5.534.6.3. Development of Smart Matrix: New Concept for Biodegradable Synthetic Biomaterials

The incorporation of bioactive signals into scaffold materials may create a series of novel 'smart' matrices[98] including scaffold materials linked to synthetic peptides, semisynthetic scaffolds incorporating protein domains, engineered mutant variants of existing proteins, and engineered peptides capable of self-assembly into nanofibers. Engineered peptide products may enhance natural-based protein or peptide application in skin tissue engineering. Numerous studies have verified that the incorporation of the integrin-binding motif RGD promoted cell attachment and spreading in tissue-engineered bioconstructs of wound healing.[99] Shu *et al.* developed a hydrogel construct comprising thiol-modified hyaluronan capable of tethering cysteine-tagged functional domains or bioactive peptides. This construct tethered with cysteine-tagged RGDS peptides was shown to induce and support NIH 3T3 fibroblast proliferation *in vitro*[100]; however, it did not support fibroblast migration into the wound area *in vivo*.[96] Since the ideal tissue-engineered construct should be both inductive and conductive, the hydrogel was redesigned to include three fibronectin functional domains, FNIII(8–11), FNIII(12–15), and FNIII(12–V–15), which did support optimal fibroblast migration in both two- and three-dimensional systems *in vitro*.[101] In addition, Ghosh *et al.* demonstrated that the HA construct modified with the aforementioned three FN functional domains stimulated primary human dermal fibroblast spreading and proliferation *in vitro* and, furthermore, promoted dermal fibroblast recruitment in a cutaneous wound porcine model *in vivo*.[96]

The major challenge for current and future research is to optimize existing and novel matrices through modifications with bioactive peptides, such as recombinant protein domains or less expensive smaller synthetic peptides. Such smart matrices may improve the biological activities of synthetic materials beyond the physical properties of its polymer composition by promoting cell adhesion and enhancing the performance of cell activity.[102]

5.534.7. The Development of Tissue-Engineered Skin Constructs: The Past and the Present Status

5.534.7.1. Overview

Fabricius Hildanus (1560–1634) was the 'Father of German Surgery.' In his book *On burns De combustionibus* (1607), one of the earliest books that addresses the treatment of thermal injuries, he categorized burns in a practical, systematic way. The acute partial-thickness wound was described as *redness and blistering of the skin or withering without charring*, and the full-thickness wound as *eschar formation and charring*.

It has been recognized for many centuries that using a 'skin-like' dressing could improve wound healing. Xenografts derived from reptiles and animals were first used in fifteenth-century Europe, and frog skin is still in use today in Brazil. Swine skin became popular in the 1960s and continues to be the most common xenograft material. The first reported use of human-derived skin substitutes were in the mid-nineteenth century. Since 1950, cadaver skin and human amnion are routinely used for wound management.

With the advancement in technology, alternative skin substitutes have been developed and commercialized to replace xenografts and allografts.[19,103] Early studies carried out by Rheinwald and Green,[104] Bell *et al.*,[105] and Yannas's laboratory[106–108] established a basis for dermal, epidermal, and composite skin replacements. Thereafter, the focus of research has been on engineered skin substitutes comprising living cells and natural or synthetic cellular matrix components.[109] From our perspective, skin substitutes can be classified as follows:

(i) Type of biomaterial
biological: autologous, allogeneic, xenogeneic;
synthetic: biodegradable, nonbiodegradable

(ii) Skin substitute composition regarding cellular component
acellular
cellular
(iii) Duration of use
temporary
semipermanent
permanent
(iv) Anatomical structure
epidermal
dermal
dermo–epidermal (composite)

In this chapter, most of the tissue-engineered skin substitutes that are currently commercialized or have been in the past are summarized and organized according to anatomical structure.

5.534.7.2. Epidermal Skin Substitutes

Human keratinocytes were first reliably cultured by Rheinwald and Green about 35 years ago,[104,110] and later developed into cultured epithelial autografts (CEAs, a sheet of cells with two or three layers thick, see **Figure 7**)[111] for the treatment of burns.[112,113] This technique has been successfully translated into the clinic and has contributed to the dramatic increase in the survival rates of burn patients (Epicel and EpiDex). Over the last two decades, confluent sheets of CEAs have successfully been used to treat extensive full-thickness burn wounds worldwide. However, CEAs are susceptible to infection, require a dermal support layer, have a graft uptake success rate that varies from 15% to 85%, and are associated with high costs and a short shelf life (24 h).[114]

The aforementioned product drawbacks have stimulated research on alternative delivery systems for preconfluent keratinocyte monolayers, such as fibrin glue or membrane (Bioseed-S). Fibrin glue has been shown to help control bleeding and improve cell attachment to the wound bed, but unfortunately did not improve the CEA uptake rate. Delivery membranes are made of synthetic materials such as silicone with a specially formulated surface coating (MySkin), polyurethane, decellularized dermis, or biological degradable/natural biomaterial such as collagen, hyaluronan (Laserskin), and fibrin.[115] Another approach to deliver keratinocytes is via an aerosol cell suspension (ReCell/CellSpray).[116] The current commercially available epidermal skin substitutes are shown in **Table 1**.

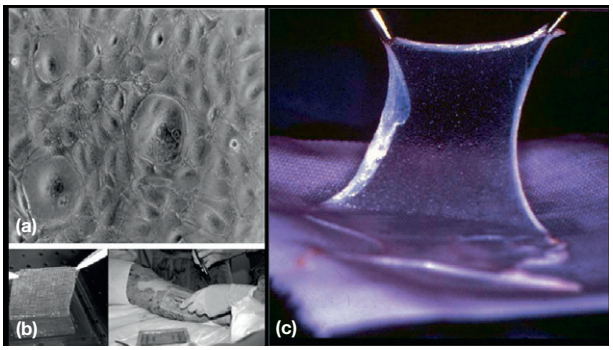

Figure 7 (a) Confluent keratinocyte sheet. (b) Keratinocyte sheet on a carrier grafted on the wound bed. Reproduced from Atiyeh, B. S.; Costagliola, M. *Burns* **2007**, *33*(4), 405–413. (c) A sheet of cultured keratinocytes. Reproduced from Anthony, E. T.; Syed, M.; Myers, S.; Moir, G.; Navsaria, H. *Drug Discov. Today: Therapeut. Strat.* **2006**, *3*, 81–86.

5.534.7.2.1. Epicel and EpiDex

Epicel (Genzyme Corp., Cambridge, MA) is an integrated CEA sheet developed from the methodology originally pioneered in 1981.[117] The patient is biopsied, and the autologous keratinocytes are isolated *in vitro* and cultured into a sheet that is applied to the wound. Similarly, Epidex (Modex Therapeutics Ltd., Lausanne, Switzerland) is an alternative CEA product derived from autologous hair follicles.

5.534.7.2.2. Laserskin

Laserskin (Fidia Advanced Biopolymers, Turin, Italy) is an example of a composite biocompatible skin graft. It comprises autologous keratinocytes cultured on a thin HA membrane that is laser-microperforated to facilitate ingrowth and proliferation of cells (**Figure 8**). Laserskin requires a lower seed density and reduced culture time, when compared to conventional CEAs. In addition, it is more easily transferred from the culture dish because the cells are grown on a transferable membrane, which avoids enzymatic digestion and contraction in the transplant site.[118] The micropores promote keratinocyte migration into the wound bed.[119]

5.534.7.2.3. Bioseed-S

Bioseed-S (BioTissue Technologies AG, Freiberg, Germany) consists of cultured subconfluent autologous keratinocytes resuspended in a fibrin encapsulant. In preclinical studies, Bioseed-S has shown re-epithelialization of full-thickness wounds[120] and the graft uptake rate was comparable to spraying keratinocytes directly without fibrin. Bioseed-S has primarily been used to treat chronic venous leg ulcers[121] and data suggest a 50% increase in wound healing when compared with standard treatment.[122]

5.534.7.2.4. MySkin

MySkin (Altrika Ltd., Sheffield, UK) is a product comprising subconfluent autologous keratinocytes cultured on a chemically defined silicone layer and applied to the patient.[123] It is indicated to treat superficial burns, skin graft donor sites, and full-thickness wounds in combination with meshed dermal grafts. It has also been applied to diabetic, neuropathic, and pressure foot ulcers with positive clinical outcomes.[124] This product has several advantages, such as ease of handling and relatively short-term cell culture, and can be applied to the wound in a flexible time frame when compared to conventional CEAs.[125]

5.534.7.2.5. ReCell/CellSpray

ReCell is a stand-alone, rapid, autologous cell harvesting, processing, and delivery technology/device as CellSpray is a cultured epithelial autograft suspension (Avita Medical, Australia). Through the spray device it delivers cultured or noncultured subconfluent autologous keratinocytes in a suspension to the wound site. First, a biopsy of skin is obtained from the patient. Then, the cells are cultured *in vitro* and the most actively

Table 1 Commercially available epidermal skin substitutes

Trade name and manufacturer information	*Cell component*	*Cell source*	*Primary cellular growth site*	*Scaffold source and material type*	*Duration of the cover*	*Advantages*	*Disadvantages*
Epicel Genzyme Corp., Cambridge, MA, US	Cultured keratinocytes (confluent cell sheet)	Autologous	*In vitro*	N/A	Permanent	• Earliest approaches in keratinocyte delivery system • Large area of permanent wound coverage with little risk of rejection and high proliferation rate • A valuable life-saving treatment in extensive injuries	• Long cell culture period (3 weeks) • Difficulties in handling and application • Fragile, risk of blistering due to incomplete anchoring • Variable uptake rate • Poor long-term results • Necessity for dermal support • High cost • Short shelf life (24 h)
EpiDex Modex Therapeutiques, Lausanne, Switzerland	Cultured keratinocytes from outer root sheath of scalp hair follicles (confluent cell sheet)						
Laserskin (Vivoderm) Fidia Advanced Biopolymers, Turin, Italy	Cultured keratinocytes (confluent cell sheet)	Autologous	*In vitro*	Recombinant Hyaluronic Acid membrane (microperforated)	Permanent	• Good graft uptake rate • High biocompatibility • Low infection rate • Easy handling properties	• Three weeks cell culture period • Short shelf life (several days)
Bioseed-S BioTissue Technologies AG, Freiberg, Germany	Cultured keratinocytes (subconfluent cell suspension)	Autologous	*In vitro*	Allogeneic Fibrin sealant	Permanent	• Outpatient procedure • Improved handling and cell attachment	• Several weeks cell culture period • Short shelf life (2 days)
Myskin Altrika Ltd., Sheffield, UK	Cultured keratinocytes (subconfluent cell sheet)	Autologous	*In vitro*	Synthetic Silicone coated with a plasma-polymerized surface	Permanent	• Easy handling and application • Decreased time for cell culture • Flexible delivery time	• Reapplication required for satisfactory clinical outcome
ReCell/CellSpray Avita Medical, Australia	Non/cultured keratinocytes (subconfluent cell suspension)	Autologous	*In vitro*	N/A	Permanent	• High proliferation rate • Easy to apply • Provides wound coverage • Reduced cell culture time	• Limited to partial-thickness and graft donor site wounds

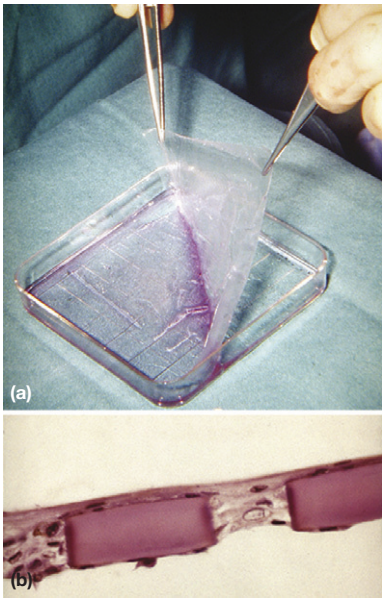

Figure 8 Laserskin: (a) raw material and (b) photomicrograph of populated material demonstrating cells migrating through pores. Reproduced from Price, R. D.; Berry, M. G.; Navsaria, H. A. *J. Plast. Reconstr. Aesthet. Surg.* **2007**, *60*(10), 1110–1119.

proliferating cells are harvested and applied to the wound site to improve wound closure and epithelialization.[115] This cell delivery system utilizes a reduced cell culture period and is an extremely convenient way to treat partial thickness and graft donor site; however, CellSpray must be used in combination with a dermal layer to function as a permanent skin replacement in full-thickness wound treatment.

5.534.7.3. Dermal Skin Substitutes

The dermis is an extremely important component of a skin substitute which may drastically improve the epidermal graft uptake success rate. *In vivo* studies have shown that keratinocyte spraying requires a dermal bed to achieve complete re-epithelialization.[126] Clinical practice has emphasized that therapies consisting of cultured keratinocytes are of limited value in treating full-thickness wounds without a well-vascularized recipient dermal wound bed.[127] The dermal construct should mimic the three-dimensional morphology of the natural ECM. The tissue-engineered construct may or may not incorporate cells, such as fibroblasts. The dermal construct may be commercialized alone or as a bilayered construct that includes epidermal cells. Many commercialized dermal constructs are acellular and avoid immunogenic response and rejection.[128] A list of commercialized dermal constructs has been compiled in **Table 2**.

5.534.7.3.1. Collagen-based dermal analogs: AlloDerm, GraftJacket, Karoderm, SureDerm, Permacol Surgical Implant, and Matriderm

Currently, there are several commercially available acellular products that serve as dermal replacements, such as allogeneic grafts (AlloDerm, GraftJacket, Karoderm, SureDerm) and xenogeneic grafts (Permacol Surgical Implant and Matriderm). Many dermal substitutes only partially engraft into the wound bed; however, they successfully serve as a dermal matrix for further autologous skin graft application. Nevertheless, both allogeneic- and xenogeneic-derived dermal grafts require rigorous screening to reduce the transmission of disease and virus infection and address safety and ethical issues.

AlloDerm (LifeCell Corporation, Branchburg, NJ) is a freeze-dried human acellular dermal matrix containing basement membrane.[129] It has a porous and fibrillar structure prepared from naturally derived human dermis by decellularization and lyophilization techniques. As a dermal replacement bioconstruct, Alloderm failed to support dermal fibroblast ingrowth due to the dense structure of the collagen fibrils[130] and has an unpredictable rate of vascularization.[27] However, Alloderm combined with extra-thin split-thickness skin grafts has performed fairly well in terms of function and aesthetics.[131] Alloderm is indicated for use in hernia repair and breast reconstruction; however, it has been used off-label on burn wounds.[132]

GraftJacket (Wright Medical Technology, Inc., Arlington, TN) is manufactured by both LifeCell Corporation and Wright Medical Group, Inc., as a premeshed human, acellular, extra-thin dermal replacement indicated for low-extremity ulcer repair.[133] It is first packaged aseptically in a peel-pouch, freeze-dried, and then sealed within a foil bag under inert atmospheric conditions. Kim *et al.*[134] reported that GraftJacket successfully treated superficial and deep wounds. In addition, a recent prospective, randomized, controlled clinical study demonstrated that diabetic foot ulcers treated with GraftJacket regenerative tissue matrix have a 2–3 times higher probability of healing compared to standard wound management.[135]

Karoderm (Karocell Tissue Engineering AB, Karolinska University Hospital, Stockholm, Sweden) is an acellular, human-derived dermis used to grow keratinocytes on full-thickness wounds. These donated dermal grafts replace the injured or debrided dermis and have been shown to accelerate wound closure and reduce scarring and contracture. Karoderm is particularly useful in treating injuries on growing children and is used to fill soft tissue defects that may result from skin cancer or trauma.

