layer of helical carbons.
Titanium A commonly used orthopedic implant material.

Abbreviations

CNTs	Carbon nanotubes
CV	Cyclic voltametry
CVD	Chemical vapor deposition
EDS	Energy dispersive spectroscopy
HA	Hydroxyapatite
MWCNTs	Multi-walled carbon nanotubes
PECVD	Plasma-enhanced chemical vapor deposition
SWCNTs	Single-walled carbon nanotubes
XRD	X-ray diffraction

5.523.1. Introduction

Osteoblasts and osteoclasts are located in bone, a natural nanostructured-mineralized organic matrix. While osteoblasts make bone, osteoclasts decompose bone by releasing acid that degrades calcium phosphate-based apatite minerals into an aqueous environment. The synthesis, deposition, and mineralization of this organic matrix, in which osteoblasts proliferate and mineralize (i.e., deposit calcium), require the ordered expression of a number of osteoblast genes. Bone has the ability to self-repair or remodel routinely (for more on bone see **Chapter 6.617, Bone Tissue Grafting and Tissue Engineering Concepts**). However, osteoporosis (unbalanced bone remodeling) and other joint diseases (such as osteoarthritis, rheumatoid arthritis, or traumatic arthritis) can lead to bone fractures. These disabilities associated with bone lead to difficulties in performing common activities and may require an orthopedic implant. However, the average functional lifetime of, for example, a hip implant (usually composed of titanium) is only 10–15 years. A lack of fixation into surrounding bone eventually loosens the implant and is the most common cause of hip replacement failure (for more on orthopedic implants see **Chapter 6.605, Porous Coatings in Orthopedics** and **Chapter 6.606, Biological Effects of Wear Debris from Joint Arthroplasties**).

Approximately 200 000 total and 100 000 partial hip replacements as well as 36 000 revision hip replacement surgeries were performed in the United States in 2003.[1] Unfortunately, only limited techniques, such as insensitive imaging (through X-rays or bone scans), exist to determine if sufficient bone

growth is occurring next to a titanium implant after surgery. Thus, techniques used in orthopedic diagnostics need to more accurately identify musculoskeletal injuries and conditions after implantation. Although there have been improvements in implants to increase bone formation, the clinical diagnosis of new bone growth surrounding implants remains problematic, sometimes significantly increasing hospital stay and decreasing the ability of doctors to quickly prescribe a change in action if new bone growth is insufficient.

Currently, a physical examination (e.g., palpation or laboratory testing) might be completed before imaging techniques are used to inform a clinician about a patient's health. Although advanced imaging techniques, such as bone scans, computer tomography scans, and radiographs (X-rays), are important in medical diagnosis, each has its own limitations and difficulties. A bone scan is used to identify areas of abnormal active bone formation, such as in arthritis, infection, or bone cancer. However, bone scans require an injection of a radioactive substance (e.g., technetium) and a prolonged delay for absorbance before performing the scan. Computer tomography combines X-rays with computer technology to produce a two-dimensional cross-sectional image of a body on the computer screen. Although this technique produces more detail than an X-ray, in some cases (e.g., severe trauma to the chest, abdomen, pelvis, or spinal cord), a dye (e.g., barium sulfate) must be injected in order to improve the clarity of the image. This often causes pain to the patient. Another technique, called electromyography, has been used to analyze/diagnose nerve functions inside body conditions. Thin electrodes are placed in soft tissues to help analyze and record electrical activity in the muscles. However, this electrode technique leads to pain and discomfort for the patient. When the needles are removed, soreness and bruising can occur.

Electrochemical biosensors on the implant itself shows promise for medical diagnostics *in situ* to possibly determine new bone growth surrounding the implant (for more on sensors see **Chapter 3.330, Carbon Nanotube-Based Sensors: Overview**). Yet, this technology has not been fully explored. Incorporation of such electrochemical biosensors into current bone implants may be possible through nanotechnology; different types of nanoscale biomaterials have varying abilities to enhance *in vitro*/*in vivo* bone formation. Carbon nanotubes (CNTs) are macromolecules of carbon, classified either as single-walled carbon nanotubes (SWCNTs) with diameters of 0.4–2 nm or multiwalled carbon nanotubes (MWCNTs) with diameters of 2–100 nm.[2,3] Because of their unique electrical, mechanical, chemical, and biological properties,[4–11] CNTs have shown promise for bone implantation. For example, nanocomposites of polylactic acid and MWCNTs increased osteoblast proliferation by 46% and calcium production by >300% when an alternating current was applied *in vitro*.[12,13] In addition, combining MWCNTs with precursor powders improves the mechanical properties of as-aligned hydroxyapatite (HA) composite coatings.[9] MWCNTs, reinforced with HA coatings, promoted human osteoblast proliferation *in vitro*, as observed in the appearance of cells near MWCNT regions.[8] Osteoblasts extended in all directions within the CNT scaffold that formed on polycarbonate membranes.[14] Osteoblasts significantly enhanced their adhesion on vertically aligned MWCNT arrays, according to Giannona *et al.*[15] by recognizing nanoscaled features. In addition, Zanello *et al.*[7] showed that CNTs are suitable for the proliferation of osteosarcoma ROS 17/2.8 cells on single and MWCNT scaffolds. Human osteoblast-like (Saos2) cells grown on the MWCNT scaffold showed a higher cell density and transforming growth factor-β1 concentration compared with those grown on polystyrene and polycarbonate scaffolds.[16]

Our previous studies have shown greater osteoblast differentiation on MWCNT-Ti than on Ti alone.[17] Moreover, MWCNTs are a promising material for electrochemical biosensors because they also possess relatively well-characterized behavior in terms of electron transport.[18–21] Coating CNTs on Ti electrodes also increases the active surface area and enhances direct electron transfer.[22,23] These studies encourage the use of MWCNTs to modify currently used Ti for orthopedic implants. CNTs can be produced by the laser furnace arc and chemical vapor deposition (CVD) methods. Unlike the laser furnace arc, CVD is a scalable and controllable method of obtaining a high purity of CNTs.[24] A strong mechanical connection between CNTs and the metal is needed for nanosensor applications,[25] and the reduced resistance between the Ti and CNTs[26] leads to increased current passage. For example, Sato *et al.* showed potential for using CNTs in electrochemical biosensors by using CVD to grow MWCNTs with Ti biometallic particles and cobalt (Co) as a catalyst. They revealed that Co has the ability to combine with Ti[27] and as CNTs were grown by using a Co catalyst in that study, a strong electrical contact between metallic Ti and MWCNTs was possible.

As mentioned, in order to form a more robust interconnection, CNTs have been anchored in the pores of anodized nanotubular Ti. MWCNTs have then been grown (using CVD techniques) out of the anodized Ti nanotubes (with diameters of 50–60 nm and depths of 200 nm) as a template. *In vivo*, many cell processes important during new bone growth rely on the redox reactions of various biomolecules and ions. The mechanisms of electron transfer reaction and the role of proteins in aiding the electron transfer of redox processes can be examined by electrochemical analysis. In electronic theory, when two different materials come in contact with each other, electron transfer will occur in an attempt to balance Fermi levels, causing the formation of a double layer of electrical charge at the interface. Because the formation of electric contact between the redox proteins and the electrode surface is the fundamental challenge of electrochemical biosensor devices, in one study, the redox reactions of iron(II/III) and the osteoblast extracellular components at the surface of Ti, anodized Ti, and MWCNT-Ti have been investigated. How to create such novel orthopedic sensors along with the latest data concerning their use is presented below.

5.523.2. Making Orthopedic Implant Sensors

5.523.2.1. Step 1: Preparation of Nanotubular Anodized Titanium

In order to create orthopedic sensors, currently implanted titanium (Ti) has been modified to have a nanotube-structured thin layer of titanium dioxide (TiO_2) by anodization.[17] Briefly, 99.2% commercially pure Ti sheets (Alfa Aesar) can be cut into squares (1 cm^2) and cleaned with acetone and 70% ethanol under sonication for 10 min each.

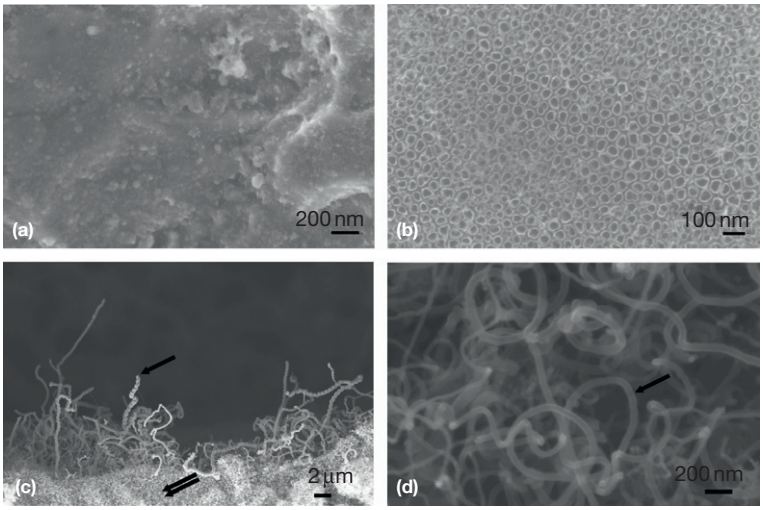

Figure 1 Scanning electron microscopy (SEM) micrographs of the electrode surfaces: (a) conventional Ti and (b) anodized Ti; (c) side view and (d) top view of multiwalled carbon nanotube Ti (MWCNT-Ti). Single arrow shows MWCNTs, whereas the double arrows show the anodized Ti template.

After rinsing with deionized water, Ti can be etched for 10 s in a solution of 1.5% by weight of nitric acid and 0.5% by weight of hydrofluoric acid to remove the existing oxidized layer on Ti. Immediately after etching, Ti can be placed as an anode and a high purity platinum (Pt) mesh (Alfa Aesar) can be used as a cathode. In a Teflon beaker, both electrodes can be immersed in an electrolyte solution of 1.5% by weight of hydrofluoric acid in deionized water. The distance between Ti and the platinum mesh should be around 1 cm. A direct current power supply (3645A; Circuit Specialists) can then be used at 20 V between the anode and cathode for 10 min to create uniform nanotubes of TiO_2 on commercially pure Ti. It is from these uniform titanium nanotubes that electrically active sensing MWCNTs can be grown, as described next.

5.523.2.2. Step 2: Cobalt-Catalyzed CVD for Growing MWCNTs

Afterward, MWCNTs can be grown out of the nanoporous TiO_2 by CVD. A plasma-enhanced chemical vapor deposition (PECVD) system (Applied Science & Technology, Inc.) can be used to grow MWCNTs from the nanotubular anodized Ti. To do this, the anodized Ti samples can be soaked in a solution of 5% by weight of cobaltous nitrate (Allied Chemical) in methanol for 5 min prior to CVD process. Then, cobalt-catalyzed anodized Ti should be rinsed with distilled water and dried with compressed air. The samples can then be placed in the CVD chamber and the air pumped out to a base pressure below 10 mTorr. The samples can be heated at 700 °C in a flow of 100 sccm (standard cubic centimeters per minute) hydrogen gas (H_2) for 20 min. The gas composition can be changed to 40 sccm H_2 and 160 sccm acetylene gas (C_2H_2) for 30 min to grow MWCNTs. The MWCNT-Ti should be cooled in a 100 sccm Argon flow. The dense and entangled MWCNTs can form a three-dimensional structure on the Ti surface with exceptional electrical conductivity and surface area. In particular, conventional Ti, shown in Figure 1(a), exhibits a smooth Ti oxide surface. After anodization, nanopores of Ti oxide formed on the Ti surface uniformly with diameters of 50–60 nm and depths of 200 nm, as shown in Figure 1(b). After the CVD process described here, MWCNTs covered the anodized Ti as shown in Figure 1(c) side view and 1(d) top view.

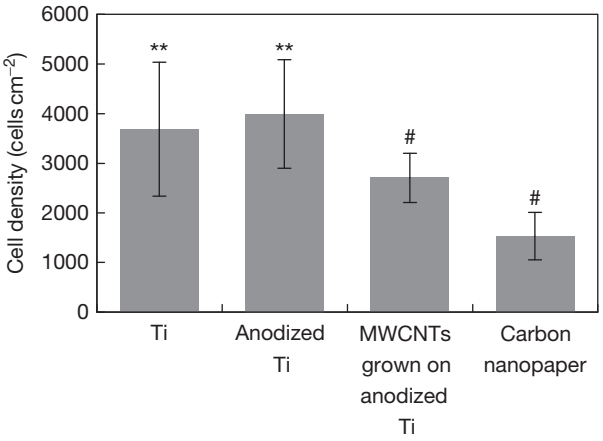

Figure 2 Osteoblast adhesion for 4 h on Ti, anodized Ti, multiwalled carbon nanotubes (MWCNTs) grown on anodized Ti, and carbon nanopaper. Values are mean ±S.E.M; $n = 3$; $^{**}p < 0.05$ compared to carbon nanopaper; # $p < 0.05$ compared to MWCNTs grown on anodized Ti.

5.523.3. Biological Responses to Orthopedic Implant Sensors

Importantly, results have shown that similar numbers of osteoblasts adhered after 4 h on unanodized Ti, anodized nanotubular Ti without MWCNTs, and anodized nanotubular Ti with MWCNTs (Figure 2); the numbers of osteoblasts adhering on all were greater than the number adhering on the carbon nanopaper (used as a chemical control). This initial data was important as it indicated that the MWCNT sensor was not detrimental to osteoblast functions. Moreover, osteoblasts were observed with cytoplasmatic prolongation on the

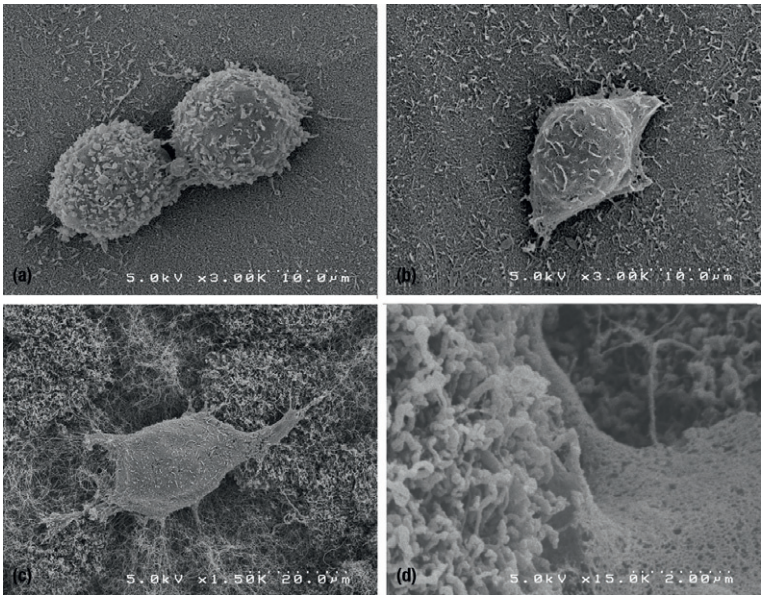

Figure 3 Osteoblast morphology after 4 h adhesion on (a, b) anodized Ti (Scale bars = 10 μm). Round-shaped osteoblasts are on the anodized Ti substrate without multiwalled carbon nanotubes (MWCNTs); and (c, d) MWCNTs grown on anodized Ti (Scale bars = 20 μm left and 2 μm right). Single arrow shows the cytoplamatic prolongations of osteoblasts to MWCNTs. Double arrows show MWCNTs, while triple arrows show the osteoblast membrane.

surfaces of MWCNTs grown out of anodized nanotubular Ti (**Figure 3(c)** and **3(d)**), resulting in stronger adhesion (more density of the points of contact) and some might say resembling osteoblast interactions with extracellular matrix proteins.[17] In contrast, osteoblasts on anodized Ti without MWCNTs were not observed to have cytoplasmic prolongation (**Figure 3(a)** and **3(b)**). Zanello *et al.* also observed a thin neurite-like cytoplasmic prolongation of osteoblasts that reached the nanotube bundles after cell culture for 5 days. More impressively, results have demonstrated that alkaline phosphatase activity and calcium deposition by osteoblasts increased on the MWCNTs grown from anodized nanotubular Ti sensors compared to that on anodized nanotubular Ti without MWCNTs, unanodized Ti, and carbon nanopaper after 21 days (**Figure 4**). This result suggested even better osteoblast responses on MWCNT sensors than currently used Ti.

5.523.4. Sensing Ability of Orthopedic Implant Sensors

Of course, the next question is how well do these MWCNTs sense new bone growth? As a starting point, experiments were conducted with the $Fe(CN)_6^{4-/3-}$ redox system. The $Fe(CN)_6^{4-/3-}$ redox system with an exhibition of heterogeneous one-electron transfer ($n = 1$) is one of the most extensively studied redox couples in electrochemistry.[28] The study has been performed in the cyclic voltammetry (CV) experiments of the $Fe^{2+/3+}$ redox couple by placing MWCNT-Ti in an electrolyte solution of 10 mM $K_3Fe(CN)_6$ and 1 M KNO_3. In potassium ferricyanide ($K_3Fe(CN)_6$), the reduction process is $Fe^{3+}(Fe(CN)_6^{3-} + e^- \rightarrow Fe(CN)_6^{4-})$ followed by the oxidation of Fe^{2+} $(Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-} + e^-)$ under a sweeping voltage. In such studies, the iron(II/III) redox couple did not exhibit any observable peaks for bare Ti or anodized Ti electrodes, as shown in **Figure 7(a)** and **7(b)**. This implies that the electrochemical reaction is slow on both these electrodes. However, the highly direct electron transfer at the MWCNT-Ti sensor electrode were observed as redox peaks, shown in **Figure 10(c)**. At a scan rate of 100 mV s^{-1} in **Figure 10(c)**, a well-defined redox peak appears with the anodic (E_{pa}) and cathodic (E_{pc}) potentials at 175 and 345 mV, respectively. Moreover, on the inner set of **Figure 7(c)**, the relationship is linear between the anodic and cathodic peak currents versus the square root of the scan rate, while the ratio of I_{pa}/I_{pc} is about 1, corresponding to the Randles–Sevcik eqn [1]. Because the root scan rate has this linear relationship with the peak currents, the mass transport in this process must be by diffusion. Zhang *et al.* found that the heterogeneous charge-transfer rate constant (k) of the $Fe(CN)_6^{4-/3-}$ complex with H_2O as a solvent is 0.05 cm s^{-1}.[29] As the k value is in the range of 10^{-4}–10^{-1} cm s^{-1} and $\Delta E_p > 59/n$ mV (in this case $n = 1$ and $\Delta E_p \sim 170$ mV), this process is quasireversible.

To analyze the electrochemical behavior at the surface of the MWCNT-Ti sensor electrodes, researchers have used the Randles–Sevcik equation for quasireversible processes, eqn [1]. Hence, the peak current (I_p) is given by

$$I_p = 2.99 \times 10^5 A D^{1/2} n (n_a \gamma)^{1/2} C \qquad [1]$$

where n is the number of electrons participating in the redox process, n_a is the number of electrons participating in the charge-transfer step, A is the area of the working electrode (cm^2), D is the diffusion coefficient of the molecules in the electrolyte solution ($cm^2\ s^{-1}$), C is the concentration of the probe molecule in the bulk solution (molar), and γ is the scan rate of the sweep potential ($V\ s^{-1}$). When the $Fe(CN)_6^{4-/3-}$ redox system exhibits heterogeneous one-electron transfer ($n = n_a = 1$) and the concentration C is equal to 10 mM, the diffusion coefficient

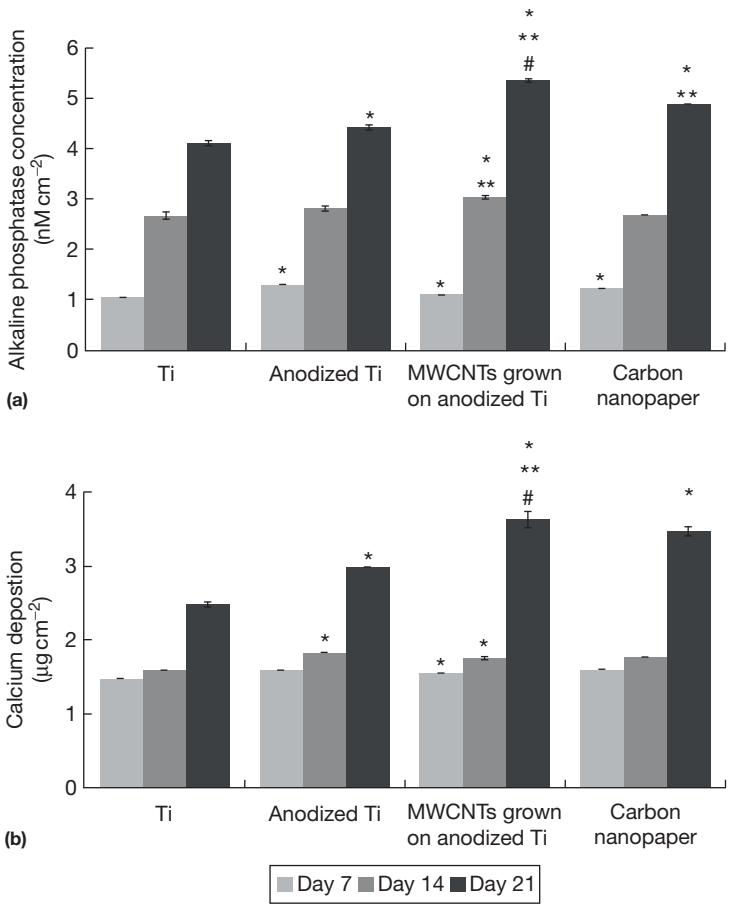

Figure 4 Osteoblast long-term functions: (a) alkaline phosphatase activity; values are mean ± S.E.M; $n = 3$; * $p < 0.05$ compared to Ti; ** $p < 0.1$ compared to anodized Ti; and # $p < 0.1$ compared to carbon nanopaper and (b) calcium deposition; values are mean ±S.E.M; $n = 3$; * $p < 0.1$ compared to Ti; ** $p < 0.1$ compared to anodized Ti; and # $p < 0.05$ compared to carbon nanopaper.

D is equal to $6.7 \pm 0.02 \times 10^{-6}$ cm^2 s^{-1}.[30,31] Hence, the quasi-reversible redox of iron(II/III) is truly enhanced by the novel MWCNT sensors.

To estimate how such sensors would work for bone growth, osteoblasts were cultured for 21 days and energy dispersive spectroscopy (EDS) was performed to verify the presence of the various minerals in newly formed bone. Figure 5 shows the results of one such study doing this in which the peaks of many inorganic substances, consisting of magnesium (Mg), phosphorus (P), sulphur (S), potassium (K), and calcium (Ca), were detected. The Ca/P weight ratio of minerals deposited by osteoblasts in that study on Ti (1.34) was less than that on a MWCNT-Ti sensor (1.52). However, the Ca/P ratio of HA, the main calcium phosphate crystallite in bone, is typically about 1.67.[32,33] This study demonstrated that the minerals deposited by osteoblasts on MWCNT-Ti were more similar to natural bone than the minerals deposited on Ti. X-ray diffraction (XRD) analysis also showed that more HA was deposited on MWCNT-Ti sensors than on both conventional and anodized Ti after 21 days of culture, as shown in Figure 6. In addition, the amount of calcium deposited by osteoblasts as determined by a calcium quantification assay kit was 1.481 μg cm^{-2} for 7 days, 1.597 μg cm^{-2} for 14 days, and 2.483 μg cm^{-2} for 21 days on conventional Ti, as shown in Figure 10(b). These results imply a greater deposition of calcium by osteoblasts on MWCNT-Ti sensors than on currently implanted Ti.

Bone resorption and remodeling involve the secretion of hydrochloric acid (HCl) by osteoclasts.[34] Osteoclasts dissolve bone mineral by isolating a region of the matrix and then secreting HCl and proteinases at the bone surface, resulting in the bone acting as a reservoir of Ca^{2+}, PO_4^{3-}, and OH^- minerals.[35] This can be the reason that HCl is so prevalent in laboratories to dissolve calcium minerals deposited on osteoblast-seeded scaffolds *in vitro* and the supernatant solution is used in a calcium deposition assay. Thus, after dissolving with 0.6 N HCl, it is likely that Ca^{2+}, PO_4^{3-}, and OH^- are contained in the solution of the osteoblast extracellular components.

The formation of bone matrix minerals first depends on achieving a critical concentration of calcium and phosphorus. Then phospholipids, anionic proteins, as well as calcium and phosphorus aggregate in nucleation pores that are in the 35 nm 'hole-zone' between collagen molecules.[36] The addition of calcium, phosphate, and hydroxyl ions contributes to the growth of crystalline HA. However, the crystals are not pure as they also contain carbonate, sodium, potassium, citrate, and traces of other elements, such as strontium and lead. The imperfection of HA contributes to its minerals' solubility, which plays a role in the ability of osteoclasts to resorb the

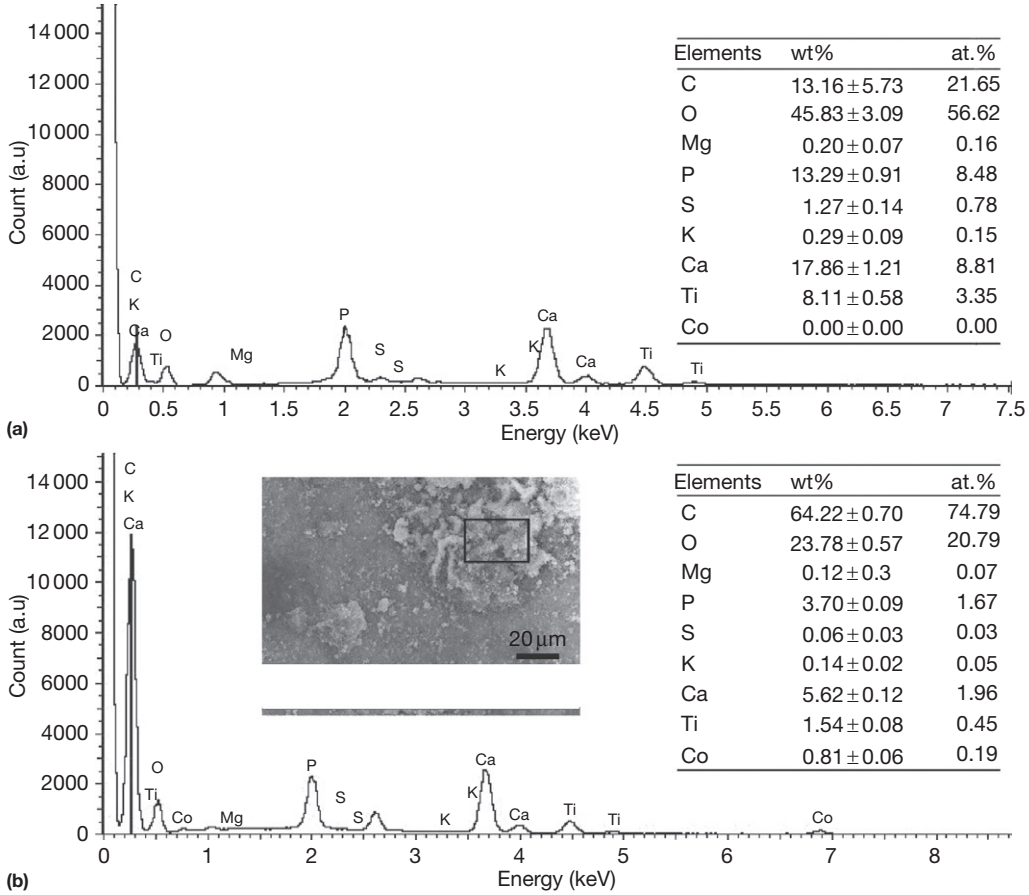

Figure 5 Energy dispersive spectroscopy analysis of osteoblasts cultured for 21 days on (a) Ti and (b) multiwalled carbon nanotube Ti (MWCNT-Ti). Scanning electron microscopy micrograph of inset (b) shows the analyzed area. For the MWCNT-Ti, more Ca and P deposited by osteoblasts were observed. Tables in (a) and (b) show the composition of the mineral deposits after osteoblasts were cultured for 21 days. The Ca/P weight ratio on bare Ti was 1.32 and on MWCNT-Ti was 1.52.

mineral phases. Although osteoblasts synthesize type I collagen, which is the predominant organic component of bone, type III/V/VI collagens also exist in bone. Moreover, noncollagen proteins in bone (such as growth factors, osteocalcin, osteopontin, and osteonectin) and proteins in serum and other tissues (such as fibronectin, vitronectin, and laminin) are absorbed into the mineral component during bone growth. These components are directly involved in the genesis and maintenance of bone. Thus, not only minerals, but also other noncollagen proteins are broken down after dissolution with HCl. As such, nonspecific proteins may exist in the supernatant of bone formation when CV is performed with MWCNT-Ti sensors and may contribute to the observed redox process presented in this chapter. On an electrode surface, the native conformation of a protein may be retained (reversible or diffusion-controlled) or distorted (irreversible or adsorption-controlled), depending on the extent of the interactions (such as the electrostatic or covalent bonds) between them.

The type of electrolyte is important to the redox reaction because the gained capacitance and scan rate window are dependent on it.[37] Studies to date have not degassed with nitrogen or argon when performing the CV with MWCNT sensors; therefore, the redox reactions in CV are related to the H_2O decomposition, which includes H^+ reduction and OH^- oxidation. The pH of the electrolyte also affects the H_2O decomposition. In the case of acidic 1 N HCl solution (without other electroactive molecules), the H^+ ions induced the formation of H_2 gas at -0.2 V as a result of the increased reduction current.[37] In the alkaline 1 M KOH solution, OH^- ions resulted in the formation of O_2 gas at 0.7 V by the oxidation process. This fact should be noted because *in vivo*, these decompositions may occur at the interface of the Ti implant because of pH changes and the presence of H_2O and O_2 around the implant.

Other studies have shown promising results when using CNT-modified electrodes in biosensing. As MWCNTs have good electrochemical characteristics as electron mediators and adsorption matrices,[38] they may further enhance applications in biosensor systems. For example, Harrison and Atala[11] showed that CNTs offer a promising method to enhance detection sensitivity because they have high signal-to-noise ratios. The structure-dependent metallic character of CNTs should allow them to promote electron-transfer reactions for redox processes, which can provide the foundation for unique biochemical sensing systems at low overpotentials.[19] The electrolyte–electrode interface barriers are reduced by CNTs because they facilitate double-layer effects.[39] Typically, when the supporting electrolyte is at least a 100-fold stronger than the active electrolyte,[40] the charge in the electrolyte solution causes the Debye layer

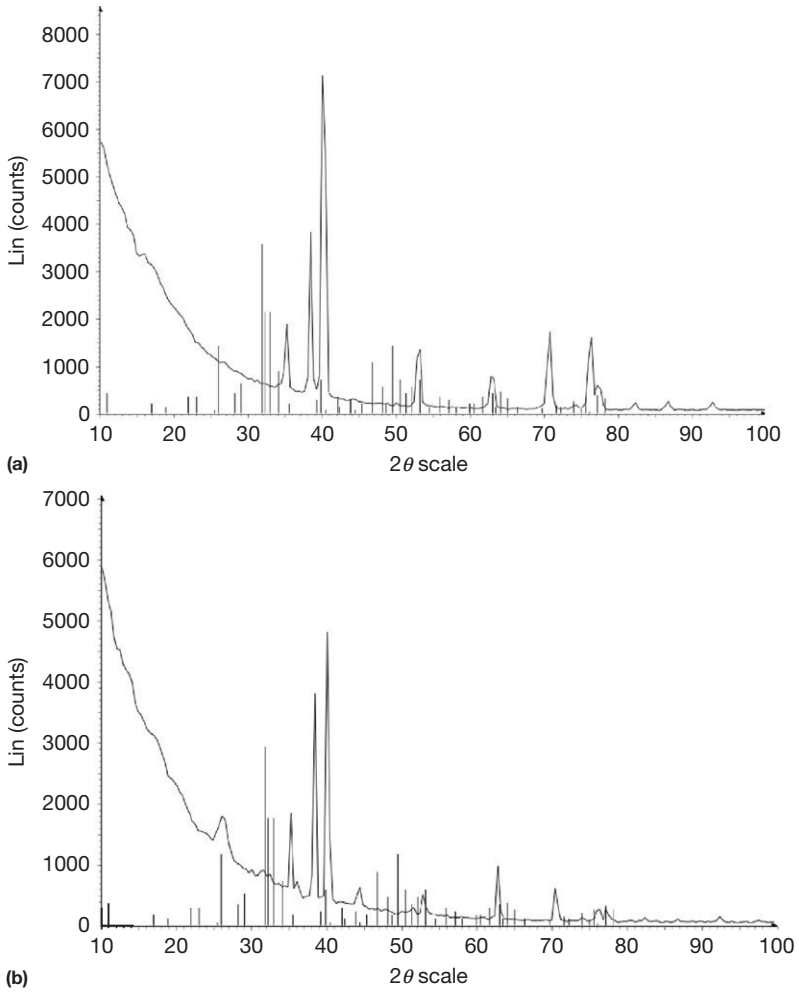

Figure 6 X-ray diffraction analysis of hydroxyapatite-like (HA; $Ca_5(PO_4)_3OH$) deposited minerals after osteoblasts were cultured for 21 days on (a) Ti and (b) multiwalled carbon nanotube Ti (MWCNT-Ti). The micrographs show that the peak pattern of HA more closely matches that of the mineral deposited by osteoblasts when cultured on MWCNT-Ti than on Ti.

to be more compact. Therefore, this compact layer can rapidly exchange electrons between electroactive proteins and the surface of an MWCNT-Ti electrode. This is likely the reason why sharpened cathodic and anodic peaks have been observed in CV, as shown in Figures 7(c), 8(c), 9(b), and 7(a).

Although the area of the working electrode is constant in the presence of MWCNTs, the overall surface area and the electroactivity of the surface are increased. The MWCNTs act as a nanobarrier between the titanium oxide layer, which was their growth template, and the electrolyte solution. The surface atoms or molecules of MWCNTs play an important role in determining their bulk properties because of their nanosize effects.[41] A large surface, corresponding to the greater electrocatalytic activity, confers a catalytic role on the MWCNTs in the chemical reaction. Well-defined and persistent redox peaks are shown in Figure 7(c), confirming the increases of electron transfers and higher electrochemical activities at the MWCNT-Ti surface. CV was also performed with a glassy carbon electrode (GCE; bioanalytical) and a platinum electrode (PTE; bioanalytical), and it also showed $\Delta E_p > 59/n$ mV (data not shown). Importantly, for the same scan rate, CV of GCE and PTE showed the redox reactions with similar but more widely separated anodic and cathodic peaks, confirming the performance of the MWCNT-Ti electrode.

However, in Figure 7(a) and 7(b), the Ti and anodized Ti did not show any redox peaks. This is likely due to the inert inhibiting property of the titanium oxide on electron transfer through them. Figure 7(a) and 7(b) show that bare Ti has less capacitance than MWCNT-Ti. The capacitance relation is derived from $i = C\left(\frac{dv}{dt}\right)$, where $\frac{dv}{dt}$ is a scan rate.[28] Hence, the capacitance between the working and reference electrodes during CV was calculated by dividing the current in CV by the specific scan rate, as shown in Figures 7(d) and 9(d). In summary, the electrochemical response of the MWCNT-Ti electrode promoted a higher charge transfer than the Ti and anodized Ti electrodes.

5.523.5. Discussion

The result from the previous section and studies showed the utility of MWCNT-Ti as an electrode for detecting $Fe^{2+/3+}$ redox couples. For biological applications, it is also necessary

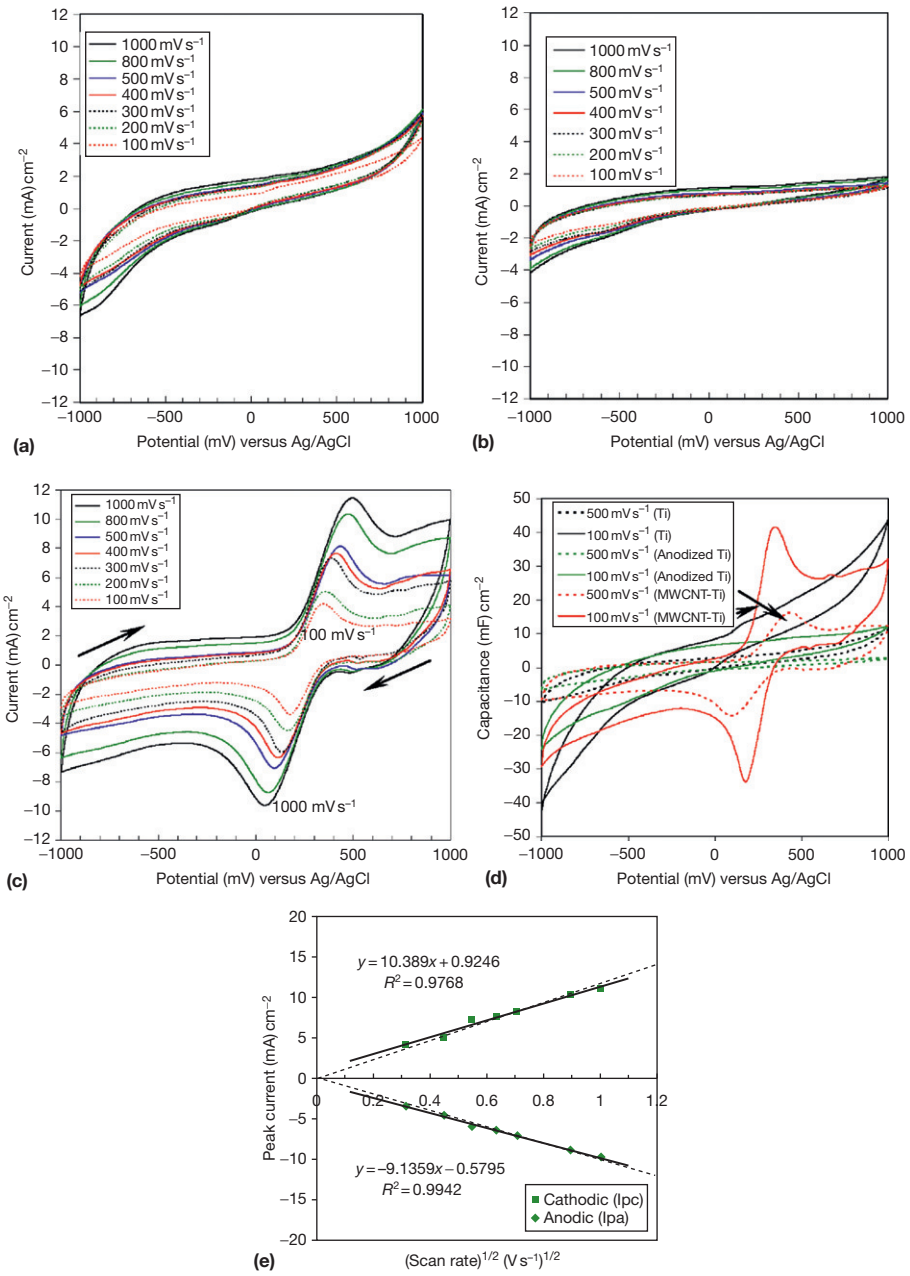

Figure 7 Cyclic voltammograms with an electrolyte solution of 10 mM $K_3Fe(CN)_6$ in 1 M KNO_3 for: (a) conventional Ti; (b) anodized Ti; and (c) multiwalled carbon nanotube Ti. (d) The capacitance of all the electrodes in comparison. (e) The plot of the square root of scan rates with anodic peak currents (I_{pa}) and cathodic peak currents (I_{pc}).

to show that MWCNT-Ti can detect redox reactions associated with osteoblast differentiation. The extracellular components from osteoblasts in an HCl solution have been used to mimic the biological environment around an orthopedic implant. Figure 8(a) and 8(b) show that the bare Ti and anodized Ti electrodes cannot detect any redox process. The results in Figure 8(c) confirmed that MWCNTs enhance the direct electron transfer through Ti by means of the highly conductive surface of the MWCNTs.

After decreasing the surface area of the MWCNT-Ti electrode from 1 cm^2 to 1 mm^2, the redox potentials were also decreased as shown in Figures 8(c) and 9(b). The faradic current of the oxidation process dropped ~10 times with respect to a decrease in surface area A, corresponding to eqn [1]. Corresponding with the Randles–Sevcik equation, the peak current was linearly proportional to the area. When plotting the anodic (I_{pa}) and cathodic peak (I_{pc}) currents of MWCNT-Ti, a linear relationship to the square root of the scan rates was observed, as shown in Figure 9(c).

The CV showed well-defined redox peaks in the osteoblast supernatants at all concentrations. The peaks detected in the solution at the calcium concentrations of 1.481 $\mu g\,cm^{-2}$ (after 7 days), and 1.597 $\mu g\,cm^{-2}$ (after 14 days) have less faradic current and I–V graph area than the concentration

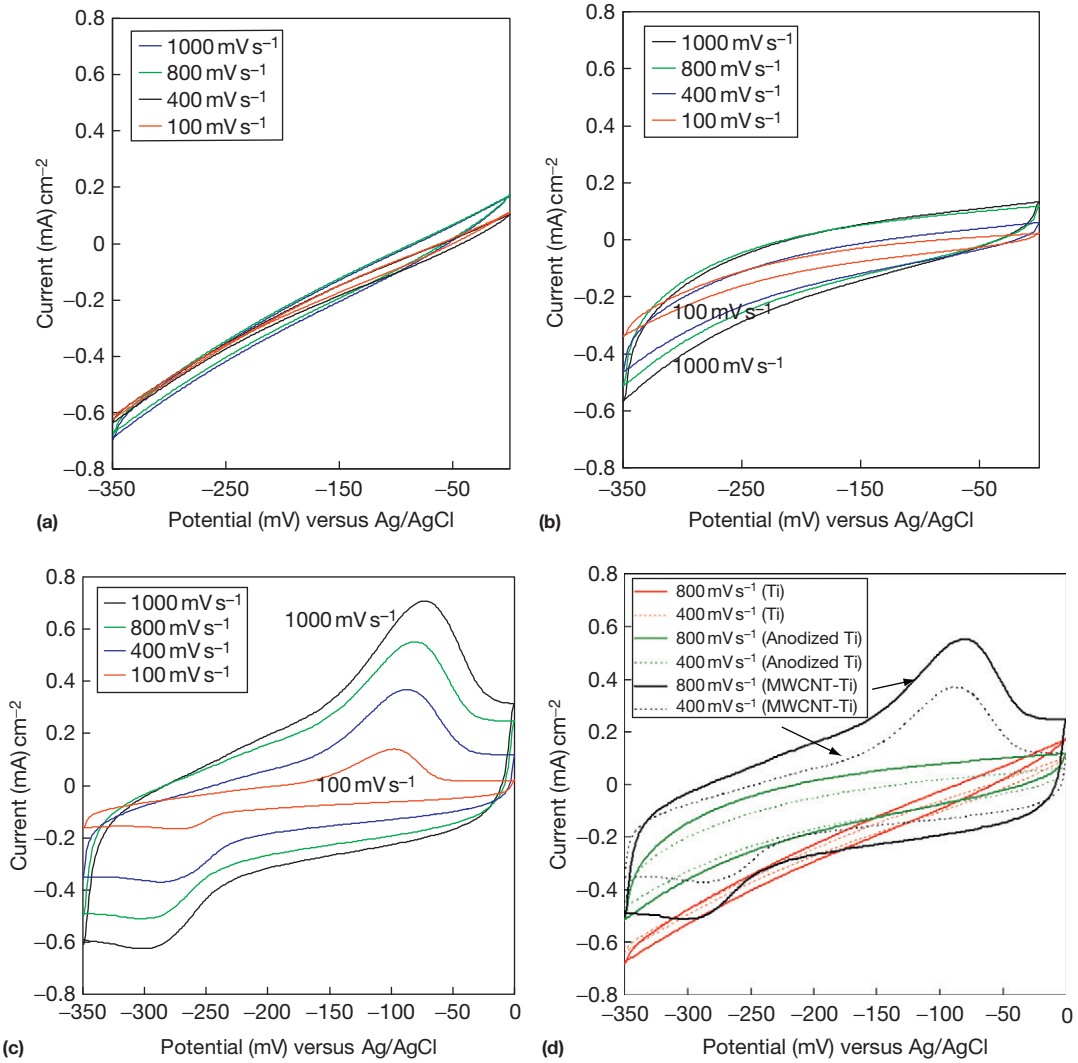

Figure 8 Cyclic voltammograms (CVs) with an electrolyte solution of the extracellular matrix secreted by osteoblasts after 21 days of culture for (a) conventional Ti; (b) anodized Ti; and (c) multiwalled carbon nanotube Ti (MWCNT-Ti) with a working area of 1 cm^2. (d) CV of all three electrodes in comparison. Only MWCNT-Ti possessed the quasireversible redox potential, while conventional Ti and anodized Ti did not.

of 2.48 $\mu g\,cm^{-2}$ (after 21 days), as shown in Figure 10(a) and 10(b). Typically, the more HA deposited and synthesized by osteoblasts, the higher the calcium and protein concentrations are. Therefore, it is likely that the supernatant of 21 days had higher protein concentrations than the solutions of 7 and 14 days, leading to the stronger redox reactions and higher capacitance between the electrode surfaces.

In addition, interpretation of CV results must consider other factors. In particular, a measurement of the redox reactions when oxygen was dissolved in the electrolyte solution showed that the peak currents were shifted toward negative values. Furthermore, a change in the pH of the electrolyte solution and the presence of water may also shift the current and affect the potential of the redox peaks. Thus, CV with the potential range between − 1 and 1 V of MWCNT-Ti was performed in a pure solution of 0.6 N HCl without other proteins or ions. An H^+ reduction peak at a potential between − 0.5 and − 0.8 V was found (data not shown). Moreover, the H^+ reduction peak still appeared when window ranges from − 5 to 5 V and from − 0.35 to 0 V were used, confirming that H_2O decomposition occurred in our CV experiments.

It is clear the MWCNT-Ti electrodes showed the potential for better performance than commercially available electrodes, such as GCE and PTE. When using the sweep voltage from − 1 to 1 V, a set of mixed redox peaks with two oxidations and two reductions appeared (data not shown). These two redox peaks in the CV indicated that the process likely involved more than one-electron transfer. For each couple, the amplitude and position of the oxidation peak in CV were unequal to those of the reduction peak. The second oxidation peak (omitted from Figures 8(c) or 6(b)) was observed at 236 mV for the MWCNT-Ti electrode, 405 mV for the GCE, and − 33 mV for the PTE, all with a scan rate of 100 $mV\,s^{-1}$. However, for the GCE and the PTE electrodes, a second reduction did not appear, while the MWCNT-Ti showed two complete and well-defined redox reactions. These two peaks reflected that more than one-electron transfer was involved; one occurred at a positive and the other at a negative potential

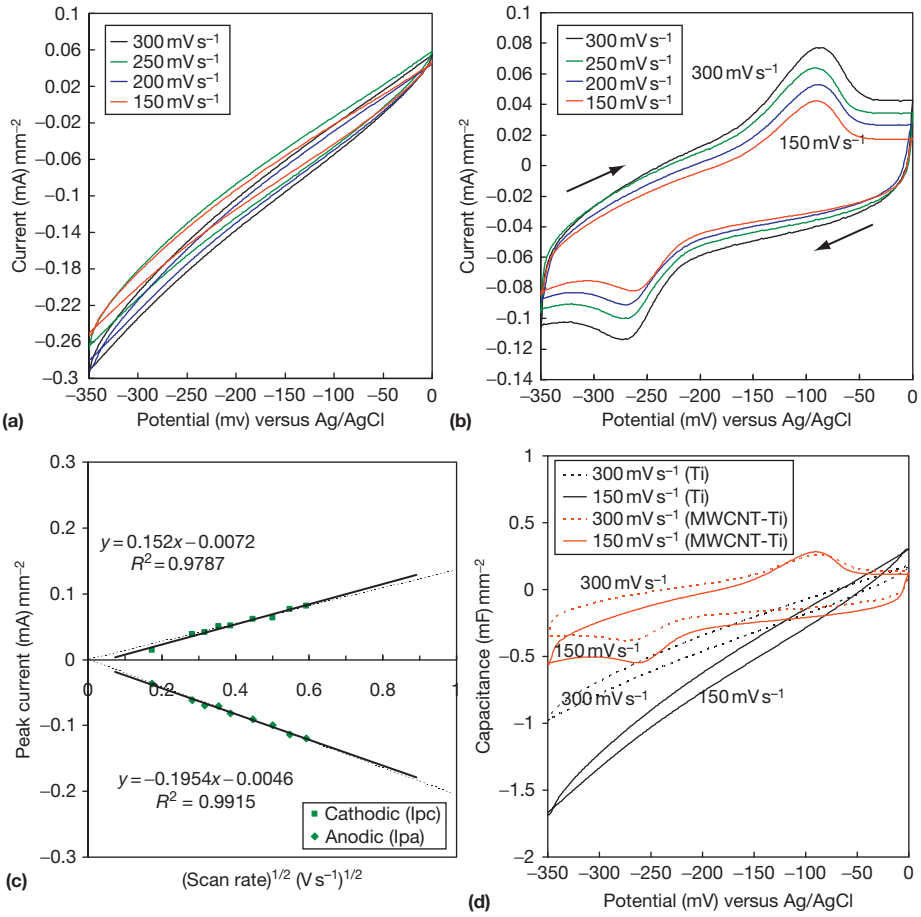

Figure 9 Cyclic voltammograms with an electrolyte solution of the extracellular matrix secreted by osteoblasts after 21 days of culture for (a) conventional Ti and (b) multiwalled carbon nanotube Ti (MWCNT-Ti) with a working area of 1 mm^2. (c) Plot of the experimental cathodic and anodic peak currents, obtained from (b), versus the square root of the scan rates, and (d) the compared capacitance of MWCNT-Ti and Ti.

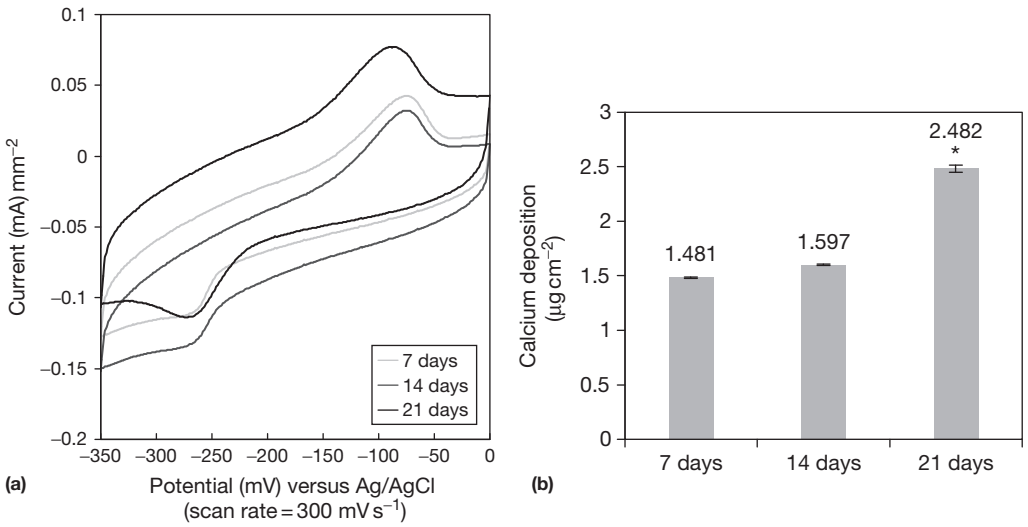

Figure 10 (a) Cyclic voltammograms of multiwalled carbon nanotube Ti electrodes in an electrolyte solution of the extracellular matrix secreted by osteoblasts cultured on conventional Ti after 21 days. (b) Results from the calcium deposition assay determined calcium concentrations in an electrolyte solution of the extracellular matrix secreted by osteoblasts on conventional Ti after 7, 14, and 21 days of culture. in the CV. Further, the current amplitude for the MWCNT-Ti peaks was noticeably larger than that for GCE and PTE. Thus, it can be concluded that the MWCNT-Ti electrode had higher electron transfer as well.

At first, it can be hypothesized that these redox reactions happened because of redox of inorganics such as Ca or P. In the case of Ca, the reduction of Ca^{2+} to Ca crystal (nucleation) typically is expected with the reduction current for a highly negative potential. A positive feedback on IR compensation (IRC) needs to be applied to the CV in order to drive the oxidation current to dissolve the Ca crystal into Ca^{2+}. For example, an overpotential of more than − 1 V, IRC of 0.771 Ω, melting temperature of 900 °C, and scan rate of 50 mV s^{-1} were required.[42] Without applying IRC in this study, diffusion-controlled behavior, which electrochemically depletes calcium cations near the electrode surface, has been impossible to achieve. In addition, the reduction and oxidation of titanium oxides, which are the reaction counterparts of calcium redox, appeared at a positive potential between 0 and 0.25 V, respectively, which did not appear in our CV studies. In the case of P, the CV experiments have been performed further in phosphate buffered saline (PBS). A final concentration of 1 M PBS, which was prepared in-house, had 137 mM NaCl, 10 mM phosphate, 2.7 mM KCl, and a pH of 7.4. The metal orthophosphate ions exhibit a high stability to reduce from P(V) (such as PO_4^{3-}, PO_4^{-}) to P(III), or further to P(I). However, no redox peaks appeared in the potential range of − 1 to 1 V (data not shown). It is therefore likely that neither the redox reactions of calcium ions nor of phosphate occurred because of the absence of the peaks. Instead, it has been hypothesized that the appearance of the redox peaks when using an MWCNT-Ti electrode is likely because of the reduction and oxidation of proteins from the osteoblast supernatant.

The observed quasireversible redox reaction reflected the fact that MWCNT-Ti sensors promote electrochemical reactions. However, an irreversible process can occur at the interface of an electrode because of the denaturation of proteins, or ion reduction. Typically, when the carbon bonds of proteins are changed, irreversible organic reduction or oxidation only happens.[43] The configurations of ions (Ca^{2+}, PO_4^{3-}, OH^{-}) which remain unchanged can also lead to the irreversible process, only because of their reduction or oxidation. Importantly, without MWCNTs on the Ti surface, nonspecific protein adsorption may readily occur, leading to an electrochemically insulating surface layer. Nevertheless, the redox at MWCNT-Ti did not decrease its oxidation and reduction current after applying the sweep voltage for some time, so protein adsorption did not occur apparently in significant amounts at the MWCNT-Ti electrode. Indeed, in the osteoblast supernatant, the MWCNT-Ti electrode provides a relatively specific surface to which the proteins can bind reversibly by diffusion while retaining their function. The protein redox is also dependent on the pH of the electrolyte solution (acidic or basic).[44] This shift appears because of the influence of 0.6 N HCl with H_2O as a solvent which influences proteins, leading the peak shift into the negative potential, as shown in **Figures 8(b)**, **9(c)**, and **10(a)**.

It has been hypothesized that proteins were involved in these redox reactions at the surface of MWCNT-Ti in the solution of osteoblast extracellular components. If those proteins maintain their function and are detected by the MWCNT-Ti electrode, the excellent electrochemical behavior explained here may show that MWCNT-Ti sensors are superior candidates for biosensor applications. However, investigating the type and size of acidic resistant proteins is still in progress.

As shown here, the electrodic performance of MWCNT-Ti sensors, but not of the bare Ti, provides excellent redox reactions. As mentioned, the electrochemical experiments were performed so far without degassing with bubble nitrogen gas. This omission may have resulted in an apparent background signal, which was mixed and appeared in current–voltage curves (*CV*). Moreover, the redox reaction at the MWCNT-Ti sensor mentioned here may depend on various ion sources, including reversible protein adsorption, dissolved oxygen, and acidic nature of HCl. However, the redox reactions of iron(II/III) and the osteoblast extracellular components still occurred only when using MWCNT-Ti sensors, and not when using Ti or anodized Ti. Importantly, it was shown that MWCNT sensors performed as the electrocatalysts for the oxidation and reduction of iron(II/III) and of extracellular components, which included various proteins and inorganic substances synthesized and deposited by osteoblasts.

The electrolyte solution of osteoblast extracellular components was composed of inorganic and organic substances. This solution was not classified in terms of the types of molecules in solution, but rather, all components were dissolved together in the acidic solution and used in all CV experiments in this study. Future work needs to classify the type of proteins in such osteoblast supernatants.

However, it is likely that *in vivo* the capacitance and the electroactive surface of Ti will be enhanced after bone tissue is formed without the presence of MWCNTs. After hip implant insertion, blood and body fluids surround the Ti implant, creating a specific capacitance for the Ti electrode in the beginning. Within 1 month, as osteoblasts deposit calcium around the implant, the capacitance of the implant and bone tissue increases. Cell membranes also have electric potentials and perform redox processes,[45,46] and it has been found that after 14 days *in vitro* these redox processes at the surface of bare Ti increased.

In vitro, nevertheless, MWCNTs have been used to modify the electrodes to detect other biomolecules, such as nicotinamide adenine dinucleotide (NADH),[47] hydrogen peroxide,[21,47] glucose,[22] putrescine,[48] and DNA,[49] Specifically, the growth of MWCNTs from nanoporous metals electrodes can enhance many diverse sensor applications. For example, MWCNTs functionalized with thiol groups have been used for sensing aliphatic hydrocarbons (such as methanol and ethanol), forming unique electrical identifiers.[18] Moreover, MWCNTs grown on silicon substrates enhanced ionic conductivity and have been integrated with unmodified plant cellulose as a film, and used as a cathode electrode in a lithium ion battery, or as a supercapacitor with bioelectrolytes (such as biological fluid and blood).[50] Interestingly, both supercapacitors and batteries derived from a MWCNTs-nanocomposite film, can be integrated to build a hybrid, or dual-storage battery-in-supercapacitor device. The cytocompatible MWCNT device may be useful to integrate with an orthopedic implant biosensor as passive energy storage.

Not only can an implanted electronics circuit be powered by an implant battery (fabricated or self-integrated) within the

implant material, but it also can be induced by an external power supply. For orthopedic applications, telemetric devices started in 1966 and became imperative as telemetric orthopedic implants in order to transmit a signal to an external device.[51–56] For example, Graichen *et al.*[57] developed a new 9-channel telemetry transmitter used for *in vivo* load measurements in three patients with shoulder Ti endoprostheses. The low radio frequency (RF) of an external inductive power source generates power transmission through the implanted metal. At the end of the Ti implant, the pacemaker feedthrough rounds a single loop antenna to transmit the pulse interval signal, which is modulated at a higher RF by the microcontroller, to an external device. Then, the RF receiver of the external device synchronizes with the modulated pulse interval to recover the data stream and report to a clinician. Thus, either an implanted battery or a telemetry system can supply the electrical power to a calcium-detectable chip inside the orthopedic implant for clinical use.

The automatically sensing concept for bone growth juxtaposed to orthopedic implants can also apply for determining infection and scar tissue formation (for more on bacteria and the immune response to implants see **Chapter 4.404, Adaptive Immune Responses to Biomaterials**; **Chapter 4.406, Protein Interactions with Biomaterials**; and **Chapter 4.407, Bacterial Adhesion and Biomaterial Surfaces**). An energy source energizes a telemetric-implanted circuit, and allows it to transmit data to an external receiver to determine bone growth. Indeed, the electrochemical biosensor may reduce the complexity of imaging techniques and patient difficulties.

5.523.6. Conclusions

The capabilities of using titanium (Ti) as an electrochemical electrode have been increased remarkably by growing MWCNTs out of anodized Ti nanopores (MWCNT-Ti). MWCNTs improved the sensitivity of the bare Ti electrode displaying redox peaks in CVs and interestingly high capacitance. Such results provide evidence that MWCNT-Ti can serve as a novel electrochemical electrode with great electrocatalytic properties due to increased surface area and conductivity. Moreover, MWCNTs were shown to be more highly electroactive in chemical transformation than the metallic (Ti) surface, which typically undergoes electrochemical oxidation or dissolution of metal oxides, but is chemically susceptible to corrosion. MWCNTs promoted a redox reaction by enhancing the direct electron transfer through their electrically conductive surface surrounded by ionic solutions, which contained the electroactive species, herein ferri/ferricyanide and the extracellular components from osteoblasts. Moreover, MWCNTs are cytocompatible, promoted osteoblast differentiation after 21 days, and can be integrated into a supercapacitor or battery to enhance the functionalities of biosensing systems *in vivo*. Therefore, MWCNT-Ti sensors are exceptional candidates as electrochemical electrodes to determine *in situ* new bone growth surrounding an orthopedic implant. Further, the ability of MWCNT-Ti to sense osteoblast extracellular components by detecting their redox reaction profiles in specific concentrations may improve the diagnosis of orthopedic implant success or failure, and thus improve clinical efficacy.

Glossary

Annulus fibrosus (AF) A highly organized fiber-reinforced, layered fibrocartilage and critical component of the intervertebral disc in the spine. The AF is a highly organized fiber-reinforced, layered fibrocartilage. Within each lamella, collagen fibers are oriented at 28°–44° with respect to the transverse axis and fiber angles in adjacent lamella alternate. AF mechanical properties are anisotropic (i.e., directionally dependent) and intrinsically nonlinear.

Fibrocartilage A tissue whose composition is reflective of fibrous tissues (such as tendons and ligaments) that are collagen-rich and designed to withstand tensile loading, and cartilaginous tissues (such as the articular cartilage lining the ends of long bones) that are both collagen- and proteoglycan-rich and designed to withstand a more complex compressive loading environment.

Intervertebral disc A mechanical fibrous tissue-bearing surface between vertebrae that supports loads, permits motion, and dissipates spinal loading energy with daily activities. Incorporated into the motion segment, this semi-flexible symphysis joint (i.e., the bone–disc–bone unit) is subjected to compression, tension, bending, and torsion with normal activities. The intervertebral disc comprises four distinct subcomponents: the vertebral body attachments, the cartilaginous endplate, the gelatinous nucleus pulposus (NP), and the fiber-reinforced annulus fibrosus (AF).

Knee meniscus A cartiligous tissue in the knee joint positioned such as to add congruity to the joint and act as a bushing to complete the curvature of the femoral condyle as it impinges on the tibial plateau. Its chief functions are to transmit and distribute load over the tibial plateau, increase joint congruency, stabilize the joint, and improve articular cartilage nutrition and lubrication.

Abbreviations

ACL	Anterior cruciate ligament
AF	Annulus fibrosus
BMP2	Bone morphogenetic protein 2
CAIS	Cartilage autograft implantation system

5.524.1. Overview

Dense fibrous connective tissues play critical load-bearing roles in the musculoskeletal system and represent a significant medical problem when their function is interrupted by progressive degeneration or acute injury. In this chapter, we outline the functional aspects of two such tissues, the fibrocartilaginous knee meniscus and the annulus fibrosus (AF) of the intervertebral disc of the spine. We discuss the hallmark mechanical and biochemical features of each tissue, the incidence and most common avenues through which the tissues are damaged or degenerate, and the current clinical practices for their repair and/or replacement. Given the prevalence of damage to these tissues, numerous commercial products are, or will soon be, available in the marketplace. These products are discussed in the context of the structure and function of the native tissue they are intended to replace. The biomaterials chosen for the implants, the engineering principles applied to the design of the products, and their current regulatory status are explored. Finally, functional benchmarks, preclinical models, and future directions in this burgeoning field are reviewed.

5.524.2. Introduction

As the name implies, a fibrocartilage is a tissue whose composition is reflective of fibrous tissues (such as tendons and ligaments) that are collagen rich and designed to withstand tensile loading, and cartilaginous tissues (such as the articular cartilage lining the ends of long bones) that are collagen and proteoglycan rich and designed to withstand a more complex compressive loading environment. Specific examples of fibrocartilaginous tissues are the knee meniscus, the temporomandibular disc, and the intervertebral disc. However, other structures, such as the regions of tendons that wrap around a boney prominence, exhibit a local transition toward the fibrocartilaginous phenotype, indicating that fibrocartilage can arise inhomogeneously through otherwise homogeneous tissues, based on the local mechanical environment. These and other fibrocartilages are distributed throughout the body (see Table 1).

In the adult, fibrocartilage is typified by a dense collagenous structure, most of which is type I collagen (see Table 2). These molecules are generally assembled into large bundles oriented in the direction of primary tensile loading. Proteoglycans (PGs) are present within the tissue, but at a considerably reduced level compared to articular cartilage. Indeed, rather than being distributed throughout the tissue substance, in the meniscus, for example, most PG is located between fiber bundles. These tissues are also relatively acellular in the adult, though all progress through a cell-rich phase during development. They likewise generally lack a robust vascular supply. This, coupled with the low cellularity, severely retards endogenous repair when such tissues are damaged acutely after skeletal maturity.

In this chapter, we focus on two prominent examples of fibrocartilage, the knee meniscus and the AF of the intervertebral disc of the spine (see Figure 1). This focus is mandated by the unique features that define these tissues, the incidence with which their function is interrupted, and the negative sequelae that result from their dysfunction in terms of health and quality of life.

5.524.3. Structure and Function of the Knee Meniscus

The tibiofemoral joint represents a significant engineering challenge, where stability and the need for significant range of motion countermand one another. Unlike hinge joints (e.g., in the digits), multiple degrees of freedom are required to allow mobility. Anatomically, the knee consists of the interaction between the rounded femoral condyles and the relatively flat tibial plateau. The two boney portions are held together via the intraarticular (i.e., anterior cruciate and posterior cruciate) and extra-articular (i.e., medial and lateral collateral) ligaments, with contributions via the patellar tendon and the flexors and extensors of the thigh. The knee menisci, of which there is a medial and a lateral in each knee, are positioned such as to add congruity to the joint and act as a bushing to complete the curvature of the femoral condyle as it impinges on the tibial plateau.

In the adult meniscus, the inner avascular region is more like hyaline or articular cartilage, with a higher concentration of PGs, while the outer vascular region is more fibrous, with a higher collagen content. This is particularly the case in the body of the meniscus as compared to the horns.[5] The meniscus extracellular matrix (ECM) contains 85–95% dry weight collagen, of which greater than 90% is type I,[6] with the remaining collagen consisting mostly of types II, III, V, and VI[7] (see **Table 2**). These collagens of the meniscus are of the most highly cross-linked in the body, providing the tissue with a tough fibrous character.[8] PGs makes up less than 2–3% of the dry weight, eight times less than is seen in articular cartilage.[7–9] The meniscus, like articular cartilage, is highly hydrated, with 72–77% of the wet weight comprised of water.[9]

In terms of vascularity, the peripheral 10–25% of the meniscus is supplied by a perimeniscal capillary plexus, while the inner stroma is largely avascular.[10,11] During development, the meniscus is vascular throughout, though these vessels regress with time.[11–13] Similarly, the cell type of the meniscus (i.e., the meniscus fibrochondrocyte) is a heterogeneous population – in the inner avascular region these cells have a chondrocyte-like phenotype, while in the outer rim these cells are fibroblast-like in appearance and matrix deposition.[14,15] In both regions, a significant decrease in cell density is observed with skeletal maturation.

As may be expected for such a fiber-reinforced matrix, the mechanical properties of this tissue are highly anisotropic and strongly dependent on the prevailing fiber direction[16,17] (see **Figure 1**). The tensile properties of the meniscus range from 48–259 MPa in the circumferential direction and 3–70 MPa in the radial direction.[2,8,16–21] The compressive properties of the meniscus varies between the species and with location (e.g., it is highest anteriorly)[8,12,22] but it is approximately one-half that of articular cartilage (100–400 kPa, aggregate modulus). The meniscus, while having a lower modulus, is also much less permeable than articular cartilage,[8] suggesting that the tissue is optimized to enhance congruency, load distribution, and shock absorption across the joint.[17]

The main functions of the meniscus are to transmit and distribute load over the tibial plateau, increase joint congruency, stabilize the joint, and improve articular cartilage nutrition and lubrication.[23] These functions are achieved by the unique load shifting that occurs between the more hyaline inner region and the more fibrous outer region of the meniscus. When the joint is loaded, axial loads impinging on the wedge-shaped portion of the meniscus are redirected laterally, causing lateral extrusion. This extrusion is resisted by the osseous anchors originating from the anterior and posterior horns,[17] generating hoop stresses within the dense network of circumferentially oriented collagen fibers. Lateral extrusion is thereby resisted and the joint stabilized.[2,12,23,24] The secondary stability offered by the meniscus is particularly important in the anterior cruciate ligament (ACL) deficient knee.[25] With normal knee kinematics, forces that are many times the body weight may be generated within the joint.[26–30] The menisci transmit 50–100% of joint load in a healthy knee,[24,27,31] which results in deformations within the tissue on the order of 2–6% with normal activity.[32,33]

5.524.4. Structure and Function of the AF

The spine is comprised of repeating soft and hard segments; the hard segments are the boney vertebral bodies, and the soft

segments are the intervertebral disc (IVD) that is interposed between them. The function of the IVD is mechanical – it supports loads, permits motion, and dissipates energy with daily activities. This semiflexible symphysis joint (i.e., the bone–disc–bone unit) is sometimes referred to as the motion segment. Motion about this joint subjects the intervening disc to compression, tension, bending, and torsion with normal activities. Loads acting across this joint can reach many times the body weight, given the relatively short lever arms (e.g., the spinous processes and the inferior and superior articular processes that interact through synovial facet joints) over which the muscles of the back operate. This translates to stresses acting on the IVD reaching ~1 MPa applied at frequencies of 1 Hz, with superimposed rotations ranging up to ±6°.[34] These considerable and varied mechanical forces necessitate the complex and durable organization and mechanical properties of the IVD and its substructures.

The IVD itself is typically considered as having four distinct subcomponents: the vertebral body attachments, the cartilaginous endplate, the gelatinous nucleus pulposus (NP), and the fiber-reinforced AF (see **Figure 1**). The AF is a highly organized fiber-reinforced, layered fibrocartilage. Within each lamella, collagen fibers are oriented at 28–44° with respect to the transverse axis,[35,36] and fiber angles in adjacent lamella alternate. The mechanical properties of AF are anisotropic (i.e., direction dependent) and nonlinear, and are compromised in degeneration.[37–41] The major constituents of the IVD are collagens (50–70% dw) and PGs (10–50% dw).[42,43] The collagens provide high tensile properties to the AF, while PGs in the NP allow it to resist large compressive loads. AF and NP cells are distinct in phenotype, with NP cells more chondrocyte-like, producing type II collagen and PG, while AF cells are fibrous, producing less PG and a mix of collagen I and II.[44–48]

5.524.5. Current Clinical Treatments for Damage to or Degeneration of the Meniscus and AF

Given the central location of the meniscus in terms of knee function, and the AF in terms of spine function, it is not surprising that these two tissues are prone to injury, and that failure leads to significant health issues. This section describes current treatment modalities that do not rely heavily on the use of implanted biomaterials.

5.524.5.1. Current Meniscus Repair Methods

While the meniscus can function well over a lifetime of use, 60–70 meniscus tears per 100 000 persons occur each year.[49–51] Given this prevalence, arthroscopic treatment of meniscal injuries has become one of the most common orthopedic procedures performed in the United States.[52] Tears that occur longitudinally (i.e., splitting between fibers) are amenable to repair when located in the peripheral or vascular zone. The most common and successful repair strategy for these tears is to suture torn structures back into apposition, either via open repair or arthroscopic surgery.[53] Arthroscopic methods include the inside-out technique (i.e., inside the joint capsule to outside the meniscus periphery) and the outside-in technique (i.e., from the periphery to the internal space).[54,55] Symptomatic radial tears located in the avascular region that interrupt collagenous architecture present a more difficult problem, and current treatment strategies involve partial meniscectomy without an effective alternative. Partial meniscectomy changes load transmission in the knee, and can lead to radiographic narrowing of the joint space.[56] In animal models, partial meniscectomy leads to erosion of the underlying cartilage over the long term. If repair is attempted in the avascular region, rasping of the synovium or the intercondylar notch is employed to increase the vascular response.[57,58] Indeed, it has been suggested that whenever repair of the avascular zone is attempted, some form of healing enhancement technique should be considered.[54]

When damage to the meniscus is considerable, such that all the meniscus is compromised, allograft transplantation of a whole fresh-frozen or cryopreserved meniscus from a human donor can be attempted. Allografts restore some aspects of load transmission after total meniscectomy. However, several studies have reported cartilage degeneration following implantation, most likely attributable to improper sizing of the implants.[59–62] This finding may be related to the fact that isolated tears and partial meniscectomy have very similar results,[63] suggesting that even a minor structural abnormality can lead to a change in meniscus function and can translate into significant damage to the articular surface. Moreover, allografts raise concerns regarding the methods of cryopreservation, graft sterility, and the proper method of fixation.[61] Clinical results suggest that function is only partially restored and that poor integration makes the grafts susceptible to premature failure.[64] These findings highlight the need for a functional repair strategy short of total replacement for the clinical treatment of meniscal tears.

5.524.5.2. Current AF Repair Methods

As with the meniscus, back pain arising from damage or degeneration of the soft tissues of the spine is a significant health problem in society; it is the most common reason that adults under the age of 45 limit their daily activities.[65] While genetics and other factors play a role, patterns of activity also have an impact on spine health and back pain. Disc pain is particularly prevalent in active populations, such as those in active duty military service. In one study, as many as 44% of US Gulf War veterans reported low back pain within 2–5 years following service, an incidence rate that is 14% higher than nonactive duty veterans and nearly twice that of the general US population.[66] Degeneration of the disc involves progressive failure of each of the substructures. In the NP, a loss of PG results in depressurization and increasing tissue fibrosus. In the AF, tensile mechanical properties decrease and internal collapse is observed.[37]

When the source of back pain is typically from tears of the AF, patients typically present with pain and radicular neurological complaints (e.g., weakness and parasthesias) resulting from the extruded NP impinging on a nerve root or nerve. Imaging and a thorough physical exam can help identify the level of involvement of the spine. In many patients, nonsurgical methods of treatment can alleviate symptoms; these treatments include activity modification, traction, soft collars, nonsteroidal anti-inflammatory drugs, selective nerve root injections, and physical therapy. Failing those treatments,

surgical intervention may offer relief in indicated patients. The mainstay of surgical treatment is a decompression of the affected nerve root, usually involving a foraminotomy or laminoforaminotomy, and possibly fusion.[67] A foraminotomy is the surgical opening (or deroofing) of the interverbral foramina, while laminoforaminotomy refers to surgically opening the lamina as well. Decompression can be achieved by annulotomy followed by discectomy or microdiscectomy. Newer experimental methods utilize low-energy radiofrequency waves to create an ionic plasma field from sodium atoms within the nucleus. The tissue is converted into gas by molecular disassociation, thereby achieving intradiscal decompression.[68]

When decompression is not enough, the next level of surgical intervention is rigid stabilization or fusion of adjacent vertebral bodies. Rigid stabilization involves fixing the distance between two adjacent vertebral bodies via metal implants that run along the spinal column and are fixed to the bone stock of the vertebral body. Fusion describes the process by which the disc is removed and replaced with materials, usually bone graft, to encourage boney connections between adjacent vertebral bodies. Fusion is a terminal procedure that completely eliminates motion at that segment. Products on the market, based on BMP-2 delivery from collagenous sponges within a titanium cage, seek to achieve fusion in a faster and more predictable way and reduce the need for allograft or autograft bone materials (e.g., INFUSE Bone Graft, Medtronic Sofamore Danek). While both traditional and BMP-2 enhanced fusions do reduce pain at the affected spinal segment, adjacent disc disease has been reported due to the reduced mobility at the fused segment.[69–71]

While not in widespread use, several reports of allogeneic disc transfer from cadaveric sources exist. In the mid-1990s, disc allograft transplants were performed in canine and nonhuman primate studies.[72–74] In the rhesus monkey, disc autografts and allografts were anchored from the outer AF to the adjacent transverse processes via sutures; no other fixation was applied.[72,73] Complete bony union was achieved, some cell metabolism was reported, and biomechanics were similar to control. However by 24 months, disc height loss, decreased water and PG content, and gross morphological evidence of degeneration were observed.[73] This team recently reported human cervical disc allograft transplant in five patients with mixed results.[75] Good bony union was achieved by 3 months, neurological symptoms improved, no immunoreaction occurred, and only mild degenerative changes were seen. However, disc height loss, reduced sagittal motion in one disc, and significant hydration loss, as measured on MRI at 5 years, were reported in three discs. Overall, the evidence for disc implantation is promising, but quite limited, and is subject to the same general limitations as for meniscus allograft procedures, namely the potential for disease transmission, limited availability of donor materials, and limited sizing options.

5.524.6. Current Products for Meniscus and AF Repair and Replacement

To address the limited and often unsatisfactory performance of current repair strategies, private sector research and development programs have focused innovation toward devices for the treatment of meniscus and disc degeneration. These devices, comprised of a variety of biomaterials depending on the specific application, are in varying stages of development, from basic science *in vitro* research to implants with full US Food and Drug Administration (FDA) approval. Early regulatory successes have come largely from mechanical arthroplasty solutions, while tissue engineered devices are new to the marketplace. This section and the corresponding tables (see **Tables 3** and **4**) overview several such devices for the knee meniscus and the AF.

5.524.6.1. Current Products for Meniscus Repair

Pathology in the knee meniscus can frequently lead to knee arthropathy and eventually arthritis. Approaches to treat end-stage arthritis of the knee have historically focused on arthrodesis and arthroplasty, with newer innovations centered on early prevention of progressive later stage disease. These devices are of three types: arthroplasty, meniscal repair, and tissue engineered cartilage and meniscal replacement. Our focus is on the latter two categories, though some common athroplasty tools are shown in **Table 3**.

As discussed above, there is a strong association between damage to the meniscus and the precipitous onset of osteoarthritis (OA). Focus in this field is thus on maintenance of meniscus anatomy (e.g., minimizing the size of the meniscectomy performed) and restoring stability to the damaged segment. Meniscus tears in the outer portion of meniscus, and some of those in younger patients, can be repaired primarily using suture, screw, barbed anchor, or hybrid repair systems.[104] MaxFire (Biomet, Inc.) uses a braided polyethylene/polypropylene suture applied with a harpoon style deployment system. The RapidLoc Meniscal Repair System (DePuy Mitek, Inc.) is another hybrid system that consists of an absorbable poly(lactic acid) (PLA) or poly(dioxanone) (PDS) anchor, a Panacryl or Ethibond suture, and an absorbable PLA or PDS 'top hat' that compresses the tear against the anchor. Biostinger (ConMed Linvatec) is a poly(L-lactic acid) (PLLA) absorbable barbed cannulated anchor. A similar concept device that begins to harness biological means of healing is seen in the BioDuct device (Stryker Orthopaedics). This is a cylindrical, biodegradable PLLA device with a suture that is intended to repair peripheral meniscus tears in less vascular regions. The device purports to allow a central axis channel for fibrin clot formation and a conduit for later migration of cells and blood vessels.[79] Many of these devices can be employed using arthroscopic all-inside techniques that shorten surgical times, allow easier approaches for implantation, and reduce surgical risk. While promising and generally easier to use, the fixation strengths resulting from these devices are no better than vertical mattress sutures.[105–109] These fixation devices also degrade with time, depending on their polymer composition, and exhibit different failure modes depending on implantation duration and mechanical testing modality.[105,110,111]

5.524.6.2. Current Products for AF Repair

Treatments for axial spine symptoms have trended away from fusion, with new surgical solutions that attempt to be more anatomic and functional. Medical devices that address spinal

Table 3 Characteristics of knee and meniscus products

Name	*Composition*	*Function*	*Status*	*Manufacturer*
Arthroplasty, generally	Typically a metal (e.g., cobalt chrome alloy) femur and tibia and an ultra-high-molecular-weight polyethelene (UHMWPE) spacer	Total knee arthroplasty	FDA approved	Varies
Marketed devices				
Small intestinal submucosa (restore)[76]	Ten layers of processed porcine small intestine submucosa	Used to reinforce a meniscus repair or bridge gaps in the meniscus	FDA approved for reinforcement of the soft tissues, which are repaired by suture or suture anchors, during rotator cuff repair surgery	DePuy Orthopaedics/ Johnson and Johnson
Menaflex/collagen meniscus implant[77]	Molded type 1 collagen scaffold (derived from bovine Achilles tendon)	Indicated for reinforcement and repair of the medial meniscus; the patient must have an intact meniscal rim and anterior and posterior horns for attachment of the mesh. In addition, the surgically prepared site for the collagen scaffold must extend at least into the red/white zone of the meniscus to provide sufficient vascularity	FDA approved for use in the medial meniscus (CE Mark approval for both medial and lateral meniscus), Undergoing post-FDA approval review	Regen Biologics, Inc.
Actifit[78]	Porous scaffold made of aliphatic polyurethane with both soft segments and stiff segments. About 80% of the material is soft, made of poly(ε-caprolactone) (PCL). The other 20% is stiff, made of urethanes derived from 1,4-butanediisocyanate and 1,4-butanediol moieties. Reportedly has a pore size of 150–355 μm and 80% porosity	Indicated as an implant to fill partial lateral or medial meniscectomy defects	CE Mark (July 2008)	Orteq Ltd.
Bioduct[79]	Bioabsorbable cannulated poly(lactic acid) (PLA) device secured with suture	Intended for arthroscopic fixation of longitudinal vertical meniscus (bucket handle) lesions located in the vascularized (red-white) zone of the meniscus when used with suture	510(k) (April 2007)	Stryker Orthopaedics
Preclinical				
Engineered hydrogel meniscus[80]	A hydrogel meniscal replacement made from Salubria, a nondehydrated poly(vinyl alcohol) cyrogel	Formed hydrogels intended for full or partial meniscal replacement	Preclinical results showed failure at 1 year in an ovine model	Salumedica, Inc.
Engineered hydrogel meniscus[81]	Anatomic constructs formed from image guided injection molding techniques. Bovine microfibrillar collagens (MFCs) are seeded into an alginate gel, which is cross-linked after injected into the mold	Anatomically shaped meniscal constructs for replacement of meniscal defects	Preclinical	n/a
Engineered porous polymer meniscus [82]	Synthetic porous polymer meniscal scaffold composed of Estane polymers and formed using a sucrose porogen	Meniscal scaffold for replacement of meniscal defects	Preclinical	n/a
Engineered nanofibrous meniscus[83]	Aligned PCL nanofiber scaffold implanted into defects in the posterior horn of the ovine medial meniscus	Meniscal scaffold for the replacement of meniscal defects	Preclinical	n/a
Tarexx[84]	Injectable collagen cross-linking reagent (e.g., genepin)	Nonsurgical prevention of knee meniscus degradation	Preclinical	Orthopeutics, L.P.
Frog glue[85]	Protein-based adhesive elastomer secreted by the Australian frog *Notaden bennetti*	Biological adhesive for meniscal tears	Preclinical	n/a

Table 4 Characteristics of spine and IVD devices

Name	*Composition*	*Function*	*Stage of development*	*Manufacturer*
Discal arthroplasty				
Arthoplasty, generally	Typically metal (e.g., cobalt chrome alloy) endplates and a UHMWPE spacer	Total disc replacement	Several FDA approved	Varied
Facet arthroplasty				
TFAS (total facet arthroplasty system)[86]	Titanium alloy, cobalt, chromium, molybdenum, barium sulfate, and poly(methyl methacrylate) bone cement	Total facet arthroplasty	FDA IDE	Archus Orthopedics, Inc. (currently dissolved)
Dynamic stabilization				
X-Stop[87]	Titanium alloy device	Dynamic stabilization: interspinous distraction devices	FDA approved (November 2005)	St. Francis Medical Technologies, Inc./ Medtronic Sofamor Danek
Dynesys[88]	Titanium alloy (Protasul-100) pedicle screws, poly(ethyleneterephthalate) (Sulene-PET) cords, and poly(carbonateurethane) (Sulene-PCU) spacers	Dynamic stabilization: ligaments across pedicle screws	FDA approval as an adjunct to fusion (March 2004)	Zimmer Holdings, Inc.
Nucleus pulposus arthroplasty				
Nubac[89]	PEEK on PEEK mechanical articulation, tantalum markers	NP intradiscal arthroplasty	FDA IDE	Pioneer Surgical Technology
EBI Regain[89]	One piece: graphite substrate with pyrolytic carbon coating	NP intradiscal arthroplasty	Preclinical	Biomet, Inc.
Nucleus pulposus replacement, without mechanical articulation				
Knitted titanium,[90]	Knitted titanium filaments formed into a mesh	NP replacement	Preclinical	BUCK Enterprises
Prosthetic disc nucleus (PDN-SOLO)/ hydraflex (2nd gen)[91]	Hydrolyzed poly(acrylonitrile) and poly (acrylamide) copolymer preformed within a jacket	NP replacement	FDA IDE	Raymedica, Inc.
Newcleus[91]	Poly(carbonate urethane) coiled into a spiral	NP replacement	Preclinical, ceased development	Zimmer Spine
Aquarelle[89]	Semihydrated poly(vinyl alcohol) hydrogel, without a jacket	NP replacement	Preclinical, ceased development	Stryker Orthopaedics
Neudisc[89]	Radially anisotropic implant, modified hydrolyzed poly(acrylonitrile) polymer (aquacryl) reinforced with a Dacron mesh	NP replacement	Preclinical	Replication Medical, Inc.
DASCOR[92]	Polyurethane polymer in polyurethane balloon	Injectable NP replacement	CE Mark (2005), FDA IDE	Disc Dynamics, Inc.
Gelifex	Thermoresponsive polymer hydrogel injected into an NP void	Injectable NP replacement	Preclinical	Synthes, Inc.
NuCore[89]	Silk elastin polymer with a chemical crosslinking agent	Injectable NP replacement	FDA IDE	Spine Wave, Inc.
SINUX ANR[93]	Liquid poly(methylsiloxane) polymer, curing in 15 min	Injectable NP replacement	CE mark	Sinitec AG/DePuy Spine
BioDisc NPR[94]	Injectable NP void filler made of 45% purified bovine albumin, and 10% gluteraldehyde	Injectable NP replacement	Clinical	CryoLife, Inc.
Partial disc replacement device	Silicone composites forming an injectable viscous liquid that cures *in situ*; injected into an expandable silicone shell	Injectable NP replacement	Australia, clinical trial (on hold)	Columna Ltd.
Annulus fibrosus repair				
Barricade	Woven polyethylene mesh backstop that is anchored to the bone through a titanium insert	Mechanical annular defect buttress	CE Mark (April 2009)	Intrinsic Therapeutics, Inc.
Disc annular repair technology (DART)	PEEK cone-shaped device inserted into an annular defect	Mechanical annular defect buttress	CE Mark (April 2009)	Magellan Spine Technologies, Inc.
Inclose	Polyethylene mesh	Mechanical annular defect buttress; opens as an umbrella within a defect	FDA approved (August 2005)	Anulex Technologies, Inc.

(*Continued*)

Table 4 (Continued)

Name	*Composition*	*Function*	*Stage of development*	*Manufacturer*
Xclose	Suture device system	Intended to suture closed an annulotomy	FDA approved (September 2006)	Anulex Technologies, Inc.
Atelocolalgen AF sponge[95]	Purified type 1 atelocollagen, molded into honeycomb structures with freeze-drying and UV irradiation. Cultured with AF cells	Tissue engineered scaffold for AF regeneration	Preclinical	n/a
Hybrid alginate/ chitosan fibers[96]	Alginate fiber scaffolds wet-spun into loops and coated with chitosan	Tissue engineered scaffold for AF regeneration	Preclinical	n/a
Engineered collagen AF[97]	Collagen gels seeded with ovine annulus fibrosus cells. Alignment induced by contracting annular gels around a cylindrical post	Tissue engineered aligned AF	Preclinical	n/a
Intralink[84]	Injectable collagen cross-linking reagent (e.g., genepin)	Nonsurgical modification of spinal discs	Preclinical	Orthopaeutics, L.P.
Composite discs				
Composite engineered disc[98,99]	IVD composite composed of PGA and PLA mesh (AF) seeded with ovine AF cells, surrounding an alginate gel (NP) seeded with ovine NP cells	Tissue engineered composite disc scaffold	Preclinical	n/a
Engineered collagen disc[100]	Condensed type 1 collagen matrix	Tissue engineered disc scaffold	Preclinical	n/a
NP/AF amalgam (HANFS)[101]	IVD composite composed of electrospun PLLA (AF) surrounding a seeded hyaluronic acid hydrogel center (NP)	Tissue engineered composite disc scaffold	Preclinical	n/a
Composite nanofibrous/ hydrogel disc[102]	IVD Composite composed of electrospun aligned PCL, spot welded with angle-ply orientation to form the AF, surrounding an agarose NP, both seeded with bovine mesenchymal stem cells	Tissue engineered composite disc scaffold	Preclinical	n/a
Composite nanofibrous/ hydrogel disc[103]	IVD composite composed of electrospun PCL (AF) surrounding a chondrocyte seeded agarose gel	Tissue engineered composite disc scaffold	Preclinical	n/a

disc degeneration fall into three broad categories: arthroplasty, NP replacement, and AF repair. Examples of several such devices are shown in **Figure 2** and **Table 4**. Our focus in this chapter, however, is on the final category, namely, AF repair.

Annulus repair technologies have been sought after, in part, to solve the problem of NP device extrusion. Some repairs have sought to further traditional suture designs (Xclose, Anulex Technologies, Inc.), while others are developing novel constructions. These include Barricade (Intrinsic Therapeutics, Inc.), which combines a titanium bone anchor to a woven mesh backstop, Disc Annular Repair Technology (DART, Magellen Spine Technologies, Inc.), which is a bullet-shaped device made of poly(ether ether ketone) (PEEK) that resembles a wine stopper, and Inclose (Anulex Technologies, Inc.), which is specially designed for cannulated defects in the AF. It is a polyethylene mesh barrier that expands like an umbrella once inserted through the AF. Nonsurgical exogenous cross-linking therapy (NEXT and Intralink, Orthopeutics, L.P.) is a novel strategy of directly injecting a collagen cross-linking reagent into the AF. Genepin is one such candidate reagent. As may be appreciated from the description of NP devices above, there exist many newer devices specifically focused on AF repair. This may be partly attributed to the primary focus on restoring and maintaining disc height, and partly in recognition that repair of fiber-reinforced tissues is a more intractable problem.

5.524.7. Emerging Products for Meniscus and AF Repair and Replacement: Tissue Engineering

Considerable advances have already been made, centered on new material-based devices, for furthering the repair of the meniscus and AF. Indeed, the last decade has witnessed an explosion in the development of such devices, providing the surgeon with numerous options for restoration of function without compromising anatomic integrity or motion about the damaged area. Notwithstanding this progress in device design, additional steps are being undertaken to minimize the biomaterial footprint, that is, how much artificial materials are implanted and for how long they persist, and to maximize the biologic underpinnings of these repair techniques. Into this research space falls tissue engineering (TE). The goal of TE is the creation of fully biologic substitutes for tissue repair that may serve as an alternative or functional bridge to prosthetic replacement. Since first coined, the original TE paradigm has changed little from the concept of combining cells, scaffolds, and inducers of neotissue formation.[112] A TE construct typically consists of a natural or synthetic polymer scaffold seeded with autologous cells possessing functionality similar to that of the native cell type. Alternatively, these tissues may be generated from adult mesenchymal stem cells (MSCs), a progenitor population

found within bone marrow that can be induced to differentiate along a number of relevant musculoskeletal lineages. In many of these TE formulations, chemical or mechanical stimuli are provided as part of the *in vitro* culture environment via the delivery of growth factors or the action of bioreactors that duplicate some portion of the normal *in vivo* mechanical environment. These various parameters (i.e., cells, scaffolds, and culture environment) have been extensively explored for the creation of tissue equivalents for most tissues of the musculoskeletal system, including the meniscus and the AF. For fiber-reinforced tissues in particular, challenges include recapitulating the dense ordered collagenous structure, as well as biologic union of these neotissues within the wound site. This section describes recent advances in meniscus and AF tissue engineering.

5.524.7.1. Recent Developments in Meniscus Tissue Engineering

Arthroplasty solutions still dominate the treatment of knee disorders; however, TE approaches are beginning to gain ground. Early focus in the knee was on the articular cartilage itself, with Carticel (Genzyme Corp.) emerging as the first cell-based solution to cartilage damage. This technique consists of harvesting autologous cartilage cells, expanding them in culture, and reimplanting the cells under a flap at the defect site. Types of flaps include autologous periosteum and processed porcine small intestine submucosa (SIS) (Restore, DePuy Orthopaedics, Inc.). More recent approaches have simplified this approach toward a single procedure where cartilage cells are harvested and placed on a bioabsorbable scaffold before being reimplanted into the patient. An example of this is the Cartilage Autograft Implantation System (CAIS), also from DePuy Orthopaedics, Inc. Similarly, NeoCart (Histogenics Corp.) involves harvesting cartilage cells, seeding them onto a collagen scaffold, and then culturing the cells in a bioreactor that emulates the biomechanical milieu of native cartilage. An early area of focus for tissue engineers, cartilage engineering has taught investigators valuable lessons that are applicable to meniscus and disc TE.

With therapies such as Carticel, CAIS, and Neocart addressing focal cartilage damage, attention is turning toward meniscus TE, given its important role in forestalling OA progression. While meniscus TE is an active area of development and innovation (see **Figure 3**), only one device has received FDA approval for marketing in the United States. Menaflex (ReGen Biologics, Inc.) is a molded collagen scaffold derived type 1 collagen purified from bovine Achilles tendon. Following purification, the collagen is swollen in the presence of hyaluronic acid and chondroitin sulfate.[113] One-year follow-up biopsy specimens have suggested that the porous implant appears to encourage meniscus-like fibrochondrocytic matrix production.[77]

Porcine SIS, already discussed with autologous cartilage implantation, is another tissue engineered device for treating meniscus defects. SIS is a naturally occurring ECM containing collagens, PGs, and growth factors. It is believed to provide a three-dimensional scaffold for clot formation and cell conduction, allowing for new meniscal tissue production.[76,114] One-year outcomes in dogs were reported to be good when the

(d) A poly(vinyl alcohol) hydrogel meniscal implant with embedded sutures (reproduced from Kelly, B. T.; Robertson, W.; Potter, H. G.; *et al. Am. J. Sports Med.* **2007**, *35*, 43–52). (e) SEM of an Estane polymer scaffold (reproduced from Tienen, T. G.; Heijkants, R. G.; de Groot, J. H.; *et al. Biomed. Mater. Res. B Appl. Biomater.* **2006**, *76*, 389–396). (f) Anatomic constructs fabricated by injection molding techniques using bovine meniscus cells in an alginate gel (reproduced from Ballyns, J. J.; Gleghorn, J. P.; Niebrzydowski, V. *et al. Tissue Eng. A* **2008**, *14*, 1195–1202).

meniscal defect extended to the vascular zone, a source for initial clot was ensured, the implant was stabilized, and the implant was protected for an initial period.[76,114] As yet, this product has not been approved by the FDA for use in treating meniscus defects in humans.

As an alternative to these biologic materials, a synthetic meniscus replacement device has received CE Mark approval in Europe. Actifit (Orteq Ltd.) is a porous scaffold comprised of 80% soft segments and 20% stiff segments. The soft segments are made of poly(ε-caprolactone) (PCL) and the stiff segments consists of urethanes made from 1,4-butanediisocyanate and 1,4-butanediol moieties.[115] After the soft segments degrade, about 4% of the implant volume will remain as stiff segments, slowly degrading over 4–6 years. This biphasic degradation pattern allows prolonged structural strength during the period of cellular ingrowth.

In addition to these products at or near market, preclinical candidate tissue engineered substrates for meniscus regeneration abound. Chiari *et al.* reported the *in vivo* results of one such scaffold in replacing a total meniscus in sheep.[116] They produced a porous composite of PCL and a class of benzyl esters of hyaluronic acid (HYAFF, Fidia Advanced Biopolymers). Meniscus-like structures were molded with pore sizes of 200–300 μm and augmented with circumferential PLA to enable fixation through bone tunnels. After 6 weeks, the authors reported compression of the porous structure and partial extrusion. However, the partial replacement arm of the study showed thorough tissue ingrowth and some vascular invasion deep into the implant.

Tienen *et al.* reported on two other synthetic porous scaffold materials created for meniscal replacement; one was based on Estane polymers and another on an aliphatic 1,4-butanediisocyanate-based poly(esterurethane) (PCLPU).[82] The Estane material consisted of a hard component to provide for the compressive modulus, 4,4-methylenediphenyldiisocyanate, and a soft component poly(tetramethyl adipate). Its production used sucrose as a porogen. The PCLPU material consisted of a hard segment of 1,4-butanediisocyanate and butanediol and a soft segment of poly(caprolactone) initiated on 1,4-butanediol. The porogen used was sodium chloride crystals. Estane implant outcomes at 6 months in dogs showed fast tissue ingrowth and collagen deposition, but poor cartilage preservation properties.[82,117] The group ultimately preferred the PCLPU material over the Estane material due to less toxicity and synovial reaction.[82]

Hydrogels have also been investigated as suitable meniscus replacements. Kelly *et al.* reported *in vivo* results using Salubria (SaluMedica), a poly(vinyl alcohol) cyrogel, in sheep.[80] The hydrogels were formed to match sheep meniscus anatomy and were secured with suture running through the peripheral circumference. While results were promising at 2 months following surgery, graft failure and cartilage degeneration harbingered a worse performance at 4 and 12 months compared to allograft transplantation. More recently, Ballyns *et al.* demonstrated the feasibility of image-guided production of anatomically shaped mensical implants using injection molding of meniscal cells in alginate gel.[81] These alginate gels provide for cell delivery and maturation upon implantation, and can be formed by advanced three-dimensional techniques to perfectly mirror the native meniscus anatomy.

5.524.7.2. Recent Developments in Disc Tissue Engineering

Though significant development is still occurring with traditional spinal devices, innovation for treating spinal disc pathology is moving toward tissue engineered devices. In the

simplest formation, work has begun on the delivery of scaffold-only (i.e., cell-free) biomaterials to the defect site. In a slightly more complicated formulation, cell-based TE is also an emerging area of device innovation in NP and AF replacement. These methods involve seeding cells – frequently stem cells – onto structural scaffolds to fabricate functional tissues to match the native tissue properties. Several efforts are underway in preclinical stages to design spinal devices with biomechanical properties resembling native tissue, and clinical testing is expected in the next decade.

In one early example of disc TE, Sato *et al*. designed an atelocollagen honeycomb-shaped scaffold with a membrane seal[118] (see **Figure 2**). The scaffold is derived from a gel created from type 1 atelocollagen from bovine dermis.[119] The scaffold may be delivered on its own or preseeded with native tissue cells. In this study, AF cell seeded constructs were implanted into the disc space of Japanese white rabbits; these constructs showed 90% viability at 12 weeks and improved preservation of disc height compared to controls. Another approach is elastomeric materials augmented with cells, vis-à-vis hydrogels, which can reproduce some of the functional properties of native NP tissue[120] and are amenable to cell delivery. Reza and Nicoll encapsulated bovine NP cells in a photopolymerizable gel of carboxymethylcellulose, a water soluble derivative of the same cellulose in plant cell walls.[121] Other naturally derived materials have also been studied as potential NP hydrogel candidates, including chitosan hydrogels, hyaluronic acid hydrogels, and alginate hydrogels.[122] The scaffold portion of these constructs provides early mechanical stability, while cultured cells are expected to provide long-term biological integration and native tissue mechanical properties. Naked type I collagen that has been condensed into a three-dimensional matrix has also been shown to restore disc height and stability.[100] Alini *et al*. cultured both AF and NP cells in a 9:1 collagen:hyaluronan cross-linked scaffold.[123] Séguin *et al*. created scaffolds by sintering calcium polyphosphate powder into porous cylindrical substrates that were then seeded with bovine NP cells.[124] Chang and colleagues showed that AF cells attach to and produce AF-like ECM on porous silk-based biomaterials, and that dynamic culture improved this outcome.[125,126] More recently, alginate microfibers have been produced and seeded with AF cells; these fibers provide some directionality in the engineered AF construct, and begin to approximate native tissue architecture.[96] Along a similar line, Bowles and Bonassar recently reported on the formation of collagen-based AF constructs. In their work, collagen gels seeded with cells were allowed to contract around a cylindrical post, allowing for cell alignment in a lamellar pattern.[97]

As progress is made in engineering of the NP or the AF alone, these two goals are merging into the TE of composite devices that contain both regions. In one of the earliest examples, Mizuno *et al*. created a composite disc using a nonwoven mesh of 15 μm poly(glycolic acid) (PGA) fibers coated with PLA and seeded with AF cells. This AF segment was filled with an alginate gel containing NP cells.[98] Similarly, Wan and colleagues produced a laminate structure containing bone matrix gelatin and poly(polycaprolactone triol malate).[127] Nesti *et al*. also recently described a disc-like amalgam with a hyaluronic acid NP and a PLLA nanofibrous scaffold annulus, both seeded with human MSCs and induced into IVD cell-like phenotype with a chemically defined medium containing TGF-β1.[101]

With each increasing step of complexity, it is the intent that these TE efforts more completely reproduce the complexity of the native tissue structure. Though less studied, it is a requisite, for clinical translation, that the mechanical properties of these materials and cell-formed constructs, both at the time of implantation and after a period of maturation *in vivo*, approach that of the native tissue. The benchmarks for these requisite mechanical properties have recently been reviewed in the context of disc TE.

5.524.8. Engineering Fiber-Reinforced Tissues with Nanofibrous Scaffolds

A challenge in the development of any tissue engineered construct is matching the complex mechanical properties of the native tissue, which in the case of the meniscus and the NP are anisotropic and inhomogeneous. The use of fibers allows for unique control over the directional-dependent properties of a construct and this realization has led to the development of novel nanoscale fabrication methods specific to the manufacture of fiber-reinforced TE implants. In this section, we briefly review the technology behind electrospinning and illustrate several applications that may forward this technology toward clinical relevance for the repair of these two tissues.

5.524.8.1. Electrospinning: The Base Technology

Electrospinning is a relatively simple but elegant scaffold fabrication technique involving the electrostatic charging of a polymer solution until charge repulsion overcomes surface tension, resulting in the formation of a polymer jet.[128,129] As the jet is drawn through a high-voltage gradient, drawing and stretching occurs.[130] With time, these polymeric fibers accumulate to create a random mesh with fiber diameters ranging from 50 to 1000 nm, similar in scale to collagen fibers found in native tissues[130,131] (see **Figure 4(a)**). When formed as random meshes, nanofibrous scaffolds exhibit isotropic mechanical properties reflective of their polymer composition.[132,133] Production of nanofibrous meshes via electrospinning has been carried out with numerous polymers, including biodegradable polyesters and natural biopolymers, as reviewed in Refs.[134,135] Additionally, aligned nanofibrous scaffolds with controllable anisotropic mechanical properties can be formed by focusing deposition onto a rotating drum.[132,136,137] Given the importance of ordered matrix for both meniscus and AF tissue, this technology has proven useful for directing formation of these tissues *in vitro*.

5.524.8.2. Engineering the Meniscus with Nanofibrous Scaffolds

Given the ordered composition of the meniscus (i.e., the prevailing circumferential collagen bundles that define its tensile anisotropy), an ideal scaffold would be one that can direct new tissue formation to mimic this order. Over the past several years, considerable progress has been made in the formation of engineered meniscus constructs based on aligned nanofibrous scaffolds. In early work, it was demonstrated that the aligned

substrate dictates cell orientation and three-dimensional matrix deposition, and that this ECM provides enhanced functional properties in the fiber direction over long durations of *in vitro* culture[138,139] (see **Figure 4(b)**). These findings were apparent for both bovine and human meniscus fibrochondrocytes.[138,140] Improvements in scaffolding technology, for example, the inclusion of a sacrificial, pore-forming fiber population,[141] as well as combinations of different fiber populations in the same scaffold[142] have improved the ability of cells to populate these scaffolds, as well as provided for tuning of the tensile properties of the implant to match that of the native meniscus. More recently, these scaffolds have been further modified to provide the capacity to deliver growth factors and other biologic agents directly from the scaffold, further increasing their functionality upon implantation.[143] At present, one scaffold formulation, composed purely of PCL nanofibers, is undergoing evaluation in a sheep model of partial meniscus replacement. Early findings from this work show that the scaffold does not elicit any inflammatory responses, and is partially colonized by native tissue cells over a 6-month time course (see **Figure 4(e)**, inset). Ongoing work is exploring how scaffold modifications can improve cell and tissue deposition in this *in vivo* setting. In the long term, the goal of this work is to provide a fully formed, anatomically shaped scaffold that can guide meniscus regeneration through the topography of the aligned nanofibers (instructing cell and matrix organization) as well as growth factor delivery (instructing cell behavior and colonization).

5.524.8.3. Engineering the AF with Nanofibrous Scaffolds

Just as the meniscus has a defined collagenous order, so too does the AF. In the AF, this order may be considered even more complicated, in that there are lamellae of organized collagen that do not coincide with the circumferential direction, but rather alternate at ~30° with respect to this direction, and switch polarity in each layer. This hierarchical 'angle-ply' structure has important implications for the mechanical function of the disc, and is necessitated by the complex loads experienced about this joint (i.e., bending, compression, and torsion). To address this complexity, recent work from our group has used aligned nanofibrous scaffolds to produce AF constructs (see **Figure 5**). By excising the base scaffold unit at an angle from the primary fiber direction, a single ply of the AF can be formulated with a fiber direction that is not coincident with the long axis of the scaffold.[144] When these scaffolds are seeded with AF cells and MSCs, the tensile properties of the construct increase with time in culture.[145] Layering one cell-laden scaffold ply upon the other and culturing in this conjoined fashion produces mechanically viable laminates that begin to recapitulate the structural hierarchy of the native AF tissue. Indeed, such biologic laminates can match native tissue properties within 10 weeks of culture.[146] Finally, toward complete recapitulation of an entire disc, these layers can be formed concentrically to generate an angle-ply multilamellar AF region, which can then be combined with biocompatible stem cell-laden hydrogel NP-like regions. These disc-like angle-ply

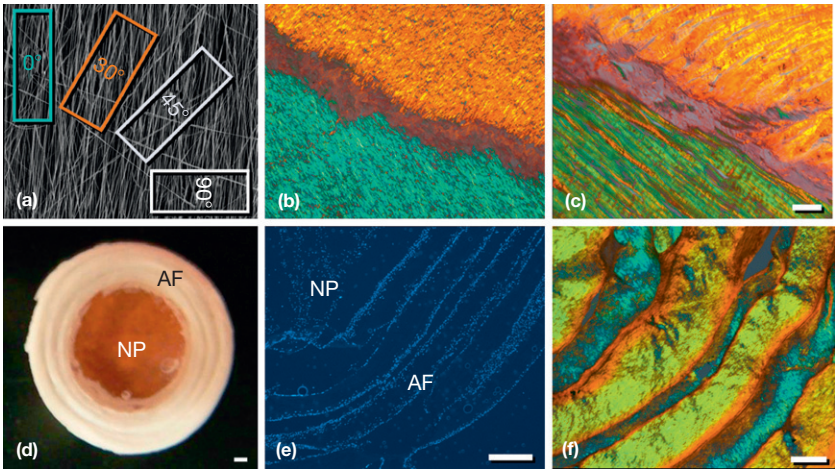

Figure 5 AF and disc tissue engineering with nanofibrous scaffolds. (a) Removal of rectangular scaffolds rotated from the prevailing fiber directions recapitulates the single lamellar fiber architecture of the AF. Reproduced from Nerurkar, N. L.; Elliott, D. M.; Mauck, R. L. *J. Orthop. Res.* **2007**, *25*, 1018–1028. (b) Formation of bilamellar constructs produces biologic laminates that direct ordered and opposing ECM deposition in adjacent layers, mimicking the angle-ply structure of the native AF (c, scale bar: 100 μm). Reproduced from Nerurkar, N. L.; Baker, B. M.; Sen, S.; Wible, E. E.; Elliott, D. M.; Mauck, R. L. *Nat. Mater.* **2009**, *8*, 986–992. Higher-order disc-like structures (d, scale bar: 1 mm) can be formed by concentric wrapping of alternating nanofibrous lamellae (AF) around a central gelatinous core (NP). Seeding with MSCs produces cell laden disc-like constructs with distributed cellular morphology representing the native disc (e, scale bar: 1 mm), with alternating angle-ply deposition of ECM. (f) Polarized light microscopy of a Picrosirius Red stained section from a disc-like construct (scale bar: 250 μm).

composites increase in mechanical properties with time in culture, and begin to approximate the full anatomy of the IVD.[102] Efforts are under way now to test these disk-like constructs *in vivo*.

5.524.9. Preclinical Models and Evaluation Tools for Engineered AF and Meniscus Products

Product development lines for tissue engineered replacements follow a similar pattern to that of traditional materials, namely a gradual evolution from cadaveric testing, through small and large animal trials, and eventually into clinical trials. As TE becomes more prominent, the outcome measures and their limitations need to be considered and optimized to reduce the iteration times during product development. For example, in meniscus applications, the most common outcome measure after meniscectomy is joint space narrowing. This is a gradual process, taking years in humans to become apparent after partial meniscectomy. Animal trials of the meniscus implants described above have outcomes related to the quality of the tissue formed within the implant, as well as the quality of the existing cartilage at up to 1 year of followup. Longer term followup is required to determine the true efficacy of these products, though this comes at a considerable expense. New methods that offer quantitative assessment of the healing meniscus may provide better guidance during this technology development phase, and shorten the time to market for these projects. For example, studies by Maher and colleagues have shown that force distribution under the meniscus can be dynamically measured using newly emerging measurement technologies (e.g., Tekscan sensors)[147,148] (see **Figure 6**). As shown, these measurements can provide important information regarding load transfer through meniscus replacement devices, both at the time of implantation as well as after a period of *in vivo* growth. Such outcomes will provide for ready optimization of the material itself, as well as the methods used to anchor it to native tissue. In addition, imaging techniques such as specialized MRI sequences adapted to visualize meniscus structure and the articular cartilage content[149,150] can be used as noninvasive tools for charting progress of implant integration and function *in vivo*. Similar concerns can be addressed for IVD replacement. Traditional measures of biomechanical function (i.e., motion segment testing[151]) are invaluable as final outcomes. Short of that, noninvasive imaging of disk height and NP and AF proteoglycan content (via MRI) can provide real-time insight into the function of the implant. In both meniscus and disc applications, however, pain is not typically measured, but is the primary concern of the patient. Most large animal models do not necessarily address this, as it is a difficult parameter to measure in a nonverbal population. Methods to address this, such as gait analysis coupled with force plate recordings, may provide additional insight into the ability of the implant to improve overall functionality, over and above simply reproducing anatomic form. Advances in these disciplines will lessen the time it takes for these tissue engineered materials to make their way to clinical application.

5.524.10. Conclusions and Future Directions

The last two decades have been characterized by an explosion in the development of biomaterial-based devices for musculoskeletal repair. In this process, the route is proceeding inexorably from metal and plastic implants toward a day when biologics will be the standard of care. This progress has been noted by the continual optimization of existing biomaterials for new applications in meniscus and AF repair, as well as by

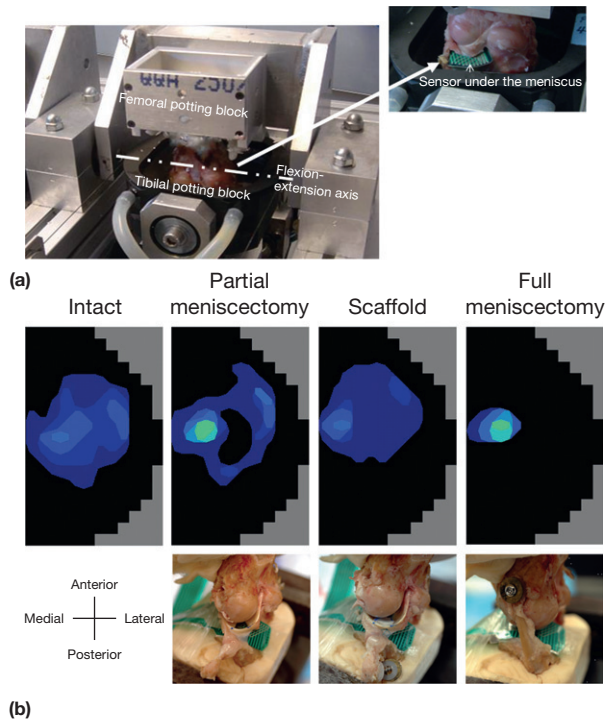

Figure 6 Quantitative preclinical assessment of engineered meniscus products. *In vitro* pressure-force mapping of ovine stifles with implanted tissue engineered meniscus scaffold candidates. (a) Modified knee joint simulator showing a potted stifle and Tekscan sensor in place (arrow). Reproduced from Cottrell, J. M.; Scholten, P.; Wanich, T.; Warren, R. F.; Wright, T. M.; Maher, S. A. *J. Biomech.* **2008**, *41*, 2324–2349. (b) From left to right, peak pressure map showing intact stifle, increased pressure concentration away from the meniscus with a partial meniscectomy, improved pressure distribution with implanted scaffold, and high concentration of pressure after full meniscectomy. Reproduced from Brophy, R. H.; Cottrell, J.; Rodeo, S. A.; Wright, T. M.; Warren, R. F.; Maher, S. A. *J. Biomed. Mater. Res. A* **2009**, *92*, 1154–1161.

considerable work in new materials and devices developed specifically for this purpose.

As history shines upon the groundbreaking work by Fernström, Nachemson, and Gluck, so too will it illuminate the biomaterial development described herein as the foundations of future biological devices. We have already started seeing traditional mechanical devices, such as total disc replacements, adopting anatomically influenced features (cf. the M6 device). As the complexities of tissue regeneration are unraveled, engineers will produce biomaterials that harness the ability of tissues to heal. One such biomaterial substrate is the electrospun nanofiber scaffold, which holds great promise in recapitulating the complex mechanical properties and function of fibrocartilaginous structures.

While some limitations have been encountered with TE based on the program of electrospinning synthetic materials, newer innovations are being developed to address these problems. Combinations of synthetic materials are being devised that will allow tuning of mechanical performance that will rival and perhaps exceed that of native tissue. Newer methods of electrospinning will enhance our ability to create materials that match the contour of meniscus anatomically. Concerns about the physiological toxicity of polymer metabolites *in vivo* may be met by the development of natural fiber scaffolds, such as collagen. Limitations in tissue colonization of these scaffolds are being addressed by presenting larger ingress routes in the scaffold and channels within the scaffolds, as well as by incorporating chemotactic moieties into both natural and synthetic fibers. Combined with the potential for geographic drug delivery, scaffolds will move closer to the reality of expeditious autocolonization and maturation.

These advances will not be limited to meniscus and AF treatments but can be generalized to all musculoskeletal tissues, as well as other organ systems. The intuition is that, as we move away from the mechanical age of orthopedics into a biological age, scientists and physicians will effectively harness the inherent healing capacity of the human body and so provide better, more durable, and more functional treatments for damage and degeneration of musculoskeletal tissues.

Acknowledgments

This work was supported with funding from the National Institutes of Health (R01 AR056624 and R01 EB02425), the Penn Center for Musculoskeletal Disorders, and the Penn Department of Orthopaedic Surgery. The authors would like to acknowledge Mr. Brendon Baker and Mr. Nandan Nerurkar for providing images of engineered meniscus and AF tissues, respectively.

Abbreviations

ACL	Anterior cruciate ligament
ACLFs	ACL fibroblasts
bFGF	Basic fibroblast growth factor
bMSCs	Bone marrow-derived mesenchymal stem cells
ECM	Extracellular matrix
EGF	Epidermal growth factor
IGF	Insulin-like growth factor
MCL	Medial collateral ligament
NDGA	Dicatechol nordihydroguaiaretic acid
PDGF	Platelet-derived growth factor
PLGA	Polylactide-*co*-glycolide
PLGA	Poly-L-lactic acid
PTFE	Polytetrafluoroethylene
RT-PCR	Real-time reverse transcriptase-polymerase chain reaction
SEM	Scanning electronic microscopy
SIS	Small intestinal submucosa
TCP	Tissue culture plate
TGF	Transforming growth factor
VEGF	Vascular endothelial cell growth factor
3D	Three dimensional

5.525.1. Introduction

The anterior cruciate ligament (ACL) plays an essential role in the knee joint, providing stability as well as guiding joint motion. It connects the femur to the tibia and is completely enveloped by the synovium. The primary function of the ACL is mechanical in nature. It is to limit excessive anterior translation and twisting of the tibia with respect to the femur. Its mechanical properties are well suited to its function. However, the ACL is the most frequently damaged ligament in the knee joint. Among the general population of the United States, the annual incidence of acute ACL disruptions has been estimated at 1 in 3000 and as many as 95 000 ACL reconstructions are carried out each year.[1,2] The seriousness of ACL injury is exacerbated by the fact that the ACL exhibits a very poor capacity for healing. Currently, the 'gold standard' treatment is autograft reconstruction; however, it cannot completely restore knee joint function. Furthermore, it may lead to donor site morbidity, causing pain and tendonitis as well as long recovery periods and muscle atrophy.[3–6]

5.525.1.1. Structure and Function of the ACL

In order to reconstruct a damaged ACL, it is necessary to understand the anatomy, orientation, and attachment sites of the normal ligament. The human ACL has a length of between 27 and 32 mm and a cross-sectional area of between 44.4 and 57.5 mm^2.[7] The ACL is part of the bone–ligament–bone

complex that includes bone, fibrocartilage, and a soft-tissue midsubstance, consisting largely of type I collagen, a sheath for protection, vascularity for nourishment, and nerves for proprioception. The ACL attaches the femur and tibia via collagen fibers that integrate to bone structures at both ends. The abrupt change from flexible ligament tissue to rigid bone is mediated by a transitional zone of fibrocartilage, which allows a gradual change in even distribution of stress.[8] The normal ACL comprises parallel collagen bundles, which are cross-linked to one another. The collagen fibers, cross-linked to one another, give high tensile strength. As they withstand cyclic loads of ~300 N for about 1.5 million times per year, it is important for fibroblasts to maintain collagen fibers in good condition dynamically.[9] It is interesting to note that cell densities in ligaments are generally low. The fibroblasts in the ACL are attached to individual collagen bundles and have elongated morphology along the longitudinal axis.[9] Fibroblasts not only synthesize fibrillar collagen but also enzymatically break down and remove old collagen as part of a renewal process. The collagen molecule is a glycine-rich triple helix. The molecules assemble sequentially into microfibrils, subfibrils, and fibrils (20–150 nm in diameter) before forming fibers (1–20 μm in diameter) with cross-links to one another and further make up a subfascicular unit (100–250 μm in diameter). These subfascicular units are surrounded by a loose band of connective tissue known as the endotenon. Three to twenty subfasciculi subsequently form a fasciculus (from 250 μm to several millimeters in diameter), which is surrounded by an epitenon. This interfascicular connective tissue also supports the neurovascular elements of the ligament.[8] These individual fascicles are either oriented in a spiral fashion around the long axis of the ligament or they pass directly from the femur to the tibial attachment. The entire continuum of fascicles is surrounded by the paratenon, a connective tissue cover similar to, but much thicker than, the epitenon.[10]

5.525.1.2. Limitations in Traditional Implantable Solutions

In the regeneration of the ACL, the graft must be positioned so as to minimize the change in length within the ligament, as the knee is flexed and extended.[11] Traditionally, ACL injuries have been treated with biological grafts, autografts, or allografts.[12] Autograft material for ACL repair is usually taken from the patellar tendon, hamstring tendon, or quadriceps tendon of the patient. The patella and hamstring tendons have been the autografts of choice for most surgeons. The patellar tendon graft material is usually removed with a piece of bone from the patella and from the insertion point at the tibia. The 'bone–patellar bone' graft is then fed through a tunnel drilled through the tibia, drawn across the knee, and anchored into a tunnel drilled through the femur. Allografts are tissues such as the patellar tendon, hamstring tendon, and Achilles tendon, obtained from cadavers.[12] The benefits of using allografts include the elimination of a second surgery for tissue harvest. There is also no limit to the supply of graft tissue as experienced with autografts. Both autografts and allografts possess good initial mechanical strength and promote cell proliferation and new tissue growth. However, both these options suffer from a number of disadvantages. For example, autografts have limited availability and require additional surgery for tissue harvest, which may cause donor site morbidity. Allografts could potentially transmit disease, cause bacterial infection, elicit an unfavorable immunogenic response from the host, and cannot be sterilized without altering the mechanical properties of the tissue.[13]

5.525.1.3. A New Option: Tissue Engineering

Despite significant progress in understanding ACL anatomy, structure, biomechanics, and healing, there is still no biological graft or prosthesis ideally suited for ACL regeneration. Clearly, such a complex structure is very difficult to replicate using traditional biomaterial approaches and/or biological grafts. Tissue engineering offers the possibility of creating functionally engineered tissues to treat ACL injuries without many of the undesirable side effects associated with current reconstructive options. The advantage of a tissue-engineered scaffold over other treatment methods lies in its interdisciplinary approach to tissue repair. Tissue engineering is the application of biological, chemical, and engineering principles toward the development of substitutes for the repair or restoration of tissue function.[14] The components to tissue engineering are as follows: three-dimensional (3D) porous scaffolds that promote tissue regeneration, isolated cells that have been expanded *in vitro*, and bioreactors and growth factors. A combination of all or any of these components may be used. The fundamental basis of ligament tissue engineering is the development of a biocompatible, resorbable, cell-seeded scaffold that can provide functional support while gradually transferring the mechanical loads borne by the scaffold to neoligament tissue.

5.525.2. Biomaterials for Ligament Tissue Engineering

5.525.2.1. Synthetic Biomaterials

Synthetic biodegradable polymers are biocompatible and commercially available. They are appealing for this application because their critical properties, such as strength, strength retention, and degradation rate, can be customized during processing.

It is well known that polylactide-*co*-glycolide (PLGA, 10:90) is commonly used as surgical suture material. In our previous studies, we studied the adhesion, proliferation, and morphology of rabbit ACL cells and bone marrow-derived mesenchymal stem cells (BMSCs) on several synthetic biodegradable polymeric films. From the results, high molecular weight PLGA (50:50, 75:25) was shown to be better in allowing BMSCs and ACL cell attachment and proliferation.[15] As for a 3D scaffold, knitted scaffolds of poly-L-lactic acid (PLLA) yarns and copolymeric yarns of PLLA and PLGA were fabricated and characterized.[16–18] The knitted scaffolds were immersed in a medium for 20 weeks, and changes in mechanical properties, as well as mass loss, molecular weight, and pH value change in the medium, were evaluated at different time points. Results showed that the knitted scaffolds had 44% porosity. There was no significant pH value change during degradation, while there was obvious mass loss during the initial 4 weeks, as well as smooth molecular weight drop of PLLA. PLGA degraded at a high rate, while PLLA kept its integrity for at least 20 weeks. Young's modulus increased while tensile

strength and strain at break decreased with degradation time; however, all of them could maintain the basic requirements for ACL regeneration. Moreover, knitted PLGA scaffolds seeded with BMSCs and wrapped with fascia have been used to reconstruct the ACL in a rabbit model.[16–18] However, the *in vivo* results of tissue engineering using these synthetic materials demonstrated rapid degradation rates and inferior mechanical properties compared with the normal tissues.

5.525.2.2. Natural Biomaterials

Collagen is the major structural component of connective tissues, especially the tendon and ligament; therefore, it is reasonable to reconstruct the ACL with it.[19,20] Collagen is widely used in cell culture studies, as fibroblasts attach, proliferate, and secrete matrix extremely well on collagen scaffolds. Collagen has numerous biological functions, serving as the natural scaffold supporting cell attachment, proliferation, and matrix synthesis within the body.[21–23] Highly purified type I collagen, which is commercially available, has been used either in gel form or bundles of parallel fibers.

Collagen has been the material of choice because of its ability to support the growth of ligament fibroblasts under static tension. Previous studies had used cross-linked collagen fibers seeded with human BMSCs and had shown that fibrous collagen supported cell attachment, spreading, and fiber coverage with extracellular matrix (ECM) deposition. After 1 day of culture, the cells formed focal contacts, adopted a spindle-like morphology, and aligned along the scaffold fibers. After 3 days of culture, a smooth cell sheet was formed, and the number of cells increased with time in culture. Unfortunately, the capacity of the engineered construct to support mechanical loading decreased with time in culture, and as a result, the scaffold fibers could not impart repeatable stresses to the attached BMSCs as previously observed.[24–26] The poor mechanical integrity of the fibers created further concerns regarding anchoring of the fibers both *in vitro* (in the bioreactor) and *in vivo* (in the knee). The mechanical deficiencies, the bioburden associated with the use of bovine collagen products, and leaching of chemical cross-linking agents, combined with the poor mechanical integrity of the collagen fibers, prompted the search for improved biomaterials.[27]

Methods for stabilizing collagen-based materials with catechol containing monomers were developed to produce fibers with mechanical properties in tension comparable to those of normal tissues.[28] Fibers produced from pepsin-solubilized, bovine tendon type I collagen were polymerized with the dicatechol nordihydroguaiaretic acid (NDGA). Polymerization was based on the chemical oxidation of the constituent *o*-catechols to reactive *o*-quinone functionalities. NDGA caused a dose-dependent increase in the tensile strength and stiffness of the type I collagen fibers. A second treatment with NDGA improved the tensile properties significantly. Comparison of the effects of NDGA with those of biologically relevant monocatechols indicated that the bicatechol functionality of NDGA was responsible for generation of the superior tensile properties. Elimination of unreacted intermediates from the treated fibers with ethanol increased the effectiveness of the cross-linking process while simultaneously sterilizing the material. Catalyzing oxidation by saturating the reaction buffer with oxygen increased the effectiveness of polymerization and the resulting tensile properties of the treated fibers. The ultimate tensile strength of the optimized NDGA-treated fibers averaged 90 MPa; the elastic modulus of these fibers averaged 580 MPa. Both values are comparable to native tendon and ligament. The material properties of the NDGA cross-linked fibers exceed the properties of collagen fibers treated with other cross-linking strategies such as glutaraldehyde and carbodiimide. These results indicate that NDGA cross-linking may provide a viable approach to stabilizing collagenous materials for use in repair of ruptured, lacerated, or surgically transected tendons and ligament, as well as other biomaterial constructs for surgical repair of musculoskeletal injuries and disease.

Sandusky *et al.*[29,30] have shown that acellular resorbable scaffold material derived from the small intestinal submucosa (SIS) can be rapidly resorbed. Furthermore, it is capable of supporting early and abundant new blood vessel growth, and several studies had concluded that it can serve as a template for the constructive remodeling of several body tissues, including musculoskeletal structures,[31–33] for example, skin[34] and blood vessels.[35] The SIS material consists of naturally occurring ECM, which has been shown to be rich in components that support angiogenesis, such as fibronectin, glycosaminoglycans, several kinds of collagens including types I, III, IV, V, and VI, and angiogenic growth factors, for example, basic fibroblast growth factor-2 (FGF-2) and vascular endothelial cell growth factor (VEGF).[36,37] Badylak *et al.* evaluated the tissue response to the SIS when this material was used to repair an experimentally induced Achilles tendon defect in a dog model.[32] A unilateral 1.5-cm segmental defect of the Achilles tendon was surgically created in 20 dogs, which was subsequently repaired with the acellular connective tissue derived from porcine SIS. Results showed that the SIS remodeled neotendons tend to be stronger than the musculotendinous origin or the bony insertion (>1000 N) by 12 weeks after surgery and consisted of organized collagen-rich connective tissue similar to the contralateral normal tendons. Immunohistochemical studies suggested that the SIS biomaterial degraded within the first 8 weeks and therefore could serve only as a temporary scaffold around which the body deposited appropriate and organized connective tissue.

Xenogeneic and allogeneic cellular antigens are, by definition, recognized as foreign body by the host and therefore will normally induce an inflammatory response or an immune-mediated rejection of the tissue. However, components of the ECM are generally conserved among species and are well tolerated even by xenogeneic recipients.[38,39] ECM from tendons[40] and ligaments[41] has been studied for ligament tissue engineering. The goal of decellularization is to efficiently remove all cellular and nucleus material while minimizing any adverse effect on the composition, biological activity, and mechanical integrity of the remaining ECM. Harrison and Gratzer[42] developed a decellularized bone–ACL–bone allograft for treatment of the ACL disruption in young or active patients. This study demonstrated the feasibility of seeding decellularized ACL tissue with primary ligament fibroblasts. Porcine ACLs were decellularized by one of the three protocols, each differing only by the detergent/solvent used during the second wash (SDS, Triton-X, or TnBP). Cell counting on histological sections verified that Triton-X and TnBP-treated ligaments were

more receptive to cellular ingrowth than SDS-treated samples. Both the Triton-X and TnBP decellularization treatments provide suitable, naturally derived scaffolds for the ingrowth of primary ACL fibroblasts.

5.525.2.3. Silk Biomaterials

Silk fibers offer a novel alternative to traditional native and synthetic nondegradable and degradable biomaterials by combining the optimal traits of both groups. Superior mechanical properties and environmental stability make silk fibroin (the core protein of silk) a more suitable biomaterial for ligament tissue engineering applications. Silk has already been investigated as a possible scaffold material for ligament tissue engineering, particularly by Kaplan's group at Tufts University.[43–45] The fundamental facts about silk are well known. The core silk fibers are encased in a sericin coat, a family of glue-like proteins that hold the fibroins together to form the composite fibers. Sericin is a globular protein and water-soluble glue, unlike silk fibroin which is an oriented fiber protein. When subjected to physical, chemical, or enzymatic processes, sericin can be degraded into sericin peptides or partially hydrolyzed. Sericin proteins are known to be the major cause of adverse biocompatibility and hypersensitivity reactions resulting from implanted native untreated silk.[46,47] Therefore, sericin must be removed if silk fibers are to be used as a biomaterial.

In the process of removing sericin from the raw silk scaffold, the fibroin's structural integrity is often challenged, leading to mechanical depreciation. Our recent study identified the factors and conditions contributing to fibroin degradation during alkaline degumming and the parameters involved in achieving the preservation of fibroin structure and properties. The methodology involves degumming knitted silk scaffolds for various durations (5–90 min) and temperatures (60, 75, and 100 °C). Mechanical agitation and the use of refreshed solution are included in the degumming process to study how the respective factors contribute to sericin removal, mechanical integrity, and structural aspect of degummed silk fibroin. Characterization of the silk fibroin morphology, mechanical properties, and protein components are determined by scanning electronic microscopy (SEM), single fiber tensile tests, and SDS-PAGE analysis, respectively. Sericin removal is ascertained via SEM imaging and a protein fractionation method involving SDS-PAGE. Knitted scaffolds degummed with mechanical agitation for 30 min at 100 °C have sericin effectively removed and experience negligible mechanical and structural degradation. This study thus presents an optimization process for sericin removal from silk scaffolds, where the mechanical and structural properties are to be preserved.

"The US Pharmacopia defines an absorbable material as one that loses most of its tensile strength within 60 days" *in vivo*. By this definition, it is correct to classify silk as a nondegradable material. However, in scientific literature, silk has been shown to degrade over a longer period of time as a function of proteolytic degradation that is usually mediated by an *in vivo* foreign body response.[46,48–50] Several studies have described silk degradation *in vivo* at variable rates, depending on the model and implantation site.[51–54] In general, silk fibers lose the majority of their tensile strength within 1 year *in vivo* and fail to be recognized in the implantation site within 2 years. Silk loses 55% of its tensile strength over a 6-week period when circumferentially implanted subcutaneously in rats.[43,45] Bucknall *et al.*[55] reported an 83% loss in silk fiber tensile strength after 10 weeks *in vivo* when implanted subcutaneously in rats. Lam *et al.* were unable to detect silk as well as a foreign body response 24 weeks following implantation in the abdominal muscle layer in rats.[50] Salthouse *et al.*[46] observed a reduction in the number of silk filaments and the overall diameter of silk sutures 42 days following implantation in the cornea, sclera, and ocular muscle of the rabbit and complete absorption within 90 days *in vivo*. Our *in vivo* studies in a rabbit model showed that, after 24 weeks, the strength retention of tissue-engineered ligament with BMSCs seeding on the silk scaffolds was 18.7% of native ACL's maximum load. Moreover, the strength retention of tissue-engineered ligament was comparable to the reported retention (15%) of autograft (patellar tendon) for ACL regeneration in a rabbit model.[56,57]

5.525.3. Scaffold Design

5.525.3.1. Scaffolds Design Criteria

Tissue engineering scaffolds provide a structural and logistic template for cell adherence and tissue development, and they biodegrade in parallel with the accumulation of neotissue components. Most studies suggest that a scaffold is essential for promoting orderly tissue repair.[58–62] Scaffold structure, mechanical properties, and the rate of degradation largely determine the mass transport and mechanotransduction at the cellular and tissue levels. Ideally, a scaffold should be made of biocompatible, biodegradable material and should degrade at a rate matching the rate of new tissue deposition.[63] An important requirement for scaffold design while engineering load-bearing tissues is the maintenance of the mechanical properties of the scaffold until the new tissue becomes mechanically competent.

The musculoskeletal tissues will have to bear significant mechanical loads *in vivo*; therefore, the mechanical properties of the scaffold must be considered for tissue engineering applications. In fact, some early attempts to develop tissue-engineered ligaments failed because the scaffold had inadequate strength and stiffness. Examples include the use of collagen gels seeded with cells *in vitro*.[24–26] Although these cell-seeded scaffolds appeared to be 'ligament-like' based on histology and biochemical markers, they lacked the key functional component required for a ligament, that is, mechanical strength. Recently, the concept of functional tissue engineering has emerged as a hot topic. The principles of functional tissue engineering defined by Butler *et al.*[64] stress the importance of the mechanical properties of skeletal tissues and recognize the need to define mechanical requirements for tissue-engineered grafts and utilize physical signals to direct cellular activity and phenotype toward functional tissue assembly, and thereby achieve mechanical-competent tissue repair.

Native ACL comprises bands of dense collagen fibers. A fiber is a simple element of anisotropic structure. As such, ACL scaffolds and synthetic ACL prostheses developed so far are practically made up of fibers in various textile-type

structures. However, the simplest form being parallel structure, the lack of interlinking between fibers restricts its application. Twisting fiber bundles is an elegant way to solve the problem.[44] Twisted fiber grafts are morphologically closer replicas of the normal ACL that may be able to accommodate the peak forces in extension.[65] Due to the complexity of the ACL mechanical environment, researchers have been keen to adopt more complex textile structures in ACL regeneration, and therefore, all four textile patterns, that is, woven, knitted, braided, and nonwoven, have been explored for ligament regeneration. However, the braided and knitted structures have inherent advantages and have been well studied.

5.525.3.2. Braided Scaffolds

The properties of textile grafts depend on the characteristics of the constituent yarns or fibers as well as the geometry of the formed structure. In general, braided grafts are dimensionally very stable but less extensible and porous than the other structures, for example, the Gore-Tex ligament prosthesis, which is a braided bundle of polytetrafluroethylene (PTFE).[66] This graft has high strength and fatigue life, but poor tissue ingrowth due to low porosity.[27] However, the pore size of the braided structures can be regulated by yarn bundle size and braiding angles.[67]

Laurencin and his colleagues have developed a tissue-engineered solution based on a cell-seeded, degradable, 3D braided PLLA scaffold.[67] This method produces a heterogeneous scaffold that is able to adapt to the intraarticular region of the ligament, withstand the rigors of surgical fixation within the bone tunnels, and promote guided healing. The study showed that the tissue-engineered ligament scaffold has the mechanical properties of the normal ACL and the porosity for tissue ingrowth. During cell culture, the attachment and proliferation of primary ACL cells and BALB/C mouse fibroblasts demonstrated the biocompatibility of the scaffold.

Altman *et al.*[44] reported on the development of a 6-cord silk wire-rope matrix as a scaffold for ACL tissue engineering. The matrix was successfully designed to match the complex and demanding mechanical requirements of a native human ACL, including satisfactory fatigue performance. The protein matrix supported the attachment, expansion, and differentiation of adult human progenitor bone marrow stromal cells, according to SEM examination, DNA quantitation, and the expression of collagen types I and III and tenascin-C markers. The results supported the conclusion that properly prepared silkworm fiber matrices, in addition to providing unique benefits in terms of mechanical properties as well as biocompatibility and slow degradability, can provide suitable biomaterial matrices for the support of adult stem cell differentiation toward ligament lineages. These results point toward this matrix as a new option for ACL repair to overcome current limitations in synthetic and other degradable materials.

Our group has developed a silk-cable-reinforced gelatin/silk fibroin hybrid scaffold for ligament tissue engineering.[56,57] The scaffold was fabricated by lyophilizing the cross-linked gelatin and silk fibroin mixture with braided silk cables. SEM observation showed that microporous gelatin/silk fibroin sponges formed around silk cables mimicked the microstructures of ligament ECM. The silk cables significantly increased the tensile strength of the scaffold to meet the mechanical requirements for ligament tissue engineering. The scaffold possessed good cell adhesion property, and when BMSCs were seeded on it, cells proliferated profusely. After 2 weeks of culture, seeded BMSCs were distributed uniformly throughout the scaffold and were highly viable. Occurrence of cell death during culture was not significant. Deposition of collagen on the scaffold was found to increase with time. Differentiation of BMSCs into ligament fibroblasts was verified by expressions of ligament ECM-specific markers in gene and protein levels. Immunohistochemistry stains also confirmed the production of key ligament ECM components on the scaffold.

5.525.3.3. Knitted Scaffolds

When compared with braided fabrics, knitted structures are highly porous and have the potential to support tissue ingrowth. Barrett *et al.*[68] reported that using a knitted velour layer over the Dacron artificial ligament promoted ingrowth of fibrous tissue, although the overall result of the artificial ligament was unfavorable. Textile materials for tissue engineering applications typically have specific performance requirements relating to porosity and mechanical properties.

Unlike braided fabric, knitted scaffolds have been shown to favor deposition of collagenous connective tissue matrix, which is crucial for ligament regeneration. Cell seeding on knitted scaffolds often requires a gel system, which was found to be practically unsuitable for ACL regeneration as the cell–gel composite often gets dislodged from the scaffold in the *in vivo* dynamic situations. A biodegradable nano-microfibrous polymer scaffold was developed by our group by electrospinning PLGA nanofibers onto a knitted PLGA scaffold to provide a large biomimetic surface for cell attachment.[69] Porcine BMSCs were seeded onto either the nano-microfibrous scaffolds by pipetting a cell suspension (Group I) or the knitted PLGA scaffolds by immobilizing in fibrin gel (Group II). Cell attachment was comparable and cell proliferation was faster in Group I. Moreover, cellular function was more active in Group I, as evident by the higher expression of collagen type I, decorin, and biglycan genes.

In order to improve cell attachment on the knitted silk scaffolds, we fabricated a combined silk scaffold with web-like microporous silk sponges formed in the openings of a knitted silk scaffold[70,71] (**Figure 1**). BMSCs adhered to and grew well on the combined silk scaffolds. Moreover, in comparison with the knitted silk scaffolds seeded with BMSCs in fibroin gel, the cellular function was more active on the combined silk scaffolds as evident from real-time reverse transcriptase-polymerase chain reaction (RT-PCR) analysis for ligament-related gene markers, as well as immunohistochemical and Western blot evaluations of ligament-related ECM components. While the knitted structure holds the microporous silk sponges together and provides the structural strength of the combined silk scaffold, the microporous structure of the silk sponges mimic the ECM which consequently promotes cell proliferation, function, and differentiation. This feature overcomes the limitation of knitted scaffold for ligament tissue engineering application.

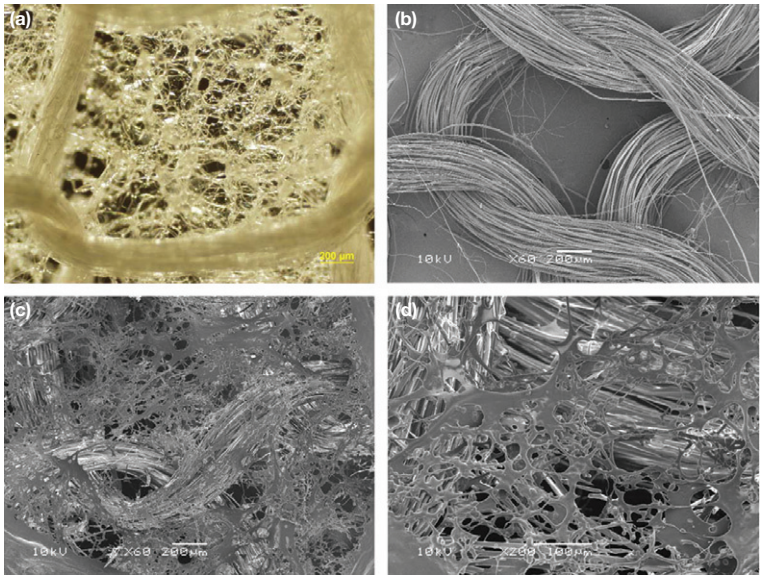

Figure 1 Phase contrast (a) and SEM (b–d) images of the knitted (b) and combined (a, c, d) silk scaffolds showing web-like microporous silk sponges formed in the openings of the knitted silk scaffold. (a–c) Scale bars = 200 μm; (d) scale bars = 100 μm.

5.525.4. Cell Source

Although scaffolds provide temporary mechanical support, the long-term success of tissue-engineered ligaments depends on the ability of cells to deposit and remodel a new matrix. Due to differences in phenotypes and functionalities of various cell types, seeding of different cells on scaffolds will greatly influence the outcome of tissue-engineered ligament grafts. A variety of cell types have been scrutinized in our laboratory in an attempt to enhance our understanding of ligament development and define a suitable cell line for ligament engineering. The appropriate cell type for ACL tissue engineering must show enhanced proliferation and production of an appropriate ECM and must be able to survive in an intraarticular environment in the patient's knee.[72] ACL fibroblasts (ACLFs) are cells specialized in producing all the ligament constituents and maintaining the ligament tissue in the appropriate conformation. In comparison with cells derived from the medial collateral ligament (MCL), Achilles tendon, and patellar tendon, ACLFs have the highest gene expression for the phenotypic markers.[73] Another possible candidate is BMSC, which has been shown to have the potential to differentiate into various types of mesenchymal cell phenotypes, including osteoblasts, chondroblasts, myoblasts, and fibroblasts.[74] They are present in large quantities in the human body and can also be easily obtained just by a simple aspiration of iliac crests and expanded *in vitro* to large amounts.[75,76] Moreover, BMSCs have been successfully used to promote repair of a number of connective tissues, such as bone,[77] cartilage,[78] tendon,[79] and ligament.[16–18]

In our previous study, fibroblasts isolated from rabbit ACL, MCL, and BMSC were cultured on a tissue culture plate (TCP) and compared using the following parameters: proliferation rate, collagen excretion, and expression of ligament-related ECM markers. It was found that BMSC, ACL, and MCL fibroblasts were all highly stained with antibodies for collagen types I and III and α-smooth muscle actin, while BMSCs had the best proliferation and collagen excretion rate among the three cell types.[16–18] However, the choice of cell may also be mediated by its affinity for the scaffold that is used and its susceptibility to molecular and mechanical influences. Therefore, our recent study has focused on rabbit ACLFs and BMSCs culturing on the combined silk scaffolds, to investigate their biological cellular responses *in vitro* and *in vivo*, which can be used to determine the cell source most appropriate for a tissue-engineered ligament.[70,71] The results of comparing cell proliferation indicated that BMSCs proliferated faster than ACLFs (**Figure 2**). Gene expression of the phenotypic markers measured using RT-PCR indicated the transcript levels of BMSCs were significantly increased after 2 weeks of culture, whereas those of ACLFs had no significant difference. The protein levels and localization were determined by Western blots and immunohistochemical staining, and the results showed more production of ligament-related ECM by BMSCs as compared to ACLFs. Moreover, at 4 weeks postoperatively, more fluorescent cells were present in BMSC-loaded constructs than in ACLFs-loaded constructs. Therefore, based on the cellular response *in vitro* and *in vivo*, BMSC was found to be a better cell source than ACLFs for ACL tissue engineering. In the future, other cell sources may also be available, including embryonic stem cells, synovium stem cells, and induced pluripotent stem cells.

5.525.5. Bioreactor System

The disadvantages of static culture are well documented; they include inefficient nutrient delivery by diffusion, reduced cell viability, minimal cell activity at the center of tissue constructs, inadequate distribution of nutrients, and removal of waste products within the constructs.[80–82] The rationale for using perfusion bioreactors is that it is capable of transporting nutrients and metabolites to the interior of the construct. The culture

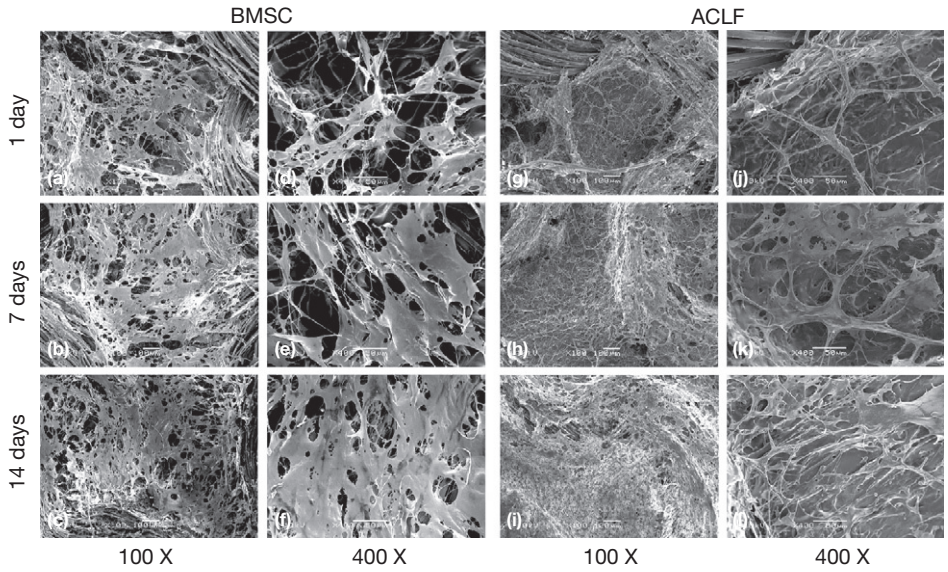

Figure 2 SEM photomicrographs showing adherence, proliferation, and cell sheet formation by BMSCs (a–f) and ACLFs (g–l) cultured on the novel knitted silk scaffolds for 1, 7, and 14 days. (a–c, g–i) Scale bars = 100 μm; (d–f, j–l) scale bars = 50 μm.

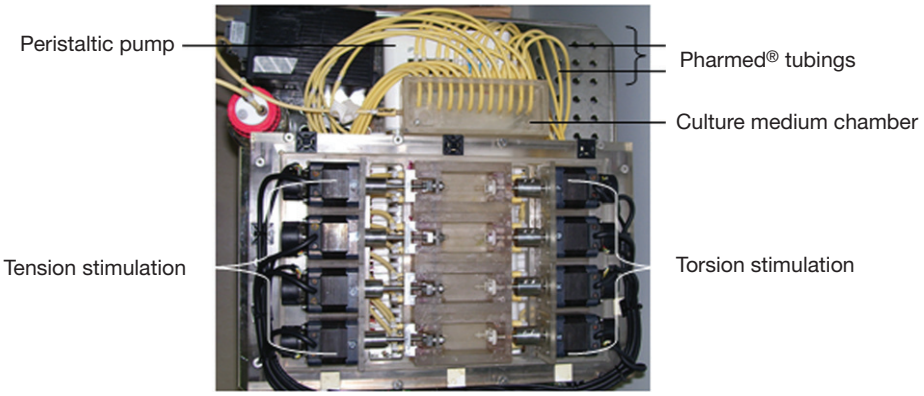

Figure 3 Four-chamber bioreactor system.

medium is continually renewed to supply gas and nutrients to cells, remove metabolites and catabolites (this will improve mass transport throughout the 3D tissue-engineered constructs cultured *in vitro*), and provide flow-mediated mechanical stimuli such as shear stress, compression, and hydrostatic pressure for cells to accurately grow, differentiate, and function. Mechanical loads can provide critical signals that influence cells[83–85] and help control musculoskeletal tissue development, growth, remodeling, and repair.[86,87] In addition, mechanical loads can increase collagen production by ligament fibroblast and interact synergistically with growth factors to influence fibroblast behavior.[84,85]

There are two approaches to tissue engineering: one is to implant a cell–scaffold composite directly into the injured site, so that the body acts like a 'bioreactor'; the other is to culture the cell–scaffold composite in a bioreactor *ex vivo* for a period of time before transplantation.[88] The *ex vivo* bioreactor allows controlled introduction of biochemical and physical regulatory cues to guide cell differentiation, proliferation, and tissue development. As such, engineering of tissue *ex vivo* in a bioreactor offers several exciting prospects, such as better understanding of tissue development and the mechanisms of disease, off-the-shelf provision of essential transplantable tissue, and possible scale-up for commercial production of engineered tissues.

As shown in Figure 3, a four-chamber perfusion cum mechanical stimulation system has been designed by our group to sustain cell viability and promote cell proliferation and tissue formation *in vitro*. The focus is on growing BMSCs on combined silk scaffolds for tissue engineering of ACL. Key functions of the bioreactor system include the following:

- enabling perfusion throughout the scaffold–cell construct;
- allowing environmental condition monitoring;
- providing cyclic translational and rotational mechanical loading;
- using software-controllable multidimensional tension and/or torsion effects on 3D cell growth;
- providing force monitoring and feedback system;

- providing independent but concurrent control over translational and rotational strains.

5.525.6. Local Delivery of Growth Factors

Growth factors are soluble peptides that influence normal tissue morphogenesis, repair, and regeneration. Numerous studies have tried to define the role of growth factors in ligament healing and determine appropriate strategies for the use of growth factors in ligament tissue engineering. Various growth factors, such as transforming growth factor (TGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and insulin-like growth factor (IGF), have been shown to have the ability to improve ligament cell proliferation or matrix formation *in vitro* or *in vivo*.[89–94]

A potential problem with these soluble growth factors is rapid diffusion away from the site where activity is required *in vivo*. The duration of growth factor activity may be prolonged by incorporating these soluble factors within a scaffold delivery vehicle. In our recent study, we have demonstrated that basic fibroblast growth factor (bFGF) could be successfully incorporated as well as randomly dispersed within blended-electrospun nanofibers and released in a bioactive form over 1 week[95] (**Figure 4**). The released bioactive bFGF activated tyrosine phosphorylation signaling of seeded BMSCs. The bFGF-releasing nanofibrous scaffolds facilitated BMSC proliferation, upregulated gene expression of ligament-specific ECM proteins, increased production and deposition of collagen and tenascin-C, reduced multipotency of the BMSCs, and induced ligament-like fibroblastic differentiation.

5.525.7. Animal Models for ACL Regeneration

In the investigation of *in vivo* ligament regeneration, it is prudent to choose animal models that have a similar type and degree of ligament injuries to those found in humans. It is also imperative to realize that the results from animal research may be species and ligament specific and may not necessarily simulate those of humans. Frequently used animal models in ligament research are dogs, rabbits, goats, and sheep. The reasons for using dogs are the ease in handling, receptiveness to various exercise regimens, and availability of well-published information.[96] Goats and sheep are widely used for ACL regeneration, particularly in studies related to biological grafts and ligament prostheses. This is because goats and sheep have large knee joints and a lesser degree of flexion.[97,98] Rabbits are commonly used in biomedical research because of their docile nature and relatively inexpensive cost of maintenance. Furthermore, there is extensive information on the biochemical and functional properties of rabbit knee ligaments.[99]

Our group had investigated ACL regeneration using BMSCs and silk scaffold in a rabbit model.[56,57] After 24 weeks, histological observation showed that BMSCs were distributed throughout the regenerated ligament and exhibited fibroblast morphology. The key ligament ECM components were produced in significant quantities. Furthermore, direct ligament–bone

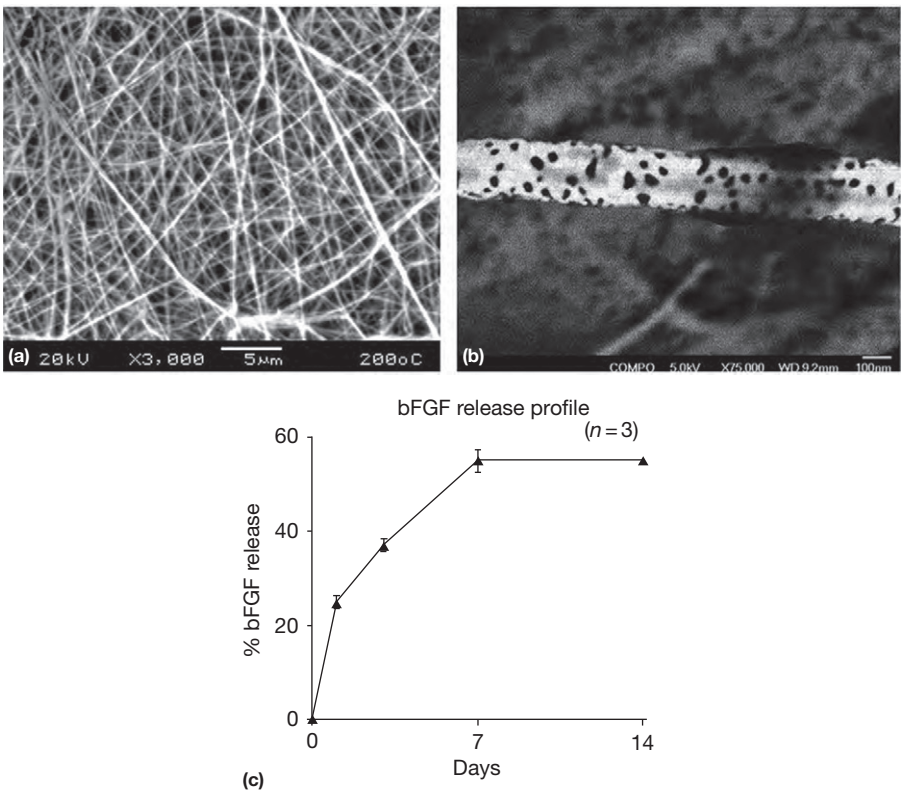

Figure 4 SEM images showing blended nanofibers of 200–700 nm diameter, with a random distribution of protein within. The bFGF was released over 1 week.

insertion (i.e., the typical four interfacial zones – bone, mineralized fibrocartilage, nonmineralized fibrocartilage, and ligament) was reconstituted. It resembled the native structure of ACL–bone insertion (Figure 5). The tensile strength of regenerated ligament also met the mechanical requirements. Moreover, its histological grading score was significantly higher than that of the control group (i.e., without cell seeding).

However, it should be noted that rabbits spend a larger part of their time in deeper knee flexion when compared with large animals (e.g., pig, goat, and sheep). Although the ACL has been regenerated in rabbits, studies on large animals are still needed to extrapolate the findings from animal data to humans.[56,57] The ACL is a two-bundle ligament consisting of anteromedial (AM) and posterolateral (PL) bundles. The differences between the ACLs of various species may be due to variations in AM bundles but not PL bundles. Studies indicate that pig knee differs from human knee only in the magnitude and direction of force in the PL bundle. In contrast, sheep and goat knees show different magnitude and direction of force in both bundles when compared with human knee. Therefore, goat and sheep knees may have limitations in modeling the human ACL, while pig knee may be the preferred model for experimental studies.[100,101] To further investigate the clinical potential of silk material, we were able to regenerate the ACL in a pig model using BMSCs and silk scaffold.[102] At 24 weeks postoperatively, the key ligament-specific ECM components were produced prominently and indirect ligament–bone insertion with three zones (bone, Sharpey's fibers, and ligament) was observed. The maximum tensile load of regenerated ligament did not decrease after 24 weeks of implantation. In conclusion, the results imply that the silk-based tissue-engineered ligament has great potential for clinical application in the future.

5.525.8. Ligament–Bone Interface

One of the keys to success in surgical reconstruction of damaged ligament is the healing of graft ligament to bone. Acceleration of the appropriate healing process at the insertion site would allow patients to undergo early rehabilitation. Normal ACL insertion is characterized as a direct ligament insertion

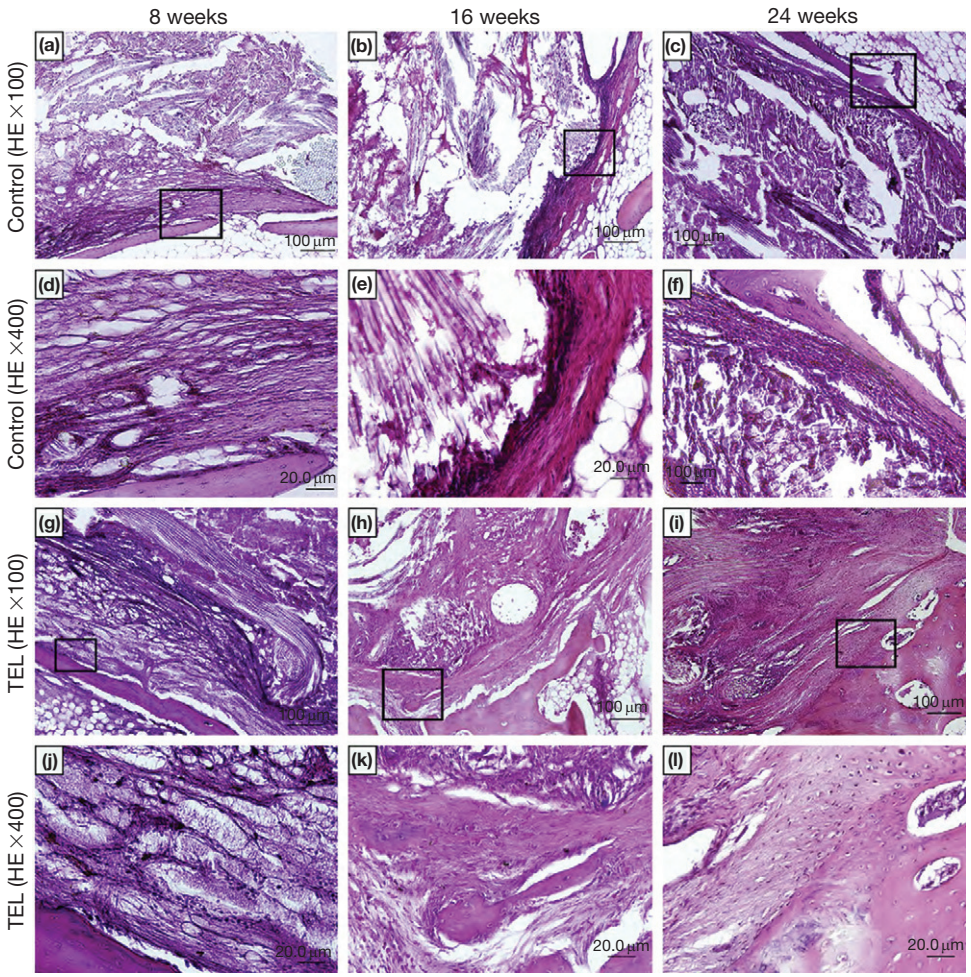

Figure 5 Histological observation of reconstructed ligament–bone insertion in control group without cell seeding (a–f) and tissue-engineered ligament group (g–l) by HE staining at 8, 16, and 24 weeks postoperatively. (Note: d–f and j–l are magnified views of black rectangles from a–c and g–i, respectively.)

consisting of four distinct zones: bone, mineralized cartilage, fibrocartilage, and ligament.[43–45] This specific insertion site structure is designed to distribute longitudinal and shear forces from the ligament proper into the subchondral bone plate, thus minimizing stresses on individual collagen bundles. There is a tidemark between the zones of calcified and uncalcified cartilage, which represents the mineralization front. The normal insertion site is a highly specialized zone of tissue that functions to transmit stress from hard tissue to soft tissue.[103] In contrast, indirect insertion comprises three zones including ligament, Sharpey's fibers, and bone. Sharpey's fibers extend from ligament tissue deep into bone.[104]

Helen Lu and her colleague developed a stratified scaffold predesigned to mimic the multitissue transition found at the ACL-to-bone interface.[105] The scaffold consists of three distinct yet continuous phases: Phase A for ligament formation, Phase B for the interface, and Phase C for the bone region. Interface-relevant cell types, specifically fibroblasts, chondrocytes, and osteoblasts, were tricultured on this scaffold, and the formation of cell-type- and phase-specific matrix heterogeneity as well as fibrocartilage formation was evaluated over 8 weeks in a subcutaneous athymic rat model. Acellular scaffolds as well as scaffolds cocultured with fibroblasts and osteoblasts served as controls. It was found that the triphasic scaffold supported multilineage cellular interactions as well as tissue infiltration and abundant matrix production *in vivo*. In addition, controlled phase-specific matrix heterogeneity was induced on the scaffold, with distinct mineral and fibrocartilage-like tissue regions formed in the tricultured group.

In the rabbit model we used, direct ligament–bone insertion with the four typical zones (bone, mineralized fibrocartilage, fibrocartilage, and ligament) was reconstructed, which resembled the native structure of ACL–bone insertion. In the pig model, the healing of regenerated ligament–bone junction began with proliferation of fibrovascular tissue in the interface. A mature direct insertion with the four typical zones was observed after 24 weeks, which was consistent with other studies.[106,107] However, the healing proceeded by means of fibrous tissue at the regenerated ligament–bone junction in the pig model. The collagen fibers resembling Sharpey's fibers projected from regenerated ligament into bone tissue. The indirect insertion was observed after 24 weeks. The disparities between these two animal models may be due to differences in the species and mechanical environment. This would require further investigations.

5.525.9. Summary

Ligament tissue engineering has achieved much progress in recent years and many potential tissue-engineered ligaments used for ligament regeneration have been reported. The success of ligament regeneration procedure depends on three major factors: implant characteristics (scaffolds, cells, and signals), surgical procedure, and postsurgery rehabilitation protocol. The main difficulties are complex mechanical stress faced by tissue-engineered ACLs, harsh environment, and poor blood supply after ACL ruptures. As tissue-engineered ligaments combine three dominant components, that is, scaffolds, cells, and signaling molecules, we have discussed ACL anatomy, current challenges in tissue repair, biomaterials and scaffold design, cell sources, bioreactors, delivery of growth factors, and animal models in ligament tissue engineering. With greater research intensity and better understanding, a suitable substitute for ligament regeneration can be developed for clinical application.

Glossary

Angiogenesis The formation of new blood vessels.
Bolus A single, large dose of a drug.
Cross-link To covalently or ionically bond two polymer chains.
Electrospin A process in which an electric charge is used to draw up very fine fibers from a liquid polymer solution.
Innervation The distribution of nerve fibers to an organ or body region.
Micropattern To control the spatial arrangement at a microscopic level.
Photolithography The use of light energy to transfer a geometric pattern to a light-sensitive material.
Quiescent In a state of rest; a cell that is not dividing.
Sarcomere The contractile unit of a myofibril in striated muscle.
Striated muscle Contractile tissue under conscious control that consists of fibrils combined into a parallel fiber.
Topography The form and structure of a surface.
Vascularization The formation of blood vessels and capillaries in living tissue.
Xeno-free Solely of human origin (without animal contaminants).

5.526.1. Introduction

As specific cell types and their environments are becoming increasingly well characterized, it is becoming possible to manipulate and direct cells for precise functions. Scientists are studying how to grow and differentiate cells with the hope that any tissue in the body can be replaced. For instance, advances in tissue engineering could allow skeletal muscle fibers or muscle precursor cells to be grown in culture and then transplanted into a patient whose natural muscle regeneration has been impaired due to disease, age, or injury. However, much work remains to be done studying the complex signaling pathways and environmental cues that direct cell function and fate. In order to effectively grow tissue for therapeutic use, it is important to understand and perhaps, to mimic at least to some degree, the natural molecular composition of

such tissue. Currently, a major obstacle in tissue engineering using transplanted cells has been the efficient survival, proliferation, and differentiation of cells *in vivo*.

When designing a modern biomaterial for use in tissue engineering, various properties must be taken into account including the chemical composition of the material, the mechanical properties of the material, and any biological factors that will be incorporated. This chapter discusses several of the most common biomaterials including synthetic polymers and biomaterials based on natural nonmammalian and mammalian proteins. Additionally, since the natural environment is dynamic, this chapter discusses current work on the effect of stress, strain, and electrical current on biomaterials. Last, it discusses which biologically active molecules, such as peptides, growth factors, and other signaling molecules, can be incorporated in order to efficiently direct cell fate in tissue engineering.

Since cells inhabit a diverse range of environments, a universal biomaterial would not be suitable for all tissue types. To be most effective, a biomaterial should be designed for a specific type of tissue. This chapter focuses on defining the environment and important signaling molecules for skeletal tissue engineering by highlighting the importance of skeletal tissue engineering, discussing natural skeletal muscle development and repair, and discussing the current and future state of applicable biomaterials.

5.526.2. Importance of Skeletal Muscle Tissue Engineering

One of the major diseases affecting skeletal muscle is muscular dystrophy, a genetic hereditary disease, in which patient's muscles are weakened due to a loss of muscle-specific proteins, such as dystrophin. There are several types of muscular dystrophy ranging in severity: some cause little disability while others such as Duchenne muscular dystrophy (DMD) are often fatal. DMD mostly affects children from a young age and gets progressively worse. People with this form of muscular dystrophy are often unable to walk by the time they are a teenager and many die before their mid-twenties. There is currently no cure for muscular dystrophy, but skeletal muscle tissue engineering offers the prospect of regenerating a patient's muscles.

Additionally, tissue engineering can be used to help facilitate muscle regeneration in aged individuals whose ability to maintain or regrow muscle is greatly reduced, which causes the debilitating age-specific muscle wasting, lack of mobility, and independence.

Last, the development of biomaterials that emulate the natural tissue milieu can be used for *in vitro* studies. By studying cells in a more realistic, yet closely controlled environment, new models of young and aged, normal or pathological tissues can be studied with higher molecular precision.

5.526.3. Muscle Development and Repair

Skeletal muscle is composed of many individual fibers which are grouped into bundles and surrounded by connective tissue. Each muscle fiber is a long multinucleated cell composed primarily of actin and myosin myofibrils arranged into repeat units known as sarcomeres. In order for the muscle to function properly, it is critical that it is both highly vascularized and innervated.

During embryonic development, skeletal muscle arises from mesodermal precursor cells.[1] Upregulation of MyoD and Myf5 transcriptional activators directs these precursor cells to the myogenic linage.[2] MyoD/Myf5 positive cells become myoblasts then stop proliferating and terminally differentiate into cells that begin expressing myogenin, myosin heavy chain (MHC), and muscle creatine kinase (MCK), which are muscle-specific genes. The fusion-competent myoblasts fuse to form multinucleated myotubes which later on mature into muscle fibers. Additionally, quiescent satellite cells, a myoblast precursor that escaped terminal myogenic differentiation, populate the myofibers and are activated upon injury to regenerate damaged myofibers.[3–5]

Adult muscle regeneration can be broken into two phases, a degenerative phase in which damaged tissue is removed and a regenerative phase in which new tissue is grown. Injury often results in an increase of myofiber permeability, which results in increased serum levels of muscle proteins released by dying muscle fibers. At this time, molecular signals are sent for neutrophils to invade the muscle. Then, macrophages enter the injured site to phagocytose damaged cells and clear the way for muscle regeneration to begin.[6] It has been shown that the removal of damaged tissue and the secretion of growth factors by macrophages are required for normal muscle regeneration.[7] Furthermore, undergoing regeneration requires remodeling of the extracellular matrix (ECM). Where extensive damage occurs, or in the aged tissue, the ECM does not get completely remodeled, muscle injury site does not regenerate entirely, and fibroblasts form scar tissue which impairs muscle repair and muscle function.

The ECM serves as a structural support for tissue and is also vital for controlling cellular responses, for example, adhesion, migration, growth, and differentiation. Therefore, when designing biomaterials to be used in tissue engineering, it is important to accurately recreate the ECM effects on the key regenerative properties of muscle cells. *In vivo*, the basal lamina, which constitutes much of the skeletal muscle ECM, is composed of numerous components, including collagen, perlecan, laminin, entactin, fibronectin, as well as several glycoproteins and proteoglycans.[8] These proteins serve as a scaffold to provide support for cells to bind to and align in order to form parallel myofibers. Fibronectin in particular is important for the maintenance of skeletal muscle because it can bind to both integrin receptors on cells and other molecules in the ECM. Additionally, the ECM traps and regulates the diffusion of growth factors whose effect on cell fate will be discussed later in the chapter. Last, once the fibers have matured, movement generated from the contraction and relaxation of muscle fibers relies on cells binding to the ECM.

Adult skeletal muscles have a robust system of repair. It has been found that a large number of new myotubes arise within a couple days of acute muscle damage.[9] As mentioned earlier, skeletal muscle is made up of many muscle fibers which are long, multinucleated cells which arise from the fusion of myoblasts, a muscle progenitor cell. These myoblasts derive from satellite cells which are involved in postnatal regeneration of

skeletal muscle throughout adult life.[3,10] Satellite cells are mononucleated cells located on top of the plasma membrane of a muscle fiber and beneath the basal membrane, which surrounds the muscle fiber.[11,12] Satellite cells are believed to be the primary stem cells responsible for muscle regeneration and have been shown to be capable of self-renewal as well as differentiation into more specific muscle precursor cells (two key characteristics of stem cells).[13,14] The idea that they are self renewing is supported by the fact that in normal healthy individuals the number of satellite cells and their regenerative capacity remains fairly constant through multiple rounds of injury and repair.[9] Additionally, the theory that they are responsible for muscle regeneration is supported by experiments that show satellite cells alone are capable of regenerating damaged skeletal muscle.[9]

Satellite cells are quiescent, meaning that they remain in G0 phase of a cell cycle, until they receive certain stimuli at which point they activate, proliferate, and differentiate into muscle progenitor cells called myoblasts. Several common stimuli which trigger the activation of satellite cells include exercise, injury from myotoxins, disease, denervation, or other muscle damage. The satellite cells quickly become myoblast precursor cells, which differentiate into fusion-competent myoblasts. These myoblasts continue proliferating until there is a sufficient number for them to begin fusing with existing fibers or with other myoblasts to form new multinucleated myotubes.[5] Much work still needs to be done to characterize satellite cells and their niche (a specific microenvironment where muscle stem cells reside) in order to determine the exact combination of factors promote quiescence, self-renewal, and differentiation of satellite cells.

Currently, much of the research around muscle regeneration is focused on myoblasts since they are a muscle progenitor cell that can easily be expanded *in vitro*. However, myoblasts can only be cultured for a certain number of passages before the cells lose their regenerative capacity. Additionally, experiments using transplanted myoblasts have run into several issues.[15] First, majority of transplanted myoblasts die within the first few days after transplantation.[5] Second, myoblasts do not migrate more than ~200 μm from their initial injection site.[16] Last, transplantation requires immunosupressants, otherwise the cells are rejected by the host's immune system. Therefore, it would be ideal to develop a biomaterial that would allow satellite cells to be cultured.

Interestingly, it has been found that muscle stem cells maintain telomerase activity as opposed to their more differentiated progeny, myoblasts; and that aged mouse muscle fibers do not have shortened telomeres.[17] Therefore, it is advantageous to engineer muscle tissue from satellite cells which have telomerase activity, as opposed to expanded in culture myoblasts which would likely have shortened telomeres.

For functional muscle, innervations and vascularization are just as important as proper myofiber development. Functional muscle requires the transport of oxygen, carbon dioxide, and nutrients as well as waste, all of which is carried through the blood. Therefore, skeletal muscle requires an abundant blood supply, with blood vessels permeating throughout the muscle. A recent study emphasizing satellite cells' reliance on being close to blood vessels found that in humans 68% of satellite cells and in mice 82% of satellite cells are found within 5 μm of either capillaries or vascular endothelial cells.[18] Furthermore, in order for muscle to be functional, it must be able to receive and respond to nerve impulses. Therefore, any methods of engineering skeletal muscle must be capable of forming and promoting neuromuscular junctions. Summarily, for any engineered muscle tissue to be successful *in vivo*, it will have to promote and maintain the formation of vascularized and innervated myofibers.

5.526.4. Scaffolding Materials

5.526.4.1. Hydrogels

A hydrogel is classified as a highly hydrated polymeric material, usually with a water weight content of at least 30%. Due to this high water content, hydrogels have a high degree of flexibility that is often similar to that of natural tissue.[19] Hydrogels are composed of hydrophilic polymer chains and can be made from either natural or synthetic materials. These polymer chains exist as a liquid polymer solution in which cells of interest can be suspended. The polymer chains can be connected by a process called cross-linking: linking by an ionic or covalent bond. Cross-linking can be triggered by light, allowing for control over gelation based on light exposure. These scaffolds are advantageous in tissue engineering for many reasons: hydrogels are typically degradable, are highly variable in composition, can be produced under mild conditions, can be delivered in a minimally invasive manner, and share many mechanical and structural properties with natural tissues and the ECM.[20] Hydrogels provide a three-dimensional (3D) environment for which cells can adhere to and grow in. This environment can be varied based on the materials used or by the method of gel formation.[21]

5.526.4.2. Synthetic Materials

The use of synthetic materials in scaffolds allows for strict control of composition and chemical properties making the gel variable and reproducible. The degree of variation possible in synthetic hydrogels makes them an attractive choice as a scaffold for a wide variety of tissue engineering applications. Factors such as molecular weight, cross-linking sites, and degradable linkages can be varied in order to manipulate gel formation, density, and degradation properties.[20] These manipulations aid in the development of biomaterials that can have a specific, desired biological effect on cells.[22]

Of the synthetic materials currently being used in tissue engineering, poly-ethylene oxide (PEO), poly-ethylene glycol (PEG), and poly-vinyl alcohol (PVA) are polymers that are used most prevalently. These polymers are hydrophilic and can be modified by the addition of acrylates or methacrylates to each end.[20] These are salts and esters of acrylic and methacrylic acid, respectively, and they are used in polymer synthesis because they contain very reactive double bonds. This reactivity allows for the linking of polymer chains. The addition of these salts or esters is done by a process called photo-cross-linking in which light energy is used to make a covalent bond between two macromolecules. A hydrogel can then form when these modified polymers are exposed to UV light and cross-linked. The gel can be modified further to be degradable

by the creation of block copolymers, which incorporate hydrolytically degradable poly-lactic acid (PLA) and enzyme specific cleavage sequences of oligopeptides. The rate of degradation can then be controlled by the number of cleavage sites in the polymer and the amount of enzymes present in the scaffold environment.[20] This technique can be used to vary the degradation times of synthetic scaffolds for specific applications.

Although many of these synthetic materials have shown promise as scaffolds for artificial muscle growth, they suffer from a few drawbacks. Hydrogels, while largely nontoxic and nonimmunogenic, do not promote significant cell adhesion, which is critically required for myoblast migration and fusion. Therefore, for a functional scaffolding material, these hydrogels must be modified in order to create an adhesive surface. This modification involves covalent bonding of ECM proteins or peptide sequences to the polymer that are recognizable to myogenic cell receptors. Such technique has been, in fact, utilized in many recent studies, some of which are discussed below.

Another disadvantage to polymeric scaffolds in muscle tissue engineering is that they have a very high tensile modulus and a low yield elongation (3–4%), rendering them relatively inflexible and unable to undergo significant compaction. It is hypothesized that functional skeletal muscle tissue will fully develop *in vitro* only when subjected to strains that mimic those that occur during growth in the natural niche.[23] The inability of polymeric scaffolds to be compacted means that these scaffolds do not serve as an accurate representation of the natural environment in which muscle tissue develops functions and regenerates. During early phases of development of skeletal muscle, contractions of muscle fibers help stimulate the expression of proteins required for continued growth and development of muscle tissue. Without compaction of the scaffold, several key proteins involved in muscular development, namely actin and integrin, may not be properly induced for expression or become mislocalized within muscle cells. The lack of compaction and protein misexpression will likely hinder the synthesis and deposition of collagen and other key ECM proteins, ultimately perturbing the 3D structure of skeletal muscle.[24] Thus, correct compaction of the scaffold is required for the formation of artificial muscle tissue to be able to properly form and contract.

Many recent studies have attempted to alter polymeric scaffolds to overcome the drawbacks mentioned above. These alterations largely involve the specific geometric shaping of scaffolds in order to favor the growth of muscle tissue that is similar to natural muscle. By incorporating components into these scaffolds to which cells can bind, progress has been made in engineering muscle tissue that is structurally and functionally quite similar to natural tissue. Additionally, by using fabrication tools, such as photolithography (described below), etching, and molding, polymeric (and natural) scaffolds can be altered so as to provide a favorable topography for directional growth of tissue.[25,26] A few recent applications of polymeric scaffolds are discussed next.