SureDerm (Surederm, Hans Biomed Corp., Korea) is similar to Karoderm in that it is an acellular, human-derived dermal replacement.[136] It has been indicated to repair soft tissue, such as nasal septal perforation,[137] abdominal wall defects,[138] and wounds due to burns. The product requires a 10-min rehydration procedure before use and can be stored for up to 2 years.

Permacol Surgical Implant (Tissue Science Laboratory, Inc., Covington, GA) is a sterile, off-white, moist, tough, and flexible fibrous flat sheet of acellular porcine dermal collagen and its constituent elastin fibers. Permacol is a patented product that is processed to remove noncollagenous and cellular components and is cross-linked to enhance biocompatibility and durability. It is used mainly for abdominal wall hernia reconstruction[139]; however, its clinical use is limited due to the slow ingrowth of cells and angiogenesis.[140]

Matriderm (Dr. Suwelack Skin & Health Care AG, Billerbeck, Germany) is a dermal replacement comprising structurally intact native bovine collagen coated with α-elastin hydrolysate. The collagen fibers are less densely packed as compared to Integra dermal regeneration template, which

Table 2 Commercially available dermal skin substitutes

Trade name and manufacturer	*Cell component*	*Cell source*	*Primary cellular growth site*	*Scaffold source and material type*	*Form*	*Duration of the cover*	*Advantages*	*Disadvantages*
AlloDerm Life Cell Corporation, Branchburg, NJ, US	N/A	N/A	*In vivo*	Allogeneic Human donor acellular lyophilized dermis	Collagen-based dermal analogs	Permanent	• Reduce antigenic components and immune response • Extra-thin for rapid host tissue incorporation (take) • Premeshed for easy passage of wound exudate • Immediately available • Small and large surface	• Risk of graft rejection and viral disease transmission • Deep surgical excision required • Secondary grafting necessary • Donor screening difficulties • Multiple donors
GraftJacket Wright Medical Technology, Inc., Arlington, TN, US								
Karoderm Karocell Tissue Engineering AB, Karolinska University Hospital, Stockholm, Sweden								
SureDerm HANS BIOMED Corporation, Seoul, Korea							• Nonimmunogenic • Easy manipulation	
Matriderm Dr Suwelack Skin & HealthCare AG, Billerbeck, Germany				Xenogeneic Bovine non-cross-linked lyophilized dermis, coated with α-elastin hydrolysate			• Comparable biological properties such as take rate, revascularization with Integra	• Combined with autologous skin grafts necessary for full-thickness skin defects
Permacol Surgical Implant Tissue Science Laboratories InC, Covington, UK				Xenogeneic porcine acellular diisocyanite cross-linked dermis			• Nonimmunogenic • Supports host fibroblast infiltration and revascularization	• Revascularization inefficient to support epidermal graft
Pelnac Standard/Pelnac Fortified Gunze Ltd., Kyoto, Japan	N/A	N/A	*In vivo*	Xenogeneic+synthetic Out layer-silicone/ silicone fortified with silicone gauze TREX; Inner layer-atelocollagen derived from porcine tendon	Collagen-based sponge	Semi-permanent	• Long shelf life • Easy to handle • Excellent long-term results	• Two-stage operative procedure • Combined with autologous skin grafts necessary for full-thickness skin defects

(*Continued*)

Table 2 (Continued)

Trade name and manufacturer	*Cell component*	*Cell source*	*Primary cellular growth site*	*Scaffold source and material type*	*Form*	*Duration of the cover*	*Advantages*	*Disadvantages*
Terudermis Olympus Terumo Biomaterial Corp., Tokyo, Japan				Xenogeneic + synthetic Out layer-silicone; Inner layer- lyophilized cross-linked bovine collagen sponge				
Integra (Dermal Regeneration Template) Integra LifeSciences Corporation, Plainsboro, NJ, US	N/A	N/A	*In vivo*	Xenogeneic+synthetic Epidermal-synthetic polysiloxane polymer; Dermal-bovine cross-linked tendon collagen (type I collagen) and GAGs	Collagen-based composites Bilayered template	Semipermanent	• Control fluid loss • Immediate wound cover • Encourages ingrowth of fibroblasts and epithelial cells	• Antigenicity and risk of disease transmission • Risk of infection • Three weeks *in vitro* lag period required to expand cells
Biobrane/Biobrane-L Smith & Nephew UK Limited, London, UK	N/A	N/A	*In vivo*	Xenogeneic + synthetic Epidermal-silicon film; Dermal – tri or monofilament nylon fabric mesh coated with porcine collagen	Collagen-based composites Wound dressing	Temporary	• Long shelf life • Dressing changes is unnecessary	• Difficult to remove if left more than 2 weeks
TransCyte Advanced BioHealing, Inc., Westport, CT and La Jolla, CA, USA.	Cultured neonatal fibroblasts	Allogeneic	*In vitro*	Xenogeneic + synthetic Epidermal-silicon film; Dermal – porcine dermal collagen-coated nylon mesh	Collagen-based composites Cassette with two sheets (frozen)	Temporary	• Cells provide a source of cytokines and growth factors to aid wound healing • No deep surgical excision needed	• Need for subsequent autograft or reapplication • Potential risk of rejection and disease transmission

Dermagraft Advanced BioHealing, Inc., Westport, CT and La Jolla, CA, USA.	Cultured neonatal fibroblasts	Allogeneic	*In vitro*	Allogeneic + synthetic ECM, PGA/PLA	Frozen film	Temporary	• Cells provide a source of cytokines and growth factors to aid wound healing • Long shelf life (6 months)	• Potential risk of rejection and disease transmission
EZ Derm AM Scientifics Limited, Geneva, Switzerland	N/A	N/A	*In vivo*	Xenogeneic Porcine aldehyde cross-linked reconstituted dermal collagen	Perforated or nonperforated dressing rolls	Temporary	• Long shelf life • Reduced pain	• Increased wound exudate • Does not vascularize and sloughs off • Mesh-like final appearance
Hyalomatrix PA Fidia Advanced Biopolymers, Turin, Italy	N/A	N/A	*In vivo*	Allogeneic + synthetic Out layer-silicone Inner layer-HYAFF (an ester of hyaluronic acid)		Temporary	• Biocompatible due to allogeneic or xenogeneic components • Good barrier function	• Temporary wound coverage • Use requires dermabrasion
Hyalomatrix 3D Fidia Advanced Biopolymers, Turin, Italy	Cultured fibroblasts	Autogeneic	*In vitro*	Allogeneic HYAFF membrane (microperforated)		Permanent	• Living cellular 3D layer • Enhance epidermal construct take when combined use • Reduce hypertrophy and wound contracture rates	• Complicated surgical intervention
OASIS Wound Matrix Healthpoint, Ltd., US	N/A	N/A	*In vivo*	Xenogeneic Porcine acellular lyophilized small intestine submucosa		Permanent	• Long shelf life	• Several reapplications may be required

is an irreversibly cross-linked collagen/glycosaminoglycan matrix (Figure 9). Recently, Schneider *et al.* compared the use of Matriderm to Integra in a rat study.[141] They demonstrated that Matriderm was not significantly different from Integra regarding their biological properties or performance, such as engraftment rate, granulation tissue accumulation, and neovascularization. Matriderm has also shown promising effects on healing when used in conjunction with split-thickness skin grafts on various wound types including full-thickness skin defects,[142] burns,[143–145] and electrical injuries,[144,145] as well as for covering exposed tendons.[146]

5.534.7.3.2. Collagen-based sponge: Pelnac, Terudermis

Pelnac (Gunze Limited, Kyoto, Japan) is an artificial bilayered dermis composed of an inner porcine collagen sponge layer about 3 mm thick with pore sizes ranging from 70 to 110 μm, a pore volume fraction of 80–95%, and an outer silicone layer of 150 μm thickness.[147] This dermis is freeze-dried and can be stored in dry conditions under ambient temperature for 3 years. Prior to use, it must be immersed in physiologic saline solution for 1 h to remove residual air. Suzuki *et al.* reported successful long-term results in 90% of cases when used in conjunction with extra-thin split-thickness skin grafts to treat full-thickness skin defects and deep burns.[148] In a clinical study of 55 patients, Pelnac was shown to induce rapid granulation tissue formation superior to that of Integra and Terudermis.[149]

Terudermis (Olympus Terumo Biomaterials Corp., Tokyo, Japan) has been available in Japan since 1993. It comprises a lyophilized collagen sponge cross-linked by dehydrothermal treatment. The collagen is reconstituted from fibrillar and heat-denatured low-antigenic bovine atelocollagen (a water-soluble form of collagen used in cosmetics and for culturing cells), where fibrillar atelocollagen provides scaffolding for surrounding cells and heat-denatured atelocollagen stimulates infiltration of host cells. Terudermis can be applied to mucosal and dermal defects resulting from burns, palatoplasty, trauma, and excisions.[150–152] It is useful in reconstructive surgery, and four versions of the product are available: silicone membrane type, mesh-enforced type, collagen monolayer type, and drainage slits type. The silicone membrane prevents infection and controls moisture flux,[153,154] similar to Integra.

5.534.7.3.3. Collagen-based composites: Integra, Biobrane, TransCyte

Integra Dermal Regeneration Template (Integra LifeSciences Corporation, Plainsboro, NJ) (Figure 10) was first designed by Yannas and Burke in 1980.[108] It is a bilayered dermal replacement that comprises an inner layer of lyophilized bovine type I collagen and shark chondroitin-6-sulfate glycosaminoglycan (8 wt%) and an outer layer of silicone which serves as a temporary epidermal barrier. It is necessary to remove the nondegradable silicone layer 2–3 weeks after granulation tissue formation and neovascularization is complete.[38] Integra has been successfully used in the clinic in burn wound management since 1981[38,155] and was shown to improve full-thickness wound closure with aesthetically pleasing results. Thus, Integra has become the clinical 'gold standard' dermal substitute. In addition, it is biocompatible, easy to use, and associated with a limited risk of transmissible infection, and has a relatively long shelf life. Although it seems to meet the design principles of skin substitutes, there are still some major associated product drawbacks: it is not a stand-alone treatment, it requires a second operative procedure to approach permanent wound closure, it requires a 2-week period required for neovascularization, and it cannot be used on infected wounds.

Biobrane (Smith & Nephew UK Limited, London, UK) is an acellular biosynthetic temporary skin construct of a silicone film bonded to a porcine collagen cross-linked with trifilament nylon fabric. It has a long shelf life without special storage requirements, and has a high cost-effective ratio.[156] Biobrane

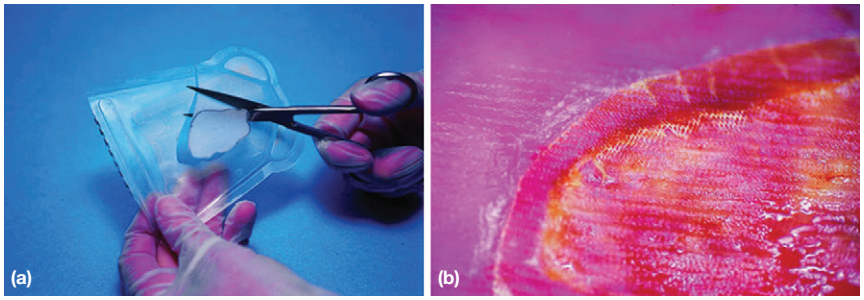

Figure 11 Dermagraft: nonimmunogenic neonatal fibroblasts cultured on a polyglactin mesh. (a) The dressing is stored frozen and the edges are trimmed after warming in a saline bath. (b) It is applied to the wound which lies within the ulcer boundary. Reproduced from Harding, K. G.; Morris, H. L.; Patel, G. K. *Br. Med. J.* **2002**, *324*(7330), 160–163.

has been commercially available since 1979 and is used to treat patients with partial-thickness burns and relatively fresh wounds (<24–48 h) with low bacterial counts.[157,158] In addition, Biobrane has been shown to decrease pain and reduce exudate when used on autograft donor sites[159]; however, no effects have been observed on deep partial-thickness and full-thickness burns. After healing, Biobrane can be intentionally removed or is naturally separated from the wound bed as healing progresses.

TransCyte is a cellular Biobrane product originally termed Dermagraft-TC, which was commercialized by Advanced Tissue Sciences, Inc., and received FDA approval in March 1997. In 2006, Advanced BioHealing, Inc. (ABH) purchase Dermagraft and TransCyte from Smith & Nephew. TransCyte is composed of a semipermeable silicone membrane and human neonatal fibroblasts cultured on a collagen-coated nylon mesh.[42] The fibroblasts are responsible for secreting various ECM components, such as FN and collagen, and growth factors onto the nylon mesh to provide an environment that stimulates wound healing.[160] TransCyte serves as a temporary wound covering for surgically excised full-thickness and deep partial-thickness burn wounds in patients who require autografts.[161] However, the price of TransCyte is 16 times more than that of Biobrane, 13 times more than that of an allograft, and 2.3 times more than that of Integra.[162] The product must be stored between −20 and −70 °C, and thawed at 37 °C prior to use. It has a shelf life of 18 months at the proper temperature and is difficult to handle, when compared to the above synthetic products.

5.534.7.3.4. Dermagraft

Dermagraft (ABH) is a cryopreserved skin construct with knitted polyglycolic acid/polylactic acid (PGA/PLA, namely polyglactin) mesh and living cultured human neonatal fibroblasts from foreskin within it. The typical polyglactin mesh is shown in Figure 11. The bioresorbable scaffold degrades via hydrolysis in 3–4 weeks while fibroblasts proliferate and produce ECM components to reconstitute a dermal layer (Figure 12).[134] The product does not have an epidermal equivalent layer. Dermagraft stimulates the ingrowth of fibrovascular tissue, but does not close the wound. It is primarily used to treat debrided, uninfected, and well-vascularized chronic wounds, such as diabetic foot ulcers and venous ulcers.[163,164]

5.534.7.3.5. OASIS Wound Matrix

OASIS Wound Matrix (Healthpoint, Ltd., USA) is an intact, freeze-dried, decellularized matrix naturally derived from porcine small intestine submucosa that serves as a temporary skin substitute/bioactive wound dressing.[165,166] It has been shown to support epidermal differentiation and basement membrane formation *in vitro*,[167] but has no effect on epithelialization *in vivo*.[168]

5.534.7.3.6. EZ Derm

EZ Derm (AM Scientifics Limited, Geneva, Switzerland) is a reconstituted porcine-derived collagen that has been chemically cross-linked with an aldehyde to improve its tensile strength and durability and allowing convenient storage at

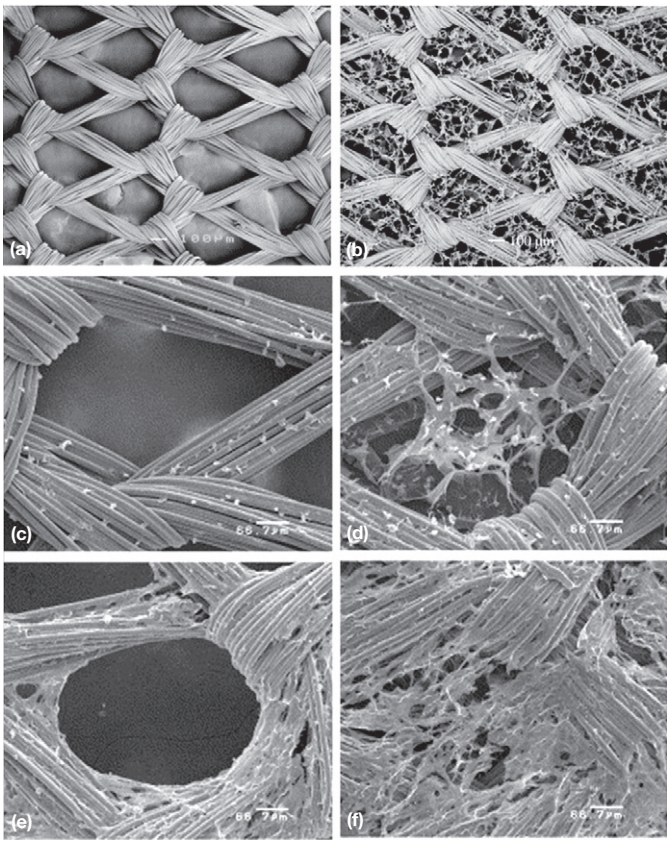

Figure 12 SEM photomicrographs of (a) PLGA (Polyglactin) knitted mesh. (b) Collagen-hybridized polyglactin mesh (Dermgraf) at original magnification × 90. (c) Fibroblasts cultured in polyglactin knitted mesh for 30 min and (e) for 5 days. room temperature. The product acts as a temporary protective barrier/bioactive wound dressing that allows the natural healing process to continue undisturbed.[169] EZ Derm is available in both perforated and nonperforated versions for wounds requiring early exudate management and those requiring maximum fluid retention and optimum cosmetic results, respectively.