Poly(L-lactic acid) (PLLA) has been used as a scaffolding substrate in both film and fiber forms. Strong, elastic fibers can be created by a process called wet-spinning, in which PLLA in a solvent (usually chloroform) is drawn up through a thin needle and extruded into a coagulating solution. In this solution, PLLA particles agglomerate and form fibers, which can then be removed from solution and integrated into scaffolds.[27] The fibers, when coated with ECM proteins such as laminin and fibronectin, allow for improved cell adhesion because the presence and moreover fibrillar topography of these proteins provide cells with numerous points for attachment. Additionally, the synthetic fibers provide a 3D scaffold favorable to elongated muscle fiber formation. In one study, these coated fibers were shown to promote myoblast differentiation into multinucleated myofibers, expressing muscle-specific markers such as myosin and α-actinin. The myoblasts were able to fuse to form linear, parallel myofibers along the individual PLLA fibers, mimicking natural skeletal muscle development.[28]

Similarly, polypropylene fibers (10–15 μm in diameter) coated with laminin have been used to create cell sheets. By stringing fibers together in close proximity, such as with a small comb, the individual coated fibers are allowed to interact with adjacent fibers. When placed 30–55 μm apart, the coated fibers encouraged the formation of a contractile skeletal muscle cell sheet with parallel-oriented myofibers.[29] The parallel alignment of these myofibers is directed by the geometry of the fibers; the small diameter allows for growth only along the axis of the fiber. When placed in close proximity, the layers of cells on single fibers can merge and form a cell sheet. However, as the study pointed out, upon sheet formation, the forced-parallel effect of single fibers disappears. As layers grow higher on the scaffold, they are no longer restricted by the fibers to a longitudinal alignment, so myotubes on the outermost layers will be less aligned than those in the center. This divergence in alignment could be limited by stacking thinner cell sheets together or by creating a 3D scaffold with horizontal and vertical planes so as to inhibit overly thick (and therefore misaligned) cell layers.[29] Once the techniques for functional cell sheets are perfected, these sheets could have important clinical use, such as use in grafts for abdominal hernias or muscle tears.

Polydimethylsiloxane (PDMS) is another material that has been used for scaffolding, especially in the field of microfabrication. PDMS is a silicon-based organic polymer with a repeat unit of $SiO(CH_3)_2$. It is generally nontoxic and inert and is FDA approved making it a good choice for use in scaffolding. Because of its dual elastic and viscous (viscoelastic) nature, PDMS can be used as a molding material. At high temperatures, PDMS will be viscous, while at lower temperatures and longer set times it will act as an elastic solid. Therefore, PDMS can be poured over a mold and left overnight (long set time) and it will take the shape of the mold and harden.[30]

In a recent study, PDMS scaffolds with microgrooves were shown to promote the growth of organized muscle tissue. In this approach, a photoresist was patterned by light in a process called photolithography, which uses light to transfer a geometric pattern to a light-sensitive material by selectively removing parts of the material. The microgrooves, which were 2 μm wide and 7 μm tall, were designed to be narrower in width than, but about the same height as, the size of the myoblasts that would be cultured on the scaffold. This was so the myoblasts in the bottom layer would be forced to sit either on the top of the ridge or to squeeze into a groove. Most myoblasts preferentially sunk into the grooves, allowing directional organization of the primary layer of cells. This was compared to shallower

microgrooves (2 μm in height) in which the myoblasts could lie across several layers and aligned poorly. When additional layers of myoblasts were seeded on top of this aligned primary layer, the myoblasts followed the parallel alignment of the first layer and formed mostly aligned myotubes. This muscle construct had multinucleate myotubes that also stained positive for myosin, showing its similarity to natural striated muscle. Furthermore, it was shown that the multilayered construct could be peeled off the PDMS scaffold, pointing to the utility of this approach.[30] Fabricated tissues could be grown on this scaffold and then detached for use in grafts and other clinical applications. It is important to note, however, that the myotubes in the secondary and higher layers differed morphologically from the primary layer of cells. Namely, the nuclei in the primary layer were elongated while those in the higher layers were rounded, and the expression levels of myosin differed between layers.[30] These differences show that surface topography has an important impact on myotube morphology and gene expression and, thus, should be considered in scaffold designs aimed at skeletal muscle engineering.

In another interesting study, PDMS scaffolds were created on molds patterned with abrasives. These molds were fabricated by grinding fine sandpaper (150 and 400 grit) linearly along an iron block. PDMS was poured over these molds to create micropatterned scaffolds. When coated with laminin, these scaffolds were also shown to promote proliferation of myoblasts and alignment of myotubes along the direction of grinding.[31] As opposed to other commonly used methods, this method is very easy, low cost, and does not require special equipment.

Patterned scaffolds have also been created out of other materials such as glass. Glass is a noncrystalline solid that can be micropatterned by several different methods. A recent work showed that borosilicate glass (composed of silica and boron oxide) patterned with aluminum allowed for myotube formation and alignment without any coating. This scaffold was created by layering aluminum on top of the glass where a photoresist and photolithography were used to create a micropattern on the aluminum. The aluminum was then patterned using a process called reactive ion etching followed by an etching of the glass. The final scaffold consisted of only a 1.5-μm thick aluminum layer and etched glass. The channels, which were optimally 6.7-μm deep and 20-μm wide, promoted neat, parallel arrangement of myoblasts, which fused to form myotubes. Visualization by staining showed long bundles of actin filaments, as well as elongated nuclei – properties evocative of natural muscle. The myotubes were also shown to be capable of spontaneous and electrically induced unidirectional contractions, demonstrating that this technique could be useful for studying the basis of contraction in muscle tissue. Also, due to the neat arrangement of myotubes, individual cells with their protein expression were able to be distinguished.[32]

In order to overcome the drawback of inflexibility of typical polymeric scaffolds, recent attempts have been made to create a synthetic material with more favorable mechanical properties. One such material is a degradable block copolymer of polyesterurethane called DegraPol. This scaffold is created by a process called electrospinning in which an electric charge is used to draw very fine fibers from a liquid.[33] DegraPol exhibits linear elastic behavior up to 10% deformation, meaning it can be stretched significantly without losing its shape. It also has an elastic modulus around 10 MPa, a 1000-fold reduction from other polymeric scaffolds.[23] This high elasticity of the scaffold owes to the reticulated structure of the membrane (from electrospinning) as well as the elasticity of the block copolymer itself. This elasticity is a suitable match to the elasticity of soft tissues such as skeletal muscle. Regarding cellular response on these scaffolds, myoblast adhesion and directional organization along the scaffold fibers were similar to the physiological muscle in which myoblasts develop into parallel-oriented myotubes. Additionally, DegraPol has been shown to be nontoxic and it is degradable by hydrolysis.[23] These findings point to the potential of DegraPol as an alternative promising scaffold for muscle tissue engineering.

5.526.4.3. Natural Materials

Naturally derived polymers have also been widely used in hydrogel and scaffold synthesis. These natural polymers either are part of, or contain components similar to the natural ECM. Collagen, fibrin, hyaluronic acid (HA), alginate, and chitosan are some of the most common natural polymers used. Collagen is the most abundant protein in mammalian tissues and therefore is a suitable choice for a hydrogel matrix. Similarly, HA, alginate, and chitosan are found in all tissues of adult mammals. These are linear polysaccharides that integrate well *in vivo* due to their natural niche. These purified or recombinantly produced ECM components can be combined with other natural components, for example, bioactive peptides, growth factors, etc., to create a well defined and potentially less immunogenic muscle engineering scaffold.

5.526.4.4. Collagen

Collagen is composed of three polypeptide chains wrapped around one another to form a rope-like structure. The strands are held together by both hydrogen and covalent bonds and can self assemble stably. Collagen fibers can be manipulated with the help of cross-linkers, so as to vary their mechanical properties. This manipulation includes cross-linking with chemicals such as glutaraldehyde or formaldehyde, physical cross-linking using UV radiation or freezing/heating treatments, and by the addition of other polymers such as HA, PLA, and PGA (poly-glycolic acid). Another advantage of collagen as a scaffold material is that it is naturally degraded by collagenase. This means that the degradation of collagen gels can be controlled locally by cells included in engineered tissue or adjacent to the transplant.[20]

Collagen has been a popular choice for use in muscle engineering scaffolds. Hydrogels composed largely of collagen have been shown to induce the formation of mature sarcomeres. However, one notable limitation is that collagen gels have been shown to exhibit poor nutrient diffusion, which leads to a lower oxygen consumption by the artificially created muscle.[34] Collagen matrices have also been combined with microfabricated scaffolds in order to promote 3D tissue formation. This is done with PDMS molds with staggered posts. These molds can be layered with a collagen/fibrin hydrogel in order to create porous tissue networks. These networks allow

for improved nutrient and oxygen transport through the gel as well as effective cell alignment.[24] Using this technique, pore size, thickness, and spatial cell distribution can be reproducibly varied, allowing for controlled manipulation of artificially engineered muscle tissue. For example, by creating a PDMS mold with tall and very thin posts, the size of the pores will be minimized, thereby maximizing the tensile strength of the engineered muscle while still allowing nutrients and oxygen to reach the growing cells.[24]

5.526.4.5. Fibrin

Fibrin is a naturally occurring fibrous, elastic protein that also has favorable properties for scaffold formation. Fibrin plays an important role in the body for blood clotting; when injury occurs, a soluble precursor to fibrin, called fibrinogen, is cleaved by a protease called thrombin. Fibrin fibers then are cross-linked to form an interlacing, insoluble mesh, known as a clot. This clotting process can be utilized in order to create self-assembling scaffolds of fibrin, which is a natural biocompatible and biodegradable protein. Unlike polymeric scaffolds, fibrin has a high affinity for biological surfaces and molecules making it a good candidate for muscle tissue engineering and transplantation vehicle.

Taking the advantage of the fibrin–thrombin system, a recent work demonstrates a dual compartment injection device that is a 3D injectable scaffold. In the device, one compartment was loaded with fibrinogen and the other was loaded with thrombin and cultured myoblasts. When these two compartments were combined in a lower chamber, fibrin polymerized in about 30 s creating a 3D fibrin–myoblast matrix. This liquid to gel transition allowed successful 'filling' of muscle defects in a rat model.[35] This study focused on the idea of culturing myoblasts *in vitro* but allowing differentiation to occur *in vitro*. This ensures that the artificial muscle will fit the muscle defect, as opposed to prefabricated constructs, which might not be of optimal shape. Upon implantation, the matrix allowed the localization of myoblasts at the site of injury and fusion of the transplanted male myoblasts with host female muscle fibers successfully occurred.[35] Introducing vascularization into the fibrin–myoblast matrix could further improve the therapeutic potential of this scaffold.

5.526.4.6. Hyaluronic Acid

HA is a simple glycosaminoglycan composed of a repeating disaccharide and is often seen *in vivo* during wound healing. Hydrogel formation with HA is done by esterification, by annealing, and by covalent cross-linking with hydrazide (a compound with a nitrogen–nitrogen covalent bond and an acyl group) derivatives. HA can also be combined with collagen and alginate to form compounded hydrogels. HA is naturally degraded by hyaluronidase, and like collagen, its degredation can be regulated by cells present in the engineered tissue.[20]

5.526.4.7. Alginate

Alginate is another commonly used natural material, though the purity of commercially available alginate has continually been a problem. Alginate is a linear polysaccharide that is derived from brown seaweed and bacteria. It is composed of alternating mannuronic acid and guluronic acid monomers. In order for gel formation to occur, divalent cations such as Ca^{2+} come into contact with the monomer blocks and interact with the guluronic acid to form ionic bridges between polymer chains. Variation of the amount of mannuronic acid compared to guluronic acid will change the cross-linking density of the gel, and therefore, properties such as pore size and stiffness can be tuned. Another technique of gel formation is cross-linking of alginate with adipic hydrazide (a dicarboxylic hydrazide) and PEG.[20] An important aspect of alginate scaffolds is the addition of cell adhesion ligands so that mammalian cell interaction can occur. RGD can be covalently attached to alginate scaffolds and, at specific densities, has been shown to promote efficient myoblast differentiation.[36]

The degradation of ionically cross-linked alginate hydrogels is not specific, but rather the gel degrades very slowly and without control. The rate of dissolution depends on the ionic environment that the scaffold is placed in. As ion exchange of calcium occurs, individual polymer chains dissociate leading to a loss in mechanical stiffness. As a result of dissolution, high molecular weight polymer chains are released, which may present a problem when using these gels for *in vivo* tissue engineering applications.[20] In order to counter this unfavorable degradation, work has been done to synthesize partially oxidized alginate that can undergo hydrolysis in aqueous solutions. It was shown that alginate that is oxidized to about 5% will degrade with a rate depending on the pH and temperature of the aqueous solution. This partially oxidized polymer retained all of the functionality of a traditional alginate hydrogel, but its degradation time was reduced to nine days.[37] Another study showed that myoblasts had a high proliferation rate on degradable alginate gels of controllable mechanical stiffness (13–45 kPa) compared to nondegradable gels.[38] Additionally, alginate has been used as part of a polymeric delivery vehicle for myoblasts. A system consisting of a macroporous alginate scaffold and growth factors (HGF and FGF2) greatly increased the viability and migration potential of seeded myoblasts over a period of 5 days.[39] This kind of delivery system, once perfected, would be of great utility to site-specifically deliver myoblasts and

5.526.4.8. Chitosan

Chitosan has been used in tissue engineering scaffolds due to its similarity to natural glycosaminoglycans. Chitosan is derived from chitin and is a linear polysaccharide composed of D-glucosamine derivatives. The free amino groups of chitosan can be protonated making chitosan soluble in acids. The dissolved chitosan can then form a gel with an increase in pH or by the extraction of the solution into a nonsolvent. Gel formation can also occur by cross-linking with glutaraldehydes, UV radiation, and temperature changes. Chitosan is degradable by lysozyme, a common enzyme present in humans. The speed of degradation can be controlled by the intrinsic properties of the chitosan: the degree of nitrogen deacetylation varies usually from about 50% to 90% and will determine the crystallinity of the chitosan gel. The rate of

degradation of these gels is inversely related to the degree of crystallinity: the less crystalline the material, the faster it degrades.[20]

An important potential application of hydrogels is their ability to be reversibly cross-linked based on changing conditions. This property can be used when tuning these gels for clinical applications. For example, many studies have shown development of hydrogels with specific gelling temperatures. These so-called thermoreversible gels will transform from solution to a gel above a certain temperature. This is especially applicable for the development of injectable hydrogels as an *in vivo* tissue engineering scaffold. In one study, a PEG–chitosan copolymer was shown to gel above 25 °C and in a pH range of 6.4–8.5, and thus gels readily in physiological conditions.[40] The mechanism behind thermoreversible behavior has to do with changes in intermolecular bonding with temperature variation. At low temperatures, hydrogen bonding between water and chitosan and PEG chains prevails, disrupting association between polymer chains, thus making the PEG–chitosan copolymer soluble in water. As the temperature is increased, water molecules begin to fall off the polymer chains, allowing an increased interaction between the polymer chains. Without competition from water, hydrogen bonding between chitosan chains as well as intermolecular interactions between PEG chains can occur, leading to gelation.[40] As opposed to other studies in which cross-linking was used to create copolymers, this study utilized a process called grafting. In this process, a PEG–aldehyde was reacted with chitosan to create an imine (a compound containing a carbon–nitrogen double bond) and then reduced to form the PEG-grafted chitosan. Using this technique, the amount of PEG grafted can be varied in order to tune the viscosity, gelling temperature, and solubility of the copolymer.[40] As a side note, it is also important to note that the use of chitosan, a natural polysaccharide, and PEG, an FDA-approved polymer, makes this gel biocompatible as well as biodegradable. With these properties, this gel has the potential to be used clinically as an injectable scaffold loaded with cells.

Chitosan has also been used as a biodegradable surface onto which cellular micropatterns have been added.[41] These micropatterns can contain growth factors or cells themselves, so as to facilitate spatial control over the adhesion and differentiation of cells. In this way, cells can be exposed to different signals on the same scaffold, allowing a more dynamic signaling network and therefore a more biologically relevant growth environment. One example of such micropatterning is the stamping of lanes of immobilized vascular endothelial growth factor (VEGF) (covalently attached to collagen IV) onto a non-cell adhesive layer of photo-cross-linkable chitosan. When embryonic stem cells (ESCs) were seeded onto this surface, they were shown to preferentially differentiate into endothelial cells when on the VEGF lanes, but differentiated into vascular smooth muscle-like cells on the collagen only lanes (without VEGF). By using this technique with further improvements, such as layering of sheets, it may be possible to grow vascularized tissue by using a common progenitor population. However, the study mentioned involves the growth of smooth muscle tissue, and work remains to be done with this technique and skeletal muscle tissue.[42]

5.526.4.9. Matrigel

Matrigel is a commercially available matrix that is often used for coculture with other natural matrix materials such as collagen. Matrigel is derived from a mouse tumor rich in laminin, collagen, and other ECM proteins.[43] Due to its murine origins and potential tumorigenicity, Matrigel cannot be used in humans. However, it is a useful component in scaffolds as a growth factor and adhesion factor combination and was extensively used to study approaches to engineering muscle and other tissues and to maintain ESCs in culture.[44]

5.526.4.10. Hydrogels for Vascularization

Skeletal muscle is a thick, highly vascularized tissue and in the engineering of skeletal muscle tissue, a critical hurdle to overcome is the difficulty in obtaining well-vascularized engineered tissue. Vascularization of artificial muscle tissue *in vitro* is an important factor in maintaining cell viability during tissue growth, inducing proper structural organization of the muscle, and promoting functional vascularization upon implantation.

Many studies have attempted to induce vascularization of muscle tissue *in vivo* by delivery of growth factors.[45–47] However, recent attempts have been focused on the induction of endothelial vessel networks in engineered muscle tissue *in vitro*. In this approach, a highly porous 3D matrix composed of 50% PLLA and 50% poly-lactic-glycolic acid (PLGA) was seeded with mouse myoblasts and human embryonic (or umbilical vein) endothelial cells. With this construct, it was shown that the myoblasts successfully differentiated to form partially aligned and elongated myotubes. Moreover, the endothelial cells organized into tubular structures in between these myotubes to form vessel networks. When implanted, the prevascularized construct showed functional integration with *in vivo* muscle tissue; host blood vessels permeated into the constructs and after 2 weeks, the construct-derived vessels had anastomosed with host vessels.[45] Consequently, blood perfusion to the implant was relatively effective, pointing to an improved survival probability of these prevascularized implants *in vivo*. The success of this multicell tissue engineering illuminates the potential to provide the appropriate signals for organization and vascularization of skeletal muscle tissue first *in vivo* and then successful transplantation into a patient.

As an alternative to using biomaterials as scaffolding materials for growth of functional tissue, the use of polymer-coated materials has been explored. By coating conventional surfaces with a temperature sensitive polymer (poly(*N*-isopropylacrylamide)) at nanoscale thickness, changes in the surface properties of the scaffold can be manipulated by simply changing the temperature. At high temperatures, that is, those above a certain critical temperature, the polymer-coated surface is slightly hydrophobic, allowing for cell adhesion and proliferation. However, at temperatures below the critical temperature, the surface becomes slightly hydrophilic, allowing for the formation of a hydration layer between the attached cells and the culture surface. This permits easy harvest of intact cell sheets so as to maintain the important cellular connections within the sheet. This technique facilitates not only the growth

of thick, vascularized tissue, but also the easy transfer of cell sheets to other cultures or host tissues.[48]

5.526.5. Additions to Current Matrices

As discussed, current polymers serve as an important first step when designing a scaffold for tissue regeneration.[49,50] However, in the body, cells are tightly regulated and directed by a myriad of signals. To construct a more useful matrix and to better mimic the *in vivo* environment, biologically active molecules such as proteins and growth factors can be incorporated into polymers. During natural regeneration, there are three types of factors that act on the cell: molecules that make up the ECM, both autocrine and paracrine signaling molecules, and physical forces (such as pressure, flow, and shear). When designing a matrix which is more complex than a simple polymer, there are several requirements that must be considered. These requirements include the ability to embed cells, degradability to allow natural tissue formation, incorporation of factors that promote the growth of specific cell types (myofibers, capillaries) while impeding the growth of other cell types (scar tissue), as well as the spatial and temporal release of these growth factors.

Currently, the transplantation of myoblasts has not been very successful. Studies have found that myoblasts injected systemically are unable to cross vasculature barriers and must, therefore, be transplanted at the site of injury.[51] However, a large number of injected myoblasts die within several days. A material's ability to elicit aspects of natural regeneration in conjunction with transplanted cells may improve cell survival and integration.

Before discussing more advanced biomaterials, it is important to note that the natural environment of an organ (especially pathological or injured and regenerating tissue) is incredibly complex, and it is likely that it will be impossible to recreate it perfectly. However, cells secrete their natural extra cellular matrix proteins.[52] Furthermore, it has been shown the molecules that make up the ECM are upregulated as myoblasts fuse and mature to form myotubes. If suitable matrices can be engineered that effectively promote the initial cell viability, migration into injury site and support the regenerative responses, then, as these cells expand and differentiate, they will secrete molecules and proteins that change the engineered ECM into the natural ECM of skeletal muscle. Signals are passed bidirectionally between cells and their environment and cells contained in the muscle transplant will dynamically change their responses based on environmental cues that are provided by engineered niche and those emanating from the site of the transplantation.[53]

One way to vastly improve engineered matrices is with the incorporation of growth factors. These growth factors are often absorbed in the ECM so that the signals are targeted to the surrounding cells rather than throughout the body. By introducing desired growth factors, it is possible to enhance the proliferation of myoblasts, formation myofibers and encourage vascularization.[6,52] Various growth factors that are important in adult muscle tissue formation have been identified. A few important ones include: hepatocyte growth factor (HGF) which activates satellite cells, fibroblast growth factor (FGF) which increases satellite cell proliferation and perturbs differentiation, and insulin-like growth factor (IGF) which increases proliferation and increases differentiation.[3,54] Furthermore, culturing muscle precursor cells *in vitro* in the presence of growth factors increases their survival upon implantation.[55] These molecules are of course tempting candidates to be added to scaffolds for skeletal muscle engineering.

Several studies have tried to improve muscle tissue engineering by supplementing transplantation of matrices and/or cells with injections of growth factors. However, bolus injects have proved ineffective due to their low specificity for the target cell population, the short half life of many growth factors, and the possible side effects of increased growth factor concentration in other parts of the body.[56,57] Growth factors can be incorporated into polymers and then released over time to a precise location. By embedding proteins within the polymer, they are protected from premature denaturation and loss of activity. Furthermore, the creation of high-pressure gas foaming technique allowed the growth factors to be incorporated into polymers without using harsh chemicals or high temperatures which often lead to denaturation and loss of function.[57] As discussed earlier, the degradation of a polymer or its permeability can precisely be controlled, which means that the release rate of embedded growth factors can be tightly regulated. One of the most studied uses of growth factors is to promote vascularization in regenerating tissue is VEGF.[52,56,58]

5.526.6. Vascularization

As discussed earlier, vascularization is critical for cell survival and thus neovasculizarization will be an important consideration when attempting to regenerate muscle. A variety of approaches are being explored ranging from using growth factors to recruit endothelial cells *in vivo* to attempting to induce vasculzarization *in vitro* and then form transplant capillaries. To emphasize again the importance of efficient vascularization, it has been found that if the distance between capillaries and cells is greater than a few hundred microns, cells will not receive adequate oxygen and hypoxia will occur.[58] Vascularization begins with the recruitment of endothelial progenitor cells that bind to signaling molecules, for example, specific peptide sequences and growth factors. For example, the amino acid sequence REDV, which is derived from fibronectin, specifically binds endothelial cells.[59] By incorporating REDV into a polymer, it might be possible to attract endothelial cells to desired location (e.g., at the site of transplantation or injury) and induce them to form capillaries there.

Polymers embedded with growth factors that regulate the formation of blood vessels' vascularization are also being developed. PDGF, VEGF, and basic fibroblast growth factor (bFGF), which are some of the most important and well characterized regulators in endothelial cell responses, have been successfully incorporated into hydrogels. VEGF has been found to be one of the most important growth factors in all stages of neovascularization. It facilitates the recruitment of endothelial progenitor cells and induces their proliferation. It also initiates the sprouting of new blood vessels and keeps immature vessels alive until they are stabilized by mural cells and

the surrounding ECM.[56,58] Platelet-derived growth factor (PDGF) regulates the maturation of blood vessels. bFGF participates in vascularization by promoting endothelial cell proliferation and physically organizing endothelial cells so that they can form vessels.[57] While these factors are important for vascularization, they must be delivered properly in order to coordinate the desired ogranogenic effect. As mentioned earlier, bolus inject can result in severe side effects. It has been found that excess VEGF can cause vascular leakage, hypertension, malformed vessels, abnormal vascular stress, and cardiovascular malformation in addition to neovascularization of nontarget tissue.[58] Additionally, over expression of bFGF has been found to increase the risk of tumor formation.[60] Furthermore, some studies have found that using increasing levels of VEGF through adenovirus or direct injection did not lead to a significant increase in vascularization.[58] These findings suggest that it might be necessary to mimic the release kinetics of natural neovascularization by embedding the growth factors in a polymer and controlling their release more precisely through the degradation rate.

Additionally, some research is being done vascularizing the tissue *in vitro* before transplantation.[61] For example, endothelial cells were positioned in between myoblasts and allowed to form vessel networks *in vitro*. This prevascularization resulted in increased blood perfusion and muscle tissue survival after transplantation.[62] This concept is being explored by microfabrication techniques that would allow endothelial cells and growth factors to be printed into networks on a polymer and induced to form vascular networks in predictable way and either prior to or during the transplantation of the engineered muscle.

In addition to introducing growth factors themselves, ways to genetically modify cells to secrete overxpressed exogenous growth factors are being explored. Human myoblasts which were genetically engineered to secrete VEGF promoted vascularization.[63] Additionally, engineered matrices allow one to use plasmid DNA that can be incorporated into synthetic polymers and transfect neighboring cells *in vivo* in order to produce specific growth factors in the desired location. It has been shown that the constant release of plasmid DNA coupled with the right mechanical cues greatly increases transfection levels *in vivo*.[64] All these methods might one day greatly improve the ability to engineer and transplant artificial muscle tissue. At the same time, the danger of hyperactive formation of blood vessels should be certainly considered in such approaches as it might lead to tissue neoplasty.

5.526.7. Innervation

Another consideration when dealing with large muscle injuries is denervation. After injury, lack of innervation is the main cause of poor restoration of muscle regeneration, resulting in the lack function and muscle atrophy. Denervated muscle can become reinnervated as axons grow across lesion sites eventually reaching denervated muscle and reestablishing neuromusclular junctions.[65,66] The bioengineering approaches to control muscle innervation are not yet well developed. However, there have been some studies in which synthetic conduits with growth factors have been used to successfully improve innervation. Neurotrophins are a type of growth factor that influence the survival and differentiation of neurons. During innervation and muscle regeneration, neurotrophins are secreted by the muscle to promote the regeneration of axons. In an interesting study, over expression of glial cell-derived neurotrophic factor (GDNF) resulted in enhanced reinnervation after muscle injury.[66] Additionally, brain-derived neurotrophic factor (BDNF) is expressed by skeletal muscle and is important for the survival, growth, and differentiation of neurons in that tissue.[66] Glial growth factor (GGF) embedded in PLGA increased the number of axons and blood vessels in living animals.[67] Additionally, nerve conduits based on natural ECM molecules or synthetic polymers are being developed. These scaffolds can be used to guide and aid the regeneration of axons. Natural ECM molecules such as fibronectin and collagen have been shown to influence axon outgrowth.[66] Fibronectin has also been shown to promote Schwann cell migration.[68,69] Furthermore, some ECM scaffolds appear to have interesting inherent properties that help innervating muscular tissue.One study has found that ECM scaffolds promote neuronal and Schwann cell survival and outgrowth in regenerating muscle. The study found that the topology of ECM scaffolds supported neuronal growth *in vitro*. The study also found that, during remodeling, the degradation of the ECM scaffold produced matricryptic peptides that caused the migration of Schwann cells into the regenerating area.[70] Additionally, other molecules such as poly-3-hydroxybutyrate (PHB) are being investigated as nerve conduits. An interesting work found that PHB can be used to aid nerve repair as well as allowing angiogenesis without evoking an inflammatory response. The study found that PHB could allow nerves to regrow across a 10 mm gap (reviewed in[66]). In addition to nerve conduits, the incorporation or activation of Schwann cells may help reinnervation. Schwann cells play an important role in nerve regeneration by supporting and guiding regenerating axons. They secrete and display many trophic factors that promote the survival, growth, and extension of motor neurons. While the role of growth factors and guiding scaffolds was extensively studied with respect to peripheral nerve regeneration, their application specifically to reinnervation of injured or pathological skeletal muscle remains unexplored.[71]

5.526.8. Alternative Cell Types for Skeletal Muscle Engineering

In addition to studying satellite cells and myoblasts for potential therapeutic uses, some researchers are also exploring myogenic potential of various stem cells. ESCs are both self renewing and pluripotent meaning that they can differentiate into any cell type in the body and maintain their pool virtually indefinitely.[72] ESCs are, therefore, very promising for regenerative medicine, since large quantities of the cells can be grown and then differentiated into the desired tissue. Currently, ESCs can be successfully cultured, but fully directing their differentiation toward skeletal muscle lineage remains elusive and the efficiency remains low, as most approaches start with embryoid body-based spontaneous differentiation. However, some studies have shown that it is possible to direct ESCs to a myogenic lineage. Specifically, by over-expressing Pax3, it was

possible to expand the numbers of paraxial mesoderm cells in embryoid bodies and then sort cells based on PDGF-αR^{+}/Flk-1^{-} profile to obtain myogenic progenitor cells.[73] It has been shown that Pax3 is an important regulator of myogenesis, which turns on several downstream myogenic factors and without Pax3 skeletal musclulature does not form during embryonic development.[5] ESCs that are induced to differentiate into myogenic lineage upregulate Pax3, Myf5, Myod1, Myogenin, and MHC in that order, demonstrating a progression from less differentiated muscle precursor to terminally differentiated myotube.[73] Additionally, these cells differentiate into skeletal muscle in cardiotoxin injured muscle and dystrophic muscle in mice, demonstrating their *in vivo* myogenic potential.[73]

However, there are several drawbacks of human ESCs (hESCs). There is a debate about whether it is ethical to use ESCs since they are derived from the inner cell mass of the blastocyst, a process which destroys a human embryo. Additionally, when hESCs are injected into an animal they form a teratoma, which is essentially a big tumor. Therefore, any hESC-derived cells must be fully differentiated and completely isolated before they can be transplanted into a patient. One alternative to ESCs is induced pluripotent stem cells (iPS). iPS cells are somatic cells which can be induced to an ESC-like state and then differentiated into a different cell type.[74–78] iPS cells have their own problems; currently, iPS cells are not identical to ESCs and the efficiency of reprogramming a somatic cell to an iPS cell is very low. Undifferentiated iPS cells also form teratomas. However, iPS cells also have several advantages. They avoid the ethical considerations of destroying a human embryo and since they can be derived from a patient's own tissue they will be a perfect match for that person and will not experience immune rejection. Another alternative cell type that people are exploring for muscle regeneration is multipotent adipose-derived stem cells (hMADS). One study found that injection to mdx mice (which serve as an animal model for human muscular dystrophy) of hMADS cells resulted in the formation of new myofibers expressing dystrophin. Furthermore, the study found that hMADS decreased necrosis in the muscle of these mice.[79]

5.526.9. Electrical and Mechanical Stimulation of Skeletal Muscle

One alternative to transplanting muscle precursor cells to an injury is to differentiate these cells *in vitro* and then transplant muscle grafts. Previous studies have shown poor delivery to the injury site as well as poor survival and integration of transplanted cells. Therefore, some researchers are exploring the possibility of developing mature muscle sections *in vitro* which can later be grafted to an injured site. In addition to the synthetic scaffolds already discussed, the use of mechanical and electrical stimulation *in vitro* is explored for mimicking some of the signals that forming muscle receives during repair after injury *in vivo*. It is believed that during early fetal development, muscle tension created by bone growth contributes to muscle development.[80] Similarly, during exercise, muscles number and the sine of muscle fibers increase if that organ is stressed.[81] Studies have shown that mechanical forces help recapitulate the natural cellular environment by providing mechanical cues to help direct cell orientation. When pulled with light tension, muscle fibers adapt and are conditioned to function correctly; studies have shown that mechanical stimulation affects metabolic activity, protein localization, gene regulation as well as increases myofiber organization and cell proliferation. Cyclic strain can activate quiescent satellite cells as well as increase the proliferation of myoblasts.[82] Additionally, an interesting work demonstrates that sustained tension regulated the alignment and fusion of myoblasts into myofibers.[82] Furthermore, strain and relaxation increased the elasticity, myofiber diameter, and myofiber area of muscle fibers engineered *in vitro*.[82]

In addition to mechanical stimulation, electrical stimulation has been shown to play an important role in skeletal muscle differentiation by increasing cell proliferation and inducing proper orientation of myoblast prior to their fusion into myotubes.[29] By incorporating an exogenous electric field across the polymer fibers, the signals of neurons *in vivo* can be mimicked: the timing of the exogenous electric signals can be matched to that of the action potentials down axons. Signals delivered as impulses, in about 3 ms intervals of 70 mV, very closely mimic those signals sent by neurons in natural development.[83] These signals help activate certain chemical cascading systems in the muscle tissue, aiding the muscle tissue's growth. In another study, it was shown that electrical stimulation did not affect cell viability and increased the release of NO which typically activates the regenerative myogenic responses of satellite cells.[84] Furthermore, it was found that electrical stimulation increased the expression of MyoD and Desmin, two myogenic markers. Overall, it has been found that electrical stimulus improves the activation of satellite cells, myoblast fusion, myotube growth, and myofiber density. Therefore, in addition to scaffolds previously mentioned, some research is being done on designing polymers with electrical conducting properties. Conducting polymers are being explored as a material for *in vitro* differentiation because they provide a scaffold for support, allow the transmission of mechanical and electrical stimuli and can be modified by biologically functional molecules such as ECM components mentioned earlier in this chapter.[85]

5.526.10. Matrix Metalloproteinases

As discussed earlier, the phagocytosis and break down of the existing ECM is essential for any new tissue, including new muscle to form. Much of this degradation is regulated by matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs). TIMPs regulate the activity of MMPs by binding them and inactivating them while membrane-type MMPs (MT-MMP) activate MMPs. In healthy tissue, MMPs are expressed in low levels, while TIMPs are expressed at a high level. During muscle regeneration and inflammation, cytokines, growth factors, and hormones are activated which in turn increases the production of MMPs and down regulates the expression of TIMPs.[86] Both MMP-2 and MMP-9 break down the major components of the ECM and the basal lamina to allow myoblasts to migrate into an injury site.[87] In several studies, it has been found that over expression of MMP-2 significantly increased myoblast migration *in vivo*.[88]

Additionally, MMPs work to prevent the accumulation of excess ECM molecules, for example, scarring and fibrosis. The formation of scar tissue impedes muscle regeneration by providing a physical barrier to vascularzation as well as myoblast migration and differentiation. Furthermore, fibrosis provides chemical signals that can disrupt the natural muscle regeneration. MMP-1 is able to digest scar tissue and thus improve muscle regeneration.[89–91] Additionally, it has been found that myogenic factors are upregulated by MMP-1 and that MMP-1 is also able to induce myoblast migration and differentiation.[91] MMPs serve a vital role in clearing an injury site so that the necessary steps for muscle regeneration, such as vascularization and formation of new peripheral nerves, can occur.[89–92] Therefore, incorporation of MMPs into biomaterials or factors which promote the production of MMPs by cells of the transplant or locally in the host's tissue may be useful to enhance muscle regeneration.

5.526.11. Immune Response to Engineered Muscle

Mediating the immune response will be vital to successful muscle regeneration. Studies have shown that an initial inflammation has a positive role in recovery; however, excessive inflammation can lead to scar formation and impede regeneration.[54,93,94] When the muscle is injured, inflammatory cells and cytokines accumulate at the site of injury. The first cells to respond are neutrophils which begin to phagocytose necrotic tissue as well as release proinflammatory cytokines to magnify the inflammatory process.[54] Next macrophages are recruited to the injury site. Macrophages are believed to be involved in many steps of regeneration including: participating in phagocytosis of cellular debris, mediating the immune response to switch from promoting inflammation to reducing inflammation when regeneration starts, releasing growth factors to promote muscle precursor cell activation, proliferation, and differentiation as well as vascularization of new muscle.[54] Studies have shown the importance of macrophages for muscle regeneration by demonstrating that a decreased number of macrophages results in reduced satellite cell differentiation and growth of myofibers. Furthermore, studies have shown that when taken for longer than several days nonsteroidal anti-inflammatory drugs (NSAID), which inhibit inflammation, lead to decreased muscle regeneration and increased fibrosis.[54] Additionally, either a coculture of myoblasts and macrophages or macrophage conditioned media increased myoblast proliferation and myotube formation.[95,96] These findings suggest that inflammatory cells play a vital role in muscle repair. First, they aid MMPs in clearing the injury site of damaged tissue so that healthy tissue can be formed, and then they secrete growth factors which promote the regeneration of muscle tissue. Using the cells and cytokines of native immune response as components in muscle tissue engineering might, thus, be a good strategy.

5.526.12. The Aged Niche

It is well known that during aging, skeletal muscle atrophies and declines in function. These effects are due to a number of age-imposed changes, including a reduced ability of muscle satellite cells to regenerate new tissue. In order to fully understand this decline in function, it is important to study the changes that occur with age in the satellite cell niche. The niche consists of many components and is a heavily dynamic environment that influences the quiescence or activation of satellite cells. During aging, several of these components are altered causing a reduced regenerative capacity of satellite cells residing in the old muscle stem cell niche.

With aging, it appears that the reduction in muscle regeneration comes not from a reduction in the satellite cell population, but rather, a reduced satellite cell functionality.[97,98] On one hand, this is influenced by changes in the satellite cells themselves; the nuclear to cytoplasmic ratio has been shown to be higher in satellite cells in an aged environment.[99] On the other hand, the activation of satellite cells is dependent on external factors, and during aging, satellite cells have shown a delayed and decreased response to activating stimuli, such as muscle injury.[97] It is now known that these changes are mostly due to the changing satellite cell niche and are evolutionarily conserved between mice and humans.[100–103]

Another important feature in the satellite cell niche is the myofiber, which serves as the main cellular contact point for the satellite cell.[7] In aged muscle, the size and number of myofibers decrease, causing a marked change in the satellite cell niche. While little is known about the molecular signals expressed by the myofibers, recent studies have illuminated the changes in the Notch pathway that occur during aging. In normal adult muscle, Delta (a transmembrane ligand) is upregulated by myofibers after injury and binds Notch, thereby activating the Notch signaling cascade in satellite cells. This induces the proliferation of satellite cells. However, in aged muscle, a failure in the induction of Delta in myofibers weakens Notch signaling and impairs muscle regeneration.[97] Additionally, it has been reported in mice that old muscle produces excessive amounts of transforming growth factor (TGF-β). This increase induces an unusually high activation of the transcription factor pSmad3, which is an antagonist to Notch in terms of satellite cell proliferation control. In young muscle, Notch blocks the TGF-β induced upregulation of cyclin-dependent kinase (CDK) inhibitors, allowing satellite cells to enter the cell cycle and begin the regenerative process. However, in aged muscle, increased TGF-β signaling along with a decrease in Notch signaling inhibits the cell cycle by the activation of CDK inhibitors. This leads to significant reduction in the regenerative capacity of aged muscle. In essence, with age, the balance of factors regulating muscle stem cell responses shifts from active Notch to active TGF-β/pSmad3, causing the aforementioned reduced regenerative capacity.[103] As stated above, these mechanisms of aging have been recently shown to be evolutionarily conserved between mice and humans.[101,102] This conservation is important, as it points to the ability to use mouse models to further the study of aging in humans.

Finally, the basal lamina, which separates myofibers and their respective satellite cells from adjacent myofibers and the interstitium, plays a key role in satellite cell activity. Fibronectin, laminin, glycoprotein, and proteoglycans and that support satellite cell proliferation and growth serve as a location for growth factors to be converted to active forms by proteolytic enzymes in response to muscle injury.[7] In aging muscle,

the by-products of these enzymatic cleavages begin to build up and become toxic. This process compromises the essential functions of a basal lamina as a scaffold for growth and has been shown to cause necrosis.[104]

In order to further understand the effects on aging on the satellite cell microniche, it is also necessary to study factors external to the niche. These factors, which include vascular, neural, interstitial, and systemic constituents, undergo age-related changes that likely influence declining satellite cell function during aging. In the vascular system, endothelial cells have been shown to positively influence skeletal muscle growth by the secretion of soluble growth factors from nearby blood vessels.[18] Secretion of these factors, such as VEGF and endothelial nitric oxide synthase (eNOS), is reduced with age.[7] This age-related reduction, no doubt, affects the satellite cell macro and microniche and contributes to the limited regenerative capacity of aged muscle. Age-related changes in the neural system include remodeling of the neuromuscular junction, partial denervation, and a decline in myotrophic (muscle strengthening) factor production.[7] All of these changes hinder neural communication in muscle tissue, causing myofibers atrophy and thereby altering the productive satellite cell–myofiber interaction. Age-specific changes in the immune system are also very significant for muscle maintenance and repair, as removal of necrotic tissue by macrophages is necessary for effective myogenesis. Aged immune cells such as neutrophils and monocytes have shown reduced phagocytic activity, which limits their ability to destroy damaged tissue.[105] Finally, some of the age-related changes in the systemic environment, such as a reduction in thyroid hormones that direct muscle metabolism and growth as well as an increase in TGF-β, levels have all been shown to negatively influence the repair of old muscle.[101,102,106]

Although several mechanisms of aging are relatively well understood in relation to muscle regeneration, as described above, this area of research is certainly in progress and much is to be defined. With a more complete understanding of the effects of aging on the satellite cell niche with all its complex elements, the success of an anti-aging therapy and muscle engineering for older individuals would become more realistic. By targeting specific processes responsible for reduced muscle regeneration, satellite cell activity could be enhanced and maintained in old muscle deliberately and independently of the aged prohibitive environments. The use of biomaterials for this type of research is a promising option. One avenue to be explored is the use of biomaterials in scaffolding to study the aged niche and suspended satellite cells *in vitro*. Both natural and synthetic biomaterials can be used to create scaffolds that support the growth of functional muscle tissue (as described earlier in this chapter). The environment of such artificial muscle tissue can then be altered so as to mimic the *in vivo* aged muscle niche. This would involve a selective deactivation of signaling molecules and other important factors, such as Delta, antagonists of TGF-β/pSmad VEGF, and immune cells, or the selective over expression of 'aging' factors such as TGF-β. Also, the rigidity of the scaffold could be increased to replicate the excessive fibrosis that occurs in aged muscle tissue with time. With a tightly controlled replica of the aged niche, the effects of aging can be studied more closely and understood better. Alternatively, old muscle stem cells could be exposed to artificial environments/scaffolds that mimic young niche in modulus and growth factors and the regenerative responses of these satellite cells could be enhanced.[97,100,103]

5.526.13. Pathological Environment

As mentioned earlier, one of the most common muscular disorders is muscular dystrophy. The most severe form is DMD which is caused by a mutation in the dystrophin gene. The lack of normal dystrophin leads to muscle degeneration and eventually death of differentiated muscle fibers.[107] The most common animal model to study DMD is the mdx mouse which has a mutation causing incorrect alternative splicing of dystrophin transcript. In mdx mice, muscle degeneration begins around 3 weeks of age with large areas of necrosis by 7 weeks.[107] The mdx mice can be used to study the mechanism by which the loss of dystrophin leads to muscle degeneration.[107] Furthermore, mdx can be used to study how satellite cell populations are eventually exhausted and muscle is unable to be regenerated.

The mdx mouse is widely used to test potential therapies for muscular dystrophy. One of the first suggested therapies was the transfer of healthy myoblasts into mdx mice. This strategy had initial success; however, early clinical trials in humans did not produce promising results. One of the main problems was the minimal proliferation of myoblasts, massive cell death, and other factors in humans that quickly diminished the population of injected myoblasts.[108] These results suggest that relying on mouse models to recreate a pathological environment in humans might not be ideal. One thing to consider is that human cells have short telomeres which limit the proliferative capacity of somatic cells, while most laboratory mice do not appear to have this limiting mechanism.[108] Additionally, the mdx model does not match the severity of DMD in humans.[107] This means that it is difficult to test the effectiveness of a therapy in mdx mice because their lifespan is only shortened by approximately 20%.[109] Many other mouse models that facilitate studies of DMD have been developed, including 5cv mice that are mildly affected, dystrophin and utropin double knockout animals which are severely ill, but none of the mouse strains emulate the human pathology or disease progression closely. One of the main reasons could be the differences in life span: in contrast to people, mice are short-lived species.

Therefore, it will be important to improve and develop alternative models to test new therapies for muscular dystrophy. Future biomaterials could alleviate some of the problems with testing current therapies in mice. For example, in order to study and understand the progression of this disease, it would be advantageous to create a human disease model in artificial scaffolds. Similar to the aged niche model, biomaterials can be used to create an environment that would mimic the *in vivo* conditions of muscle in patients with the congenital muscle wasting. Muscle cells from patients that harbor mutations in dystrophin can be grown on engineered scaffolds with specific geometries and molecular milieu to mimic the disease of interest. In this way, scientists can study the progression of the dystrophy on in order to better understand the pathology of the disease. Another benefit to

this disease model is the ability to alter the diseased environment in a controlled manner as a method to explore possible therapies.

5.526.14. Future Directions

As the previous sections have illustrated, regeneration of skeletal muscle is controlled by a tightly regulated cascade of many different signals. The preceding sections have discussed various growth factors, cytokines, peptides, and scaffolds that have been discovered and are currently being tested to improve muscle regeneration. However, as the sections have pointed out the perfect biomaterial for skeletal muscle replacement or repair does not yet exist. Currently, most research and scaffolds work on including one or a few types of growth factors or peptide mentioned above. As discussed FGF increase satellite cell proliferation, while IGF increases myoblast cell proliferation and differentiation.[3,54] Many experiments have also been carried out with scaffolds that include VEGF since it has been found to be one of the most important growth factors to promote vascularization.[52,56,58] Additionally, BDNF and GGF have been embedded in hydrogels to promote innervation.[66,67] The next step in muscle tissue engineering will be to produce a biomaterial that combines all of this previous research into a single smart scaffold. This material will have to promote the efficient vascularization and innervation of new muscle. Additionally, this material will have to modulate the immune response so that macrophages and MMPs can clear necrotic and scar tissue without preventing wound healing through excessive inflammation. Lastly, and most importantly, this material will have to promote the proliferation of muscle progenitor cells and the efficient formation of myotubes which are the functional units of healthy muscle tissue. An advanced biomaterial should support the survival of transplanted myoblasts or be able to activate sufficient number of satellite cells to produce myoblasts and ultimately, new muscle fibers. Furthermore, this material should be biodegradable and not negatively affect other parts of the body. In essence, the ideal biomaterial will orchestrate an induced regeneration without scarring and perfectly replenish any injured muscle. A schematic of what is necessary in a smart biomaterial can be seen in Figure 1.

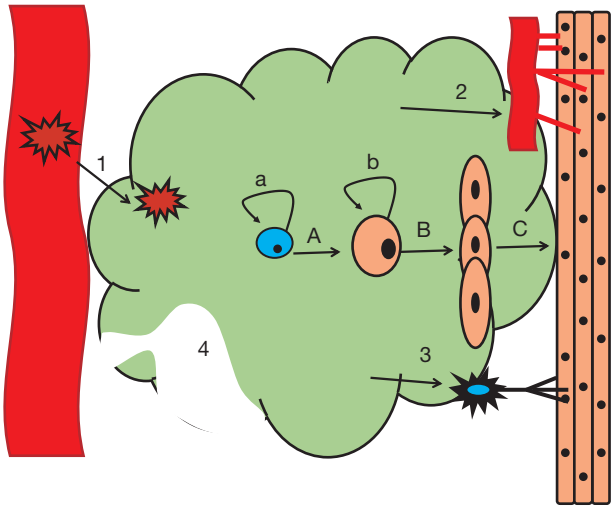

Figure 1 An optimal biomaterial will promote muscle regeneration, vascularization, innervation, and will modulate an immune response. (A–C): Artificial scaffold is embedded with muscle stem, satellite, cells which differentiate into myoblasts (A) and self-renew (a); myoblasts align and fuse into mytubes (B) and self-renew (b); myotubes mature into functional skeletal muscle fibers (C). The self-renewal and differentiation capacity of stem and progenitor cells enable their survival and integration into tissue *in vivo*. Engineered scaffold also tightly regulates cell proliferation and differentiation in order to replace all damaged muscle without neoplasty. (1–4): Regeneration of functional muscle cannot proceed without productive immune response, vascularization and innervation, which are all orchestrated by the engineered scaffold. (1) Biomaterial releases macrophage homing molecules; macrophages enter the wound site, remove necrotic tissue and secrete factors that promote myogensis. (2) Growth of new blood vessels and (3) reestablishment of neuromuscular junctions are promoted by specific growth factors released by this biomaterial. (4) Following tissue regeneration scaffold is biodegraded.

5.526.14.1. Culturing Satellite Cells

To date, most of the research exploring the muscle cell niche has been based on the culturing of primary myoblasts. Although the use of these myoblasts does allow the generation of muscle tissue, it limits the study of the satellite cell niche and yields the engineered tissue that is not regenerative and is terminally differentiated. Myoblast cultures are not similar to satellite cells in their properties, including the most important, self-renewal, as in contrast to satellite cell, which associate with myofibers and maintain muscle for life span, myoblasts exist only transiently *in vivo*.[8,9] It would be of great benefit to develop a method for robustly culturing satellite cells; currently this has not been accomplished, due to the difficulty in maintaining the 'stemness' of the satellite cells once they are removed from the *in vivo* niche. When taken out of their niche, satellite cells quickly lose their self-renewal capacity and differentiate into myoblasts.[8] In order to culture satellite cells, it is necessary to understand and recreate the complex regulatory machinery of the *in vivo* satellite cell niche.

In order to synthesize an accurate representation of the satellite cell niche, knowledge of the interplay between important signaling molecules such as Notch, TGF-β/pSmad, Wnt, and myogenic factors, such as Pax3, Pax7, MyoD, and Myf need to be used in conjunction with smart biomaterials. Strategies such as ligand patterning and release in hydrogels can be used to deliver important signaling molecules in spatial and temporal profiles that are similar to their release *in vivo*.[8,98] Further, the use of hydrogel materials that are resistant to nonspecific adhesion, experimentally determined surface modifications could be achieved and used in conjunction with particular ligands to facilitate cell adhesion through specific protein interactions. In this way, instead of encountering soluble growth factors in medium, cells interact with growth factors that are 'tethered' – a more physiologically relevant interaction.[8] Once again, a particular combination and concentration of each factor would need to be first determined and then, released by the biomaterial that is designed for the maintenance of muscle stem cells. The application of these

and other emerging biomaterial technologies brings closer the prospect of recreating the satellite cell niche. With a reliable *in vitro* representation of this niche, scientists can glean novel information about the molecular cues necessary for *in vitro* maintenance and growth of skeletal muscle stem cells.

5.526.14.2. Genomics, Proteomics, and Metabolomics

Currently, the most used methods in functional genomics and cell or tissue profiling involve gene manipulation and subsequent observation of the downstream effects. Technologies such as DNA microarrays can monitor the changes in gene transcripts (mRNAs) after a specific manipulation of the genome. This can help highlight the changes in protein synthesis that may occur due to specific genetic modifications. However, the drawback to this approach is that it does not take into account the changes in protein structure or concentration that occur downstream of transcription and/or translation. Changes in mRNA concentration will not necessarily reflect changes in protein expression and vice-versa. Protein concentration and expression can be affected by many posttranslational mechanisms such as phosphorylation, acetylation, ubiquitilation, allosteric modifications, and destruction rate.[110] The limitation of current genomic techniques to monitor these downstream changes calls for the use of newer technologies such as proteomics and metabolomics.

Both proteomics and metabolomics allow for the observation of concentrations, expression, and activity of important molecules in a certain system. More specifically, proteomics is defined as the study of the full set of proteins that are encoded by a genome, while metabolomics is the study of the range of metabolites present in the cell or other defined system. Proteomics studies are done using gel electrophoresis techniques to separate proteins of different sizes. More recently, fluorescent dying has been coupled to 2D electrophoresis in order to more accurately image the separated proteins. Metabolic profiles are developed using H NMR spectroscopy and can display concentration changes in important metabolites such as taurine, creatine, lactate, and phosphocholine.[111] An increase or decrease in the concentration of these and other metabolites can help illuminate the reason behind certain muscle behaviors and pathologies.

These techniques have been slow in development but are very important when considering the synergistic and complex environment of the cell or of stem cell niches. The number of protein interactions and metabolic pathways within these systems is vast, but the mechanisms involved are, for the most part, poorly understood. Moreover, no current biochemical technology has the ability to fully elucidate all of the proteins that are involved in skeletal muscle function; in proteomic profiling, low-concentration proteins are often masked by higher concentration proteins making them difficult to isolate.[110] To overcome this, it is necessary to perform individual studies on protein subsets so as to establish a more complete proteomic map, with both minimally and heavily expressed proteins. With this map, the exploration of protein activity in aged or diseased environments can be furthered. A deeper understanding of these complex environments affords the ability to pinpoint deleterious changes in protein expression, therefore providing opportunities for therapeutic intervention.

With regard to skeletal muscle engineering, the use of metabolomic or proteomics assays is an important avenue to consider. For example, by determining the metabolic profile of a certain state of muscle, say a pathological state, a specific biomaterial can be developed to improve the condition of the muscle. This biomaterial could contain essential metabolites that have been detrimentally downregulated or would have molecules that help inhibit inappropriately upregulated metabolites. This type of localized release to pathological tissue can potentially aid in the regeneration of functional muscle tissue.

Glossary

Alginate An insoluble anionic polysaccharide found in the cell walls of brown algae.
Allograft Tissue graft generated from the same species as the recipient.
Elastin An elastic, fibrous glycoprotein in connective tissue, important role in blood vessels function.
Extracellular matrix (ECM) Multifunctional component of the extracellular portion of tissue providing structural support, growth factor sequestering, intracellular communication, and a key component of wound healing.
Fibrin An insoluble, nonglobular protein made from fibrinogen.
Hydrogels Derived from either synthetically or natural polymers are water-insoluble, and display flexibilities similar to natural tissue.
Polyglycolides (PGAs) Biodegradable, synthetic polymer that degrades through hydrolysis.
Polyhydroxyalkanoates (PHAs) Bacterial derived polyesters from fermentation of sugar or lipids.
Tissue engineering The *in vitro* construction of working biological systems utilizing a combination of cells and biomaterials to replace or repair either whole organ or portions of compromised tissue.
Vicryl Absorbable, synthetic polyglactin which becomes absorbed by hydrolysis.
Xenograft Tissue graft generated from a different species than the recipient.

Abbreviations

BOOST trial	Bone-marrow-derived cell transfer after ST-elevation myocardial infarction trial
BPAECs	Bovine pulmonary artery endothelial cells
BPV	Bovine pericardial valves
CAD	Coronary artery disease
CaP	Calcium phosphate
ECM	Extracellular matrix
ECs	Endothelial cells
EHT	Engineered heart tissue
ePTFE	Expanded polytetrafluoroethylene
ESRD	End-stage kidney disease
GAGs	Glycosaminoglycans
H&E	Hematoxylin and eosin
hECM	Human extracellular matrix
IEL	Internal elastic lamina
IL-1	Interleukin-1
IL-6	Interleukin-6
IM	Internal membrane
MSCs	Mesenchymal stem cells
PAV	Porcine aortic valves
PCL	Poly-ε-caprolactone
PCU	Polycarbonate soft segment
PEG	Polyethylene glycol
PET	Polyethylene terephthalate
PEU	Polyether urethane
PGA	Polyglycolides
PHA	Polyhydroxyalkanoates
PIPAAm	Poly(*N*-isopropylacrylamide)
PLGA	Poly (D, L-lactic-*co*-glycolic acid)
POSS-PCU	Polyhedral ologomeric silsesquioxanes – polycarbonate soft segment
PTFE	Polytetrafluoroethylene
PUs	Polyurethane
PVA	Polyvinyl alcohol
PVD	Peripheral vascular disease

TEHVs	Tissue-engineered heart valves
TESA	Tissue engineering by self-assembly
TEVG	Tissue-engineered vessel grafts
TNF	Tumor necrosis factor

5.527.1. Introduction

The fields of cardiovascular tissue engineering and regenerative medicine have experienced tremendous expansion and progress over the past 20 years. Strategies have focused on the use of cells, tissues, scaffolds, and numerous combinations of these three components to address both scientific questions and clinical needs.

The most widely used definition of tissue engineering was proposed by Langer and Vacanti in a 1993 issue of *Science*, as "an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function or a whole organ."[1] This working definition is still relevant to the application of tissue engineering toward solving cardiovascular diseases. The subsequent chapter will focus on the following applications of tissue engineering in the cardiovascular field:

1. Cardiac patches
2. Cell delivery using biomaterials
3. Artificial blood vessels
4. Heart valves

While not an exhaustive list of topics within the field of cardiovascular tissue engineering, this list covers major areas of research advancement over the past few decades. Whether cardiac or peripherally focused, progress in these areas of research has the potential to impact tissue and organ function throughout the body. Because the cardiovascular system is dispersed throughout the human body, cardiovascular tissue engineering advancements can be seen as a rate-limiting factor for the development of thick tissues to repair or replace every critical physiological system (circulatory, endocrine, urinary, respiratory, musculoskeletal, digestive, lymphatic, integumentary, etc.). Without a well established cardiovascular system or microvascular perfusion, tissues would be confined by the limitations of the diffusion distance of oxygen in various tissues. This limitation would ultimately confine and restrict future advancements in tissue engineering. Therefore, long-term advancements in tissue engineering will depend, in part, on the ability to stimulate or facilitate the development of an appropriate vascular supply.

5.527.1.1. Bench Top to Bedside

The successful translation of discovery – when cardiovascular tissue engineering advancements find clinical or commercial homes – will depend on choices made during the development pathway from science to product. For example, the success of the translation from basic research findings into preclinical models depends, in part, on the appropriateness of the *in vitro* model. Likewise, the subsequent transition into the clinic depends, in part, on the relevance of the preclinical model to the clinical disease targeted. Finally, a balance of risks versus benefits must be considered when exploring the clinical translation of new discoveries. For certain technologies, a peripheral cardiovascular route to first-in-man clinical trials may have lower hurdles to overcome than a route going directly to cardiac applications. Initial clinical success in a lower risk procedure can help set the stage for future trials in higher risk applications.

To create a successful tissue-engineered construct, device, or technology, manufacturing as well as economic issues must be taken into account.[2] For example, scale-up considerations for tissue engineering products can present serious challenges. Researchers and scientists often view the reproducible creation

of small series of tissue-engineered constructs for benchtop or preclinical testing as a significant problem. This problem is only amplified when the production must be scaled up to meet the demands of a US population suffering in record numbers from vascular diseases. These diseases include the following:

1. heart failure that affects close to 6 million Americans (American Heart Association),
2. coronary heart disease that led to 448 000 bypass procedures in 2006,[3]
3. peripheral vascular disease that affects ~5 million adults,[4]
4. aortic valve stenosis that affects ~2% of people over the age of 65 and 3% of people over age 75.

If these manufacturing challenges can be overcome, mass production can transform a very expensive *in vitro* model into a commercially viable product. Thanks to economies of scale, the average cost per unit to create a product decreases as the volume is increased. This, in fact, may influence the choice of first target markets for tissue engineering companies looking for a hugely successful product launch. While this 'economies of scale' strategy has proven very successful in the device world, it has not been a lucrative approach for most tissue engineering companies. An alternative approach is to aim at niche markets with high-value products where economies of scales play a lesser role but where even a limited percentage margin results in significant profits. This can lead to sustainability and long-term growth. This model may be particularly appropriate for more complex technologies that still face significant development steps, and thus, more costly processes.

5.527.1.2. Successful Tissue Engineering Translations

Despite all of these challenges, many new tissue-engineering technologies are finding their way to successful clinical translation. In fact, economic activity in the combined fields of tissue engineering, regenerative medicine, and stem cell therapies has grown a remarkable fivefold from 2002 to 2007.[5] As of mid 2007, ~50 businesses offered commercial tissue-regenerative products or services with collective annual sales > $1.3 billion.[5] For continued success in cardiovascular tissue-engineered technology, scientists will need to overlay the future regulatory, clinical, manufacturing, and economic hurdles. The ability to do so will help secure the translation of future benchtop findings into the clinic.

5.527.2. Cardiac Patches

As the use of cell-based therapies in regenerative medicines has developed over the last decade, enthusiasm remains high that such treatments will provide a therapeutic option for patients with life-threatening cardiomyopathies. Work to date in this field has evaluated numerous cell types in both basic science and clinical settings for their ability to provide a source of cardiomyocytes (or promote their growth) and for their ability to provide tangible tissue regeneration *in vivo* (see **Chapter 5.507, Tissue Engineering and Selection of Cells**). A great deal of this work has utilized direct injection methods (i.e., syringe or catheter based), in which the desired cells are injected directly into the troubled heart tissue. Newer approaches rely on techniques where biologically active scaffolds or tissues are engineered *in vitro* and then implanted (see **Chapter 6.624, Cardiac Patch with Cells: Biological or Synthetic**). Most of these constructs utilize a biomaterial scaffold to support tissue assembly; however, other methods favor completely biological approaches.

5.527.2.1. Direct Injection Versus Tissues Constructs

To date, a number of cell-based therapies for treating cardiac injuries have been evaluated. These studies, both in the laboratory and in patients have primarily utilized direct injection as a delivery technique. While results from these clinical trials have demonstrated that these delivery techniques are safe and the cells well tolerated,[6–12] their limited success in regenerating lost heart muscle or regaining cardiac function leaves room for improvements. Evidence suggests that the major problem with direct cell injection into the heart is that few of the injected cells survive.[13,14]

In order to improve cell retention, many newer cell delivery methods have focused on bioengineered constructs, in which the desired cells are cultured and grown into biologically active tissue-like constructs,[15–17] which are currently being evaluated. They include (1) scaffold-based systems where cells are grown onto a degradable[18–20] material, (2) cell-containing hydrogels,[21,22] or (3) cellular sheets, free of any scaffold support.[17,23] Investigators have proposed that constructs for cardiac repair should be (1) contractile, (2) electrophysiologically stable, (3) mechanically robust, (4) quickly vascularized, and (5) nonimmunogenic (see **Chapter 5.503, Biomaterials and the Microvasculature**).[16,21,22]

5.527.2.2. Biomaterials for Cardiac Tissue Engineering

5.527.2.2.1. Scaffold-based systems

Various biological and synthetic materials are currently being evaluated as the structural backbone for a number of *in vitro* engineered constructs. These include biological extracellular matrices such as collagens, elastin, fibrin, alginates, silk, etc., as well as biodegradable synthetic polymers such as polyglycolides (PGAs) (e.g., Vicryl™), polylactides, poly-ε-caprolactone (PCL), etc. Collagens, such as collagen type I sponge scaffolds, are flexible and porous allowing cellular integration. The placement of inert collagen type I scaffolds supplemented with adjunct cytokine administration has been shown to promote microvessel formation within injured rat myocardium.[24] Alginates have proven efficient in constructing tissue-engineered scaffolds. They can be efficiently seeded, retaining a high percentage of seeded cells within a brief time.[25,26] Alginate patches, however, appear to have poor integration into the myocardium because of limited microvessel formation. Integration may be improved through heterotopic transplantation, but questions about its clinical application exist.[15]

Extracellular matrices or various combinations of extracellular matrix (ECM) proteins have been explored as scaffold structures for tissue engineering purposes such as carriers for cell-based therapies. These materials can be readily casted, electrospun, or cultured using a variety of strategies to optimize surface area and void volume to create specifically designed scaffold carriers for cell therapies[27–29] (**Figure 1**).

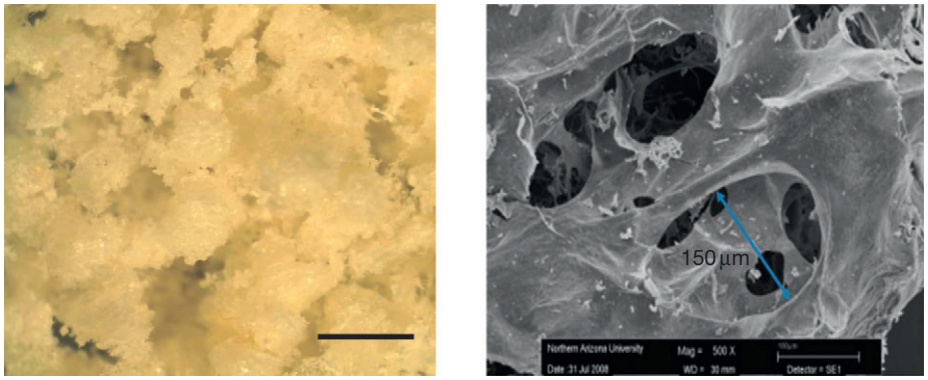

Figure 1 Left, lyophilized human extracellular matrix (ECM). Scale bar = 1 mm. Right, scanning electron micrograph of lyophilized human ECM. Arrow shown = 150 μm.

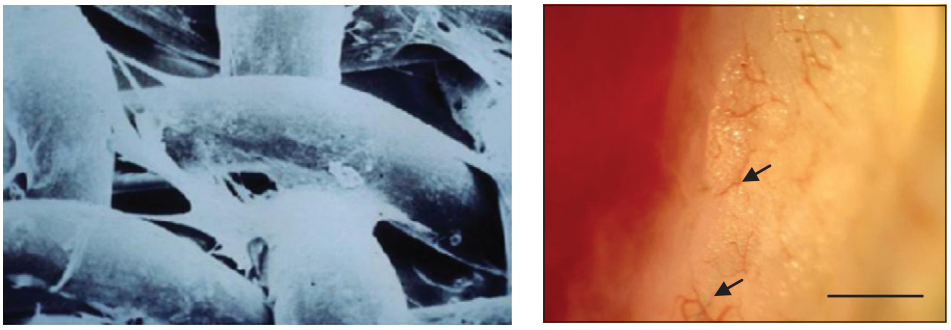

Figure 2 Left, scanning electron micrograph of a Vicryl™ scaffold seeded with human fibroblasts (cardiac patch). Scale bar = 50 μm. Right, cardiac patch placed onto the epicardial surface in a rodent infarct model. Arrows highlight new microvessels. Scale bar = 150 μm.

A number of laboratories have used Vicryl™ mesh or PGAs in construct formations. In addition, PGAs are employed in preseeded dermal repair constructs currently on the market (Theregen Inc.; Figure 2). PGAs are flexible and degradable and can be used to create woven or nonwoven scaffolds. Under standard culture conditions, PGAs degrade roughly 50% over 4 weeks. Such materials allow for spontaneous and synchronized contractions of seeded cardiomyocytes.[19,30,31]

5.527.2.2.2. Hydrogels

There has been work with liquid collagen I and Matrigel™ with additional growth supplements to create engineered heart tissue (EHT) *in vitro*.[21,22] These constructs were fabricated as circular bands and then fused together into 'multiloop' EHTs. These EHTs beat spontaneously and have been sutured onto the epicardial surface of the myocardium following acute myocardial infarction in rats. After 4 weeks, implanted EHTs remained on the epicardial surface of the myocardium with limited integration into the myocardium. Implanted EHTs contributed to improve cardiac function and even electrically coupled with the host myocardium.[21,22]

5.527.2.2.3. Cellular sheet structures

The creation of cells sheets that can be removed from their culture containers dates back to, at least, the mid-1970s and the work of Green and his associates. After painstakingly developing the appropriate culture media for the serial proliferation of human keratinocytes, a method was developed to produce, and enzymatically detach, cohesive sheets of human epithelium.[32,33] Soon after, this approach was used clinically and autologous sheets were produced and successfully implanted in seriously burned patients.[34] To our knowledge, this is the first cell-based therapy using cultured cells.

In the last decade, Okano and his group have popularized the use of poly(*N*-isopropylacrylamide)-coated cell culture plates to successfully create thin sheets of epithelial cells as well as cells of mesenchymal origin.[23,35,36] This coating is a temperature-sensitive polymer that allows for harvesting of fully intact cell sheets by lowering the ambient temperature, without the need for enzymatic digestion or mechanical manipulation (see **Chapter 5.530, Medical Applications of Cell Sheet Engineering**). Constructs grown and harvested in this manner can have multiple advantages. First, they do not include any foreign scaffolding that could create inflammatory responses and compromise the healing of a typically very fragile tissue, for example, cornea epithelium.[37] Second, the elimination of any enzymatic treatment preserves the integrity of the basement membrane of the cells sheets. As a result, these tissues can be directly applied to the desired tissue areas without the need for suture or other means of adhesion because of the preserved basal surface. Finally, the lack of enzymatic treatment also preserves the cellular organization of the sheet, and more particularly, relevant to cardiac applications, can help

maintain the cell–cell communication through gap junctions.[38] This is a critical advantage to create a contractile tissue as gap junctions are the structures that allow electrical transmission that results in the synchronous pulsation of the entire heart.[39] Culture containers coated with temperature responsive polymers are now commercially available under the brand name UpCell™ and are produced by Nunc™ (now part of ThermoFisher Scientific).

The creation of cardiac tissue using this approach is encumbered with two limitations. While cultured sheets of stratified epitheliums are notoriously fragile, which is part of the attraction of the thermally responsive culture surfaces, even sheets made out of cardiomyocytes or mesenchymal stem cells (MSCs) appear to also be mechanically weak (Biomaterials 2005).[40] As the weakness of epithelial sheets is likely due to the lack of ECM in these constructs, one would expect cells of mesenchymal origin to be able to produce a more robust tissue. However, in some studies, cells were cultured in the absence of ascorbate compounds that are known to be necessary to stimulate maximal collagen production. Recently, cell sheets were produced using this same approach from cultures of smooth muscle cell (SMC) and fibroblasts.[41] These cultured cell sheets were supplemented with ascorbate 2-phosphate and 18.8 pM of copper (II) sulfate (believed to increase collagen cross-linking by lysyl oxidase) but were only cultured for a total of 7 days, which may be insufficient to generate sufficient mechanical strength. No sheets produced using this approach have been formally tested for their mechanical strength, and this appears to be a significant challenge for the design of cardiac patches that would play a significant mechanical role. Using much longer culture periods could provide sufficient time for the cell to assemble complex and relatively mature ECM structures leading to the production of stronger sheets. Another option could be to introduce a synthetic scaffold to provide the requisite mechanical strength, but some preclinical results suggest that a biological patch can lead to better tissue regeneration and function even in not cell seeded.[42]

Another limitation of this approach, and of most other tissue engineering approaches, is the limited thickness of tissues that can be produced as a result of diffusion limitations. This is particularly important for a clinically relevant heart patch as the wall of the human heart is over 1 cm thick. While a heart patch product can aim at having a purely parachrine effect, particularly if applied to a recently injured heart (myocardial infarct), it would be clearly beneficial to also be providing mechanical support as such support has been shown to be beneficial.[43] In addition, a robust patch that could be used to repair full- or near full-thickness defects could be used for more aggressive surgical intervention that would be needed to address many degenerative heart diseases. To address this limitation, Okano's group has proposed a number of strategies. One general method is to include endothelial cells in a stack of cells of mesenchymal origin (Biomaterials 2010).

This can be achieved by creating sheets from co-cultures, including endothelial cells or sheets made exclusively from endothelial cells as intercalated in the stack. Initial results *in vitro* were promising as the endothelial cells appear to reassemble into a network of elongated channels mimicking the native microvasculature. However, it remains to be seen if this network can be assembled and connected to the host circulation before cells in the middle part of the construct suffer from hypoxia. While preliminary studies in rats are promising,[44] scaling-up to a human size construct could be challenging. Another strategy proposes to serially implant sheets to allow each layer to be vascularized by the host[45] before the implantation of the next layer. This method has produced contractile and well perfused myocardial tissues of up to 1 mm in a rat model. Furthermore, these tissues could be successfully ectopically transplanted with their newly formed vasculature. This strategy of using the body as an *in vivo* bioreactor has certainly gained momentum in recent years.[46,47] While the multiple surgeries required would be a significant risk to the patient, the upside would clearly justify the risk in the case of a cardiomyopathy (**Figure 3**).

5.527.2.2.4. Limitations of cardiac constructs

While biomaterials such as polymer scaffolds provide structural support for culture of tissue constructs, there are a number of potential limitations surrounding biomaterial-based scaffolds,[17,21,22] including (1) the potential for inflammatory response, (2) possible toxic degradation products,[23,48] (3) variance of compliance between polymers and heart tissue,[21,22] and (4) the lack of interconnectedness between cells because of interference from the scaffold material.[21,22,48] The use of

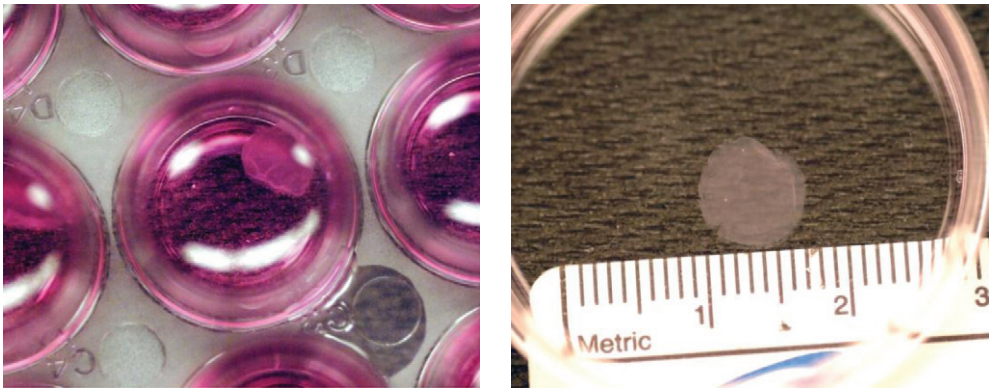

Figure 3 Bovine pulmonary artery endothelial cells (BPAEC) sheets harvested using 24-well PIPAAm temperature sensitive culture plates. Left, disassociated BPAEC cell sheet in culture well and media. Right, harvested BPAEC cell sheet harvested from original culture plate. Courtesy by J. Lancaster, 2009.

completely biological cell-sheets would likely avoid all the limitations mentioned above but may be restricted by their mechanical strength. Apart from the limitations described, a major obstacle of further developments, particularly enrollment into clinical applications, will be the procurement of suitable human stem or progenitor cells.

5.527.3. Cell Delivery Using Biomaterials

In recent years, many investigators have invested significant efforts into the use of living cells as a therapeutic agent (see **Chapter 5.507, Tissue Engineering and Selection of Cells**). These cells are intended to deliver certain products (e.g., growth factors) or to be a replacement cell type to replace lost tissues. These living cell therapies require that cells maintain their activity at the transplant location whether it is the bone marrow, skin, liver, or heart. This has presented a significant hurdle. Thus far, the best-published results of the beneficial effects of bone marrow cell transplantation after acute myocardial infarction come from the bone marrow transfer to enhance ST-elevation infarct regeneration (BOOST) trial.[49] In this study, significant improvements in left ventricular ejection fraction were seen at 6 months after treatment with bone marrow cells. However, these improvements were no longer significant at 18 months. A few investigators have reported cell retention as a major obstacle for these types of cell replacement therapies, indicating that only 1.3–2.6% of infused bone marrow cells are retained in the heart.[50] While these cell-based therapies continue to advance through the clinical trial gauntlet, many investigators are looking into a variety of delivery agents such as hydrogels, alginates, and polymer scaffolds to provide a hospitable environment for transplant cells that can subsequently be delivered into the target tissue.

Future cell therapy will depend on the delivery of a sufficient number of living functional cells, to the appropriate location for an ideal amount of time. While most therapies are initially combined with a traditional surgical intervention, these therapies can also take advantage of the wealth of minimally invasive strategies that have been developed to avoid traumatic procedures such as a thoracotomy. These minimally invasive techniques rely on injectable or collapsible biomaterials combined with a target cell population. The development of such interventional techniques has multiple advantages. For example, in cardiac applications, minimally invasive cell delivery can allow high-risk patient populations to be treated who may not be medically stable for large open surgical procedures. Additionally, recovery time for these patients can be minimized, which significantly benefits the patient's quality of life and decreases morbidity and mortality rates. A recent example of the clinical benefits of minimally invasive approaches for the treatment of cardiovascular disease is demonstrated by the rapid adoption of thoracic endografting instead of open surgical repair in patients with descending thoracic aortic aneurysms. The benefits of thoracic endografting are (1) less perioperative morbidity, (2) lower hospital costs, and (3) equal mid-term life expectancy when compared to open surgical repair.[51] Another clinical example where minimally invasive approaches have been leveraged in efforts to treat higher surgical risk patients is the use of minimally invasive robotic coronary bypass using the da Vinci S System. These procedures are performed under endoscopic vision with surgical assistance from the da Vinci S robotic system. These conditions allow for minimally invasive coronary artery bypass grafting with an enhanced ability to control precise and stable operative manipulations.[52]

Future cell-based therapies will likely focus significant efforts upon minimally invasive delivery. Additionally, the delivery vehicle or the avenue by which transplant cells are introduced into the target tissue will remain a key area of investigation. A variety of delivery formats are described below.

5.527.3.1. Hydrogels

Polymers that form hydrogels are potentially useful for both tissue engineering and drug delivery therapeutic approaches. Hydrogels offer multiple advantages such as a good safety profile, a simple and rapid assembly process, and a large range of achievable geometries. They can also be injectable, and are a cost effective and cell-friendly substrate. However, because of their very high water content, hydrogels lack sufficient mechanical strength to be used as the main scaffold in many applications. Another drawback of hydrogels is that cell activity will often alter their shape. One classic example of this phenomenon is the so-called 'contraction' of collagen gels seeded with cells.[53] This compaction process is typically anisometric and can reduce the dimensions of these constructs by a large percentage. This can limit the usefulness of these scaffolds for the production of an intricate structure. Hydrogels can be classified as either naturally occurring or synthetically derived. Natural hydrogels include collagen (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**), gelatin, fibrin (see **Chapter 2.217, Fibrin**), alginate, agarose, and hyaluronate (see **Chapter 2.214, Hyaluronic Acid**). Some synthetically derived polymer hydrogels include poly(acrylic acid), poly (vinyl alcohol), polyphosphazene, and poly(ethylene oxide).[54] Compatibility with the patient is an important consideration when using hydrogels because potential for mild or severe inflammatory response exists.[55] For example, alginates rich in mannuronic acid have been shown to stimulate an inflammatory response through a monocyte-activation pathway. These stimulated monocytes produced a variety of proinflammatory cytokines including TNF, IL-1, and IL-6.[56] It is also important to consider the rate of degradation once administered, as each hydrogel has its own specific characteristics and degradation profiles.[57] Ideally, the degradation behavior of the hydrogel should match or be closely compatible to the rate of new tissue formation.[58] The rate of new tissue formation is greatly tissue-dependant and the mechanical properties of these hydrogels are critical to their ability to create and maintain a space for new tissue formation *in vivo*.

5.527.3.2. Nanofibers

Another biomaterial approach for cell delivery for cardiovascular repair utilizes self-assembling peptide[59–61] or alginate[62] nanofibers (see **Chapter 2.205, Self-Assembling Biomaterials**). Both peptide and alginate nanofibers provide the heart with structural and physical support by replacing the lost or

compromised ECM; meanwhile, alginate derived versions appear to gradually dissolve[62] and therefore lack a long-term contribution of mechanical support. As reported by Davis *et al.*[59] and Padin-Iruegas *et al.*,[61] peptide nanofibers appear to help significantly with cellular survival, whether in conjunction with the exogenously administered cells or the endogenous cell populations of the target tissue, possibly through the establishment of microenvironments. In addition, incorporation of growth factor or cell signaling elements could greatly contribute to the therapeutic potential of nanofiber-based therapies.

5.527.3.3. ECM Proteins

ECM proteins have been evaluated as a potential scaffold structure to support various cell-based therapies (see **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials** and **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**). For example, stem cell therapies have evaluated the use of a complex tumor matrix, Matrigel™. This product is marketed by BD Biosciences and is composed of Engelbreth-Holm-Swarm (EHS) mouse sarcoma cells. Matrigel™ has demonstrated the ability to facilitate the growth of various stem cell populations and maintain an undifferentiated state for a period of time.[63] The main ECM proteins within Matrigel™ are laminin and collagen. However, some of the challenges of Matrigel are that its origin is from a tumor-based etiology and the matrix itself is poorly defined.

Other investigators have looked at harnessing the cell-based ECM produced by tissue culture. Here, human ECM (hECM) can be produced to have embryonic-like characteristics and therefore may serve as a hospitable environment for culturing transplant cells (**Figure 4**), especially adult or embryonic stem cells.[64] Utilizing a hECM material as a delivery vehicle for cell-based therapies may facilitate improvement in engraftment and long-term outcomes of the therapy. In these studies, bioreactors were developed to expose neonatal fibroblasts to early embryonic conditions during the production of their ECM and conditioned culture media. The resulting hECM contained a protein matrix that includes collagen I (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses** and **Chapter 2.216, Collagen–GAG Materials**), tenacin, hyaluronic acid, and fibronectin, as well as proteins that have been found to be prevalent in embryonic ECM such as collagens III, V, and SPARC.

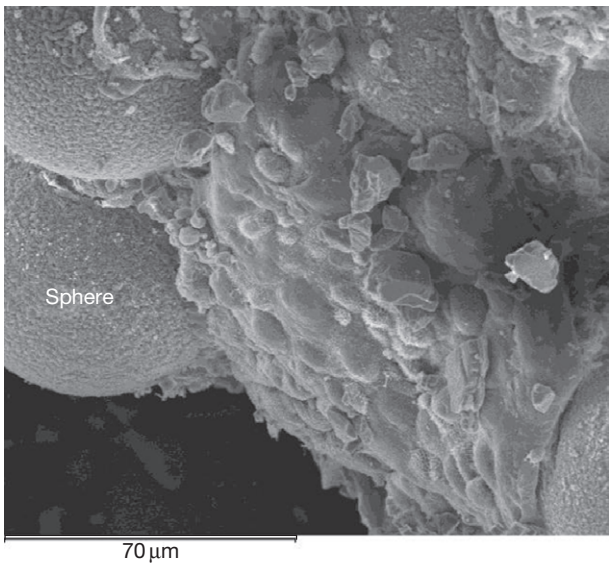

Figure 4 Embryonic stem cells were grown and expanded on the human extracellular matrix material.

5.527.3.4. Synthetic Polymer Scaffolds

Other cell delivery strategies have focused on the use of synthetically created polymer scaffolds. For orthopedic tissue engineering applications, biomimetic scaffolds provide a necessary framework for bone analogs. The osteogenic potential of PCL/calcium phosphate (CaP) matrices have been closely studied for their ability to facilitate growth and residence of a human MSC population for periods of up to 8 weeks. In these studies, MSCs were able to adhere, migrate, and differentiate along the osteogenic lineage within these scaffolds. The PCL/CaP scaffolds showed up to a 27-fold increased degradation compared to PCL scaffolds alone.[65]

Other synthetic polymer scaffolds that have been explored as cell delivery agents are resorbable or degradable poly(D,L-lactic-*co*-glycolic acid) (PLGA) microspheres. While these polymer scaffolds, to date, have not seen wide use within the cardiovascular research space, they are actively being studied for orthopedic applications.[66] In this application, initial cell viability studies have demonstrated the feasibility of using a PLGA/Polyethylene glycol (PEG) polymer matrix and a cell or drug technology.

Furthermore, a PLGA microsphere platform has been demonstrated to support bovine chondrocyte culture onto the PLGA microspheres. Positively charged PLGA microspheres showed the highest cell attachment, growth, and function compared to hydrophobic and negatively charged microspheres. It has been concluded that surface-modified PLGA microspheres can potentially be used as an injectable delivery system for cells into a tissue defect site.[67]

The resorbable PLGA microsphere platform has been widely evaluated as a drug delivery[68–71] platform but its use has been limited as a cell delivery vehicle, mostly into the orthopedic field.[67,72] This resorbable polymer technology may be limited by the relatively rapid degradation rate of PLGA *in vivo*, resulting in obliteration of its mechanical integrity prior to adequate tissue growth.

5.527.4. Tissue Engineering of Artificial Vesseles

Synthetic polymeric vascular grafts were developed to address three issues in vascular surgery: (1) the fact that there are no 'spare' large diameter vessels in the human body for autologous repair, (2) the unsatisfactory performance of nonautologous natural grafts (xeno- and homografts), and (3) the limited availability of small diameter autologous grafts (see **Chapter 6.628, Vascular Grafts**).[73] The development of synthetic vascular prosthesis is often credited to Voorhees, Jaretski, and Blakemore, who first published on synthetic

tubes.[74] In the following decades, two synthetic materials rapidly emerged as the most clinically successful; expanded polytetrafluoroethylene (ePTFE) and woven or knitted polyethylene terephthalate (PET) fibers (Dacron). While these materials performed well as large and even medium diameter conduits, synthetic vascular grafts have not proven successful in small diameter applications (<6 mm ID).[75,76]

Today, coronary artery disease (CAD) is the largest single cause of mortality in both men and women in the United States (American Heart Association). Despite the rapid adoption of percutaneous interventions for coronary procedures, there were still 448 000 bypass procedures performed in 2006. Peripheral vascular disease (PAD) is also a condition that can be treated by the use of a small diameter bypass graft. PAD affects ~8 million Americans and is associated with significant morbidity and mortality.[77] CAD and PAD have similar risk factors and, not surprisingly, are often found in the same patients.[78] In cardiac and peripheral bypass surgery, the best outcomes are achieved when diseased vessels are replaced with autologous veins or arteries. For example, the internal mammary artery has >90% patency over 7 years in cardiac applications, while the saphenous vein maintains ~50% patency after 7.5 years in peripheral sites.[79] However, many patients do not have adequate blood vessels for use as grafts because of either poor quality or insufficient quantity after a previous harvest. This is particularly true for PAD cases where good autologous vessels are often preferentially used to treat CAD. In these cases, the patients are restricted to modest treatment modalities often leading to myocardial infarction or limb amputation. Therefore, there is a substantial unmet clinical need for an alternative supply of vessels to replace small diameter diseased arteries.

5.527.4.1. The Evolution of Tissue-Engineered Blood Vessels

The clinical complications of small diameter synthetic prostheses commonly result from an inflammatory response to and pathologic remodeling of the prosthetic material. These failure modes have led to enhanced interest in new approaches for designing vascular grafts. A tissue engineering approach may overcome certain obstacles faced by synthetic grafts in small-diameter vascular applications.[80] For example, a tissue-engineered blood vessel (TEBV) would presumably be more responsive to physiological signals and avoid the pathological remodeling seen in synthetic grafts. To be successful, a tissue-engineered vessel grafts (TEVG) must have sufficient strength to withstand cyclic loading and changes in blood pressure. It should also have an antithrombotic luminal surface, and ideally, should match the compliance of the host vessels at the anastomotic sites.[80] While one would hope that tissue-engineered constructs would enhance their functionality over time via tissue remodeling *in vivo*, it should be noted that a TEVG must fulfill its mechanical role immediately upon implantation. Similarly, unlike tissue-engineered skin, cornea or other nonload bearing tissues, the remodeling of the blood vessel must not lower its mechanical strength below a certain threshold to avoid dilation and rupture. Consequently, inflammation, rejection, or other biodegradation processes are of particular importance for the successful outcome of a TEBV.

Often cited as the first TEBV, a construct produced by casting a tube of collagen gel containing bovine vascular cell lines (SMCs, fibroblasts, and endothelial cells) was reported by Weinberg *et al.*[81] in 1986. This first model did not have any synthetic material with the aim of avoiding the detrimental effect of introducing foreign materials into the body. This was in line with the developing concept, which would later be called 'tissue engineering,' of creating 'biological substitutes that restore, maintain, or improve tissue function.' However, without additional mechanical support, these vessels were highly distensible and failed during burst strength testing at low intraluminal pressures.[81] This approach was widely repeated in the following decade with collagen or other biological gels, and while valuable as *in vitro* models, these completely biological constructs still displayed limited burst strengths.[53,82–84] The next generation TEBVs were hybrids incorporating synthetic and biological materials.[85] In the ensuing years, the field of vascular tissue engineering became dominated by biomaterial design and the original vision of a biological construct was relegated to the realm of 'desirable but unachievable.' However, it eventually became evident that the presence of a permanent synthetic scaffold would negate the potential benefits of including biological or living components.

5.527.4.2. Biodegradable Scaffolds

In the late 1980s and early 1990s, numerous investigators used various resorbable synthetic polymers to produce fully biodegradable vascular grafts.[86–89] The hope was to produce an 'off-the-shelf' template that would guide the body's natural repair process toward vascular regeneration. However, to this day, finding the right balance between scaffold degradation and extracellular regeneration in order to maintain sufficient mechanical strength has proven to be very challenging. In 1999, Niklason *et al*. produced TEBVs by culturing bovine and porcine cells under pulsatile conditions on poly(glycolic acid) (PGA) felt for 8 weeks. These small diameter vessels had rupture strengths of up to 2150 mmHg.[90] However, it was found that PGA degradation may have led to dedifferentiation of the SMCs, which could possibly lead to hyperplasia and graft occlusion.[91] Over the last decade, this approach did not yield mid- or long-term results in an animal model and attempts to develop a construct with similar mechanical strength using human cells were unsuccessful.[92–94] Around the same period, Shum-Tim *et al.*[95] produced medium diameter graft using a PGA:polyhydroxyalkanoate (PHA) copolymer and ovine vascular cells. Short segments implanted in the abdominal aorta of lambs showed promising results up to 3 months with favorable patency. In parallel, Shin'oka *et al.*[96] developed a similar approach, using PCL and PGA, which led to the first implantation of a TEVG in a human. These TEBVs were implanted in the low-pressure pulmonary circulation of infants with severe congenital defects. This method has evolved toward the use of bone marrow cells and a PGA/ε-caprolactone/L-lactide copolymer.[97] While this tremendous success does not address the need for arterial bypass conduits, it finally established the feasibility and potential of vascular autologous cell-based therapy.

Other researchers have examined the use of various processed animal tissues as another type of biodegradable scaffold

for tissue engineering. While homografts and xenografts have been shown to be poor conduits, over a decade of efforts in developing decellularization technologies has brought the promise of natural scaffolds that would not trigger immune response. This approach is based on the idea that the removal of all cellular components could leave behind exclusively the ECM. One of the first and most widely used decellularized ECM is the porcine small intestinal submucosa (SIS), which has been used clinically for many years. As a vascular graft, SIS has been used in animal models since 1990 with relatively positive results[98,99] but has yet to be tested in humans for that application. Recently, a modified porcine SIS was used as a vascular prosthesis.[100] After implantation in a rabbit, these grafts required native endothelial cell infiltration and aggressive anticoagulation therapy in order to prevent thrombosis. These results underline the importance of endothelial cell coverage in TEBV for small diameter arterial bypass. This was also exemplified in studies using ePTFE grafts endothelialized with autologous EC isolated from vein, fat, or blood.[101–103] Using this technique, dramatic improvements have been seen in some clinical cases, particularly for below-the-knee procedures.[104,105] While decellularized tissues offer an attractive option for many regenerative approaches, these tissues appear to, at least partly, trigger some immune recognition.[106,107] This suggests that they may not be appropriate for vascular tissue engineering where even a minor inflammatory reaction could lead to a negative outcome.

5.527.4.3. A Cell-Synthesized Scaffold

In the mid-1990s, L'Heureux *et al*. came to the conclusion that reconstituted ECM proteins such as collagen were unlikely to provide the requisite mechanical strength needed for creating an implantable TEBV. Even if these reconstituted matrix proteins did provide the requisite mechanical strength after various physicochemical treatments, these scaffolds would be aggressively degraded by the immune system because of their unnatural chemical or tridimensional organization. Faced with this realization, L'Heureux turned to cultured cell as a source of unprocessed and naturally organized ECM. The general approach, which was later termed 'tissue engineering by self-assembly' (TESA), takes advantage of the ability of cells of mesenchymal lineage to assemble complex and abundant ECM when cultured for extended periods in the presence of ascorbate. While TESA can be used to direct cells to deposit natural ECM in various geometries, the initial developmental work was aimed at producing sheets of living cells and the ECM they produced. This particular version of TESA was labeled 'sheet-based tissue engineering' (SBTE).

For building blood vessels, L'Heureux *et al.*[108] created sheets from human adult dermal skin fibroblasts and from umbilical vein SMCs. After a month of culture, the sheets were detached from their culture substrate and were wrapped around a temporary tubular support. After an additional culture period, referred to as 'maturation,' of 8 weeks in a bioreactor providing active perfusion, all the individual layers fused together to form a cohesive living cylinder. In this initial model, three concentric layers were formed to mimic the native architecture of a human blood vessel. The outermost layer was formed by a rolled fibroblast sheet and played the role of the adventitia. The median layer was formed by a rolled sheet of SMCs and played the role of the tunica media. The innermost layer was called the 'internal membrane' (IM) and was made of a rolled fibroblast sheet that was matured and then devitalized by dehydration. The IM was included in the design to mimic the antimigratory role of the internal elastic lamina (IEL). The IEL is an effective physical barrier that separates the SMCs of the media from the plasma and the more fragile and less proliferative endothelial cells. Damage to the IEL has been identified as an important factor in the development of atherosclerosis but also of intimal hyperplasia observed after balloon angioplasty.[109,110] One would also expect it to be a key factor in the development of intimal hyperplasia at the anastomosis with a vascular graft. The IEL is largely made of elastin, which is known to be resistant to most enzymes produced by SMCs. However, the IM is largely made of collagen, which is sensitive to many matrix metalloproteinases. Accordingly, the IM was designed to be much thicker than the native IEL; the strategy being that cell migration toward the lumen would be significantly inhibited during the inflammatory phase following implantation. In fact, future long-term *in vivo* studies would confirm that the IM is not readily degraded and remains acellular for months.[111] These constructs could then be removed from around the mandrel and its lumen that is seeded with endothelial cells (**Figure 5**).

These TEBVs had supra-physiological burst pressures in excess of 2500 mmHg at 3 mm internal diameter. They were implanted in a canine arterial bypass model and, as such, were the first completely TEBVs with clinically relevant mechanical properties.

In the next decade, L'Heureux and his team focused on translating these promising early results into clinical reality. For that purpose, the assembly strategy was streamlined and SMCs were eliminated from the process without affecting the mechanical strength of the vessels. In addition, the TESA method was adapted to cells (fibroblasts and venous endothelial cells) isolated from age- and risk-matched individuals, that is, older individuals suffering from cardiovascular disease. Finally, the bioreactor system was simplified to be compatible with a high-throughput, reliable, and economically viable production process. The resulting vessels displayed an average burst pressure of 3468 ± 500 mmHg at a diameter of 4.2 mm.[111] This new human TEBV design was tested in immunosuppressed canines and primates as well as in nude rats for up to 9 months without signs of mechanical failure. On the basis of the promising preclinical results, vessels were built for a series of 10 patients (age 29–89) suffering from end-stage renal disease (ESRD) and in need of a vascular graft for hemodialysis access. These TEBVs displayed burst pressures as high as 5763 mmHg (average 3340 ± 849) at a diameter of 4.8 mm and were implanted as an arteriovenous shunt. The clinical protocol called for a 3-month observation period to demonstrate mechanical stability followed by the use of the graft for hemodialysis access, that is, the graft would be punctured with two 16-gauge needles 3 times per week. In the initial report, one graft had a primary patency (patency without intervention) of 11.5 months despite the very unfavorable hemodynamics and mechanical injuries associated with this clinical application.[112] In a later report, these TEBVs showed primary

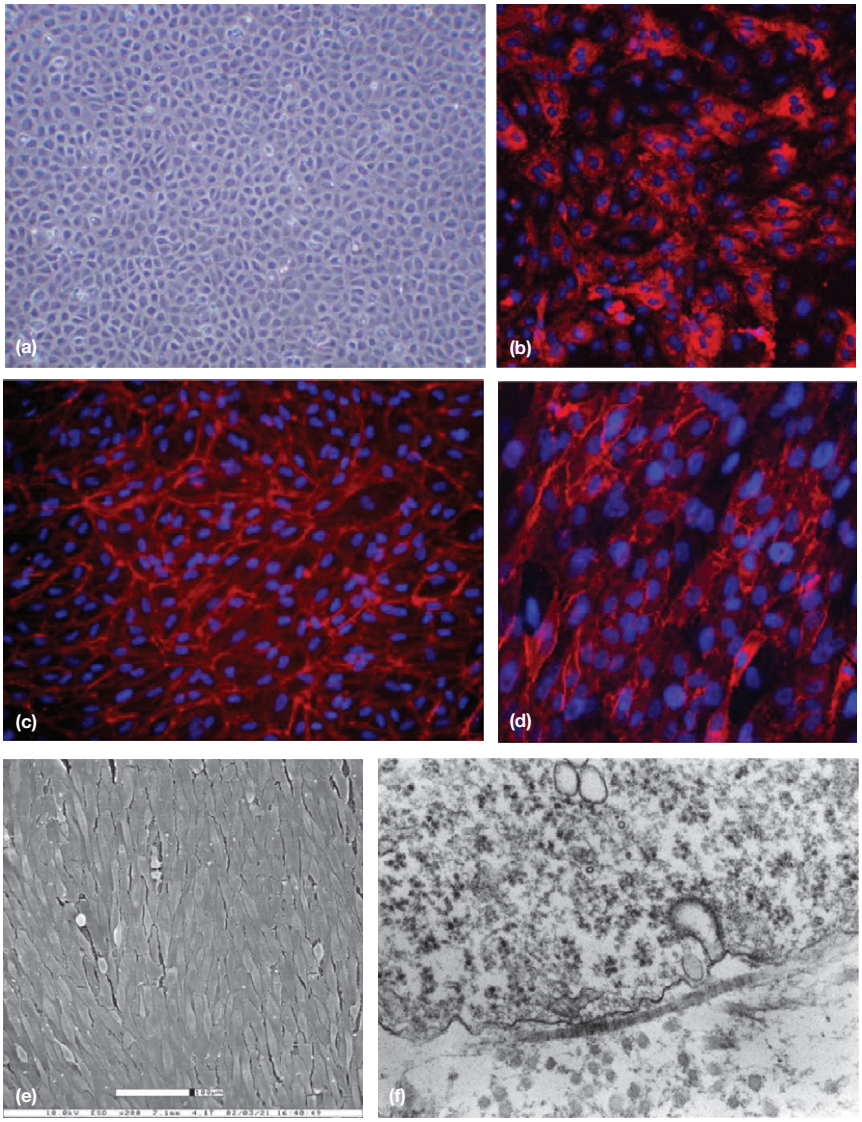

Figure 5 Endothelialization of tissue-engineered blood vessel produced by tissue engineering by self-assembly. (a) A phase contrast micrograph shows the typical 'cobble stone' appearance of a confluent culture of human venous endothelial cells on polystyrene tissue culture flask. (b) Von Willebrand factor (red) is a marker specific to endothelial cells and is commonly used to identify and characterize the purity of culture *in vitro* using immunolabeling techniques (nuclei are blue stained by Hoechst 33258). ECs can also be labeled on the surface of tissue-engineered blood vessel to determine the degree of confluence of the cells as well as their phenotype. (c) *En face* view of a confluent endothelium on the luminal surface. The actin microfilaments have been stained with phalloidin (red) to demonstrate a pericytoplasmic arrangement suggestive of a mature endothelium (nuclei in blue). The endothelium of the tissue-engineered blood vessel can also be stained for specific markers to confirm the nature of the monolayer. (d) PECAM/CD31 (red) specifically labels the cell–cell contacts between endothelial cells in confluent endothelium. (e) Scanning electron microscopy can also be used to ascertain the coverage of the luminal surface of a tissue-engineered blood vessel but this method can often cause cell losses due to the harsh treatment. (f) Transmission electronic microscopy can be used to study biomaterial/EC interaction. In this micrograph, the cytoplasmic membrane of an EC can be seen in close apposition with a collagen fiber of the luminal surface. The characteristic 67 nm periodicity of the striation of a native collagen fiber can be observed.

patency rates of 78% at 1 month, and 60% at 3 and 6 months after implantation.[113] These rates approached the objectives of the Dialysis Outcomes Quality Initiative (a program run by the National Kidney Foundation Disease) across all patient populations for native vein fistulas.[114] Considering that native veins perform practically twice as well as ePTFE grafts and that this study included only patients with a high-risk of graft failure, these results suggest that this new self-assembled 'biomaterial' could be particularly well-suited for vascular applications (**Figure 6**) (see **Chapter 2.205, Self-Assembling Biomaterials**).

5.527.4.4. Elastin as a Natural Scaffold

Natural polymers such as elastin are potential alternatives to synthetic materials. Unlike collagen, this ECM has the potential to be assembled in mechanically strong tissues that are capable of resisting the body's degradative responses.[115]

Elastin, derived from its water-soluble precursor tropoelastin, consists of repetitive glycine-rich hydrophobic domains of variable length interspaced with alanine-rich regions containing crosslinkable lysine residues. In its native form, elastin is a network of elastic fibers that are cross-linked between lysine residues. Cross-linking enhances elastin's biostability and controls its mechanical properties. Cross-linking occurs after cellular secretion of tropoelastin with local fiber deposition. Because elastin cannot be recovered from tissue in its native form, simpler proteins comprising repetitive polypeptide sequences have been assembled in an effort to duplicate the desirable properties of elastin.

McMillan and coworkers have produced large elastin-like proteins by assembling gene segments encoding the peptides VPGVG and VPGKG that represent the mobile domains in elastin. The genes isolated from this assembly process are up to 3000 base pairs long, contain 39 repeats of the sequence $(VPGVG)_4$ (VPVKG), and produce an 81 kDa protein after expression in *E. coli*.[116] This protein can be spun into fibers, filaments, and ribbons with a tensile strength of about 35 MPa and the material modulus 1.8 GPa.[117] Elastin-like polymers made by these methods have been used as carriers for antitumor drug delivery.[118]

Polymeric scaffolds of varying sizes based on the repeating elastin sequence VPGVG have also been constructed by sequential polymerization of the pentapeptide after solid-state chemical synthesis. These elastin-like proteins will self assemble to form fibers.[119] Materials with similar properties comprising the pentapeptides VPGKG and VPGIG have also been made using recombinant approaches,[120] and elastin-mimetic proteins can be crosslinked into flexible films and filaments by a variety of methods.[121–123] In addition, the solid polymer blocks that form from these proteins have also been used as a substrate to assemble functional biomotors.[124]

Further modifications to these polypeptides, providing additional complexity, are necessary for the attachment or adhesion of human endothelial cells, an important milestone for the *in vivo* use of these polymers as substrates.[29] A sequence derived from the cell binding domain of fibronectin[125] has been incorporated during assembly of polypeptides as an essential component of the polymer substrate[126–130] to support endothelial cell adhesion, function, and activity.

Elastin-like materials with as many as four different domains have been synthesized and assembled to provide additional functionality to the synthetic elastin-like molecules.[131,132] These structures may potentially be useful in tissue engineering applications such as vascular grafts, stem cell matrices, and organs such as bladders.[117] However, assemblies of repeating peptides cannot match the complexity or biological activity of native elastin. With the exception of some early work by Urry *et al.*,[133] no *in vivo* data on elastin-like proteins have been published, and their performance as engineered structures is unknown. In contrast, electrospun tropoelastin fibers support attachment, migration, and extensive proliferation of human mesenchymal cells.[134] What is already known about tropoelastin suggests that this material may serve as a novel biomaterial with complex structure and superior performance for vascular scaffolds.[27]

The challenge of engineering blood vessels that have the mechanical properties of native vessels has been and remains significant. The native human artery structure is ~30–50% elastin (Figure 7). In a variety of rat strains, the percent dry weight of elastin has been reported to be between 30 and 40%.[135] The aging process has been shown to produce a number of vascular changes including a progressive rise in arterial stiffness.[136,137] Studies show that elastin's characteristics are critical to vascular grafts and that 'to ensure appropriate mechanical function of the vessel and to prevent vessel stenosis, successful tissue-engineered vascular replacements must incorporate an elastic component.'[138] According to leading researchers, "successful tissue-engineered blood vessels incorporating elastin are, therefore, the Holy Grail of future vascular interventions."[139]

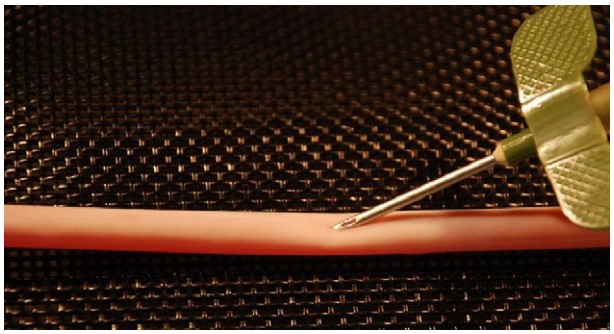

Figure 6 A completely biological human tissue-engineered blood vessel. This small diameter blood vessel (4.8 mm internal diameter) was produced with cells from a female patient suffering from end-stage renal disease and on dialysis. Vessels produced for this patient had an average burst pressure of 5204 ± 424 mmHg, which is higher than the burst pressure of the saphenous vein commonly used for bypass surgery, and higher than most human arteries of a similar diameter. The vessel is shown as it is being tested for its ability to resist a puncture from a 16 Ga hemodialysis needle. While burst pressure may be a good indicator for the suitability of a graft to perform as a typical bypass graft, resilience to injury is a key property for a good arteriovenous shunt. This *in vitro* test is performed under hydrostatic pressure to observe leaking during puncture, which will last up to 4 h in the clinical setting, and after removal of the needle. Synthetic grafts are notorious for their propensity to bleed once the needles are removed from the graft. This natural tissue, because it can be easily punctured at an angle, easily seals after removal of the needle even *in vitro* where only aqueous solutions are used.

5.527.4.5. Mechanical Testing

The mechanical properties of native vessels are well understood scientifically and held as the primary reason for their outstanding performance as bypass grafts. However, the field has not yet been able to produce a biomaterial that ideally matches the mechanical characteristics of native arteries and that has a low biological impact. Native arteries such as the canine carotid artery are not only composed of a variety of cell types (e.g., endothelial cell lining and SMC media layer), but also have an important basement membrane and ECM composed of elastin (Figure 8). These specific cell types have important biological and mechanical properties for a functioning blood vessel. Additionally, the biomechanical properties offered by elastin have not yet been replicated synthetically in the field by any of a variety of polymer scaffolds.

For example, Figure 9 shows the stress–strain curves of a canine carotid artery versus a polyurethane scaffold tube. The dramatic differences can be seen where the native carotid artery exhibits the typical viscoelastic behavior in contrast to the linear behavior of the polyurethane scaffold tube.

5.527.4.6. Size and Scope of the Peripheral Market

As many as 12 million Americans over the age of 50 are affected by peripheral artery disease (biotechnologyireland.com (a)). Approximately 600 000 grafts are implanted each year in the United States alone and this is growing annually because of an aging population (gore.com). The estimated $2.0 billion market for vascular grafts (biotechnologyireland.com (a)) is a subset of the worldwide interventional cardiology market, which was estimated at $11 billion in 2008 (biotechnologyireland.com (b)). The market for vascular grafts is global in reach, but the vast majority of vascular grafting procedures occur in the United States and other developed nations. Only the most remote third world medical providers do not have regular access to these grafts. In determining the ideal initial market, the regulatory environments are key factors. With recent changes in European regulatory practices, it is expected that the time required for obtaining approvals will become substantially similar to those in the United States.

5.527.4.6.1. Market size and growth

A clearly defined market size for vascular grafts is somewhat difficult to obtain as each existing player in this market defines it differently. A general study of this market tells us that today this market is in the $20–30 billion range.

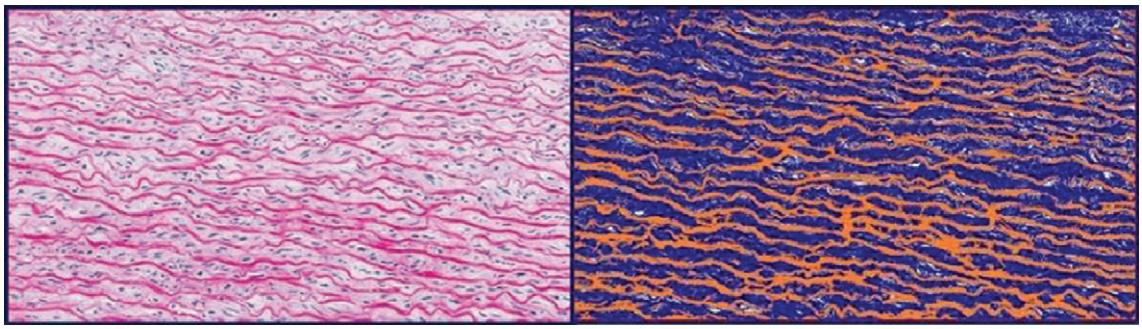

Figure 7 Left: H&E staining of a porcine aorta. Right: Area quantification of elastic fibers in a porcine aorta. Orange markup shows elastic fibers at 39.1% of total area.

Figure 8 Immunohistochemical staining of smooth muscle cell differentiation markers and basement membrane protein (elastin) in canine carotid arteries.

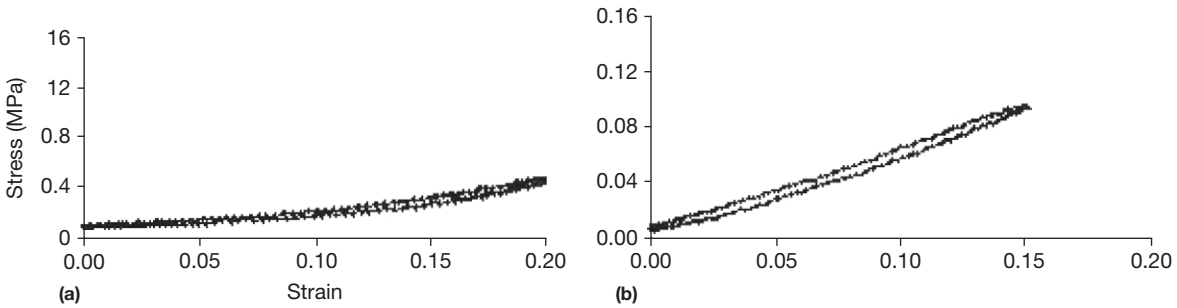

Figure 9 Stress-strain curves for (a) native carotid artery, (b) unseeded polyurethane vascular scaffold.

The vascular graft market has been consistently showing an average growth of 10–20% for last several decades (data from annual reports). As population grows and ages, the need for such devices increases. The market for these devices is directly dependent on aging population and is somewhat resilient to economic recessions and fluctuations.

An example of a peripheral target for first-in-man clinical application is a TEBV for vascular access in hemodialysis patients. Dialysis vascular access is the lifeline of the ESRD patient undergoing hemodialysis. A typical ESRD patient receives 1.5–2 interventions per year to maintain vascular access for hemodialysis. The grafts implanted to provide this access typically fail because of compromised patency. A tissue engineering solution to this problem has been the Holy Grail for many investigators who aim to improve patency rates and long-term survival of the vascular access graft. Once a TEBV technology demonstrates clinical success in the dialysis vascular access market, numerous additional clinical markets will likely follow (e.g., peripheral bypass).

In 2004, the total annual cost of vascular access complications was estimated to be nearly $8000 per patient risk year, with a total of $1–1.5 billion, or ~10% of the total ESRD budget. More than 20% of hospitalizations of ESRD patients are attributed to complications with vascular access. The growth of ESRD patients is expected to double by the year 2010. Thus, dialysis access care will grow into a multibillion dollar cost.

5.527.5. Tissue Engineering of Heart Valves

The first replacement heart valves were made from autologous or homologous sources of human tissue (Figure 10).[140] Since the 1960s, allograft replacement valves have been used to repair compromised or nonfunctioning heart valves in patients. These replacement valves are classified as either mechanical or biologically derived (see Chapter 6.626, Cardiac Valves: Biologic and Synthetic). To date, efforts to create tissue-engineered heart valves (TEHVs) have shown limited effectiveness. In this section, we will briefly discuss the field as a whole, how biomaterials will contribute to future developments, and the place tissue engineering may serve for this clinical application (see Chapter 5.528, Tissue Engineering of Heart Valves).

5.527.5.1. Classic Mechanical and Biological Heart Valves

Currently, a number of mechanically and biologically derived heart valves are available. Mechanical valves are derived mainly from nonbiological materials such as polymers or other biomaterials. Biological valves or bioprostheses are derived from human or animal tissues.[141] Bioprostheses are derived mainly from porcine aortic valves (PAV) or bovine pericardial valves (BPV) and are glutaraldehyde preserved.[142] These valves are defined by predictable rates of deterioration, with >50% of the replacement valves failing within 15 years.[143]

5.527.5.2. Device Challenges

Heart valve replacement surgery represents the only therapy for end-stage aortic valve disease. However, prosthetic valves have a number of limitations. Both the classic mechanical and biological heart valves are limited by deterioration that results from either calcification or noncalcification.[144] These problems ultimately affect the overall function and implant life of the valves. Calcification deterioration arises when calcium accumulates within the valve as a result of the inability of the glutaraldehyde treated tissue to maintain low calcium levels. Noncalcification degradation generally refers to the natural deterioration of replacement valves.

Additionally, mechanical valves are typically recognized by the body as a foreign substance and therefore facilitate concerns with thromboembolic complications, requiring lifelong anticoagulation therapy.[145] Because of the well described leaflet deterioration and calcification with biological or bioprosthetic valves, reoperation and replacement are common future clinical outcomes.[145,146]

Finally, both mechanical and biological valves lack the fundamental ability to grow, repair, or remodel in the patient.[147] This is especially important when considering the treatment of congenital heart valve disease in pediatric patient populations.[148]

5.527.5.3. Tissue-Engineered Heart Valves

Tissue engineering is currently being evaluated to determine if it can offer an alternative to mechanical or biological heart valves.

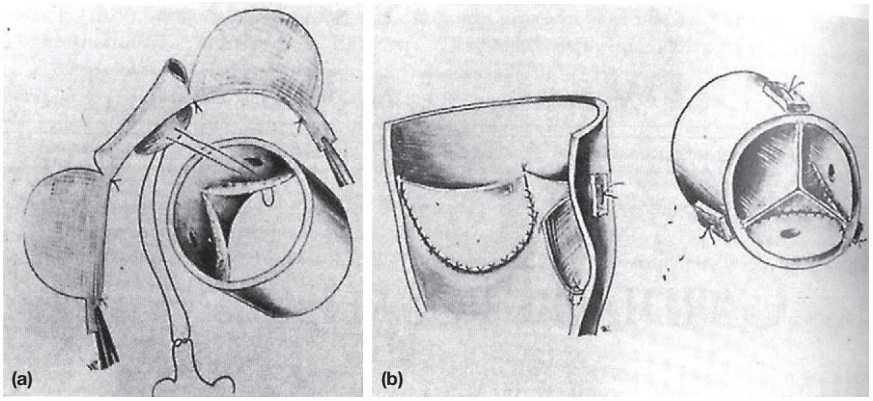

Figure 10 (a) Fascia lata strip cut to form three cusps. Then it is sutured to the aortic annulus. (b) The commissures are anchored with sutures placed through the aortic wall and tied over Ivalon sponge pledgets. Reproduced from Senning, Å. *J. Thorac. Cardiovasc. Surg.* **1967**, *54*, 465–470.

Tissue engineering may offer solutions to overcome current limitations of mechanical or biological heart valves while offering unique advantages. These advantages may include a living autologous structure, improved biocompatibility, and the ability to grow, repair, and remodel.[149–151] Classically the 'Holy Grail' of replacement valves would be neither obstructive nor thrombogenic, capable of lasting the lifetime of the patient, and would possess cellular regenerative and homeostatic properties.[144] In theory, TEHVs may allow for creation of such a replacement valve. Recent works for developing TEHVs have evaluated varying endothelial cell types cells for population of decellularized[152,153] or synthetic valves.[154]

Focus on decellularized scaffolds has presented promising opportunities for the development of a TEHV (see **Chapter 2.221, Decellularized Scaffolds**). Once the field has progressed to the point of wide-utility of a decellularized scaffold, the next major decision that needs to be addressed is whether it should be an allograft only (e.g., human origin), or if it could be a xenograft (see **Chapter 5.507, Tissue Engineering and Selection of Cells**). If decellularized xenograft scaffolds are to be explored, they present source and acquisition advantages while presenting certain key complications such as disinfection criteria and suspected antigenicity of xenograft (ECM) proteins.[155] This idea has previously been suggested by *in vitro* and *in vivo* studies.[156–158]

A significant concern exists with the concept that a decelluarized xenograft scaffold may actually be more inflammatory than current iterations of cryopreserved homografts. An unfortunate clinical example of a decelluarized xenograft heart valve (Synergraft) highlights the importance of truly understanding the ability of a decellularized ECM to provoke the immune system as well as the innate nonspecific inflammatory pathway.[159] In other studies, decellularized porcine leaflets were reported to be more attractive (stimulated macrophage response) than extracts of human native pulmonary cusps that had not been decellularized.[155] These studies suggest that future decisions on an appropriate decellularized ECM point to the human allograft over a xenograft source.

5.527.5.3.1. Regeneration versus repopulation

Attempts at producing TEHVs are classified as either regeneration or repopulation based. Regeneration methods involve an implantable biologically active matrix comprising both cellular and connective elements. Repopulation methods utilize harvested valves rinsed and voided of cellular elements and repopulated *in vivo* by the recipients own cells.[147]

5.527.5.3.2. Biomaterials used for heart valves

The use of biomaterial scaffolds for the development of replacement heart valves will continue to face the complex offering provided in the native biological ECM of heart values. Specifically, this ECM consists of collagen, elastin, and GAGs (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses** and **Chapter 2.216, Collagen–GAG Materials**). Collagen is primarily responsible for the structural integrity and biomechanical strength of native heart valves.[160] Elastin provides significant tissue resilience over time and over repetitive heart cycles. glycosa minoglycans (GAGs) play a pivotal

Table 1 Summary of biomaterials evaluated for use in the development of heart valves

Material	*Advantages*	*Disadvantages*	*Comments*	*References*
Silicone	Favorable flexibility and biocompatibility	Short durability; distorted and thickened leaflets; tearing; thrombosis formation	Structural failures and impaired hemodynamic performance and durability	[163,164]
Polytetrafluoroethylene (PTFE)	Favorable hemodynamic properties	Low resistance to thromboembolism and calcification; free edge inversion and stiffening of the leaflet	PTFE was found to be unsuitable because of major complications	[165–168]
PUs: Polyester	Good viscoelasticity	Susceptible to hydrolysis	Biodegradation and calcification have been reported as the main problems	[168,169,170]
PUs: Urethane	Good resistance to hydrolysis	Low resistance to oxidation (PEU) and prone to calcification (PCU)	Biodegradation and calcification have been reported as the main problems	[171–173]
PVA	Good mechanical properties	Not suitable for dipcasting	Mechanical properties were satisfactory but PVA needs to be further studied	[174]
SIBS	Enhanced resistance to hydrolysis, oxidation	Causes platelet activation and thrombogenicity	Resistance to oxidation and hydrolysis along with its biostability makes it a leading material for development of heart valves	[170,175]
POSS-PCU nanocomposite	Excellent resistance to oxidation, hydrolysis and calcification; excellent biocompatibility; antithrombogenicity	No reports yet	Positive material characteristics have led to the current evaluation of POSS-PCU as a heart valve	[162,176]

role in enabling valve tissue to withstand compressive forces.[148] In recent years, a number of biomaterials have been evaluated during the development of mechanical heart valves. These include polymers such as polylactic acid (PLA)/PGA and copolymers, which were used in the mid 1990s and more recently, PHAs. PHAs are naturally occurring bacteria derived polymers and a possible alternative to petroleum-based plastics with many potential uses.[147,161]

Efforts in the development of synthetic heart valves leaflets have included strategies that use nanocomposite polymers. For example, polycarbonate soft segment (PCU) and polyhedral oligomeric silsesquioxanes (POSS) nanoparticle (POSS-PCU) has been evaluated as a synthetic material for heart valve leaflets because of its favorable biocompatibility and biostability.[163] Tensile strength of POSS-PCU has been shown to be significantly higher than PCU alone materials, 55.9 ± 3.9 versus 28.8 ± 3.4 N mm^{-2} at 37 °C, respectively.[163]

Numerous other biomaterials have been explored for use in polymer heart value development. A summary in **Table 1** helps to describe some of the key biomaterials that have been evaluated to date.

Glossary

Alpha smooth-muscle actin (α-SMA) Cytoskeletal protein.
Ethylenediamine-tetraacetic acid (EDTA) Chelating agent with the ability to sequester di- and tricationic metal ions.
Glycosaminoglycans (GAGs) Unbranched polysaccharides consisting of a repeating disaccharide unit.
Low-density lipoprotein (LDL) Lipoprotein that transports cholesterol/triglycerides from the liver to peripheral tissues.
Vascular endothelial growth factor (VEGF) Platelet-derived growth factor involved in vasculogenesis and angiogenesis.

5.528.1. The Ideal Valvular Substitute

5.528.1.1. Heart Valve Disease and State of the Art

Heart valve disease represents a major part of the global disease load with high incidence in the developing world due to rheumatic disease, and in the developed world, in an increasing number of patients who are affected by degenerative valve disease.[1–3] Consequently, the advances in medical treatment of cardiovascular diseases have also been significant; particularly, treatment with tissue substitution has proved that functional replacements of tissue and organs could be lifesaving. In particular, the replacement of diseased and insufficient heart valves has markedly improved the life expectancy of patients with severe valvular heart disease and receiving optimum medical therapy.[4] Annually, more than 290 000 heart valve replacements are performed worldwide and the number of patients requiring heart valve replacement is estimated to triple by the year 2050.[5,6] In spite of this remarkable progress in treatment, valvular heart disease still remains a significant cause of morbidity and mortality worldwide.[7]

The most common treatment for end-stage heart valve disease is surgical replacement of the dysfunctional tissue with either a mechanical or bioprosthetic substitute. Today's valve replacement surgery is efficacious, and currently available valvular substitutes display excellent structural durability (reviewed by Ruel and Lachance[8]). However, the state-of-the-art heart valve prostheses in clinical use possess a series of substantial limitations. These include the lack of growth, repair, and remodeling capabilities once they are implanted into the patient. Additionally, mechanical valvular substitutes are inherently prone to thromboembolic events due to high shear stress, nonphysiological flow profiles and blood damage. Lifelong anticoagulation therapy seems indispensable in these patients, which results in a substantial risk of spontaneous hemorrhage and thromboembolic incidences (reviewed by Yoganathan *et al.*[9] and Dasi *et al.*[10]). Apart from this, further complications may occur due to the side effects of these drugs, for example, embryo toxicity in young females. Bioprosthetic valves, either of animal origin (xenografts) or from human donors (homografts), are more susceptible to structural valve degeneration, and the associated need for repeat reoperations makes them less suitable for middle-aged and younger patients.[11] This is also reflected by the current clinical guidelines that recommend the use of bioprostheses in patients aged 65 years and older.[12] Theoretically, cryopreserved donor heart valves represent the valvular replacements closest to natural valves with low thrombogenicity and infectious risk.[13] However, the lack of availability, reflecting worldwide organ scarcity, represents a seemingly unsolvable obstacle with regard to a widespread implementation of this cardiac valve replacement concept.[14] (see **Chapter 6.626, Cardiac Valves: Biologic and Synthetic**)

Overall, these considerable shortcomings indicate that current options for heart valve replacements are suboptimal for a substantial group of patients and that the ideal valvular replacement has yet to be developed.[6] The native heart valve is composed of living, dynamic tissue capable of continuous remodeling to adapt to its constantly alternating hemodynamic environment *in vivo*.[15] None of the currently available valve replacements is capable of fully restoring the native valvular function due to the lack of these adaptive capacities. Ultimately, this will also affect the integrity of the physiologic cardiac function. Tissue engineering of heart valves represents an emerging field of research with the potential to overcome these limitations by creating a viable living autologous valve replacement that prevents an immune response, clotting activation, and valvular degeneration on the one hand, and makes allowances for growth, remodeling, and repair throughout the patient's lifetime on the other hand (see also **Chapter 6.626, Cardiac Valves: Biologic and Synthetic**).

5.528.1.2. The 'Gold Standard': Architecture of Native Heart Valves

The ultimate rationale of tissue engineering is the creation of living neo-tissues identical, or at least very close to, native human valvular structures. Therefore, an accurate understanding of the fundamentals of normal heart valves – representing the 'gold standard' – constitutes an inalienable prerequisite to a successful development of native-analogous tissue-engineered valvular substitutes. Interestingly, it is the research on tissue engineering in recent years that has fundamentally stipulated a novel interest in native heart valve architecture and development, giving many important implications to the entire field of valvular heart disease.

In general, all four human heart valves share several microstructural similarities. However, the semilunar aortic valve best illustrates the essential features, and also serves as a paradigm for microstructural and cellular adaption to functional requirements. This trileaflet valve facilitates the blood flow from the left ventricle to the aorta and peripheral blood vessels through a complex opening and closing mechanism in an unrelenting, physiologically demanding environment over a wide range of hemodynamic conditions.[4,16] Its valvular leaflets are covered by a continuous layer of endothelial cells (ECs), enabling the smooth blood flow during opening and closing of the valve and regulating immune as well as inflammatory reactions (reviewed by Simmons[17]). The load-bearing part of adult semilunar valve leaflets reveals a layered architecture within the endothelial coverings, allowing for the remarkable changes in shape and dimension. The human heart valve leaflet tissue itself consists of three layers: the ventricularis, the fibrosa, and the spongiosa (**Figure 1**). These individual layers within the valvular leaflets show different mechanical characteristics, which are mainly due to their disparities in microstructural composition. In particular, the collagen and elastic fibers show a preferential arrangement and orientation within specific valvular connective tissue layers (reviewed by Misfeld and Sievers[18] and Hjortnaes *et al.*[19]).

The ventricularis, the layer at the inflow surface, predominantly consists of radially aligned elastin fibers. The inner layer, the spongiosa, is largely composed of loosely arranged collagen and abundant amounts of glycosaminoglycans (GAGs). The fibrosa or arterial layer, which is situated at the outflow surface, contains coarse bundles of circumferentially aligned collagen fibers that form the macroscopical folds parallel to the free edge of the leaflets. These collagen fibers represent the strongest part of the valve leaflets and are mainly responsible for bearing diastolic stress. All of these collagen bundles diverge into the aortic wall, thereby transferring the gross load of the leaflets to the wall of the aortic root. Thus, the fibrosa layer is considered the major load-bearing part of the valvular leaflet, enabling a stress increase while preventing a prolapse of the leaflets.[20–22] In contrast, the elastin in the ventricularis layer restores the contracted configuration of the leaflets in a systolic pressure environment. During opening of the valve, elastin extends at minimal load in the ventricularis to return the fibrosa in its original corrugated state, facilitated by the spongiosa that dissipates the arising shear stresses. When the valve is closing, the elastin fibers get unfolded and the main load shifts from elastin to collagen. In addition, the hydrophilic GAGs in the loose spongiosa layer may serve as a shock and shear absorber by readily absorbing water and decreasing the pressure difference across the valve.[23–25]

Between the extracellular components reside valvular interstitial cells that can be divided into two major cellular phenotypes: smooth muscle cells, arranged in bundles or just as single cells,[26,27] and fibroblasts, maintaining the extracellular matrix (ECM). Approximately 60% of the fibroblasts represent myofibroblasts,[28] cells that possess phenotypic features of both fibroblasts and smooth muscle cells, depending on their biological and mechanical microenvironment.[29,30]

5.528.1.3. Requirements for the Ideal Valvular Substitute

The ideal valvular substitute would be a copy of its native counterpart comprising durability, resistance to infections, adequate hemodynamic performance, and potential to grow, as well as the absence of thrombogenic, immunogenic, and/or inflammatory reactions. Dwight E. Harken, a pioneer in heart valve surgery, first outlined these essential characteristics of the ideal valvular substitute and summarized them as the 'Ten Commandments'.[31] Unfortunately, these requirements – equaling the fundamental properties of natural, living, autologous tissues – are not met by today's cardiovascular replacements.

Apart from these characteristics, the ideal replacement would exhibit mechanical properties similar to its native counterpart comprising appropriate physiological compliance and tissue strength in order to withstand hemodynamic pressure changes without failure, and it would adequately respond to physiological changes within the cardiovascular system as well (see **Chapter 3.308, The Mechanics of Native and Engineered Cardiac Soft Tissues**).

5.528.2. Strategies in Autologous Heart Valve Tissue Engineering

Langer and Vacanti[32] defined the term 'tissue engineering' as an interdisciplinary field, applying the methods and principles of engineering to the development of biological substitutes that can restore, maintain, or improve tissue formation. According to this definition, two principle strategies have been developed to generate living autologous heart valve replacements. One requires an *in vitro* phase, generating the valvular substitute *ex vivo*.[32] This traditional tissue engineering paradigm comprises the isolation and expansion of cells from the patient, subsequent seeding onto an appropriate scaffold material, *in vitro* tissue formation, and finally, reimplantation into the patient from whom the cells were taken. This paradigm, further referred to as the *in vitro* tissue engineering approach, is being employed as the principal approach for heart valve tissue engineering and aims at full development of the tissue substitute *in vitro* (**Figure 2**). The second approach, *in vivo* heart valve tissue engineering, circumvents the *in vitro* tissue culture phase by straight implantation of natural tissue-derived heart valve matrices, aiming at potential cell ingrowth and remodeling *in situ*.[33]

5.528.3. *In Vitro* Heart Valve Tissue Engineering

5.528.3.1. Principal Strategies

According to the approach of *in vitro* tissue engineering, the successful fabrication of viable autologous heart valve replacements similar to the native prototype is supported by three main elements. First, autologous cells that resemble their native counterparts in phenotype and functionality are isolated and expanded using standard cell culture techniques. Second, these cells are then seeded onto a temporary biodegradable supporter matrix fabricated in the shape of a trileaflet heart valve, termed the scaffold, which promotes tissue strength until the produced ECM guarantees functionality on its own. Third, in order to promote adequate tissue formation and maturation, the seeded scaffolds are exposed to stimulation transmitted via a culture medium (biological stimuli) or via 'conditioning' of the tissue in a bioreactor (mechanical stimuli). This aims at optimal cellular differentiation, proliferation, and ECM production to form a living tissue model, called the construct. This construct is subsequently implanted orthotopically as a valvular replacement, and further *in vivo* remodeling is intended to recapitulate physiological valvular architecture and function.[15,34,35] (see **Chapter 5.507, Tissue Engineering and Selection of Cells**).

The attempt to develop a scaffold for heart valve tissue engineering has proceeded along two fronts: a fully synthetic scaffold and a biological matrix material.[36] Regardless of the matrix material used, the design of a scaffold capable of supporting cellular growth and of withstanding the unrelenting

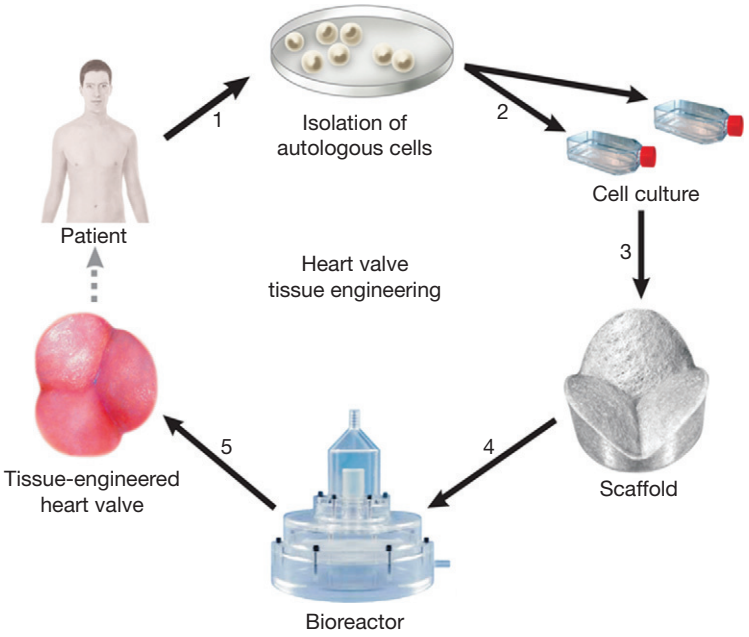

Figure 2 The concept of *in vitro* heart valve tissue engineering. Autologous cells are harvested from the patient (1) and expanded *in vitro* (2). When sufficient numbers are reached, cells are seeded onto a biodegradable scaffold (3). Constructs are positioned in a bioreactor (4) and conditioned. When *in vitro* tissue formation is sufficient, tissue-engineered heart valves (5) are ready for implantation into the patient.

cardiovascular environment, while forming a tight seal during closure, is critical to the success of the tissue-engineered construct. In addition to meeting all the standard design criteria of traditional tissue heart valves – in which durability and biocompatibility are effectively passive attributes of the underlying materials – and selecting the optimal scaffold material, it requires consideration of the active behavior of the cells in the regulation of tissue growth, remodeling, and homeostasis for fully laying the foundation for a future clinical implementation. Overall, the major goal is the *in vitro* creation of a living autologous tissue-engineered heart valve with structural differentiation, anatomically appropriate and high-quality ECM, viable valvular interstitial cells available to respond to varying physiological needs and to repair structural injury by remodeling ECM, and the capacity to grow with the patient (reviewed by Brody and Pandit[37] and Sacks *et al.*[38]). In this chapter, we provide a comprehensive overview of the two key bioengineering aspects of *in vitro* heart valve tissue engineering: the development of an optimal biodegradable and biomimetic scaffold material, and the use of bioreactors targeting at the guidance of valvular tissue formation *in vitro* (see **Chapter 5.507, Tissue Engineering and Selection of Cells**).

5.528.3.2. Scaffold Materials

As part of the *in vitro* heart valve tissue engineering concept, isolated and expanded cells are seeded onto appropriate scaffolds, serving as starter matrices of the heart valve fabrication process (**Figure 3**). The matrices must be capable of supporting cellular growth and cell-to-cell interaction, thus guiding tissue formation into a functional organ with organotypic ECM. The surfaces of these starter vehicles must be biodegradable, providing an optimized degradation rate for cellular expansion, and biocompatible, allowing for adequate cellular ingrowth and

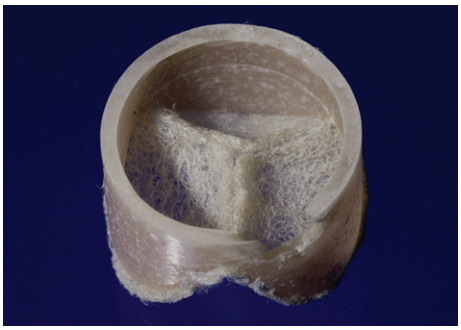

Figure 3 Stented heart valve design based on a nonwoven PGA coated with 1% poly-4-hydroxybutyrate. Reproduced from Mol, A.; Driessen, N. J.; Rutten, M. C.; *et al. Ann. Biomed. Eng.* **2005**, *33*(12), 1778–1788.

the formation of antithrombogenic cell linings (reviewed by Brody and Pandit[37]). These specific requirements entailed the development of various approaches in order to identify the optimal scaffold material, including the creation of biological[39] and synthetic scaffold materials.[35,40,41] These can be further subdivided into native tissue-derived ECM scaffolds,[42] polymeric scaffolds,[43–47] biological/polymeric hybrid scaffolds,[48–50] and fibrin gel or collagen scaffolds.[51–54] Although significant advances have been made in all these approaches, the polymeric scaffolds have, to date, received most attention with regard to *in vitro* heart valve tissue engineering (see **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**).

5.528.3.2.1. Native, decellularized biological matrices

Animal-derived heart valves (xenografts) or donor heart valves (homografts) are among the most obvious choices for scaffold materials. They are fixed and depleted of cellular antigens,

which makes them less immunogenic, and thus, eligible to be used as scaffold material in cardiovascular tissue engineering. The removal of cellular components results in a template composed of ECM proteins that serves as an intrinsic medium for subsequent cellular attachment. Nonetheless, they still possess a native-like geometry and architecture with biomechanical and hemodynamic properties comparable to their native counterpart (reviewed by Brody and Pandit,[37] Schmidt *et al.*,[35] and Mol *et al.*[55]).

Several different decellularization techniques have been extensively investigated in order to minimize the residual immunologic potential of biological matrices. Although it is crucial to remove all cellular components, the decellularization treatment should at the same time avoid any harm or alteration of the ECM properties. This efficiency of cellular removal, as well as preservation of the matrix integrity, is highly dependent on the method used for acellularization.[56] Various decellularization methodologies for heart valve scaffold fabrication have been reported, including trypsin/EDTA,[56–58] freeze drying,[59] osmotic gradients,[60] nonenzymatic detergent treatment,[56,61–64] and multistep enzymatic procedures.[65] The use of nonenzymatic detergent-based techniques has been shown to result in a much more efficient cellular removal while preserving the overall matrix integrity of the scaffold when compared to other more aggressive acellularization techniques such as trypsin/EDTA.[56,64,66,67] In order to avoid this impairment of function and matrix integrity due to tissue-derived protease activation, the use of suitable protease inhibitors has been recommended.[63] In addition, nuclease digestion steps should be included into the decellularization procedure to remove any remaining DNA or RNA within the scaffold matrix.[61–63]

After seeding of decellularized matrix scaffolds with ECs, and subsequent *in vitro* culturing, the constructs showed a confluent EC lining.[59,61,68–71] In 2003, Schenke-Layland *et al.* even proved that complete decellularization of porcine pulmonary heart valves with preservation of ECM structure and subsequent reseeding is feasible. Also, *in vivo* implantation of decellularized valves repopulated with autologous ECs and myofibroblasts in the pulmonary position in a sheep model revealed promising results.[58] In addition, Kim[72] demonstrated partial recellularization and endothelialization of decellularized scaffolds repopulated with bone marrow-derived cells 3 weeks after implantation as aortic valve replacements in dogs. Analysis of explanted valve substitutes also showed that originally seeded cells were still present on the engineered valve constructs, implying that seeded cells contribute to the regenerative process of implanted tissue.

Despite this proof of principle and great strides toward a clinically applicable xenogenic scaffold, decellularized biological matrices, as an obvious source of scaffold materials for heart valve replacement therapy, have mainly been used for the *in situ* tissue engineering approach. To some extent, this might also be due to their major shortcomings, in particular when compared to synthetic materials. When using xenografts, the risk of zoonoses, in terms of human diseases caused by animal-derived infectious agents, is a critical aspect that has to be considered.[73,74] In particular, the recent identification of porcine endogenous retroviruses (PERV[75–82]) and prionic diseases[83,84] has given rise to widespread concern. Even if deemed to be minimal,[85] the hypothetical risk of infection in the course of xenotransplantation constitutes a substantial shortcoming of a possible large-scale clinical application of the concept.[86] When the matrix material is from homogenic origin, the limited availability of donor valves and associated ethical concerns represent a considerable limitation. In addition, the lack of evidence of growth and remodeling capacities of valvular replacements when using biological scaffolds seems to be a further drawback as this represents an indispensable prerequisite for a future clinical implementation into the pediatric field.[87,88] These shortcomings and uncertainties raise a common concern associated with the use of decellularized starter matrices, also fuelling the search for synthetic scaffold alternatives.

5.528.3.2.2. Polymeric starter matrices

The use of polymeric scaffold matrices for heart valve tissue engineering has already been broadly demonstrated. The ideal scaffold material has to be at least 90% porous[89] and comprise an interconnected pore network, as this is essential for cell growth, nutrient supply, and removal of metabolic waste products. Besides being biocompatible, biodegradable, and reproducible, the scaffold material should also display a cell-favorable surface chemistry and match the biomechanical properties of the native heart valve tissue.[35] In addition, the matrix degradation rate should be controllable and commensurate with the rate of novel tissue formation in order to provide a sufficient mechanical stability of the construct over time.[15,90]

Several different synthetic biodegradable polymers have been investigated as potential starter matrices for heart valve tissue engineering. Polyglactin (PG), polyglycolic acid (PGA), polyhydroxyalcanoates (PHA), polylactic acid (PLA), polyvinyl alcohol (PVA), polycaprolactone (PCL), poly-L-lactic acid (PLLA), poly-4-hydroxybutyrate (P4HB), as well as a copolymer of PGA and PLA (PLGA/PGLA) were the materials of choice (reviewed by Brody and Pandit[37]). All of them represent biodegradable scaffold materials that vary in their manufacturing possibilities and degradation rates.

5.528.3.2.2.1. Aliphatic polyesters

PLA, PG, and PGA are all part of the aliphatic polyester family, and degrade by cleavage of the polymer chains due to hydrolysis of their ester bonds. The resulting monomer either enters the tricarboxylic acid cycle or is excreted via urinary secretion.[89] In order to fabricate single valvular leaflets, the creation of scaffolds was initially based on combinations of aliphatic polyesters, including PG nonwoven PGA meshes with layers of PGLA and nonwoven PGA meshes. The major shortcomings of aliphatic polyesters are their thickness, initial stiffness, and nonpliability, making the fabrication of trileaflet heart valves a difficult process.

5.528.3.2.2.2. Polyhydroxyalcanoates

The PHA family comprises polyesters built up from hydroxyacids that are produced as intracellular granules by various bacteria.[91] P4HB as well as polyhydroxyoctanoates have been used to fabricate trileaflet heart valve conduits.[92,93] These materials possess thermoplastic properties and can be molded into any desired shape with the use of stereolithography.[94,95] The major drawback of PHAs can be found in their slow degradation. Combinations of PHAs and aliphatic polyesters have also been employed as alternative composite materials.[96–98]

Particularly, the use of PGA coated with P4HB, combining the thermoplastic properties of P4HB and the high porosity of PGA, for the fabrication of complete trileaflet valvular structures revealed promising results in a rapidly growing sheep model.[35,96,97,99,100]

5.528.3.2.3. Biological/polymeric hybrid starter matrices

Recently, a further strategy for the fabrication of scaffold materials in tissue engineering emerged, using biological/polymeric composite materials as starter matrices.[101] These hybrid starter matrices can also constitute complex three-dimensional structures such as heart valves, for example, fabricated from decellularized porcine aortic valves and dip-coated with a bioresorbable polymer.[48–50] Furthermore, scaffolds equipped with molecular cues mimicking certain structural or functional aspects of extracellular microenvironments have been developed in recent years.[102,103] In particular, gene delivery from the scaffold represents a versatile approach to manipulate the local environment for directing cellular function and promoting tissue formation.[104]

5.528.3.2.4. Collagen-based scaffolds

In an attempt to provide heart valve replacements consisting solely of autologous tissue, biodegradability turned out to be an indispensable prerequisite for scaffold materials. Collagen is one of these biological materials that display bioresorbable properties and can theoretically be obtained directly from the patient. Thus, it has been investigated as a possible matrix material for heart valve tissue engineering by using collagen (type I) foams,[105,106] gels or sheets,[51,90,107–111] sponges,[112] and even as fiber-based scaffolds.[113,114] However, besides a low degradation rate, collagen has the major drawback of a very low availability in humans as it is difficult to obtain from the patient. Therefore, most collagen scaffolds are based on animal-derived collagens, which potentially involve common shortcomings associated with the use of animal-derived tissues such as the risk of transmission of zoonoses.

5.528.3.2.5. Fibrin-based scaffolds

Fibrin is a further biological material that also offers controllable bioresorbable properties. Besides its potential to serve as an autologous biodegradable scaffold material, fibrin gel has also been used as a cell carrier to seed cells into a fiber-based[115] or porous synthetic scaffold.[116] As the patients' blood could serve as a source for fibrin gel production, no toxic degradation or inflammatory response is expected upon reimplantation.[13] By using the technique of injection molding of the cell–gel mixture followed by enzymatic polymerization of fibrinogen, three-dimensional structures can be obtained. The rate of degradation is controlled by adding aprotinin, a proteinase inhibitor that slows down or even stops fibrinolysis.[117–119] Immobilization of growth factors in specific areas has also been shown as a feasible option to control degradation of fibrin scaffolds.[120]

Besides these seemingly favorable features, the use of fibrin as a scaffold material has several drawbacks, including its tendency to shrink, its poor initial mechanical properties, and importantly, its reduced diffusion and washout capacity into the surrounding medium compared to other porous matrices.[117,119] Although various measures have been developed to limit these shortcomings, such as poly-L-lysine chemical fixation that prevents shrinkage and improving mechanical properties, further investigations are needed to determine its effective value as a scaffold material for heart valve tissue engineering in the future.

5.528.3.2.6. From animal to human: in vivo performance of tissue-engineered heart valves

In 1995, the first successful replacement of a single pulmonary valvular leaflet with an *in vitro* tissue-engineered substitute, based on a synthetic scaffold, was demonstrated in a lamb model.[121,122] In the following years, complete trileaflet valve replacements based on synthetic scaffolds were introduced.[64,92,98,123] After the development of the mechanical conditioning approach as a substantial improvement of the *in vitro* culture phase, the fabricated valves showed adequate functionality and remodeling into native-like heart valves up to 5 months in animal studies (**Figure 4**[96]). A 2 year follow up study of pulmonary artery substitutes in a lamb model even showed clear evidence of growth of implanted tissue-engineered structures.[124] However, the actual proof of a growth capacity of valvular structures fabricated on the basis of synthetic scaffolds is still missing. In first clinical experiences, synthetic scaffold-based tissue-engineered patches were successfully used for the reconstruction of the pulmonary artery in humans.[125,126] Besides these promising *in vivo* results, biodegradable synthetic polymers offer a number of advantages over biological scaffold materials, including greater control over mechanical properties and fabrication, better reproducibility and degradation rates, advanced geometrical design specifications, and lower immunogenicity. Even if several challenges such as improvement of the elastic network formation and matrix degradation control remain to be addressed by further investigations prior to a clinical implementation of the concept, synthetic scaffold-based heart valve replacements hold great promise for the future.

5.528.3.3. *In Vitro* Heart Valve Tissue Formation

A major challenge in tissue engineering of functional heart valve substitutes is to mimic the biomechanical properties and dominant tissue structures of native heart valves in order to provide valvular replacements that hold promise for long-term graft functionality after implantation. According to native tissues, these biomechanical properties are predominantly based on the structural organization, composition, and quality of the ECM. In the effort to create adequate ECM production,

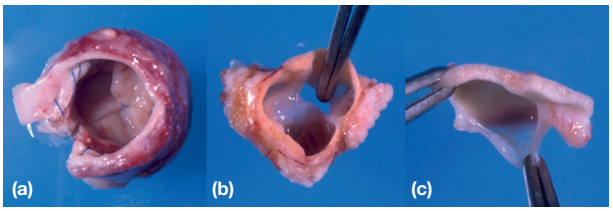

Figure 4 Tissue-engineered heart valves explanted after 6 weeks (a) and 20 weeks (b) from a lamb model. Note the thin and pliable leaflet structure at 20 weeks postimplantation (c). Reproduced from Hoerstrup, S. P.; Sodian, R.; Daebritz, S.; *et al*. *Circulation* **2000**, *102*(19 Suppl 3), III44–III49, with permission from Wolters Kluwer Health.

cellular differentiation, and proliferation, the seeded scaffolds are exposed to stimulation transmitted via a culture medium (biochemical stimuli) or via 'mechanical conditioning' of the tissue (mechanical stimuli) prior to *in vivo* implantation. This comes along with strict isolation of the *in vitro* system ensuring a long-term maintenance of sterile culture conditions.[96,127] Besides ECM production, the collagen cross-link concentration has also been shown to play a critical role for the biomechanical behavior of heart valves.[128]

The use of biochemical conditioning in terms of using biological stimuli, such as growth factors, to promote tissue growth and regeneration during *in vitro* development, represents a common conditioning approach in tissue engineering. In heart valve tissue engineering, different growth factors such as bFGF,[129] HGF,[130] TGF-β1,[52,131] EGF,[58] vascular endothelial growth factor (VEGF),[129] and PDGF,[131] have been investigated to render preferred cellular differentiation within the engineered constructs. However, precaution is recommended when considering a possible clinical implementation of the concept, as several pathways of the mentioned growth factors have not yet been fully elucidated.

For further improvement of tissue architecture and biomechanical properties, mechanical stimulation during the *in vitro* culture phase has also been widely used in heart valve tissue engineering.[132–135] Various mechanical conditioning approaches have been investigated in view of their influence on ECM development and biomechanical tissue properties using model systems of fast degrading scaffolds seeded with human adult vascular-derived cells. As a substantial amount of these vascular-derived cells exhibit a myofibroblast-like phenotype, they generate a long-lasting tensile activity in terms of continuous isometric tension on their environment.[136,137] Allowing these myofibroblasts to exert their tensile activity by application of static mechanical constraint has been shown to be an asset for tissue component alignment during tissue organization.[138] In particular, the beneficial effects of intermittent dynamic straining[139] and continuous long-term dynamic straining[140,141] have been shown to further optimize tissue formation in various ways. In return, large straining magnitudes revealed a negative effect on the mechanical properties of tissues.[140] In addition, stretch, flow, and cyclic flexure have been demonstrated to exhibit both independent and coupled stimulatory effects on cell and ECM development in tissue-engineered heart valves.[140,142–144] By using this system, Engelmayr *et al.*[145,146] demonstrated the profound role of the coupled effects of two physiological mechanical stimuli – cyclic flexure and laminar flow – that seem to be highly relevant to heart valve tissue formation *in vitro* using a novel flex–stretch–flow (FSF) bioreactor system (reviewed by Sacks *et al.*[38]). Recently, Balguid *et al.*[147] presented another highly promising conditioning approach using hypoxia. By culturing tissue-engineered valvular constructs under hypoxic culture conditions (7% O_2), they were able to generate valvular substitutes displaying near-native mechanical properties.[147]

5.528.3.4. Bioreactors for Heart Valve Tissue Engineering: Design and Function

A bioreactor is a biomimetic system that exposes the developing tissue to mechanical conditioning, primarily through pressure changes and cyclic flow (**Figure 5**; reviewed by Breuer *et al.*,[36] Mertsching and Hansmann,[148] Mol *et al.*,[55] Ruel and Lachance,[8] and Sacks *et al.*[38]). By mimicking the physiological environment of native heart valves *in vitro*, the bioreactor enhances neo-tissue development, changes cellular orientation, improves cell attachment, and increases production of ECM proteins, such as collagen and elastin.[149] Importantly, bioreactors can also be used to modulate the biomechanical properties of developing neo-tissues, which is of particular importance in the development of tissue-engineered heart valves.[127,133,134,142,144,150,151] Different bioreactors have been developed using strain,[152–154] flow,[95,127,151,155,156] and cyclic stretching[53,157] as their main mechanical cues to fabricate living blood vessels and heart valves *in vitro*. For the engineering of heart valves, a diastolic pulse duplicator (DPD) system has been developed in order to mimic only the diastolic phase of the cardiac cycle – the phase in which the leaflet tissue is primarily exposed to cyclical straining.[152] This pulsatile conditioning approach provides physiological pressure and flow to the developing heart valve structure and promotes both the development of mechanical strength and the modulation of cellular function.[127,150,151] In particular, the application of a pressure difference across the growing valvular leaflets, inducing local dynamic strains, is of critical importance. On the whole, this strategy of *in vitro* conditioning, which solely mimics the straining phase of the cardiac cycle, offers a highly innovative bioreactor design that has

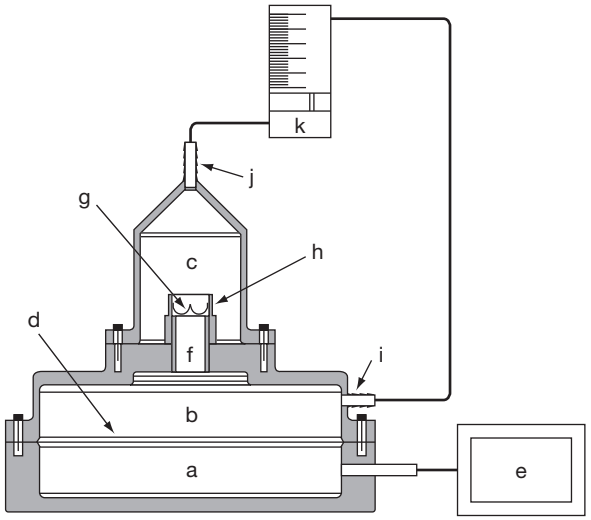

Figure 5 The two-chamber bioreactor design. The pulsatile flow chamber (bioreactor) consists of two principal chambers: the air chamber (a) at the bottom level and the cell media fluid chamber (b,c) at the upper level, separated by a thin silicone diaphragm (d; 0.5 mm). The air chamber is connected to a respirator pump (e; dual phase). The fluid chamber (total volume: 500 ml) is divided into two compartments: the lower compartment (b) is connected via a tube (f) to the smaller top compartment (c; valve perfusion chamber). The tissue-engineered heart valve (g) is fixed to a removable silicone tube (h) by suturing. The media flow is directed from the bottom compartment (b) via the connecting tube (f) to the mounted tissue-engineered heart valve in the perfusion chamber. The upper compartment is connected via a valved inlet (i) and outlet (j) tubing to a separate media reservoir (k; total volume: 500 ml).

been used by several groups up to now for heart valve conditioning.[35,40,99,127,158–160] By rendering human tissue-engineered valvular structures that may even sustain the systemic circulation, the DPD regime represents a major step toward a tissue-engineered aortic human heart valve replacement.[100] Recent investigations have also pursued the idea of monitoring and simultaneously controlling the applied deformations during tissue culture in terms of developing a feedback control loop design.[38,161] In consideration of this effort, Kortsmit *et al.*[162,163] demonstrated the value of volumetric deformation measurement and the inverse experimental-numerical estimation method as to the realization of a real-time quality control system next to a controllable culture environment. Overall, the optimal conditioning protocol depends on various parameters such as the sensitivity of the cell phenotype to mechanical cues, the scaffold design, the transfer of mechanical cues from the scaffold to the cells, as well as the type and degree of mechanical exposure.

5.528.4. *In Vivo* Heart Valve Tissue Engineering

5.528.4.1. Principal Strategies

The *in vivo* tissue engineering approach, also known as '*in situ* tissue engineering' or 'guided tissue regeneration,' relies on the natural regenerative potential of the body. Its principal strategy aims at the implantation of a nonhemolytic, nonthrombogenic, and nonimmunogenic, functional scaffold that is capable of autologous host cell reseeding and subsequent remodeling *in vivo*. It is sometimes deemed to offer a more clinically attractive alternative in comparison to the *in vitro* approach considering a possible off-the-shelf availability. By circumventing the extensive *ex vivo* processing of valvular substitutes of the *in vitro* approach, it would certainly represent a cheap, quick, and on-demand approach. In particular, the absence of the complex preseeding procedure could significantly minimize and simplify the fabrication process, and postimplantation, this approach might have the potential to reduce immunogenic reactions *in situ* (reviewed by Vesely,[164] Sievers,[165] and Schleicher *et al.*[166]).

5.528.4.2. Native, Decellularized Scaffold Materials

Several investigations have focused on decellularized homo- or xenografts as these suggest highly attractive scaffold materials, in particular, for guided tissue regeneration of heart valves. Several groups have demonstrated the overall feasibility of *in vivo* repopulation of decellularized scaffolds in animal models.[57,167–175] However, the success of these attempts was mainly linked to the actual mode of decellularization and whether homo- or xenografts were used.[66] When using SynerGraftTM as the acellularization technique, leaflet explants showed up to 80% cellular repopulation and a distribution of α-SMA positive cells comparable to that of natural valves.[168,169,171] Conversely, when trypsin/EDTA digestion was used for decellularization, allogenic ovine valve conduits did not show any interstitial valve tissue reconstitution due to severe calcification. Only xenogenic porcine valves implanted into the pulmonary position in sheep revealed histologic reconstitution of valvular tissue.[57,174] A comparative study of different decellularization approaches indicated that a novel detergent-based technology, using Triton X-100 combined with sodium deoxycholate, offers the most favorable scaffold for cellular repopulation.[66] Accordingly, several *in vivo* studies further indicated that besides cellular repopulation also adaptive matrix remodeling and even growth could be found in implanted acellularized valvular constructs.[167,170]

However, the transferability of these promising results from animal models to the human organism still has to be evaluated, even if several groups have reported promising results in adult heart valve recipients[171,176,177] – in particular, when considering the clinical results of Simon *et al.*[178] that showed early failure of porcine SynerGraftTM-treated heart valves in children. In the course of their clinical trial, implanted valvular substitutes caused a strong inflammatory response, followed by structural failure and rapid degeneration of the graft within a few weeks to months.[178] These results, clearly demonstrating the ineffectiveness of the 'SynerGraftTM technology,' also suggest that acellularization of xenogenic heart valves, according to this technology, holds significant risks for the patient and should be avoided. Subsequent investigations, focusing on the molecular mechanism of this residual immunogenicity of decellularized grafts, indicated that acellularization of porcine xenografts, even when fully depleted of cells and cellular components, did not fully eliminate thrombogenicity and inflammatory stimulation response. In spite of missing attraction of monocytes and lymphocytes in completely decellularized tissue, the recruitment of granulocytes was still evident.[179,180] Bastian *et al.*[181] suggested that this inflammatory response is predominantly caused by the loss of specific ECM proteins during the decellularization process, which normally prevents these excessive immunologic phenomena. Several investigations, aiming for a substantial decrease of the susceptibility of acellularized matrices to an immunologic response, that is, by using polymer impregnation, offered several improvements, also with regard to a possible future clinical establishment of the concept.[50,182–184] However, some of them may have yet exceeded the scope of the *in vivo* tissue engineering approach, that is, by using *ex vivo* endothelialization of matrices.

By contrast, the use of decellularized homografts seems to be beneficial over the use of xenogenic decellularized scaffold materials due to their reduced risk of infection and lower thrombogenicity.[185,186] Even the clinical use of SynerGraftTM-treated homografts as pulmonary valve replacements in adults showed surprisingly good results.[168,169,187,188] Yet, actual clinically manifest benefits of decellularized substitutes over conventional homografts, and thus, conclusive reasons for preferable clinical application, are still missing.[189,190] Altogether, the clinical applicability of acellularized homogenic as well as xenogenic heart valve replacements with spontaneous cellular repopulation *in vivo* remains a controversial field within tissue engineering.

5.528.4.3. Synthetic Scaffolds Materials

The use of synthetic scaffold materials constitutes another approach to *in vivo* heart valve tissue engineering, offering several advantages when compared to decellularized scaffolds. Besides their decreased immunogenic potential, they also

enable a better definition of expectant physical and chemical properties. While the implantation of a plain scaffold was unsuccessful, leading to thrombus formation and inappropriate cellular repopulation,[191] scaffolds compounded with a collagen microsponge matrix revealed promising results in several animal studies.[192–195]

Another concept, also utilizing synthetic matrix materials, is the seeding of freshly isolated autologous cells onto scaffold materials prior to implantation. Several different cell sources and surgical procedures have been investigated using this principle of same-day harvesting of desired cell types via a single biopsy and subsequent reimplantation of preseeded synthetic scaffolds.[125,196–200] However, it seems as if this is an approach that is again located at the interface between *in vivo* and *in vitro* heart valve tissue engineering, given the use of *ex vivo* cell seeding technologies.

5.528.4.4. The 'Biovalve' Concept: The Patient as a Perfect Bioreactor?

First implemented by De Visscher *et al.*,[201] a novel subtle way of repopulating scaffold materials for valvular replacement surgery is the use of the peritoneal cavity as a 'natural bioreactor.' By using this approach, scaffolds are preimplanted into the abdominal cavity, inducing an intraperitoneal foreign body reaction and an *in vivo* cellularization that is mainly driven by a host-mediated immune response.[201,202] Also, a subcutaneous implantation of scaffold prototypes in rabbits revealed fairly good results.[203,204]

At any rate, the concept of *in vivo* autologous heart valve tissue engineering with the patient as an autologous 'bioreactor' is doubtlessly appealing. However, it remains exceedingly questionable whether this concept renders correct cell types and if these obtained cells, which are primarily due to an encapsulation reaction, are capable of withstanding the unrelenting hemodynamic forces of a native valvular position.[165,205]

5.528.4.5. The *In Vivo* Tissue Engineering Approach: Significance of a Novel Concept

By using the patient as a 'natural bioreactor,' the guided tissue regeneration approach in heart valve tissue engineering seems to be highly attractive in view of avoiding the extensive *in vitro* conditioning phase. It may have also shown some success in animal studies[206]; however, up to now there is no striking scientific evidence that heart valve scaffolds will be sufficiently recellularized when implanted into humans.[164] In return, several authors described this approach as 'highly unlikely' or 'highly speculative'.[207] Even if some endothelial repopulation has been found to develop on vascular grafts implanted into animals, studies have also proven that vascular grafts implanted into humans do not spontaneously form an endothelial lining.[178] As an adequate endothelial lining of the construct seems indispensable for providing a thromboresistant surface, and also constitutes a precondition for the formation of a proper interstitial cell compartment, the *in vivo* approach remains highly questionable and its position will have to be justified as a feasible approach for heart valve tissue engineering in the future.

5.528.5. Cell Sources for Heart Valve Tissue Engineering

In tissue engineering of implantable cardiovascular structures such as heart valves, the *in vitro* formation of a durable, well structured, and viable tissue is known to be crucial for an adequate *in vivo* functionality of the construct. Therefore, several technologies have been introduced in order to meet these demands of designing heart valve replacements with optimum functional durability. However, the cell source used for engineering these cardiovascular structures remains the least controlled factor, yet being most important for the quality of the viable part of the replacement. The quality of these cells depends on the individual tissue characteristics of its origin, and thus, varies between individuals.[208,209] Therefore, the choice of the optimal cell source constitutes the key to the long-term success of heart valve regeneration (**Figure 6**[15]).

5.528.5.1. Cardiovascular-Derived Cells

In most heart valve tissue engineering approaches, cells were harvested from donor tissues, for example, from peripheral arteries, and mixed vascular cell populations were obtained for seeding.[34,210] Out of these, two cell lines can be isolated: ECs, forming a confluent EC lining with antithrombogenic features, and myofibroblast/fibroblast-like cells, responsible for the ECM development.[122,209,211] With regard to the clinical implementation of the concept, several human cell sources have been investigated throughout the last few years. Following extensive studies using ovine vascular-derived cells,[96,121,122,209,212] the suitability of human cells from different sources was evaluated. Experiments using human aortic myofibroblasts and ECs demonstrated easy isolation and *in vitro* culture.[92] These human aortic-derived cells were then seeded on biodegradable scaffolds where they revealed a layered tissue formation. Moreover, cells from saphenous veins also showed excellent growth properties and tissue formation after seeding on biodegradable scaffolds, comparable to aortic cells[208] and mammary artery cells.[213] Saphenous vein cells can be obtained by a minor surgical intervention under local anesthesia, and thus, represent an even more attractive cell source for cardiovascular tissue engineering.

5.528.5.2. Bone Marrow-Derived Cells

With regard to the future routine clinical realization of the cardiovascular tissue engineering concept, human bone marrow-derived stem cells (BMSCs) were identified as promising alternative candidates.[99,214,215] The overall capability of BMSCs of forming solid organ tissue cells, including hematopoietic stem cells, in particular, functional cardiomyocytes and vascular structures, has already been demonstrated by several groups.[216,217] Human BMSCs were also successfully used for the *in vitro* fabrication of living trileaflet heart valves (**Figure 7**[99,214]) and showed satisfactory *in vivo* function as pulmonary valve substitutes for at least 8 months.[123] The usage of BMSCs in cardiovascular tissue engineering may offer several advantages: (i) BMSCs can be obtained without major

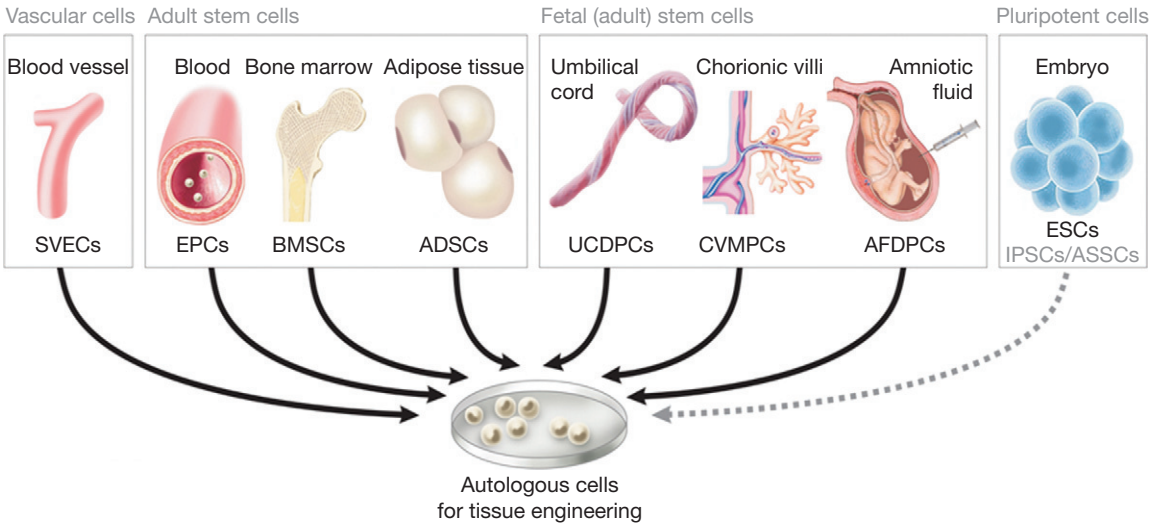

Figure 6 Available cell sources for heart valve tissue engineering: standard vascular endothelial cells (SVECs), endothelial progenitor cells (EPCs), bone marrow-derived mesenchymal stem cells (BMSCs), adipose-derived stem cells (ADSCs), umbilical cord-derived progenitor cells (UCDPCs), chorionic villi-derived mesenchymal progenitor cells (CVMPCs), amniotic fluid-derived progenitor cells (AFDPCs), embryonic stem cells (ESCs), adult spermatogonial stem cells (ASSCs), and induced pluripotent stem cells (IPSCs).

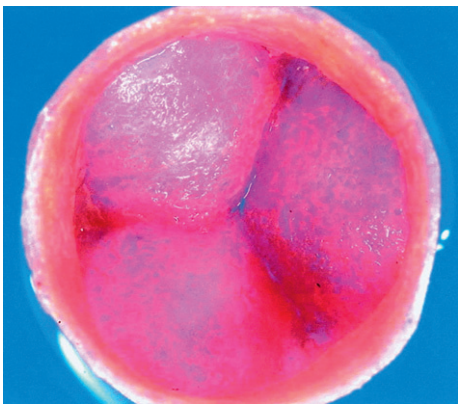

Figure 7 BMSC-based tissue-engineered heart valve leaflets after 14 days in the *in vitro* pulse duplicator system (bioreactor). Reproduced from Hoerstrup, S. P.; Kadner, A.; Melnitchouk, S.; *et al. Circulation* **2002**, *106*(12 Suppl 1), I143–I150, with permission from Wolters Kluwer Health.

surgical interventions by a simple bone marrow puncture, thus representing an easy-to-access cell source in a clinical scenario; (ii) they exhibit the potential to differentiate into multiple cell lineages under biochemical[218] and mechanical[219] stimulation, showing the potential to differentiate into multiple cell lineages; (iii) they demonstrate unique immunological characteristics, allowing the persistence in allogenic settings; and (iv) they also show an extensive *in vitro* proliferation capacity.

5.528.5.3. Blood-Derived Cells

It has been shown that the presence of endothelium on cardiovascular surfaces significantly reduces the risk for both inflammatory complications and coagulation (reviewed by Tanaka *et al.*[220]). Therefore, in order to improve the functional capacities, the tissue-engineered heart valve constructs are usually covered with a layer of autologous human ECs as an antithrombogenic lining.[221] Fully matured ECs have been isolated from several different vascular donor sources, demonstrating promising results in heart valve tissue engineering.[92,96,121,122] However, the expansion rate of these mature ECs is comparatively slow and the proliferation capabilities are limited, requiring a large number of ECs to be harvested for therapeutic use.[222] Endothelial progenitor cells (EPCs), first discovered in human peripheral blood by Asahara *et al.*,[223] have been established as possible sources of ECs. These blood-derived EPCs constitute a highly attractive alternative cell source of ECs, in particular, for pediatric patients, as they can be isolated from bone marrow, peripheral blood, as well as from umbilical cord blood (reviewed by Kim and Recum[224,225]). They have been successfully used for the repair of injured vessels, regeneration or neovascularization of ischemic tissue in both preclinical models,[226–228] and more recently, early-phase clinical trials (reviewed by Martin-Rendon *et al.*[229] and Pearson[230]). Importantly, further studies[231–234] also demonstrated the feasibility of using human umbilical cord blood-derived EPCs (HUCB-EPCs) for the generation of constant neo-endothelial phenotypes in tissue-engineered cardiovascular replacements. Lately, they also showed the fabrication of biologically active living heart valve leaflets by using peri- and prenatally available human umbilical cord-derived progenitor cells as the only cell source.[87]

Overall, EPCs constitute an auspicious cell source for endothelialization of engineered cardiovascular replacements, such as heart valves. In spite of these pioneering studies showing great promise, the application of EPCs in tissue engineering is still in its infancy.[224] Since EPCs are easily accessible, current research increasingly aims at their transdifferentiation into a mesenchymal, myofibroblast-like phenotype in an

attempt to provide new strategies to guide tissue formation in engineered cardiac valves[235] and to ultimately establish blood as a single cell source for heart valve tissue engineering.

5.528.5.4. Umbilical Cord-Derived Cells

In an attempt to provide tissue-engineered constructs for congenital heart defects, including heart valve disease, alternative cell sources have been investigated, paying particular attention to preserving the intact vascular donor structure of the newborn patients.[236] The human umbilical cord is readily available, easy to obtain, and by means of modern cell and tissue banking technologies, it could be used as an autologous cell pool during the patient's lifetime.[236,237] Overall, the umbilical cord contains several different cell sources that can be utilized for heart valve tissue engineering: (i) SVECs (standard vascular ECs) including HUVECs (human umbilical cord vein-derived ECs) and HUAECs (human umbilical cord artery-derived ECs), (ii) HUCMF (human umbilical cord-derived myofibroblasts), and (iii) HUCB-EPCs.

In culture, these human umbilical cord-derived cells demonstrated excellent growth properties and sufficient cell numbers for seeding of biodegradable scaffolds. After seeding and *in vitro* culture, good tissue formation was observed. Micro- and ultrastructural analysis revealed viable, layered tissues showing cell and matrix features known from native tissue.[236,238–240] Schmidt *et al.*[232] used differentiated HUCB-EPCs seeded on vascular scaffolds for the formation of vascular neo-tissue in both biomimetic and static *in vitro* environment. In 2005, Schmidt *et al.* demonstrated the successful *in vitro* generation of living autologous cardiovascular replacements (patches) based on myofibroblasts derived from Wharton's jelly and EPCs derived from umbilical cord blood. Recently, they were able to optimize the usage of umbilical cord-derived cells for cardiovascular tissue engineering by generating functional tissue-engineered blood vessels,[234] and by ultimately fabricating biologically active living heart valve leaflets *in vitro*.[87] Sodian *et al.*[160] demonstrated the use of cryopreserved human umbilical cord cells (CHUCCs) for the *in vitro* fabrication of tissue-engineered heart valves.

Taken as a whole, the major advantage of UCCs as an autologous cell source, is deemed to be the avoidance of invasive harvesting of intact vascular structures from pediatric patients and the easy perinatal availability of a large amount of juvenile, fast growing cells for scaffold seeding in a short period of time.[241] With regard to the approach in the pediatric population, the umbilical cord may serve as an optimal perinatal autologous cell source for tissue engineering of cardiovascular constructs in the future.

5.528.5.5. Prenatally Harvested Progenitor Cells

In most congenital heart defects, the early surgical correction of the malformations is deemed to be indispensable to prevent secondary damage to the immature neonatal cardiovascular system. Owing to the advances in imaging technology, these cardiac pathologies are often already detectable prior to delivery by routine ultrasound examination. Therefore, the ideal pediatric tissue engineering paradigm would comprise a prenatal cell harvest, providing time for the *in vitro* fabrication of an autologous living implant that is ready to use directly or shortly after birth to prevent any secondary damage. In a first attempt, human progenitor cells derived from umbilical cord tissue, as well as umbilical cord blood[87,160,232,234] have been established as a promising cell source for this concept as prenatal ultrasound-guided precutaneous umbilical cord blood sampling is already a routine and well-established procedure. Moreover, a new concept using human prenatal progenitor cells derived from chorionic villi and umbilical cord blood for the fabrication of living autologous heart valve leaflets, was introduced by Schmidt *et al.*[88] This was seen as a further milestone toward the clinical realization of the pediatric heart valve tissue engineering approach.

Besides the umbilical cord and the chorionic villi, the amniotic fluid represents an accessory attractive fetal cell source for this concept, as it also enables an easy prenatal access to fetal progenitor cells from all three germ layers in a low-risk procedure (reviewed by Miki and Strom,[242] Toda *et al.*,[243] and Parolini *et al.*[244]). This is of particular importance for the possible clinical realization of the concept in order to further reduce the risk associated with prenatal cell sampling, as both cell types should ideally be obtained in a single procedure from a single cell source. In a recent investigation, Schmidt *et al.*[40] demonstrated the use of prenatally harvested human amniotic fluid-derived progenitor cells (AFDPCs) as a sole cell source for the fabrication of living autologous heart valves prior to birth resulting in functional tissues *in vitro*. In order to expand the versatility of these cells, also for adult application, cryopreserved AFDCs were investigated as a potential lifelong available cell source, once again showing successful fabrication of viable heart valve leaflets *in vitro*.[159] Despite this futuristic strategy of prenatally harvested progenitors as a novel class of cardiovascular replacements potentially leading to innovative therapies for both pediatric and elderly patients in the future, several concerns associated with this cell source have to be addressed in further investigations.

5.528.5.6. Adipose Tissue-Derived Cells

Human adipose tissue has been shown to contain mesenchymal stem cells that have the potential to differentiate into various phenotypes *in vitro*, depending on the presence of lineage-specific induction factors.[245,246] Due to the high availability of adipose tissue – as it can be obtained in large quantities with minimal discomfort – adipose-derived stem cells (ADSCs) have been considered a potential alternative stem cell source to bone marrow-derived MSCs.[247] Several studies revealed that ADSCs hold characteristics of EPCs, express endothelial-specific markers *in vitro* when cultured with VEGF, and hold the potential to differentiate into ECs *in vivo*.[248–250] First investigations on ADSCs, focusing on their use as potential reservoirs of autologous stem cells for cell-based therapies, suggest that adipose tissue appears to be a viable cell source for cardiovascular tissue engineering.[251,252] When compared to vascular-derived cells, potential advantages of ADSCs seem to be the ease of harvest and their high availability, thus preventing sacrifice of donor vascular structures.

However, at present, the long time required for differentiation may offset this advantage of ADSCs for their use in the field of cardiovascular tissue engineering.

5.528.6. Toward Clinical Application – Outlook for the Future

Heart valve tissue engineering represents a highly promising approach for the creation of living functional autologous replacements that holds exciting potential for significantly improving treatment of heart valve disease in the future. Pediatric patients, in particular, would greatly benefit from growing replacement materials for the repair of congenital heart defects. Since its inception in the early nineties, major advances have been made, and for the first time, the ultimate goal of the transition from experimental models to clinical reality is within our grasp. However, before clinical application of this concept will be routine, several steps have to be surmounted in the laboratory. Primary among these is our limited knowledge about the immunological and biochemical characteristics of the cells and tissues undergoing *in vitro* growth. Even when having first indications as to the influence of age and *in vitro* conditions, the most favorable cell sources for *in vitro* seeding and ultimate survival *in vivo* still have to be defined. Furthermore, the disposition of implanted structures to typical biomaterial tissue interactions of medical devices, such as thrombosis, calcification, and excessive inflammatory response, have to be elucidated. A further important consideration concerns the definition of the ideal scaffold material for heart valve tissue engineering, providing a template for directing new tissue growth and organization, as well as for regulating cellular migration, adhesion, and differentiation. Importantly, while ECM is produced and organized, the ideal scaffold would degrade until the matrix material has been completely replaced by functionally integrated neo-tissue. In view of the inevitable concerns as to the potential transmission of microbiological hazards by tissues of xenogenic origin, it seems as if synthetic scaffold materials will make the grade as standard scaffolds for future clinical implementation. These biodegradable synthetic polymers may offer several advantages over biological materials, including greater control over degradation rates, fabrication, mechanical properties, and reproducibility.