5.534.7.3.7. Hyalomatrix PA, Hyalograft 3D

Hyalomatrix PA and Hyalograft 3D (Fidia Advanced Biopolymers, Turin, Italy) were developed from HA derivatives (Figure 13). Hyalomatrix PA is an acellular dermal construct with a temporary silicone epidermal replacement, while Hyalograft 3D lacks the silicone layer but contains cultured autologous fibroblasts that secrete growth factors and cytokines. Hyalomatrix PA serves as a temporary dermal substitute to cover deep partial-thickness burns after dermabrasion. It acts as 'bridge' between necrotic debris and stimulates regeneration in a humid and protected environment (Hyalomatrix PA dressing). Recently, a national retrospective study was done to compare the treatment of deep partial-thickness and full-thickness burns with Hyalomatrix PA and autografting.[170] The Vancouver Scar Scale showed more promising results for those adults treated with Hyalomatrix PA; however, no difference was observed for burn depth. As a result, Hyalomatrix PA is indicated for use as a temporary covering before grafting or alone on deep partial-thickness and full-thickness burns in both children and adults.

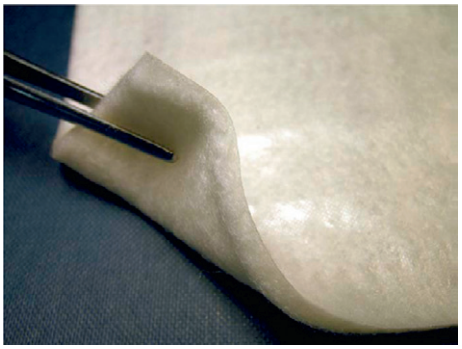

Figure 13 Hyalomatrix 3D with the addition of an upper silicon layer. Reproduced from Anthony, E. T.; Syed, M.; Myers, S.; Moir, G.; Navsaria, H. *Drug Discov. Today: Therapeut. Strat.* **2006**, *3*, 81–86.

In clinical practice, Hyalograft 3D is used for foot ulcer management in conjunction with Laserskin,[171] which is also known as the TissueTech Autograft System (see below). This product is reported to improve epidermal architecture with regular differentiation development *in vitro*, provide the basis

of epidermal homeostasis, and help DEJ maturation in the reconstructed skin constructs.[172,173]

5.534.7.4. Dermo–epidermal (composite) Skin Substitutes

Composite skin substitutes are bilayered skin constructs consisting of both epidermal and dermal layers aimed to mimic the anatomy of normal skin. There are three purposes that a composite skin substitute should have: (1) engraft into the wound site and serve as a replacement to an autograft; (2) act as a temporary covering until the autograft is applicable; and (3) stimulate the host's wound healing response by providing a scaffold and supply of bioactive molecules and/or ECM components.[174] Most composite skin grafts that have been developed incorporate allogeneic fibroblasts and keratinocytes into the dermal and epidermal compartments, respectively. Since these cellular constituents are derived from allogeneic sources, they only survive for a few weeks.[19] For example, clinical studies[175] and porcine studies[176] have shown that allogeneic fibroblasts can survive for 7 days post implantation, 3 weeks,[177] or even up to 2 months.[178,179] Although allogeneic cells act as a temporary solution, they supply bioactivity to wound dressings[23] by producing growth factors, cytokines, and ECM components, which deposit into the scaffold and modulate the recipient's wound healing process. The commercially available dermo–epidermal skin substitutes are summarized in Table 3.

5.534.7.4.1. Karoskin

Karoskin (Karocell Tissue Engineering AB, Karolinska University Hospital, Stockholm, Sweden) is human full-thickness skin obtained from donors, which is used as a temporary, durable covering for acute or chronic partial- and full-thickness wounds awaiting autologous split-thickness skin grafts. The allograft provides a reduction in pain and protection from infection for the first few weeks post injury. If the allograft is left in the wound for 3–4 weeks, the keratinocytes stimulate a host reaction, which results in graft tissue rejection and requires a replacement with an autograft.

Table 3 Commercially available dermo–epidermal (composite) skin substitutes. PEO, polyethylene oxide terephthalate; PBT, polybutylene terephthalate; HAM, hyaluronic acid membrane (microperforated)

Brand name and manufacturer	*Cell component*	*Cell source*	*Primary cellular growth site*	*Scaffold source and material type*	*Duration of the cover*	*Advantages*	*Disadvantages*
Karoskin Karocell Tissue Engineering AB, Karolinska University Hospital, Stockholm, Sweden	Native skin	Allogeneic	Native	Allogeneic Native human cadaver skin with dermal and epidermal cells	Temporary	• Provide pain relief and temporary durable cover	• Risk of graft rejection and disease transmission • Material availability uncertain
Apligraf Organogenesis Inc., Canton, MA, US	Cultured keratinocytes and fibroblasts	Allogeneic	*In vitro*	Xenogeneic Bovine collagen	Temporary	• Graft high take rate • No signs of keratinocyte rejection observed	• Risk of disease transmission
Orcel Forticell Bioscience, Englewood Cliffs, NJ, US	Epidermal-human allogeneic neonatal Keratinocytes Dermal-human allogeneic neonatal foreskin fibroblasts	Allogeneic	*In vitro*	Xenogeneic Bovine collagen sponge	Temporary	• Cells provide a source of cytokines and growth factors to aid wound healing • Nine months shelf life	
TISSUETech Autograft system (Laserskin and Hyalograft 3D) Fidia Advanced Biopolymers, Abano Terme, Italy	Cultured keratinocytes and fibroblasts	Autologous	*In vitro*	Recombinant Hyaluronic acid membrane (microperforated)	Permanent	• Successful treatment of diabetic foot ulcers with low reocurrence rates	• Requires two consecutive grafting procedures, associated with a complicated surgical intervention

5.534.7.4.2. Apligraf

Apligraf (Organogenesis, Inc, Canton, MA) (formerly known as Graftskin and Living Skin Equivalent) (Figure 14) is a composite skin substitute based on the pioneering work of Bell *et al.* on a collagen-based cellular construct.[105] It was the first FDA-approved medical device that incorporated living allogeneic cells. Apligraf contains two types of cells: fibroblasts and keratinocytes. In the dermal layer of the construct, human neonatal foreskin fibroblasts are suspended in a bovine type I collagen solution and converted into a contracted matrix within 6 days. In the epidermal layer, neonatal keratinocytes are seeded on the dermal layer and exposed to an air–liquid interface to promote maturation and cornification of a stratum corneum. Although Apligraf is reported to remain viable in the wound bed for 14 days and improve healing of acute and chronic wounds, such as chronic venous leg ulcers and diabetic foot ulcers,[179,180] it cannot support the regeneration of dermal appendages. Apligraf is supplied as a round disk that is 75 mm in diameter and 0.75 mm thickness. The product is packaged in a polyethylene bag containing a 10% CO_2/air ratio and agarose nutrient medium. Apligraf has a 5-day shelf life and must be stored at 20–23 °C.

5.534.7.4.3. OrCel

OrCel was first invented by Dr. Mark Eisenberg of Australia[181] and further developed by Forticell Bioscience Inc. (Englewood Cliffs, NJ) and licensed in 2001 to treat autograft donor sites required for the treatment of burns and dystrophic epidermolysis bullosa (EB). Like Apligraf, it contains both fibroblasts and keratinocytes that secrete many cytokines and growth factors, such as FGF-1 (bFGF), NGF, GM-CSF, IL-1α, IL-1β, IL-6, HGF, KGF-1 (FGF-7), M-CSF, PDGF-AB, TGF-α, TGF-β1, TGF-β2, and vascular endothelial growth factor (VEGF), that condition the wound bed for the application of an autogolous skin graft. In the dermal layer of the construct, human neonatal foreskin dermal fibroblasts are incorporated into a porous collagen matrix. In the epidermal layer, keratinocytes are incorporated into a nonporous collagen gel that is coated onto the dermal layer.[182] OrCel is as a resorbable, biocompatible matrix that provides a favorable environment for host cell migration and wound healing; however, it does not contain dermal appendages, such as Apligraf and Dermagraft.[53] Like all devices containing allogeneic cells, OrCel-treated donor sites retain no allogeneic cell deoxyribonucleic acid (DNA) after three weeks.

5.534.7.4.4. TISSUETech Autograft system

TISSUETech (Fidia Advanced Biopolymers, Turin, Italy) is an equipment that can fabricate autologous skin substitutes from tissue biopsies. From a small biopsy, fibroblasts and keratinocytes are isolated and separately cultured on HA to form an autologous epidermal and dermal replacement, known as Laserskin and Hyalograft 3D, respectively.[183] Reports from clinical trials have shown that TISSUETech has successfully been used to treat diabetic foot ulcers, many of which were full-thickness wounds with surface areas greater than 5 cm^2.[183] Recently, another prospective study showed that TISSUETech prevented depression or neck scars after parotid surgery.[184] Although this system may improve wound closure, it is not a 'true' composite skin substitute because it requires a two-layered grafting procedure.

5.534.8. Problems and Challenges of Available Skin Substitutes

The optimal skin substitute should mimic the performance and multifunctionality of the natural skin, such as permeability and infection barrier, color match, durability, compliance/stiffness and elasticity (physical properties), vascularization (take rate), regeneration of sweat and sebaceous glands, and hair follicles. However, all of the currently available skin substitutes are suboptimal, and in this section we will describe a few of their major limitations.

5.534.8.1. Biocompatbility

A challenge in the design of many currently available skin substitutes is the lack of biocompatibility. In general, autologous cells are biocompatible, whereas allogeneic and xenogeneic cells will eventually be rejected by the immune system of the host. In addition, specific allergies to animal-derived products can restrict their use in skin substitutes. For example, Orcel, Apligraf, and/or TransCyte cannot be applied to patients with known allergies to bovine products.[185] Although biocompatibility is a crucial criterion of the ideal skin substitute, autologous cells, which are typically derived from a small biopsy, require a 3-week *in vitro* culture period to expand cells to the needed population size. On the other hand, allogeneic and xenogeneic cells offer 'off-the-shelf' availability and these cells secrete a plethora of bioactive molecules and ECM components that play an invaluable role in wound healing.[186]

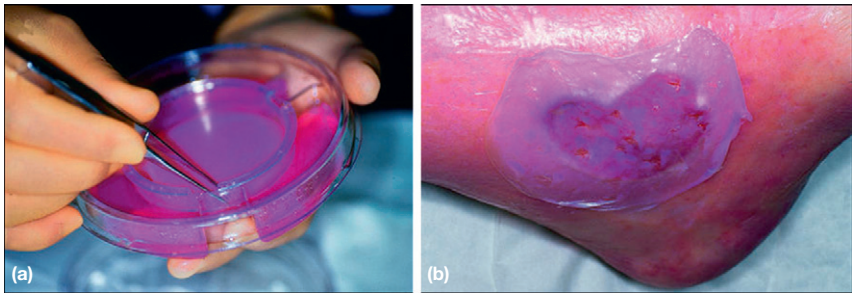

Figure 14 Apligraf: a bilayered skin equivalent containing newborn dermal fibroblasts cultured in a bovine collagen matrix with overlying epidermal cells. (a) It is stored frozen lying on a culture gel, and (b) small slits are trimmed after warming and is laid onto the wound surface whose the edges overlie the ulcer boundary. Reproduced from Harding, K. G.; Morris, H. L.; Patel, G. K. *Br. Med. J.* **2002**, *324*(7330), 160–163.

The body's defense mechanism can also vary according to the composition of the skin substitute. For example, Integra has been reported to cause greater foreign body reaction than the acellular dermal matrixes Alloderm and Dermagraft.[187]

There are three major sources of cells that may be considered when designing a skin substitute: local, systemic, and progenitor cell populations. Cells found locally include fibroblasts, keratinocytes, melanocytes, adipocytes, and follicular cells, and these systemically reside in the peripheral blood or bone marrow. Progenitor cells are found locally in the hair follicles and subcutaneous fat and systemically in adult bone marrow and in the embryo inner cell mass. Currently available skin substitutes are designed as a single-layer or bilayered structure and typically utilize two locally derived cell types, namely, keratinocytes and fibroblasts. The lack of melanocytes, Langerhans cells, and endothelial cells leaves the skin vulnerable to ultraviolet radiation and contamination and with inadequate vascular supply for oxygenation and nutrition, respectively. Commercially available devices also lack other skin structures, like sweat glands, sebaceous glands, nerves, and hair follicles, and as a result they do not provide thermoregulation or sensation to temperature, pressure, and touch.

Many investigators have studied improving skin substitutes through the addition of other cell types, including endothelial cells,[188,189] Langerhans cells,[190,191] melanocytes,[192–194] hair follicles, and sebaceous glands.[195] Among them, the incorporation of melanocytes in the correct concentration and from an appropriate donor for functional and cosmetic purposes seems to be most promising. For example, human skin substitutes containing cell slurries of keratinocytes and fibroblasts, with or without melanocytes, were grafted onto severe combined immunodeficient (SCID) mice.[192] At 16 weeks, Caucasian donor-derived skin substitutes with melanocytes were clearly darker than those without melanocytes, and a darker pigmentation was produced from donors of African descent.