A further key consideration is the fact that today's valvular replacements reveal predictable behavior in terms of durability and biocompatibility, whereas tissue-engineered substitutes, potentially relying on remodeling *in situ*, might show substantial variability among different individuals due to the heterogeneity of the physiological tissue remodeling potential. This implies that the implementation of tissue-engineered constructs, such as heart valves, into the clinical field has to be accompanied by the development of consistent clinical guidelines, specifying the inclusion criteria for certain patient populations according to quality, efficacy, and safety of the engineered products. Therefore, the demonstration of a long-term efficacy and benefit, as well as safety of implanted constructs in specific patient populations in preclinical studies will be of fundamental importance for a possible routine clinical translation of the concept. In the course of this attempt to understand, monitor, and potentially control individual differences of *in situ* tissue remodeling capacities, the identification of biomarkers as independent predictors of implant outcomes increasingly becomes a point of contention. This is closely associated with the major need for substantial advances of our understanding of valvular cell biology. A thorough understanding of molecular mechanisms as well as embryonic and fetal heart valve development may also permit control of heart valve morphogenesis both *in vitro* and *in vivo*.

Due to the demographic development the prevalence of heart valve disease shows an increasing trend with increasing age. More and more elderly patients will suffer from heart valve disease and will thus require valvular replacement therapy. Therefore, the development of tissue-engineered heart valves based on a stented design might represent an important step toward improving the expectancy and quality of life of these patients. Ideally, when tissue engineering technologies make it to the clinical scenario in the future, the schedule for this specific patient population, primarily diagnosed with degenerative valve disease, may be: (i) cell isolation from designated sources (i.e., by a bone marrow puncture under local anesthesia); (ii) differentiation and expansion of cells and engineering of an autologous valvular substitute *in vitro*; and (iii) following yet-to-be-defined quality criteria (histological, biological, biosafety, etc.,), reimplantation of the tissue-engineered construct into patients after a time period of, at the most, 6–8 weeks.

Abbreviations

bFGF	Basic fibroblast growth factor
BMCs	Unfractionated bone marrow cells that include hematopoietic stem cells (HSCs), endothelial progenitor cells (EPCs), and mesenchymal stem cells (MSCs)
BMMNC	Bone marrow mononuclear cell
CHF	Congestive heart failure
EF	Ejection fraction; also LVEF – left ventricular ejection fraction
EPC	Endothelial progenitor cell
FS	Fractional shortening
HSC	Hematopoietic stem cell
HyA	Hyaluronic acid
MSC	Mesenchymal stem cell
P(NIPAAm)	Poly(*N*-isopropylacrylamide)
PEG	Polyethylene glycol
PLG	Poly(lactide-*co*-glycolide) – a copolymer composed of poly(glycolide) (PG) and poly (lactide) (PL)
RGD	Arginine-glycine-aspartic acid
VEGF	Vascular endothelial growth factor

5.529.1. Introduction

Cardiovascular disease is the leading cause of death worldwide. Of the almost 17 million people who die each year from cardiovascular causes, over 11 million die as a result of cardiac disease. Myocardial infarction (MI) carries a short-term mortality rate of ~7% in patients under optimal treatment, while congestive heart failure (CHF) reaches a 20% one-year mortality rate. Despite major advances in therapy over the last few decades, the global burden remains substantial,[1] as the standard therapeutic strategies fail to reconstitute dead myocardium with new functional cardiomyocytes and vessels. Therefore, the need for new therapies for myocardial preservation and regeneration has led to intense research aiming at the identification of new therapeutic approaches.[2–4]

The discovery of stem cell populations with cardiogenic potential, followed by the development of techniques for the isolation and expansion of these cells, has made cell-based

therapies a potential novel treatment modality in cardiovascular disease (Figure 1).[5–10] For cardiac repair, many clinical investigators use unfractionated bone marrow cells (BMCs), which include hematopoietic stem cells (HSCs), endothelial progenitor cells (EPCs), and mesenchymal stem cells (MSCs). This strategy provides ease in cell accessibility and does not require extensive manipulation *in vitro*. After nearly two decades of research, the overall clinical evidence suggests that stem cell therapy is safe and has a modest degree of positive impact on cardiac function and cardiac remodeling after an infarct (see Table 1). However, these studies have had contradictory performance results, and it has become clear that many challenges need to be overcome before this therapy achieves its full potential.[11–18] For example, The HEBE and ASTAMI trials showed no benefit with infusion of BMC. The BOOST trial showed a short-term benefit from stem cell transplantation, and the REPAIR-AMI trial indicated a sustained improvement in left ventricular ejection fraction (LVEF) with infusion of BMC in patients with larger infarcts treated after 5 days. There may be many reasons for the differences in outcomes. Notably, there was no standardized protocol for the collection and infusion of stem cells in these studies. Even the types

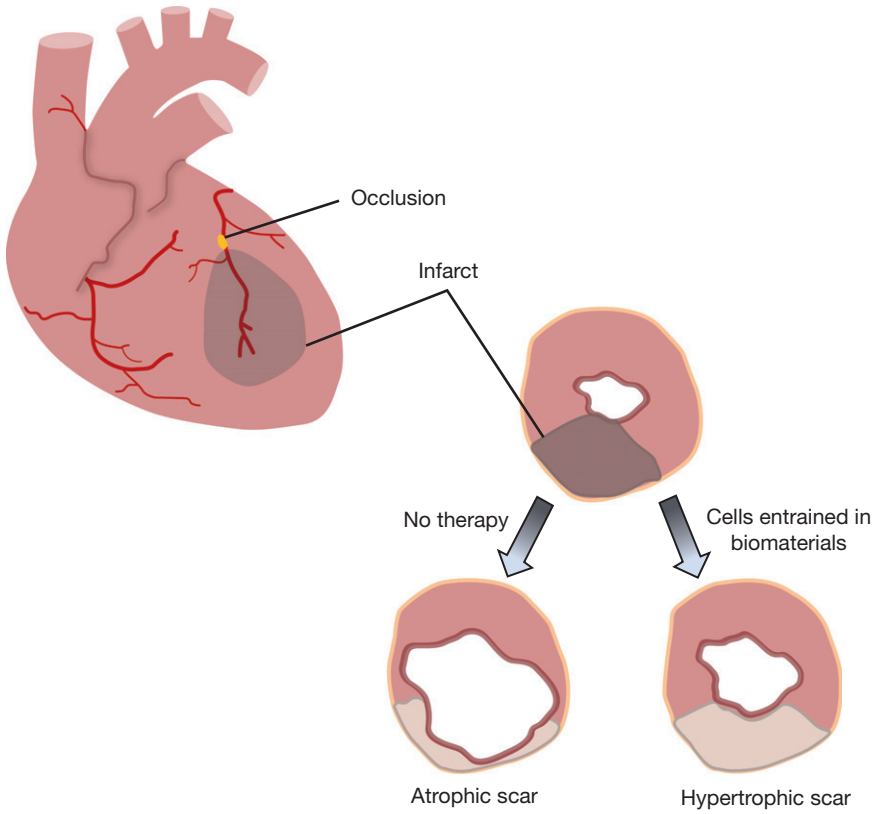

Figure 1 An occlusion in a coronary artery leads to a myocardial infarction downstream of the blockage. The scar region eventually extends and expands outward causing ventricular dilation and wall thinning. Laplace's law predicts that tension in the heart wall increases when wall thickness decreases. Therefore, by increasing the wall thickness with a cell–biomaterial therapy, the tension in the heart wall will decrease and lead to a hypertrophic scar instead of an atrophic scar. Figure adapted from Laflamme *et al*.

Table 1 Summary of randomized clinical trials evaluating cell therapy for acute myocardial infarction or ischemic heart failure

Trial name	*Type of cell*	*Number of patients*	*Results*
BOOST	BMC	60	Improvement in LVEF short term[20]
REPAIR-AMI	BMC	187	Improved LVEF for 12 months[21]
HEBE	BMC	200	No change in systolic function at 4 months[22]
ASTAMI	BMC	97	No difference after 6 or 12 months[23]
FINCELL	BMC	77	Improvement in LVEF[24]
REGENT	BMC	200	Improvement in LVEF only in severe patients[25]
Leuven-AMI	BMC	67	No change in LVEF, reduction in myocardial infarct size[26]
MAGIC	Skeletal muscle cells	97	No change in LVEF, reduction in LV end diastolic and systolic volume[27]
TOPCARE-CHD	BMC vs. blood derived CPC	58	Improvement in LVEF with BMC, not with CPC[28]

of stem cells used for transplantation were not consistent among the trials. The number of cells transplanted in each study varied greatly and thus could drastically change outcomes. Finally, the numbers of patients in these trials were small. Therefore, larger trials that use an established protocol for stem cell transplantation may provide more consistent and reproducible results. Currently, there are numerous ongoing trials to evaluate the safety and efficacy of cell infusion.[19]

One of the most significant barriers to cardiac cell transplantation is the limited cell retention and engraftment after cell delivery into the myocardium.[29–31] To improve outcomes after cell therapy, a sizeable percentage of the injected stem cells into the heart would presumably need to remain viable, differentiate into fully functional cardiomyocytes, and electromechanically couple with the existing cardiomyocytes. Alternatively, increased viability of BMCs that secrete paracrine factors, rather than differentiate into CMs, may also lead to significant improvements in cardiac function. In either case, biomaterial or matrix-assisted stem cell transplantation has emerged as a potential method to increase cell retention, survival, and engraftment.[32–36] The ability to entrain the stem cells in a biomaterial scaffold that mimics the natural myocardial extracellular matrix (ECM) and retains the cells at the location of interest, potentially acting as a substitute for malfunctioning myocardium, is a major focus of ongoing research. This chapter addresses the biomaterial design criteria for cell transplantation and the different synthetic and naturally derived biomaterials used in cardiac cell transplantation, and summarizes the various techniques used to characterize these biomaterials.

5.529.2. Biomaterial Design Requirements for Cardiac Cell Transplantation

5.529.2.1. Three-Dimensional Scaffold

The success and viability of the transplanted cells depends largely on the surrounding matrix having the appropriate molecular composition, biological cues, architecture, and mechanical behavior to stimulate robust proliferation of the transplanted cells and their coupling to the viable myocardium's blood supply (Figure 2). In addition, these cells must be able to dynamically infiltrate and remodel the diseased ECM, and deposit their own matrix over time. Therefore, the three-dimensional (3D) scaffold should serve as a structural and logistic template for tissue regeneration while degrading at a rate controlled by the transplanted cells.[37–40] This could be achieved using two disparate strategies: a classic tissue

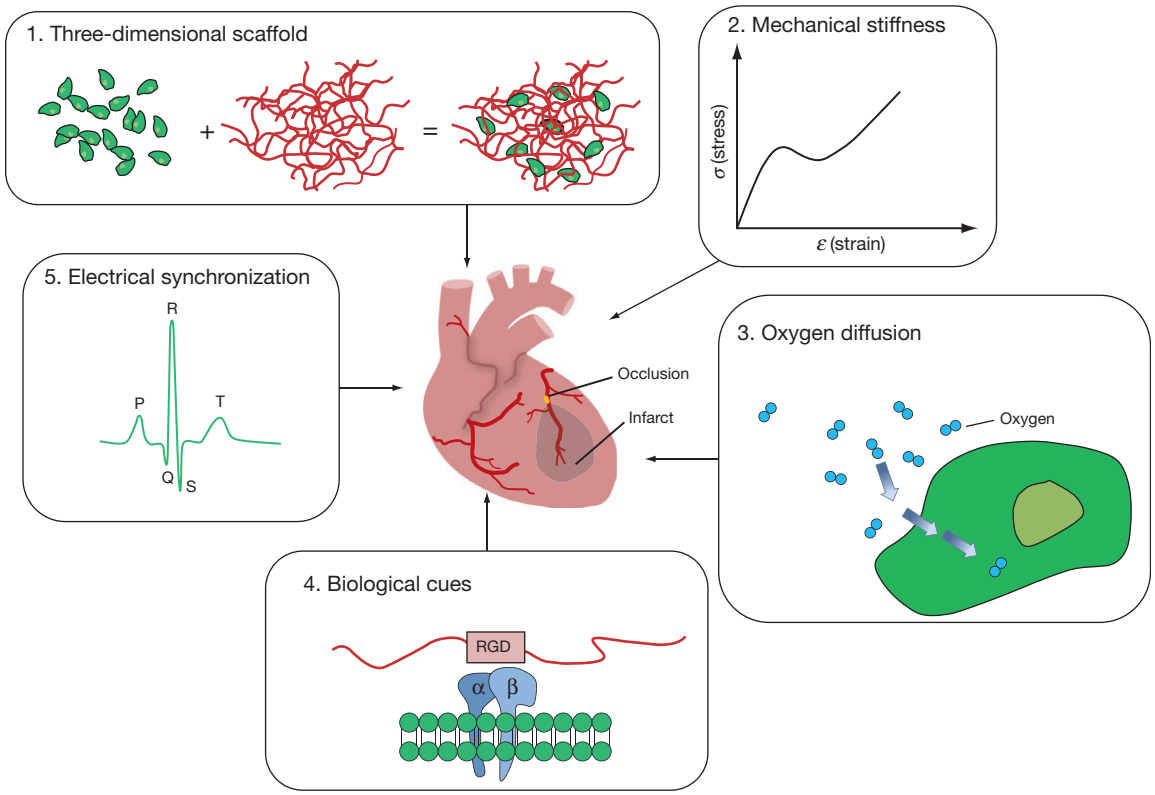

Figure 2 The five biomaterial design strategies for addressing the challenges of cardiac cell transplantation: (1) The transplanted cells are entrained in a 3D biomimetic scaffold to mimic the natural myocardium. (2) Cardiomyocytes are sensitive to the mechanical properties of the extracellular matrix, suggesting that biomaterial modulus is an important design criteria. (3) The infarcted region is a highly hypoxic environment and biomaterials should be designed for optimal oxygen diffusion. (4) Incorporating biological cues into the biomaterial such as specific ligands or growth factors will help with cell adhesion, regulation of cellular phenotype, cell survival, and remodeling. (5) Integrated cardiac beating can occur only when electromechanical coupling occurs between the transplanted cells and the host myocardium.

engineering approach by seeding cells on an engineered matrix, promoting cell expansion *in vitro*, and then surgically implanting the construct; or, alternatively, by simultaneous implantation of the biomaterial and the stem cells using minimally invasive techniques. The focus of this chapter is on the latter, as it has the potential for significant savings in cost, minimal intervention, and wider clinical adoption.

5.529.2.2. Biological Cues: Cells Communicate with the ECM Through Cell–Surface Receptors

The absence of cell adhesion to the ECM can lead to transplanted cell death.[41] Therefore, controlling cell–materials interactions is a promising approach for enhancing cell viability for transplantation strategies. Integrins are heterodimeric transmembrane receptors that are the fundamental components in ECM cell interactions. They play major roles in cell adhesion to the ECM, regulation of cellular phenotype, cell survival, remodeling, cell migration, and tissue development. Integrins are mechanotransducers that provide ligand–integrin engagement causing intracellular signaling events that lead to a cascade termed 'outside-in' signaling.[42,43] These receptors are important mediators between the cell and the ECM. Therefore, one promising design strategy is to incorporate specific ligands into cardiac biomaterial scaffolds in order to specifically guide the cells of interest.

Integrins are heterodimers composed of α- and β-subunits that are transmembrane glycoproteins. They interact with numerous ECM proteins such as fibronectin, laminin, collagen, and vitronectin. Each subunit is composed of a large extracellular domain (700–1100 amino acids long) and a short cytoplasmic segment (20–60 amino acids). Currently, there are 18 α-subunits and 8 β-subunits, and they preferentially associate with each other for a total of 24 pairs of integrin receptors.[44,45]

The integrins on a particular cell type are unique and can vary depending on the pathological state and developmental stage of the cell. Specific integrins and subunits have also been identified as key players during the remodeling process following an AMI. For example, Shewchuck *et al.* reported that impaired integrin activity can be linked to cardiac remodeling.[46] They investigated how oxidative stresses affect integrin upregulation. By using hydrogen peroxide to mimic the hypoxic conditions of the infarct area, they showed that the β_3-subunit increases at the site of infarction in a rat ligation model. This subunit plays an important role in preventing cardiomyocyte apoptosis under hypoxic conditions.[46] Additionally, Yang *et al.* reported the importance of the α_4-subunit in cardiac remodeling and development.[47] They reported that α_4 associates with β_1 and β_7 to bind to a non-arginine–glycine–aspartic acid (RGD) peptide motif in fibronectin as well as to vascular adhesion molecule 1. Therefore, by determining which integrins are present on the cell of interest through RT-PCR and fluorescence-activated cell sorting, complementary peptide ligands can be identified and then immobilized onto the surface of the biomaterial to engage with the cell.[48,49] Although it may be easy to identify the integrins present on a cell, it is challenging to identify peptide ligands, which has led to the use of both phage and bacteria display technologies to identify peptide ligands for a specific cell type.[50,51] This strategy could aid in cell retention and localization that has plagued the field of myocardial infarct therapy.

5.529.2.3. Mechanical Properties

The modulus of the material used as an artificial matrix in cardiac tissue engineering is critical for cardiomyocyte survival, proliferation, and differentiation. Mechanotransduction is the cellular mechanism whereby physical signals of the ECM are transduced, via cell surface receptors (e.g., integrin receptors) engaging with the ECM, into cytoskeletal organization and intracellular biochemical signals that consequently affect cell behavior and fate decisions. Engler *et al.* demonstrated that MSCs differentiated into various tissue-specific cells when the matrix stiffness was tuned to a stiffness range that matched the mechanical properties of native tissue.[52] This phenomenon of matrix modulus-induced differentiation was observed for MSCs, seeded on the surface of collagen-coated poly(acrylamide) hydrogels, that committed to muscle, osteogenic, and neural lineages. To date, no studies have demonstrated that cardiomyocyte differentiation is affected by matrix stiffness, but it is logical to assume that BMSs and MSCs transplanted into an infarcted myocardium could be influenced by the supporting matrix mechanics.

It is known that cardiomyocytes are highly sensitive to the mechanical properties of the ECM as well as to the tension imparted by surrounding myocytes in the dynamically beating environment of the heart. A 3D matrix based on fibrinogen was developed as an *in vitro* system to investigate the effects of matrix stiffness on the coordinated contraction of cardiomyocyte and overall tissue construct contraction.[53] An inverse relationship was observed between the stiffness and the amplitude of contraction for the neonatal cardiomyocytes seeded within the matrix, where stiffer hydrogels resulted in less-synchronized contraction of the constructs.

In vivo, the compliance of the infarct scar post-MI has been associated with the attenuation of negative LV remodeling.[54] Normal LV remodeling after MI involves the overproduction of collagen and consequently results in a highly stiff scar. By injecting human MSCs directly into the infarcted region of a rodent myocardium, cardiac function was improved, apoptosis reduced, and myocardial thickness increased, without regenerating contracting cardiomyocytes. Theoretically, the injected MSCs 'softened' the infarct environment and attenuated post-MI remodeling, thereby improving the compliance of the cardiac muscle. Mathematical models of noncontractile materials with a wide range of mechanical properties, either synthetic materials or dead cells, implanted in the border zone (BZ) of the infarct can reduce elevated wall stresses,[55] suggesting that injection of biomaterials in the left ventricle might attenuate postinfarct myofiber stresses and ameliorate both ventricular remodeling and infarct extension.

Collectively, these studies implicate the mechanical properties of matrices for cell transplantation as a critical design parameter in promoting the differentiation into specific cell lineages or the coordinated contraction of cardiomyocytes, or modifying the mechanical properties of the infarct. The exact modulus of the matrix may depend on whether

undifferentiated cells (i.e., BMS or MSC) or committed cardiac progenitors are used as the cell type, and on the engineering limitations imposed by minimally invasive placement.

5.529.2.4. Oxygen Transport

The infarct region post-MI is a hypoxic environment that contributes to massive cell death. One of the biggest challenges to the regeneration of the damaged myocardium is the transport of oxygen into the scar region, as it determines potential host stem cell remodeling, cell viability, and function. In order to meet this oxygen demand, cells throughout the body are typically found no more than 100–200 μm from the nearest capillary to ensure adequate diffusion of oxygen and nutrients, and clearance of waste products.[56] In the heart, however, the oxygen consumption is significantly higher and this demand is met with a dense vasculature with capillaries spaced only 20 μm apart.[57]

Various methods are used to address the problem of oxygen transport. One approach is to functionalize the scaffold with angiogenic growth factors, such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), and sonic hedgehog (SHh) to promote neovascularization.[58–65] The growth factors of interest can be loaded into the biomaterials using a variety of methods including encapsulation, the release of which is dictated by diffusion or controlled by material degradability; tethering to natural or synthetic materials, which may release the factor by enzymatic degradation; or by affinity binding to heparin or heparin-binding components.[66] For example, to promote vascularization, VEGF has been incorporated into alginate scaffolds[67], loaded into poly(lactic-*co*-glycolic acid) (PLGA) scaffolds[68], and associated within fibrin networks for cell-mediated release by local cell-associated enzymatic activity.[69,70] The latter approach, being more sophisticated, avoids known issues with VEGF-induced angiogenesis (e.g., aberrant leaky vessels) and promotes formation of vessels with normal morphologies and ultrastructure. Alternatively, one can take a physical approach and decrease the volume fraction of the matrix by fabrication of channels to increase the perfusion of oxygen.[71–73] The latter approach has limitations for minimally invasive transplantation approaches, but is creditable for traditional tissue engineering *ex vivo* cell expansion.

5.529.2.5. Electromechanical Coupling

Understanding the interplay between electrophysiology and the mechanics of myocytes is a central challenge in designing a scaffold for myocardial therapy. One of the key challenges in stem cell transplantation is achieving electromechanical synchronization between the host myocardium and the engineered construct while not eliciting arrhythmias. This coupling allows for integrated beating, whereby electrical signals are transmitted across intracellular junctions in an organized manner to form the necessary mechanical contractions for pumping blood through the heart.

The structure of the heart muscle is a complex hierarchical assembly of oriented components: 75% of the solid heart consists of cardiomyocytes, which are cylindrically shaped with diameters of 10–25 μm and lengths of 100 μm.[74] These myocytes are arranged in bundles of myofibers that are oriented from outside in with a clockwise rotation and from inside out with a counterclockwise rotation (e.g., reciprocal spiral architecture).[75] Therefore, the heart is a highly reinforced structure with a heterogeneous architecture that requires 1D contraction of myocytes for mechanical pumping. Maintaining this architecture and alignment of the fibers when designing a scaffold implant may be an important requirement for electrical coupling with the host myocardium. It is unlikely that minimally invasive approaches for cell transplantation will achieve this level of tissue architecture. However, engineered grafts have been shown to develop electrical coupling host myocardium.[76] They observed a normalization of epicardial electrical propagation between the engineered heart graft and the host myocardium, which was attributed to the host heart overpacing the construct and electrically conditioning it with time.[76] It has also been shown that electrical stimulation as well as electrical gradient exposure can induce cell alignment and coupling. Thus, there are two possible mechanisms of electrical integration: stretch-induced depolarization and direct electrical stimulation.[77,78] These different strategies should be incorporated into the design of the biomaterial scaffold for cardiac repair.

5.529.3. Current Materials

5.529.3.1. Naturally Derived Materials as Scaffolds

Naturally derived materials have frequently been used as scaffolds for cardiac tissue engineering.[79] These materials have advantages over their synthetic counterparts because they are components of or have similar biological properties to the natural ECM. Natural materials engage cell surface receptors and also provide the physiological environment to regulate cell function.[39] The natural biomaterials used to date for stem cell transplantation are listed in **Table 2**. However, they also have disadvantages, such as lot-to-lot variability, immune rejection that may come from xenogeneic protein components, and high contamination potential.[79]

5.529.3.1.1. Collagen

Collagen is a major component of connective tissue and makes up ~30% of all proteins in the human body.[91] It is widespread and found in skin, bone, fascia, and in most areas requiring strength and flexibility. There are at least 29 different types of collagens, of which collagen type I is the most prevalent.[79] All types of collagen are composed of 3 peptide subunits that are each approximately 1050 amino acid residues long

Table 2 Natural biomaterials used for cardiac cell delivery and tissue engineering

Material	*Applications*
Collagen	Cell delivery into infarct region[80–83]
Alginate	Cell delivery into infarct region[34,84]
Fibrin	Cell delivery into infarct region[32,85,86]
Chitosan	Thermoreversible, cell delivery into infarct region[87]
Hyaluroinc acid	Improving neovascularization into ischemic tissues[61,88–90]

and show a strong sequence homology. These chains coil to form a triple helix that is cross-linked through covalent and hydrogen bonding. The resulting collagen fibrils offer opportunities for specific cell adhesion events, as collagen contains integrin-binding domains such as RGD and GFOGER[92–94] to assist in cell attachment. Additionally, the free ε-amines on the lysine residues can be used for chemical modification with bioactive molecules, such as peptides. Moreover, collagen is broken down by collagenases and serine proteases, which allows for localized biodegradation when cells are present.

Studies by Dai *et al.* have shown that injecting collagen with or without MSCs into the infarcted heart is beneficial.[95] Injecting collagen alone into 1-week-old myocardial infarcts of rats showed significant thickening of the LV wall, improved LV stroke volume, and increased EF after 6 weeks.[95] A later study in 2009 by the same group showed that a collagen matrix considerably improves the localization of transplanted MSCs in the infracted myocardium. Using radioactive-labeled bone marrow-derived rat MSCs labeled with isotopic colloidal nanoparticles containing europium measured the radioactivity in the myocardium as well as remote tissues, such as the lung, liver, spleen, and kidney. Four weeks after the injection, the tissues were sampled for radioactivity signals. It was concluded that the collagen matrix effectively retained the MSCs in the infarcted myocardium, preventing cell loss in the noninfarcted myocardium and the remote organs after 4 weeks. Moreover, Kutschka *et al.* reported that collagen matrices enhanced the survival of H9c2 cardiomyoblasts when injected into infarcted hearts. After 4 weeks, fractional shortening (FS) and EF of the scaffold injected with cells showed improvement compared with the saline control.[82]

5.529.3.1.2. Alginate

Alginate is a naturally derived polysaccharide harvested from brown algae that is composed of (1→4)-linked β-D-mannuronic acid and α-L-guluronic acid, as shown in **Figure 3**.[96] In the presence of divalent cations such as Ca^{2+}, adjacent alginate chains cooperatively bind to form ionic interchain bridges.[96] Alginate is an attractive material for injectable cell transplantation as it gels in the presence of Ca^{2+}. As alginate is derived from algae, it has no biological interaction with mammalian cells, and acts like a blank slate that can be chemically modified with specific peptides via the carboxylic acid functional groups to promote cell anchorage and cell–material interaction.[96] Therefore, this biopolymer is comparable to synthetic polymers in that it elicits minimal biological response and can be decorated with integrin-engaging peptides with a high signal-to-noise biological response.[96]

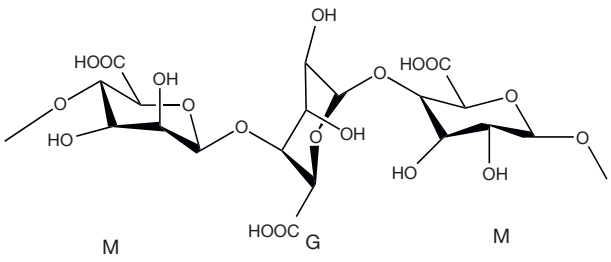

Figure 3 Chemical structure of the naturally occurring polymer alginate with the repeating subunits β-D-mannuronic acid (M) and α-L-guluronic acid (G).

Many groups have reported the benefits of injecting alginate without cells, both chemically modified and unmodified, to attenuate the negative remodeling process in myocardial infarcted hearts. For example, Yu *et al.* injected alginate conjugated with RGD peptides into the infarcted area of rats.[97] Both the modified and nonmodified alginate hydrogels significantly improved cardiac function and also increased arteriole density compared with the BSA in the PBS control group.[97] Landa *et al.* demonstrated that injecting biotin-labeled alginate into infarcted rat hearts 7 and 60 days post-MI resulted in thicker LV walls and attenuated LV systolic and diastolic dilatation. They also reported that the benefits of the alginate surpassed those of the neonatal cardiomyocyte group.[98] Moreover, alginate has been shown to be an effective injectable hydrogel system that also serves as a delivery vehicle for growth factors. Hao *et al.* reported improved cardiac function after injecting an alginate hydrogel that sequentially delivered VEGF-A_{165} and PDGF-BB.[99] The sequential delivery of these growth factors promoted a high density of α-actin positive vessels (i.e., vessels with a mature smooth muscle layer) compared to the single-dose administration.[99] Furthermore, Leor *et al.* reported the success of injecting alginate with fetal cardiac cells into the infarcted region of rat hearts. After 9 weeks, a large number of blood vessels were observed along with significant attenuation of LV dilation.[84] This study is one of the longest successful *in vivo* studies reported that predicts alginate as a promising biomaterial for myocardial infarct therapy.

5.529.3.1.3. Fibrin

Fibrin, also referred to as fibrin glue, is a plasma-derived biopolymer that is used as a biodegradable tissue sealant in a number of surgical applications.[100,101] During the last step of the coagulation cascade, thrombin enzymatically cleaves fibrinogen to polymerize a semirigid fibrin clot.[32] This biopolymer acts as a tissue sealant by binding to biological tissue via covalent, hydrogen, or electrostatic bonds. Mechanical interlocking also plays a large role in the anchoring of the fibrin clot to the tissue.[101] Furthermore, many studies have reported that fibrin has considerable angiogenic properties.[32,102,103] The degradation products stimulate the migration of monocytes and subsequent macrophages to the clot, where they remove the degraded fibrin by-products via phagocytosis. Fibroblasts bind and migrate into the clot network and secrete urinary plasminogen activators or tissue type plasminogen activators that lyse fibrin, favoring neovascularization.[101] Fibrin also serves as an attractive cardiac tissue scaffold material since it is biocompatible, approved in devices by the FDA, does not exhibit extensive fibrosis or tissue necrosis, is biodegradable, and promotes angiogenesis.[101]

Studies have reported that fibrin can improve cardiac function after MI. Ryu *et al.* reported that injecting bone marrow mononuclear cells (BMMNCs) into a cryoinjured rat myocardium using a fibrin matrix resulted in enhanced neovascularization and extensive tissue regeneration compared to the BMMNC implanted without the matrix.[85] Christman *et al.* injected skeletal myoblasts with fibrin glue into the LV of infarcted rat hearts. After 5 weeks, it was apparent that the fibrin scaffold increased cell transplant survival, improved

blood flow to the ischemic region, and decreased the infarct size.[102] It was noted that the fibrin glue did not significantly increase cell retention, but instead increased cell survival over the BSA control group. They attribute the cell survival to the fact that fibrin promotes angiogenesis, increasing blood flow to the cells in the ischemic environment of the infarct. Additionally, they attributed the low cell retention to the fact that the fibrin solution remains a liquid only for a few seconds before gelling, which would allow enough time for the cells to leak out of the injection site.[102] Therefore, optimizing the rate of cross-linking so that the cells remain at the desired site upon injection would be important for further investigatation.

5.529.3.1.4. Chitosan

Chitosan is a linear polysaccharide of β(1→4)-D-glucosamine units derived from the exoskeletons of animals such as crustaceans, mollusks, and insects.[104,105] It can also be extracted from the fungal fermentation processes.[91] In aqueous solutions, chitin is insoluble; however, partial deacetylation of chitin in an alkaline environment[104] forms chitosan (deacetylation <60%), which is soluble in aqueous acids, such as acetic acid.[106] An arbitrary molecular structure of chitosan is shown in Figure 4. It is a biodegradable cationic biopolymer that is known to cause slight inflammation in mammals. The biodegradation rate of chitosan is determined by the residual acetyl content, a parameter that can be easily tuned. The major pathway for the biodegradation *in vivo* is through lysozyme that depolymerizes the polysaccharide.[91] Due to its low toxicity and acceptable biocompatibility, it has been used in many medical applications.

In a study by Lu *et al.*, thermoresponsive chitosan with ESCs were injected into the infarcted regions of rat hearts. This 4-week-long study showed that the hydrogel and ESC injection preserved cardiac function and exhibited significantly higher microvessel densities than the PBS group. Additionally, the chitosan hydrogel facilitated ES cell retention.[35] Yeo *et al.* made a photo-cross-linkable hydrogel composed of chitosan and acryloyl-poly(ethylene glycol)-RGDS for encapsulating VEGF and C2C12 cells derived from murine myoblasts. They showed that the hydrogel supported attachment, proliferation, and differentiation of the myoblasts. Finally, the hydrogel was successfully localized at the surface of the rat heart and in the ventricle wall due to the photo-cross-linkable qualities of the hydrogel.[107]

5.529.3.1.5. Hyaluronic acid

Hyaluronic acid or hyaluronan (HyA) is an anionic, nonsulfated linear glycosaminoglycan that is found in the ECM of all mammalian connective tissues.[108] This biopolymer is composed of repeating units of β-D-glucuronic acid and *N*-acetyl-β-D-glucosamine, where the linkage is (1→3) from glucuronic acid to *N*-acetyl-β-D-glucosamine and (1→4) from *N*-acetyl-β-D-glucosamine to glucuronic acid, and has molecular weights ranging from 10^4 to 10^7 Da, as shown in Figure 5.[109] It is a desirable biomaterial since it does not elicit significant inflammatory or foreign body reactions *in vivo*. HyA also serves many biological functions in the body, but it is most commonly known for its inert lubricating functions in the synovial fluid of joints.[88] HyA is naturally degraded by the enzyme hyaluronidase, which causes the lowering of the molecular weight to decrease viscosity and increase tissue permeability. Furthermore, as a chief component of the ECM, HyA has the ability for specific binding through its main classes of cell surface receptors.[108] For example, CD44 is a type I single-pass transmembrane glycoprotein that is a receptor for HyA. It is responsible for mediating cell adhesion, migration, and proliferation. Additionally, RHAMM is a soluble protein that binds to HyA and is thought to play a role in the regulation of mitosis.

HyA has biological properties that are dependent on molecular weight. For example, low molecular weight HyA is an attractive biopolymer for tissue engineering scaffolds because of its angiogenic properties during wound-healing processes.[89] Encouraging blood vessel growth is especially important for cardiac tissue engineering because the post-MI myocardium is an ischemic environment for transplanted cells.[90] In a study by West *et al.*, electron microscopy showed a significantly larger number of small blood vessels in myocardial infarcts from animals treated with high levels of hyaluronidase to degrade the HyA than in hearts from untreated (no hyaluronidase) animals.[90] The size distribution of HyA for angiogenic activity was determined to be between 4 and 25 disaccharides in length. Therefore, incorporating low molecular weight HyA or high levels of hyaluronidase into tissue engineering scaffold may be a beneficial therapy for blood vessel growth in cardiac cell transplantation.

A challenge to this approach is that the low molecular weight fragments will have weaker biomechanical properties, but HyA can be chemically cross-linked to form infinite molecular weight hydrogel networks. One solution is to covalently

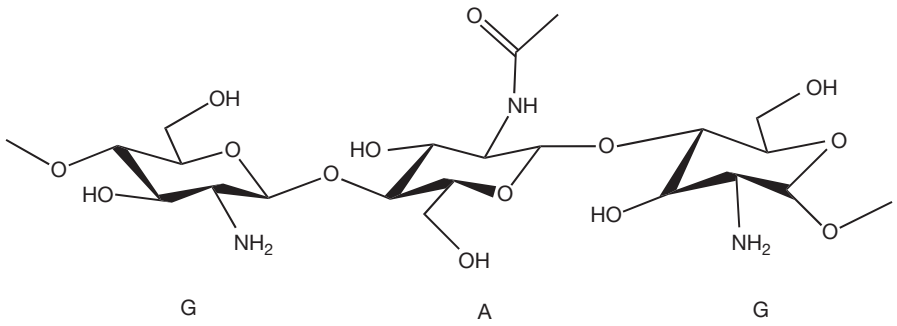

Figure 4 Chemical structure of the naturally occurring polymer chitosan. This linear polysaccharide is composed of randomly distributed β(1→4)-D-glucosamine units (G: deacetylated unit) and *N*-acetyl-D-glucosamine (A: acetylated unit).

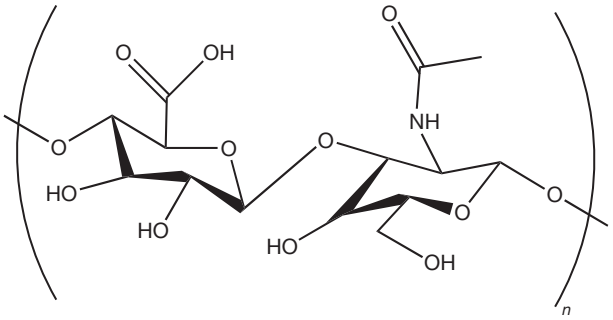

Figure 5 Chemical structure of the naturally occurring polymer hyaluronic acid. The repeating disaccharide is composed of D-glucuronic acid (left) linked β(1→3) to *N*-acetyl-D-glucosamine units (right), which is then β(1→4) linked to the D-glucuronic acid.

cross-link the low molecular weight HyA fragments to add mechanical integrity to the scaffold. Ghosh *et al*. have reported the feasibility of cross-linking thiol-functionalized HyA with polyethylene glycol diacrylate (PEGDA) through a controllable Michael-type addition reaction.[88] It is also possible to use a diacrylate cross-linker that is biodegradable such as an MMP-sensitive peptide sequence so that the low molecular weight HyA fragments are delivered overtime while simultaneously maintaining mechanical integrity. HyA may also be used as a carrier for angiogenic molecules. For example, Wall *et al*. have covalently conjugated SHh protein through the carboxyl group on the HyA using the heterobifunctional cross-linker, EMCH.[61] The polyvalency of the SHh–HyA conjugate leads to enhanced angiogenic activity.

5.529.3.2. Synthetic Biomaterials as Scaffolds

Synthetic biomaterials offer advantages over naturally derived materials as scaffolds in cardiac stem cell transplantation as they can be chemically, mechanically, and structurally well defined. These important features are advantageous for scaffolds because they can be easily tuned and systematically optimized with batch-to-batch reproducibility. They also offer a range of chemistries unavailable to natural materials, which have the potential for various applications such as time-controlled release of bioactive compounds from the matrix and tunability of mechanical properties. Furthermore, biomaterials can be redesigned and modified in an iterative manner for improved performance, which is a benefit over naturally occurring materials, which typically have little latitude in modification. Synthetic biomaterials do not have the problems associated with injecting naturally derived materials *in vivo* such as disease transmission and/or rejection. However, a downside to synthetic materials is that the biodegradation can often induce inflammatory responses such as small-particle disease. For example, the acidic degradation products from polylactic- and polyglycolic acid-based materials can lower the pH of the microenvironment, which may have serious physiological effects.

5.529.3.2.1. Poly(glycolide) and poly(lactide)

The polyesters belonging to the poly (α-hydroxy acid ester) family, such as poly(glycolide) (PG), poly(lactide) (PL), and poly(ε-caprolactone) (PCL), are the most widely used

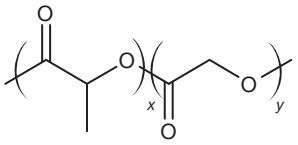

Figure 6 Chemical structure of the repeating unit of poly(lactide-*co*-glycolide).

synthetic biodegradable polymers in medicine. PL is typically synthesized by ring-opening polymerization of the lactide monomer, a chiral molecule with three forms (i.e., D, L, and *meso*), that can produce PDL, PLL, or PDL.[110](*Note*: PL is also referred to as poly(lactic acid) (PLA) and PG as poly(glycolic acid) (PGA) based on earlier synthesis methods exploiting condensation polymerization of lactic or glycolic acid.) While PL is a hydrophobic polymer because of its extra methyl group that retards hydrolytic degradation, PG is relatively more hydrophilic and therefore degrades more rapidly. To improve mechanics and vary degradation rates, lactide monomers are generally copolymerized with glycolide monomers to make a wide range of copolymers.[110,111] The chemical structure of poly(lactide-*co*-glycolide) (PLG) is shown in **Figure 6**. PLG copolymers exhibit a highly tunable degradation rate over the individual polymers and are commonly used as controlled-released carriers for various exogenous agents.[112] The ratio of PL to PG can be modulated to change the degradation rate to coincide with the amount of time necessary for cellular infiltration and matrix deposition.[112] PL, PG, and PLG are FDA approved in devices because of their proven biocompatibility. PCL is polymerized from a cyclic lactone monomer to produce a semicrystalline polymer that degrades more slowly *in vivo*. Copolymers of PCL with other polyesters such as PLL are commonly produced for tissue engineering applications.[113,114]

PLG is a common biomaterial used in tissue engineering scaffolds, vascular grafts, and cardiac tissue constructs. Wang *et al.* reported a tubular scaffold system composed of PLGA loaded with bFGF that was implanted into the infarcted area of the heart. The PLGA scaffolds with bFGF showed significant improvement in FS compared to the control group.[112] Additionally, there was increased neovascularization and perfusion in the scaffold groups.

One concern regarding the use of PLGA as a bulk implant material is the delayed inflammatory reaction that often occurs due to the release of the acidic degradation products.[115–118] Hydrolysis of PLG leads to lactic acid and glycolic acid as degradation products, resulting in a local pH decrease in the vicinity of the implant.[118] Agrawal *et al*. investigated the use of incorporating basic salts such as calcium carbonate, calcium hydroxyapatite, and sodium bicarbonate into PLG scaffolds to offset the acidic by-products.[118] The control media with the implant showed a significant drop in pH (3.0) after 9 weeks. In comparison, implants that contained calcium carbonate, calcium hydroxyapatite, or sodium bicarbonate controlled the pH values in the range of 7.4–6.3, 6.9–4.3, and 8.2–4.5, respectively. Although incorporating basic salts into the PL, PG, and PLPG implant helps to avoid the harmful acidic levels that arise from the degradation products, this approach may lead to ectopic calcification in the heart and is therefore a high risk approach.

5.529.3.2.2. PEG-based hydrogels

PEG has been used in numerous tissue engineering applications because of its low toxicity and nonfouling character. The chemical structure of PEG is shown in Figure 7. In a study by Dobner, *et al.*, a PEG hydrogel was chosen as an injectable therapy because of its biocompatibility and mechanical strength.[119] Studies by Wall *et al.* and Sabatine *et al.* have shown that the injection of stiffer materials maximizes the attenuation of remodeling by relieving the buildup of stress felt by cardiomyocytes[55,120]. Therefore, in this study, a stiff 5% PEG (20 kDa) hydrogel was injected into the infarcted region of Wister rats, and the resulting FS and infarct volume decreased significantly at 2 and 4 weeks. At these time points, there was also complete prevention of wall thinning and decreased heart dimensions. However, these benefits were lessened by week 13 when dilation occurred. Perhaps, this late negative remodeling in the PEG-treated group was due to a delayed buildup of cardiomyocyte stresses above a threshold level. The therapeutic benefits of the PEG hydrogel were only present in the immediate postinfarct healing phase, unlike the results from the poly(*N*-isopropylacrylamide-*co*-acrylic acid) semi-interpenetrating polymer network (sIPN) hydrogels study.[36] In addition, a study by Zhang *et al.* showed that a MPEG–PCL–MPEG triblock copolymer hydrogel injected into rabbit MIs prevented scar expansion and wall thinning compared to the PBS control. They also reported that the hydrogel injected group had a significantly higher EF (56%) compared to the control group (37%), with no difference in vessel density between the two groups.[121]

5.529.3.2.3. Poly(N-isopropylacrylamide)

Thermoresponsive materials are attractive candidates for noninvasive cardiac therapies because they preclude the need for invasive open heart surgeries. One strategy could be the employment of the principle of lower critical phase separation. Polymer mixtures that demonstrate this behavior phase-separate as the temperature is increased above the lower critical solution temperature (LCST).[122,123] One such polymer is poly(*N*-isopropylacrylamide) P(NIPAAm), which is an amphiphilic thermoresponsive polymer that swells significantly in water to form a hydrated 3D hydrogel network (Figure 8). When P(NIPAAm) is heated, it undergoes a coil to globule transformation at its LCST, which occurs at ~34 °C, conveniently situated between room and body temperature. The polymer exists as a free-flowing viscous liquid at room temperature and a rigid viscoelastic solid above the LCST. Lower critical phase separation is generally regarded as a phenomenon governed by the balance of hydrophilic and hydrophobic moieties on the polymer chain and driven by a negative entropy of mixing.[124–126] In addition, the temperature dependence of certain molecular interactions, such as hydrogen bonding and hydrophobic effects, contributes to this type of phase separation.[127] At the LCST, the hydrogen bonding between the polymer and water becomes unfavorable compared to polymer–polymer and water–water interactions,[126] and an abrupt transition occurs as the hydrated hydrophilic macromolecule quickly dehydrates and changes to a more hydrophobic structure.[126,127]

sIPNs composed of P(NIPAAm) have been used as biomimetic ECMs for cardiac stem cell transplantation and myocardial stabilization.[36] GFP-positive BMSCs were entrained in environmentally responsive poly(*N*-isopropylacrylamide-*co*-acrylic acid) hydrogels incorporated with matrix metalloproteinase labile cross-linkers (e.g., MMP-2, -9, and -13) and peptides containing integrin-binding domains (i.e., RGD), and were directly injected into infarcted murine left ventricles without inducing arrhythmias. Wall *et al.*[36] reported significant differences in comparisons of pooled data from treatment groups that received MSCs. At 2 weeks, the addition of MSCs resulted in a significantly higher FS and a numerically higher EF compared to controls; however, at 6 weeks, hearts that received stem cells had worse FS as well as EF. Interestingly, injection of the sIPNs without cells resulted in superior LV function at 6 weeks compared to groups with cells and saline controls. Donor GFP(+) cells were detected only 6 weeks after matrix-enhanced transplantation, but not without matrix support, and infarct thickness was increased in animal subgroups that had histologically confirmed matrix contained within the infarct border zone ($p < 0.05$). Thus, sIPN hydrogels succeeded in both mechanically supporting the injured myocardium and enhancing donor cell survival. These results are consistent with a theoretical mathematical model that reported that injection of biomaterials in the left ventricle might ameliorate both ventricular remodeling and infarct extension.[55]

Fujimoto *et al.* reported copolymerization of P(NIPAAm), acrylic acid, and hydroxyethyl methacrylate-poly(trimethylene carbonate) as a bulking agent for myocardial repair.[128] The goal was for the hydrogel to gel at 37 °C and then slowly solubilize at physiological temperature as the PTMC residues were hydrolytically cleaved. The authors reported an 8-week *in vivo* study showing that the LV cavity area and contractility were preserved in the hydrogel group. Additionally, tissue ingrowth and a higher capillary density were observed in the hydrogel injected versus the PBS control group.[128] Both of these studies indicate that biomaterials alone, without the inclusion of stem cells, may be a viable treatment for post-MI injuries.

5.529.3.3. Hybrid Biosynthetic Materials

To take advantage of the tunability of synthetic materials and the bioactivity of naturally occurring materials, many groups have coupled these two types of materials as a biosynthetic strategy for treating MIs. As described previously, PEG is one of

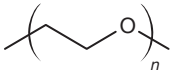

Figure 7 Chemical structure of the repeating unit of poly (ethylene glycol).

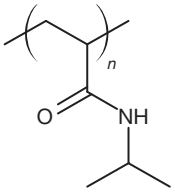

Figure 8 Chemical structure of the repeating unit of poly(*N*-isopropylacrylamide).

the most commonly used synthetic polymers in biomedical applications. Many groups have incorporated bioactive components through chemical conjugation to synthetic PEG-based backbones. For example, Kraehenbuehl *et al*. showed that synthetic MMP-sensitive 3D PEG hydrogels with matrix-bound RGDSP peptide could direct differentiation of pluripotent cardioprogenitors *in vitro*.[129] The passive and synthetic qualities of PEG allowed for the bioactive components to be modulated independently from the matrix stiffness.[129] This kind of study would not have been possible with a natural material where the bioactivity and the mechanical properties are coupled. Therefore, the use of a synthetic base material with added bioactivity allowed for a more comprehensive study to determine the important features involved in directed cardioprogenitor differentiation. This study showed that the softer PEG-based matrices that had comparable stiffnesses to cardiac tissue ($E = 322 \pm 64.2$ Pa) directed the cardiac commitment of pluripotent P19 EC cells (**Figure 9**).[129]

Other studies have demonstrated the use of synthetic conducting polymers blended with naturally occurring materials as a potentially successful MI therapy. A conducting material is attractive for this application because it is hypothesized that it helps restore electrical conduction in the infarct. Additionally, the attachment, proliferation, and migration of cells may be tuned by electrical stimulation of the conducting polymer. One of the most commonly used conducting polymers is polypyrrole, a polycationic polymer that is easily synthesized into thin films, thick films, and colloidal particles. *In vivo*, the material has been shown to be noncytotoxic and can support the proliferation and differentiation of many cell types such as neurons and endothelial cells. However, one limitation of polypyrrole is that it can be brittle and difficult to process. To overcome this limitation, Mihardja *et al*. blended polypyrrole with naturally occurring alginate, which is a more compliant material.[130] They chose to introduce polypyrrole because of its conductivity as well as its cationic charge to help with proliferation and differentiation of vascular cells. The group found that higher ratios of polypyrrole to alginate increased attachment of human umbilical vein endothelial cells *in vitro*. They also reported that injection of 0.025% polypyrrole blended with alginate into the infarcted zone of a rat model resulted in significantly greater arteriogenesis at 5 weeks compared to the alginate only and saline control groups.

Another biosynthetic strategy is to use synthetic hydrogels as a delivery vehicle for biological agents. Wang *et al*. used a hydrogel composed of α-cyclodextrin MPEG–PCL–MPEG triblock copolymer to deliver erythropoietin (EPO).[131] EPO is a hormone that protects the myocardium by stimulating endothelial cells to promote ischemia-induced neovascularization. However, it also plays a role in potential thromboembolic complications. If delivered in a locally sustained way, the systemic toxicity is reduced. In this study, they injected the triblock copolymer with recombined human EPO (rhEPO) into MI rats. The controls were PBS, hydrogel alone, and rhEPO in PBS. Overall, the hydrogel with rhEPO improved cardiac performance significantly by inhibiting cell apoptosis, increasing neovasculature, and decreasing the infarct size compared to either PBS alone, hydrogel alone, or rhEPO in PBS. Therefore, this study demonstrated greater cardioprotective effects when the synthetic hydrogel and hormone were delivered in combination.

5.529.3.3.1. Smart biomaterials: growth factors and self-assembling peptides

Cardiac tissue engineering is not limited to cell- and cell–material-based approaches. A promising strategy in this field is the delivery of growth factors for myocardial protection against apoptosis, enhancement of angiogenesis, and recruitment of cells. As described previously, many studies have reported poor retention of transplanted cells in the myocardium with little functional integration. This observation might suggest that the benefits from cell transplantation therapies are

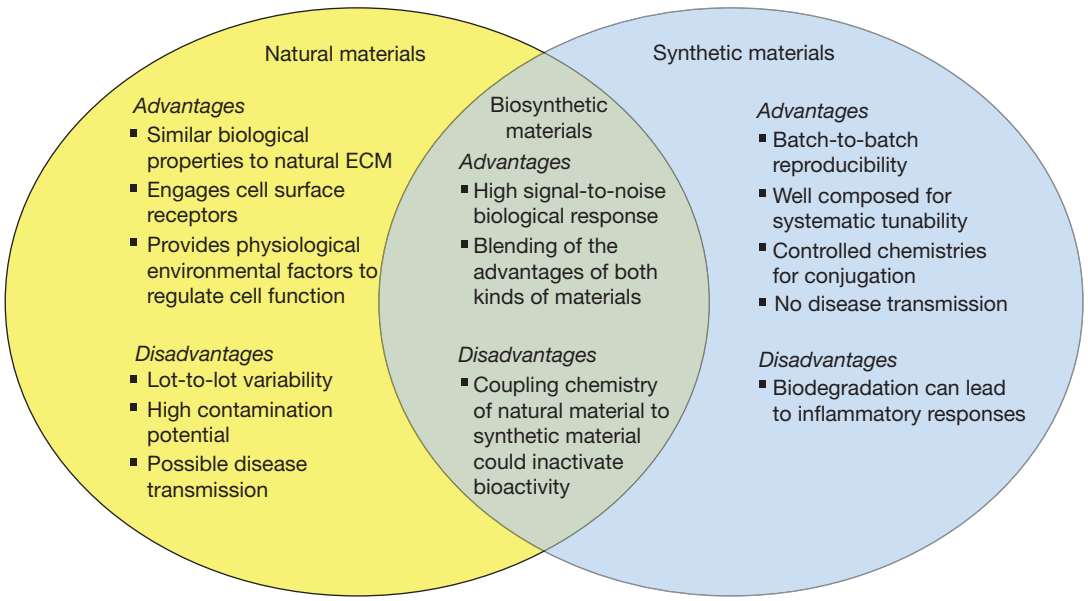

Figure 9 Comparison of synthetic, biosynthetic, and natural materials for cardiac cell transplantation.

paracrine-factor related and that growth factors may enhance this effect.[132] Growth factors are small in size and, consequently, they rapidly diffuse out of the injection site.[133] Many groups have tethered these growth factors onto self-assembled nanofibers through different chemistries for controlled release.[132–136] These nanofibers are composed of amphiphilic peptides that thermodynamically self-assemble upon exposure to physiological osmolarity and pH.[133] The resulting nanofibers are approximately 5–10 nm in length and mimic the filamentous structure of naturally occurring ECM fibers.[133]

Davis and Motion *et al*. used RAD16-II peptides, which are short sequences of 8–16 amino acids.[133,137] When injected into the myocardium of mice, the self-assembled nanofibers recruited progenitor cells that expressed endothelial markers and vascular smooth muscle cells, despite the fact that the peptides themselves have no known biological signaling sequence.[137] In another study by the same group, insulin-like growth factor 1 (IGF-1) was tethered to the same peptide (RAD16-11) nanofibers through a biotin sandwich strategy.[133] The complexation with IGFF-1 did not interfere with the self-assembly process. IGF-1 is a cardiomyocyte growth and survival factor and has been reported to protect against apoptosis after MI.[133] Neonatal cardiomyocytes that were injected into infarcted rat myocardium with the IGF-1-biotinylated nanofibers improved systolic function and reduced ventricular dilation. Finally, they showed that the IGF-1 complexed with the nanofibers decreased cell apoptosis and improved maturation of neonatal cardiomyocytes as evidenced by troponin expression.

Similarly, Dubois *et al*. investigated the use of RAD16-1 and RAD16-II self-assembling peptide nanofibers for delivering skeletal myoblasts to the infarcted left ventricle of rats[134] alone and tethered to PDGF-BB. PDGF-BB has been shown to be a crucial factor in endothelial cell-mediated cardiomyocyte protection.[133,134,138] All of the experimental groups were injected into rats 2 weeks after infarctions were induced. After 4 weeks, LV function was not improved in any of the experimental groups compared with the controls, but there was improved angiogenesis. This experimental study was similar to the study by Davis *et al*., but showed opposite results. The authors suggest that the benefits of the self-assembling nanofibers are highly dependent on (1) the time of injection and (2) the cell type.[134] Davis *et al*. injected neonatal cardiomyocytes with self-assembling peptides immediately after MIs, while Dubois *et al*. injected skeletal myoblasts 2 weeks after infarction.[134]

5.529.4. Concluding Remarks

In order to overcome the burden of MIs and related CHF in patients, novel treatment approaches are needed. Biomaterials alone or in combination with transplanted cells hold great promise as a therapy to treat CHF. Cell transplantation for cardiac tissue regeneration will hinge upon enhanced cell survival after injection, integration into the host tissue, and temporal expansion, which can be controlled by the material scaffold. To drive cardiac regeneration, the appropriate temporal, spatial, and signaling regulatory factors are necessary to incorporate into the biomaterial in order to stimulate the appropriate response. To do this, five major scaffold design goals have been proposed: (1) 3D support, (2) myocardial stiffness matching, (3) adequate oxygen and nutrient transport, (4) electromechanical integration with the host tissue, and (5) appropriate biological cues incorporated into the biomaterial. The field of biomaterials holds considerable promise at addressing these challenges to bring cardiac tissue engineering into clinical application.

Glossary

Cell sheet Cultured cells are connected through cell–cell junctional proteins and are harvested as an intact monolayer cell sheet containing native deposited extracellular matrices.
Cell sheet engineering Reconstructing tissue with cell sheets harvested from temperature-responsive culture dishes.
Extracellular matrix (ECM) Complex network that consists of proteins and polysaccharides, and it is secreted from cells.
Gap junctions Functional structures which bridge gaps between adjacent cells, creating direct passageways from the cytoplasm of one cell into the other.
Hydrophilic surfaces Proliferating and adhering cells spontaneously detach themselves from temperature-responsive culture dish surfaces at temperatures below 32 °C.
Hydrophobic surfaces Adhered cells can proliferate to confluence and flatten on the surface of temperature-responsive culture dish surfaces at temperatures above 32 °C.
Poly(*N*-isopropylacrylamide) Polymer material exhibits temperature-responsive soluble/insoluble changes in an aqueous solution and has a lower critical solution temperature (LCST) at 32 °C.
Polysurgery Cell sheets are repeatedly implanted into a living body for more than two times.
Prevascularizing method Multilayered cultures combining micropatterned endothelial cells with fibroblast monolayer sheets are used for fabricating prevascularized tissue equivalents.
Temperature-responsive culture dish Poly (*N*-isopropylacrylamide) is grafted on cell culture dishes, and the surfaces show a temperature-responsive characteristic (LCST: 32 °C).

Abbreviations

2-D	Single-layer sheet
3D	Three-dimensional
BNP	Brain natriuretic peptide
COE	Center of Excellence
DCM	Dilated cardiomyopathy
EB	Electron beam
ECM	Extracellular matrix
EGM-2	Endothelial growth medium
HRC	High-Tech Research
HUVECs	Human umbilical endothelial cells
LCST	Lower critical solution temperature
LV	Left ventricle
LVAD	Left ventricular assist device
MSCs	Mesenchymal stem cells
NEDO	The New Energy and Industrial Technique Development Organization
PIPAAm	Poly(*N*-isopropylacrylamide)
PIPAAm-TCPS	PIPAAm-coated TCPS
TCPS	Tissue culture polystyrene

5.530.1. Introduction

5.530.1.1. Cell Sheet Engineering

The basic principle of tissue engineering is the seeding of cells into a three-dimensional (3-D) biodegradable scaffold, to be used for the replacement of damaged or lost tissues of living organisms and for the reconstruction of living tissues.[1–3] The use of these scaffold-based designs in the recreation of some tissues such as bone,[4] cartilage,[5–7] skin,[8] blood vessels,[9,10] and heart valves has been reported by many

researchers.[11,12] However, the applications in cell-dense reconstruction have been limited by these conventional tissue engineering approaches because bone and cartilage are far less complex and cell-sparse tissues and require reduced internal vasculature. On the other hand, for thicker structures such as the heart, the liver, and the kidney, finding a way to integrate the requisite blood supply into a 3-D tissue without using a scaffold, which may cause pathological fibrosis, remains a challenge. Furthermore, if structures lack appropriate vasculature, cells will become necrotic in the center of the constructs, due to the limits of passive diffusion. The insufficient delivery of oxygen and nutrients, and the poor removal of metabolic waste results in reduced functionality and, ultimately, necrosis. Naturally, the high cell-density and the complex structure of heart tissue is more difficult to recreate with conventional tissue engineering strategies. Additionally, resorbable polymers can be associated with proinflammatory degradation byproducts, which can limit the functionality of the various organs that are being repaired.[13] Therefore, a new method that avoids the current limitations in clinical tissue reconstruction using biodegradable scaffolds is necessary for the further development of tissue engineering.

In 1990, cell sheet engineering using temperature-responsive culture dishes was developed by our group with an innovative approach.[14,15] Temperature-responsive polymer, poly(*N*-isopropylacrylamide), (PIPAAm) is polymerized and grafted onto various surfaces by electron beam radical polymerization. These intelligent temperature-responsive surfaces can control the attachment and detachment of living cells with temperature changes from 37 to 32 °C. The principal advantage of the cell sheet approach is that a monolayer cell sheet can be harvested without using proteolytic enzymes. By simply reducing the culture temperature to lower than 32 °C for less than 30 min, the sheet can be harvested. Eliminating the necessity for proteolytic enzymes preserves the basal surface extracellular matrix (ECM) proteins even after detachment and produces a basic building block that can be further manipulated to assemble more complex tissues and organs.[16–18] Using this technology, living cell sheets can be immediately transplanted into the various kinds of host tissues without using biodegradable scaffolds and sutures. We have also demonstrated thicker, multilaminate tissue constructs by layering cell sheets. More complex versions of this stacking approach can include cocultured or patterned cell sheets, using two or more different kinds of cell sources. We have succeeded in demonstrating the *in vivo* long-term survival of tissue-engineered pulsatile cardiac grafts in animal models.[19] We have also used cell sheet technology to repair various tissues and organs, including the cornea,[20–22] esophagus,[23,24] heart,[25–29] liver,[30,31] kidney,[32] lung,[33], periodontium[34,35], and many others (**Figure 1**). Other groups have similarly demonstrated clinical successes with the use of sheet-based approaches.[36–38] In this chapter, we review our achievements with the use of temperature-responsive cell culture dishes, temperature-dependent cell attachment, and the applications of this technique for regenerative medicine.

It is popularly known that PIPAAm is an 'intelligent' polymer, meaning that the material exhibits temperature-responsive soluble/insoluble changes in an aqueous solution and has a lower critical solution temperature (LCST) at 32 °C[39] (**Figure 2**). PIPAAm was introduced on the surfaces of commercially available tissue culture polystyrene (TCPS) dishes.[14,15,40] Using temperature-responsive culture dishes, IPAAm monomers are first dissolved in 2-propanol solutions, and then the solutions are uniformly spread over TCPS dish surfaces. IPAAm monomers are polymerized and simultaneously coated covalently onto the TCPS surface with a 0.3 MGy dose of electron beam (EB) irradiation. Owing to the hydration of the grafted PIPAAm chains, PIPAAm-coated TCPS (PIPAAm-TCPS) surfaces exhibit hydrophilic and cell-repellent surfaces at temperatures below 32 °C. In contrast, PIPAAm-TCPS surfaces alter from a hydrophilic to a hydrophobic state due to the dehydration of the grafted PIPAAm chains, as the temperature rises above 32 °C. Consequently, cells attach, adhere, and proliferate on PIPAAm-TCPS at temperatures above 32 °C.

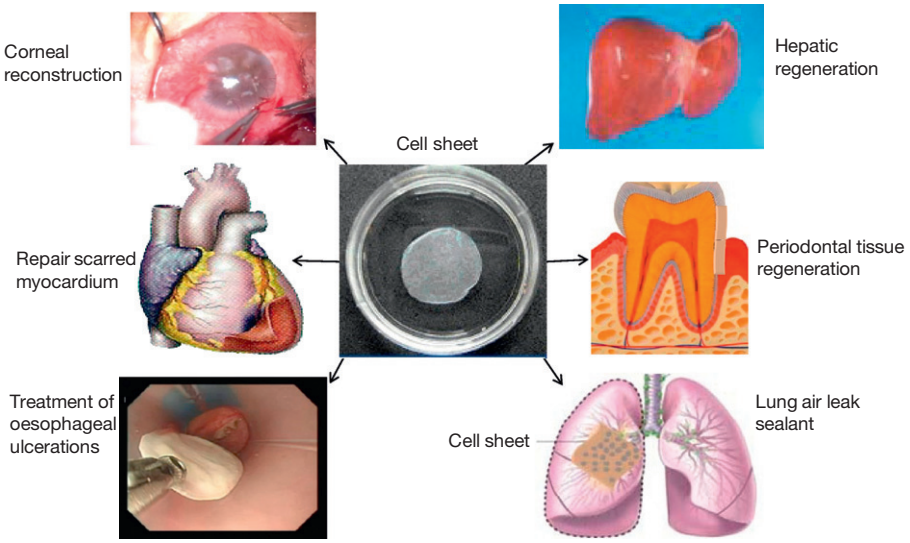

Figure 1 Tissue reconstruction from cell sheets. Many clinical trials in the field of regenerative medicine, such as corneal, heart, esophagus, liver, periodontal tissue, and lung have successfully applied cell sheet engineering.

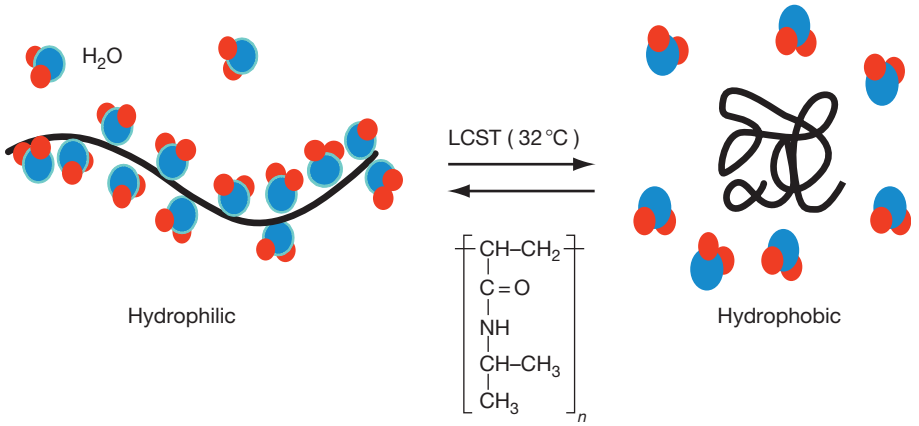

Figure 2 Coil–globule transition of poly(*N*-isopropylacrylamide) (PIPAAm). PIPAAm exhibits temperature-responsive soluble/insoluble changes in an aqueous solution and has a lower critical solution temperature (LCST) at 32 °C. At temperatures below 32 °C, PIPAAm molecules are highly hydrated, so the PIPAAm-grafted surfaces are hydrophilic. At temperatures above 32 °C, the surfaces suddenly change to hydrophobic due to extensive dehydration of PIPAAm molecules.

The adhered cells spontaneously detach themselves from PIPAAm-TCPS surfaces, when the temperature is reduced below 32 °C. This change is completely determined by wettability, which is measured by the captive bubble method in pure water and confirmed by the observation of the ability of endothelial cells to adhere to the surface.[41]

The temperature-dependent cell attachment and detachment is observed on 15–20 nm thick PIPAAm-grafted surfaces, between 20 and 37 °C. When the coated layer is more than 30 nm in thickness, cells are unable to attach. The contact angle of the layer is small at 37 °C and decreases the degree of thermal change of the angle. Because the dehydration of PIPAAm chains is incomplete, it provides a poor interaction between the PIPAAm layer and the cells. As the contact angle for the highest grafting density is much smaller than the others, the PIPAAm layer is still highly hydrated even at 37 °C and suppresses cell adhesion.

In contrast, when the coated layer is less than 15 nm in thickness and the temperature is reduced to below 32 °C, the surface is fully covered with PIPAAm molecules, and the effect of the uncoated polystyrene surfaces is insufficient to induce cell detachment; thus, the contact angle of the surface reduces with an increase in the polymer density and thickness.[42] Indeed, the coating thickness and density are dominant parameters for driving cell attachment and detachment.

It was reported in previous studies that the configuration of the polymer chain and its mobility affect the wettability of PIPAAm-grafted surfaces with changing temperatures. Single terminal coatings of PIPAAm with liberated mobile chains give more hydrophilic surfaces. In contrast, the looped-chain configuration followed by the multipoint coating of PIPAAm chains gives more restricted polymer chains, showing more hydrophobic surfaces. A comparison of the swelling ratio of single-side fixed / cross-linked PIPAAm hydrogel and nonfixed/cross-linked PIPAAm gel reveals a higher swelling ratio, which is significantly restricted with the single-side fixed gel. Further comparison of single-side fixed/cross-linked PIPAAm hydrogels with different thicknesses reveals that the swelling ratio of the thinner gels is less than half of that of the gels with double thickness.[40,41] These results suggest that the mobility of polymer chains in PIPAAm gel fixed on a covered glass surface is limited at the interface of the basal cover slips. The limited mobility produces extensive hydrophobic aggregate and also limits the hydration of the polymer chain. The limitations of polymer chain mobility progressively reduce the responses of the general polymer network, through cross-linked points inside the polymer gel. PIPAAm chains have more free mobility and a greater ability to respond to stimuli and hydration in the outer regions than in the inner regions. This consideration is extended to PIPAAm-TCPS systems, with an ultrathin PIPAAm layer.

For a thinner PIPAAm layer, the limited mobility of the polymer chains in the restricted layer promotes the dehydration of PIPAAm chains. The outermost surfaces are sufficiently hydrophobic to show adhesive properties for cells at 37 °C. The restricted layer region is considered to be between 15 and 20 nm (**Figure 3**). Such dehydration promotion and the limitations of the polymer chains result in the modulation of the cell attachment and detachment, in response to temperature changes. In contrast, for thicker PIPAAm layers, the dehydration of PIPAAm chains at the outermost surface (hydrated region) is discouraged even above the LCST, and the surface is free from the limitations of the polymer chains and dehydration generated at the basal PS surfaces. It is well known that cells are unable to adhere to thicker PIAAm hydrogels even at 37 °C. PIPAAm chains in the dehydrated layer are still hydrated without physical restriction like a free molecule.[42] As a result, cells are unable to adhere onto the surface of the PIPAAm-TCPS with a thick PIPAAm layer. Therefore, controlling PIPAAm surface graft density is a critical issue to reliably produce the temperature-responsive cell adhesion and detachment behavior of the surface.

5.530.1.2. Organized Combination of the Structure and Function of Cell Sheet

Conventionally, enzymatic treatment is required for recovering cultured cells from cell culture surfaces such as TCPS.[43] Cells physically adhere more strongly to hydrophobic surfaces than hydrophilic surfaces. When ATP is used after cells have come

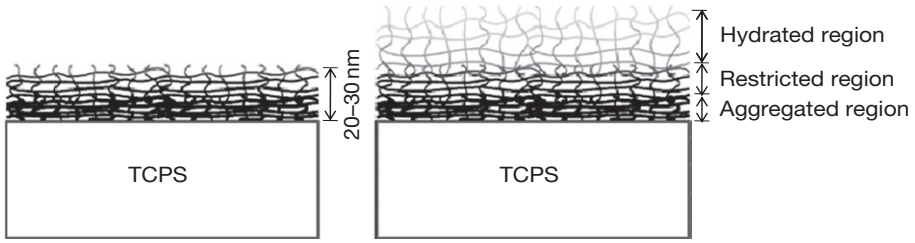

Figure 3 Schematic illustration of the influence of molecular mobility of grafted chains of PIPAAm layers on cell-adhesive characteristics at 37 °C. When grafted, PIPAAm layer thickness is between 20 and 30 nm, cell adhesion and detachment are observed (left side). No cell adhesion occurs when grafted PIPAAm layer is thicker than 30 nm (right side). Aggregated region: highly hydrophobic and aggregated PIPAAm chains do not let adhered cells detach by lowering temperature. Restricted region: restricted hydration and mobility of PIPAAm chains due to the strong hydrophobicity of the aggregated layer allow temperature-dependent cell adhesion-detachment behavior. Hydrated region: dehydrated but less restricted PIPAAm chains do not support cell adhesion.

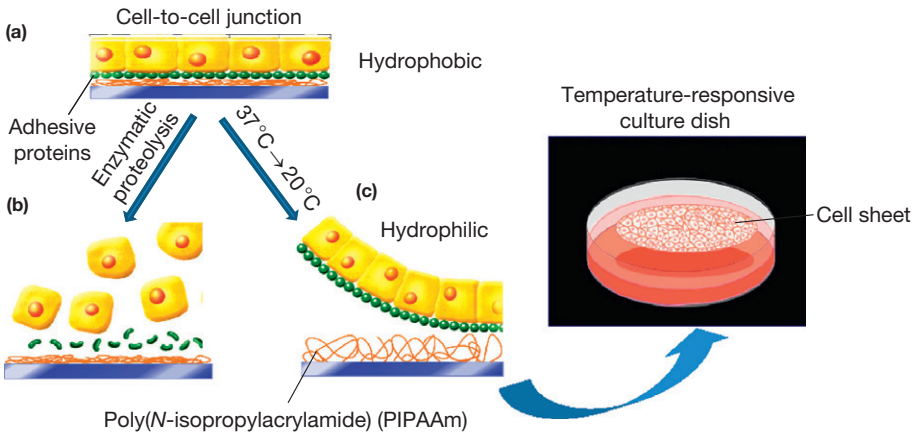

Figure 4 Confluent cells are subjected to two types of harvest methods. (a) Cells attach to hydrophobic culture surface via ECM and connect to each other through cell-to-cell junction proteins. (b) When enzymatic digestion is used, cell-to-cell connections and ECM are disrupted and cells are released separately. (c) When cells are cultured on temperature-responsive culture surfaces, the interconnection between ECM and hydrophilic culture surface is released only by low temperature. Cell-to-cell connections are completely preserved and the cells are detached as a contiguous cell sheet. ECM retained underneath the cell sheets works as an adhesive agent.

into physical contact with a surface, the metabolic process causes attached cells to undergo morphological changes. Adhered cells proliferate to confluence and flatten on the hydrophobic surface of the temperature-responsive culture dish as well as they would on a normal polystyrene culture dish. Spreading cells detach themselves from the hydrophobic surface, without the reversing events associated with morphology changes from spread to round cell shapes and the release of surface-engaged receptors. By simply reducing the temperature of the culture to below 32 °C, proliferating and adhering cells spontaneously detach themselves from the temperature-responsive culture dish surface. This is the result of the hydration of the PIPAAm surface. No enzyme such as trypsin or neutral protease (Dispase®) is required in this detachment process, just the physically mild condition of temperature change. Enzymes cut cell-to-cell junctions and free cells from their ECM, producing single cell suspensions. Using a temperature-responsive culture dish, confluent cells can be collected as a contiguous intact monolayer that retains cell-to-cell junctions[17,44] (Figure 4). Moreover, the ECM of the recovered cell sheets is preserved by this method. This is a novel concept that allows us to modulate the cell attachment and detachment on PIPAAm-coated surfaces. Various kinds of cells such as stem cells, oral mucosal epithelium cells, myoblast cells, cardiomyocyte cells, endothelial cells, and hepatocytes have been harvested from PIPAAm-coated culture dishes, under general incubation conditions.

Metabolic changes occur in the cell during detachment from hydrated PIPAAm-coated surfaces.[45] Optimum temperatures for maximizing cell recovery efficiency from PIPAAm-grafted surfaces vary with cell types. Temperature 20 and 10 °C are optimized culture temperatures for endothelial cells and hepatocytes, respectively. Even cells treated with sodium azide, an ATP synthesis inhibitor, or other chemicals, undergo no change in morphology and keep their adherent status on PIPAAm-coated surfaces at low temperatures. These findings suggest that cell detachment from hydrated PIPAAm-coated surface is governed by active energy-consuming metabolic processes, which contain intracellular signal transductions and the reorganization of the cytoskeleton.[46]

During the detachment process, morphological transitions in the cell sheet observed at 20 °C begin to detach from the periphery of the dish surfaces, while maintaining cell-to-cell connections and producing some sheet contractility. In order to collect and manipulate the cell sheet, supporting membranes such as poly(ethylene terephthalate), and poly(vinylidene-difluoride), and parchment paper sheets have been used

to prevent contraction.[17,47] The cell sheets can be manipulated with the supporting membranes by physicochemical interaction such as interfacial tension. They can then be directly transferred onto other cell sheets or native tissues, using the adhesive effects retained by the ECM on the basal surface of the recovered cell sheets.

This cell sheet engineering produces various tissues and organs such as myocardial cell sheet 3-D tissue,[26,27] microspherical heart-like pump,[19] and prevascularized 3-D cell-dense tissues. The cell sheet technique allows the reconstruction of functional, 3-D myocardial tissue, prepared by layering multiple cardiomyocyte sheets harvested from the temperature-responsive culture dishes. When the culture temperature is reduced from 37 to 20 °C, the cultured cells remain connected to each other through cell–cell junctional proteins and are harvested as a single sheet, with their deposited ECM intact. As this method allows the cell sheets to be harvested without disturbing the cell–cell connections and ECM proteins such as ion channels and growth factor receptors, cardiomyocyte sheets can beat synchronously after detachment. Single cell sheets can be directly transplanted onto host tissues with 2-D (single-layer sheet) manipulation and can improve cardiac function.

Using the homotypic layering of cell sheets, 3-D (multilayer sheet) functional cardiac tissues, such as cardiac muscle, can be constructed. Having no biodegradable scaffolds, the sheets interact directly with each other and can couple electrically, resulting in synchronous beating *in vitro* and long-term survival *in vivo*. Moreover, there is no adverse reaction due to the degradation of by-products, which results from the breakdown of a biodegradable scaffold. Therefore, cell sheet engineering is recognized to be the best approach to organize the structure and function of cell sheets without any adverse effects from unnecessary by-products.

5.530.1.3. Gap Junctions and Cell Sheet Engineering

It is known that gap junctions are functional structures that bridge gaps between adjacent cells, creating direct passageways from the cytoplasm of one cell into the other. The channels formed by the gap junctional proteins allow inorganic ions and other molecules smaller than 1200 Da to pass through a narrow path between the cells, thereby coupling the cells both electrically and metabolically.[48,49] Individual gap junction is found in transmission electron micrographs as a patch where the membranes of two adjacent cells are separated by a uniform narrow gap of ~2–4 nm.

Gap junction channels are formed by the members of the protein family called connexins, which share homologous extracellular and transmembrane regions but contain unique cytoplasmic domains that likely constitute physiological gating structures.[50] Different connexins form channels with varied biophysical properties.[51–53] Cell–cell communication through these channels is considered to play an important role in the control of cell embryonic development, proliferation, cell differentiation, and the regulation of differentiated function in postmitotic cells.[54–57] This communication is also an important mechanism for regulating events among cells during embryogenesis and during the functional development of organs such as the heart.

In heart tissue, gap junctions in mammalian cardiac function provide low-resistance channels between adjacent cells for the exchange of small molecules as the secondary messengers.[58,59] Several studies relating to the assembly of gap junctions in the heart have suggested that, during the postnatal development of ventricular myocardium and hypertrophic cardiomyopathy, the gap junctions may play an important role in the maturation of electromechanical function.[60,61] Furthermore, altered gap junction distribution occurs in ischemic heart disease.[62–67] The abnormal distribution of gap junctions in the epicardial border zone of infarcts may contribute to arrhythmogenesis. Thus, it is very important to establish these functional gap junctions among cells for synchronous beating and reconstruction of damaged heart tissues.

5.530.2. Functional Tissue Engineering with Cell Sheets

5.530.2.1. Electrical Coupling Between Layered Cardiomyocyte Sheets

Gap junctions are very important in normal and abnormal heart tissues. Electrical conduction in the heart tissue is dependent on current transfer through gap junctions. It has been reported that metabolic inhibitors or protein synthesis inhibitors fail to affect gap junction assembly in prostate epithelial cells. Therefore, it is proposed that gap junction formation proceeds through previously existing precursors within cell membranes.[68,69] Several reports that gap junction precursors exist on cell membranes show unveiled connexin hemichannels by electrophysiological measurements, dye transfer assay, or connexin-43–GFP chimera.[70–76] We identified that connexin-43 existed on the cell membrane as well as at cell-to-cell interfaces[77] (**Figure 5**). These gap junction precursors are preserved during the harvest of confluent cardiomyocytes from temperature-responsive culture dishes and can give a rapid electrical coupling between layered cell sheets. In addition, the cell sheets also maintain ECM on the basal surface and can adhere to other cell sheets or various surfaces. For this reason, the presence of ECM also promotes intimate attachment between layered cell sheets and may accelerate the docking of gap junction precursors.

Using cell sheet engineering, rat cardiomyocyte sheets were fabricated on temperature-responsive culture dishes to produce 3-D structures. We examined the electrical communication of two partially overlapped monolayer cardiomyocyte cell sheets by using microelectrodes (**Figure 6**). After one cardiomyocyte sheet was placed on a collagen-coated multielectrode dish probe for 1 h, the second sheet was partially overlapped on the first. Then, the electrical potentials of the cardiomyocyte sheets were recorded simultaneously, and the synchronization time and conduction velocities were analyzed.

We observed that once some gap junctions were established between the two cell sheets, electrical impulses reached the monitoring electrode through both direct conduction from the pacemaker cell sheet and detour conduction through the established gap junctions. Eventually, the conductions began to synchronize, with a slight delay after 30 min. These delays diminished in a time-dependent manner, and the electrical potentials became completely synchronized after 45 min. These findings suggest that additional gap junctions are randomly formed between the layered cell sheets and electrical communication is established throughout the interface within 45 min

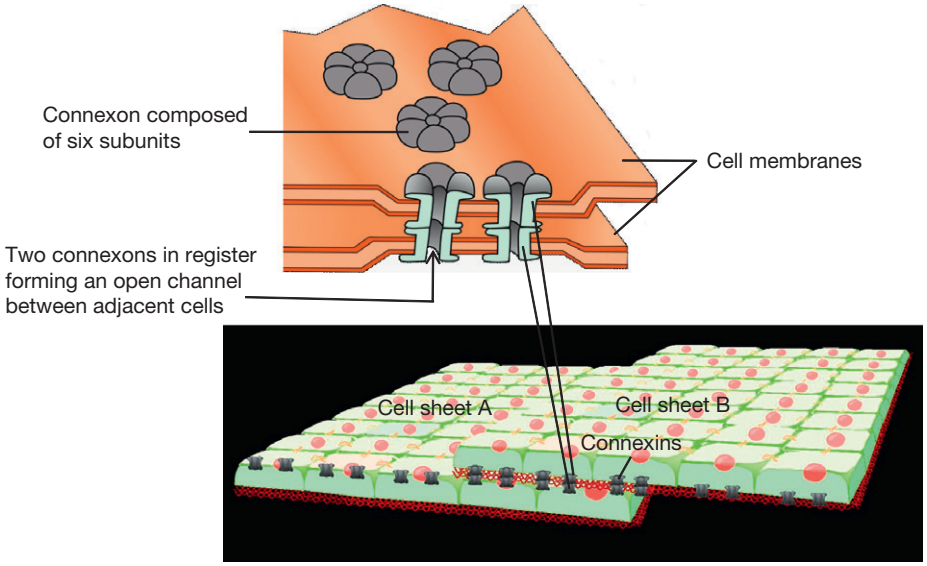

Figure 5 Connexon composed of six subunits. A gap junction consists of many connexon pairs in parallel, forming a sort of molecular sieve. Since the cell sheets contain intact gap junction precursors in addition to the deposited ECM when two pulsing cell sheets (a, b) are layered, they were found to synchronize their pulsations through their gap junction-related protein, connexin-43.

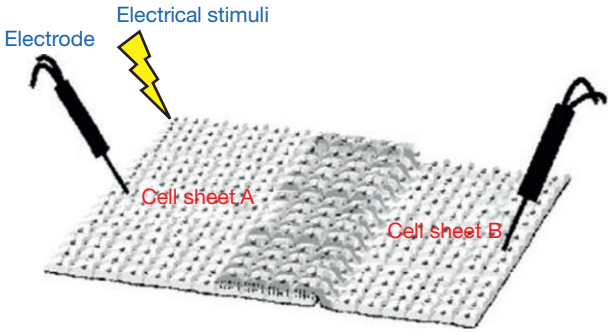

Figure 6 Electrical communication between layered sheets. Two cardiomyocyte sheets (a, b) detached from PIPAAm-coated culture dishes are overlaid partially for examining the electrical synchronization. Two electrodes are set over monolayer parts of both cell sheets to detect the electrical potentials separately. Reproduced with permission from Shimizu, T.; Yamato, M.; Kikuchi, A.; Okano, T. *Biomaterials* **2003**, *24*, 2309–2316.

(Figure 7). This agrees with the established fact that the ECM side of the bone marrow mesenchymal stem cell multilayered cell sheet significantly enhanced the adhesion of the multilayered cell sheets onto the surface of normal heart tissue for more than 30 min after the transplantation in large animal models (Figure 8). ECM proteins, which are one of the key factors in tissue regeneration, are distributed on the bottom of the cell sheet and directly contact the host heart tissue. The presence of ECM on cell sheets reduced the time required for creating stronger adhesion between cell sheets and heart tissue. Histological and scanning electron microscope analysis indicated that the transplanted cell sheets were almost totally separated from native heart tissue at 30 min posttransplantation. This study clearly indicated that the existence of ECM proteins facilitated the attachment process between cell sheets and native heart tissue in a shorter amount of time.[78]

Several reports show that three gap junction proteins, connexin-43, connexin-45, and connexin-40, have been found in mammalian cardiac myocytes. These proteins form channels with different electrophysiological properties and have different distributions in cardiac tissues with disparate conduction properties.[50] Precursors are detected on the free cell membrane as well as on the cell-to-cell interface. We found that connexin-43, a gap junction-related protein, existed not only at cell-to-cell interfaces but also on the free cell membrane in the cardiomyocyte sheet. Moreover, only connexin-43 was identified between bilayer cardiomyocyte sheets within 30 min of layering; neither connexin-40 nor connexin-45 was detected. We also confirmed that connexin-43 is preserved upon the harvest of cardiomyocytes from temperature-responsive culture dishes, and the protein may facilitate a rapid electrical coupling between layered cell sheets.[77]

In cardiac tissue engineering, electrical and structural cell-to-cell tight junctions are critical to synchronized, functional beating because they are very important in the electrical and morphological communication that is established between two cell sheets. In comparison to the general approach of the enzymatic seeding of dissociated cells into biodegradable scaffolds, cell sheet engineering is advantageous in that it enables rapid formation of gap junctions and functional communication between layered cardiomyocyte sheets.

Cells are less compact when biodegradable scaffolds are used, and the material used to fabricate the scaffold may itself be electrically obstructive. However, cell sheet engineering that layers cell sheets fabricated on temperature-responsive culture dishes to form 3-D structures results in rapid gap junction formation and functional communication between layered cardiomyocyte sheets.[26,27] The transplantation of cardiomyocyte sheets to reverse damage caused by myocardial infarction also promotes electrical communication and coupling between cell sheets and host tissue due to the presence of initial gap junction precursors for direct cell-to-cell communications.

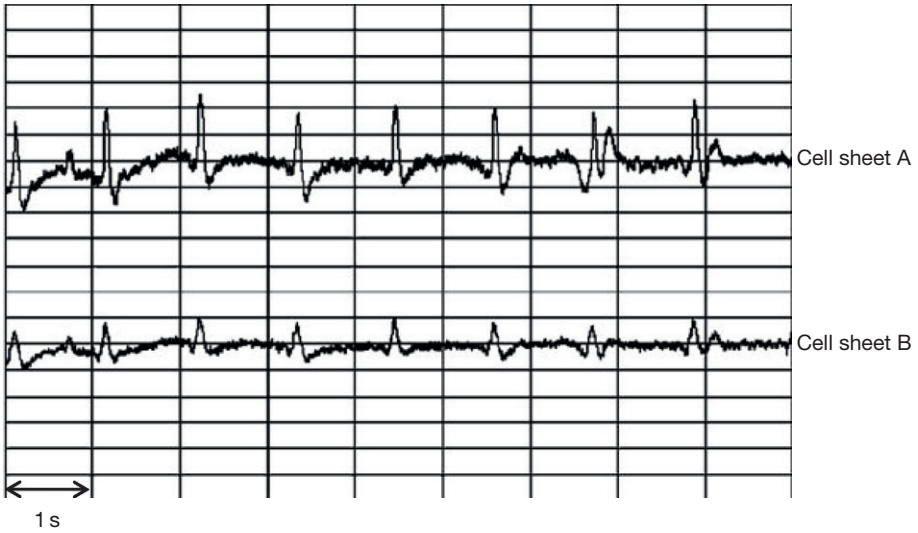

Figure 7 Schematic illustration of electrical analysis of layered cardiomyocyte sheets. Synchronization of layered cardiomyocyte sheets. Representative tracings of electrical potentials of cell sheet A and B show complete synchronization. Figure 8 The multilayered sheets (three layers) from bone marrow-derived mesenchymal stem cells (MSCs) of a pig were transplanted onto the myocardium of the left ventricle with the ECM-side (a). Histological analysis of heart-sheet by hematoxylin-eosin staining (b) and azan staining. Collagen-rich epicardium was identified as a blue band by azan staining (c). At 30 min posttransplantation, the adhesion between the cell sheet and the native heart tissue has been significantly detected.

5.530.2.2. 3-D Manipulation of Cardiomyocyte Sheets

As previously discussed, when cardiomyocyte sheets are used alone or layered, they electrically couple and display impressive functional characteristics. However, the establishing of a method for growing functional multilayered 3-D structures continues to be a significant challenge. *In vitro*, triple cell layers (the thickness: ~100–130 μm) are recognized to be the maximal number of layers for cell sheets (Figure 9). In an effort to build a thicker construct, quadruple- and quintuple-layered cell sheets were assembled by stacking one- to three-layered constructs. We were attempting to simulate the presence of blood vessels to allow tissues to attain greater thickness.

In cardiac cell sheets, we observed cardiomyocyte clusters surrounding areas enriched with endothelial cells. This finding suggests that the endothelial networks are activated by both direct cell-to-cell interactions and secreted proteins from cardiomyocytes. On this ground, a mutually beneficial relationship between cardiomyocytes and endothelial cells is likely to contribute to the formation of endothelial cell networks *in vitro*. Neovascularizations within the grafts were observed to start promptly after the implantation, and the vascular networks were organized after a few days *in vivo*. The observed blood vessel reconstruction was completed by endothelial cell networks that originated from within the graft.[79] These newly

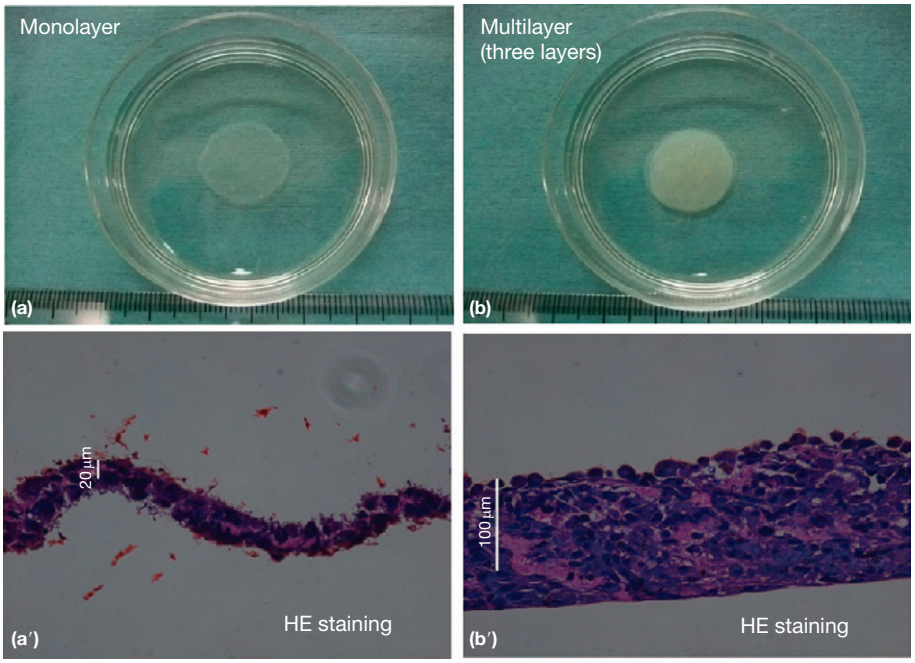

Figure 9 Multilayered construct made from bone marrow-derived mesenchymal stem cells. Photographs and histological cross-section of cell sheets from bone marrow-derived mesenchymal stem cells. (a) Cell sheet composed of a monolayer of MSCs and (b) cell sheet composed of three layers of MSCs. Each cell sheet is ~20 mm in diameter; (a′) the thickness is ~50 μm for monolayer and (b′) the thickness is ~20 μm for three layers of MSCs. Scale bars: 100 μm.

formed graft-derived arterioles also sprouted into the underlying host tissue to form functional connections with the host vasculature. Similarly, endothelial cell networks *in vitro* formed functional microvessels and sprouted into the host tissues after the transplantation.

In cardiac cell sheets harvested from temperature-responsive culture dishes, their deposited ECM is preserved, and the cell sheets are also able to retain intact and undisrupted endothelial networks as well as the expression of angiogenesis promoters such as VEGF and HGF. By controlling the endothelial cell population within the cardiac cell sheets, a potential for vascularization can also be regulated, which may resolve the limits of mass transport in the manufacture of thick and functional tissues. However, perfusion flow and shear stress are necessary to form mature vascular networks under *in vitro* conditions.[80,81] Most thick layers are simply unable to supply enough oxygen and nutrients for growing tissue. On the contrary, living human heart muscle is up to 2 cm thick. When three sheets are layered, the innermost cells are far from the supply of fresh growth medium and struggle to thrive.

One approach to sidestepping the problem is by growing single layers of cells that can then be implanted into an animal's body to create functional 3-D tissues.[26,27] Neonatal rat cardiomyocyte cell sheets, which consisted of monolayer to triple layers, were stacked, one on top of another, until they fused, and then multilayered cardiac cell sheets were implanted into the dorsal subcutaneous tissue of immunodeficient rats, using the animal body itself as a bioreactor for creating a 30-layered cell sheet with a final thickness of ~1 mm.

A critical obstacle facing cardiac tissue fabrication is the inability to constantly and rapidly supply sufficient vascularization to prevent necrosis. This obstacle prevents the unlimited stacking of additional cell sheets. Two days after the transplantation, the separation of two grafts by connective tissue was observed (Figure 10). Three days after the transplantation, two grafts were completely separated by thick connective tissues and were electrically dissociated. By contrast, when triple-layered cell sheets were transplanted ten consecutive times, with one-day intervals between implantations, spontaneous and synchronized pulsation was observed (Figure 11). The surface electrograms of the sheet were detected independently from the host electrocardiograms 3 weeks after the transplantations.

One month after the procedure, the constructs were retrieved and analyzed. We observed cell-dense, thick tissues with whole tissue survival and well-organized microvascular networks. Constructs with three or fewer layers survived without necrosis. Quadruple- and quintuple-layered constructs formed *in vitro* demonstrated disordered vasculature and connective tissue. Azan staining of the decupled triple-layered graft revealed that the construct had multilayered cell-dense myocardium and well-organized microvessels throughout the transplanted tissues. The engineered cardiac tissue demonstrated spontaneous beating and was vascularized by host blood vessels, which could be observed macroscopically when the skin was opened 6 months later. These engineered synchronously beating heat-like tissues survived for over 1 year. Thus, we conclude that the serial stacking 'polysurgery' with cell sheet technology can overcome the critical thickness-restricted limitation caused by passive diffusion limit and allows us to grow 3-D structures that contain more than a few layers of muscle cells and functional myocardial tissue.

We are also attempting to move toward reconstruction of organ-like structures, using tissue-engineered cell sheets.

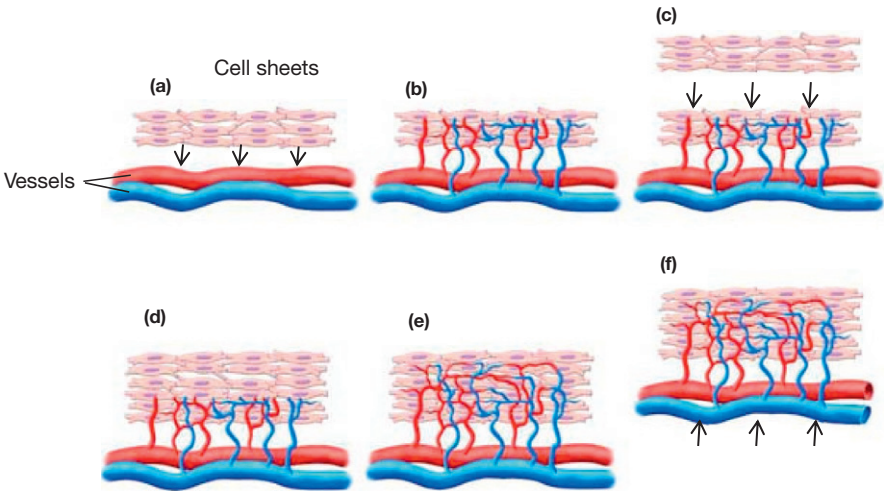

Figure 10 Schematic illustration of bioengineering multilayer grafts with surgically connectable vessels (a). Graft was transplanted over a surgically accessible artery and vein (b). The graft was supplied with both new vasculature and blood directly from the existing vessels in this case (c, d). After sufficient vascularization had occurred in the first graft, the second graft was then transplanted onto the first graft (e, f). Eventually, the microvascularized construct accompanied by graftable vessels harvested from the host is fully perfused by host vessels and surgically resected. Reproduced with permission from Shimizu, T.; Sekine, H.; Yang, J.; *et al*. *FASEB J*. **2006**, *20*.

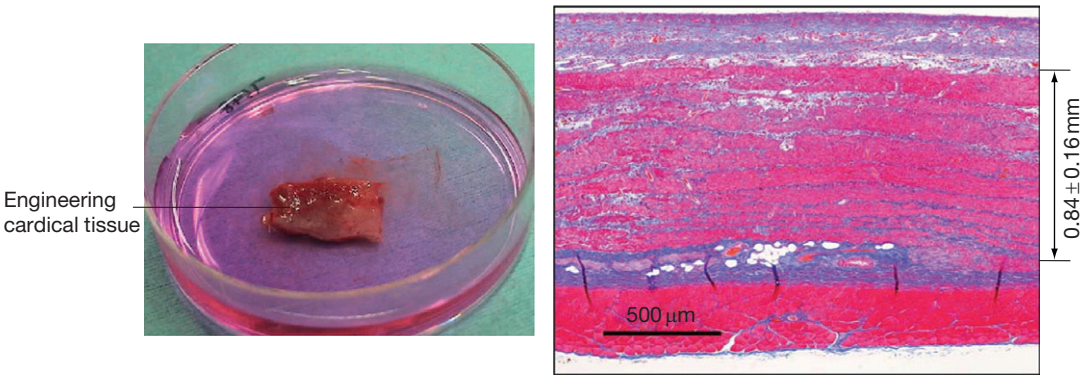

Figure 11 The engineered cardiac tissue by using 10-times polysurgery was beating and blood vessels had permeated it (left side). Azan staining shows that multilayer cell-dense myocardium with well-organized microvessels can be created by using 10-times polysurgery with a 1-day interval. Bidirectional arrow indicates viable myocardial cell sheet layers. The measured thickness of the grafts was 0.84 ± 0.16 mm. Data are mean $\pm$ SD ($n = 3$). Reproduced with permission from Shimizu, T.; Sekine, H.; Yang, J.; *et al*. *FASEB J*. **2006**, *20*.

In cardiac tissue engineering, the ultimate goal is the creation of a functional myocardial chamber that pumps blood around the body, with the ability of generating significant independent pressures from its spontaneous contractions.[82,83] In this regard, we have given the construction of pulsatile myocardial tubes a potential for circulatory support *in vivo*.[84] Three neonatal rat cardiomyocyte sheets were harvested and wrapped around fibrin tubes, using a novel cell sheet-wrapping device. The tubular constructs demonstrated spontaneous, synchronized pulsation within 3 h of cell sheet wrapping. The tissue-engineered myocardial tubes presented measurable inner pressure changes induced by tube contraction (~.15 mmHg). Histological analyses revealed both well-differentiated sarcomeres and diffuse gap junctions within the myocardial tissues that resembled native cardiac muscle. These data indicate that tissue-engineered myocardial tubes have native heart-like structure and function.

We have created myocardial tubes by wrapping six neonatal rat cardiomyocyte cell sheets around a resected rat aorta. These are potentially capable of providing independent cardiac support. We believe that the construction of pulsatile myocardial tubes will provide *in vivo* circulatory support. Sextuple-layered cardiomyocyte sheets were wrapped around the 1.5 cm portion of resected thoracic aorta from adult rats *in vitro*. The myocardial tubes were then transplanted into the abdomen of other nude rats to connect abdominal aorta by cuff method with sutures[19] (**Figure 12**). The implanted myocardial tubes provided a spontaneous and synchronized pulsation 4 weeks after the transplantation. The myocardial tubes produced a circulatory supportive blood pressure of 5.9 ± 1.7 mmHg, independent of the host hearts (**Figure 13**). Interestingly, 4 weeks after the transplantation, the thickness of the aortic replacement tubes was significantly higher than the myocardial grafts that had simply been inserted into the abdominal cavity; this was due to the pulsations created by blood flow within the lumen of the aortic replacement tubes and had an inductive effect on generating thicker, hypertrophic

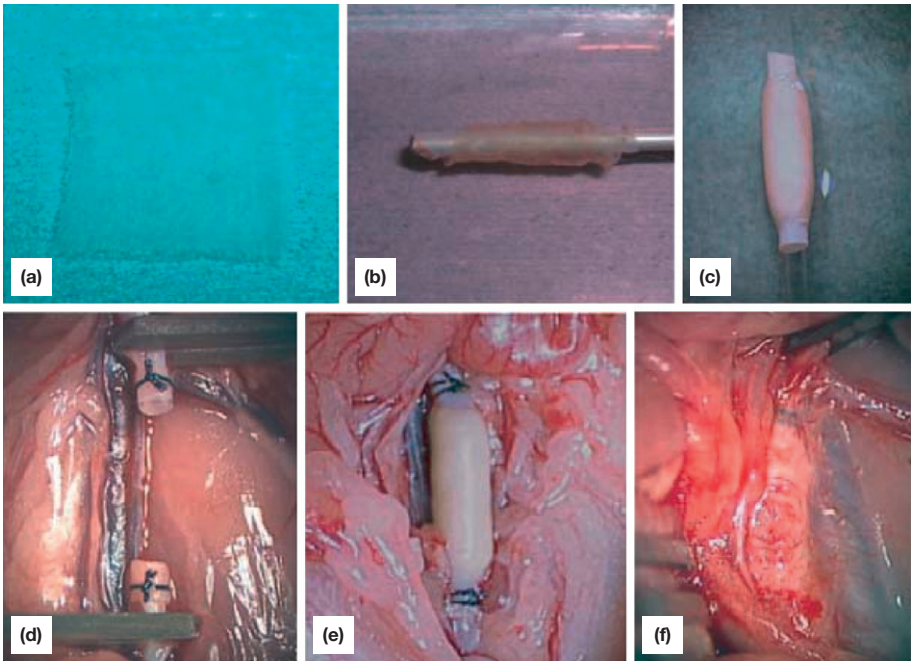

Figure 12 Fabrication and transplantation of myocardial tubes. Cardiomyocyte sheets detached from temperature-responsive culture dishes (a) were sequentially wrapped around a resected thoracic aorta (b) to manufacture six layers of myocardial tubes *in vitro* (c). After the clamping and resecting of the host abdominal aorta (d), the myocardial tube is anastomosed to host vasculature (e). Four weeks after the aortic replacement, the myocardial tubes integrated with the host tissues (f). Reproduced with permission from Sekine, H.; Shimizu, T.; Yang, J.; Kobayashi, J.; Okano, T. *Circulation* **2006**, *4*, 88–93.

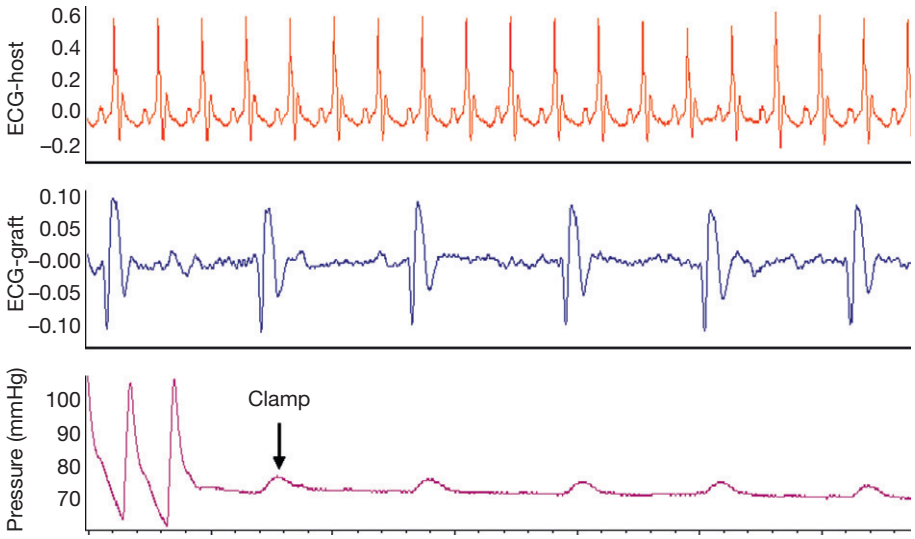

Figure 13 The implanted myocardial tubes provided a spontaneous and synchronized pulsation four weeks after the transplantation. The myocardial tubes produced a circulatory supportive blood pressures of 5.9 ± 1.7 mmHg, independent of the host hearts. Reproduced with permission from Sekine, H.; Shimizu, T.; Yang, J.; Kobayashi, J.; Okano, T. *Circulation* **2006**, *4*, 88–93.

myocardial tissues. These findings suggested that the hypertrophy of the functional myocardial tube is induced by mechanical stretching due to host blood flow pulsation within the lumen of the tube.

By growing tissues in the body cavity of artery and vein, it is conceivable to create an environment that duplicates the conditions for the development of a normal tissue. Using cardiomyocyte sheets wrapped around fibrin frameworks, we are continuing to develop tissue-engineered myocardial tubes for producing functional tubular structures that can act as potential cardiac assist devices. On the basis of these findings, we assert that layering of cardiomyocyte sheets has a significant edge over the use of biodegradable scaffolds in creating cell-dense, functional myocardial tissues.

5.530.2.3. Production of Multilayer Myoblast Sheet Constructs *In Vitro*

We were experimenting with the use of an animal's body itself as a bioreactor to create 3-D manipulations of cardiomyocyte sheets *in vivo*. This method faces challenges such as production of multilayer cell sheets *in vitro*, preservation of 3-D cell-dense thick tissues that can keep heart-like tissues beating during implantation until the patient's own vessels begin to colonize the implant, and furtherance of improvements in dealing with hypoxia, nutrient insufficiency, and the accumulation of waste products affecting the survival of 3-D cell-dense thick tissues after transplantation. Most researchers are working on ways of simulating the presence of blood vessels in or around the scaffold to allow tissues to achieve greater thicknesses. It has been reported that endothelial cells can be cocultured with other cell types to form capillary-like networks *in vitro*, using scaffold-based 3-D cell culture[85] or scaffold-free 3-D cell aggregate culture.[86] However, some common drawbacks of the use of scaffolds are insufficient cell migration into the scaffolds and host inflammatory reactions. In contrast to the conventional scaffold-based tissue engineering, we used cell sheet stacking manipulation technology and designed prevascularized 3-D cell-dense tissues.[87]

Human umbilical endothelial cells (HUVECs) were sandwiched between two myoblast sheets by a gelatin-coated plunger. Then, the sandwiched construct was transferred onto an FBS-coated dish. The double-layer myoblast sheet construct containing HUVECs was cultured with sterile endothelial growth medium (EGM-2) for 3 days. The inserted HUVECs formed network structures after 3 days of culture (**Figure 14**).

To further examine the organization of prevascularized tissues *in vitro*, we attempted to produce quintuple-layered myoblast sheet constructs containing HUVECs between the layers collected by the fibrin-coated plunger. The endothelial cells connected through the layers and partially formed capillary-like structures in the quintuple-layered myoblast sheet constructs after 4 days of culture. We also confirmed that the quintuple-layered myoblast sheet constructs with endothelial network have the ability of neovascularization *in vitro*.

Myoblast sheets with or without HUVECs were stacked up to five layers, and two types of five-layer myoblast sheet constructs combined with fibrin gel were engrafted on the dorsal subcutaneous tissue of immunodeficient rats after 4 days of culture. One week after the transplantation, capillary-like networks were connected to the host vessels and a number of microvessels containing red blood cells were observed in the HUVEC-positive transplanted grafts (**Figure 15**). These results suggest that prevascularized myoblast sheet constructs with HUVECs can induce functional anastomosis. A rapid and sufficient vascularization is important for the survival of 3-D cell-dense thick tissues after transplantation.

A practical approach to solving this problem is making endothelial cell networks in engineered tissues before transplantation. Moreover, the transplantation of engineered myocardial tissues containing capillary-like networks enhances neovascularization and improves the cardiac function of ischemic hearts.[79] Therefore, the preparation and setting up of prevascularization in engineering tissues before anastomosis to the surrounding host vessels is important. Using ell sheet stacking manipulation technology, we fabricated prevascularized cell dense tissue constructs *in vitro* and examined the contribution of these constructs *in vivo*. This cell sheet engineering-based 3-D sandwich coculture system can enhance the cellular density and orientation of inserted endothelial cells by the microfabrication techniques of culture surfaces such as patterning[88] and microtexture.

Multilayered cultures that combined micropatterned endothelial cells as vascular precursors, with fibroblast monolayer

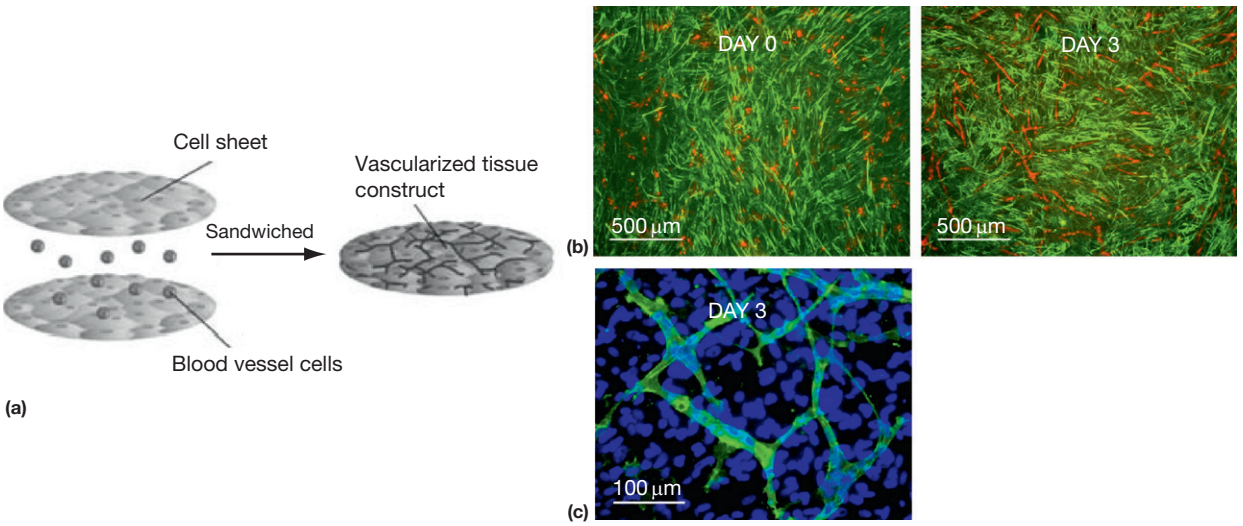

Figure 14 Formation of endothelial cell network in double-layered myoblast sheet construct. (a) Schematic illustration shows the vascularized tissue fabrication strategy by sandwiching blood vessel cells between two cell sheets. (b) The human umbilical vein endothelial cells (HUVECs) were sandwiched between two myoblast sheets by a gelatin-coated plunger. This sandwich construct was transferred onto another culture dish to culture. Sandwiched HUVECs and the cells formed on the myoblast sheet were strained with UEA-I (the red color) and antidesmin antibody (the green color), respectively. (c) The networked cells were stained with antihuman CD31 (the green color). Nuclei were counterstained with Hoechst 33342 (the blue color). Reproduced with permission from Sasagawa, T.; Shimizu, T.; Sekiya, S.; *et al*. Biomaterials **2010**, *3*, 1646–1654.

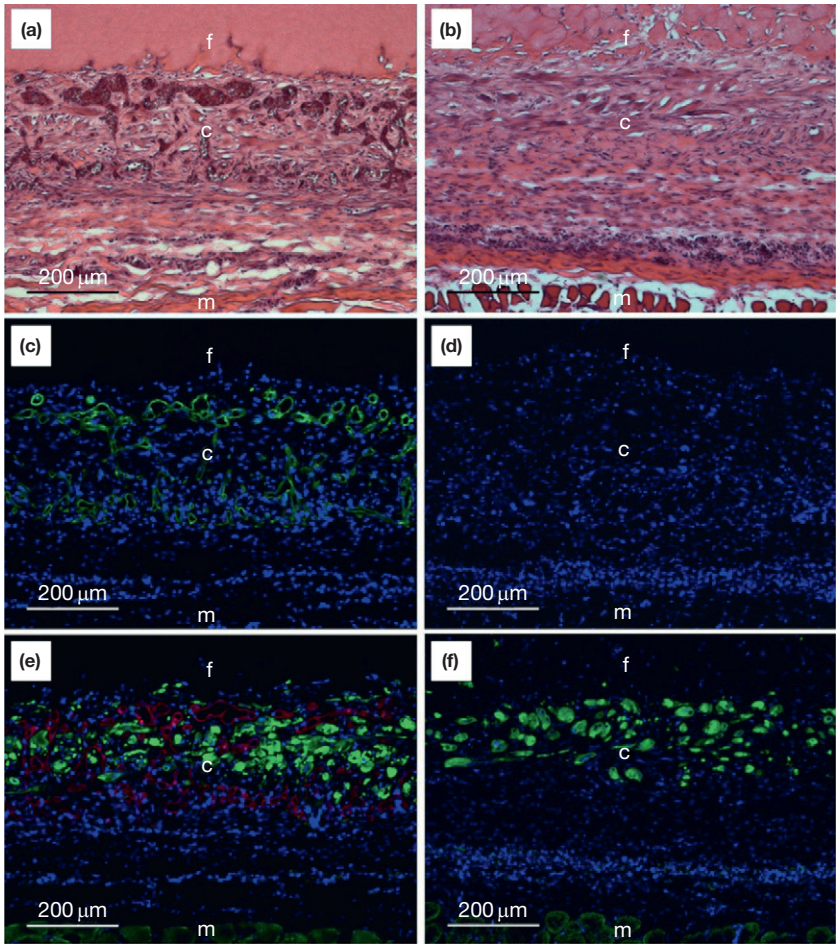

Figure 15 Induction of neovascularization by the transplantation of five-layer myoblast sheet constructs containing endothelial networks. The left and the right are the five-layer myoblast sheets with and without human umbilical vein endothelial cells (HUVECs), respectively. The specimens of the transplanted constructs in the first row (A and B) were stained with hematoxylin and eosin at one week after the transplantation. The specimens in the second row (C and D) were stained with antihuman CD31 antibody (the green color). The microvessels containing host blood cells were observed in HUVEC-positive specimen (C), but no stain was seen in HUVEC-negative specimen (D). The specimens in the third row (E and F) were stained with antidesmin antibody (the green color) and human endothelial cell-specific lectin (UEAI) (the red color). The nuclei of both the specimens were also counterstained with Hoechst 33342 (the blue color). The marked region with f, c, and m are the fibrin gel, the cell sheet construct, and the muscle tissue of the animal, respectively. Reproduced with permission from Sasagawa, T.; Shimizu, T.; Sekiya, S.; *et al.* Biomaterials **2010**, *3*, 1646–1654.

sheets as tissue matrix, were used to fabricate prevascularized tissue equivalents. Stratified tissue equivalents are constructed by alternately layering fibroblast monolayer sheets with patterned endothelial cell sheets harvested from temperature-responsive micropatterned surfaces, alternating 20-mm-wide cell-adhesive lanes with 60-mm nonadhesive zones. Cell culture substrates covalently coated with different thermoresponsive polymers permit the spatial switching of cell attachment and detachment, with the application of slight temperature changes. Endothelial cell patterning fidelity was maintained within the multilayer tissue constructs after assembly, leading to self-organization into microvascular-like networks after 5 days of tissue culture. This technique holds promise for the study of cell–cell communications and angiogenesis in reconstructed, 3-D environments as well as for the fabrication of tissues. Prevascularizing methods, using cell sheet stacking manipulation technology, provide substantial scope for the development of various types of 3-D tissues and for the furtherance of regenerative medicine. These can also shorten the time for connecting the cell sheet vascular system in secret to the host vascular system.

5.530.3. Clinical Application of Cell Sheet Tissue Engineering

5.530.3.1. Heart Failure Therapy by Using Cell Sheet Engineering

Many clinical trials in the field of regenerative medicine, such as corneal reconstruction,[20,21] esophageal transplantation, and blood vessel construction,[36–38] have successfully applied cell sheet engineering. Several tissue engineering applications have also utilized the cell sheet technique. Nearly all organs are complicated multilayer tissues composed of various types of cells. For this reason, multilayered cell sheets from multipotent mesenchymal stem cells (MSCs) or cardiomyocytes

may be a useful technology for organ repair[18] (Figure 16). In both acquired and congenital heart defects, a large number of myocardial cells are damaged and lose their functions. One of the clinical approaches to the treatment of myocardial injury is the repair and regeneration of the damaged tissue through the direct transplantation of stem or myocardial cells into the injured area.[89–92] Unfortunately, this approach has failed to live up to its potential in applications in clinical trials. Although direct injection of cells can successfully mend small damaged areas,[93,94] repairing the large areas of ischemic damage requires lab-grown patches of cell sheets. In addition, the direct injection of cells into the heart is hazardous because of possible blockage of circulatory pathways, which might result in more life-threatening complications. Also, injected or transplanted cells are unable to fuse stably with the host heart tissue following the transplantation. Therefore, it is important to improve adhesion between the host heart and the transplanted cells for localizing the cells directly onto the host heart wall.

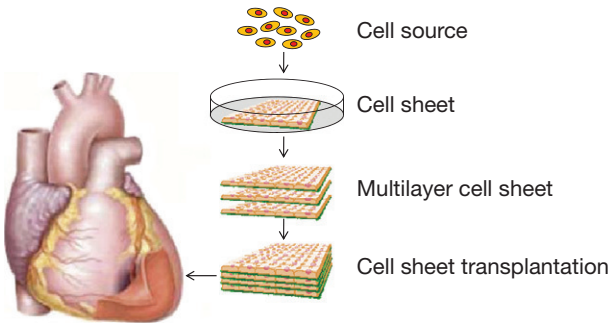

Figure 16 Cardiac patch cell sheet engineering. Cardiac myocyte sheets are harvested from temperature-responsive culture dishes when the temperature is reduced from 37 to 20 °C. Three or four cell sheets are stacked together to form a multilayered sheet that retained all cell–cell contacts. The multilayered sheets are then transplanted to ischemic hearts as cardiac patches. Reproduced with permission from Shimizu, T.; Yamato, M.; Kikuchi, A.; Okano, T. *Biomaterials* **2003**, *24*, 2309–2316.

Cell sheet transplantation may be a promising strategy for partial cardiac tissue reconstruction. Cell sheets assembled from autologous MSC were used to treat a patient suffering from dilated cardiomyopathy (DCM). DCM is one type of chronic heart failure whose pathology is characterized by global myocardial remodeling, which mainly consists of myocardial fibrosis associated with changes in the cytoskeletal and sarcolemmal proteins in cardiomyocytes, leading to a reduction in the number and function of these cells.[95,96] Today, medical therapy has improved the prognosis of heart failure, such as left ventricular remodeling operations, implantable defibrillators, and cardiac resynchronization.[97] However, mechanical support using left ventricular assist device (LVAD) and heart transplantation are the accepted ultimate lifesaving means for supporting these patients.[98,99] The patient had been fitted with an LVAD till the time that a donor heart became available. However, cardiac transplantation has limitations, such as donor shortages, rejection, and infection, and the usefulness of an LVAD is limited by its durability. Therefore, novel strategies are necessary for treatment of ischemic cardiomyopathy.

The skeletal myoblast sheets were transplanted onto the patient's heart.[100] Muscle tissue from the patient's thigh was collected because cells differentiate through a way similar to those found in the heart. Ten skeletal myoblast sheets ~4 cm in diameter were created by growing the cells on temperature-responsive culture dishes. After removal from the dish, the cell sheets were transplanted onto the patient's heart (Figure 17). As the cells in the sheets continued to produce growth factors, they were able to improve the damaged heart's function significantly. Three months after the transplantation of the cell sheets, the echocardiography demonstrated that the dilated left ventricle (LV) dimension was significantly reduced, the heart showed a progression of LV dilation, and the patient was able to get off the LVAD. The brain natriuretic peptide (BNP) was significantly reduced from ~1000 to 10 pg ml^{-1}. The transplanted sheets enhanced the left ventricular ejection fraction and allowed the patient's weakened heart to grow strong. After 6 months, the patient was able to walk out of

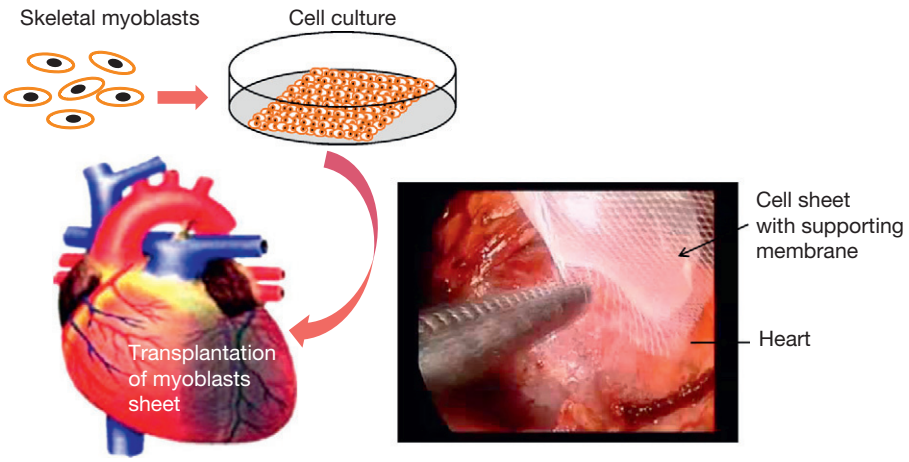

Figure 17 Skeletal myoblasts from patients were cultured on temperature-responsive culture dishes to form cell sheets to treat cardiomyopathy (left side). Ten skeletal myoblast sheets approximately four centimeters in diameter were transplanted onto the patient's heart by supporting membrane (right side).

hospital. The transplantation of cell sheets improves cardiac performance and prolongs life expectancy.

Additionally, the longer preservation of cardiac performance by sheet-shaped myoblast implantation in DCM in an animal model was investigated by using cell sheet technology.[101] Myoblasts isolated from hamsters were cultured on temperature-responsive culture dishes to produce the cell sheets. After the sheet-shaped myoblast grafts were implanted, the echocardiography demonstrated that the dilated LV dimension was significantly reduced, and the hearts were found to have a progression of LV dilation. Three months after the operation, the LV wall thickness was increased with viable myoblasts. These findings suggest that the implantation of myoblast grafts can preserve cardiac performance and decrease the extent of myocardical remodeling.

The adult heart lacks reserve cardiocytes and cannot regenerate on its own. Therefore, a large acute myocardial infarction often develops into congestive heart failure. Monolayered cell sheets prepared from adipose tissue-derived mesenchymal stem cells have multipotent and self-propagating properties after transplantation into infarcted rat heart.[25] Adipose tissue-derived mesenchymal stem cells characterized by flow cytometry were cultured on temperature-responsive culture dishes to prepare a monolayer cell sheet, which was then transplanted onto the scarred myocardium of rat. The engrafted sheet gradually grew to form a thick stratum that included newly formed vessels after transplantation. The mesenchymal stem cell sheet also acted through paracrine pathways to trigger angiogenesis, reversed wall thinning in the scar area, and improved the cardiac function in rats with myocardial infarction. Thus, the transplantation of monolayered mesenchymal stem cells may be a novel strategy for cardiac tissue regeneration. The cell sheet system made on temperature-responsive dishes provides a powerful advanced tissue engineering matrix that can be easily transplanted and applied in various tissue engineering indications. Cardiac tissue engineering based on cell sheet engineering is feasible for clinical cardiovascular tissue repair.

5.530.4. Conclusions

These cell sheet manipulation techniques can be applied to various cell types and tissue structures. As cardiomyocyte sheets containing intact gap junction precursors in addition to deposited ECM give rapid and complete electrical communications, 2-D or 3-D cell sheets can be manufactured. Cell sheet engineering is recognized to be a useful, fundamental, and generalized technology for next-generation tissue engineering and regenerative medicine.

Acknowledgments

We are deeply grateful to Prof. Masayuki Yamato, Prof. Tatsuya Shinmizu, Dr. Hidekazu Sekine, Dr. Yuji Haraguchi, Dr. Tadashi Sasagawa, and Dr. Sachiko Sekiya for their contributions to this study. We also appreciate Dr. Norio Ueno, Dr. Todd McAllister, Ms. Marissa Peck and Prof. Hossein Hosseinkhani for proofreading this manuscript. This work was supported in part by the Center of Excellence (COE) Program for the 21st Century, the High-Tech Research (HRC) Program from the Ministry of Culture, Sports, Science, and Technology and the New Energy and Industrial Technique Development Organization (NEDO) of Japan.

PNI	Peripheral nerve injury
PNS	Peripheral nervous system
PPE	Poly(phosphoester)
PTFE	Polytetrafluoroethylene

5.531.1. Introduction

In the United States, 200 000 peripheral nerve injuries (PNIs) occur each year.[1] In cases where the gap is small (~<10–12 mm), spontaneous regeneration occurs, where the blood clot/fibrin bridge enables Schwann cells to play a significant role by their proliferating and migrating into the nerve gap, successfully physically bridging the gap between the proximal and distal nerve ends, and promoting axonal regeneration. However, in cases of more severe injuries, causing a more significant gap (>10 mm), the migration of Schwann cells into the gap is limited and regeneration is compromised. In such cases, surgical intervention by means of implantation of an autograft, allograft, or a tissue engineered nerve guidance conduit (NGC) is necessary to serve as a bridge to physically reconnect the severed nerve ends together.[2,3] The focus of this chapter is to review engineered biomaterials and how their interplay with extracellular matrix (ECM) proteins, trophic factors, and cells may be used to aid in peripheral nerve regeneration.

5.531.1.1. Anatomy and Physiology of the Nervous System

Anatomically, the nervous system is complex with a physical and biochemical architecture that allows it to control and modulate the function of other organs. The nervous system is composed of two main components, the peripheral (PNS) and the central (CNS) nervous systems. The CNS is located inside the cranial and spinal cavities and the PNS is subdivided into the sensory-somatic and the autonomic nervous systems. The sensory-somatic nervous system consists of the cranial and spinal nerves and the autonomic nervous system consists of sensory and motor neurons between the CNS and the internal organs. The nervous system consists of the neurons and the supporting glia, which have synergetic roles to play in the proper functioning of the nervous system. In the PNS, the neurons play a significant role in the transfer of information and are composed of a soma (cell body), an arbor (dendritic tree), which does not extend beyond a few millimeters, and the axon, which carries the impulses over long distances, from a few centimeters to meters. The dendrites play a major role in

receiving and processing chemically rich synaptic inputs and then transmitting electrical signals to and from the neural soma. An axon, on the other hand, typically extends from the soma to target organs and tissues and transports information through electrochemical signals to and from the CNS.[4]

On the other hand, the glial cells usually account for 90% of total cell numbers in the nervous system and play very diverse roles, depending on their location, usually ranging from insulation to production of a growth and regenerative milieu. In the PNS, the major glial cell type are the Schwann cells, and they myelinate axons, enabling fast electrical propagation, and also produce key proteins that are vital for the survival, regeneration, and maintenance of the nervous system.

On the basis of functional classification, the peripheral nerve axons are subdivided into those with motor functions and those with sensory functions. The motor neurons connect the muscles to the CNS; meanwhile, the sensory neurons play roles where senses of touch, vision, and taste are involved. However different their roles might be, structurally motor and sensory axons are composed of a bundle of connective tissue forming an anatomically defined trunk.

5.531.1.2. Peripheral Nerve Injury: Degeneration and Regeneration

Common causes of PNI are trauma, tissue resection due to plastic surgery, or tumor removal and congenital defects. Based on the type of injury, the axon is usually damaged, leading to a disruption of neuronal contiguity with or without a physical gap, leading to loss of motor or sensory functions. In such cases, the distal part of the axon is separated from the cell body, and the axons begin to degenerate; the degeneration is termed as anterograde or Wallerian degeneration. Waller described these changes using a frog injury model in the PNS.[5] The degeneration mechanism involves dissociation of the distal stump from the nutrient rich cell body and an upregulation of calcium-dependent protease activity.[6] On the other hand, due to the lack of contact with an innervating muscle or organ, slight degeneration of the proximal portion of the axon occurs over a short distance, which is termed retrograde degeneration.

Retrograde degeneration however does not affect the survival of the axon as specific proteins and cell markers begin to infiltrate into the site, playing a major role in the survival of the axon. Postinjury, the cytoskeleton of the supporting glial cells degrades and the Schwann cells surrounding the distal end of the axon shed their myelin lipids. This event causes the Schwann cells in the proximal and distal nerve portions to proliferate. Also, an increased influx of macrophages occurs, and along with the Schwann cells, begins to clear up debris from the degenerated axon fragments present in the nerve segments.[7] This is usually followed by a remodeling at the site of injury and the formation of a fibrin cable. This further enhances the influx of glial cells and blood vessels, which provide nutrients for the regenerative process and the survival and targeting of the ensuing axon along this cable.

Schwann cells and macrophages, apart from playing major roles in the signaling and repair of an injury site, produce critical cytokines, growth factors, and ECM proteins, which help in regeneration across the nerve gap, either with or without surgical intervention.[8–11] Also, mast cells proliferate at the injury site and produce copious amounts of histamine and heparin, which affect the vascular permeability and facilitate proliferation of yet more macrophages into the wound site. In cases with small nerve gaps or successful surgical intervention, regeneration starts at the proximal end and extends toward the distal end, being rich in nutrients as a result of connection to the cell soma. Here, the Schwann cells play a significant role in the regenerating process by flooding the microenvironment with growth-promoting factors and biological compounds as well as creating a conducive basal lamina, composed of aligned matrix proteins known as the Bands of Büngner, which form the path for axonal migration and reconnection with the distal end.[12] Some of the most common factors that the Schwann cells produce for matrix modification are collagen, fibrin, and laminin, and they also produce diffusive cues or neurotrophic factors that are essential for the survival of axons and axonal migration.[13,14] An understanding of the process described above is important as it is the basis for some of the regeneration promoting strategies described below.

5.531.2. Current Approaches to Bridging Nerve Gaps

5.531.2.1. Physical Versus Biological Contributors to Peripheral Nerve Repair

Injury to the nerve in the PNS can result in spontaneous regeneration if the gap is within 4 mm. For this phenomenon, various cellular and molecular events occur that provide both a physical and biological support for regeneration. Nerve gaps that are between 4 and 10 mm can be sutured together. The severing of the nerve requires surgical treatment, referred to as direct repair, where the two ends of the nerve are sutured together. There are three types of direct repair: (1) end-to-end, (2) end-to-side, and (3) epineural sleeve. If the tension within the nerve is too great, then direct repair no longer remains an option and the alternative is the use of nerve or synthetic grafting. Therefore, current strategies to regenerate the PNS incorporate both the physical and biological attributes.

5.531.2.2. Biological Grafts and Synthetic Nerve Guidance Conduits

Throughout the progression of peripheral nerve regeneration, various forms of grafts and conduits have been developed and investigated. Autografts, allografts, and synthetic NGCs have been studied to determine which one regenerates the peripheral nerve allowing full functional recovery; this involves looking at the electrophysiology, behavioral analysis, histology, and weight conservation of the innervating muscle.

5.531.2.2.1. Biological-based grafts

Autografts and allografts provide a similar microenvironment to that of the distal segment of a damaged nerve. The use of autografts emerged in the late nineteenth century and soon after was implemented clinically. After further refinement of the required surgical skills, autografts have now proven to be the 'gold standard.' Although autografts are the preferred therapeutic treatment for PNI, if the deficit in the nerve is large, or if donor nerves are limited as a result of disease or other factors, the availability of an autograft is limited and an alternative

becomes necessary. Allografts can also be used to promote full functional recovery in the PNS. However, the main disadvantages in using a nerve allograft are the host rejection, possible risk of disease transmission, and complications due to immunosuppression. The development of acellular nerve grafts involves eliminating the immunogenic host response to nerve allografts. This was done by decellularizing the graft and leaving the ECM components intact. It has been demonstrated that the length of axonal growth in acellular grafts was similar to that in cellular grafts up to a 20 mm distance, and clinically restoring motor function and sensation[15]; however, axons failed to extend through the entire 40 mm gap.[16] It has been shown that when ECM, trophic factors, and various cell types are utilized in the grafts, there are increased number of axons, the migration of endogenous Schwann cells that aid in the axonal growth through the graft, and improved vascularization. In more recent studies, further treatments have been applied to make the acellular grafts more conducive for axonal growth and promote endogenous Schwann cell migration. Pretreatment of the acellular autograft or allograft with vascular endothelial growth factor improved the migration of endogenous Schwann cells and neovascularization, where as the treatment with nerve growth factor (NGF) increased the number of axons that grew into the graft.[17] In the same study, laminin was also used in the pretreatment of the acellular graft, but no beneficial effect was observed.[17] In another study, the acellular nerves were treated with promoting biomolecules; however, in another short duration study, the acellular allografts were pretreated with chondroitinase ABC, an enzyme that cleaves the glycosaminoglycan side chains of chondroitin sulfate proteoglycans, which are inhibitory to axonal growth, and it was demonstrated that there was a significantly higher number of axons entering into the graft compared to controls.[18] Studies also investigated the beneficial effect of cells cultured within acellular grafts. When isogenic Schwann cells were cultured within the acellular grafts, the grafts did not display improved number of axons compared to the control grafts.[19] However, in another study, in a primate long nerve gap injury, autologous Schwann cells in the cold-preserved allografts displayed enhanced nerve density and fiber counts compared to that in the controls.[20] In a study using Rhesus monkeys, autologous nonhematopoietic mesenchymal stem cells were implanted into acellular allogenic grafts that bridged a 40 mm nerve gap, and it was demonstrated that after 6 months, the ulnar nerves were structurally and functionally repaired to an extent similar to that of autologous nerve grafts.[21]

Other biological alternatives to using cellular and acellular nerve autografts and allografts have been veins, muscles, and arteries as biological nerve conduits to bridge nerve gaps. The vein wall is made up of three layers, the laminin-rich basal lamina, the muscle layer in the middle, and the adventitia, which is collagen rich. In a study, the vein was turned inside out so that the adventitia is the inner lumen.[22] This change presented the growth promoting collagen to the regenerating axons, thus demonstrating a greater number of axons entering into the graft.[22] Vein grafts injected with Schwann cells demonstrated axons regenerated across the entire nerve gap,[23] as well as evoking muscle action potentials and new myelinated nerve fascicles similar to autografts.[24] A study compared the use of only a nerve graft with that of a nerve graft within a vein conduit graft to determine whether the number of axons, nerve conduction, and gait function were enhanced; however, there was no significant difference.[25] Besides veins, arteries were also used as potential grafts to bridge the nerve lesion. In a study that compared the axonal regeneration through nerve, muscle, and arterial grafts, the artery-based graft did not exhibit promising properties and it was concluded that arteries should not be utilized.[26] Although the failure of the use of the artery graft was published, Rodrigues and Silva later published a study that compared the arterial graft to an inside-out artery graft, similar to the inside-out vein graft conducted by Wang *et al.* Axons were present in the inside-out artery graft, where as the standard artery graft had axons that were surrounded by connective tissue.[27] For muscle grafts, the appealing feature of using this biological graft is the thick basal lamina that surrounds the muscle, which is similar to the vein and artery basal lamina, providing growth promoting proteins. Acellular muscle grafts in a 6 mm nerve gap in a mouse model demonstrated that the remaining basal lamina tubes allowed axons to regenerate through the graft, forming thick myelinated fibers.[28] Fawcett and Keynes demonstrated that the muscle basal lamina bridging a 40 mm nerve gap had an increased number of axons into the distal stump and improved functional limbs recovery compared to nerve autografts.[29] Although vein and muscle grafts have shown to have regenerating myelinated axons, problems such as collapsing of the vein grafts and axons growing outside of the muscle grafts have led to studies that combined both the muscle and vein grafts. The muscle was used to fill the vein graft to prevent collapsing. When comparing nerve, vein, and muscle grafts with the combination of vein and muscle, it was found that only the vein and muscle grafts were inferior in performance compared to the combination, which provided a functional recovery similar to that of the nerve grafts, and greater number of axons.[30] Similar results were also seen in other studies.[31,32] In a study to understand the microenvironment that makes the combined vein–muscle graft successful, it was determined that within 5 days of the graft implantation, endogenous Schwann cells were present within the graft, as well as the neurotrophins, NGF, and brain-derived neurotrophic factor (BDNF).[33]

Because of disadvantages with the nerve auto- and allografts, other biological grafts were investigated. However, compared to the autograft, axonal regeneration and functional recovery remain unsatisfactory in the other grafts and do not match autograft performance. Therefore, the development and use of synthetic NGCs and other biological alternatives have been appealing and further investigated.

5.531.2.2.2. Biomaterials and tissue engineered nerve guidance conduits

Although autografts are successful in facilitating regeneration across large nerve gaps (>10 mm), they have drawbacks such as limited availability, size mismatch, and importantly loss of function at the donor site. With the advent of several microtechnologies, nanotechnological tools and biomaterials tissue engineered grafts have been developed and applied as conduits to evaluate their ability to regenerate nerve gaps. Several classes of materials ranging from natural to synthetic and nonbiodegradable to biodegradable have been fabricated for repair and regeneration of peripheral nerve conduits typically with a

tubular conduit design to physically bridge the two nerve endings. The tubular architecture provides a closed physical environment to allow for concentration and accumulation of cells, growth factors, and other ECM components. It also provides a barrier that limits the migration of undesired macrophagic cell types into the site of injury. Nerve conduits also serve as a platform to include exogenous surface bound and topographical guidance cues, 3D gels, and nano/microcarriers for controlled release of critical growth factors such as NGF, glial-derived growth factor (GDNF), neurotrophin-3 (NT-3), and BDNF.

Among the first polymeric materials to be used as a nerve conduits were silicone grafts.[34] Grafts made of silicone were considered as a gold standard among artificial nerve conduits, and studies with other materials and fillings, such as collagen, were compared against those with silicone-based materials.[35,36] However, impediments in the application of silicone to human subjects for regeneration of large nerve conduits, such as the nonbiodegradable nature and inherent rigidity of the graft, lack of allowance for swelling of the regenerating nerve, as well as causing compressive stresses and scarring on the nerve, caused failure of the implant to regenerate large gaps.[37] Also, as suggested earlier, in order to enhance the rate and the quality of regeneration, several 'filler' materials have been included into the lumen of the tubular silicone-based nerve conduits. Some of the common biological materials to be tested as fillers and conduits include collagen, laminin, a cocktail of growth factors in saline, fibrin, and even tissues such as gut, muscle, vein, and subintestinal mucosa. Also, several nondegradable materials such as PTFE-,[38,39] polycarbonates-,[40] and nylon-based[41] constructs have been used for repair of PNIs, albeit only limited repair was observed (**Figure 1**).

5.531.2.2.3. Filler materials for nerve guidance conduits

Natural biomaterials, such as collagen, have been used as fillers in the nonbiodegradable materials and have enhanced their performance when compared to unfilled or saline filled tubular constructs.[36] This can be attributed to the fact that autografts, the current gold standard, are composed of a matrix essentially made of collagen and other basement membrane proteins such as laminin and fibronectin, and allografts are typically decellularized collagen grafts. Collagen-based nerve conduits perform similar to autografts over short lengths.[42] A collagen-based microstructured three-dimensional (3D) NGC containing numerous longitudinal guidance channels with dimensions resembling natural tubes has been produced.[43] Bozkurt *et al.* showed that the grafts enhanced Schwann cell migration, axonal regeneration, and even formation of significant bands of Büngner. Also, several blends of collagen with other materials such as collagen with polycaprolactone (PCL) and collagen with chitosan have been developed and have shown improved performance as compared to the single components in its entirety. Patel *et al.* have shown enhanced sensory and motor neural functions using blends of collagen and chitosan, 12 weeks postimplantation in a rat model.[44,45]

However, collagen may be associated with an immune response, and isolating collagen from the patient or a different species remains challenging. In order to minimize the immune activity of collagen, gelatin, a thermally denatured collagen, has been applied as a nerve conduit. Several studies have shown enhanced regeneration in gelatin containing scaffolds, with gelatin either in entirety or as a blend with common materials, such as PCL[46–53] or poly (lactide-*co*-glycolic) acid (PLGA).[54–61] Several gellation techniques have been employed to fabricate gels based on gelatin.[62–70] Commonly, photocurable gelatin, genipin cross-linked,[63,67,70–72] and glutaraldehyde cross-linked gelatin[62,65,67,73] have been employed as grafts for regeneration across nerve gaps.

Another natural biomaterial, fibrin, has demonstrated positive outcomes in the peripheral nerve regeneration. The use and favorable results of fibrin as a material may be due to its critical role as a fibrin clot in the wound healing process, and it forming an oriented matrix that guides cell migration across the length of injury.[74,75] Also, fibrin binds to neurotrophic factors that are critical in the regeneration process, and fabrication of fibrin-based hydrogel scaffolds has the advantage of not requiring any cytotoxic chemicals or reagents unlike collagen- or gelatin-based scaffolds.[76,77]

Several studies have also shown that hydroxyethylated agarose has appropriate mechanical, charge, and stiffness characteristics to support 3D neurite extension and regeneration across nerve gaps.[78–86] Functionalized agarose-based scaffolds have

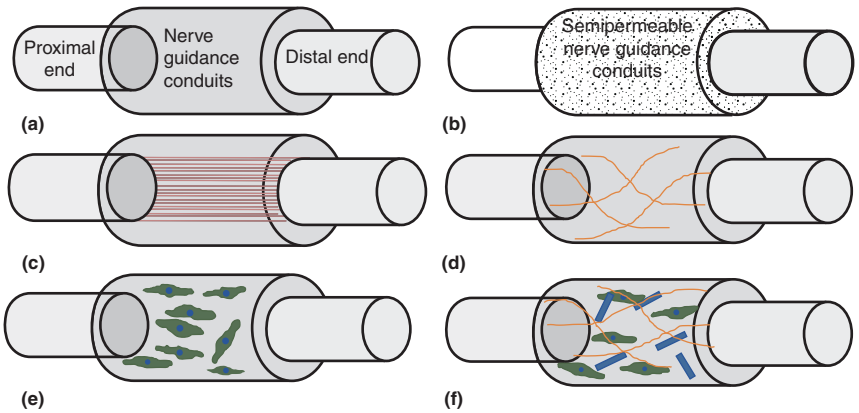

Figure 1 Therapeutic strategies for peripheral nerve regeneration. (a) Nerve gap bridged with nerve guide conduits (NGCs). (b) Semipermeable NGCs. (c) Aligned nanofiber-filled NGCs. (f) Example of a combinational strategy containing hydrogel matrix, slow releasing delivery vehicles and transplanted cells within NGCs.

demonstrated regeneration comparable to autografts across 10 mm nerve gap. Agarose, being thermally phase reversible does not require any secondary cross-linking agent and also allows for functionalization with suitable growth factors and ECM proteins such as laminin.[2,82,86,87] It has been demonstrated that several blends of agarose, usually collagen[88] or chitosan,[80,81] have shown promising regeneration in the PNS and CNS.

Additionally, chitosan has been promising as a scaffolding material for nerve repair.[46,89–98] It provides several surface active moieties that allow for functionalization, is not water soluble and therefore does not necessarily need an external cross-linking mechanism, and more importantly has shown to possess electron conductive properties, which are essential in the regeneration process, especially in the nervous system. Also, chitosan can be fabricated into films, blends, nanofibrous mesh-like scaffolds, and hydrogels. However, there have been studies that have shown some macrophage responses to chitosan implantation, leading to inflammation and ultimately rejection of the implant in longer study durations.

Other natural biomaterials, such as alginate,[99–106] hyaluronic acid,[107–113] cellulose,[107,114] and dextran[115–117] have been used to promote regeneration in the PNS. Unfortunately across these many systems, axonal regeneration has typically not been comparable to that of the autografts when the gaps are larger than 10 mm.

In order to overcome these drawbacks, several studies have shown the application of synthetic biodegradable materials for peripheral nerve regeneration NGCs. Some of the most common materials used for such applications are polyglycolic acid (PGA), poly lactic acid (PLA), and its copolymers PLGA. Also, PCL, poly anhydrides, and poly hydroxyl butyrates have been developed for such applications. One advantage of synthetic polymers is their capability to be fabricated to several architectures with micro and nanoscale control. Also, most of these polymers do not need any external cross-linking mechanism as they are soluble in organic compounds and only slowly degrade when exposed to water, usually via ester bond cleavage mechanisms. Some of the most common biomaterials and their associated studies with outcomes are delineated in **Table 1**.

Another interesting outcome of using a biodegradable matrix is the fact that it can act as a reservoir to include critical growth factors for peripheral nerve regeneration and the agents are usually released over long durations as needed by the regeneration process, as the material slowly degrades over time.

5.531.2.3. Scaffold Fabrication Strategies

Several fabrication techniques have been developed to fabricate scaffolds for peripheral nerve regeneration from synthetic and natural polymers. In the choice of the biomaterial and the fabrication process, it is essential to note that several factors might affect the response of neural cells on the scaffolds, which include material composition, end groups, and concentration, as well as macro-, micro-, and nanoarchitecture, porosity, and mechanical properties. Chemical composition has shown to affect the response of sensory neurons in several studies.[2,85,93,144,150] Some of critical considerations for materials choice, design, and fabrication of grafts for peripheral nerve include, but are not limited to, biodegradability at the rate of regeneration; optimal mechanical properties for ease of implantation, prevention of collapse, ability to suture easily, and allowing for diffusion of nutrients through the wall of the scaffold; and resistance to deterioration in chemical, mechanical, and biological properties upon sterilization.[2,46,47,59,90,131,151,152] Upon consideration of the above required properties, there are several principles by which scaffolds could be manufactured from biomedical polymers. Some of the procedures that are used include phase separation, solvent casting, electrospinning, extrusion based either from melts or solvents, photo-cross-linking, and gellation systems for hydrogels.

For the phase separation and solvent casting techniques, use of a suitable solvent–polymer combination is essential. Upon solvent evaporation the polymer usually exhibits a microfiber like architecture with appropriate mechanical properties and pore geometries.[153–157] Also, in order to enhance the porosity of the matrix, salt crystals of similar dimensions are usually included in the matrix prior to solvent casting. Upon scaffold fabrication, the scaffolds are leached in water to extract the salt from the scaffolds and leave behind a porous architecture. Furthermore, in order to obtain tubular constructs that mimic native nerves, molds of different shapes and materials have been shown to be suitable for tube preparation.[57,59,60,116,118,129,140,147,148,158,159] In order to create oriented architectures that mimic native nerves, combined techniques have been developed to construct grafts. Typically scaffolds with microchannel architectures that allow for guidance of axons across the grafts and also enhance nutrient diffusion into the scaffolds have been developed.[2,116,138,160]

Recently, melt-processing-based approaches have been used to fabricate nerve guidance channels. The inherent

Table 1 Biodegradable polymers for peripheral nerve regeneration

advantage of this technique is that it does not need a solvent to fabricate the required shape. However, as the temperatures are higher for fabrication of such systems, incorporation of temperature labile growth factors and cells becomes challenging. Several new polymer systems are currently being developed, where in the fabrication temperatures are in the physiological range, thereby allowing for incorporation of growth factors and cells.[46,134]

Anatomically, peripheral nerves are composed of an aligned matrix, which plays very critical roles in the contact guidance process, thereby orienting the regrowing or developing axons across the gap. Therefore, during the fabrication of grafts for PNS repair, consideration should be given to fabricate a matrix that mimics native ECM. Several studies have shown a favorable response in the regeneration process for aligned nanofibrous scaffolds as compared to scaffolds without a specific architecture (**Figure 2**).[2,3,50,125,126,137,161–166]

One other approach to create scaffolds with microarchitectures mimicking native ECM is via freeze drying. The advantage of this technique is that aqueous as well as organic solvents have been used to create scaffolds of required geometry. Also, this technique allows for fabrication of scaffolds from natural biomaterials such as collagen and chitosan. Furthermore, as this technique allows the use of aqueous solvents, incorporation of growth factors during scaffold fabrication can be achieved (**Figure 3**).[59,89,94,160,167–169]

5.531.2.4. The Use of Bioactive Biomolecules

During development, there are various families of molecules that allow for the growth of axons to make the connections to their targets; these include neurotrophic factors, ECM proteins, and intracellular signaling pathway molecules. In the previous section, we reviewed the use of synthetic grafts as replacement nerves. This section discusses the combination of the synthetic grafts with the use of biomolecules to promote axonal regeneration. Predominantly, neurotrophic factors, such as NGF, BDNF, and NT-3, are used in the PNS. The ECM molecules that are used are laminin, collagen, and fibronectin. These proteins act as a chemoattractant to Schwann cells and also are secreted by the cells to attract axons to extend. Oligopeptides from these proteins, such as RGD, YIGSR, and IKVAV, are also used instead of the whole protein to promote cell adhesion and migration. Typically these bioactive moieties are presented to the nerve gap using the conduits, filler materials, or nano/microparticles.

As mentioned earlier, growth factors, neurotrophic factors specifically, have an important role in neural development and in adult life for axonal regeneration. After injury, NGF is upregulated because of Schwann cells and other cells migrating to the injured area and releasing the neurotrophin. Another growth factor, fibroblast growth factor (FGF) has also shown to enhance axonal growth,[170] as well as angiogenesis.[171] When using biomaterials in conjunction with biomolecules, it is important to construct a scaffold that allows axons to extend through; has the mechanical integrity to support cell migration, such as that of Schwann cells, into the scaffold; allows the delivery of growth factors, such as neurotrophins, that encourage axonal growth; and integrates the scaffold and ECM.

In order to covalently couple proteins and oligopeptides to modify scaffolds, carriers, fibers, and conduits, different types of cross-linkers have been used. There are thermochemical bifunctional cross-linkers, such as 1,1′-carbonyldiimidazole (CDI), which can couple the protein to a surface. Another class of cross-linkers that have been used for PNS repair is photo-cross-linkers, which are activated by shining UV light.[82,87,172,173] Using UV light to photo-cross-link proteins to scaffolds allows the laser beam to create protein-based patterns in the hydrogel. In the study, UV laser beam was used to create protein channels through the agarose gel, providing directional cues for the neuritis.

As mentioned in an earlier section, agarose is a hydrogel that is used as a scaffold for PNS regeneration. Besides its favorable mechanical properties, the hydrogel is also beneficial for covalently coupling growth promoting molecules to the agarose hydrogel, which would mimic the microenvironment allowing for axonal outgrowth through the nerve gap into the distal nerve. *In vitro* studies have shown that tethering a growth promoting ECM molecule, such as laminin, to the agarose gel encouraged neurite outgrowth compared to a scaffold that did not have any modifications.[174,175] Oligopeptides have been cross-linked to the hydrogels as well. The oligopeptides that influence cell–matrix interactions include RGD, which is involved in the interaction between fibronectin and an integrin receptor, and YIGSR, a peptide on the β1 chain of laminin aiding in cell attachment.[176] In an *in vivo* study, laminin was covalently coupled to the agarose scaffold contained within a polysulfone tube and a slow release system of NGF within the agarose was implanted within a nerve gap, demonstrating that regenerated myelinated axons were comparable to the regeneration found in autografts across 10 mm gaps.[86]

There are other hydrogels that are made from ECM proteins. Matrigel, NeuroGel™, and Biomatrix are three of those hydrogels. Matrigel is a mixture of laminin and collagen, which when embedded with Schwann cells has shown to promote axonal regeneration.[177,178] NeuroGel™, made of *N*-2-(hydroxypropyl) methacrylamide, used for regeneration in the CNS, has shown beneficial properties.[179,180] Lastly, Biomatrix is another hydrogel composed of ECM proteins; however, other hydrogels have shown to be more beneficial.[181]

Polymeric fibers have also been used to direct axonal growth through the nerve gap. For regeneration, the fibers are contained within an NGC and the ends are sutured to the proximal and distal nerve ends. Poly (L-lactide) (PLLA) is a common polymer used to make the fibers. In an *in vitro* study, laminin was coated around the PLLA fibers, which demonstrated significantly greater neurite outgrowth compared to uncoated PLLA and poly-L-lysine coated fibers.[182] Besides using the full laminin protein, oligopeptides, YIGSR, and IKVAV were tethered to various polymeric biomaterials to improve neurite extension.[174,183,184]

The third polymeric surface that presents ECM and trophic factors is NGCs. NGCs have been extensively reviewed elsewhere;[185–188] therefore, only NGCs that have been used to present trophic factors and ECM molecules to promote axonal regeneration are discussed here. In one study, NGF was encapsulated into poly(phosphoester) (PPE) microspheres and were then loaded into the NGCs. It was demonstrated that the density, diameter, and population of the fibers at the distal

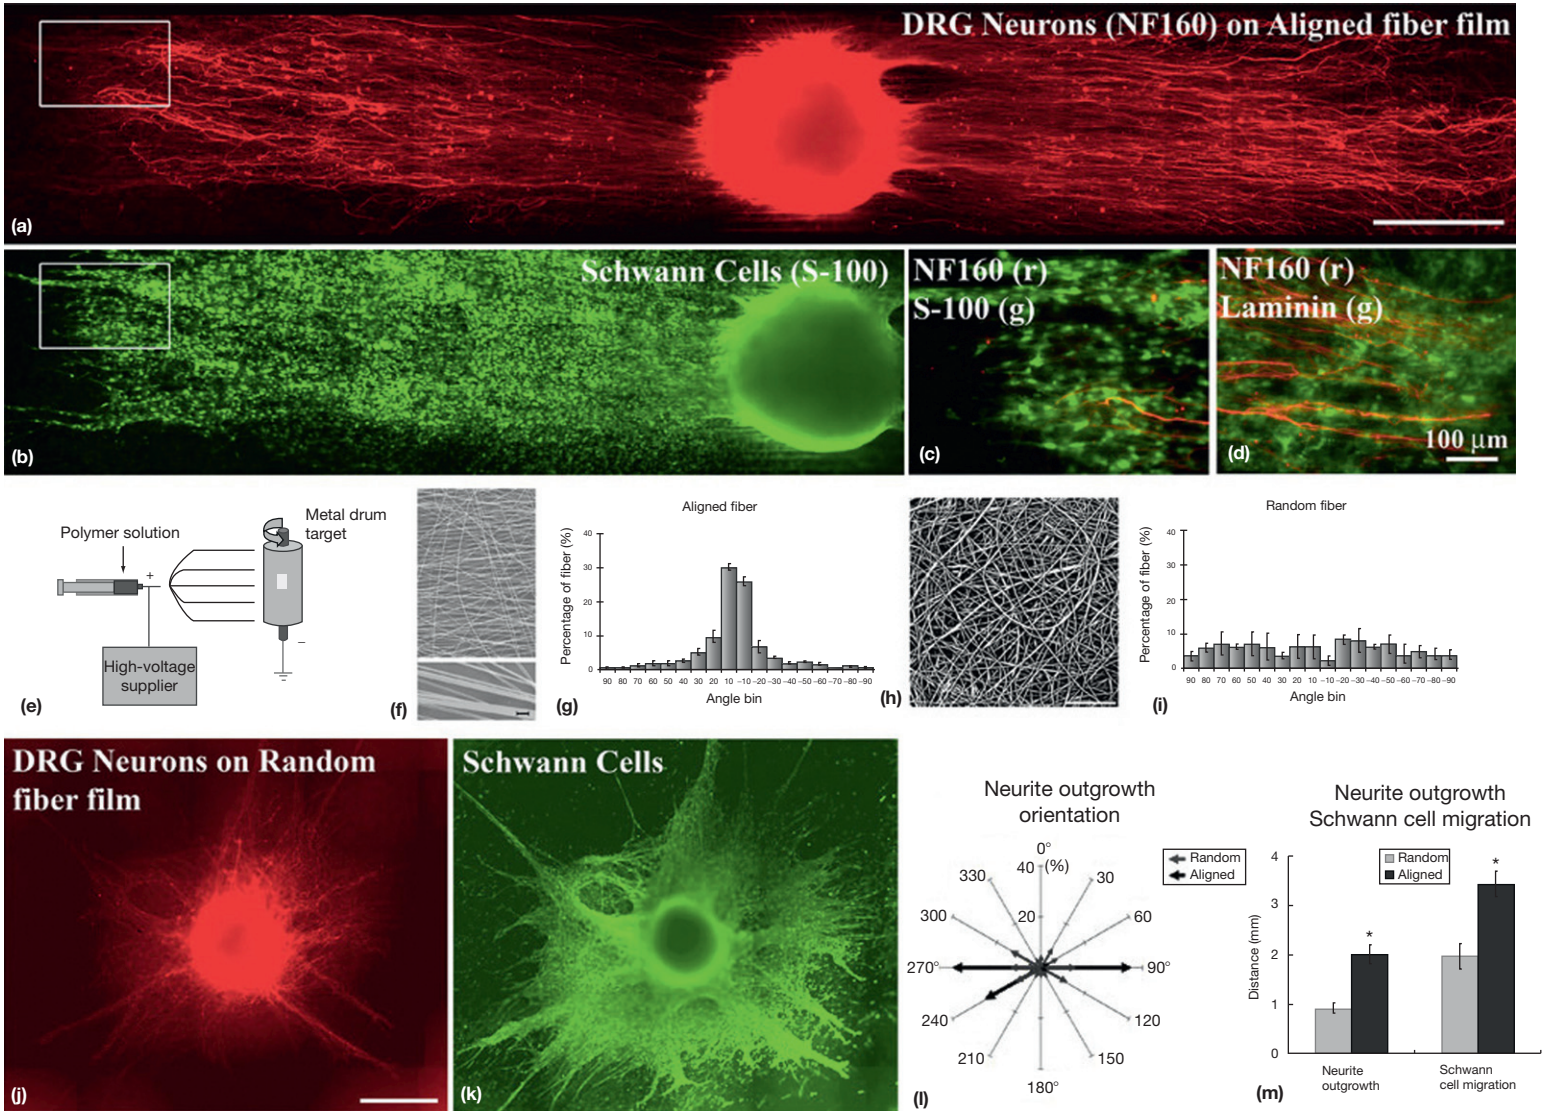

Figure 2 Dorsal root ganglia (DRGs) on aligned and random fiber film *in vitro*. (a–d) Double immunostained DRG on the aligned fiber film: (a) representative montage of NF160 (a marker for axons) immunostained DRG neurons on the film and (b) montage of S-100 (a marker for Schwann cells) immunostained Schwann cells on the film. (c) Magnified NF160 (red, from box in (a) and S-100 (green, from box in (b) overlapped image. (d) Double immunostained aligned axons (NF160, red) and endogenously deposited laminin protein (laminin, green). (e–i) Fabrication of the fiber films and distribution of alignment of the films. (e) Schematic of aligned fiber film fabrication by electrospinning process. Random fiber film was deposited on a flat metal target instead of on a high-speed rotating metal drum. (f and h) Representative SEM image of the aligned fibers (f, magnified fibers below) and the random fibers (h). Scale bar = 1 and 30 μm, respectively. Distribution of fiber alignment in aligned (g) and random fiber (i). (j and k) Double immunostained DRG on the random fiber film: (j) representative montage of $NF160^+$ neurons and (k) $S\text{-}100^+$ Schwann cells. Scale bar = 500 μm. (l) shows the quantitative comparison of orientation of neurite outgrowth on the aligned and random fiber film. Direction of arrows indicates the orientation of neurite outgrowth, and length of arrows indicates the rate of occurrence (percentage) ($n = 25$ per DRG). (m) shows the quantitative comparison of the extent of neurite outgrowth and Schwann cells migration on the films. The distance between the longest neurite outgrowth ($n = 25$ per DRG)/the furthest migrated Schwann cells ($n = 10$ per DRG) and DRG was measured and averaged. $^*P < 0.05$. Error bar = SEM. Reproduced from Kim, Y. T.; Haftel, V. K.; Kumar, S.; Bellamkonda, R. V. *Biomaterials* **2008**, *29*, 3117–3127, with permission from Elsevier.

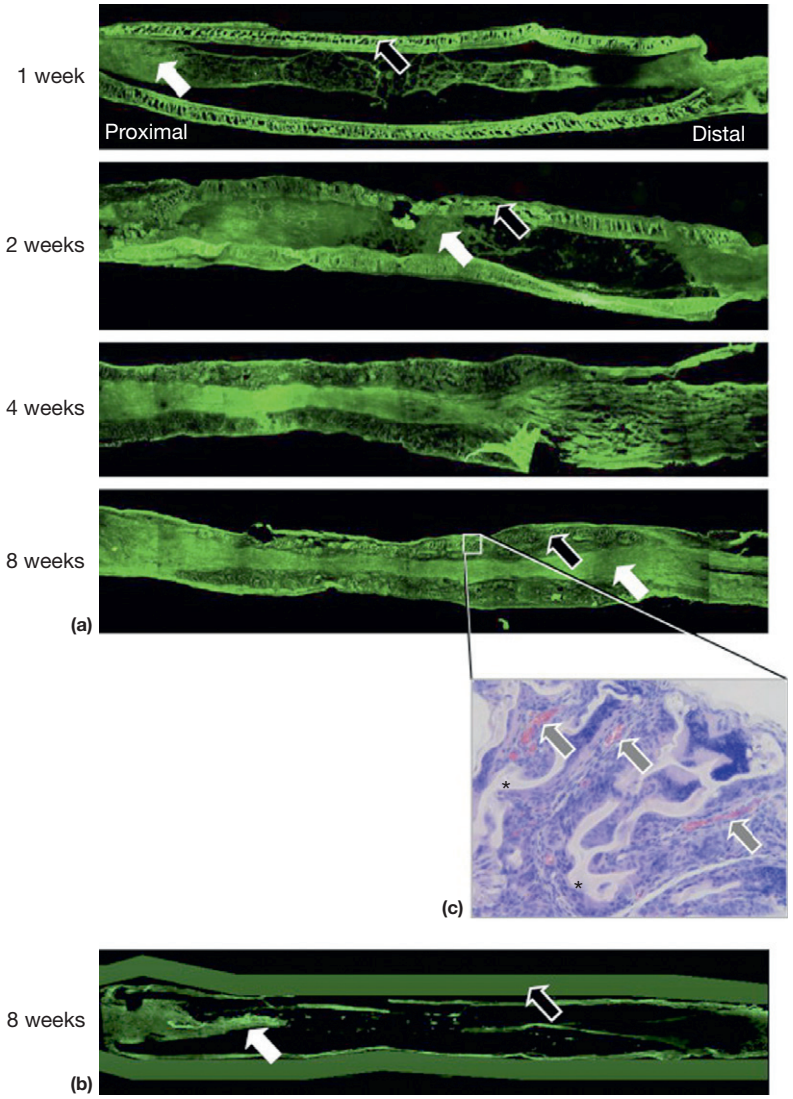

Figure 3 Longitudinal sections of the regenerated nerve through (a) PLGA/F127 (3 wt%) and (b) silicone tubes (anti-neurofilament staining, ×4; white arrow, regenerated nerve; black arrow, tube wall), and (c) cross-sectional view of PLGA/F127 (3 wt%) tube wall showing the existence of blood vessels infiltrated inside the wall (H&E staining, ×400; gray arrow, blood vessel; asterisk, PLGA/F127). nerve end were significantly greater than that of the axons found in empty conduits.[189] In a similar study, NGF was encapsulated into the PLGA microspheres and then mixed into the polymeric NGC solution to fabricate either single or multiple lumen NGCs. It was shown in conditions with the multiple versus single lumen, as well as NGF mixed into the polymer solution without microspheres, that there was no significant difference in neurite length for *in vitro* cultures. In a subsequent study, NGF was used to coat the inner lumen of poly(2-hydroxyethyl methacrylate-*co*-methyl methacrylate) (PHEMA-*co*-MMA)-based conduits using three different methods for encapsulating NGF into the NGCs: (1) NGF encapsulated in a PLGA microsphere, which was then added to the polymer solution prior to fabricating the NGCs, similar to the Xu *et al.* study; (2) NGCs were fabricated and then soaked in a NGF solution; and (3) studies were performed by Shoichet's laboratory where NGCs were fabricated with chitosan or PHEMA-*co*-MMA and then the inner lumen was coated with microspheres encapsulating NGF.[130,131] Of the three different NGF embedded conduits, the NGF mixed in the polymeric solution and then used to coat the inner lumen presented the greatest amount of NGF release over a 30-day period; however, *in vitro* or *in vivo* biological data were not published.[131] Another study investigated the release of NGF, but instead of using microspheres as the controlled release vehicle, two layers of PLGA were coated on the inner lumen of polyelectrolyte alginate/chitosan conduits, where the NGF was loaded between the two PLGA layers. This release system allowed for NGF to be released on the order of nanograms per day for 15 days.[190]

Lastly, the micro- and nanocarriers utilize various polymers to release trophic factors to promote axonal growth. The first of the carriers is microspheres. Studies have used microspheres

that are 12–16 μm in size to promote axonal regeneration. The polymeric materials that have mostly been used are PLGA, PLA, and PPEs. The use of copolymers and altering the ratio of polymers can affect the biodegradation profiles because of the polymeric characteristics, such as glass transition temperature and hydrophilicities.[191] In the previous section regarding NGCs, it was mentioned that microspheres encapsulating NGF were used. This has been the predominant utilization of the microspheres for PNS regeneration. In another study, NGF was encapsulated into PLGA microspheres, which were mixed into fibrin glue that surrounded the acellular nerve conduit in the microenvironment. Although the acellular graft surrounded by fibrin glue containing NGF microspheres had improved conserved muscle mass and improved axonal diameter, number, and myelination, the graft performance was inferior to that of the autograft.[192] It has been noted however that microspheres may elicit severe immunological response, thus leading to the engulfment of the microspheres by macrophages prior to any therapeutic benefit, and creating an obstruction to axonal regeneration.

Another delivery method to release protein for axonal regeneration in the nervous system is lipid microtubes or lipid-based 'hollow straws.' Lipid microtubes are hollow cylinders with an inner diameter of 0.5 μm (**Figure 4**).[193–196] The length of the microtubes can be altered during fabrication on the basis of the desired release profile of the biomolecule of interest. The microtube releases the molecule from the ends of the hollow tube through passive diffusion into the surrounding environment. To aid in axonal regeneration in the PNS, a two-step release system was developed. The first release step incorporated the diffusion of NGF from the microtubes to agarose, which filled an NGC. The second release entailed diffusion of the NGF from the agarose to the surrounding microenvironment.[86] This two-step release system allows the NGF to last longer in the nerve gap and prevents degradation or dilution by macrophages and other fluids. Two months postimplantation, the number of myelinated axons was comparable to that of autografts. A study was conducted that contained a fibrin matrix that had heparin tethered to the backbone, which interacted with neurotrophins. It was shown *in vitro* that the neurite outgrowth was enhanced by the neurotrophins released from the matrix rather than by soluble neurotrophins added to the matrix.[74] When the heparin immobilized fibrin matrix was implanted between the nerve gaps, fiber sprouting was observed at the distal end of the conduit.[76]

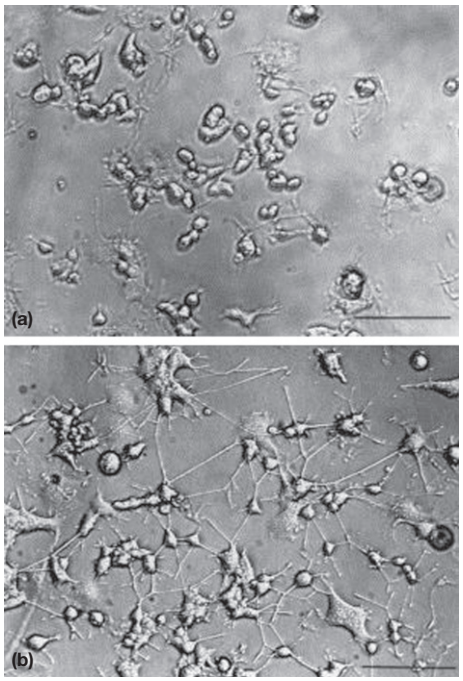

Figure 4 PC12 cells incubated with lipid microtubules loaded with (a) PBS and (b) NGF. PBS-loaded microtubules produced very little (<5%) neurite outgrowth (see (a)). Microtubules loaded with NGF were able to deliver sufficient NGF on their seventh day of release at 37 °C to induce PC12 cells to extend neurites (see (b)). Scale bar 100 μm. Reproduced from Meilander, N. J.; Yu, X.; Ziats, N. P.; Bellamkonda, R. V. *J. Control. Release* **2001**, *71*, 141–152, with permission from Elsevier.

Most of the delivery systems and scaffolds that have been mentioned thus far have uniformly distributed protein and trophic factors. However, during the developmental stages in the nervous system, proteins, trophic factors, and other molecules are presented in a spatially and temporally controlled fashion to regulate neuronal migration.[197] However, *in vitro* studies have shown that gradients of ECM proteins would promote axonal growth more than isotropic environments.[198] Recently, in an *in vivo* peripheral nerve regeneration study, anisotropic scaffolds were made of laminin and NGF. Laminin was covalently coupled to agarose and the NGF was delivered using microtubes. It was demonstrated that the anisotropic scaffolds had axonal diameter distribution, as well as conserved muscle weight, similar to that of the autografts, and both factors were significantly greater compared to those of the isotropic scaffolds (**Figure 5**).[82]

5.531.2.5. Role of Schwann cells in the Peripheral Nerve Regeneration Process

As described earlier, Schwann cells are the most abundant cells in the PNS. Their major roles include the process of myelination of axons,[199] provision of guidance cues to the regenerating axons (**Figure 6**),[132,161,200] secretion of critical growth factors for survival, and maintenance and regeneration of the PNS postinjury.[13] Also, several studies have indicated the enhanced potential of Schwann cells to produce growth factors when genetically altered to contain the gene of interest.[201] Considering these factors, Schwann cells are considered a major candidate for transplantation and application in the regeneration process.

Employing such hypothesis, several studies have shown the successful transplantation of Schwann cells within a synthetic nerve conduit.[60,101] However, the success of the regeneration process varies owing to several factors, mostly related to the source of the cells, cell number, and age of the patient. Mosahebi *et al.* demonstrated that the presence of Schwann cells in the graft enhanced the regeneration rate in a PNI model.[142,202,203]

However, this approach is hindered by the availability of Schwann cells for transplantation. Autologous source of Schwann cells is the most ideal source of cells; however, this approach is deemed unfeasible because the time required in

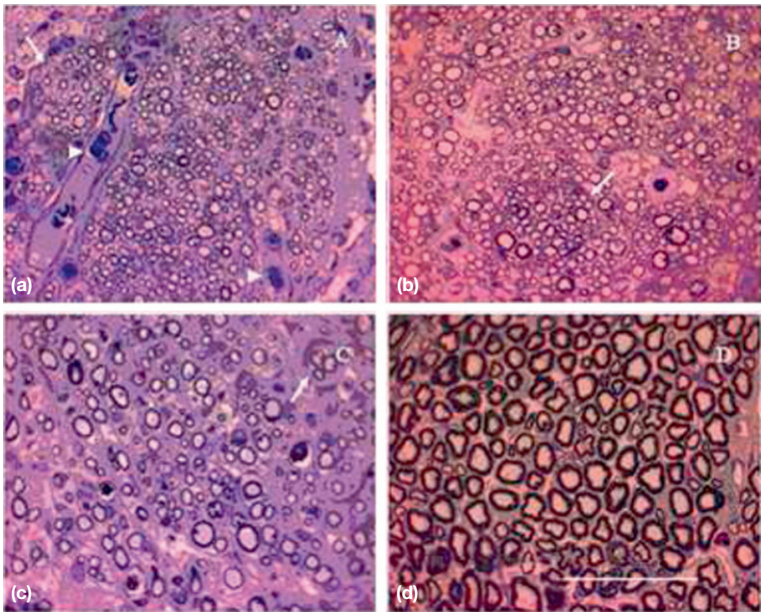

Figure 5 Light micrographs of nerve sections from groups with successful axonal regeneration. Toluidine-blue stained cross-sections at mid-length (10 mm) are shown here. Anisotropic scaffolds with step-gradient (a) and continuous-gradient (b) of LN-1, have higher density of axons and smaller-diameter axons than nerve grafts (c) and normal nerve (d). Note the fiber grouping in small fascicles (indicated by arrow) and presence of red blood cells (arrowhead). Scale bar 50 μm. Reproduced from Dodla, M. C.; Bellamkonda, R. V. *Biomaterials* **2008**, *29*, 33–46, with permission from Elsevier.

harvesting and expanding cells to sufficient quantities is very long, usually long enough that it causes retrograde axonal death and scar formation, thereby decreasing the chances of a complete functional recovery.[202,204] Several other approaches have been studied to mitigate retrograde degeneration of the axons, primarily by the application of neuroprotective agents or growth factors such as NGF that enhance the survival of the severed axon.[205]

On the other hand, allogenic source of Schwann cells allows for banking, postharvest, and expansion and the cells are available for transplantation in large quantities. However, this technique elicits immune responses and needs administration of immunosuppressive agents, which have other side effects. Mosahebi *et al.*, showed the application of allogenic Schwann cells, without the support of immune suppression.[142] They observed no significant enhancement in the regeneration, and on detailed analysis, it was observed that the immune related clearance of the allogenic Schwann cells implanted was much faster than the migration and beneficial effect of the Schwann cells that could be observed.

Meanwhile, several other studies have shown successful transplantation and outcome of Schwann cell containing grafts with immunosuppression.[206,207] Minimal rejection and enhanced regeneration have been observed in both these studies. However, the quality of functional recovery was minimal and had been attributed to the migration of Schwann cells in the graft and the uniformity of cell loading in the grafts. In order to overcome this, several studies have shown the application of ideal matrices with appropriate ECM chemistry,[208–211] contact guidance cues,[137,140,212] and nanotopographies to promote Schwann cells migration uniformly and completely into the scaffolds.[2,163] Also, several studies have employed a bioreactor-based approach to uniformly and completely seed grafts with Schwann cells in the inner lumen. Even though the studies did not include any *in vivo* studies, positive results in terms of increased Schwann cell attachment and proliferation were observed.[60,114]

Despite observing positive responses from the inclusion of Schwann cells in the grafts, more detailed studies are required to elucidate the interface between the role of Schwann cells and the regeneration process. Also, grafts that support uniform and complete cellularization with either allogenic or autologous source need to be developed if any significant improvement in the regeneration process is to be observed.

5.531.2.6. Stem Cells for Peripheral Nerve Regeneration

Recently, there has been a lot of interest in the application of stem cells for the regeneration of PNIs. The reason for this increased interest is the ability of the stem cells to differentiate into glial cells and neuronal cell lineages along with other cells that help in the regeneration process.[213–217] Bone marrow-derived mesenchymal stem cells have shown potential for transplantation in models of PNI and increased expression of markers for glial cell lineages, typically Schwann cell like, on exposure to suitable differentiation factors composed of a cocktail of growth factors and agents.[215,218–221] Several other studies have shown that undifferentiated mesenchymal stem cells implanted into nerve conduits in the PNI model stimulate axonal growth and motor function recovery.[215,222–225] Several different biomaterials-based nerve conduits have been employed for *in vivo* delivery of the differentiated or undifferentiated mesenchymal stem cells. The outcomes in a rat model for similar studies have been very promising and have resulted in enhanced nerve regeneration.[222,226–229] The reason for the success of such an approach in the peripheral nerve regeneration milieu has been attributed to the ability of the differentiated mesenchymal stem cells to secrete critical neurotrophins[220,221] that have shown ability to upregulate myelin associated genes and proteins when cocultured with neuronal cells in an *in vitro* model.[230]

Similarly, there have also been studies showing the application of adipose-derived stem cells in the peripheral nerve regeneration process.[51,231–233] The advantages of the adipose-derived stem cells are that a large amount of cells can be obtained from lipoaspirates and the isolation of the cells does not require a painful procedure involving cell retrieval from the bone marrow and also that the amount of stem cells found in the adipose tissue is several fold higher than in the bone marrow.[234–236]

Neural crest-derived stem cells (NSCs) can be isolated and differentiated from several neural crest target structures, in addition to the migratory neural crest.[237–244] Of particular interest in the peripheral nerve regeneration arena are the NSCs that are found at the site of gliogenesis, including the sciatic nerve and dorsal root ganglia (DRG).[245] On observation and expansion, these cells displayed multipotency and self-renewal capacity and have clearly expressed glial markers such as P0, S-100, and PMP22.[245] There have also been several studies delineating the interaction of the glial cells derived from the NSCs with the axons of the PNS. Also, upon maintenance in an optimal cocktail over longer durations, the NSCs did not dedifferentiate into other cell types and maintained their phenotypes over such studies. All these results point towards a very successful application of differentiated neural stem cells in the regeneration of the PNS.