Recently, bone-marrow-derived mesenchymal cells or adipose tissue-derived stromal cells (ATSCs) have gained widespread attention because of their unique proliferative and differentiation abilities.[196–198] Nambu *et al.* mixed freshly isolated ATSCs with an atelopeptide collagen/silicon membrane (ACMS) and demonstrated significantly advanced granulation tissue formation, capillary formation, and epithelialization in diabetic healing-impaired wounds compared to vehicle alone.[197] Although the aforementioned cell sources show promise for improving skin substitutes, their low host acceptance rate and the trend to tissue repair rather than tissue regeneration are major hurdles.[46]

Concerns regarding the potential of disease transmission via cadaveric human sources or even xenogenic sources (pig endogenous retrovirus) are still an issue.[162,185,186]

5.534.8.2. Physical Properties

Mechanical fragility and blistering of the epidermal component can occur during the maturation period of the basement membrane formation and constitute a limitation for the use of skin substitutes seeded with keratinocytes. Additional failures are likely if the skin originates from autologous sources isolated from older donors where the keratinocyte growth rate is slow, culture life span reduced, and colony forming ability diminished.[199] The absence of a dermal component in the skin substitute can often result in a reduced engraftment rate, as reported for Laserskin, EpiDex, and Epicel.[23,53,185,199–201] Keratinocytes in Epicel achieve stratification at 6 days but undulations at the epidermal–dermal interface known as 'rete ridges' that depend on basement membrane are lacking.[162] Only at 3 weeks can the basement membrane be distinguished and hemidesmosomes observed.[162] Anchoring fibrils such as collagen type VII are sparse and immature for the first 6–12 months, a fact that explains the fragility of this layer.[162] Additional destabilizing effects inflicted on the basement membrane could be attributed to the proteases used when harvesting keratinocytes cultured *in vitro*.[201]

Frequently, more than one surgical intervention is necessary to achieve satisfactory healing. Full-thickness wounds need time to develop a dermal component and skin substitutes such as BioBrane and TransCyte, which stimulate dermal repair, require the synthetic layers to be removed prior to autologous keratinocyte application.[185] For use of autologous cells, the lag period between skin biopsy and the requisite cell expansion can take 2–3 weeks. This time involves hospitalization and nursing care, which adds to the intrinsic high cost of these tissue-engineered products.[162,185] Furthermore, the short shelf life of not only autologous but also allogeneic skin substitutes is a practical disadvantage for the commercialization of some products. For example, Apligraf lasts for only 5–10 days at room temperature.

5.534.8.3. Limited Vascularization and Poor Engraftment into Wound Site

One of the most common limitations of bilayered cell-containing skin substitutes, or any scaffold for that matter, is the scaffold's limited vascularization rate.[202] The survival of the uppermost cell layer in the scaffold will be in jeopardy if adequate blood perfusion and nourishment are not provided, which would consequently threaten successful engraftment.[203] In clinical practice, skin substitutes applied to fat or to a poorly vascularized wound bed often fail and require replacement. However, the success of engraftment significantly increases when the wound bed is pretreated with a dermal substitute, such as Integra, which stimulates vascularization prior to grafting.[204,205]

Vascularization also affects the attachment of keratinocytes to the underlying dermis. In general, thicker grafts lead to better mechanical (resistance to pressure and shear forces, graft shrinkage), functional (sensibility), and aesthetic properties; however, they are more difficult to vascularize.[206] The maximum depth that new blood vessels can reach in a skin bioconstruct that stimulates angiogenesis is about 400 μm. When grafts are thicker than 400 μm, new blood vessels cannot grow quickly enough from wound bed into the whole layer to sustain viability, thereby resulting in graft loss.[207]

Prevascularization involves creating a microvasculature inside an engineered tissue prior to implantation. It is believed that the preexisting vascular network will lead to the generation of engineered skin substitutes of more physiologically functional complexity and improved regenerative potential.[208,209] One strategy has been to reconstruct a human capillary-like network *in vitro*. Black *et al.* cocultured dermal fibroblasts, keratinocytes,

and human umbilical vein endothelial cells on chitosan/collagen scaffolds, which stimulated the self-organization of endothelial cells into capillary-like structures.[210] Immunohistochemical analysis and transmission electron microscopy of the endothelialized skin substitute showed typical microvasculature characteristics: that is, von Willebrand factor, Weibel–Palade bodies, basement membrane material, and intercellular junctions. Tremblay *et al.* observed similar results when human keratinocytes, fibroblasts, and endothelial cells were cocultured on a collagen sponge *in vitro* and implanted at a wound site.[56] The study suggested that prevascularization of the skin substitute resulted in inosculation within the recipient's capillaries, rather than neo-vascularization.

5.534.8.4. Scarring

Poor cosmetic results, namely scarring, of most of the skin substitutes are still a problem and therefore constitute a limitation for their use. Scars are areas of fibrous tissue (fibrosis) that have replaced normal skin. Scars are assessed clinically by a scar scale such as the Manchester Scar Proforma[211] or Vancouver Scar Scale[212]: atrophic, hypertrophic, and keloidal. An atrophic scar takes the form of a sunken recess in the skin that has a pitted appearance. These are caused when underlying structures supporting the skin, such as fat or muscle, are lost. Hypertrophic scars occur when the body overproduces collagen, which causes the scar to be raised above the surrounding skin. Keloids are a more serious form of scarring, with elevated, expansive, and excessive growth beyond the margin of the original wound.[213]

Uncontrolled scarring results in loss of function and poor aesthetics. Some scar formations can result in tightness, pain, and itching, and may result in tissue contractures that restrict movement. In addition, most skin appendages, such as sweat glands, sebaceous glands, and hair follicles, do not regenerate with scar tissue, and, in general, scar tissue is less resistant to ultraviolet radiation due to the lack of melanocytes. Uneven pigmentation due to the absence of melanocytes and the lack of dermal appendages (hair follicles and glands) are the most frequently reported undesired cosmetic outcomes.[23,51] The use of autologous fibroblasts is still preferred over allogeneic fibroblasts, as scar formation and inflammatory reaction are substantially reduced in the former.[214] Therefore, it is important that any new generation of skin substitute target scarless healing.

5.534.8.5. Others

The application of any skin substitute requires that the recipient's physiologic state is optimized, any underlying condition is stabilized, and the wound bed is properly prepared[199] including debridement of all microbial contamination and necrotic tissue to increase the probability of engraftment.[215] Products such as Integra, Alloderm, BioBrane, TransCyte, Apligraf, Dermagraft, and OrCel have been reported to be prone to developing contamination, and extra care is needed on maintaining aseptic environment[185,200] via physical or chemotherapeutic methods. Poor patient compliance is another factor that cannot be underestimated in wound healing and is often the cause of the high incidence of ulcer recurrence.[216] Other factors, such as disturbance of normal daily activities, have been linked with the level of patient compliance. The patient's adherence to a recommended course of treatment could also be influenced by religious and ethical issues. Some biologically based products,[185] in particular the use of cadaveric skin, are factors in these latter matters. If the local and systemic pathobiological states of the patient as well as personal and societal issues are considered along with the inherent characteristics of the engineered skin biomaterial, improvement in success rates will be obtained. From the use of cultured autologous epidermal sheets to the development of complex bilayered skin substitutes, the evolution of tissue engineering constructs and their clinical application has truly been phenomenal.

5.534.9. Divine Garments Without Seams (Ancient Chinese Proverb): The Inspiration for Tissue-Engineered Skin Substitute from Lessons of Nature

Regenerative medicine is a new and expanding field in biomedical engineering research and is focused on the 3R principle: replace, restore, and regenerate damaged or diseased cells, tissues, and organs.[217,218] The key objective is to produce novel skin substitutes that mimic the structural and functional properties of normal skin and integrate them into the host tissue without scarring, like the famous Chinese proverb states, 'divine garments without seams.' In nature, there are few vertebrate species capable of perfect regeneration. For example, the xenopus and axolotl can regenerate entire limbs,[219,220] deer can replace lost antlers,[221,222] bats can fix wing membranes, rabbits,[223] pikas, cats, echo-locating bats,[224] and two experimental mice strain, namely, MRL/MpJ mouse[225] and athymic nude-nu mice,[226] can regenerate external ears, and fetal skin can regenerate with scarless healing.[227,228] A deeper understanding of these mechanisms may result in a breakthrough in skin substitute technology and lead to regeneration rather than healing with scars.

5.534.9.1. Mammalian External Ear: Examples of Regeneration in Adult Animal

5.534.9.1.1. Rabbit ear

Rabbit was one of the first mammals discovered to have the capacity to regenerate new skin tissue for through-and-through holes ear repair (observation originally described by Markelova (1953), translated by Vorontsova and Liosner (1960)).[229] Wound healing around the margins of rabbit ear holes is uniquely characterized by the development of prominent epidermal downgrowths adjacent to the severed sheets of dermis in the integument of the ear. These downgrowths act as epidermal blockades and play an important role in scarless regeneration by allowing blastema cell accumulation. Unlike rabbits, dogs and sheep were not able to regenerate ear tissue due to the absence of these epidermal downgrowths.[223,224]

5.534.9.1.2. MRL/MpJ mouse ear

A similar ear punch regeneration phenomenon was found on MRL/MpJ strain murine model where 2-mm punch wounds regenerated completely after 4–5 weeks.[225] In 2003, histological

analysis revealed that regenerating MRL/MpJ ear edges closely resembled the blastema of a regenerating limb.[230] Rajnoch *et al.* hypothesized that regeneration was the result of a thickened epithelium that provided growth and differentiation factors in the proper spatiotemporal pattern. Interestingly, the regenerative ability of MRL/MpJ strain mice is restricted to the ear.[229] A possible reason is that the small dimensions of the ear may promote the diffusion of growth factors and establish appropriate gradients similar to embryonic development, whereas in large thick tissues, for example, the skin, this may not be possible.[230] In addition, reduced inflammatory infiltrates,[231] decreased concentrations of TGF-β1 and PDGF,[232] and the absence of CD8+T-lymphocytes[226,232] have correlated with scarless healing and suggest that regeneration is highly modulated by the inflammatory system.

5.534.9.2. Mammalian Skin Hair Follicle: Examples of Regeneration in Adult Animal

The mammalian skin hair follicle is believed to develop only during embryogenesis and is lost as an adult. However, there were several profound reports of the development of adult hair follicles *de novo* following wounding in rabbits, mice, and humans nearly 60 years ago.[233–237] Recently, Ito *et al.*[238] discovered that the epidermis of wounded murine adult skin can regenerate new hair follicles during healing, which was shown to recapitulate embryogenesis at the molecular level. Wounding activated the Wnt-mediated signaling pathway, which is essential for normal hair development and cycling. Inhibition of Wnt signaling after re-epithelialization completely abolished wounding-induced folliculogenesis, whereas overexpression of Wnt ligand in the epidermis increased the number of regenerated hair follicles.[238] These results provide a potential therapeutic window for promoting the growth of hair follicles by manipulating the Wnt signaling pathway.

5.534.9.3. Embryonic Skin: Examples of Scarfree Regeneration in Fetal Animal

Early fetal wound healing is essentially a scarless regenerative process,[239,240] with minimal inflammation and complete restoration of normal skin structure, including ECM deposition of hyaluronan, various collagen types, and tenascin-C,[241–243] and regrowth of hair follicles, capillaries, and glands. Repair and regeneration of the skin is correlated with the degree of skin differentiation and the inflammatory response to wounding.[240] Fetal skin repair changes with gestation age and varies with wound size.[244] In large- and small-animal models, early gestation skin wounds heal without scarring.[245] In monkeys, sheep, and rats, the transition between scarless healing and wounds that heal with scarring occurs around 80 days of gestation (early second trimester),[246] middle of the third trimester,[247] and between 16–18 days of gestation (full term is 21.5 days),[248] respectively. In general, wounds of 2–4 mm in diameter are more likely to heal without scarring, whereas wounds of 6–10 mm in diameter were more likely to heal with a scar.[249]

It is has been shown that the differential expression of healing-related cytokines plays a key role in modulating early fetal scarless healing and late fetal or postnatal healing with scar formation.[239] The fetal wound environment has a diminished acute inflammatory response with a decreased number of differentiated inflammatory cells,[243] reduced fibrin clot formation and platelet degranulation, and increased levels of molecules relevant to skin morphogenesis and growth,[46,250] when compared to adult wounds. In addition, concentrations of growth factors in adult and fetal wounds are different.[251] For example, fetal wounds contain decreased levels of TGF-β1 and TGF-β2 and increased TGF-β3 (a skin morphogenetic molecule), as compared to adult wounds.[252] Similarly, PDGF, FGF-1, and FGF-2 expression in fetal wounds is lower than in the adult.[243,252] Therefore, the ideal skin substitute may require the modulation of the adult wound environment to mimic more closely that of the fetal wound. For example, some approaches to reduce scar formation have been to block TGF-β1 and TGF-β2 with neutralizing antibodies, and add exogenous TGF-β3 to the wound.[239,253,254]

The capacity for regeneration is probably inherent to the composition of fetal skin. Coolen *et al.* reported that the levels of dermal ECM molecules such as FN, chondroitin sulfate, and elastin in fetal skin were different from adult skin.[255] Similarly, fetal skin and wounds have a relatively high amount of collagen type III[245,248] and hyaluronan.[90] In the rat model, fetal wounds expressed greater amounts of matrix metalloproteinases in relation to tissue inhibitor of metalloproteinases.[256,257] These data suggest that dermal components are essential to fetal scarless wound healing.

5.534.9.4. Inspiration from Mammalian External Ear and Fetal Skin Regeneration

Understanding and characterizing the elements involved in scarfree embryonic wound healing and adult skin regeneration from a tissue engineering perspective may provide important clues for the ultimate goals of skin tissue engineering: (1) Create a skin construct that promotes complete regeneration of functional skin, including all its layers (epidermis and dermis) and appendages (hair follicles, sweat glands and sensory organs); (2) Promote the rapid uptake (vascularization) and establishment of a network of nerves; (3) Integrate with the surrounding host tissue without scarring. As reported in this section, the issues of cell source, structure, vascularization, and scarring are major limitations of the currently available skin substitutes. However, solutions may be inspired from the aforementioned examples of adult skin regeneration and fetal scarless wound healing.

5.534.9.4.1. Stem cells: cell-based regeneration strategy

Stem cells are central functional units of regeneration. These multipotent cells are capable of both self-renewal and differentiation. The use of stem cells in cell-based regenerative medicine for skin tissue engineering shows promise toward the improvement of therapeutic technologies.

Epidermal stem cells may be an important source of cells relevant to cutaneous wound healing.[258–260] There are two subpopulations of epidermal stem cells located in the skin: stem cells residing in the bulge region of the outer root sheath, and a basal keratinocyte population found in the interfollicular epithelium.[195,261,262] Epithelial keratinocytes have been successfully utilized in skin grafting for many years (see **Section 5.534.7** on CEAs).[104,204,263] Recently, several

studies have demonstrated that progenitor cells offer superior qualities to that of differentiated keratinocytes[264–266] because of their multipotency and easy accessibility.[267,268] Although *in vitro* and *in vivo* assays exist to label, culture, and analyze skin-derived stem cells, it is currently not possible to isolate a pure stem cell population. The identification of one or more specific epidermal stem cell markers is imperative to the successful use of this technology. Furthermore, there are a limited number of stem cells within the interfollicular epithelium and the outer root sheath of the hair follicle, and this mandates cell culture technology that maintains their viability post isolation and rapidly expands them to a useful concentration.