5.531.3. Concluding Statements

Nerve bridges are needed for injuries greater than 10 mm to promote peripheral nerve regeneration. The nerve autograft remains the gold standard to treat such nerve injuries. This chapter reviewed natural and synthetic grafts that have been used as potential alternative to autografts to promote axonal regeneration. Future nerve conduits/grafts should exploit our increasing understanding of the critical limitations in nerve regeneration across gaps to design novel scaffolds that embody unique combinations of physical and biochemical cues so that endogenous repair mechanisms are optimized, and regeneration across long nerve gaps is successful.

Glossary

Apoptosis Active process of programmed cell death (PCD), including chromosomal DNA cutting, chromatin condensation, and nuclear and cell fragmentation, that may occur in multicellular organisms.

Astrocytes The most important glial cells in the central nervous system (CNS), having nutritive functions and forming, in CNS peripheral zones, a continuous cellular coating around blood vessels, creating the blood–brain barrier.

Autograft Tissue transplantation from one part of the body to another in the same individual.

Blood–brain barrier Anatomofunctional barrier, consisting of astrocytes in contact with the wall of cerebral vessels, which selectively restricts the entry of substances within the central nervous system.

Cerebrospinal fluid Liquid composed of 90% water, rich in sodium, potassium, and chlorine. It is located in the intrathecal space, the brain ventricles, and the central canal of the spinal cord. It is important for metabolic activities and protection of the CNS.

Chromatolytic reaction Series of cellular modifications in the nerve cell body, including the soma swelling, the fragmentation of the endoplasmic network, the eccentric position of the nucleus, a global increase of protein and RNA synthesis, and a variation of neuron-expressed genes.

Corticosteroids Hormones produced in the adrenal cortex. Corticosteroids are involved in a wide range of physiological processes such as immune response and inflammation regulation.

Frequency of reinnervation Percent of defects that were bridged by myelinated axons.

Gene therapy Inclusion of genetic material (DNA) inside cells. This inclusion process is called transfection.

Intrathecal space Space located between the arachnoid and the pia mater of the brain and the spinal cord.

Macrophages Phagocytic white blood cells performing an important role during inflammatory and immune response.

Neural parenchyma Nervous tissue functionally active in genesis and transmission of electrochemical impulses.

Neurotrophic factors Nutritive (trophic) factors necessary for the growth of nerve endings, playing an important role in their postinjury survival.

Plasticity Changing of the structure, function, and organization of neurons in response to particular stimuli.

Abbreviations

AcNHGlc	N-Acetylglucosamine
aFGF	Acidic fibroblast growth factor
bFGF	Basic fibroblast growth factor
BMPs	Bone morphogenetic proteins
BDNF	Brain-derived neurotrophic factor
CNS	Central nervous system
CNTF	Ciliary neurotrophic factor
DG	Dentate gyrus
DNA	Deoxyribonucleic acid
ECM	Extracellular matrix
ES	Embryonic stem cells

EtO	Ethylene oxide
GDNF	Glial cell line-derived neurotrophic factor
GMP	Good manufacturing practice
HPMA	*N*-2-Hydroxypropyl methacrylamide
MAG	Myelin associated glycoprotein
MSCs	Mesenchymal stem cells
NGF	Nerve growth factor
NHGlc	Glucosamine
NPCs	Neural progenitor cells
NT-3	Neurotrophin-3
OECs	Olfactory ensheathing cells
OMgp	Oligodendrocyte myelin glycoprotein
OPCs	Oligodendrocyte precursor cells
PAN/PVC	Polyacrylonitrile/polyvinylchloride
PCL	Poly-ε-caprolactone
PGA	Poly(glycolic acid)
PHB	Poly-β-hydroxybutyrate
PHEMA–MMA	Poly(2-hydroxyethyl methacrylate-*co*-methyl methacrylate)
PHPMA	Poly[*N*-(2-hydroxypropyl) methacrylamide]
PLA	Poly(lactic acid)
PLGA	Poly(lactic-*co*-glycolic) acid
PNS	Peripheral nervous system
RGD	arginine (R)-glycine (G)-aspartic acid (D), peptide sequence
RNA	Ribonucleic acid
SCI	Spinal cord injury
SCID	Severe combined immune deficiency
Sema4D/CD100	Semaphorin-4D, also known as cluster of differentiation 100
SGZ	Subgranular zone
SVZ	Subventricular zone
TGF-β	Transforming growth factor beta

5.532.1. Introduction

5.532.1.1. Why Nerve Tissue Engineering?

Permanent cells are defined as cells that are unable to replicate in postnatal life. Nervous cells, also termed neurons, together with skeletal muscle and cardiac cells, are included in this group, which traditionally identifies the human tissues that are incapable of spontaneous regeneration.

It is well known, however, that the ability of cells to proliferate does not ensure regeneration of an injured adult tissue. Tissues that can regenerate spontaneously may not do so when severely injured (e.g., bone); also, cell replacement (i.e., cell transplantation) and/or recruitment of endogenous stem cells in nonregenerative tissues may not suffice to induce regeneration. Indeed, adult tissues tend to repair themselves by replacing the injury site with connective tissue (i.e., scar tissue), which closes the wound and limits a further extension of the damage. Tissue engineering aims at inducing tissue regeneration by (a) identifying the endogenous factors that prevent spontaneous regeneration and (b) modifying the postinjury cellular microenvironment, by suppressing or limiting the action of the inhibitory factors, to direct cells toward regeneration rather than repair.

The intrinsic ability of axons to regrow under specific environmental stimuli makes nerve regeneration a possible, realistic goal, together with the possibility of inducing or regulating the plasticity of intact axons for some functional recovery. However, the sophisticated wiring of peripheral and central nervous systems (PNS and CNS, respectively) makes nerve tissue engineering particularly challenging. Even in cases where a certain degree of axonal regeneration has been induced, the full recovery of motor or sensory functions, which depends on the establishment of proper nerve reconnections, is far from being a reality. As yet, the clinical treatment of PNS neurotmesis (i.e., the most severe PNS injury, the complete transection of the nerve) mostly relies on the use of autograft tissues, when these are available, while the current therapies for CNS injury are directed toward minimizing inflammation in the acute setting and stimulating the little endogenous plasticity of the adult CNS. Unfortunately, the efforts made so far by tissue engineers to develop novel molecular, cellular, and/or scaffold-based therapies for functional recovery after nerve injury have often led to clinical trials that yielded equivocal results with regard to the safety and effectiveness of a given therapy.

The aim of this chapter is to discuss the state of the art of nerve tissue engineering, with a critical view of the tremendous gap existing between the laboratory/experimental setting and clinical practice. The development of a tissue-engineered medical product is a highly complex process, and this is especially true in nerve tissue engineering, where the supply of exogenous cells and molecules is likely to be necessary (at least for CNS repair), making the regulatory requirements harder to meet compared to those for cell-free products. In the following introductory sections, a brief description of PNS and CNS pathophysiology is provided, with some insights into the socioeconomic impact of nerve injuries, in an attempt to explain why nerve tissue engineering is likely the most promising way to go for functional nerve recovery.

5.532.1.2. Social Impact of Nerve Injuries

There are several factors that can give rise to PNS injuries or damage: systemic diseases (e.g., diabetes), infections (e.g., Lyme disease), and direct trauma or pressure on the nerve, which may result from motor vehicle accidents, falls, sports injuries, surgical interventions, etc. Although relatively little data are available on the incidence of PNS injuries, it is estimated that in the United States alone, approximately 200 000 surgical procedures are performed annually, while in Europe up to 300 000 cases of nerve injury are reported each year.[1] The consequences of PNS injury depend on the extent of the damage and may range from pain or impaired sensitivity to muscle weakness or paralysis, which could dramatically restrict the patient's daily activities. The PNS's capability of functional recovery is also affected by the extent of the damage, and lifelong disabilities, unfortunately, are common.

The incidence of CNS injuries is lower than that of PNS injuries, but their impact on the patient's life, as well as their socioeconomic costs, is definitely more devastating. As an example of CNS injury, in this and in the following paragraphs, we refer to spinal cord injury (SCI), which, if complete, leads to permanent loss of sensorimotor function at all body parts below the lesion site. SCI is highly complex and no cure currently exists. It is estimated that 253 000 people are affected by SCI in the United States, 45.7% of whom have permanent paraplegia or tetraplegia, with 11 000 new cases of SCI each year.[2] As for PNS injuries, the etiology of SCI accounts for multiple factors. Motor vehicle crashes represent approximately 40% of injuries, followed by falls and acts of violence (about 20% each) and sporting activities.[3] The human cost is incredibly high, also considering that SCI patients are mostly young adults (the median age is 26), who have to cope with their SCI disability for the rest of their lives.

5.532.1.3. PNS and CNS: Structures and Physiological Responses to Injury

The nervous system represents a complex network of coordination and control that receives, elaborates, and responds to all information coming from the external and internal environments. In vertebrates, it is organized in two main units: the CNS and the PNS. The former includes the brain and the spinal cord, while the latter is formed by the nerves branching out from the CNS and going to the periphery, called the cranial and spinal nerves, respectively. Although it corresponds to the definition of cranial nerve, the optic nerve is derived from the diencephalon during embryonic development and thus is structurally similar to CNS nervous tissues. Therefore, it is considered part of the CNS and is often used as a model in studies regarding the capability of the CNS for recovery following an injury.

The nervous system includes several kinds of cells, which can be grouped into two classes: nervous cells, or neurons, and glial cells, or simply glia. The neuron represents the functional unit of the nervous system and, from a morphological point of view, it shows four different zones (Figure 1). The cell body, or soma, is the cell metabolic center. Dendrites of short length develop from it and represent the main apparatus for receiving messages from neighboring neurons. The axon, a cytoplasmic extension of the cell body, represents the conductive element through which messages or signals, in the form of electric impulses, are delivered. The presynaptic endings are the units devoted to transferring the messages to their proper target, that is, other neurons, muscle cells, or glands. Glial cells, typically 10 times more numerous than nervous cells, are not directly involved in the processing of information, but provide supporting tissues. Some glial cells (i.e., oligodendrocytes in the CNS and Schwann cells in the PNS) are responsible for the ensheathing of axons with insulating myelin, which improves the conduction and the speed of the electric impulse. Microglia cells may play an important role in inflammation processes, working as phagocytes.

5.532.1.3.1. Peripheral nervous system

Peripheral nerves making up the PNS are complex organs whose structure presents a cylindrical arrangement (Figure 2).

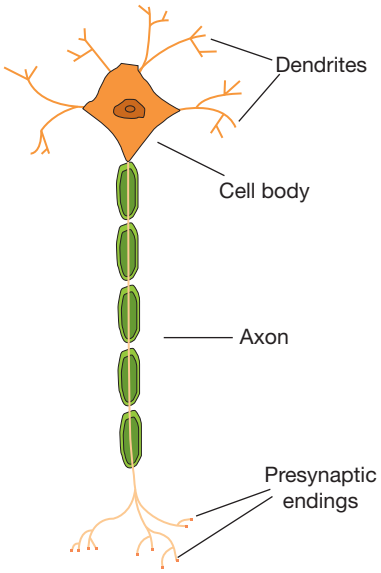

Figure 1 Schematic view of a neuronal cell. The axon is surrounded by myelin sheaths generated by Schwann cells. The gaps between the myelin sheaths are the nodes of Ranvier, which give rise to a saltatory conduction.

A nerve trunk can comprise one or more fascicles, each consisting of many nerve fibers. Each nerve fiber comprises an axon, wrapped in a sheath of myelin that is synthesized by Schwann cells, and a tubular basement membrane lining the external surface of the Schwann cells and myelin. Nerve fibers, which are also referred to as neuronal tissues, are surrounded and supported by nonneuronal tissues, that is, the endoneurium, the perineurium, and the epineurium. The endoneurial stroma surrounds each nerve fiber and provides support to it by means of vascularization. The perineurium is a tight, multilayered tissue that surrounds each nerve fascicle and acts as a permeability barrier. The epineurium is a strong sheath that surrounds the entire multifascicular assembly or nerve trunk.

Most injuries to the PNS and CNS affect the axons. Injured peripheral nerves are capable of spontaneous regeneration only when the nerve trunk is not transected and the Schwann cell basal lamina is undamaged, that is, in mild crushing injuries. Seddon's classification[4] divides PNS injuries into three classes: neuropraxia, axonotmesis, and neurotmesis. Neuropraxia is the mildest injury, which may result from mechanical compression or ischemia, but it does not cause any structural damage or loss of nerve continuity. Recovery is rapid and complete.

Regeneration is still obtained in case of axonotmesis, where the axon is interrupted but the basement membrane and the stromal tissues attached to it are preserved. Following axonotmesis, the proximal segment, which is directly linked to the cell body, is able to survive, although the cell body may undergo a series of morphological and metabolic reorganizational changes, comprehensively called chromatolytic reaction, that are reversible in case of regeneration. Some retrograde degeneration, in the form of demyelination of the proximal end, also occurs but is usually limited to only a few myelin segments. Conversely, the distal segment is subjected to anterograde or Wallerian degeneration. The primary histological

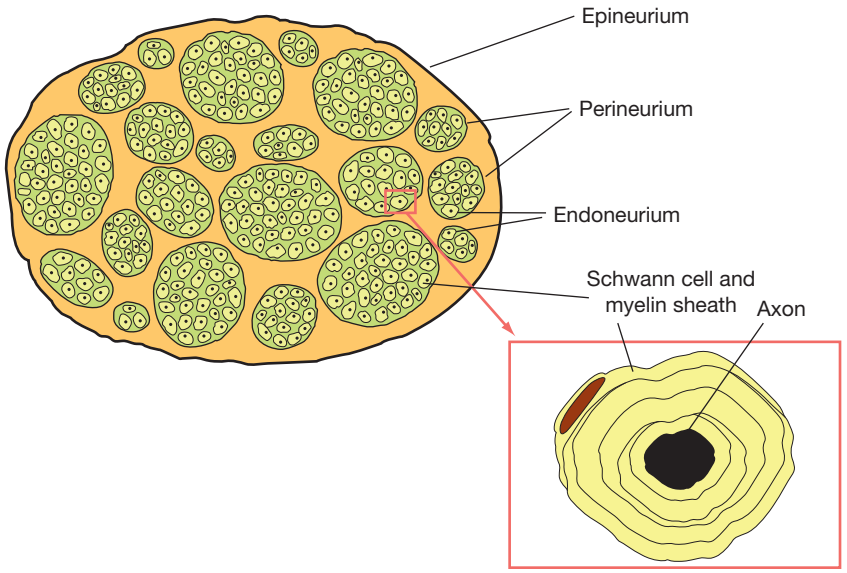

Figure 2 Schematic cross-sectional view of a peripheral nerve. For the sake of simplicity, the epineurial, perineurial, and endoneurial blood vessels are not reported in the scheme.

change in Wallerian degeneration involves physical fragmentation of both axons and myelin, a process that begins within hours after the injury. In the degeneration of the distal stump, the axoplasm (composed of neurofilaments and microtubules) disintegrates and is converted into granular and amorphous debris. The main event that triggers this process appears to be an increase in the axoplasmic calcium level due to the transection of the nerve fibers. The debris resulting from the degeneration is efficiently cleared by macrophages and Schwann cells, and the final outcome is the formation of an endoneurial tube (i.e., a cylindrical basement membrane free of axons and myelin). While Wallerian degeneration is taking place, an intense proliferation of Schwann cells, which is not observed in undamaged nerves, occurs both in the proximal and distal segments. Once the degeneration is complete, regeneration can finally occur. Schwann cells form linear structures (bands of Büngner) along the empty basement membrane, while the proximal end sends out sprouts, which are attracted by the growth factors secreted by the Schwann tube. When a sprout reaches the tube, it can penetrate the distal segment and finally reinnervate the target tissue.

In the case of neurotmesis, in which the complete interruption of the entire nerve bundle occurs, there is a local vascular trauma that leads to hemorrhage and edema, resulting in a vigorous inflammatory response. Fibroblasts proliferate and a dense fibrous scar is formed at both nerve stumps (neuroma formation). Both the scar and the long gap between the stumps interfere with the spontaneous axonal regeneration discussed above (i.e., the proximal sprouts cannot reach the endoneurial tubes formed in the distal stump), permanently compromising the nerve structure and functionality. In such cases, nerve regeneration can be stimulated by means of surgical techniques involving the implantation of autograft tissues or synthetic grafts between the nerve stumps, as discussed later. The quality of the nerve regeneration induced by the graft compared to that of the normal nerve can be evaluated quantitatively in terms of histological and/or electrophysiological data.[5] However, if the surgery is delayed or the nerve gap is too long, the endoneurial tubes formed in the distal stumps may undergo degeneration before the proximal axons can reach them. In such cases, the disruption of the Schwann cell basement membrane does not support further reinnervation, and chronic denervation of the distal stump is established.[6]

5.532.1.3.2. Central nervous system

Unlike what happens in the PNS, the proximal ends of injured CNS axons are mostly unable to elongate and form new synapses, preventing the *de facto* restoration of pretrauma conditions. Several hypotheses have been formulated in an attempt to explain this striking difference between the CNS and the PNS with regard to regenerative capacity. A line of research focuses on the inherent differences in the maturation of the two nervous systems, characterized by the loss of growth capacity in central neurons with increasing age. However, the main hypotheses are related to the intrinsic structural differences and the different microenvironments established after an injury in the CNS and the PNS.

SCI provides a CNS injury model that encompasses all the environmental changes to which CNS axons are exposed following the initial mechanical insult. The spinal cord, located in the vertebral column, extends from the brain stem to the first lumbar vertebra, beyond which the spinal nerves form the so-called cauda equina, which extends to the coccyx. When viewed in cross section, the spinal cord reveals a butterfly-shaped core of gray matter, consisting mostly of cell bodies and glial cells, and an exterior region of white matter, consisting mostly of axons and oligodendrocytes that wrap axons in white insulating myelin. The ventral half of the gray matter, divided into two ventral lobes or horns, contains the cell bodies of motor neurons, which send out axons to muscles; on the other side, the two dorsal horns contain the cell bodies of sensory neurons, which receive information from the

periphery through the dorsal roots. Thirty-one pairs of spinal nerves enter and exit the spinal cord throughout its length: 8 pairs of cervical nerves, 12 pairs of thoracic nerves, 5 pairs of lumbar nerves, 5 pairs of sacral nerves, and 1 pair of coccygeal nerves (**Figure 3**). Damage to the spinal cord usually occurs where the spine is more flexible, which is at regions C5–C7 in the neck and T10–L2 in the lower back.[7] While damage to the segmental gray matter affects function only at that segment, damage to the long tracts of white matter has devastating consequences as it eliminates function at all levels below the injury site.

The initial mechanical insult to the spinal cord triggers a cascade of secondary events that lead to neuronal death and to a highly inhibitory microenvironment for axonal growth.[8,9] A brief description of such a complex cascade is provided in the following section. With regard to neuronal death, several events have to be considered. First, as a direct result of the injury, blood flow is disrupted, causing oxygen deprivation in some parts of the spinal cord and eventually cell death, as these cells become oxygen-starved. Internal bleeding can occur at the site of injury, resulting in a further compression of the spinal cord through increased swelling of the surrounding tissues. The disruption of the blood–brain barrier that regulates the delivery of substances between the CNS and the blood supply exposes the spinal neurons to toxic molecules such as free radicals.[10] This harsh environment can cause a further loss of neurons and glial cells, triggering the immune system's response to the injury. Retrograde degeneration of the proximal end of a transected axon is another mechanism that can lead to neuronal death.

Multiple events are thought to lead to the establishment of a cellular microenvironment opposing axonal regeneration. Following axotomy, distal segments of CNS axons are subjected to Wallerian degeneration. However, oligodendrocytes do not intervene in the clearance of the myelin debris, as

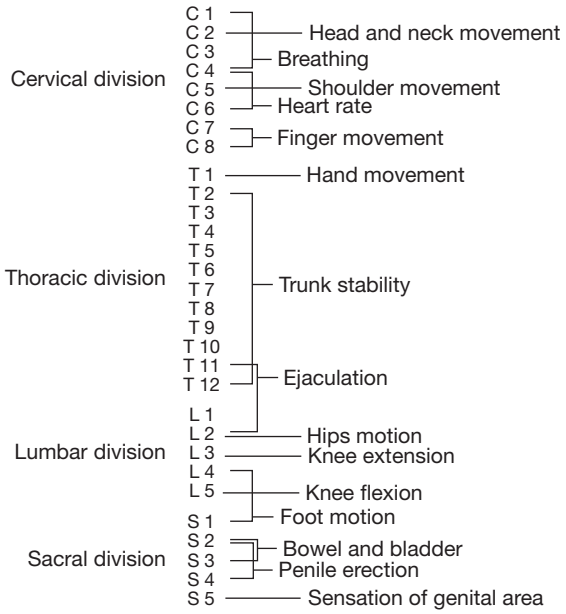

Figure 3 Functional levels along the spinal cord. Damage to the white matter at a specific level compromises function at all levels below the site of injury.

performed by Schwann cells in the PNS; they rather undergo apoptosis or enter a state of rest.[11] Myelin debris, which is cleared by microglia cells and macrophages in a much slower fashion than in the PNS, is known to contain several molecules inhibitory to axonal regeneration. It is thus postulated that the persistence of myelin at the injury site might be one of the causes of the failure of the CNS to regenerate. Furthermore, astrocytes are recruited at the damaged site following the injury, and they begin to form the glial scar, a dense connective tissue representing both a physical and chemical barrier to axonal regeneration and remyelination.[12]

However, the adult CNS shows some plasticity.[3,13] Axonal sprouting by surviving neurons can occur, but the reconnection with the appropriate targets is, of course, limited, leading to very little functional recovery or improvement following SCI. Besides surgical stabilization and decompression to limit further damage to the spinal cord, a high-dose administration of corticosteroids to minimize inflammation is the only treatment clinically available for SCI. Several strategies to stimulate the endogenous CNS plasticity and/or axonal regeneration are currently under investigation, which are mainly based on either increasing the permissive cues or decreasing the nonpermissive cues of the existing microenvironment. A combination of strategies is likely required to improve the extent of functional recovery.

5.532.2. State of the Art of PNS Tissue Engineering

5.532.2.1. Entubulation Technique and Nerve Conduit Design (see Chapter 00183)

As discussed earlier, while regeneration and functional recovery occur spontaneously in neuropraxia and axonotmesis, neurotmesis requires surgical intervention. In cases of small gap lengths (<5 mm), direct end-to-end suturing is still feasible without causing tension of the nerve, which would be detrimental to regeneration.[14] For longer gaps, the most widely used treatment consists in bridging with autograft tissue, which represents the gold standard for PNS regeneration. Donor nerves are usually small-diameter sensory nerves harvested from either the arm or the leg (e.g., the sural nerve). However, the morbidity caused to the donor site, the possible lack of a sufficient amount of donor tissue, and the wide variation in functional recovery (which may range from poor to good, depending on age, injury site, and time of surgery) make the alternative use of synthetic grafts attractive. Indeed, although some studies have reported complete restoration of sensation by means of autogenous nerve grafts, the recovery of motor function is usually less than 40%.[15] Since the first examples of entubulation, that is, the use of tubular conduits to bridge peripheral nerve defects, in the late nineteenth century,[16] a number of synthetic tubes, including nonresorbable ones (e.g., silicone tubes), have been investigated and demonstrated to facilitate PNS regeneration. The time needed for surgery has also been reduced compared to autografting procedures.

However, the regenerative mechanisms induced by the entubulation of the nerve stumps began to be understood only in the early 1980s. At the time, an impermeable silicone tube was implanted in a 10-mm rat sciatic nerve gap and the content of the implanted tube analyzed at various time points along the nerve regeneration process.[17] In particular, a clear fluid secreted

by the damaged nerve ends and containing neurotrophic factors was found to fill the tube lumen within hours. After 7 days, a fibrin cable connecting the two stumps was detectable within the exudate fluid. Notably, the cable tended to taper slightly toward the center of the gap. Fibrin fibers were longitudinally oriented and served as a matrix for the immigration of cells from both nerve stumps, including Schwann cells, fibroblasts, endothelial cells, and perineurial cells. After a few weeks, the cable was remodeled into a nerve trunk. In particular, the prior presence of Schwann cells within the cable appeared to be necessary for the elongation of axons from the proximal stump. Additionally, this and later independent investigations revealed that the regenerated nerve trunk was ensheathed by a thick connective tissue comprising myofibroblasts.[18–22] This contractile cell type[23] is likely responsible for the closure of the transected stumps by contraction, in the event of neuroma formation.

The tubular device is thus expected to provide a chamber environment, which is likely to play multiple key functions required for axonal elongation, such as allowing the formation of a fibrin matrix to direct axons from the proximal to the distal stump, concentrating the growth factors secreted by the injured nerve cells at the site of injury, preventing the infiltration of surrounding tissues, and minimizing the formation of scar tissue. Even though a silicone tube suffices to induce axonal elongation,[24,25] nonresorbable conduits give rise to a chronic foreign body reaction in the long term, causing nerve compression and requiring surgical removal.[26,27] Therefore, their use is not recommended for clinical applications, although a great deal of research has been focused on nonresorbable nerve guides other than silicone chambers.[28–31] Among nonresorbable conduits, it is worth citing those based on piezoelectric polymers,[32] which may promote axonal growth by electrical stimulation,[33] and those made of synthetic hydrogels, such as poly(2-hydroxyethyl methacrylate-*co*-methyl methacrylate) (PHEMA–MMA) hydrogels.[34] Although some successful results have been reported in animal studies in the short term, PHEMA–MMA hydrogel conduits have failed in the long term compared to autografts, likely due to their biodurability and, in some cases, to mechanical deformation.[35,36]

When approaching the design of a nerve conduit, a few basic requirements should be kept in mind. An ideal conduit should be resorbable, with a degradation rate preferably matching the rate of nerve trunk formation; flexible, but also able to retain its shape during the implantation and along the regeneration process; easily processable and sterilizable; and easy to handle and suture. Clearly, the design variables affecting the regenerative performance of the conduit are dictated by the biomaterial used and by the processing variables that can affect the functional properties of the conduit in terms of diameter, wall thickness, permeability, porosity, surface roughness, degradation rate, and mechanical strength (**Table 1**).

Synthetic polymers are usually preferred for tube fabrication, as their degradation and mechanical properties are more easily tunable compared to those of naturally derived biomaterials. Among the most widely employed synthetic polymers, several polyesters have been reported to have gained successful results, including poly(lactic acid) (PLA), poly(glycolic acid) (PGA), poly(ε-caprolactone) (PCL), and their copolymers.[37–40] Polyphosphoesters and polyurethanes have also been investigated, although their fast degradation rate and degradation-induced fracture limit their potential for the fabrication of therapeutic devices (see **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**).[41,42]

Polymers of natural origin used to produce tubular nerve chambers mainly include macromolecules derived from the extracellular matrix (ECM), such as collagen and laminin, and, more recently, chitosan, although the latter is usually combined with synthetic polymers, such as PLA, because of its brittleness (see **Chapter 2.213, Chitosan**; **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**; and **Chapter 2.216, Collagen–GAG Materials**).[43–46] Other natural biomaterials, such as alginate and decellularized matrices, have been reported in studies related to PNS regeneration, but they have been employed in the form of full cylindrical matrices rather than empty conduits. Although the chemical composition of natural polymers cannot be regarded as a design variable, it is possible to adjust both the degradation rate and the mechanical strength of such polymers by means of cross-linking methods. When increasing the degree of cross-linking of a given polymer network, the stiffness increases while the degradation rate is lowered, as demonstrated for collagen-based scaffolds.[47,48] Clearly, cross-linking treatments that avoid the incorporation of any toxic molecules are strongly recommended, such as those based on ultraviolet irradiation, dehydrothermal treatment, and carbodiimide-mediated cross-linking reaction.[49,50]

It is worth stressing that, although the degradability of the nerve chamber is well known to improve the quality of nerve regeneration, the quantification of the degradation rate for

Where the symbol ✓ is not present, the design variable is supposed to have either no effect at all or, at least, no significant known effect on the selected device property.

different tubular devices, expressed as mass half-life, is rarely reported in the literature.[51] It is reasonable to postulate that the degradability of a conduit can significantly affect the nerve regenerative process if the timescales of the two processes are approximately coincident. Evidence from several independent investigations seems to suggest that the initial regeneration of a rat sciatic nerve in a 10-mm gap, with innervation of the distal stump for some functional recovery, requires about 10–12 weeks to occur,[17,52,53] although the completion of the regenerative process can take as long as 2 years.[43] Resorbable conduits requiring a much longer time than 12 weeks to degrade in a rat model would likely have no significant effect on the quality of nerve regeneration, at least in the short term.[41] Conversely, a comparative study related to the application of collagen tubes with different degrees of cross-linking (corresponding to half-lives in the range of 1–10 weeks) into a 15-mm rat sciatic nerve gap confirmed that an optimal degradation rate of the conduit does exist for improved nerve regeneration.[49] For the collagen tubes tested, a chamber half-life of approximately 2–3 weeks provided the best histomorphometric results at the gap midpoint, after a 9-week period (see **Chapter 2.216, Collagen–GAG Materials**).

The permeability of the tube wall appears to play a key role in the regenerative processes induced by the tube. In particular, cell-permeable tube walls (i.e., with pores approximately equal to or larger than 20 μm) have been reported to perform better than protein-permeable or nonpermeable ones, at least when considering porous collagen conduits.[5] The documented presence of myofibroblasts in the inner wall of the collagen-based tubes[19,44,45] has led to the reasonable hypothesis that the device's capability to host myofibroblasts might limit or prevent the myofibroblast-exerted contraction on the nerve stumps, thus facilitating nerve regeneration. However, the effect of this speculative mechanism on the favorable action of pores in the inner tube wall needs further investigation. What is generally considered when designing a conduit is that the tube wall should be porous enough to allow an efficient transport of nutrients and oxygen from the surrounding environment, and at the same time prevent infiltration into, or formation of fibrous tissue in, the wound site. These requirements translate into a porous tube wall that is at least protein-permeable. The limitation of fibrous tissue formation within the defect would be addressed by cell-impermeable pores, but, in principle, these could be present either at the outer tube wall or at the inner tube wall. While the role of conduit cell permeability has not been widely explored, recent studies have highlighted the development of fabrication techniques that lead to a gradient in pore size along the tube wall.[54–56] Two of these studies, in particular, have focused on the control of pore orientation, in addition to pore size. Collagen-based tubes with radially aligned porosity, cell-permeable pores at the inner wall, and cell-impermeable pores at the outer wall show the potential to regulate myofibroblast attachment and migration.[55] Conversely, PLGA–pluronic composite tubes, possessing radial pores with a cell-impermeable inner wall and a cell-permeable outer wall, have been developed to allow a good nutrient transport while isolating the defect from external fibrous tissues.[56] Regardless of the different biomaterials used, the application of these devices in animal models could help in understanding the effect of tube wall porosity (in terms of both pore size and orientation) on the quality of nerve regeneration, which is still unclear. Nonetheless, findings from a number of independent investigations suggest that the surface area of the inner wall of the tubular device is a key variable to be considered when designing a nerve conduit, better nerve regeneration being achieved with increased surface area.[57–60] For PCL tubes with a macroporous outer wall, a microporous inner wall (pore size 1–10 μm) is found to be more advantageous for nerve regeneration, compared to nonporous and macroporous inner walls.[58]

However, it is worth noting that, for some devices, the presence of pores on the tube wall might be detrimental. This has been recently confirmed by a study on polyester-based conduits, which evidenced that the tubes possessing porous walls, with a pore size of 10–20 μm, hampered nerve regeneration compared to nonporous tubes, likely due to the porosity-induced change in the mechanical properties and degradation rate of the conduit.[61]

The tube macro- and microstructures depend on the processing method used to produce the conduit. Some pioneering techniques for the fabrication of conduits with porous tube walls included the rolling and sealing of foam sheets,[62] fiber deposition onto a rotating mandrel and subsequent freeze-drying,[63] and immersion precipitation methods.[64] The current approach is to combine multiple manufacturing methods to increase the level to which the scaffold microstructure can be manipulated. Microfabrication by means of soft lithography is also largely exploited for the production of microgrooved conduits, which increase the available surface area for cell interaction and may provide contact guidance to Schwann cells and axons.[65] As more technologically developed alternatives, rapid prototyping techniques are emerging as excellent methods to produce customized tissue engineering scaffolds, including nerve conduits. However, only a limited number of materials can be processed by means of such techniques. Some recent progress has nevertheless been reported regarding the applicability of rapid prototyping techniques to collagen-based composites for nerve regeneration.[66]

The overall experimental evidence collected so far suggests that the regenerative capability of a tubular device depends strongly on its size. Traditionally, the gap length has been considered the limiting factor for induced nerve regeneration. For a given conduit or tubular configuration, there seems to be a critical length size related to the animal species, above which the capability of the device to allow axonal regeneration drops below 50%, in terms of frequency of reinnervation.[5] For example, in the case of an empty silicone tube, the critical gap length for the rat sciatic nerve is about 10 mm.[67] Assuming the silicone tube as a negative control, it makes sense to compare the regenerative performance of any novel device with that of the silicone tube only for gaps equal or longer than the critical size. Unfortunately, investigators often choose the main variables of their experiments arbitrarily (i.e., animal species, gap length, and time and location of observation along the regenerating nerve trunk), which makes a comparison among the different devices tested hard to perform. Importantly, the lack of experimental standardization also hinders the comprehension of the regenerative mechanisms induced by the specific device configuration.

In addition to the gap length, another important and often underestimated factor that determines the defect size and

affects the performance of a conduit is the nerve diameter. The inner diameter of the conduit is, of course, directly related to that of the nerve, being slightly larger than the latter for a smooth accommodation of the nerve stumps. Even when encouraging animal data have been provided for a given tubular device, clinical studies on relatively large human nerves, such as the ulnar and median nerves (which have a diameter of ~3–4 mm), have mostly led to unsuccessful results with very rare positive outcomes.[31,68,69] It is important to underscore the fact that animal models, including nonhuman primates, are not able to reproduce the large caliber of human nerves (with the exception of porcine sciatic nerve), which is a factor to be considered in view of clinically bridgeable gap lengths in humans. The nerve diameters treated in rodent models, which are the most widely employed, are in the range of 1–2 mm. It has been recently hypothesized that the overall volume of the nerve chamber, determined by both length and diameter, is the true limiting factor in nerve regeneration.[70] This would imply that, for a given chamber and a fixed animal species, the critical gap length is dramatically reduced as the nerve diameter is increased (i.e., the gap length is reduced by 4 when the nerve diameter is doubled). A possible explanation for a critical chamber volume lies in the inability of the chamber to provide a sufficient concentration of neurotrophic factors as well as a crossing fibrin cable, in larger volumes.

Due to the wide range of animal species and gap models employed in independent investigations, it is difficult to estimate the largest nerve defect volume bridged experimentally by an empty conduit. Currently, only a small number of nerve conduits have reached the field of clinical practice (Table 2), and their use is limited to the treatment of small defects (not longer than 30 mm) in small-diameter nerves (e.g., digital and radial sensory nerves). Moreover, in spite of the advances in the tube manufacturing techniques and the optimization of the surgical procedures, no tubular device has proved superior to the nerve autograft as yet, even in small animal models.

An important aspect to evaluate is the morphology of the regenerated nerve trunk, compared to that of the normal nerve. In particular, the evidence collected so far shows that the ability of nerves to remyelinate after regeneration is not optimal, leading to thinner myelinated axons and impaired functional recovery. G-ratio measurements (axon diameter vs. fiber diameter) are far below the normal value of uninjured axons.[71] A long-term study regarding the use of collagen tubes to bridge a 10-mm gap in the rat sciatic nerve showed that myelinated axons undergo significant remodeling and increase their diameter between 30 and 60 weeks of the tube implant.[44,45] However, in spite of this late remodeling, the number and the diameter of myelinated axons remain below the normal values. Very little is currently known about the mechanisms because of which Schwann cells do not remyelinate completely after injury. Another important difference between a regenerated nerve and a normal nerve lies in their stromal tissues. Clear evidence of the *in vivo* regeneration of physiological endoneurium and epineurium has not been reported.[5] The evolution from tubular conduits to more complex tissue-engineered devices to improve both the quality and the extent of nerve regeneration is the subject of extensive research and is concisely discussed in the following section.

5.532.2.2. Overview of Ongoing Research and Potential for Therapeutic Use

The ongoing investigations on PNS tissue engineering are mostly directed toward increasing the bridgeable gap length and diameter as well as improving the quality of the regenerated nerve trunk to enhance functional outcome.

Table 2 Commercial nerve guidance conduits for the regeneration of peripheral nerves

Commercial products	*Biomaterial/description*	*Available sizes (mm) (L = length; ID = inner diameter)*	*Manufacturer/Web site*
Axoguard™ Nerve Connector (formerly Surgisis® Nerve Cuff)	Surgisis® (porcine acellular small intestinal submucosa)	$L = 10$ ID up to 5	Cook Biotech, Inc., IN, USA, www.cookbiotech.com
Neuragen®	Bovine type I collagen	$L = 20; 30$[a] ID = 1.5; 2; 3; 4; 5; 6; 7	Integra Lifesciences Corp., NJ, USA, www.integra-ls.com
Neuroflex™ Neuromatrix™	Bovine type I collagen; Neuroflex™ is more flexible compared to Neuromatrix™	$L = 25$ ID = 2; 2.5; 3; 4; 5; 6	Collagen Matrix, Inc., NJ, USA www.collagenmatrix.com
GEM Neurotube®	Polyglycolic acid (PGA) mesh tube	$L = 20; 40$[a] ID = 2.3; 4; 8	Synovis Micro Companies Alliance, Inc., AL, USA, www.synovismicro.com
Hydrosheat™ (formerly SaluBridge™)	Tubular implant, made up of Salubria (PVA-based hydrogel); nondegradable	N/A	SaluMedica, LLC, GA, USA, www.salumedica.com
Neurolac®	Tubular implant, made up of poly (D,L-lactide-ε-caprolactone); transparent	$L = 30$ ID = 1.5; 2; 2.5; 3; 4; 5; 6; 7; 8; 10	Polyganics BV, Netherlands, www.polyganics.com
RevolNerv®	Porcine type I/III collagen; transparent	$L = 10; 15$ ID = 2; 4; 6	Orthomed, SA, France, www.orthomed.fr

[a] The longest size is available only for the smallest inner diameter.

The presence of a filling in the tube lumen is considered fundamental to improve the regenerative response of a conduit, by providing adequate neurotrophic support and directional guidance in cases where endogenous supply is limited (i.e., in large defects). Many tube fillings have been investigated in recent years (**Figure 4**), including porous- or fibrous-oriented matrices, hydrogels, cell suspensions, molecular regulators (e.g., growth factors), and their various combinations. The regenerative activity of several filled nerve chambers has proved significantly higher than that of empty ones in terms of increased critical gap length.[5]

Several devices that possess axially oriented pores of various sizes can be included among the porous matrices explored so far as luminal fillers (for different kinds of conduits) in an attempt to mimic the structure of the fibrin cable formed between the nerve stumps and originating from the nerve exudate. Such scaffolds, which can become coated with endogenous fibrin *in vivo*, are meant to provide an immediate support for the migration of Schwann cells within the chamber and for the elongation of axons. The pore size is expected to play an important role in determining the matrix bioactivity as it affects the specific surface area available for cell attachment. Oriented collagen matrices with a pore size of 20 μm have proved optimal for PNS regeneration in the rat sciatic nerve model and provided results comparable to the nerve autograft when coupled with a collagen tube in a 10-mm gap.[45,52,72] As collagen is a component of the ECM, it is reasonable to question whether, and to what extent, this ECM nature may contribute to the regenerative activity of the tube filling. Recent evidence suggests that the aligned microstructure of the collagen matrix is likely the key element for a successful nerve regeneration.[73] Indeed, porous collagen fillings without any appreciable orientation have been found to hamper regeneration when inserted into collagen conduits.[74] The same negative effect on nerve regeneration has also been reported when using collagen gels to deliver exogenous Schwann cells within the nerve chamber.[75]

In addition to matrices with longitudinally oriented pores, fibrous matrices, obtained by assembling filaments or fibers of several biomaterials, such as collagen,[76] polyesters,[77,78] and silk,[60] have also been investigated. However, the existence of an optimal fiber configuration, in terms of number and diameter of fibers, has not been widely addressed. With regard to collagen filaments used to bridge a rat sciatic nerve defect, a higher number of filaments was found to enhance the number of regenerated axons,[79] likely due to increased surface area and contact guidance. A recent study related to the application of electrospun fibers on the inner surface of a nerve conduit confirmed that the surface area of the nerve chamber may play a key role in nerve regeneration and also affect the diameter of the regenerated nerve trunk.[57] In this study, a 15-mm gap in the rat sciatic nerve was bridged by conduits possessing electrospun fibers, oriented either longitudinally or circumferentially, on the inner surface. Surprisingly, there was no significant histomorphometric difference in the nerve trunk regenerated by means of these two types of conduits, suggesting that the increased surface area of the conduit may affect its regenerative capacity more significantly than the contact guidance. However, functional recovery was not appreciable for those conduits, unless the fibers were used to deliver exogenous glial cell line-derived neurotrophic factor (GDNF). Moreover, evidence from another independent study highlighted that contact guidance of the tube wall affects the quality of induced nerve regeneration[80,81] significantly. In spite of the different results reported for different conduits, it is possible to argue that a luminal filler possessing proper surface area and directional guidance cues, rather than a surface modification of the conduit, is more likely to elicit a functional nerve recovery.

The use of a nerve conduit filled with either fibers or an aligned matrix, in the absence of any other exogenous

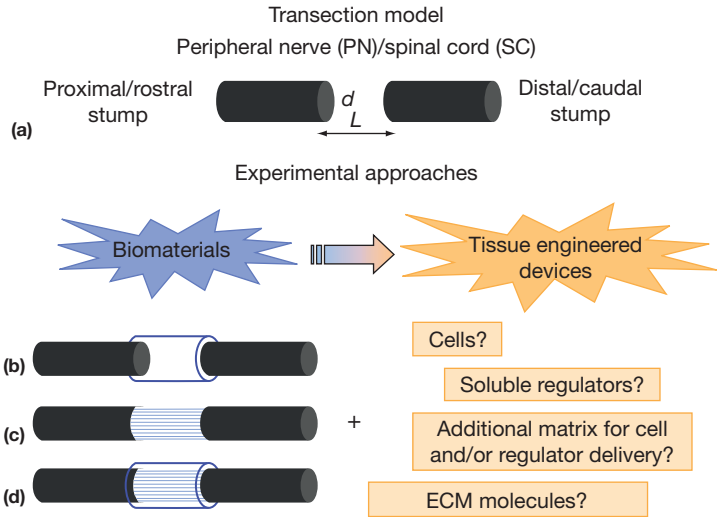

Figure 4 Transection model (a) and experimental approaches to bridge the gap (b–c–d) for either peripheral nerves or spinal cord. (a) The volume to be bridged is determined by the nerve diameter *d* and the length *L* of the induced gap; (b) entubulation; (c) gap bridged by a porous matrix with pores that are preferentially axially oriented; (d) combined use of a tube and a porous matrix. Cells, soluble regulators, any additional matrix for cell and/or regulator delivery (e.g., hydrogels, microspheres) and/or any ECM molecules can be added to the basic configurations (b–c–d) to develop complex tissue-engineered devices.

factor (cells and soluble molecular regulators), has dramatically increased the bridgeable gap length in animal models. For example, a gap of 30 mm in the dog sciatic nerve has been bridged by using PGA filaments within a chitosan conduit, leading to a degree of functional recovery comparable to that of the autograft control.[78] A limitation of this study, however, was that it lacked an evaluation of the regenerative activity of the chitosan empty tube, to reliably evaluate the effective contribution of the tube filling to regeneration.

The use of an axially oriented matrix within a tube is particularly attractive for the development of combinatorial approaches, as the matrix may also serve as a delivery vehicle for exogenous cells (e.g., Schwann cells) and/or molecular regulators. Indeed, although injections of cell suspensions into the tube lumen may improve nerve regeneration, a structural support is recommended to ensure the survival of transplanted cells. It is worth recalling that the regenerative process of a nerve fiber, described previously, does not require an exogenous supply of cells. The rationale for delivering exogenous cells to the injury site thus lies in the fact that such cells may work as an invaluable source of neurotrophic factors, which help nerve regeneration and early functional outcome. As reported above, nerve conduits may indeed be unable to bridge large defects also due to a lower local concentration of soluble growth factors released by the nerve stumps.

Hydrogels, especially those based on ECM macromolecules, can also be used to embed exogenous cells and/or provide a sustained release of selected growth factors. However, as reported above for collagen gels, hydrogels may not provide a permissive environment for axonal regeneration, likely due to the absence of oriented fibers and/or sufficient surface area for cell migration. As an alternative method of cell delivery, the micropatterning of the conduit surface may be exploited to increase the specific surface area for improved cell seeding.[65]

Schwann cells appear the most promising autologous cell type for transplantation, compared to mesenchymal stem cells (MSCs)[82] and olfactory ensheathing cells (OECs).[83,84] Heterologous cells have also been investigated for PNS regeneration, but they are definitely less likely to find their way to clinical application, due to ethical issues and the requirement of an immunosuppression therapy. Even when delivered as a cell suspension or in a hydrogel matrix, Schwann cells can dramatically increase the regenerative activity of a nerve conduit.[85] While hydrogels are the most common devices used to deliver Schwann cells, a number of recent investigations have focused on the seeding of exogenous cells on the conduit inner wall, proving that such a method for cell delivery is successful in terms of improved regenerative outcome.[86,87] Very recently, a collagen gel sheet seeded with Schwann cells has also been proposed as a nerve conduit.[88] Although the use of aligned porous or fibrous matrices to deliver Schwann cells *in vivo* appears promising, the seeding of cells within such matrices gives rise to some practical problems that limit the application of this combinatorial approach for nerve regeneration.

The regenerative performance of a nerve conduit can also be enhanced by coupling exogenous growth factors to it, instead of cells. Neurotrophic factors can enhance nerve regeneration by controlling the survival, migration, proliferation, and differentiation of various neural cell types. A number of factors have been investigated and proved effective for PNS regeneration, including nerve growth factor (NGF),[89] neurotrophin-3 (NT-3),[90] brain-derived neurotrophic factor (BDNF),[91] GDNF,[57] fibroblast growth factors (acidic (aFGF) and basic (bFGF)),[90] and many others.[92] Due to the short half-life of many growth factors *in vivo*, these can be delivered efficiently by means of polymeric devices that allow their sustained release for a relatively long period. Hydrogel matrices and polymeric microspheres are the most widely employed delivery devices in experimental settings. However, for most growth factors, with very few exceptions, the dosage range to be used for a therapeutic effect is yet to be determined.[91] It is also important to highlight the recent approach of combining multiple growth factors in a nerve chamber. Although the underlying molecular and cellular mechanisms are unclear, these studies evidence a synergistic effect of growth factors, which may lead to improved nerve regeneration by using lower doses of each single growth factor. The most recent advances in PNS regeneration experiments have favored the exploitation of gene therapy to instruct the desired cell type to overexpress a given neurotrophic factor. The cell transfection can be achieved either *in vivo*[93] or *ex vivo*,[94] showing some promising results in both cases. However, some concerns exist regarding the ideal gene vector, and the benefit/cost ratio of this approach is likely to be more convenient in studies concerning CNS rather than PNS regeneration, due to the more hostile environment of CNS following an injury.

Several detailed and up-to-date reviews of the current experimental approaches for PNS regeneration, as well as of the clinical outcome of commercially available conduits, have been published very recently and are suggested to the reader for further information.[68,92,95–97] In this brief overview, we would like to provide some basic considerations related to the development of tissue-engineered medical products for PNS regeneration, that is, on the actual therapeutic potential of experimental devices.

The development of a tissue-engineered device comprising two or more of the four aforementioned elements (i.e., conduit, matrix, cells, and molecular regulators) is obviously complex. First of all, the choice of the biomaterial(s) to be used for the conduit and the matrix is fundamental in view of a possible clinical application. This is related not only to the safety of the biomaterial itself (and of any degradation product), but also to the processing technique(s) adopted for manufacturing the device and to the possible methods of sterilization. Every processing step should be easily controlled and permit scale-up to develop production protocols that are respectful of good manufacturing practice (GMP) guidelines. Biomaterial-based, cell-free products currently dominate the overall market of tissue engineering,[98] mainly because the regulatory requirements are less strict and the associated costs more affordable for biomedical companies. With specific regard to PNS tissue engineering, the absence of cell-based therapies in the clinical setting is also attributable to several practical reasons. For example, autologous Schwann cells need a long time to expand *in vitro*, during which period the untreated, injured nerve is likely to degenerate, thus compromising subsequent recovery.[99] Moreover, the most suitable means to deliver cells *in vivo* and the optimal cell density are still subjects of debate. Similarly, the supply of exogenous growth factors in the clinical setting is hindered by the necessity to keep the

concentration of the given growth factor in a therapeutic range for a given time window. This gives rise to yet more open questions regarding the right dosage of growth factor as well as the identification of a suitable delivery vehicle for its sustained release.

Some successful attempts to bridge long nerve gaps by using multicomponent nerve chambers have been reported in the literature. Matsumoto and colleagues reported that an 8-cm-long gap could be bridged in a dog model, with functional recovery, by using a PGA conduit filled with laminin-coated collagen fibers.[100] This seems to be the longest gap bridged to date in an animal model, and it is important to note that no exogenous cells or growth factors were employed. However, despite such encouraging results, true evidence of the efficacy of a given device in the clinical setting seems to be difficult to obtain.

It has been postulated that the discrepancy between the experimental and the clinical levels might be due to the choice of inappropriate experimental configurations. As reported above, in addition to the fact that animal models are intrinsically limited as they cannot reproduce large human nerves, a standardization of animal models and experimental design among independent investigations is still lacking. Moreover, many studies are performed without the necessary presence of both a negative (i.e., silicone tube) and a positive (i.e., autograft) control being considered, which may lead to erroneous or limited evaluations of the actual regenerative capability of a device. More importantly, the use of small animal models (e.g., rat, mouse) for PNS injury is particularly debatable, as rodents show a superior neuroregeneration activity compared to higher mammals, and the nerve distances involved are much shorter than those found in humans. Even assuming that the speed of axonal growth in humans is comparable to that found in rodents, that is, 1–4 mm day^{-1},[6,17] such a speed would be unable to cover the entire gap length before chronic denervation occurred in the distal stump of the human nerve.[6] It has been recently suggested that rodent models would likely provide more reliable data for the development of novel therapies for humans, if the evaluation of nerve regeneration was performed at relatively early time points, when differences among positive and negative control groups are still significant. Alternatively, the animal model could account for denervation of the distal segment before repair, that is, a delayed repair.[101] The timing of outcome measurement is thus an experimental variable that greatly affects the evaluation of PNS regeneration. Further studies are also directed toward overcoming the limitations in functional recovery after PNS injury by accelerating the axonal growth across the injury site, for example, by means of electrical stimulation.[102]

With regard to clinical trials currently testing scaffolds or biomaterials for PNS regeneration, the reader is directed to some accredited, free databases available online. At the time of writing this chapter, only three trials seem to be ongoing: two of them are postmarketing, comparative studies (phase IV) on the Avance™ nerve graft (acellular graft from a donor tissue), while a third trial, using a chitin conduit for bridging small nerve gaps, is reported from China. To the best of our knowledge, no trial is in progress for tubular configurations or matrices exploring the use of exogenous cells and growth factors, in spite of the plethora of studies published in the literature on the subject.

5.532.2.3. Case Study: Collagen-Based Tubes with Oriented Porous Patterns

As discussed above, the regenerative performance of a nerve conduit may be increased either by using a tube filling or by designing the conduit wall porosity and/or surface topography. In this section, we focus on the improvement of the tube wall design for a specific class of devices, that is, collagen-based tubes, with the view of developing novel nerve guides for clinical use. Such a work has been undertaken in the last few years by some of the authors of this chapter, and is discussed here as a case study, to highlight the basic issues related to the development of a medical device.

In the last two decades, collagen-based tubes have been extensively used as nerve guidance conduits in a number of independent investigations.[43,103–107] Some of these devices have been approved for clinical use and are currently being marketed (**Table 2**), although most of the literature available on them favors their application on animal models rather than humans.[43,103,104] It is worth noting that the manufacturers of the collagen devices currently adopted do not show evidence of any specific microporous structure in their devices. Either type I collagen of bovine origin or type I/III collagen from porcine skin is employed for these commercial devices.

As reported above, it has been demonstrated that a layer of myofibroblasts can attach to the inner surface of collagen tubes,[19,44,45] which thus might inhibit or limit the contraction exerted by those cells on the nerve stumps, facilitating nerve regeneration. The question arises as to whether the limited performance of currently available collagen conduits is attributable to the microstructure and cell permeability of their tube walls. To answer such a question, collagen-based tubes with controlled and oriented porous patterns within the tube wall have been recently developed.[55] The tubular structure is obtained by spinning a collagen suspension, as occurs in a centrifugal casting process. After a proper spinning time at high speed, the collagen suspension is frozen in liquid nitrogen and finally subjected to a freeze-drying process to get a porous collagen tube. A radially aligned porosity in the tube wall, as well as a radial gradient in pore size, is the direct result of the spinning process, which causes the establishment of a collagen concentration gradient within the spun suspension, due to centrifugal effects. In particular, a compact structure, with a pore size of approximately 5 μm, is achieved at the outer wall of the collagen tube, while cell-permeable pores, with a diameter of about 50 μm, are obtained at the inner wall (**Figure 5**). More recent data have also produced evidence that the centrifugation of the collagen suspension can be modeled by means of the Lamm equation.[108] With a few assumptions, the modeling provides reliable estimations of the conduit inner diameters, wall thicknesses, and collagen concentration gradients resulting from different spinning procedures. This is important for designing fabrication protocols for the production of nerve guides with different inner diameters for therapeutic use.

In view of a clinical assessment of the novel collagen-based tubes, an important factor to be considered is the industrial source of collagen. The specific collagen chosen should be already employed in the clinical setting for approval of the final device for human use or at least for acceleration of

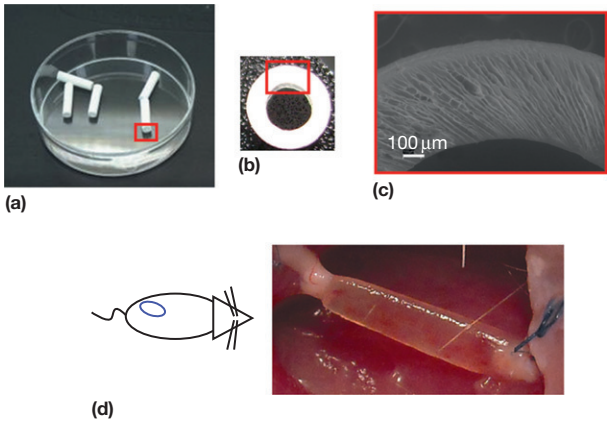

Figure 5 Morphology of micropatterned collagen-based tubes. Longitudinal (a) and cross-sectional (b) macroscopic views of the collagen tubes; the devices show an aligned microporous pattern along the tube wall (c); gross morphology of a tube implanted in a 10-mm rat sciatic nerve gap, 8 days after the implant (d).

the process of regulatory approval. Based on our own experience, the choice of the biomaterial should be made early in the design process of the medical device, before the planning of any preclinical studies. This is particularly relevant for devices based on collagen (or on any other naturally derived biomaterial), as the properties of the final device and its processing conditions are strongly affected by the specific collagen employed. Indeed, collagens of the same type can differ significantly in terms of fibrillar or microfibrillar structure, purity, solubility, cross-link density, etc., depending on the extraction process, the animal species, the animal age, the harvested tissue, and so on.

An initial design study performed in our laboratory involved, for the fabrication of micropatterned collagen tubes, the use of three different industrial sources of type I collagens derived from bovine skin, all used for clinical purposes. This study confirmed that the collagen source dramatically affects the tube processing conditions and the final properties of the tube, in terms of mechanical strength, flexibility, porosity, and degradation rate (unreported data). Such a study has thus been fundamental for the choice of the most suitable collagen source and for setting up a fabrication process tailored to the specific biomaterial.

Yet another issue to be addressed in view of a clinical application is the sterilization of the product (see **Chapter 4.410, Sterilization of Biomaterials of Synthetic and Biological Origin**), which should ensure the absence of microorganisms while preserving the structural and biological properties of the device.[109,110] First of all, in the case of the collagen tubes, the choice of the sterilization treatment should take into account the sensitivity of collagen to the combined effect of heat and water, which induce collagen denaturation.[111] Even more importantly, the treatment should not collapse the peculiar microporous structure of the collagen devices, which is the variable hypothesized to have a significant effect on nerve regeneration. At the same time, the sterilization process should not accelerate the process of *in vivo* degradation or induce any cytotoxic effects. Irradiation-based treatments, compared to ethylene oxide (EtO) ones, have been reported to induce adverse structural and biological changes in collagen sponges,[109] although some studies report that sterilization by low-dose γ or β irradiation can be performed on collagen devices.[110] Some concerns exist about the cytotoxicity of EtO-sterilized devices, which are addressed by means of an accurate monitoring of EtO residues within the sterile, final products. It is worth noting that EtO sterilization is widely employed for collagen-based devices and is the method adopted for the collagen-based nerve conduits currently available. Dry-heat sterilization (160–190 °C) on collagen has the advantages of being safe and effective, despite inducing some cross-linking of the collagen structure. As the fabrication of the novel collagen tubes encompasses a mild cross-linking by means of dehydrothermal treatment (120 °C for 48 h), we first investigated the feasibility of dry-heat sterilization to increase their mechanical strength and biostability. In particular, an additional dehydrothermal and sterilizing step at 160 °C for 2 h proved to have no detrimental effect on the pore structure of the collagen tubes or on their mechanical stability. However, dry-heat sterilization is very difficult to be implemented in an industrial production. An EtO sterilization treatment is currently under development and analysis, and preliminary results are encouraging, in terms of preservation of the microstructure and mechanical stability of the tubes.

Recent preclinical studies in a 10-mm rat sciatic nerve defect have highlighted that the novel collagen conduits (sterilized by means of dry heat) facilitate and accelerate more efficiently the processes of Schwann cell migration, axonal contact, formation of basal lamina, and remyelination, compared to the collagen devices available on the market. In particular, the conduits not only perform much better than commercial tubes, but also, more importantly, allow the formation of a normal nerve, with a normal number of fibers and a normal *G*-ratio (data to be published yet), which is an outstanding result when looking at those reported so far in the literature. Normal endoneurium and perineurium were also appreciable. Further preclinical studies on the performance of the same micropatterned tubes, sterilized by means of EtO, are currently in progress.

Although the molecular mechanisms by which the micropatterned conduits act on nerve regeneration need to be understood further, we postulate that these devices have the potential to improve PNS regeneration and functional recovery in humans. To perform a clinical trial, the fabrication of the devices has been shifted from the laboratory to a GMP facility, as required for clinical devices. The ethical committee of the San Raffaele Hospital (Milan, Italy), where the animal studies have been performed, has approved the use of the novel collagen tubes in 10 patients undergoing biopsy of the sural nerve, for diagnostic purposes. While keeping in mind the differences between animal models and humans discussed earlier, we expect that micropatterned collagen tubes will be able to create a nerve chamber environment that is more favorable to regeneration than that achieved with the currently available nerve conduits. Should the clinical trial(s) prove this, it would be conceivable to critically question whether the use of exogenous cells and growth factors is truly necessary to enhance PNS regeneration. The stimulation of endogenous regenerative mechanisms by means of artificial conduits and/or porous matrices is likely to be the most promising way to improve nerve regeneration in the clinical setting, at least in the near future.

5.532.3. State of the Art of CNS Tissue Engineering (see Chapter 00185 and Chapter 00238))

As described earlier, CNS axonal regeneration appears to be partly impeded by myelin-associated inhibitors,[112–114] loss in adult neurons of an intrinsic ability to overcome inhibitory cues,[112] and formation of a postlesion scar barrier.[115] Currently, no therapy exists for the restoration of function after CNS injury. While the traditional experimental approaches, directed toward creating a permissive environment for axonal regeneration and stimulating endogenous plasticity, involved the transplantation of exogenous cells and/or the supply of environmental regulators, the recent advances in tissue engineering have prompted the use of biomaterial-based smart devices, which can be used not only as vehicles for the controlled delivery of cells and soluble regulators, but also as collaborators with the host tissue, providing supporting guidance to axons. Some of these devices have found application, at least in animal models, in the management of both PNS and CNS injuries. The experimental evidence suggests that combinatorial strategies, involving the *in vivo* delivery of at least two exogenous factors out of cells, regulators, and biomaterials, are the most promising ones for a successful CNS repair. Both *in vivo* and *ex vivo* gene therapies are also emerging as powerful means to boost the regenerative capability of tissue-engineered devices.

The research focusing on CNS repair is still in its developmental stage because of the extreme complexity of the CNS environment; thus, the field is open to all possible therapeutic options. Due to the potentially infinite number of tissue-engineered devices that can be developed for the CNS, a detailed review of the existing literature is quite a cumbersome challenge. Some reviews have been published recently, each focusing on particular design aspects and/or applications of the devices, and the reader is directed to them for further information.[2,116–119]

In this section, the cellular, molecular, and biomaterial-based approaches attempted to date are briefly illustrated, with particular regard to the treatment of SCI, and with the aim of emphasizing the regenerative role played by the biomaterials themselves, used alone or in combinatorial strategies. The reader is also cautioned about the fact that standardization of animal models for SCI is lacking, even when considering the same animal species: site of injury (e.g., cervical vs. thoracic), type of injury (e.g., contusion, total transection, hemisection), volume of damaged area, and therapeutic time window (subacute vs. chronic SCI) are only some of the variables that researchers can choose arbitrarily. Transection models are, of course, not representative of most of the SCIs that can be found in humans. However, they are widely employed as the most severe type of injury. In this regard, some concerns exist about the actual therapeutic potential of preformed scaffolds to bridge spinal cord defects: they are widely used in animal models, but do not seem to be truly applicable in the clinical setting. The only exception seems to be provided by the use of injectable hydrogels, which can be delivered to the injured spinal cord without causing further damage and thus appear more promising as therapeutic devices. In this short overview, selected tissue-engineered devices will be illustrated, not attempting a comparative analysis of their regenerative performance but simply discussing their design. Though their potential as future therapeutic products does not seem evident, as for noninjectable devices, their accurate design might allow a deeper comprehension of the regenerative mechanisms of the CNS, for the further development of feasible therapies.

The basic concepts discussed earlier for the design of a PNS guidance device hold for the development of tissue-engineered products for CNS repair as well. The higher the complexity of the device, the more challenging and time consuming the proof of safety and efficacy required for any clinical use. However, sophisticated tissue-engineered products appear as the only therapeutic means for functional CNS recovery.

5.532.3.1. Cellular Strategies

As discussed above, SCI causes the irreversible loss of neurons. Acute SCI also results in severe loss of oligodendrocytes, leading to demyelination of surviving axons and severe functional impairment.[120] The transplantation of exogenous cells thus seems necessary to replace some of the lost cells and/or to facilitate remyelination.[121] Cellular therapy is also potentially useful for filling up any cavities or cysts that can form after SCI, and for creating a favorable environment for axonal regeneration (e.g., by means of neurotrophic factors secreted by cells).

While designing a cellular therapy for clinical application, several issues need to be addressed: (a) the optimal cell source; (b) the optimal route of cell administration; and (c) the microenvironmental mechanisms that regulate the survival, differentiation, and integration of transplanted cells within the host tissue. With regard to the cell source, different nonstem versus stem cell types have been investigated so far, at least at a preclinical level, to approach SCI, including macrophages, Schwann cells, and OECs in the former, and adult neural progenitor cells (NPCs), embryonic stem (ES) cells, and oligodendrocyte precursor cells (OPCs) in the latter. Both ES cells and NPCs are particularly promising, as they are intrinsically able to adapt their specification fate to different environmental needs.[122] The potential of ES cells in animal models of SCI, as well as the use of OPCs that have been predifferentiated from ES cells before transplantation, is currently being investigated, and results with regard to functional recovery appear encouraging.[123–125] However, apart from ethical considerations, the therapeutic use of ES cells is still constrained by some key issues, such as feeder-independent growth (expansion) and *in vivo* teratocarcinoma formation,[126] which need to be solved before proposing any ES cell-based therapy for human applications.

On the other hand, NPCs might represent a ready-to-use cell source for cell-based therapies, as they can be obtained from different tissues (e.g., embryonic, fetal, and adult) and have been widely used *in vivo* without causing tumor formation and overt toxic/side effects.[127] Adult NPCs isolated from the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus, from the subventricular zone (SVZ) of the lateral ventricles, or from the spinal cord, have been shown to self-renew and to be multipotent *in vitro* and after transplantation into the CNS.[128,129] The population of NPCs residing in the forebrain and spinal cord is maintained for life and can be considered a potential source of transplantable cells for individuals with SCI or other myelin disorders.[130,131] Transplantation of adult human NPCs into the intact and acutely injured spinal cord of severe combined

immunodeficient (SCID) mice, is associated with the differentiation of transplanted cells preferentially into oligodendrocytes (only few astrocytes)[132] and recovery of locomotor function.[133] Moreover, NPCs transplanted in the subacute phase of SCI with a combination of growth factors and anti-inflammatory molecules (e.g., minocycline and cyclosporin A) to optimize the survival of grafted adult NPCs improved functional recovery. However, chronic (8 weeks postinjury) transplantation of NPCs failed to exert any detectable ameliorative effect.[134]

This last finding suggests that the timing of cell transplantation is critical to the success of a given therapy and generates interest in the identification of the optimal route of cell administration. The anatomopathological features of focal CNS disorders, such as SCI, suggest that direct local (intralesional) cell transplantation might facilitate tissue regeneration. However, it has been recently shown that in multifocal CNS disorders, systemic (e.g., intravenous, intrathecal) transplantation of NPCs can be therapeutically efficacious, owing to the ability of transplanted cells to follow, via the blood stream or cerebrospinal fluid circulation, a gradient of chemoattractants (e.g., proinflammatory cytokines and chemokines) occurring at the site of inflammatory lesions.[135–138] While promoting interaction between transplanted NPCs and activated endothelial and ependymal cells surrounding inflamed CNS tissues, this chemoattractive gradient leads to selective and specific homing of transplanted cells in multifocal inflammatory CNS areas. In experimental models of CNS inflammation, there is solid evidence showing that NPCs survive transplantation procedures within the host (although most of the transplanted cells are lost), specifically migrate within the damaged tissue, and maintain their multipotency. However, there are limited data supporting the concept that these cells give rise to terminally differentiated neural cells that are, in turn, capable of sustaining a program of CNS repair via massive cell replacement.[139] Embryonic, fetal, and neonatal cerebellar NPCs injected into models of SCI do not differentiate at all into terminally differentiated neuronal cells.[132,140–142] The scarce and inappropriate terminal differentiation and the propensity of maintaining an undifferentiated phenotype within the host tissue suggest that transplanted NPCs might be therapeutically efficacious via mechanisms alternative to cell replacement, that is, neuroprotection and regulation of the immune response. Transplanted cells may significantly reduce the scar formation and/or increase the survival and function(s) of endogenous glial and neuronal progenitors that have survived the initial insult. This neuroprotective effect – which is usually accompanied by increased *in vivo* bioavailability of major neurotrophins (e.g., NGF, BDNF, CNTF, GDNF) – has been shown in rodents suffering from primary inflammatory CNS disorders, for example, SCI[141,142] and stroke,[143,144] as well as in rodents affected by neurodegenerative disorders accompanied by reactive inflammation, for example, Parkinson's disease[145] and epilepsy.[143,144]

A deeper understanding of the mechanisms underlying the interaction of transplanted cells with the host tissue would definitely help in developing an appropriate cellular therapy. The possible use of biomaterials as an alternative means to deliver exogenous cells is being explored and will be discussed in a subsequent section.

5.532.3.2. Molecular Strategies

Molecular therapies for the treatment of SCI might be developed with the multiple purposes of protecting neurons from secondary cell death, promoting axonal growth, preventing the action of inhibitory molecules, and/or impeding glial scar formation.

Many studies have demonstrated the neuronal survival and growth-promoting effect of neurotrophic molecules or neurotrophins, a family of polypeptides that are believed to be at least partially responsible for keeping developing neurons viable until their projecting axons reach their target tissue.[8,9] Exogenous administration of neurotrophic growth factors has thus been proposed as one potential therapeutic treatment for SCI. Different types of growth factors have been tested and BDNF,[146,147] NGF,[148] NT-3, NT-4, and NT-5,[147,149] as well as bFGF[150] have been proved to be protective when locally administered to rodents with acute spinal cord injuries.

In the injured CNS, a number of inhibitory molecules exist. While permissive molecules provide directional cues for routing axons to their correct target, inhibitory molecules either deflect growing axons from their optimal route or completely block the route.[7] Some of the inhibitory factors expressed during CNS development, such as proteoglycan NG2, keratin, and chondroitin sulfate, may be reexpressed after injury to the mature brain and spinal cord.[9] Considerable effort has been made on identifying, localizing, and reversing the effects of these growth inhibiting molecules. Several recent studies have led to the identification of certain myelin-associated components that can inhibit axon outgrowth *in vitro*, including myelin-associated glycoprotein (MAG),[151–153] oligodendrocyte myelin glycoprotein (OMgp),[152] the transmembrane semaphorin 4D (Sema4D/CD100)[154] and 3A,[155] and ephrin B3.[156]

Another target of molecular therapies for CNS repair is the undesired massive gliosis, that is, formation of the glial scar. After SCI, astrocytes proliferate reactively, resulting in the formation of the glial scar. Such a scar tissue at the lesion site has long been considered a possible detrimental factor impeding regeneration in the CNS, which in the injured spinal cord is aggravated by the formation of cystic cavities. Indeed, the glial scar tissue may act not only as a physical barrier to axonal growth, but also as a chemical inhibitor, being particularly rich in chondroitin sulfate. The massive gliosis after SCI is likely to be mediated by the local release of major glial regulators, such as transforming growth factors (TGF)-β, bFGF, and bone morphogenetic proteins (BMPs).[13] Significant upregulation of BMP-7, BMP-2,[157,158] and TGF-β has been observed in the acutely injured spinal cord.[159] Multiple types of evidence show that synthetic anti-TGF-β antibodies represent a potentially applicable tool to prevent/limit the extent of deposition of ECM components and to maintain and/or restore the functional integrity of the injured CNS.[160] An alternative and effective molecular treatment to inhibit the formation of the glial scar, recently proposed, consists of the supply of exogenous chondroitinase ABC to digest chondroitin sulfate proteoglycans.[161]

As discussed above for cellular therapies, several questions, relating to the identification of the molecule(s) to be administered, the quantification of the optimal dosage, the choice of a convenient administration route, and the identification/

selection of the time window in which the molecules are expected to be effective, need to be answered before a molecular strategy can be envisaged in the clinic. Another important aspect is the evaluation of possible synergic effects among different therapeutic strategies. So far, molecular therapies have been tested either with or without cellular therapies,[162] and the selected molecules have been usually applied to site(s) of injury by local injection,[150] continuous infusion,[148] or insertion of an artificial saturated polymeric carrier.[146] Viral vector-mediated transfer of molecules to the injured spinal cord is emerging as a new and effective strategy. *In vivo* gene therapy has been tested in models of SCI using several viruses, including herpes simplex virus, adenovirus, lentivirus, and Moloney leukemia virus (see **Chapter 2.202, Engineering Viruses For Gene Therapy**).[163] Molecular therapies on SCI have also involved *ex vivo* gene therapy approached with cells – usually fibroblasts – that have been transduced with genes encoding for neurotrophins.[149,164] The recent use of polymeric devices (e.g., scaffolds, hydrogels, microspheres) (see **Chapter 4.424, Nanoparticles for Nucleic Acid Delivery** and **Chapter 4.425, Delivery of Nucleic Acids and Gene Delivery**) to ensure a sustained release of bioactive molecules to the injured spinal cord is discussed in the following section along with combinatorial strategies.

5.532.3.3. Biomaterial-Based Strategies (see Chapter 00185 and Chapter 00238)

The basic tissue-engineering concept underlying this approach is that a biomaterial-based device, with controlled molecular, mechanical, and microstructural properties, can provide a physical system to support and guide axons to their correct targets during regeneration, as occurs with nerve guidance channels and oriented substrates in the PNS.

Several proof of principle studies have demonstrated that physically guiding the linear growth of CNS axons through the lesion site helps the axons to regenerate, even though the artificial implant, either a tubular device or a porous matrix, does not contain any exogenous molecules and/or cellular components. In such experiments, correct design of the artificial substrate is fundamental to achieving the desired regenerative response of the host tissue. In the following section, a few examples of plain biomaterial implants are reported to underscore the fact that the choice of the base material, the design of the mechanical properties, and the design of the scaffold porosity are key factors that significantly affect the cellular response to the implant. For example, an alginate sponge with random porosity, implanted in a transected infant rat spinal cord, has been found to support the elongation of both corticospinal and dorsal column axons and to guide them up to the distal stump of the transected spinal cord.[165] Although the mechanisms leading to enhanced axonal elongation remain unclear, it has been hypothesized that alginate itself may localize neurotrophic factors released from both stumps of the transected spinal cord, and the following degradation of the gel may provide a space and a supportive environment to promote the growth of CNS axons. Moreover, the alginate substrate may reduce the formation of the glial scar.

Several investigations have dealt with the role played by the mechanical properties of the implanted biomaterial. The use of an empty hydrogel channel, obtained by PHEMA–MMA, has been reported to bridge a 4-mm gap in a complete transection model in the adult rat spinal cord.[166] In this study, it was suggested that the regenerative performance of the hydrogel channel, even in the absence of exogenous cells, was likely determined by the mechanical properties of the substrate, designed to be similar to those of the spinal cord, which are between 230 and 600 kPa, depending on the species, the measuring system, and the time after death.[34] In fact, a mismatch in mechanical properties between the implant and the surrounding tissue can result in implant failure or cause the scaffold to compress or lacerate the relatively soft neural tissue. It is worth stressing that studies involving the use of nondegradable implants, such as the conduits cited above, should be considered as proofs of concept rather than as feasible therapeutic options, because of the constriction of the spinal cord and foreign body reaction that may develop in the long term.

Due to their high equilibrium water content, hydrogels provide a high permeability to trophic molecules and a viscoelastic behavior similar to that of soft tissues.[167] Moreover, injectable hydrogel formulations can be developed to deliver the biomaterial as well as any added cells or soluble regulators to the lesion site, in a minimally invasive manner. Hydrogels also exhibit a particular potential for peptide or protein addition, that is, they are ideal platforms for the design of biomaterials with specific bioactivity. Indeed, with the aim of recreating a cellular microenvironment similar to that found *in vivo*, recent efforts have been made in the field of tissue engineering to incorporate specific peptide sequences in the scaffold architecture, not only to encourage biospecific cell adhesion but also to induce and control other cellular functions such as migration, proliferation, ECM synthesis, and tissue remodeling. In an attempt to overcome the limited regenerative growth of CNS, different hydrogels of *N*-(2-hydroxypropyl)methacrylamide (HPMA) containing peptide or amino sugar sequences that exist in the natural ECM have been synthesized in a pioneering study, and implanted in either the lesioned optic tract or the cerebral cortex of rat.[168] Glucosamine (NHGlc), *N*-acetylglucosamine (AcNHGlc), and the short peptide sequence of arginine-glycine-aspartic acid (RGD) were incorporated in the hydrogel network, and the resulting scaffold was proved to increase the cellular response significantly, in terms of cellular migration and axonal ingrowth. RGD-linked polymers, in particular, contained large numbers of astrocytes and macrophages and supported the ingrowth of large numbers of axons, for the greatest distance. A similar poly(*N*-(2-hydroxypropyl)methacrylamide) (PHPMA) hydrogel containing RGD peptides was later shown to enhance tissue regeneration in the injured rat spinal cord.[167] In this study, the complex modulus of the PHPMA hydrogel was comparable with that of the rat brain tissue (~100 Pa), and it was proved that the introduction of the short peptides allowed the best match between the mechanical and viscoelastic properties of the hydrogel and those of the neural parenchyma.

With regard to the effect of the biomaterial microstructure on the growth of CNS axons, several devices with longitudinally aligned porosity have been implanted in the injured spinal cord and proved to support axonal regeneration. Agarose-based scaffolds with aligned pores promoted axonal regeneration in a transected adult rat spinal cord, either with

or without exogenous BDNF.[169] Alginate-based anisotropic hydrogels, with capillary channels, induced aligned axonal growth in an acute SCI model in adult rats.[170] Very recently, nanofiber hydrogels based on self-assembling peptides have been reported to promote locomotor functional recovery following SCI and to reduce glial reaction and inflammation in the acutely injured brain.[171,172] Laminin-coated, porous chitosan conduits have also enhanced functional recovery in adult rats following SCI.[173] Collagen filaments grafted parallel to the axis of the spinal cord have been shown to reduce scar tissue formation, to support the expression of neurotrophic factors, and to serve as a scaffold for the growth of spinal axons.[174] Functional restoration by means of collagen filaments in a rabbit SCI model has been recently reported.[175] However, the effect of the diameter and number of the collagen fibers on the regenerative response of the device has not been investigated. As observed for the PNS, the balance between contact guidance and surface area provided by the scaffold plays a key role. In our opinion, tuning those variables might lead to a deeper understanding of the interactions between the host tissue and the scaffold and to an optimal scaffold design for maximized performance.

Based on the encouraging results reported for PNS regeneration, tubular collagen implants, as well as collagen porous matrices with axially oriented pores,[176,177] have also been proposed as scaffolding materials for the treatment of SCI. It is worth noting that plain collagen-based tubes have been investigated, with positive results, in studies involving the bridging of the spinal cord to the PNS, in both rats and monkeys.[105–107]

5.532.3.4. From Biomaterials to Tissue-Engineered Devices: Combinatorial Strategies

The regenerative potential of a biomaterial-based device can be definitely improved by coupling it with exogenous cells or regulators, as proved for the regeneration of the PNS. The rationale for delivering cells by means of biomaterials is that such scaffolding can provide the necessary physical environment in which transplanted cells may survive and begin to consider integration with a very hostile domain, ultimately contributing to CNS repair.[178] Hydrogel scaffolds are particularly promising, both for cell delivery and for controlled release of any incorporated bioactive molecules.

The first approaches to combinatorial strategies involved the application of several tubular implants in combination with Schwann cells. Among the devices tested, tubes based on polyacrylonitrile/polyvinylchloride (PAN/PVC), poly(D,L-lactic acid) (PLA), and poly-β-hydroxybutyrate (PHB) coated with fibronectin-containing alginate hydrogel were all found to promote regeneration and myelination of damaged axons in the injured adult rat spinal cord.[166,179,180] More recently, advances in biomaterial processing techniques have led to the development of more complex devices, which need to be coupled with Schwann cells or other cell types. PHB conduits with predominantly unidirectional fiber orientation have been recently developed and seeded with Schwann cells, and these have been demonstrated to support cell survival as well as axonal regeneration in the adult rat injured spinal cord.[181] PLGA scaffolds with parallel channels have been seeded with Schwann cells and implanted in the transected rat spinal cord, showing promising results.[182–184] Remarkably, one of these investigations has proved that the diameter of the scaffold channels has a direct effect on the regenerative performance, with smaller diameter channels promoting greater regeneration.[183] This finding seems to suggest that, as observed for the PNS, the surface area of the implanted device should be fine-tuned for optimal nerve regeneration.

The transplantation of stem cells in combination with polymer scaffolds, rather than differentiated cells, might show a greater therapeutic potential. One of the first examples of accurate scaffold design and further seeding with NPCs for spinal cord repair was reported in 2002.[142] The scaffold was designed to mimic the architecture of the healthy spinal cord: the inner portion emulated the gray matter via a porous polymer layer designed to be seeded with neural stem cells for cellular replacement as well as for trophic support; the outer portion emulated the white matter with axially oriented pores for axonal guidance. Both the inner and outer scaffolds were fabricated from a blend of poly(lactic-*co*-glycolic acid) and a block copolymer of poly(lactic-*co*-glycolic acid)–polylysine, thus making them completely biodegradable. The experimental results suggested that the combination of NPCs with the polymer scaffold promoted long-term functional recovery in adult rats with hemisection of the spinal cord. Histology and immunocytochemical analysis suggested that this functional recovery might be attributable to a reduction in tissue loss from secondary injury processes, as well as diminished glial scarring. While the scaffold alone appeared to play an important role in functional recovery by reducing glial scar formation, NPCs remained largely undifferentiated, suggesting that their role was trophic support rather than cellular replacement. A PGA scaffold seeded with neural stem cells has also been employed to repair massive lesions in rat brain.[185] The results are quite exciting, documenting vascular infiltration of the cell-seeded scaffold, the dissolution of the PGA, and the differentiation of stem cells into neuronal and glial phenotypes, with the neurons both receiving and giving rise to axonal connections. However, the connections between the donor and the host cells have not been proved to be functional. A recent study has demonstrated that the use of multichannel PLGA scaffolds seeded with neural stem cells facilitated the bridging of a spinal cord defect.[186]

Another stem cell type explored for spinal cord repair is provided by MSCs, which can be easily obtained from bone marrow aspirates. Hydrogels based on HPMA, modified with the peptide sequence RGD, have been seeded with MSCs and used to repair a chronic contusive SCI, with some functional improvement recorded in adult rats.[187] MSCs have also been investigated in combination with a fibrin matrix.[188] However, the beneficial effect provided by MSCs, at least in models of PNS injury, seems to be comparable to that provided by Schwann cells.[189]

Among the novel technologies that enable the design of complex cell-seeded scaffolds for the treatment of SCI, it is worth citing some rapid prototyping techniques, including 3D printing[190] and biological laser printing. The latter is an emerging technology for the creation of specific patterns of living cells in biomaterials, and has been recently applied in the production of hydrogels with aligned microchannels of OECs, which hold promise for the treatment of SCI.[191]

However, the most recent investigations on the treatment of SCI are concerned with the production of tissue-engineered devices more sophisticated than cell-seeded scaffolds, that is, devices comprising cells, scaffolds, and environmental regulators, which can be either added to the scaffold, or supplied by genetically modified cells, or delivered as genes to transfect host cells *in vivo*. The direct addition of the regulators to the scaffold is usually performed in cases of a hydrogel-based scaffold, as the hydrogel can easily incorporate the selected molecules and supply them to the injury site on demand.[192–195] As mentioned above, a hydrogel scaffold may exhibit several advantages in SCI settings. It can be directly injected into the injury site for conformal repair; it can be designed for optimal cell response and degradation rate; and the hydrogel network can be finely controlled to tune the release kinetics of the embedded molecule(s). A composite hydrogel matrix has recently been shown to allow the sustained release of multiple bioactive neurotrophic factors suitable for SCI treatment, over 28 days.[196] Polymeric microspheres can also be used for a sustained delivery of exogenous molecules. Recent studies have focused on the coupling of microspheres and hydrogel matrices for the fine-tuning of the release kinetics in SCI models.[80,81,196,197] Gene therapy appears to be a versatile, alternative technique that allows the *in vivo* delivery of selected molecules by using either porous scaffolds seeded with transfected cells[169,198] or scaffolds incorporating genes encoding for them. As an example of the latter technique, multichannel PLGA scaffolds have recently been used to deliver *in vivo* DNA lipoplexes, and the experimental evidence has shown higher levels of transgene expression compared to naked plasmid.[199] This result might generate renewed interest in nonviral gene delivery, whose efficacy is usually much lower than that of viral vector-mediated gene transfer.

Despite the wide range of promising combinatorial devices found in the literature, the production of biomaterial-based, tissue-engineered devices for CNS repair is not conceivable in the near future. The short- and medium-term way to clinical application is likely easier to be achieved with cellular and/or molecular strategies, based on more traditional administration routes (e.g., bolus delivery), which might provide some, albeit modest, functional improvement following SCI.

5.532.4. Concluding Remarks

In this overview, we have attempted to provide a critical analysis of the current state of the art of nerve tissue engineering, highlighting the limitations of the field in terms of the development of feasible therapies. Apart from the choice of appropriate animal models and standardized experimental conditions, a proper design of biomaterial-based devices (e.g., nerve guidance conduits) is fundamental to the comprehension of the cellular and molecular mechanisms underlying the regeneration of both the PNS and the CNS, as well as to the development of a tissue-engineered product for clinical use. In particular, PNS tissue engineering is likely to achieve satisfactory clinical results, in terms of bridgeable nerve defects and quality of the regenerated nerve trunk, with the use of plain biomaterial devices, devoid of exogenous cells, and/or soluble regulators. On the other hand, combinatorial strategies, involving the use of scaffolds, cells, regulators, or genes encoding for them, seem the only conceivable way to a functional restoration following CNS injury. The complexity of these tissue-engineered devices leads us to presume that their application in the clinical setting cannot be envisaged in the near future. However, the promising results obtained so far in animal models should make us strive for the long-term achievement of true landmarks in restorative neurology.

Glossary

Alzheimer's disease Progressive mental deterioration that can occur in middle or old age, due to generalized degeneration of the brain. It is the most common cause of premature senility.

Amyotrophic lateral sclerosis (Lou Gehrig's disease) A progressive degeneration of the motor neurons of the central nervous system, leading to wasting of the muscles and paralysis.

Astrocyte Characteristic star-shaped glial cells in the brain and spinal cord. They perform many functions, including biochemical support of endothelial cells, which form the blood–brain barrier, provision of nutrients to the nervous tissue, maintenance of extracellular ion balance, and play a principal role in the repair and scarring process of the brain and spinal cord following traumatic injuries.

Astrogliosis Abnormal increase in the number of astrocytes due to the destruction of nearby neurons, typically because of hypoglycemia or oxygen deprivation (hypoxia).

Blood–brain barrier Separation of circulating blood and cerebrospinal fluid (CSF) in the central nervous system (CNS).

Differentiation Process by which a less specialized cell becomes a more specialized cell type.

Embryonic stem cells Pluripotent stem cells derived from the inner cell mass of the blastocyst, an early-stage embryo.

Extracellular matrix Protein-based connective tissue that usually provides structural support and instruction to the surrounding animal cells.

Growth factor Naturally occurring substance capable of stimulating cellular growth, proliferation, and cellular differentiation.

Inflammation Biological response of vascular tissues to harmful stimuli, such as pathogens, damaged cells, or irritants. Inflammation is a protective attempt by the organism to remove the injurious stimuli as well as initiate the healing process for the tissue.

Neural progenitor cells Progenitor cells have a capacity to differentiate into a specific type of cell. In contrast to stem cells, however, they are already far more specific: they are pushed to differentiate into their 'target' cell.

Neuron Electrically excitable cell that processes and transmits information by electrical and chemical signaling, the latter via synapses, specialized connections with other cells.

Neurotrophic factor Family of proteins that induce the survival, development, and function of neurons.
Oligodendrocyte A glial cell concerned with the production of myelin for insulation of the neurons in the central nervous system.
Parkinson's disease Degenerative disorder of the central nervous system that often impairs the sufferer's motor skills, speech, and other functions.

5.533.1. Introduction

Central nervous system (CNS) dysfunctions are caused by disease or trauma; they are diverse, frequently severe, and nondiscriminatory in affecting the whole world's population. Traumatic injuries such as brain injury and spinal cord injury severely and immediately affect the person's physical and/or cognitive abilities. Neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, or amyotrophic lateral sclerosis (Lou Gehrig's disease) slowly or rapidly degenerate CNS neurons, again resulting in deficits in movement and cognition. The causes of many neurodegenerative disorders are complex, mostly unknown, and may be associated with genetic abnormalities, but advancing age, environmental influences, and dysfunctional immunity are likely even more influential.[1] Even when potential treatments are discovered, the difficulties involved in accessing the CNS may make surgical intervention to implement such treatment more debilitating, and the presence of the blood–brain barrier (BBB), which normally is protective of the CNS, inhibits therapeutic molecules and proteins from passing into the CNS (**Figure 1**). Regeneration is difficult in the CNS due to the presence of many molecules inhibitory to regeneration as well as a huge heterogeneity in intricate and individualized circuitry. Additionally, diverse tissue response cascades following disease/injury in the CNS add more challenges to regeneration, such as increased inflammation, invading cells, and glial scarring.