Mesenchymal stem cells (MSCs) derived from bone marrow or adipose tissue may also be suitable candidates for skin tissue engineering. Bone-marrow-derived MSCs (BM-MSCs) leave the bone marrow, circulate in the blood, home to injured tissues, then differentiate into cells of the residing tissue, which accelerates cutaneous wound regeneration in both animals and humans[269–272] and partially restores normal function.[198,273,274] Sasaki *et al.* demonstrated that BM-MSCs could differentiate into keratin-14-positive cells (basal epidermal cell phenotype), endothelial cells, and pericytes *in vivo*.[274] Several reports on the clinical application of BM-MSCs in wound therapies have revealed that grafted MSCs facilitate skin regeneration, both in acute and in chronic wounds.[198,275–277] In Badiavas' study, it was demonstrated that autologous BM-MSCs delivered in a fibrin spray could accelerate healing in human cutaneous wounds. Autologous BM-MSCs have also been shown to play an important role in promoting tissue regeneration after radiation injury.[273] In addition, the transplantation of autologous and allogeneic MSCs on the surface of deep burn wounds in rats has been shown to decrease inflammatory cell infiltration into the wound and accelerate the formation of new vessels and granulation tissue.[217] MSCs have been also shown to produce bioactive substances that accelerate regeneration after wounding.[278] Although current studies have reported that MSCs have the ability of improving wound re-epithelialization in a site-specific manner, the perfect regeneration of hair follicles or sweat glands was not observed; such stem cells have shown a stable self-renewal potential, but their plasticity was limited.[279,280] MSC engrafting and their immunosuppressive properties are also important unintentional side effects.[281–283] Further studies are required to elucidate the underlying mechanism associated with BM-MSCs and wound healing; however, a few hypotheses include cell differentiation, wound contraction, release of pro-angiogenic factors, and maintenance of the ECM.[272,284]

ASCs isolated from liposuction procedures are currently being explored as an alternative to MSCs. In experimental wound models, ASCs accelerated wound closure by improving re-epithelialization and angiogenesis. In this model, the delivery of ASCs via a human acellular dermal matrix or a matrix composed of atelopeptide collagen or silk fibroin-chitosan to improve local tissue regeneration is also being explored.[197,285–288]

Human embryonic stem cells (hESCs) are immature, pluripotent cells that can differentiate into all human cell types, and are another potential candidate in tissue regeneration.[289] However, ethical and moral objections restrict commercial development of hESCs. Recently, scientists have generated induced pluripotent stem cells (iPS cells) from adult human skin fibroblasts and keratinocytes by gene transduction involving cells reprogramming. Cells of this type are less controversial and may prove to be as efficacious as embryonic stem cells in regenerative medical applications.[290–292] In addition, the plasticity of stem cells, especially iPS cells, and their unstable cellular phenotypes might lead to the regenerative tissue structural and/or functional instabilities and ultimately give rise to malignant cells. In conclusion, stem cells offer multiple advantages to consider when creating the ideal skin substitute; however, it is important to study and overcome their associated drawbacks.

5.534.9.4.2. Vascularization: sustaining pipelines to construct the skin substitutes

Vascularization of the engineered skin construct has been a major obstacle associated with commercially available products. The distance of nutrients and oxygen delivery by diffusion is limited to 2 mm in a vascular tissue. The vascular system acts as an important role in mass transport; furthermore, evidences have accumulated to support an intrinsic role of the vascular system in the regulation of tissue formation and differentiation.[293–295] Thus, the penetration of new blood vessels into a skin graft allows the transport of molecules or cells (i.e., macrophages or endothelial progenitor cells (EPCs)), regulating wound healing and/or grafted tissue survival and integration. As mentioned above, stem cells are central functional units of regeneration; however, those cells are oxygen sensitive. Therefore, it is necessary to stimulate rapid vascularization of skin-substitute-sustaining pipelines for their survival and function.

In theory, there are three fundamental mechanisms that incorporate vascularization into a skin bioconstruct: (i) angiogenesis, to promote sprouting and ingrowth of vessels from the host; (ii) vasculogenesis, to form *de novo* vascular network by endothelial progenitors in the construct before implantation, that is, prevascularization; and (iii) artificial functionalized ECM matrices, to promote angiogenesis and vasculogenesis.[208,296,297]

Natural maturation of a vascular system is dependent on specific spatial and temporal orchestration of cells and bioactive molecules. This can be achieved by promoting invasion and sprouting of the host vasculature into the implant through angiogenesis. The delivery of growth factors that participate in angiogenesis is an attractive way to promote vascularization. For example, Murphy *et al.* encapsulated VEGF into a synthetic poly(lactide-*co*-glycolide) scaffold and demonstrated the sustained release of VEGF, which is a critical angiogeneic factor.[298] However, the ability to simultaneously deliver multiple mitotic and differentiating factors in the proper dose, rate, and presentation is a major current challenge of the skin engineering community.[299]

An alternative approach is to fabricate a skin substitute that contains vasculature prior to implantation, which is called prevascularization. After implantation, host blood vessels would presumably connect with the preformed vasculature within the engineered construct, leading to accelerated engraftment. Clearly, this sequence of events would depend on correct clues emanating from the graft.

Another approach is to develop an artificial, but functionalized ECM that promotes angiogenesis and vasculogenesis *in vivo* or *in vitro*. Through the use of peptides/molecules that have a natural affinity for relevant growth factors, a biomimetic scaffold may be the ideal approach to guide sprouting of the host's endothelial cells.[300] However, peptide-containing scaffolds may be subject to enzymatic degradation and instability *in vivo*, which may result in a suboptimal presentation of the clues for vascularization.

Another major challenge is the source of endothelial cells that should be used to create the vascular network. The cells should be clinically easy to obtain, purify, and expand *in vitro*, and therefore autologous cells are ideal for avoiding host immune responses. To date, the use of several mature endothelial cells, including human umbilical vein endothelial cells and human dermal microvascular endothelial cells, have been used to generate vascular networks *in vivo*.[210,301,302] The utilization of hESC-ECs in regenerative medicine has also been reported.[303,304] However, as previously mentioned, the use of hESCs is currently a subject of ethical debate.[305] Alternatively, there are many significant evidences to support the angiogenic potential of EPCs.[306–308] Autologous EPCs are present in human peripheral blood, which makes them available as an attractive cell type in regenerative vascularization.[309] EPCs have been shown to form robust vascular networks in engineered tissue constructs in the presence of stromal cells, and can function *in vivo* for up to 28 days.[306–308] Recently, a three-dimensional engineered vessel network derived from cord blood EPC-derived endothelial cells (EPC-ECs) and fibroblasts was developed in a fibrin gel *in vitro*. Results demonstrated that both EPC-ECs and a high density of fibroblasts accelerated the rate of functional anastomosis significantly. Such an *in vitro* prevascularization model might have potential application in tissue engineering.[310]

In 1998, Black *et al.* demonstrated the *in vitro* formation of microvessels within an engineered skin substitute.[210] A skin bioconstruct scaffold made of chitosan/collagen was cocultured with dermal fibroblasts, keratinocytes, and human umbilical vein endothelial cells. Self-organization of the endothelial cells into a tubular network that included lumen with typical intercellular junctions, Weibel–Palade bodies, and a basement membrane of laminin and collagen IV was observed.[210] In a similar engineered skin construct, the presence of prevascularization improved the skin bioconstruct's perfusion time *in vivo* (4 vs. 4–14 days), which was comparable to that observed for full-thickness human skin grafts. The number of vessels did not significantly decrease after 14 days, indicating that the prevascularization vessel network was stable over time.[56] A third study was performed using human progenitor cell-derived endothelial cells from umbilical cord blood. The vascularized skin substitutes were prepared by seeding those endothelial cells on the surface of decellularized human dermis following keratinocytes spreading the epidermal surface. These skin bioconstructs were then transplanted onto mice model and analyzed 21 days later. The results demonstrated that endothelial cells differentiated from circulating progenitor cells can be utilized to vascularize human skin bioconstructs. However, no *in vivo* experiments were further performed to assess the functionality of the construct.[311]

5.534.9.4.3. Incorporation of bioactive molecules in the design of an intelligent skin substitute

Regeneration involves several cell types and a complex pattern of molecular cues and signaling networks, including numerous growth factors, cytokines, and chemokines in a spatiotemporal manner.[312,313] Growth factors are important molecules because they instruct cellular development and function, such as proliferation, migration, differentiation, and tissue formation, in an organized, time-dependent manner. Cell signaling results in a cascade of events that regulate and control cell function. Therefore, it has been hypothesized that the incorporation of bioactive molecules into tissue-engineered skin constructs may improve the regeneration of skin. However, the challenge is how to incorporate those molecules and in what concentration into a bioengineered material.

The growth factors involved in skin regeneration include bFGF, EGF, GM-CSF, IGF, PDGF, TGF-β, and VEGF. PDGF-BB has already been approved by the FDA (Regranex, Johnson & Johnson) and is currently used in the treatment of chronic ulcers. It has also been suggested that reduced levels of PDGF may play a role in the mechanism of scarless cutaneous repair. TGF-β family is known to contain the most potent growth factors involved in the wound healing process throughout the body.[239] In particular, TGF-β1 and TGF-β2 have been implicated in the formation of scars, whereas TGF-β3 may have antiscarring effects.[239] The FGF family has also been implicated in scarless healing.[314] Dang *et al.* hypothesized that differential expression of FGF isoforms and receptors occur during fetal skin development and that this differential expression pattern may regulate the transition from scarless regeneration to repair with scar formation.[256] The results demonstrate an overall downregulation of FGF expression during scarless healing. As with many bioactive molecules, there is a critical concentration of FGF that may promote scarless healing and sufficient angiogenesis.

Currently, multiple novel delivery systems including vectors and slow-releasing polymers are being investigated.[315] The primary role of the skin is to serve as a protective barrier. Thus, membrane-like devices have been a common design of skin substitutes capable of the incorporation and delivery of growth factors for improving healing and/or regeneration. Another approach to the design of a delivery system is the use of particles loaded with bioactive molecules. The particulate systems used to deliver growth factors are typically on the 'micro' scale and have shown very interesting properties for application in skin tissue engineering. For example, gelatin-based microspheres have been used to deliver TGF-β1[316] and bFGF.[317] The skin substitute may also combine two technologies; for example, Park *et al.* embedded bFGF-loaded gelatin microparticles into chitosan scaffolds and demonstrated accelerated wound closure of pressure ulcers.[318] Furthermore, particulate systems on the 'nano' scale are capable of more precise spatial distribution of bioactive signals when compared to microparticles[319] and may offer an optimal delivery system to modulate cell function. Recently, nanoparticles fabricated from dextran sulfate and chitosan for FGF-10 delivery provided promise as systemic (intravenous) and local therapies.[320] The particle system may also be used to deliver multiple drugs in different spatiotemporal patterns to a single site. For example, both VEGF and PDGF were loaded into a single matrix, but

their sequential release was achieved by differences in their affinities to the system's components, which spatially restricted each growth factor to a different layer of the delivery system.[299,321] The codelivery of growth factors using nanoparticles may be allowed for tunable release kinetics, elevated targeting specificity, and enhanced regeneration (Figure 15).

An alternative approach is to use living-cell systems that secrete appropriate growth factors at appropriate times. For example, both healthy keratinocytes and fibroblasts produce at least 17 different growth factors[322] that modulate signaling cascades to determine cell fate, function, and healing. Thus, living cells in bioengineered skin constructs may be suitable for sustained, simultaneous multiple growth factor delivery. To this end, much recent interest has focused on different cell type of skin and stem cell delivery (for details please see Section 5.534.9.4.1). Apligraf (Organogenesis, Canton, MA) is a bilayered bioengineered skin substitute that was the first living-cell, therapeutic, engineered skin the FDA approved to promote the healing of ulcers. However, it failed in 1998 secondary to scale-up problems but later (2000) received approval for treatment of diabetic foot ulcers.[323,324] More recently, systems that mimic embryonic development through establishment of a niche cell–matrix and/or cell–cell microenvironment have been used for growth factor/cytokine delivery.[325]

5.534.9.4.4. Smart scaffold/matrix: structural determinant biological activity

The ultimate goal of biomaterial design for skin tissue engineering is to provide the necessary signals to induce and conduct cell processes to restore both structure and function to the skin. Smart matrices possess biomimetic characteristics that induce regeneration *in vivo* through the (i) presence of ligands for cell adhesion; (ii) mechanism of controlled and localized matrix dissolution, ideally in temporal and spatial synchrony with cell invasion and regeneration; and (iii) delivery of morphogenetic signals that attract endogenous progenitor cells and induce their differentiation into a tissue-specific pathway.

Nature has optimized its microenvironment to maintain homeostasis and direct tissue development and differentiation in a spatiotemporal manner. It has been hypothesized that the optimal skin substitute should mimic the natural ECM, specifically its physical and biochemical properties. The microstructure of the ideal scaffold should have a specific chemical composition, ECM-mimicking topology,[326] high degree of porosity, interconnected pores, controlled pore size and geometry control, appropriate polymer degradation rate, and high surface area to volume ratio.[327] Yannas *et al.* have demonstrated that the induction of adult skin regeneration requires a scaffold that serves as a topological template for new stromal synthesis and provides bioactive signals, such as those that block wound contraction.[106–108,227,328,329] In addition, new-generation skin substitutes should mimic the regulatory functions of the natural ECM and its ability to bind and present growth factors to cells.

There are many new materials that have been developed and studied for skin tissue engineering, including hyaluronan coupled with FN functional domains,[96] silk fibroin and alginate,[330] poly(lactic-*co*-glycolic acid)/chitosan hybrid nanofibrous membrane,[331] peptide-derived polymers,[332] ICX-SKN skin graft replacement,[333] collagen–glycosaminoglycan–chitosan dermal matrix seeded with fibroblasts,[334] porcine collagen paste,[335] bovine collagen cross-linked with microbial transglutaminase,[336] biodegradable polyurethane scaffolds,[337] asymmetric chitosan membrane containing collagen I nanospheres,[338] marine gelatin/oxidized alginate hydrogel,[339] and many others (reviewed by Shevchenko *et al.*[103]).

5.534.10. Conclusions

There are two major approaches to achieve regeneration of the skin (Figure 16). The first is a cell-based therapy, which utilizes a matrix or carrier system for cells and/or bioactive molecules to induce morphogenesis *ex vivo*, and eventually, is implanted

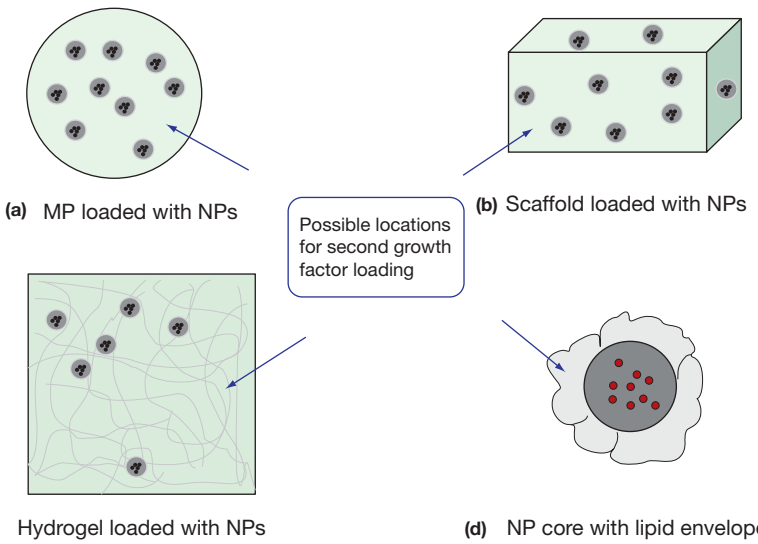

Figure 15 Different design of nanoparticles (NPs) with incorporation into (a) a microsphere, (b) a tissue engineering scaffold, (c) a hydrogel, and (d) NP core with lipid envelope for the sustained release of growth factors. Reproduced from Zhang, S.; Uludağ, H. *Pharm. Res.* **2009**, *26*(7), 1561–1580.

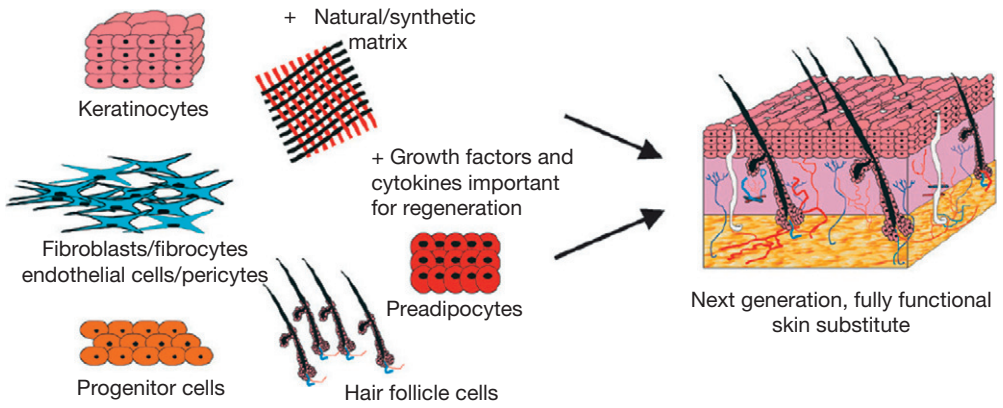

Figure 16 Next generation of skin tissue engineering. The different skin stem and progenitor cells are mixed with natural or synthetic matrix and bioactive molecules to induce regeneration of a fully functional skin. Modified from Metcalfe, A. D.; Ferguson, M. W. *Cell Mol. Life Sci.* **2008**, *65*(1), 24–32.

and ideally engrafted into to the wound site. The other approach is an acellular therapy that utilizes a biomaterial to induce and conduct host cell proliferation, migration, differentiation, and regeneration *in situ*. Regardless of the strategy employed, biomaterials play a central role in regenerative skin tissue engineering as an artificial biophysical and biochemical microenvironment that directs cellular behavior and function. The ideal biomaterials should provide a provisional three-dimensional infrastructure that mimics the natural ECM both physically and biochemically to ensure guidance in the proper spatiotemporal pattern. The rapid progress in tissue engineering in combination with stem cell therapy holds promise for the successful regeneration of acute and chronic skin defects.

Acknowledgment

Wound healing and skin tissue engineering research in the author's laboratory is funded by the RC2 stimulus award (AR059384) from NIAMS/NIH.

Glossary

Allograft Tissue that is transplanted from a donor of the same species, but different genotype.
Autograft Transplanted tissue in which the donor and recipient are the same individual.
Autologous Derived from the same donor or a donor of an identical genotype.
Hydrogel A colloidal gel which uses water as the dispersion medium.
Mesenchymal stem cells Multipotent stem cells derived from adult bone marrow; also known as marrow stromal cells.
Microtia Aplasia or hypoplasia of the external ear.
Neocartilage Neotissue that displays the properties of cartilage.
Neotissue Living tissue created through tissue engineering techniques, often involving the combination of cells, scaffold materials, and adjuvant therapies.
Porosity The ratio of the volume of a material's interstitial airspace to the volume of its mass.
Sol–gel transition The transition of a suspension of solid particles in a liquid (sol) to a solid material of jelly-like consistency (gel).
Xenograft Tissue that is transplanted from a donor of one species to a recipient of a different species.

Abbreviations

3D	Three-dimensional
DMEM	Dulbecco's modified Eagle medium
FGF	Fibroblast growth factor
GAG	Glycosaminoglycan
IGF	Insulin-like growth factor
NIPAAm	*N*-Isopropylacrylamide
PGA	Polyglycolic acid
PLA	Polylactic acid
RNA	Ribonucleic acid
TET	Tissue-engineered trachea
TGF	Transforming growth factor
TGP	Thermoreversible gelation polymer

5.535.1. Introduction

As modern medicine has advanced its understanding of how cells grow, survive, and replicate, we have found ourselves able to perform increasingly challenging reconstructive surgical procedures, with the major limitation being the source of replacement tissue. Traditionally, these sources have included living donors, cadavers, and synthetic materials. However, the utilization of these sources has its own limitations. Regarding living donors, the ethical questions behind the provision of compensation preclude many from voluntarily providing tissue. Furthermore, the potential medical complications of donation make it such that most cases are only justified by use in life-saving procedures. Transplanted tissue, whether from living or cadaveric sources, also carries with it the risks of both infection and rejection by the recipient immune system.

Functional and esthetic procedures have created a large market for synthetic replacement materials because of the scarcity of living tissue. Successful reconstructive procedures using synthetic implants include that of the auricle, the tip of the nose, and the orbital floor, among other areas.[1–3] However, the currently available materials often have their own problems, including the inability to sufficiently approximate the properties of living tissue, as well as complications of extrusion,

incomplete fusion with host tissues, and provocation of an inflammatory response.[4,5] Thus, the ultimate goal of perfecting a procedure by which adequately functional living tissue can be used for defect repair still remains.

For reconstructive operations, many of the sites that may require surgical restoration are structurally composed of cartilage. The goals of cartilage-based reconstruction depend on the desired function and location of the replacement tissue. For plastic surgery procedures, the most important feature of an implant is its ability to take on and preserve the shape of the area to be reconstructed. In contrast to the types of reconstructive procedures found in orthopedics, which usually involve weight-bearing areas of the body, cartilage reconstruction for plastic surgery generally does not have the obligation for the implanted tissue to maintain its structural integrity under a mechanical load. As such, there may not be the same mechanical requirements for tensile strength or shear. However, the implant must still have the resilience to hold against general wear and tear, as well as maintain the desired visual appearance.

Other qualities such as elasticity and flexibility are important features for forms that serve esthetic purposes, such as the nose and the ears. Yet, those that maintain a more structural support function, such as the orbital floor or the trachea, may require a more-rigid, less-elastic composition. At present, reconstructive surgical procedures utilizing autogenous cartilage include that of the auricle, trachea, nasal tip, and cleft palate, among others.[5–8]

5.535.2. Role of Tissue Engineering

The modern field of tissue engineering has added an alternative method of obtaining replacement materials for cartilage-based structures to the traditional cadaveric and synthetic sources. In order to be viable for widespread application, however, the engineering process must be able to start with a relatively small initial cell source and expand the number of functional cells for tissue generation. After viable cells are harvested, they must be maintained in a cell culture medium that not only promotes growth and replication but also prevents dedifferentiation from the chondrocyte phenotype. Once the appropriate cell count is achieved, the next step is the selection of a scaffold on which to deliver the cells to the recipient site. Many different types of vehicles have been tested, from fibrous meshes to hydrogels, each with its own set of advantages and disadvantages. Finally, after implantation, the chondrocytes must continue to survive and express the genes appropriate for cartilage formation, even in the setting of an intact recipient immune system. Only then can the final neotissue be tested for the characteristics of strength, shape, and other mechanical attributes necessary for use in surgical procedures in human subjects.

Most of the earliest tissue engineering attempts focused on cartilage or skin replacement.[9] In the 1970s, W. T. Green conducted a series of experiments aimed at the formation of new cartilage from chondrocytes that were implanted into nude mice using sterile bone as a carrier.[10] For the subsequent two decades, researchers contributed additional knowledge to the field, including that of *in vitro* culture conditions, cell attachment to various scaffold materials, and the limited capacity for cartilage self-repair.[11–13] However, it was not until the 1990s that any experiment was able to successfully produce a large quantity of cartilage tissue in any particular morphologic shape, and which was not required to be formed in association with endogenous bone or cartilage. In 1991, Vacanti *et al.*[14] described a novel method of cartilage generation using synthetic polymer scaffolds implanted subcutaneously into nude mice. Three years later, Kim and Vacanti[15] demonstrated the possibility of forming cartilage in predetermined shapes using molded fiber scaffolds.

Since that time, there have been many potential target areas for which researchers have attempted to engineer tissue. In particular, much attention has been paid to efforts in regenerating cartilage for the reconstruction of the auricle in patients with microtia, and the trachea for patients with laryngotracheal defects.

In 1997, Cao and Vacanti created neocartilage in a nude mouse model that retained the original form of a scaffold made of a combination of polyglycolic–polylactic acid (PGA–PLA) fibrous mesh that had been pressed into an auricle-shaped mold.[16] However, subsequent experiments have shown that, while the use of fibrous mesh scaffolds has produced good quality cartilage in immunocompromised animal models, when analyzed for histological properties and RNA expression, the same has not been true in immune-competent animals. For PGA, in particular, studies have shown a distinct inflammatory reaction to a local acid release by the degradation of the scaffold over time.[17] Subsequent experiments have shown hydrogel carriers to generally avoid this inflammatory response; however, the hydrogels that have currently been tested lack the ability to sufficiently maintain a complex shape in the formed neocartilage. Nevertheless, a recent study in human subjects performed by Yanaga *et al.*[18] was successful in utilizing a chondrocyte-generated gelatinous matrix for delivery in a two-step auricle reconstruction, during which a sufficient block of neocartilage was generated to allow the surgical carving that is currently done with a rib graft.

Other areas of reconstruction for which tissue engineering of cartilage has been studied include the nose, nipples, and temporomandibular disk.[19–21]

5.535.3. Cell Sources and Materials

5.535.3.1. Cells

The acquisition of cells for the creation of human body structures is one of the major challenges in reconstructive operations. The ultimate goal in this regard would be to create a large number of cell banks composed of universal cells that would be immunologically nonreactive with any recipient. At present, tissue can be harvested from autograft, allograft, or xenograft sources. However, autologous grafts are the most reliable with which to fabricate structures, as using a patient's own cells obviates the need for immunosuppressant drugs to block tissue rejection. Nowadays, stem cell biology involving embryonic stem cells holds great promise for the fields of tissue engineering and regenerative medicine. However, we are still far from complete understanding of the principles of stem cell and progenitor cell biology, and it remains a significant challenge

to apply these concepts to tissue engineering. We must also continue to be aware of the potential ethical implications of using these types of cell sources. Once the cell donor is chosen, the harvested tissues should be ones that can be dissociated easily from their surrounding structures in a minimally invasive manner. Subsequent cell growth and development, as well as the ability for population expansion, are also important factors.

There is no consensus yet as to what cell type is the best for regenerative medicine, as present practice focuses primarily on individual disease states and patient-related factors and conditions. For cartilage tissue engineering in particular, the current focus is on the use of the patient's own autologous cartilaginous tissue or mesenchymal stem cells as the donor source.

At present, the source of cartilage, which is most effective for tissue engineering applications and requires the least invasive procedure for harvesting the cellular sample, is still undefined. We have observed that the nasal septum is a promising site for obtaining an adequate sample of tissue for further tissue engineering applications. The advantage of using hyaline cartilage from the nasal septum is that it not only has properties similar to those of tracheal cartilage but is also a source of epithelial cells and connective tissue. Thus, the obvious benefit is that one is able to obtain the three cell types necessary for *in vitro* three-dimensional (3D) tissue construction from the same biopsy site. However, cartilage harvested from nasal tissue should not be considered the universal or unique source for all cases of tracheal injury in which tissue engineering could be beneficial. For instance, the availability of nasal cartilage may be limited in children or victims of smoke inhalation, and its use in these instances could be counterproductive. On the other hand, regarding reconstruction of the auricle, while hyaline cartilage can certainly be used as a viable cell source for tissue engineering, one should consider whether an auricular source containing a more flexible elastic cartilage, if available, would provide better mechanical results in the final neotissue.

Other cellular sources that have the potential for use in tissue engineering studies need further investigation. Cao's group at the Shanghai Jiao Tong University School of Medicine has done interesting work on the induction of adult dermal fibroblasts into fibrocartilage using cartilage-derived morphogenetic proteins. They have been able to demonstrate chondrogenic differentiation by immunostaining and RNA expression of *in vitro* constructs both in monolayer and 3D scaffolding using PGA. Recently, adult stem cells have also been shown to be a possible source that could be exploited by tissue engineers. Our laboratory believes that mesenchymal stem cells hold the greatest therapeutic potential for engineering bone and cartilage. An additional advantage of using mesenchymal stem cells is that the harvesting procedure is less invasive than, for example, removing a sample of nasal cartilage.

5.535.3.2. Materials

Once the donor cells have been harvested, the number expanded, and the chondrocytic phenotype maintained, the next step is to deliver them to the recipient host. There are currently so many potential scaffolds for use in tissue engineering that the challenge of choosing the correct material is enormous. Large categories include biodegradable polymers (e.g., PGA), hydrogels (e.g., Pluronic F-127), ceramics (e.g., hydroxyapatite), metals (e.g., titanium), synthetics, and even composite hybrids between types. In terms of the desirable properties of these materials, of course, it is preferable for the material not to cause an inflammatory reaction either in its natural state or in the form of breakdown products, and it should not have toxic effects on the donor or recipient cells. Furthermore, it should be a good substrate for cell attachment, so that cells are not lost from the desired implantation site. Previous studies have shown that cells injected directly into the host without a scaffold will disperse away from the injection site, such that the concentration is insufficient for subsequent tissue formation.[22]

The material should also have a porosity that allows cells and nutrients to intercalate evenly throughout the material. Without sufficient pore size, distribution, or interconnection, one risks creating merely a scaffold-shaped shell of tissue, because of cell death due to malnutrition or lack of cell dispersion to the center of the material. Pore size has also been shown to affect the differentiation of the attached cells, with studies on osteogenesis showing that smaller pore sizes lead to osteochondral formation and larger pore sizes result in direct osteogenesis.[23] Finally, the scaffold should ideally degrade at a rate that is matched with neocartilage development.

5.535.4. Characterization of Scaffolds *In Vitro* and *In Vivo*

5.535.4.1. *In Vitro* Model Using a Thermoreversible Polymer

There are several commercially available thermoreversible gels, each with different characteristics. We examined the potential of a novel thermoreversible gelation polymer (TGP) to act as a 3D hydrogel scaffold in the delivery of both chondrocytes and growth factors.[24] This TGP is composed of poly-NIPAAm aggregates and precipitates in aqueous solution upon heating above 32 °C as a result of hydrophobic interactions. This temperature, called the lower critical solution temperature, can be adjusted by randomly copolymerizing NIPAAm with other monomers. The lower critical solution temperature increases or decreases when NIPAAm is copolymerized with a more hydrophobic monomer or a hydrophilic monomer, respectively. The sol–gel transition temperature for the TGPs can be set at any temperature from 5 to 70 °C, below which the polymer will liquefy and above which the polymer solidifies. Briefly, lyophilized TGP was dissolved in Ham's F-12 medium at 4 °C overnight, yielding a 10% (by weight) viscous transparent hydrogel. The sol–gel transition temperature of the gel used in this experiment was 7 °C, and it was observed to gel immediately when heated above 7 °C.

Chondrocytes from a calf shoulder source were suspended in chilled aqueous solutions of TGP with 200 ng ml^{-1} of insulin-like growth factor-1 (IGF-1) and 50 ng ml^{-1} of transforming growth factor-β2 (TGF-β2). The cell–polymer mixtures were kept below 7 °C to maintain the liquid state of the copolymers and placed in a syringe for injection into a silicone ring for molding. The contents were immediately warmed above 7 °C in order to solidify the biopolymer, yielding a short cylindrical structure. The cell–polymer structure was

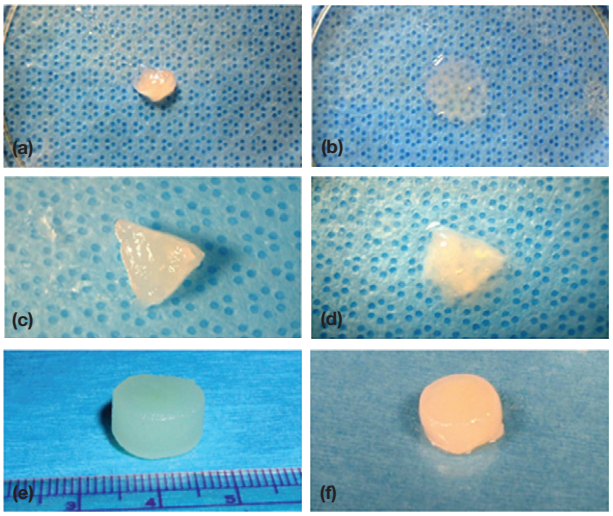

Figure 1 The sol–gel transition of the cell–polymer constructs after different *in vitro* culture periods (a, b – 2 weeks, c, d – 4 weeks, e, f – 8 weeks). The photos on the left are at room temperature (25 °C). Once the constructs were cooled below 7 °C, the cell–polymer constructs turned to liquid after 2 weeks of *in vitro* culture, but remained in a solid state after 8 weeks.