Biomaterials, especially nanotechnology derived, have begun to be utilized as tools in combating tissue response, drug delivery issues, and changes in the environmental milieu. Examples include nanofibers, liposomes, nanoparticles, nerve channels, and scaffolds. These materials can be custom-designed to provide a facilitory environment for regeneration and/or a blocker of inhibitory environmental cues and tissue processes. In this chapter, we review different categories of biomaterials that can be modified for specific CNS needs. We also present an overview of traumatic CNS injuries and neurodegenerative diseases and discuss ways in which biomaterials can assist in regeneration.

5.533.2. Biomaterial Therapy Options

5.533.2.1. Drug Delivery

5.533.2.1.1. Introduction

Generally, many substrates, including neurotrophic factors or other growth factors, mitotic drugs, anti-inflammatory medications, or antiapoptotic drugs, can not only prevent some of the secondary and tertiary expansions of CNS damage, but also encourage axonal regeneration, cell survival, and/or differentiation. One of the difficulties in the delivery of such agents to the injured CNS is the presence of the BBB, which blocks the access of many cells and proteins from the bloodstream into the CNS.[2–4] Biomaterials have begun to enter the arena to help systemic, targeted, or local delivery of drugs.[5]

5.533.2.1.2. Systemic delivery systems

Systemic delivery systems are noninvasive as they are generally administered either intravenously or through other peripheral injection, such as intraperitoneal or subcutaneous. The delivery can be continuous or repeated, and allows for dose changes throughout the treatment. However, despite attempts at targeted delivery, the systemic delivery of a drug poses challenges in terms of unexpected target finds, biodegradability, and recognition by phagocytic immune cells prior to delivery to the lesioned area. Two biomaterials in this category include liposomes and polymeric nanoparticles.

5.533.2.1.2.1. Liposomes

Liposomes are small vesicles whose outer membrane is made out of the same material composing cell membranes, a phospholipid bilayer. The vesicles can be small and simple (25–50 nm in diameter) to large and multilamellar (200–5000 nm).[6–9] The inner core of the liposome can house drugs or proteins of interest and release them once the liposome binds to another phospholipid bilayer. Because of their similarity to cell membranes, liposomes are very biocompatible and biodegradable. Unfortunately, they are also readily targeted by blood immune cells that phagocytize small foreign particles while being transported through the vascular system.[10] One approach to this problem is to add polyethylene glycol to the surface of the liposome, which inhibits the liposomal aggregation and recognition by the immune system.[2,7,8]

Also, liposomes do not cross the intact BBB well. In some cases, such as after trauma, certain disease processes, and tumors, lesioned areas of the CNS can still be accessible as they have a compromised BBB where the liposomes can pass through more easily. More targeted methods that may facilitate BBB passage may be required by a process known as active targeting. In this approach, the liposome surface can be modified with an antibody or a ligand that will specifically attach to the targeted cells.[2,8] In this case, the targeted cells would be ones that actively transport cells across the BBB. Additionally, active targeting can then assist the liposomes in finding their direct CNS cell targets.

5.533.2.1.2.2. Polymeric nanoparticles

Polymeric nanoparticles, made from synthetic (poly-lactic or -glycolic acid) or natural (alginate or gelatin) polymers, form nanospheres or nanocapsules, are similarly sized as liposomes (10–1000 nm), and are a very diverse group in which the drug can be located throughout the particle or localized to

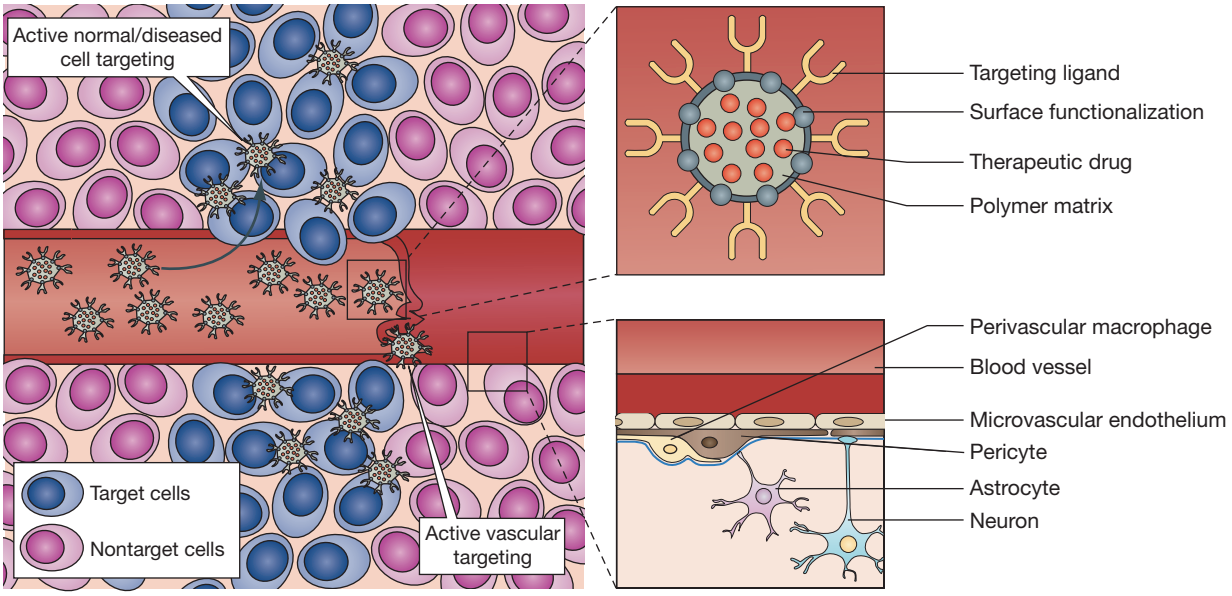

Figure 1 Blood–brain barrier and active targeting for drug delivery. The blood–brain barrier is regulated by the neurovascular unit, which comprises perivascular macrophages, astrocytes, and neurons (bottom right panel). This regulation determines the amount of communication between the central nervous system and the periphery, restricting the passage of proteins and cells through tight junctions between endothelial cells in the blood vessels. Biomaterials such as liposomes or other nanoparticles can be created to house surface ligands that will specifically bind to target cells. They will also house other proteins such as polyethylene glycol that will increase the biomaterial's longevity within the peripheral blood system. Additional targeting ligands or antibodies can further direct the biomaterial toward receptors on its end target for drug delivery. Adapted from Orive, G.; Anitua, E.; Pedraz, J. L.; Emerich, D. its core or surface.[7,10–12] They are more stable in the body than liposomes, but still require similar surface modifications to increase longevity within the body and can deliver the drug in a more controlled, time-release manner.[13] For example, nanoparticles coated with polysorbate 80 have been shown to be successfully transported through the BBB.[13]

5.533.2.1.3. Local delivery systems

As stated earlier, despite attempts at targeted delivery, the systemic delivery of a drug poses challenges in terms of unintended target finds, biodegradability and systemic side effects, and detection and removal by cells from the immune system before the drug finds the appropriate target. An alternative to systemic delivery would be a direct transplantation of the biomaterial, ideally with a timed-release delivery system and biodegradability of the nondrug material. The transplantation itself, however, may cause further trauma, and a nonbiodegradable biomaterial may cause continued inflammatory responses.

5.533.2.2. Scaffolds for CNS Repair

5.533.2.2.1. Introduction

Often, post-CNS injury or disease, the new abnormal environment plays a key role in advancing the disease process. Scaffolds can support and direct cells in the environment by creating a new extracellular matrix important for healthy and normal cell–cell interactions and signaling (Table 1).

5.533.2.2.2. Characteristics of scaffolds in CNS

Scaffolds have been created with many different biomaterials such as hydrogels, collagen, methylcellulose, and agarose in the CNS.[14–17] These scaffolds are diverse in their configuration, material strength, biodegradability, cell adhesion, and signaling.

The proper configuration of scaffolds depends on the end use. Biomaterials produced to facilitate nerve or axonal regeneration may require long channels directing the regeneration in a particular direction.[3] This scaffold may also contain certain amino acid sequences that promote regeneration in general

and also toward/away from a topographical and/or chemical gradient. Other more generally supportive materials may be used for extracellular matrix or cellular support such as nanogels or sponges.[3] These also may be at least partially constructed with specific protein sequences that promote cell differentiation, survival, or differentiation. All scaffolds for CNS regeneration, regardless of model, require general characteristics.[17,18] As in local drug delivery, the potential for additional damage when inserting the scaffold may outweigh its benefits. To this end, scaffolds must be flexible and easily inserted into the tissue. The scaffold should be biocompatible and biodegradable so as to not elicit additional chronic inflammatory responses. Also, if the permissive scaffold does not biodegrade, the regenerating cells would grow into the scaffold, but never reenter the CNS, creating a sinkhole for regeneration. The scaffold must allow for diffusion of nutrients to maintain the health of the incorporated tissue and also enough room for cells or for axons to grow through it. Examples of scaffold materials include synthetic versions such as poly-2-hydroxyethyl methacrylate and poly-*N*-2-hydroxypropyl methacrylamide as well as natural forms, such as collagen, chitosan, fibrin, and dextran.

Scaffolds also differ in their mechanical strength and biodegradability. Covalent cross-linking produces a stiffer material, which is more difficult to elegantly transplant into the CNS and usually harder to degrade. Physical cross-linking produces a more compliant, softer product, which biodegrades more easily. The closer a material is to matching the mechanical strength of the environment, the more likely it is for cells and axons to cross barriers between the natural environment and the scaffold.[19,20] As stated earlier, the biodegradability of the tissue, related to stiffness, is of importance to decrease prolonged inflammatory processes. The scaffold can degrade from hydrolysis or from proteolytic degradation of more natural materials.[21,22]

Cell or axonal adhesion and signaling are other important characteristics of a successful scaffold. If the material itself is not naturally cell-adhesive, the material can be laced with amino acid sequences presented in high-density promoting growth or bonding to CNS cells.[23] This is also quite important when considering cell transplantation along with the scaffold to provide a facilitatory niche for the cells. Most scaffolds are designed to not only physically support, but also direct cells, through scaffold–cell interaction. This does not occur without cell attachment to the scaffold. The scaffold must promote a certain function of the cells and, therefore, adhesion and signaling are key. For example, neural progenitor cells may be transplanted for neuronal differentiation to assist with local circuitry or for increased oligodendrocyte differentiation for increased myelination.

Signaling of the scaffold can be static or time release. Signaling may also be directed at endogenous adult cells for regeneration of compromised axons or differentiation of endogenous progenitor cells. Signaling can also be directed at quenching inhibitory environmental cues or attenuating scar formation postinjury. For example, brain-derived neurotrophic factor (BDNF) can facilitate regeneration and plasticity.[16,24] Alternatively, the IKVAV sequence of laminin has been shown to not only promote neurite extension and axonal regeneration, but also inhibit astrogliosis (**Figure 2**).[23,25] However, it may be beneficial at times to provide the environment with more than one signal for multiple tissue responses or for more direct topographical cues on regeneration of axons.[26] The scaffold would have to be designed in such a way that it has appropriate three-dimensional patterning.[27,28] Patterning of different peptide sequences, cell-adhesive versus cell nonadhesive areas, and texture of the surface may all have a role to play in differential events within the scaffold. Because the nature of the CNS is highly heterogeneous and that of CNS injury even more so, the most successful scaffold will need to combine techniques.

5.533.2.3. Nerve Channels

5.533.2.3.1. Introduction

Promotion of specific neurite and axonal growth and/or conductivity may require a scaffold channel consisting of nanotubes or nanofibers (**Table 1**). The length, volume, and diameter of the channel can be manipulated to promote conductivity or guide axonal growth. The shape itself can allow for a different molecular makeup within the tube than outside of the tube, thereby sending the axon or neurite an elongation cue and the surrounding environment a different cue. The nanofiber structure would also offer a high exposure of the neurite and its environment to the instructional molecules, potentially overwhelming the system toward a more permissive, less destructive niche. Alternatively, the inside of the fibers or tubes could house drugs or other proteins to be time- or gradient-released while the outside of the fiber would serve as a conduit for axonal regeneration or neurite growth or affect the extracellular matrix.

5.533.2.3.2. Characteristics of nerve channels

Nerve channels can be made out of biodegradable or nonbiodegradable material. As stated earlier, nonbiodegradable material presents increasing challenges due to not only its increased incidence of chronic inflammation, but also its mostly noncell adhesive nature. Examples of these materials are silicone, polyacrylonitrile, polytetrafluoroethylene, and poly-2-hydroxyethyl methacrylate.[29] Biodegradable material is usually superior as it does not cause these long-term inflammatory changes and degrades as the nerve and the environment regenerate. This also allows the nerve to pass from the permissive environment of the material back into the CNS. If the material is permissive enough for the axon to grow but does not degrade, the axon may grow into, and stay within, the material instead of passing through and forming the necessary connections for function. The biomaterial can be natural or synthetic, but the by-products of degradation must also be tested for toxicity. Common biodegradable compounds are the polymer family of poly-α-hydroxyacids, collagen, chitosan, and poly-β-hydroxybutyrate.[29]

An additional consideration for nerve channel composition is whether to create the channel to have electrical properties. Neurons are very electrically active cells and having an electrically charged extracellular environment may help regeneration.[30,31] The three main types that currently exist are all nonbiodegradable and include polymers with a quasipermanent charge, an electric charge generated with mechanical stress, or electrically conducting polymers. Examples of these

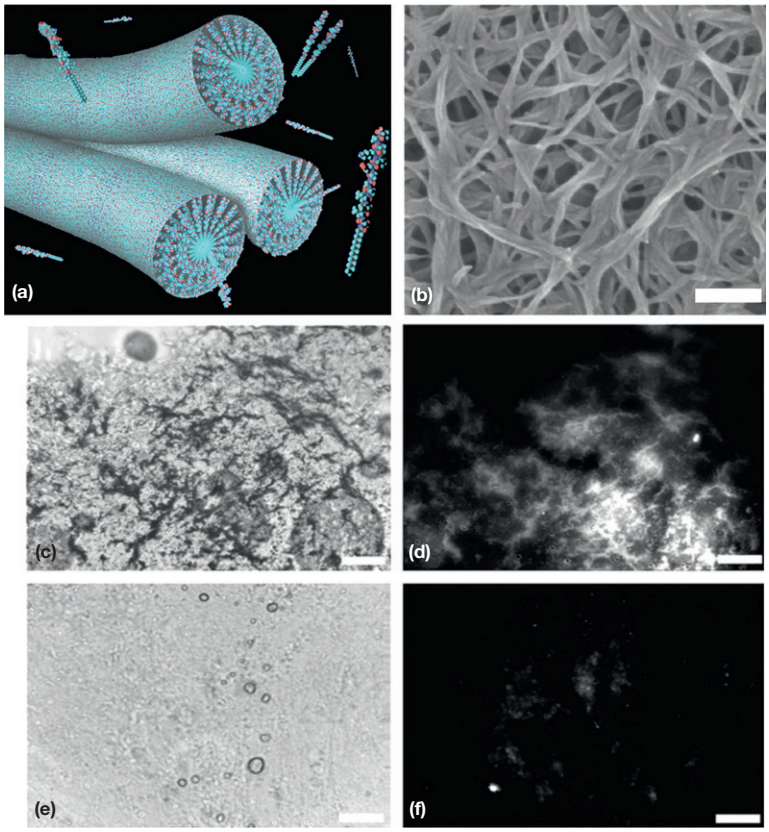

Figure 2 IKVAV PA structure, self-assembly, and biodegradability. (a) Schematic representation showing the makeup of individual PA molecules assembled into a bundle of nanofibers interwoven to produce the IKVAV PA scaffold. (b) Scanning electron micrograph image shows the network of nanofibers *in vitro*. Scale bar = 200 nm. (c–f) Phase (left) and fluorescent (right) images showing biodegradability of the PA through a fluorescent derivative in the injured spinal cord quite visible at 2 weeks (c, d) but then quite diminished at 4 weeks (e, f) postinjection. Scale bars: (b) 200 nm, (c–f) 50 μm.

materials are poly-tetrafluoroethylene, polyvinylidene fluoride, and polypyrrole.[29]

Mechanical strength can provide structure to a dysfunctional environment and prevent channel collapse and resultant nerve or axon compression, but can also inhibit biodegradability and create a sharp contrast in tissue properties between the implant and the natural CNS tissue. Many factors, including biodegradation, activity, and inflammatory cells, can cause collapse of the biomaterial channel, which in turn can cause damage to the axons or neurites that are regenerating.[32] The damage due to this collapse must be balanced against the decrease in biodegradability and the stress of a strong, firm material against the soft CNS tissue. Cross-linking of the biomaterial and/or adding coils to the walls of the channels can both provide structural permanence to the channel.

Adhesion of the axons or neurites to the channel is necessary for regeneration attempts. The key is to either mimic a permissive environment or even revert to a developmental environment to provide chemotaxis. This can be accomplished by either nonspecific binding through surface charge, roughness, or topography or specific adhesion to molecules in the environment.[33,34] Nonspecific binding can be seen using chitosan and polylysine, which assist binding via charge.[21,34] Specific adhesion, however, can more intimately guide the desired effects of the neurites by choosing whole or portions of proteins proven to promote regeneration, such as the whole protein of laminin or the five amino acid sequence of laminin, IKVAV.[35,36]

Nerve guidance channels can also have an internal medium, which increases available functions, such as internal cell adhesion, drug delivery, and neurite extension through increased surface area.[37–44] The internal environment of the nerve channels can also consist of a scaffold, such as collagen, matrigel, or laminin.[43,45–47]

5.533.3. Spinal Cord Injury

5.533.3.1. Introduction

Spinal cord injury progresses in three stages: acute, subacute, and chronic. The acute phase of spinal cord injury begins with petechial hemorrhages at the original mechanical trauma (primary injury) and lasts for 8–24 h. During this time, the injury site undergoes hemorrhagic necrosis.[48–50] Total calcium levels increase within an hour, peak at 8 h, and remain elevated for 1 week postinjury.[51–53] This excess calcium has toxic effects on many cellular functions and may serve as a common signal for cell death.[54,55] Other such signals include free radicals from

phospholipid hydrolysis, infiltrating neutrophils undergoing oxidative bursts, and the autoxidation of catecholamines.[56,57] Excitotoxicity occurs from the release of the excitatory amino acids, glutamate and aspartate, with peak levels noted shortly posttrauma.[58,59] All these events result in waves of apoptosis in the cells surrounding the primary injury. The first occurs 24–48 h postinjury in the neurons surrounding the primary site. All these toxic events cause a very rapid and intense gene response. In addition to gene upregulation, proinflammatory cytokines activate microglia and recruit lymphocytes, neutrophils, and monocytes, which kill and phagocytose cells.

The subacute phase begins at 12–24 h postinjury and is marked by the influx of polymorphonuclear granulocytes and monocytes/macrophages to the injury site to clean up the dead cells and by the reactive gliosis of microglia and astrocytes, which fill in the cavity.[60] Adult CNS neurons continue to upregulate immediate early genes, such as nuclear proteins, cytoskeletal proteins, and growth-associated protein (GAP-43), which is a major phosphoprotein of neuronal growth cones. At this time, the axons sprout, but do not elongate. After ~2 weeks, the upregulation is followed by a downregulation of these genes and a halt in the regenerative process.[61] The second wave of apoptosis occurs at 1–2 weeks affecting all neural cells but mostly oligodendroglia in the degenerating white matter tracts, resulting in a significant loss of conductance.[62–68] Also at this stage, the injury site fills with blood vessels, Schwann cells, meningeal cells, fibroblasts, and activated astrocytes.[69] Toward the end of the subacute stage, the damaged spinal tracts begin to retract and are surrounded by macrophages and apoptotic oligodendrocytes. Reactive astrocytes as well as microglia and macrophages start to form a scar at the junction between the spinal cord and the lesion consisting of a dense network of processes.[60,70] This scar formation progresses into the chronic phase of injury.

The chronic phase does not begin until several weeks postinjury. The cavity in the injured cord is filled with a matrix of the glial scar, macrophages, astrocytes, fibroblasts, and Schwann cells from spinal roots, with a thin wall of white matter tracts along the outside. The cord is thinner due to the loss of cells and myelination at the injury site. The lesion in mice fills with a dense connective tissue filled with macrophages, fibroblasts, and capillary epithelium.[71–73] The connective tissue becomes revascularized and the fibroblasts convert to myofibroblasts that actually pull together the ends of the lesion, which reduces the distance in which regenerating axons need to travel.[74,75] Some sensory axons have been shown inside the connective tissue matrix, but most sensory axons and all corticospinal, rubrospinal, reticulospinal, and sertonergic fibers retract from the injury site and form retraction bulbs.[76] By 1 month and thereafter, most axons remain myelinated, but with a very thin sheath as compared to their uninjured counterparts.[77,78]

Three main strategies have been used to promote function following SCI. First, neuroprotection strategies aim to decrease the effects of secondary inflammation and apoptosis that greatly accentuate the injury. Second, axonal regeneration or sprouting approaches attempt to restore the damaged supraspinal and intersegmental inputs. Third, modulation of the endogenous sublesional spinal cord circuitry can promote locomotor patterns without descending input.

5.533.3.2. Scaffolds in SCI

As noted earlier, damage to the spinal cord can produce cell necrosis and waves of additional cell death, leaving an environment of empty cavitations and a thick inhibitory scar. Many of these changes are reactions of the cells to the caustic lesion environment. Acutely and subacutely, changing this environment with a scaffold promoting regeneration, inhibiting astrogliosis, and/or supporting cell proliferation and survival could drastically change the tissue response.

A molecularly designed biomatrix composed of peptide amphiphile molecules that self-assemble from aqueous solution into cylindrical nanofibers displaying bioactive epitopes on their surface was used in a model of spinal cord injury and highlights the characteristics listed earlier.[23,25,79,80] The nanoscale peptide amphiphiles have a hydrophobic tail end and a charged middle that allows the separation of individual fibers under noncationic conditions.[23,25,79,80] Once the gel is injected into the spinal cord or the retina, the physiologic cationic conditions neutralize the charged peptides and the fibers undergo hydrophobic collapse, forming long nanofibers.[23,25] Thus, this is a biomaterial that is a liquid in aqueous solution as it is being delivered, but turns into a gel or more solid form after being introduced to the spinal cord. The nanofibers are biocompatible as they are entirely composed of amino acids naturally found in the body and are biodegraded in the spinal cord after a period of weeks postinjection.[23] The formed nanogel product was found not only to allow sufficient nutrient diffusion to support cell life both *in vitro* and *in vivo*, but also to support neurite outgrowth from encapsulated neural stem cells and axonal regeneration in the injured spinal cord.[23,25] *In vivo*, the nanoscale peptide amphiphile also acted as a more positive extracellular matrix by signaling via its concentrated head group to inhibit astrogliosis, attenuate cell death, and once again promote regeneration of different types of axons.[23] Most importantly, the injection of the nanofibers resulted in a behavioral improvement in the spinal cord-injured mice.[23]

5.533.3.3. Drug Delivery and Nerve Channels in SCI

Spinal cord damage following injury could greatly benefit from the delivery of neuroprotective or regenerative drugs. Acutely and subacutely, less cell death would occur if a therapy were delivered acutely that quench the excitotoxicity drenching the damaged area. Specific and temporally appropriate pro- or anti-inflammatory medications may decrease the invasion of immune cells and/or swelling that could cause further damage to cells and axons traversing the spinal cord. Neurotrophic factors or growth factors could be delivered to increase cell and axon survival or promote axonal regeneration prior to the formation of a thick, impermeable glial scar.[38,39,43] Alternatively, blockers of astrocyte hypertrophy could allow the astrocytes to cordon off the invading cells, but not to hypertrophy to a point where it blocks the regeneration of axons. Chronically, drugs that can infiltrate and break up thick scarring could promote regeneration if combined with other axonal regenerative agents. Bridges or grafts could also promote regeneration of axons around or through the lesioned spinal cord (**Figure 3**). Importantly, combined therapy reaching out to many of the processes occurring post-SCI, such as cell

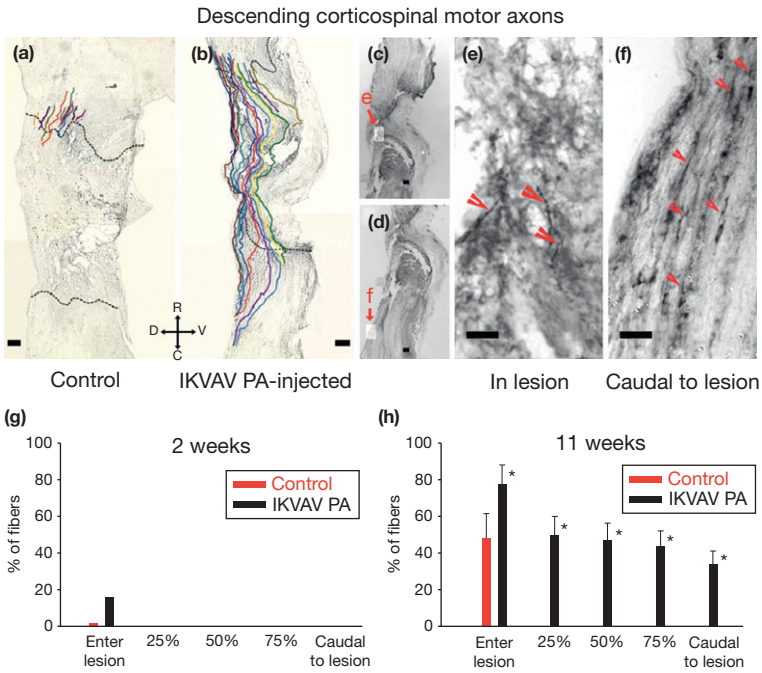

Figure 3 IKVAV PA promotes regeneration of axons after SCI. (a, b) Representative neurolucida tracings of labeled descending motor fibers within a distance of 500 μm rostral of the lesion in control vehicle-injected (a) and IKVAV PA-injected (b) animals. The dotted lines demarcate the borders of the lesion. (c–f) Bright-field images of BDA-labeled tracts in lesion (c, e) and caudal to lesion (d, f) used for neurolucida tracings in an IKVAV PA-injected spinal cord (a, b). (g, h) Bar graphs show the extent to which labeled corticospinal axons penetrated the lesion. *The groups representing three control and three IKVAV PA mice and the tracing of 130 individual axons differ from each other at $p < 0.03$ by the Wilcoxon rank test. R, Rostral; C, caudal; D, dorsal; V, ventral. Scale bars: (a–d) 100 μm, (e–f) 25 μm.

proliferation or glial scar attenuation along with axonal regeneration, will eventually have the best functional outcome.

The study of delivery of growth factors has offered new methods of releasing growth factors into the environment. Stimuli-responsive hydrogels have been developed in which external stimuli, such as temperature, light, or pH stimulate the release of growth factors. For example, Das *et al.*[81] engineered gold nanoshells into scaffolds that absorb light at a fixed wavelength, heat up, and release growth factors. Alternatively, other scaffolds release growth factors in response to pH such as to the low pH in the endosome.[82,83]

In order to combat disorganized axon growth, nerve channels have been used to promote growth unidirectionally in the injured spinal cord. Stokols and Tuszynski[84] utilized this technology along with drug delivery. They produced linearly oriented channels made of agarose by forming ice crystals from an agarose solution and freeze-drying (**Figure 4**). When crystallizing the nerve channels, the protein BDNF, was added to further promote axon regeneration. After 1 month, the nerve channels were well incorporated within the spinal cord tissue, and the combination of nerve channel and growth factor increased the amount of axon entry into the channel by 2–3 times.

5.533.4. Alzheimer's Disease

5.533.4.1. Introduction

Alzheimer's disease, the most common form of dementia, is characterized by a decline in memory and other cognitive functions that eventually leads to death within 10 years of diagnosis. Many molecular lesions have been identified in Alzheimers, although the accumulation of misfolded proteins remains the central cause. This misfolding leads to oxidative and inflammatory damage, which leads to loss of neurons and synapses and, therefore, to gross atrophy of the affected areas: temporal, parietal, and frontal lobes.[85]

The most recognizable pathological features of Alzheimer's are the β-amyloid peptide and tau plaques and neurofibrillary tangles, which are clearly visible by microscopy in brains of those afflicted by Alzheimer's disease.[86,87] The accumulation of both β-amyloid and tau is linked to the deficiency of cholinergic projections in Alzheimer's disease.

β-Amyloid is a 36–43 amino acid metabolic by-product of the proteolysis of the amyloid precursor protein consisting that is more commonly found as a monomer than in an aggregate. When there is an accumulation of β-amyloid through increased metabolism of the amyloid precursor protein and imbalance of enzymes regulating the levels of β-amyloid, the protein begins to aggregate into fibrils and can form insoluble fibers, termed amyloid plaques. Although plaques and tangles are a natural result of aging, Alzheimer's patients have a much higher percentage of them in the brain areas listed earlier.[87] In the Alzheimer's brain, β-amyloid selectively builds up in the mitochondria in the neurons, and inhibits certain enzyme functions and the utilization of glucose by neurons.[88]

Tangles (neurofibrillary tangles), another hallmark of Alzheimer's disease, are thought to follow β-amyloid accumulation. Tangles involve irregular folding of a microtubule-associated protein, tau, which normally helps stabilize microtubules for normal cell transport. In Alzheimer's disease, tau

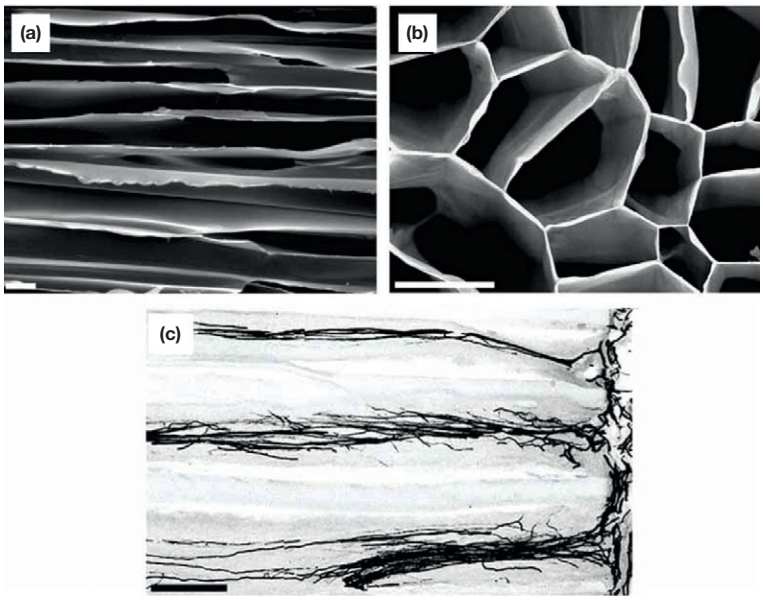

Figure 4 Aligned agarose nerve tubes synthesized by ice crystallization. (a, b) Scanning electron microscopy images of freeze-dried tubes longitudinally (a) and cross-sectionally (b). (c) Dye showing axonal penetration *in vivo* through the agarose tubes. Scale bars = 100 μm.

becomes hyperphosphorylated and, therefore, insoluble, creating neurofibrillary tangles and destroying the transport system within the neuron.[89]

As in most, if not all, other diseases and trauma processes, inflammatory processes and cytokines contribute to the pathology of Alzheimer's disease.[90]

Neurotrophic factor levels, which normally promote proliferation, differentiation, and survival of CNS cells, have also been correlated with the decline of Alzheimer's disease. Both nerve growth factor (NGF) and BDNF have shown improvements in animal studies.[91,92]

As in most, if not all, diseases and trauma processes, inflammation contributes to Alzheimer's disease. Both activated microglia and reactive astrogliosis occur around the plaques as well as throughout the brain. Again, similar to other tissue responses, it is not entirely clear whether the actions of the increased inflammatory response are positive or negative.[93–95]

5.533.4.2. Biomaterial Therapies for Alzheimer's

The amount of metal ions that accumulate in the brain increases over time and has additional deleterious effects on Alzheimer's. Metals, such as copper and zinc, can initiate oxidative stress in cells forming radicals disrupting DNA and protein cascades.[96] The hallmark plaques of Alzheimer's disease contain increased levels of both copper and zinc compared to the normal brain. Therefore, a new approach to slowdown the progression of Alzheimer's disease came with the introduction of iron-chelating compounds, which have little effect on normal brain tissue.[96,97] One study designed a nanoparticle encapsulating the chelating compounds in a design that would facilitate crossing of the BBB.[97] *In vitro*, these nanoparticles had the potential to resolubilize the plaques under reducing conditions.[97]

Another approach, also involving metals and Alzheimer's, attempts to destroy the plaques altogether. Nanoparticles that will cross the BBB are designed to carry gold particles specifically to accumulations of the β-amyloid protein. Once the gold particles have stably bound to the β-amyloid accumulation, weak and normally safe microwave fields heat up the gold-infused β-amyloid and not only break up the fibrils, but also lower the incidence of reaggregation.[98,99] A similar approach may also be effective in the treatment of many types of disorders, such as cancer, HIV, and diabetes.[100]

The introduction of subfragments of β-amyloid may also protect neurons from Alzheimer's, but permeability of the BBB remains a challenge. Early research in this area determined that chitosan nanoparticles loaded with β-amyloid crossed the BBB, were taken up in the brain, and had a favorable immunogenicity.[101] Further work will explore its efficacy in treating Alzheimer's disease.

Targeting therapeutic interventions remains challenging as well. One group examined the use of magnetic chitosan microparticles for treatment of Alzheimer's disease.[102] Tacrine, a reversible cholinesterase inhibitor used in the treatment of Alzheimer's disease, was loaded into the microparticles, and the particles were injected intravenously, while a magnet was held at the target region. This delivery system significantly increased the amount of tacrine in the brain. Another method is the use of smart nanovehicles consisting of a chitosan polymeric core with a modified antiamyloid antibody on the surface as a biosensor.[103] In this method also, the modified vehicle did cross the BBB, but the uptake of the vehicle in the brain was 8–11 times higher than in controls.

5.533.5. Parkinson's

5.533.5.1. Overview of Parkinson's

The three major symptoms of Parkinson's disease are tremor at rest, rigidity, and bradykinesia. Other nonmotor symptoms,

such as autonomic changes, cognitive changes, and sleep disturbances, are also usually seen. The underlying cause of Parkinson's disease is injury to the dopaminergic projections from the substantia nigra pars compacta to the striatum and death of the striatal dopamine and nigral neurons. Pathologically, intraneuronal Lewy bodies and Lewy neurites are readily found not only in the diseased brain areas, but also throughout out the brain.[104,105] Genetic predisposition and environmental exposure are both linked to the onset of Parkinson's.[106,107]

The neurodegeneration seen in Parkinson's could be related to mitochondrial dysfunction, oxidative stress, excitotoxicity, apoptosis, and inflammation.[108] Genes such as α-synuclein, parkin, and ubiquitin hydrolase that are linked with Parkinson's suggest the possibility that dysfunction of the ubiquitin-proteasome system in the dopaminergic cells may underlie Parkinson's disease.[109] Normally, ubiquitin proteins bind to damaged proteins and signal their need for degradation by the 26S proteasome. Mutations of all three genes will hinder the normal protein degradation process and result in damaged protein accumulation within the cell.[110] This theory is supported in that Lewy bodies include proteins that would normally be degraded, but were not and that the substantia nigra pas compacts of patients with Parkinson's have high levels of proteins resistant to degradation.[109,111] However, the definitive cause of the protein accumulation that culminates in cell death is still unknown.

5.533.5.2. Biomaterials in Treatment for Parkinson's Disease

Gene therapy has been discussed as a treatment for nearly all CNS injuries/disorders, but it may have a role in Parkinson's disease as well.[112] If the cause is genetic, the correct version of the gene may be delivered to neurons to avoid protein accumulation and dysfunction. Cell survival genes may also be delivered to ailing dopaminergic neurons. For example, a combined macrophage-nanotechnology system was designed to deliver antioxidants to the substantia nigra pars compacta. In this model, the macrophages delivered engineered enzymes, which reduce oxidative stress in models of Parkinson's disease.[113] Alternatively, an approach is being explored where DNA plasmids are condensed into nanoparticles and delivered to stop neurodegeneration.[114]

Liposomes are another vehicle for gene therapy in Parkinson's disease. PEGylated liposomes modified to cross the BBB have been used to carry gene replacement therapy in Parkinson's models. Using various reporter systems, these liposomes have been shown to transiently infect the brain with the gene of interest through the expression of a ligand to a commonly represented receptor in the brain (such as transferrin).[115,116]

Glial cell line-derived neurotrophic factor (GDNF) has also been a target for the treatment of Parkinson's due to its survival effect on dopaminergic neurons. Microspheres loaded with recombinant GDNF and injected into a rat model of Parkinson's disease, improved the function of the rats, showed an increase in dopaminergic fibers, and were determined safe as no rat developed antibodies against GDNF.[117]

5.533.6. Biomaterials Used with Stem Cell Therapy

5.533.6.1. Stem Cell Use in CNS Injury

Stem cells, which exist in all organ systems from conception through adulthood, can divide and give rise to other stem cells, as well as to a more lineage-committed cell. Different types of stem cells have been used in transplantation studies, including olfactory nervous system cells, hematopoietic stem cells, embryonic stem cells (ESCs), and many different types of neural stem cells.[118] The most success seen so far has been with utilizing neural stem cells and oligodendrocyte precursors.[119–121]

Another great use for stem cells as a therapeutic agent in the CNS is gene delivery. Genes can be delivered to the CNS through many vehicles; engineered cells, viruses, or direct injection. Continued direct injection for months into the CNS may cause unremitting damage and increased scarring and unreliable gene placement. Virus injections carrying the gene of interest have been successful, but the random site of integration may produce further complications to the endogenous tissue. Cells not endogenous to the CNS such as fibroblasts can be engineered to secrete the protein of interest and have shown success, but fibroblasts are not native to the spinal cord, and the effects of the fibroblasts on the CNS and scar formation have not been studied. Stem cells are a great option not only because they can differentiate into native neural cells, but also because ESCs are capable of homologous and nonhomologous recombination and can use environmental cues to migrate.[122–124]

The use of stem cells as a therapeutic intervention has been well studied in spinal cord injury. Transplanting neural stem cells into spinal cord injury can address the loss of local neurons and oligodendrocytes following spinal cord injury. The loss of neurons can cause both local and circuit defects, although possibly more injurious to function is the loss of oligodendrocytes. ESCs following neural or oligodendroglial differentiation have been injected into a lesioned spinal cord and shown to differentiate into tissue endogenous to the CNS, improving behavioral scores of the lesioned animals.[119,120] In mild to moderate SCI models, spared axons are present and require remyelination to function properly. Myelination supports normal axonal conduction and may help preserve spared axons.[125,126] As adult human neural progenitors syngeneic to individual patients would be difficult to obtain and culture, several groups have focused on generating neural and/or oligodendroglial progenitors from ESCs.[119,120] In these studies, oligodendrocyte precursors from ESCs have been shown to remyelinate and promote recovery.

5.533.6.2. Biomaterials and Stem Cells

In vivo, stem cells require a special niche to develop, proliferate, and differentiate. Transplanted stem cells also need such an environment to attach, survive, develop, proliferate, and differentiate. Biomaterials constructed to support stem cells utilize already established beneficial peptide sequences of integrins, growth factors, or specific differentiation cue proteins to help direct the specific needs of the injury/disease model. *In vitro*,

biomaterial scaffolds have been used to provide these cues for embryonic and neural stem cells.[25,127–129] Some success with biomaterials *in vivo* has been demonstrated in models of brain hypoxia.[130–133] The scaffolds altered the way transplanted cells survived, were distributed, and sprouted neurites.

An example of stem cell transplantation enhanced by the use of biomaterials is shown in Parkinson's research. GDNF therapies have also been used to improve the outcome of fetal dopaminergic cell transplantation studies.[134] Pharmacologically active microcarriers (PAM) are able to convey cells and release a growth factor to affect the cells. In one study, the PAM released GDNF while conveying fetal ventral mesencephalic cells. This allowed improvement of the grafted cell survival and of fiber outgrowth compared to cell transplantation alone.

5.533.7. Summary of Biomaterial Therapies in CNS Injury/Disease

As reviewed, CNS dysfunctions are heterogeneous and complex, vary widely in their symptomology, and severely affect the lives of the involved persons. The causes of many neurodegenerative disorders are complex and mostly unknown, and may be associated with genetic abnormalities, but advancing age, environmental influences, and dysfunctional immunity are likely even more influential.[1] Even when potential treatments are discovered, they are difficult to implement because access to the CNS is limited and therefore, surgical intervention to implement such treatment may prove to be more debilitating. The presence of the BBB, which normally is protective of the CNS, inhibits potentially helpful therapeutics, molecules

Table 2 Examples of preclinical and clinical biomaterial therapies in CNS disease

Preclinical studies CNS disease/ model	*Material description*	*Outcome*
Alzheimer's disease	NGF-loaded microspheres implanted into the rat basal forebrain to provide local sustained delivery	Significant protection of cholinergic neurons in the medial septum and diagonal band associated with recovery of spatial learning[135,136]
	NGF-producing fibroblasts encapsulated into polymers and implanted into the lateral ventricle of rats with fimbria-fornix lesions	Significant protection of cholinergic neurons[137]
Parkinson's disease	GDNF-loaded microspheres implanted into the 6-OHDA lesioned rat striatum	Behavioral recovery, regrowth of tyrosine hydroxylase-positive fibers in the striatum, and recovery of dopamine transporters[117]
Huntington's disease	CNTF-producing fibroblasts encapsulated into polymers and implanted into the lateral ventricle of quinolinic acid lesioned monkeys	Significant prevention of the loss of multiple populations of striatal neurons[138]
Lesioned optic tract	Positively and negatively charged amino acids that self-assembled into a nanofiber scaffold were implanted into the lesioned hamster optic tract	Axonal regeneration occurred along the scaffold between the two ends of the lesion to produce visual recovery[139]
Cortical trauma	Cylindrical porous scaffolds implanted into cortical cavities in rats	Scaffolds reduced secondary cell loss and promoted ingrowth of host neurons into the scaffold[140,141]
Hypoxia-ischemia	Polymer scaffold containing neural stem cells implanted into the infarction cavity produced by hypoxia-ischemia in mice	New brain tissue regenerated around the degenerating scaffold and a network of arborized host and donor neurites emerged with apparent axonal regeneration[131]

Clinical studies CNS disease/ model	*Material description*	*Outcome*
Amyotrophic lateral sclerosis	CNTF-producing fibroblasts encapsulated into polymers with a vitrogen matrix and implanted intrathecally	Sustained delivery of CNTF, no toxicity[142,143]
Chronic pain	Chromaffin cells encapsulated into polymers with an alginate matrix and implanted into the subarachnoid space	Prolonged cell survival, no reduction in pain[144]
Huntington's disease	CNTF-producing fibroblasts encapsulated into polymers with a vitrogen matrix and implanted into the lateral ventricles	Sustained delivery of CNTF, no toxicity[145]
Macular degeneration	CNTF-producing retinal epithelial cells encapsulated into polymers with coaxially situated poly(ethylene terephthalate) strands of yarn as a matrix	Ongoing phase II[a]
Retinitis pigmentosa	CNTF-producing retinal epithelial cells encapsulated into polymers with coaxially situated poly(ethylene terephthalate) strands of yarn as a matrix implanted into the vitreous humor	Phase I safety, sustained CNTF delivery, phase II/III ongoing[146]
Canavan disease	Nonviral plasmid-polymer-cationic liposome delivery of aspartoacyclase gene	Two children reportedly safely treated[147]

and proteins, from passing into the CNS. Regeneration itself in the CNS is difficult due to the huge heterogeneity in the CNS, presence of many ligands inhibitory to regeneration, as well as the intricate and individualized circuitry. Additionally, many tissue response cascades in the CNS add more challenges to regeneration, such as increased inflammation, invading cells, and glial scarring.

Biomaterials, especially nanotechnology derived, have begun to be used as a tool in combating tissue response, drug delivery issues, and changes in the environmental milieu. These materials can be custom-designed to promote certain activities by expressing only the relevant parts of drugs or proteins, while excluding those that may cause side effects.

Biomaterials appropriate for CNS regeneration need to be designed with general characteristics in mind. When first forming a biomaterial system, the system should be very adaptable to control many varied environments. The backbone must be ready for the discovery of different, more effective peptide sequences or different signaling cues for topographic distribution. In addition, time-release intervention may facilitate the needed processes. The material must be biocompatible with and not toxic to the host tissue. Most tissue responses post-injury or diseases already include an inflammatory component. An additional or exaggerated inflammatory response to the biomaterial may prove to be further detrimental as well or may create a barrier from use by the CNS. By-products of biomaterial breakdown may also be toxic and this should therefore be carefully considered. In most cases, however, longer-term inflammation can be limited by the biodegradability of the material. Biodegradability can also avoid a limited regenerative process. If the biomaterial itself promotes regeneration, a continued presence of the material may block reentry of the regenerating axon into its host tissue and produce a sinkhole effect. The biomaterial does have to be stable in the environment to provide its intended function.

Although a relatively new therapeutic approach, biomaterials for regeneration in CNS injury/disease have become, fairly popular, as seen in Table 2. The amazing modifications to existing technology have sped this transition. Biomaterials can address three-dimension issues in a three-dimensional way and provide a permissive and positive niche for endogenous as well as transplanted cells.

5.534.1. Skin Anatomy and Function

5.534.1.1. Basic Anatomy and Function of the Skin

Skin is the largest organ of the body in vertebrates and is composed of the epidermis and dermis with a complex nerve and blood supply (Figure 1). Average thickness of skin is 1–2 mm, being considerably thinner in infants and the elderly. Mammalian skin is typically described in the context of three major layers: the epidermis, dermis, and hypodermis. The epidermis is the outermost protective region of the skin providing barrier, immune, and photoprotective functions. It is a highly organized and stratified cellular layer that is capable of self-renewal by a continuous process of proliferation and differentiation, referred to as keratinization.[1] The dermis comprises connective tissue that provides mechanical integrity to the skin. It is primarily composed of extracellular matrix (ECM) molecules and contains skin appendages and receptors for sensory stimuli. The hypodermis predominantly consists of a subcutaneous reservoir of fat that provides insulation against heat loss, but it also contains the hair follicular roots. In addition, the hypodermis is also a source for mesenchymal stem cells.

The most important and well-recognized function of the skin is its role as a permeability barrier, preventing entry of pathogens and particulates and the loss of water from the body by evaporation. The second line of antimicrobial resistance in skin is antimicrobial proteins (AMPs), a broad class of gene-encoded antibiotics that fall into two types: defensins and cathelicidins. In the event of a successful invasion by pathogens, the immune cells of the epidermis and dermis induce an immune response. An immune response is elicited by antigen-presenting cells, which present antigen–major histocompatibility complexes to T-lymphocytes. Another major function of skin is temperature regulation. The skin also possesses pain receptors, touch receptors, and other mechanoreceptors.

5.534.1.2. Epidermis

5.534.1.2.1. Structure and cell constituents of epidermis

The key cell constituents of the epidermis are keratinocytes, melanocytes, Langerhans cells, and Merkel cells.

Keratinocytes make up 95% of the cells found in the epidermis and undergo differentiation and keratinization as they migrate through four regions that have distinct morphologies: the *stratum basale*, the *stratum spinosum*, the *stratum granulosum*, and the *stratum corneum* (**Figure 1**).

The basal layer is the deepest layer of the epidermis and contains the most mitotically active cell population, of which 10% are stem cells. The thickness of this layer depends on its anatomical location. Overall, keratinocyte morphology varies with distance from the basement membrane: cuboidal (basal layer) to polyhedral (suprabasal) to flattened appearance (upper layers). Corneocytes of the stratum corneum are almost exclusively made of cross-linked keratin fiber, which, together with intracellular lipids, forms the permeability barrier.

Melanocytes are the cells in the basal layer that produce pigment melanin which gives skin its characteristic color. Melanin production is varied as a function of genetic predisposition, photostimulus, and secretion of melanocyte stimulating hormone by keratinocytes.

Merkel cells are found clustered beneath epidermal rete ridges and are associated with sensory nerve endings. They act as neuroendocrine cells in the developing epidermis by producing nerve growth factor to aid innervation of the epidermis.[2]

Langerhan's cells are bone-marrow-derived immune cells that are located in the suprabasal layer and migrate to regional lymph nodes when an immune response is elicited.

In addition to the aforementioned differentiated cell populations, stem cells also reside in the basal layer. This population is essential for the renewal of keratinocytes in the epidermis.[3] The main class of stem cells found is the interfollicular epidermal stem cell. The other class of stem cells in the skin is the hair follicular stem cell in the dermis. Cues for cell proliferation or renewal of cell population by the stem cells are provided by the matrix proteins (glycosaminoglycans (GAGs) and proteoglycans) of the basement membrane (dermal–epidermal junction, DEJ). The DEJ serves to anchor the epidermis tightly to the dermis.

5.534.1.2.2. Functions of epidermis

The following are the functions of the epidermis:

- It acts as a permeability barrier;
- It provides sensory function;
- It carries out the social-interactive function;
- It renews skin cells every 2–3 weeks.

5.534.1.3. Dermal–Epidermal Junction

The basement membrane or DEJ is the membrane that anchors the upper epidermis to the lower dermis. Highly proliferative keratinocytes reside in the DEJ and serve to constantly renew the pool of keratinocytes in the epidermis. These are supplied by the rich vascular network of the papillary dermis. The fibrous matrix is made up largely of Type IV and VII collagen. Electron microscopic analyses[4] reveal four distinct regions within the DEJ:

- Hemidesmosomes of the basal keratinocyte layer
- Lamina lucida zone
- Lamina densa or basal lamina, made up of Type IV Collagen
- Sublamina densa fibrillar zone with microfibers and anchoring elements (Type VII collagen fibrils)
- Matrix molecules in these layers such as Laminin-1 and -5 influence key decisions in the keratinocyte life cycle: migration vs. terminal differentiation.

5.534.1.4. Dermis

In contrast to the epidermis, the dermis contains few cells and predominantly comprises extracellular fibrous matrix, which provides mechanical stability to the skin. In addition, the dermis contains nerve endings, vascular networks, and dermal cells. The dermis is highly innervated and vascularized.

5.534.1.4.1. Structure and cell constituents of dermis

The two major layers of the dermis are the upper papillary dermis and the lower reticular dermis, which are separated by a subpapillary plexus.

Papillary dermis: The papillary dermis consists of bundles of collagen fibrils and oxytalan elastic fibers. Metabolically active fibroblasts populate the dermis, with greater activity seen in the papillary than the reticular dermis. Capillaries extend leading in from the subpapillary plexus and between the rete pegs (that project from the epidermis into the dermis).

Reticular dermis: This is the thicker and deeper portion responsible for durability and anchoring of skin appendages. The reticular dermis is characterized by interwoven bundles of large-diameter collagen fibrils. Diameter of collagen fibrils in the normal mature dermis decreases from the papillary (53 ± 3.0 nm) to the reticular (82 ± 4.9 nm) dermis[5] (Figure 2). The same trend is seen in normal scars but there is a uniform decrease in fibril diameter in hypertrophic scars.[5] The collagen fibrils and surrounding elastic fibers provide the dermis with a strong mechanically stable structure because of collagen fibrils and surrounding elastic fibers. Collagen is the major fiber present in the dermis, and several types of collagen fibers have been identified in the skin; specifically, Types I and III form the interstitial fibrils.

Matrix proteins: The elastic fibers reside within a gel-like ECM composed of GAGs, proteoglycans, and glycoproteins. GAGs are linear polymers of repeating units of disaccharides. The major GAG in the dermis is hyaluronic acid (HA), made of repeating units of glucuronic acid and *N*-acetyl glucosamine.

HA is usually covalently linked to a core protein to form a proteoglycan; however, it is unique in that it exists in the body unbound. The species of GAG present determines the stability of the matrix and the relative ease of cell movement. From the fetal stage through maturation, the dermis is increasingly composed of sulfated GAGs, leading to greater stability. Dermal fibroblasts secrete a slew of proteoglycans and glycoproteins into the extracellular space, specifically, chondroitin sulfates/dermatan sulfate (biglycan, decorin, and versican), heparan/heparan sulfate proteoglycans (syndecan and perlecan), and chondroitin-6 sulfate proteoglycans. Cationic dyes must be used to view proteoglycans in the dermis.

Fibroblasts (major cell type): Fibroblasts are the cells of mesenchymal origin which are normally present in the dermis and produce normal dermal replacement components. After injury, these cells migrate into the wound and proliferate in order to produce increased quantities of these dermal proteins and matrix.

Fibroblast products: These can be collagen (type one in skin), matrix proteins (fibronectin, tenascin, others), proteoglycans, GAG, HA, other matrix components, cytokines, and other growth stimulants.

Dermal dendritic cells: These cells of mesenchymal origin are normally present in tissue but increase in number after injury, attracted by chemical messages released by the activation of inflammation. The long-lived cells release the protein chemical messages, growth factors, and growth stimulants which orchestrate healing in an organized fashion.

Dermal dendritic cell products: These are growth factors, growth stimulants, and opsonins.

Endothelial cells: These cells make up the lining of micro and macro vessels and also make up the lining of new capillaries produced after injury. These cells, like fibroblasts, do differentiate from local mesenchymal cells and are also attracted into the wound by local signals.

Dermal appendages: The dermal appendages include hair follicles, sebaceous glands, and the eccrine glands. Hair follicles sprout hair, and the length of each follicle depends on the anatomical location. Associated with the hair follicle are the sebaceous gland and the bulge region of stem cells. The sebaceous gland produces the oily sebum layer covering the skin, while the bulge region supplies stem cells to renew dermal cell populations. More sebum is produced at certain locations (face, nose) than others. In contrast are the stand-alone eccrine glands that are the sweat glands and act to control body temperature by sweating. They are controlled by postganglionic sympathetic nerve fibers. Density of eccrine glands depends on anatomical location (highest on palms and soles).

5.534.1.4.2. Functions of the dermis

The collagen composition of skin is responsible for its mechanical strength. Elastin fibers provide the elastic nature of the skin, which can extend 10–50%. This characteristic is especially important in instances where the skin is forced to stretch, such as during pregnancy. The dermis exerts control over temperature, nutrient delivery, and fluid balance by controlling blood flow. The dermis is involved in thermoregulation through special thermoreceptors.

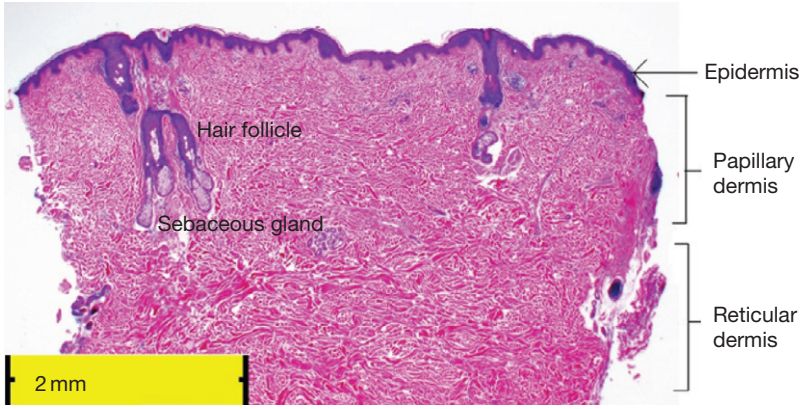

Figure 2 Dermal structure. Masson's trichrome-stained histology image of normal human dermis. Fine structure of papillary dermal collagen fibers are discerned from coarse structure of collagen fibrils in the reticular dermis. Sebaceous glands are also seen in association with hair follicles.

Thermoreceptors sense changes in body temperature and initiate sweating through the eccrine glands of the dermis.

5.534.1.5. Hypodermis (Subcutaneous Fat Layer)

Below the reticular dermis resides the hypodermis, a subcutaneous layer of fat that is highly vascularized and innervated. This layer cushions the upper epidermal and dermal layers and has cosmetic significance in shaping the body. There is a striking contrast in structure between the dermis (made of matrix proteins) and the fat-rich hypodermis. While the fat acts as a reservoir of energy, it is also the origin of fat-derived mesenchymal stem cells (MSCs) which can regenerate the cellular constituents of the upper layers. While heat loss occurs by convection, conduction, radiation, and evaporation, heat insulation is provided by the fat layer of the hypodermis.

5.534.2. Biology of Cutaneous Wound Healing

Wound healing is a complex process that involves cells, the ECM, plasma-derived proteins, and programmed angiogenesis. It is a well-orchestrated process that it is divided into three overlapping phases of inflammation, tissue formation, and tissue remodeling.

5.534.2.1. Inflammatory Phase

Inflammation is the body's highly effective, innate, initial response to injury. The inflammatory phase involves two different reactions: vascular responses including blood coagulation and hemostasis, and cellular responses including infiltration of neutrophils and macrophages.

Immediately after injury, homeostasis is achieved and a fibrin clot is developed. Platelets are the first cell type to respond to vascular injury and play a central role in normal hemostasis. Activated platelets release many mediators including adenosine diphosphate, serotonin, thromboxane A2; adhesive proteins such as fibronectin, fibrinogen, and thrombospondin; and growth factors such as platelet-derived growth factor-AB (PDGF-AB) and transforming growth factor-β1 (TGF-β1). The coagulation factors induce platelets to aggregate and form a platelet plug that facilitates fibrin clot formation. The fibrin clot acts both as a scaffold for the migration of neutrophils, endothelial cells, fibroblasts, and keratinocytes and as a reservoir of growth factors. The cells present within the clot release many vasodilators and chemoattractants, which activate the complement cascade and trigger an inflammatory response.[6]

In the early inflammatory phase, neutrophils and monocytes are the predominant cells recruited to the wound by chemotactic factors. Activated integrin receptors located at the cell surface of neutrophils interact with endothelials cells, promote diapediasis through the blood vessel wall, and facilitate cell migration through the connective tissue to the site of injury. Neutrophils are responsible for removing bacteria, damaged matrix proteins, and other foreign material from the wound via enzymatic degradation and phagocytosis. Monocytes typically transform into macrophages in the late inflammatory phase. Macrophages are the most important regulatory cells in this phase and perform multiple functions, such as release biologically active oxygen species and enzymatic proteins as well as phagocytose pathogenic organisms, destroy remaining neutrophils, and scavenge tissue debris. Macrophages produce a series of chemotactic factors, growth factors, and angiogenic factors that recruit fibroblasts and promote cell migration, proliferation, matrix production, and new blood vessel growth. Thus, macrophages play a primary role in angiogenesis, the formation of granulation tissue, and the transition from inflammation to the proliferation phase.

5.534.2.2. Tissue Formation Phase

Tissue formation, the second stage of cutaneous wound healing, overlaps with the first stage as re-epithelialization begins within hours of injury. Re-epithelialization is characterized by the migration of epidermal cells from the surrounding epidermis and skin appendages such as hair follicles, the proliferation of keratinocytes, the differentiation of the neoepidermis, and the restoration of the highly ordered basement membrane that connects the epidermis and the underlying dermis[7] (**Figure 3**). During the process of tissue repair, keratinocytes located at the wound edge secrete a plethora of matrix molecules, such as fibronectin (FN) and laminin, and express FN receptors (integrin α5β1), laminin receptors (integrin α3β1), and collagen receptors (integrin α2β1). Together, they provide 'start' signals that promote keratinocyte migration to achieve re-epithelialization.[7–9]

In contrast to the almost immediate response of re-epithelialization, dermal reconstitution begins 4 days after injury in response to the abundance of growth factors and cytokines present in the wound bed. The neodermis is characterized clinically by granulation tissue formation consisting of angiogenesis and fibroplasia. In response to the injury, angiogenesis proceeds as follows: (1) activation of endothelial cells, (2) local degradation of the vessel basement membrane, (3) new blood vessel sprouts 'punching' into the wound bed, (4) proliferation of endothelial cells, (5) new tubule structure

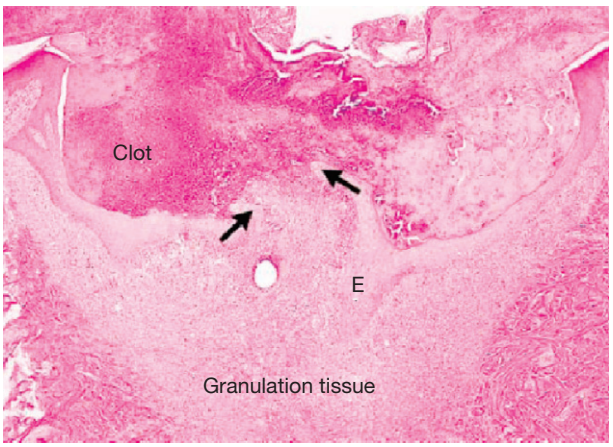

Figure 3 Re-epithelialization of a cutaneous wound in porcine (hematoxylin and eosin, × 40). Epidermal cells (E) are seen under the fibrin clot and across the wound. The advancing edge of the epidermal cells is shown with arrows. The white oval is an artifact of preparation. Reproduced from Singer, A. J.; Clark, R. A. *N. Engl. J Med*. **1999**, *341*(10), 738–746.

formation, (6) reconstitution of vessel basement membrane, and (7) regression and involution of vasculature that provides nutrition and oxygen to the newly formed dermis.

Fibroplasia is defined as the formation of fibrous tissue and characterized by fibroblast proliferation at the wound edge and migration into the fibrin clot. After fibroblasts have migrated into the wound, they transform their phenotype into a profibrotic type that functions to synthesize proteins and form new matrix. Fibroblasts are also responsible for converting the provisional fibrin/FN matrix into a collagen matrix via enzymatic degradation and massive collagen production.[10]

5.534.2.3. Remodeling Phase

The final phase of wound healing is characterized by newly synthesized ECM of mainly type I collagen, reorganization of the neomatrix, and wound contraction. ECM reorganization/remodeling goes on throughout the entire wound healing process but accelerates during the remodeling phase. Dermal remodeling is dependent on a balance between new collagen synthesis and old collagen lysis, which are tightly controlled by biomechanical stress and strain placed across the wound as well as chemical clues.

Wound contraction occurs within the second and third week post injury and involves the well-orchestrated interaction of cells, ECM, and cytokines. Wound contraction is primarily mediated by myofibroblasts and requires cell–cell and cell–matrix interaction. Myofibroblasts possess large bundles of actin-containing microfilaments that bind extracellular FN, which in turn links collagen fibers across the wound. Then, myofibroblasts gather in the collagen fibers and thereby induce wound contraction.

Once the closure of the wound has been completed, the process of remodeling can continue for months to years. Ultimately, the preinjury dermis is gradually replaced by a stable postinjury phenotype (scar) consisting predominantly of type I collagen. The tensile strength of scars reaches a maximum of about 70% of preinjury dermis.[11]

5.534.2.4. Interruption of Wound Healing

Cutaneous tissue injury results in a fairly rapid and acute wound healing response under normal physiologic conditions. However, when the underlying pathology interrupts the normal wound healing process, a failure to heal occurs, leading to a chronic wound (ulcer).[12] Many pathological factors can impair healing. Systemic factors include advanced age, malnutrition, diabetes, ischemia secondary to vascular disease, and renal disease.[13,14] Local factors include ischemia, infection, prolonged inflammation, presence of foreign bodies, and tissue maceration.[15] In addition, abnormal wound microenvironments such as the imbalance of proteolytic enzymes and their inhibitors,[16] the presence of senescent cells and/or local cellular response, abnormal time/spatial distribution of bioactive molecules such as growth factors, can also cause difficulties in healing.[17,18] Overall, cutaneous wound healing is a complex biological process that can be positively and negatively manipulated by various factors[19] (**Figure 4**). It is important to address, correct, or ameliorate the diseased state before applying engineered cutaneous therapy.

5.534.3. Wound Classifications and Prognosis

Burns resulting from thermal, electrical, or chemical contact as well as trauma are two of the most common reasons for acute skin wounds and significant cutaneous tissue loss.[20] Based on the damaged depth of skin, wounds are categorized into four groups: superficial (epidermal), superficial partial thickness, deep partial thickness, and full thickness (**Figures 5** and **6**). As a result, the standard of care and prognosis of wounds of varying severity differ to a great extent.

Superficial injuries affect the epidermis and are characterized by erythema and minor pain. These injuries can occur from sunburns or light scalds. These injuries typically re-epithelialize and heal within 21 days without a scar.

Injuries that penetrate through the epidermis and into the dermis are classified as partial-thickness wounds. These wounds are subdivided into superficial or deep partial-thickness wounds. Superficial partial-thickness wounds affect the upper layers of the dermis (papillary dermis) and are associated with burning sensation and acute pain. Such wounds heal by re-epithelialization from the wound edge and the remaining skin appendages, such as hair follicles or sweat glands. Deep partial-thickness injuries involve the deeper layers of dermis (both papillary and reticular), where most, if not all, skin appendages are destroyed. These wounds generally take longer than 21 days to close and heal with aesthetically displeasing scars and loss of function.

Full-thickness wounds affect both the epidermis and dermis and extend into the hypodermis. In this case, the skin has lost all skin appendages as well as regenerative cells and tissues. Full-thickness wounds simultaneously close via re-epithelialization from the wound edge and by contraction. The wounds repair with extensive scarring, which can result in limited joint motion and severe cosmetic deformities. Full-thickness skin wounds with a diameter exceeding 4 cm cannot heal without autologous split-thickness skin grafting,[21] which is the clinical 'gold standard' treatment.[22,23]

Another common type of skin injury is chronic wounds resulting from different diseases states, such as diabetes, genetic disorders such as bullous condition, and even surgical interventions.[24] As discussed in **Section 5.534.2**, wound healing is a complex biologic process and many systemic and local factors can potentially impair healing and cause chronic wounds.[25] Typical chronic wound management includes pressure relief, debridement of callous, pressure offloading footwear, and employing compressive bandages; however, these means are often insufficient to promote healing. As a result, several advanced healing treatments such as bioactive dressings, growth-factor-based therapies, acellular matrices, autologous skin grafts, and bioengineered skin substitutes have become available as additional therapies.[17]

5.534.4. The Significance of Tissue-Engineered Skin Application

Serious injury to the skin requires restoring barrier function and coverage to prompt healing immediately. Wound healing with large surface area and/or deep wounds are a clinical challenge. The standard of care for severe extensive skin wounds first requires excision of necrotic tissue to reduce

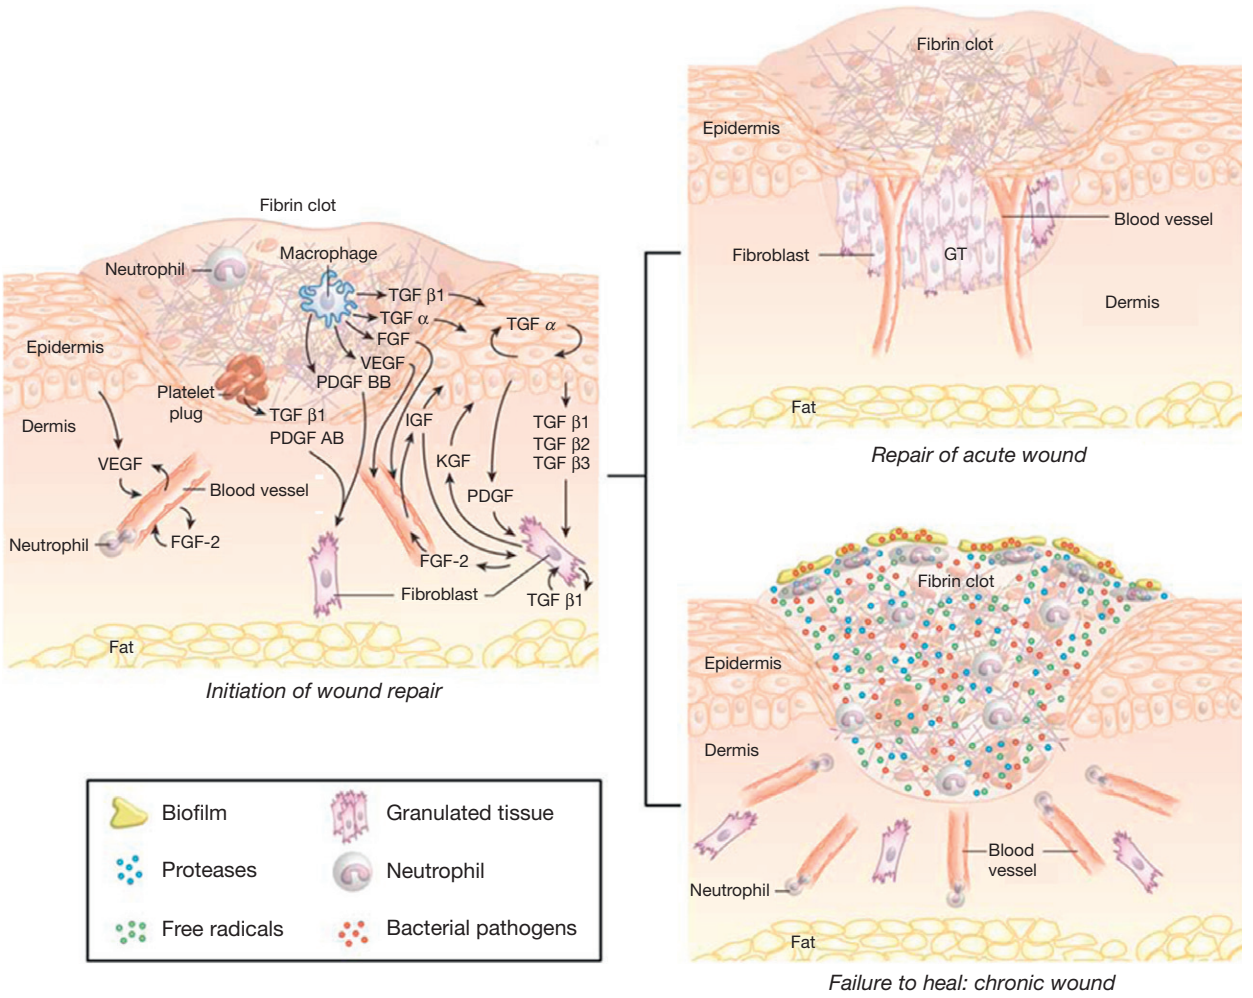

Figure 4 Different wound repair process in an acute wound healing response under normal physiologic conditions or in a chronic wound underlying pathology or microbial invasion interruption. (Left panel) Inflammatory phase: Tissue injury precipitates blood clotting, platelet aggregation, and migration of leukocytes, including neutrophils and macrophages, to the site of injury; (Upper right panel) Repair of acute wound: Under normal physiologic conditions the wound continues to heal at 5 days with an ingrowth of granulation tissue composed of fibroblasts, additional macrophages, and neovasculature; (Lower right panel) Interruption of wound healing-chronic wound/ulcer: When underlying pathobiology or microorganism invasion interferes with the wound healing process, a failure to heal occurs often leading to a chronic wound (ulcer). Reproduced from Clark, R. A.; Ghosh, K.; Tonnesen, M. G. *J. Invest. Dermatol.* **2007**, *127*(5):1018–1029.

infection, minimize hypertrophic scar formation, and avoid multiple organ failure. Autologous split-thickness skin grafting is the gold standard of treatment for deep partial-thickness and full-thickness wounds that cannot heal on their own. This treatment requires secondary surgery to harvest a sheet of autologous skin (epidermis and varying thickness of dermis). Generally, the thickness of the skin graft is inversely proportional to wound contracture. The site of the harvest, known as the donor site, heals by re-epithelialization usually within 7–14 days, similar to superficial partial-thickness wounds. However, there are two major drawbacks to this procedure: limited autograft availability and donor site management. The donor sites become increasingly limited in patients with greater than 50% burned skin area. Likewise, in chronic wounds, such as diabetic foot ulcers, the skin graft success rate is limited. In this case, naturally occurring grafts such as allografts (from a nongenetically identical individual of the same species), xenografts (from different species), and amniotic membranes have been used as an alternative to autografts for many years; however, these are only suitable as temporary wound coverings. Graft rejection is a major issue of both allografts and xenografts, which typically occurs within several days to weeks after graft implantation. Furthermore, the precarious supply source and the possibility of disease transmission limit their application.

To overcome the limitations associated with skin grafts, tissue-engineered skin substitutes are being developed to meet the need for a cost-effective and user-friendly synthetic or engineered skin graft that can be used to treat both acute and chronic wounds. During the last 40 years, a large number of biological and synthetic skin substitutes and products have been commercialized. Skin substitutes are typically categorized according to function as temporary skin substitutes used to protect the wound bed, optimize the healing environment,

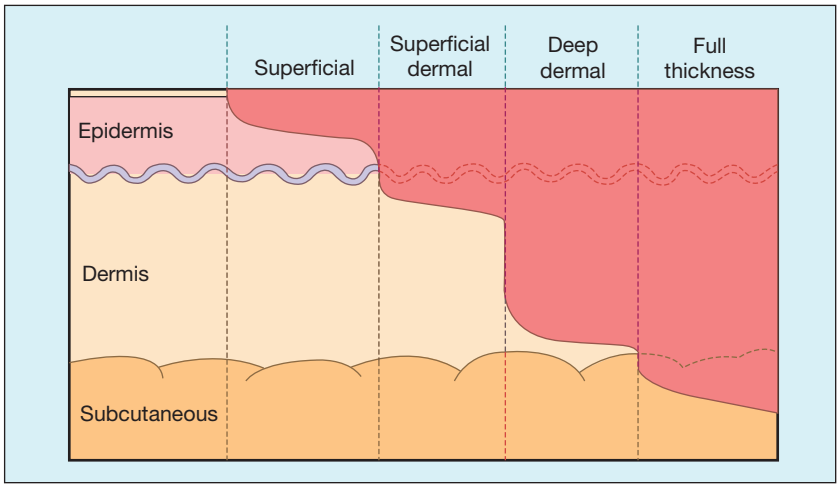

Figure 5 Diagram of different burn depths of skin tissue and the relationship of different degree of burn trauma. Reproduced from Hettiaratchy, S.; Papini, R. *Br. Med. J.* **2004**, *329*(7457), 101–103.

relieve pain, promote healing, and serve as a bridge to autografting; or permanent skin substitutes used to replace one or both skin layer components and/or complement autografts, thus restoring skin function and aesthetics. Researchers and clinicians are collaborating to design, fabricate, and test tissue-engineered skin substitute that will offer the following benefits to the patient:

decrease the need of autografts and/or facilitate donor site healing,
decrease wound scarring and contracture,
decrease treatment costs and hospital stay,
accelerate wound closure, and
improve skin functionality.

5.534.5. Design Principles of Tissue-Engineered Skin Substitute

The design and development of the ideal tissue-engineered skin substitute must be safe to the patient, clinically efficacious, and user friendly. In addition, the skin substitute must be biocompatible, that is, nontoxic, noninflammatory, and nonimmune reactive, and have no risk of transmissible infection. It is important that the skin substitute induce rapid wound closure and mimic properties and functions of normal skin, such as biomechanical properties and barrier function. Ideally, the skin substitute should promote new tissue formation and degrade as it is replaced by the regenerating skin. Finally, the skin substitute should be convenient to handle and apply to the wound, and 'off-the-shelf' availability favors rapid treatment in the clinic. In addition, a relatively long shelf life and matched cost-effectiveness ratio are also ideal.[23,26]

Shakespeare[27] outlined '4P' principles of general functions which a different bioengineered skin substitute should offer.

Protection – This is achieved by establishing a mechanical barrier to restrict fluid loss, wound colonization, and a calculable rate of vapor transit. Early studies on skin substitutes[28] indicated that the pore size of the scaffold (outer layer) must serve as a barrier to microorganisms while allowing water vapor to escape to avoid subgraft fluid accumulation.

Procrastination – Following early wound debridement, temporary wound covering is necessary to provide a stable environment in the wound bed until permanent wound closure can be achieved, especially for extensive wounds that require serial skin substitutes or cultured autologous graft applications.

Promotion – The delivery of matrix molecules, cells, and growth factors to the wound bed may create the optimal microenvironment to promote and enhance the host wound healing process. Opposite of 'protection,' the pore size of the scaffold (inner layer) should permit the ingrowth of neo-fibrovascular tissue from the wound bed, which requires a pore size diameter of greater than 80 μm.[28] Therefore, the optimum skin substitute requires at least two layers with different pore sizes, or a monolayer with different pore sizes in the inner and outer face.

Provision – The cultured cells or dermal collagen acts as an organized and persisting new cell and matrix element, which can incorporate and accelerate the wound healing process and persist in the healed wound as infill.

The effective use of the skin substitute is essential to ensure the optimal management of wound repair. One possible design is to engineer the skin substitute *in vitro* and allow it to integrate into the wound site after implantation. Another approach is to fabricate a biocompatible and bioresorbable matrix that can act as a three-dimensional scaffold and attract host cells to stimulate nonscar wound healing. The ideal temporary or permanent skin substitute should have the following characteristics, adapted from Pruitt and Levine[29]:

Absence of antigenicity
Tissue compatibility
Absence of local or systemic toxicity
Provision of mechanical protection
Water vapor transmission similar to normal skin
Impermeability to exogenous microorganisms
Pain relieving property
Rapid and firm adherence to wound and easily removable without pain or trauma (important for 'temporary' skin substitute)
Rapid and sustained adherence to wound (important for 'permanently' skin substitute)
Stimulation of wound healing
Flexibility and pliability to permit conformation to irregular wound surface
Elasticity to permit motion of underlying body tissue
Resistance to linear and shear stresses
Prevention of proliferation of wound surface flora and reduction of bacterial density of wound
Tensile strength to resist fragmentation and retention of membrane fragments when removed
Biodegradability (important for 'permanent' skin substitute)
Low cost
Long shelf life
Minimal storage requirements.

5.534.6. Materials for Skin Tissue Engineering

5.534.6.1. Development of Nonbiodegradable Synthetic Materials

Over five decades ago (1954–1960s), the earliest materials used as temporary skin substitutes/wound coverings were synthetic nonbiodegradable materials including spray-on plastics (a copolymer of hydroxyvinylchloride acetate and sebacic acid),[30] polyox (a polymer of ethylene oxide),[29] and Ivalon sponge.[31] Subsequent reports included the use of laminated nylon velour,[32] polyurethane foam laminated to polypropylene film,[33] poly amino acid films,[34] films of Goretex (polytetrafluoroethylene), and ultrathin silicone polymer membranes laminated to a meshed inner layer.[35] These incipient nonbiodegradable synthetic materials encountered many issues such as submembrane suppuration, foreign-body inflammatory reaction, and infection. Three decades ago, several unilaminate membranes were developed as wound coverings and applied to preclinical animal experiments and clinical trials. Warren and Snelling[36] reported on the application of Hydron (polyhydroxyethylmethacrylate) to burn wounds and concluded that it has limited value in the clinic. Wokalek[37] developed a transparent liquid gel that was composed of agar and copolymerized with acrylamide. Its efficacy was evaluated in fresh operative wounds; however, its low tensile strength and adherence to the wound bed limited its use solely as a temporary wound covering. In the 1980s, a series of bilaminate membrane bioconstructs (Integra, Biobrane) were developed using a thin silicone film outer layer and an irregular nylon filament weave-bonded with a type I collagen inner layer.[38–40] The silicone membrane served to mimic the natural epidermis and was semipermeable to allow the release of water vapor to the environment but prohibit bacterial contamination into the wound bed. The composite of nylon and collagen layer served to mimic the dermis having high elasticity and permit full range of motion to the grafted body part. A decade later, the inner layer of the bilaminate membrane (TransCyte) was improved by seeding with fibroblasts that secrete natural matrix molecules.[41,42]

5.534.6.2. Development of Biodegradable Natural-Based Materials

In the recent three decades, the development of biodegradable biomaterials for skin substitutes has rapidly expanded. Different materials have been used as scaffolds to support cells and promote their adhesion, proliferation, differentiation, and deposition of new ECM. The exploration of biomaterials has been based on the comprehensive understanding of the biology of wound healing and inflammation and attempts to control interactions between biomaterials and cells. Materials used as engineered ECM in skin substitutes include those derived from natural-based systems and those manufactured synthetically.[43]

Compared to natural ECM, biomaterials of natural origin, that is, biopolymers, have similar biological macromolecular structure and performance. Theoretically, natural-based biomaterials have no hazards related to immunological reactions and chronic inflammation, including foreign body reaction, which may occur with synthetic polymers. There are many different naturally derived biomaterials that are suitable for skin tissue engineering. The major classes of naturally derived materials used as main constituents of engineered constructs with or without modification include (1) protein-based biopolymers isolated from blood and soft tissue, such as fibrin, collagen, FN; and (2) polysaccharide-based materials isolated from animals, such as alginates, chitosan, and GAGs including hyaluronan.

5.534.6.2.1. Collagen

Collagen is one of the most abundant proteins in the body. It is responsible for maintaining ECM structural integrity. Collagen has a triple-helical structure and the presence of 4-hydroxyproline provides a distinctive marker of these molecules.[44] Collagens located in the skin tissue are predominantly synthesized by fibroblasts and arranged in fibrils. To date, 28 collagen types have been identified and collagen I, II, III, and V are found in the skin.[45] The dermis mainly comprises collagen with some elastin and GAGs, which provide elasticity and plasticity to the skin and buffer mechanical injury.[46] Type I collagen is the major component of the dermis, contributing 70–80% of its dry weight and providing the skin with tensile strength.[47] Collagen types III and V are also located in the dermis of skin, especially around blood vessels and appendages.[45]

Collagen has been evaluated as a biologic dressing in various forms for several decades.[48,49] Also, it is a desirable skin substitute component because it can be isolated from allogeneic and xenogeneic tissues (such as rat tail tendon, bovine hides, and porcine or bovine Achilles tendon) by acidic/enzymatic solutions to produce high yields.[50] The collagen obtained after extraction contains variable levels of telopeptide content and is mainly present in the form of monomers with different amounts of cross-linked components (dimers, trimers, and some higher components).[51] This protein has a highly conserved amino acid composition in its helical regions, resulting in minimal immunogenic and allergenic properties; however, the telopeptide regions are not as highly conserved and can elicit reactions.[52,53] Collagen can provide hemostatic activity,[52] excellent tensile strength when in the form of large fiber bundles, and cell adhesive sites mediated by its helical domains or by arginine-glycine-aspartic acid (RGD) peptide sequences.[54]

Type I collagen has been isolated, studied, manipulated, and utilized as the main component of skin substitutes for many years.[23] Scaffolds fabricated from collagen act as a temporal structural support for intrinsic dermal regeneration. In addition, collagen can be seeded with fibroblasts and used as a scaffold on which to grow stratified epidermal sheets. For example, both Apligraf (Organogenesis, Inc.) and OrCel (Forticell Biosciences) are examples of FDA-approved and commercialized bilayered skin substitutes in which allogeneic keratinocytes are cultured on xenogeneic-derived collagen sponges containing fibroblasts. Apligraf is indicated to treat diabetic foot ulcers and venous leg ulcers, and OrCel for acute surgical excisions and graft donor sites.

Collagen-based matrices have also been used to construct a vascularized dermal skin substitute. In this model, collagen was shown to promote the spontaneous formation of a capillary-like network.[55,56] In addition, composites consisting of type I collagen and GAGs have been shown to regenerate both the dermis and epidermis in a porcine model.[57] Thus, the feasibility of utilizing engineered collagen scaffolds as cell-seeded systems for skin tissue engineering has been validated *in vitro* and *in vivo*. However, there are several associated drawbacks relevant to its use, such as mechanical weakness when in the form of small randomly oriented fibers, possible immune reaction when telopeptides are present, and pathogen transmission when derived from xenogeneic sources.[58]

For skin tissue engineering applications, the most common designs employing collagen are hydrogels, sponges, and lattice matrices. They have different physical and biochemical characters. Hydrated collagen hydrogels, which are composed of small randomly oriented fibers, have lower mechanical properties as compared to the sponge or lattice design. Dehydrated collagen sponges that are produced via freeze drying have stronger mechanical properties and have been shown to promote wound healing.[59] In the past 10 years, several skin substitutes have utilized the collagen sponge technology, such as Pelnac Standard/Fortified (Gunze Ltd.) and Terudermis (Olympus Terumo Biomaterials Corp.).[60–62] Furthermore, collagen can be blended with some synthetic materials, such as polycaprolactone, and then electrospun into nanofibers to more closely mimic the fibrous morphology of the natural ECM.[63,64]

5.534.6.2.2. Fibronectin

FN is a high molecular weight ECM glycoprotein that exists as a dimer composed of 220–250 kDa monomers which are linked by a pair of disulfide bonds.[65] FN can be found in humans in both soluble and insoluble forms as major components of blood and ECM, respectively. As the concentration of soluble FN increases in the pericellular matrix, short fibrils of FN form. As the process of matrix assembly continues, the short fibrils become more robust and eventually become the insoluble fibers found in the ECM.[66]

FN serves as a substrate for cell attachment, adhesion, and spreading through RGD, found in the tenth type III repeat, and the so-called synergy site, proline-histidine-serine-arginine-asparagine (PHSRN), located in the ninth type III repeat.[67,68] Cells bind FN at these sites via the integrins $\alpha5\beta1$ (RGD + synergy site) and $\alpha v\beta3$ (RGD alone) and then form adhesion complexes that influence their ability to activate associated downstream signaling. Biomaterials have been enhanced with RGD cell-attachment peptides to promote adhesion and spreading.[69,70] However, RGD alone tethered to scaffolds may not be sufficient to promote vascularization, as the synergy site is required for the binding and activation of $\alpha5\beta1$ integrins, which are the key regulators of angiogenesis.[71,72] However, mechanical stretching is known to affect FN function,[73] and using computational simulations it has been proposed that excessive tension generated by cells in contact with biomaterials may render FN fibrils nonangiogenic and potentially inhibit vascularization.[74]

Thus, cell migration, differentiation, and wound healing are modulated by FN. Fibroblast migration is the rate-limiting step in granulation tissue formation[75] and FN is required for fibroblast transmigration from a collagen matrix that surrounds wounds into a fibrin and FN gel that comprises the wound site.[76] Furthermore, a combination of FN domains and hyaluronan optimally supported granulation tissue formation during wound repair.[20] However, FN is rapidly degraded and absent[77] in chronic wounds as a result of high protease activity.[78,79] This, in fact, may be a substantial pathobiological event in the chronic nonhealing nature of these wounds.

5.534.6.2.3. Fibrin

Fibrin is a complex network naturally formed during blood coagulation by polymerization of fibrinogen and provides the primary scaffold for the provisional matrix of the nascent wound.[80,81] It is gradually replaced by the regular constituents

of the ECM, such as collagen. Fibrin in combination with FN has been shown to support keratinocyte and fibroblast proliferation and spreading both *in vitro* and *in vivo*, and may enhance cellular migration into cutaneous wounds.[82] Fibrin has been a useful cell delivery matrix in the regeneration of the skin and is currently approved by the U.S. Food and Drug Administration (FDA) and commercialized as fibrin glue in clinical applications.[82] Also, fibrin-based matrices have been shown to be robust delivery vehicles for growth factors that may be used to accelerate wound healing and skin regeneration (see Hubbell[70] and Gwak *et al.*[83] for more detail).

5.534.6.2.4. Hyaluronic acid

Hyaluronic acid, also known as hyaluronan or hyaluronate, is an anionic, nonsulfated linear disaccharide consisting of D-glucuronic acid and D-*N*-acetylglucosamine. It is composed of disaccharide repeats and ranges from 5000 to 20 000 000 Da in molecular weight. HA was first isolated in 1934 from the vitreous humor of the eye[84] and subsequently synthesized *in vitro* in 1964.[85] Also, it has been collected from other sources such as rooster combs, soft connective tissues, synovial fluids, and umbilical cords. In addition, HA can be produced on a large scale through recombinant microbial fermentation, which is a process that avoids the risk of animal-derived pathogens and disease transmission. HA comprises a small part of the ECM but is nonallergenic among the different species secondary to its conserved structure.[86] Like FN, HA is involved in the process of wound repair by modulating the release of cytokines and other bioactive molecules and regulating cell responses to these agents.[87–89]

The degradation products of HA are variable in length, described as short or long chains, and appear to modulate wound healing. Longaker *et al*. have shown that there are elevated levels of HA present during fetal wound healing that may contribute to the limited fibrosis observed in these wounds.[90] After degradation, HA fragments appeared to stimulate fibroblast proliferation[91,92] but decrease their total collagen production, which may contribute to nonscar healing.[93] The application of exogenous HA has been shown to enhance keratinocyte proliferation[94,95] and suggests that HA may benefit the re-epithelialization aspect of wound healing. An HA hydrogel which is intermolecularly cross-linked to protect the HA from hyaluronidase digestion and tethered with bioactive FN domains beneficially enhanced cutaneous wound healing *in vivo* in a swine model.[96,97] Importantly, HA hydrogels with viscoelastic properties between that of a fibrin clot and the normal dermis promoted healing best.