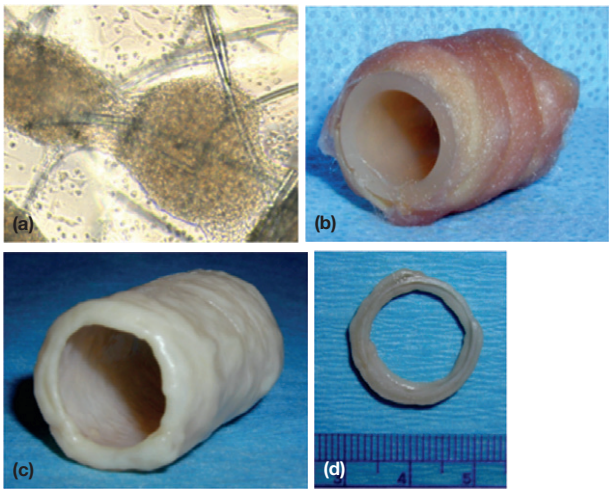

Figure 2 The cells attached to the PGA fibers during the *in vitro* culture period at 7 days (a). The cell-seeded PGA meshes were then wrapped around a silicone tube template (b). At 10 weeks after further *in vitro* culture, a solid, glistening white cartilaginous tube was formed (c, d).

subsequently cultured in Ham's F-12 medium supplemented with 10% fetal bovine serum (FBS) and 25 ng ml^{-1} L-ascorbic acid at 37 °C for up to 16 weeks. After 2 weeks in culture, the cell–polymer construct kept its 3D structure at room temperature; however, when cooled below 7 °C, the structure liquefied (Figure 1(a) and 1(b)). After a culture period of 4 weeks, much of the 3D shape was maintained, even upon cooling to 4 °C (Figure 1(c) and 1(d)). Longer *in vitro* culture periods, that is, 8 weeks, generated tissue-engineered neotissue, which did not change shape when cooled (Figure 1(e) and 1(f)).

This novel *in vitro* culture system for the generation of tissue-engineered cartilage has much potential for application in reconstructive plastic surgery, particularly in cases where defects may be filled via injection; thus, providing a relatively noninvasive technique.

5.535.4.2. *In Vitro* Model Using a Biodegradable Polymer

We evaluated the feasibility of using autologous bovine mesenchymal stem cells cultured on a PGA mesh to engineer a tube-shaped cartilage equivalent of a functional trachea. TGF-β2 has been shown to play a major role in cartilage development, and our data has demonstrated that TGF-β2 helps support chondrogenesis during the development of 3D tissue constructs. Bone marrow was obtained by iliac crest aspiration from a calf shoulder. The aspirates were cultured in Dulbecco's modified Eagle medium (DMEM) containing 10% FBS.

After 2 weeks, confluent cell suspensions were concentrated at 50×10^6 cells ml^{-1} and seeded on 100 × 10 × 2 mm nonwoven meshes of PGA fibers. The serum-containing medium was then replaced with DMEM containing ITS+Premix, L-ascorbic acid 2-phosphate, 100 nM dexamethasone, 10 ng ml^{-1} TGF-β2, and 25 ng ml^{-1} IGF-1. The cell-seeded mesh samples were cultured continuously for 1 week *in vitro* (Figure 2(a)). The structures were then wrapped around silicone templates, 20 mm in diameter × 50 mm in length (Figure 2(b)). The composite structures were cultured again in the same conditions and media for up to 10 weeks. The gross appearance of the tissue-engineered trachea (TET) was solid and glistening white, in the shape of a cartilaginous tube (Figure 2(c) and 2(d)).

The tissue surface was smooth and cartilage formation was evident. Type II collagen staining was strongly positive in the engineered cartilage.

5.535.4.3. Autologous *In Vivo* Model Using a Thermoreversible Polymer

As previously stated, one of the most complicated and challenging tasks in reconstructive surgery is to make tissue in a particular desired shape. We have had much experience with the use of Pluronic F-127, which has *in vitro* properties similar to the previously mentioned TGP. Pluronic F-127 is a solid that is soluble in water and becomes a gelatinous solid (hydrogel) at room temperature (25 °C) or above. One disadvantage of the Pluronic F-127 hydrogel, however, is its inability to maintain a stable, predetermined shape *in vitro*. Saim *et al.*[25] demonstrated the generation of mature autologous tissue-engineered elastic cartilage in the approximate size and shape of an adult human auricular helix *in vivo*. External ear cartilage was harvested from male Yorkshire swine. After the perichondrium was meticulously excised, the cartilage was minced into small fragments and digested. Under general anesthesia, folds were made in the skin of the ventral surface of the swine resembling the shape of a human auricular helix. The skin was then stitched using 2-0 Vicryl suture to create a hollow, curved channel. The autologous chondrocytes were suspended in Pluronic F-127 and injected into the skin fold channel. Ten weeks after implantation, the harvested construct demonstrated a helical shape with firm, yet flexible consistency, compatible with elastic cartilage. This injectable technique may be

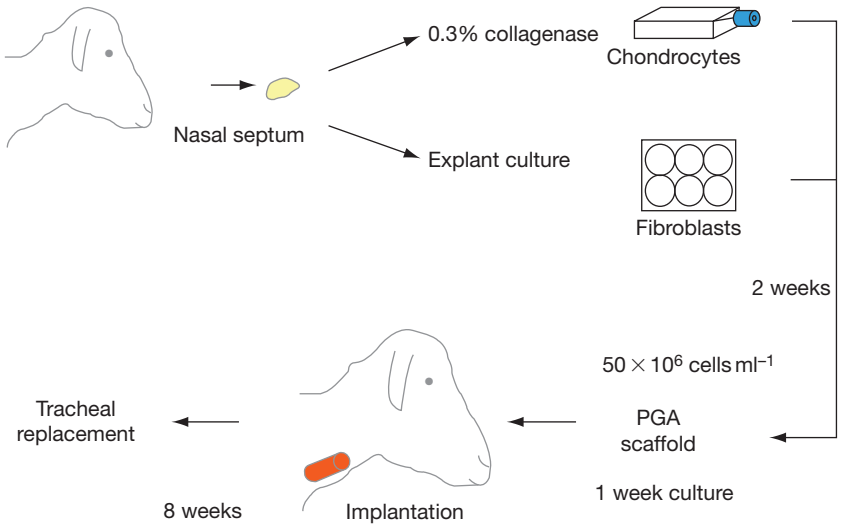

Figure 3 Diagram showing the steps of tissue harvest, cell isolation, *in vitro* culture, scaffold seeding, *in vivo* implantation, and tracheal replacement.

useful to form the shapes necessary to repair cosmetic problems such as microtia or other facial deformities.

From our unpublished data, fibroblast growth factor (FGF) can also be added to hydrogel carriers in which chondrocytes are suspended. We believe it takes fewer than 10 weeks to produce a firm, reliable cartilage using this technique.

5.535.4.4. Autologous *In Vivo* Model Using a Biodegradable Polymer

Extensive tracheal reconstruction is often required in patients with both benign and malignant diseases. Tracheal reconstruction can be safely carried out by direct anastomosis after resection of up to one-half of the trachea in adults and one-third of the trachea in children. For more extensive tracheal resection, however, there is no general agreement on the ideal reconstructive material. The use of prosthetic materials often causes complications because of their propensity for infection and extrusion, and the use of autologous tissue, thus far, has been limited by poor structural characteristics and technical complexity. As a result, laser treatment or stent placement is currently the only available temporizing therapy for patients with severe tracheal stenosis. We have been involved in the generation of an autologous TET for potential use in reconstructive surgery.[26] One of the main limitations in this approach is the need for the engineered tissue to meet the specific mechanical requirements of the native trachea. The trachea must maintain flexibility in the longitudinal direction to allow for free movement of the head, while maintaining the rigidity necessary to prevent luminal collapse during breathing.

We obtained two separate 5×5 mm samples of nasal septum from 2-month-old sheep to generate two identical templates per animal (Figure 3). Chondrocytes were harvested from the cartilage, and fibroblasts were harvested from the connective tissue in each sample. After 2 weeks of *in vitro* culture, the chondrocytes (50×10^6 cells ml^{-1}) and fibroblasts (25×10^6 cells ml^{-1}) were seeded separately onto PGA mesh and cultured for another week. A spiral helical template,

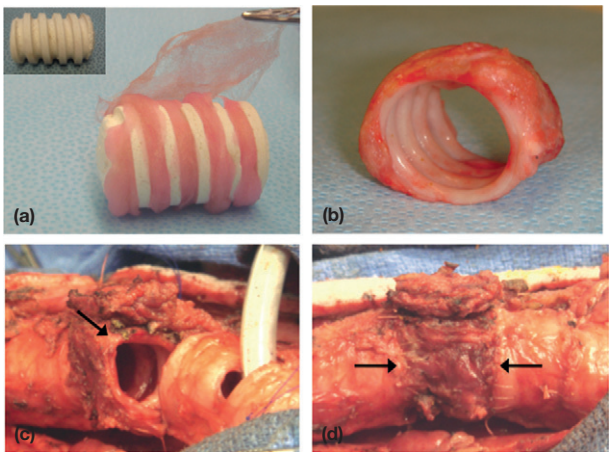

Figure 4 A spiral helical template created using a silicone mold and the chondrocyte-seeded PGA mesh wrapped around the inner groove of the template. Fibroblast-seeded mesh was subsequently wrapped around the entire structure (a). The entire structure was implanted into the neck of the autologous sheep donor, harvested after 8 weeks, and the helical template removed. The appearance of the tissue-engineered trachea (TET) was smooth and glistening white (b). A section of native trachea was resected and the TET placed into the resection site. The arrow indicates the distal end of the TET before anastamosis (c). The TET was then connected to the native trachea by end-to-end anastamoses. The arrows indicate the promixal and distal ends of the TET (d).

20 mm in diameter $\times$ 50 mm in length, was made with a Silastic ERTV mold-making kit and the chondrocyte-seeded mesh was placed into the grooves. This structure was then wrapped with the corresponding fibroblast-seeded mesh (Figure 4(a)). Each template was then implanted into its corresponding donor sheep through a longitudinal incision made in the neck, just above the sternocleidomastoid muscle. During the procedure, a pocket was created under the muscle, and the cell-seeded scaffold template was inserted into this space. After 8 weeks, the TET

was harvested from the neck (Figure 4(b)), the template removed, and a 10-cm-long resection was performed on the sheep's cervical trachea. The TET was connected to the native trachea by end-to-end anastomoses using a 3-0 absorbable running suture (Figure 4(c) and 4(d)). Postoperatively, the sheep breathed spontaneously with no subcutaneous emphysema and were voluntarily ambulatory. However, the sheep were required to be sacrificed by day 15 because of extensive tracheomalacia. The gross appearance of the TETs showed a distinct structure containing both cartilage and connective tissue, similar to native trachea. On histological examination, the engineered tracheal surfaces were smooth and cartilage formation was evident. Hematoxylin and eosin staining revealed the presence of mature cartilage surrounded by connective tissue, as observed in native trachea. These data indicate that the failure of the sheep TET is likely due to lower levels of collagen type II and glycosaminoglycan (GAG) in the tissue-engineered cartilage, resulting in deficient structural strength.

5.535.5. Conclusions

Given the immense need for replacement tissue in modern-day reconstructive and cosmetic plastic surgery, the field of tissue engineering holds great promise as a future source to fulfill this requirement. There are, however, numerous considerations that must be taken into account regarding our current state of knowledge in cartilage tissue replacement when bringing this approach to patient care.

The donor source for future chondrocytes must be considered carefully and tailored to the appropriate situation. Presently, there is a variety of choices between adult chondrocytes, adult mesenchymal cells, and embryonic stem cells. But, for example, a cancer patient with bone metastases may not have uncontaminated marrow available for autologous donation, thus reducing the available options. One must also consider which donor site in the body will provide the easiest, safest, and least invasive source to reduce donor morbidity. In a neonatal patient, the use of umbilical stem cells may be a viable option, but until cord blood banking becomes a more prevalent practice, most adults will need to endure more invasive procedures for cell extraction. Finally, the harvest source will need to provide enough cells for the initial *in vitro* expansion to generate a useful final amount of neocartilage. As we learn more about the final properties of the neotissue created from these various sources, we will need to begin devising standards for the harvesting procedure to bring this process safely and successfully to the clinical realm.

Once the cells are obtained, they must be delivered to the recipient. The material chosen for the cell scaffold preferably should not cause an adverse inflammatory reaction and should not have toxic effects. It should be a good substrate for cell attachment, have a porosity that allows cells and nutrients to intercalate evenly throughout, and degrade at a rate that is matched with neocartilage development. Although much work has been done to characterize different scaffolding materials, we still do not know which material is ideal for the production of tissue-engineered cartilage. Many of the fibrous meshes, such as PGA, are easily premolded into the desired shape and allow for even distribution of cells and nutrients, but, unfortunately, also cause an inflammatory reaction in the recipient. The hydrogels have been shown to be more biocompatible, but lack the advantage of preformed shaping, which translates clinically into the need for additional operations before attaining the desired structure.

One area that is yet to be well characterized is the choice of implantation site in the recipient. Implantation of the cells directly into the reconstruction site would reduce the number of necessary future procedures, but we have little information at present comparing the effects of different recipient sites on neocartilage formation. Some studies have been performed to examine the effect of vascularity of implantation sites on ectopic bone formation, but with conflicting conclusions as to any difference in final tissue formation.[27,28] It is also difficult to say whether the results seen with vascularized neotissues are applicable to avascular neocartilage formation. Unpublished data from our laboratory suggests that implantation subcutaneously at the back of an immunocompetent rat model provides a better environment for cartilage growth compared to the temporal-auricular region. Thus, despite the properties of cartilage as an avascular tissue, increased vascularity of the implantation site may well be important in neotissue formation. Yanaga *et al.*[18] also make an important point that, in human subjects, the thinness of the cutaneous layer and the reduced vascularity of the temporal region may lead to disastrous scaffold exposure.

Above all, perhaps the most important consideration in the application of cartilage tissue engineering techniques to plastic surgery is that, with the notable exception of tracheal reconstruction, most of the procedures utilizing cartilage perform mostly a cosmetic function. Therefore, in the transition from bench to clinic, one must be absolutely sure that the techniques and methods employed are near perfect and can be safely applied to human subjects. Nevertheless, tissue engineering is certainly an exciting and rapidly expanding field that holds great promise for the generation of new tissues for reconstructive repair.

Glossary

Allogeneic/allograft/allotransplantation Allogenic (also known as allogeneic) cells are obtained from the body of a nonself donor of the same species. Allotransplantation (or allograft) refers to a graft of tissue from a nonself donor; such grafts are invariably rejected unless the recipient is immunosuppressed.

Alloplastic An alloplast or alloplastic device (also known as an implant or prosthesis) is an inert inorganic (artificial, synthetic) material used for transplantation into living tissues.

Angiogenesis Angiogenesis is a process involving the growth of new blood vessels. It is a normal, physiological process in growth and development, as well as in wound healing. Vascularization is an essential factor for successful implants of bioengineered tissues, and a tissue of more than a few millimeters in volume cannot survive by diffusion and requires formation of new blood capillaries to supply essential oxygen and nutrients.

Autologous/autograft/autogenous Autologous cells are obtained from the same individual to which they will be reimplanted. Autologous transplantation (or autograft), also known as autogenous tissue transfer, refers to a transfer of tissue from one site to another in the same individual.

Bioreactor A bioreactor may refer to any device or system that supports a biologically active environment in order to grow cells or tissues in the context of cell culture.

Homograft A graft of tissue from a donor of the same species as the recipient.

Major histocompatibility complex The major histocompatibility complex (MHC) is a cluster of genes on human chromosome 6 or mouse chromosome 17. It encodes a set of membrane glycoproteins that play a role in antigen processing and host defense. HLA, the acronym for human leukocyte antigen, is the genetic designation for the human MHC.

Mesenchymal stem cell (MSC) A stem cell that is an isolated homogeneous population that can differentiate into cells of more than one connective tissue type (i.e., multipotent).

Primary cells Primary cells are from an organism, as opposed to secondary cells from a cell bank.

Satellite cell Elongated, spindle-shaped, quiescent myogenic cells located adjacent to the plasma membrane of myofibers beneath the basal lamina. Compelling evidence indicates that they are committed myogenic progenitors that mediate both postnatal growth and regeneration after injury of muscles. Once activated, satellite cells divide to produce

muscle precursor cells (MPCs) that proliferate before committing to differentiation and fusing into myotubes, which finally mature into myofibers.
Scaffold/matrix Tissue scaffolds (or matrices) are cell growth support structures composed of biocompatible materials that enable cell attachment (or seeding) and migration in tissue engineering.
Stem cells Cells that continuously renew themselves, while maintaining the ability to differentiate into various cell types. Adult stem cells are defined by two major functions: self-renewal and multilineage differentiation.
Syngeneic Syngeneic (also known as syngenic) or isogeneic (also known as isogenic) cells are isolated from genetically identical organisms such as twins, clones, or highly inbred research animal models.
Tissue engineering Tissue engineering is an interdisciplinary field that applies the principles andmethods of engineering and the life sciences toward the development of biological substitutes that can restore, maintain, or improve tissue function.
Xenogenic Xenogenic (also known as xenogeneic) cells are those isolated from individuals of another species (i.e., animal cells).

Abbreviations

AFS	Amniotic fluid stem cells
BDNF	Brain-derived neurotrophic factor
bFGF	Basic fibroblast growth factor
CT	Computed tomography
DMD	Duchenne muscular dystrophy
DNA	Deoxyribonucleic acid
ECM	Extracellular matrix
EDTA	Ethylenediaminetetraacetic acid
ES	Embryonic stem cells
GFP	Green fluorescent protein
HLA	Human leukocyte antigen
iPS	Induced pluripotent stem cells
MDSC	Muscle-derived stem cells
MEMS	Microelectromechanical systems
MHC	Major histocompatibility complex
MPC	Muscle precursor cell
MSC	Mesenchymal stem cells
NGF	Nerve growth factor
NT-3	Neurotrophin-3
NT-4	Neurotrophin-4
PCL	Polycaprolactone
PDGF	Platelet-derived growth factor
PGA	Polyglycolic acid
PLA	Polylactic acid
PLG	Poly(lactide-*co*-glycolide)
PLGA	Poly(lactic-*co*-glycolic acid)
VEGF	Vascular endothelial growth factor

5.536.1. Introduction

> All things are possible until they are proved impossible – and even the impossible may only be so, as of now.
> Pearl Buck, A Bridge for Passing (1962)

Airway reconstruction is necessary in patients with extensive tracheal stenosis caused by neoplasia, trauma, or congenital disease. Today, most tracheal lesions can be resected and primary reconstruction safely carried out by end-to-end anastomosis. Unfortunately, there are cases in which primary anastomosis is not possible, such as after extensive burns, trauma, tumor resection, or postintubation injuries. Additionally, the treatment of congenital tracheal atresia or stenosis can be hindered by the lack of sufficient tissue for surgical reconstruction, as the length of trachea involved may be extensive. Tracheal substitution is needed in the case of very severe stenosis that cannot be safely corrected by slide tracheoplasty, and of extended tumors in which invasion of the larynx or mediastinum does not prevent complete resection with reconstruction of the larynx. The general limits of safe resection are about half the tracheal length in adults (around 6 cm) and probably one-third in small children.[1,2] Tracheal resection longer than these limits requires replacement.

According to Belsey,[3] a tracheal substitute must fulfill the following requirements:

(i) be a laterally rigid, but longitudinally flexible tube and
(ii) possess a surface lining comprising ciliated respiratory epithelium.

Furthermore, the conduit must be initially airtight and become integrated into adjacent tissues, so that chronic inflammation, growth of the granulation tissue, infection, and erosion do not occur. In addition, materials for tracheal replacement must be biocompatible, nontoxic, nonimmunogenic, and noncarcinogenic; must not dislocate or erode over time; ideally should provide or facilitate epithelial resurfacing; should avoid stenosis or late buckling; should resist bacterial colonization; should avoid accumulation of secretions; and must be permanent constructions.

Immunosuppressive therapy is undesirable for many reasons, especially because the principal reason for tracheal replacement in many cases is extensive carcinoma (squamous cell and adenoid cystic). Finally, for a method to be practically considered, the technique of construction or insertion of the conduit must be surgically straightforward and the results predictably successful.

Given the above requirements, tracheal homograft represents the ideal substitute. However, the growth potential of the tracheal homograft is not known and long-term stenosis can often occur.[4]

5.536.2. Historical Background

5.536.2.1. Alloplastic Tracheal Transplantation: Solid Prostheses

Many types of material have been examined for use in tracheal prostheses since the first report by Daniel.[5] The apparent simplicity of tracheal replacement encouraged trials of alloplastic transplantation with tubular conduits, initially made of solid materials, such as polytetrafluoroethylene, polypropylene mesh, Dacron polyurethane mesh, and silicone rubber.[6]

However, these foreign materials could not become incorporated by local tissues, and there were problems of infection, dislodgement, migration, extrusion, and stenosis. Re-epithelialization, was, of course, impossible on the inner lumen and led to the formation of granulation tissue or dehiscence at the interface between the prosthesis and the native trachea, usually within several months. Furthermore, solid tubes can never be removed, because the connective tissue tract formed around them proceeds to obstruct with new connective tissue formation and by contraction in the absence of a stent. For the above reasons, the nonporous tracheal prosthesis is now seldom used clinically.

Despite all of these complications, a rigid prosthesis can maintain an open airway for some time, despite a lack of healing. Such a result is, however, episodic and unpredictable. This situation starkly contrasts with the use of vascular conduits, which have been safely applied in clinical settings for decades. One of the reasons that prosthetic tracheal reconstruction is more difficult than use of a vascular prosthesis may be that the trachea is in contact with the external environment (i.e., the airway represents an interface between internal and external environments), unlike an artificial vascular graft, which is placed in a sterile mesenchymal environment and has no external interface after implantation.

5.536.2.2. Alloplastic Tracheal Transplantation: Porous Prostheses

Attention then turned to porous materials – often meshes of various substances – which theoretically might encourage tissue ingrowth and possibly even epithelialization in time. It was found that a minimal porosity of 40–60 μm is necessary for capillary ingrowth.[7] It was hoped that this bed of autogenous new connective tissue would serve as a base for migration of adjacent tracheal epithelium. Regeneration of epithelium was described, with evolution from squamous to cuboidal to pseudostratified ciliated cells (respiratory epithelium). However, delayed epithelial regeneration remains a particular problem.[8,9]

Connective tissue ingrowth served to fix and incorporate some porous prostheses as noted. However, the continued proliferation of scar tissue most often led to obstruction and stenosis. Epithelium generally failed to migrate sufficiently to cover the entire neotracheal surface, allowing continued cicatrix formation and bacterial colonization, usually in the center of the replacement. Although very short interpositions might achieve full epithelialization, which seemed to prevent further cicatrization, the rate and completeness of epithelial migration was usually insufficient to prevent central granulations, cicatrization, and stenosis. Obviously, very short tracheal replacements offered no solutions to the problem addressed.

5.536.2.3. Tracheal Reconstruction with Autogenous Tissues

Autologous tissue reconstruction is always preferable to alloplastic materials. Previous attempts included free tissue autografts with and without foreign material support, vascularized autogenous tissue flaps, and autogenous tube construction.

Various autogenous tissue grafts as patches, or in tubular form, have been tried for tracheal reconstruction where primary end-to-end anastomosis cannot be performed, including fascia lata,[10,11] tracheal wall,[5] pericardium,[12–14] periosteum with omental wrap,[15,16] buccal mucosa and auricular cartilage,[17] omentum,[18] esophagus,[19–22] jejunal patches with microvascular reconstruction,[23] rib and ear perichondrium,[24] nasal cartilage with attached mucosa,[25] bronchial patches,[26] epidermis,[27] aortic grafts,[28–30] carotid artery patches,[31] auricular cartilage,[32] and costal cartilage.[33] The results indicate that small defects can be successfully treated with graft repairs. However, stenosis is a recurring problem.

Various attempts have been made to use autogenous grafts in conjunction with artificial materials, in order to maintain a rigid wall and prevent collapse of the lumen while various autogenous tissue grafts grow across the partial defects. Associated complications with foreign material were mostly related to lack of biocompatibility and included local infection, anastomotic dehiscence, vascular erosion, granulomatous lesions, and stenosis.

Although tissue grafts can successfully regenerate partial tracheal defects, circumferential or large defects require blood supply and mucosal lining for satisfactory reconstruction. The advantages of flap tissue over graft materials are the independence of its blood supply and its reliability in terms of wound healing. Flap surgery can be done to irradiated or heavily scarred areas, where grafting techniques have less chance of being successful.

Tissues from nearly every part of the body have been utilized in an attempt to find the best tissue for tracheal replacement. Local, regional, and distant free flaps, usually including a skeletal muscle component, have been reported for experimental tracheal reconstruction. Yu *et al.*[34] used a radial forearm free flap with polymex mesh and hemishield vascular graft, creating a nonstented airway with normal swallowing and voice. More recently, Maciejewski *et al.*[35] have reported success with the use of radial forearm flap combined with a biodegradative mesh suspension. Although vascularized autogenous tissue flaps have overall produced some successful results with patent, nonstenotic airways, they generally support only short segments of tracheal reconstruction. In addition, the limiting factor in nearly every procedure remains the complexity and multistage requirement, limiting the practicality of the procedure.

Clinically, autogenous tube construction has been successfully completed by several groups.[36,37] However, all procedures were multistage difficult procedures used as a last resort. Most attempts at autogenous tube construction have resulted in difficult or negative outcomes.

5.536.2.4. Nonviable Cadaveric Human Tracheal Allograft Transplantation

Cadaveric trachea and other tissues, fixed chemically, irradiated, frozen, or lyophilized, have been used both

experimentally and clinically as tracheal replacements.[38–41] They were initially developed as a more long-term tracheal preservation strategy to help overcome the anticipated shortfall in donor organs. Such implantations are often erroneously referred to as 'transplantation' or 'tracheal allografts' but both these terms are misnomers due to the graft's nonviable, denatured status. 'Bioprosthesis' or 'implant' may be a better term, because a fixed tissue is more akin to a silicone rubber tube than it is to transplanted tissue in the usual sense.

As these implants do not present viable cells and all major histocompatibility complex (MHC) markers, immunosuppression is not necessary.[42] Nevertheless, preserved or lyophilized tissues are usually replaced in time by host scar tissue,[43] the rate possibly dependent on the locus of implantation. Tracheal allografts therefore need long-term tracheal stenting where longer segments of trachea with a greater circumference have to be replaced. Despite the complete luminal epithelialization of the implanted grafts, there is no live cartilage in the donor trachea. It has been hypothesized that the lack of cell ingrowth could be responsible for the observed stenosis and tracheomalacia.[44] In addition, Liu *et al.*[45] showed that maintaining cartilage viability in a tracheal graft is necessary to maintain a patent airway.

Despite some limited successes, the exact mechanism of reduction of graft antigenicity after cryopreservation is still unclear, and the question of how long a tracheal graft can be preserved is unanswered. In addition, there are concerns regarding devitalization of cartilage and there is no standardized technique widely applicable. In short, dead tissue cannot be expected to function as a template for regeneration of the complex structure of the trachea in accord with any basic biological processes yet identified. An exception to the generally disappointing results obtained with nonviable cadaveric human tracheal allografts has occurred in the pediatric population, where pediatric tracheal homograft reconstruction has led to encouraging short- to medium-term results for children with long-segment congenital tracheal stenosis.[46,47]

5.536.2.5. Viable Tracheal and Laryngeal Allograft Transplantation

Tracheal transplantation has been studied for several decades. The reasons for the lack of success are mainly due to graft ischemia and rejection. Fresh tracheal allografts without aid of immunosuppressive therapy initiate rejection.[48] Fresh tracheal allografts were early demonstrated to necrose and liquefy,[49] or, if short, to result in fibrous stenosis.[50] In addition to the problem of immunological rejection, tissue loss also arises from devascularization, reperfusion injury, and/or surgical trauma.

Beigel *et al.*[51] found from experimentation in inbred rats that tracheal transplants carry antigens and have an immunogenic action from the donor, and that mucosa is rejected and replaced by recipient's cells. Hence, they concluded that tracheal transplants follow the same rules as other tissues, contrary to the earlier belief that the trachea had weak antigenicity.[52] Bujia *et al.*[53] also agreed that the mucosa from human trachea was most likely to be the major antigenic structure responsible for the immunogenic action of tracheal allografts.

Cryopreserved tracheal allografts seem to inhibit allogenicity while structural integrity appears to be maintained. Mukaida *et al.*[54] observed gradual replacement of graft epithelium by recipient epithelial cells after 50–60 days. Tojo *et al.*[55] in orthotopic cryopreserved tracheal allografts in rats without immune suppression also identified the late (2 months) graft epithelium to be of recipient origin while the chondrocytes were of donor origin. They concluded that the recipient origin of epithelium over the donor trachea accounted for the reduced antigenicity of the cryotransplanted trachea. These findings were confirmed by Genden *et al.*[56] MHC antigens (MHC II, MHC I) are expressed in epithelium and mixed glands of the trachea and not in cartilage.[53]

Based on the likelihood that the mucosa and mixed glands, but not the cartilage, are the major antigenic structure of the trachea, Liu *et al.*[57] removed tracheal graft epithelium and mixed glands with a detergent in dogs, in an attempt to eliminate the antigenicity of tracheal allografts completely while maintaining their viability. Omental revascularization was provided. Cartilage remained viable. Allografts (without immunosuppressive therapy) were incorporated without stenosis, compared with granulation tissue formation and stenosis in untreated controls. This concept later led to the idea of creating nonimmunogenic, decellularized matrices in tissue-engineering experiments.[58]

It would appear that viability of cartilage is also important in the preparation of low-antigenic tracheal allografts by detergent treatment in dogs. Liu *et al.*[45] showed that maintaining cartilage viability in a tracheal graft is necessary for successful immunosuppressant-free allotransplantation and consequently to maintain a patent airway. Damage to chondrocytes caused by the detergent regime resulted in serious stenosis. Early collapse of the graft was thought to be due mainly to lack of cartilage viability, rather than acute rejection, because most of the antigenic structure had been removed, and no lymphocyte or monocyte infiltration into the grafts was observed. When the viability of the cartilage was maintained, grafts were incorporated by the host trachea, without stenosis or granulation. Indeed, one dog survived for more than 26 months and no tracheomalacia was confirmed by bronchoscopic examination.

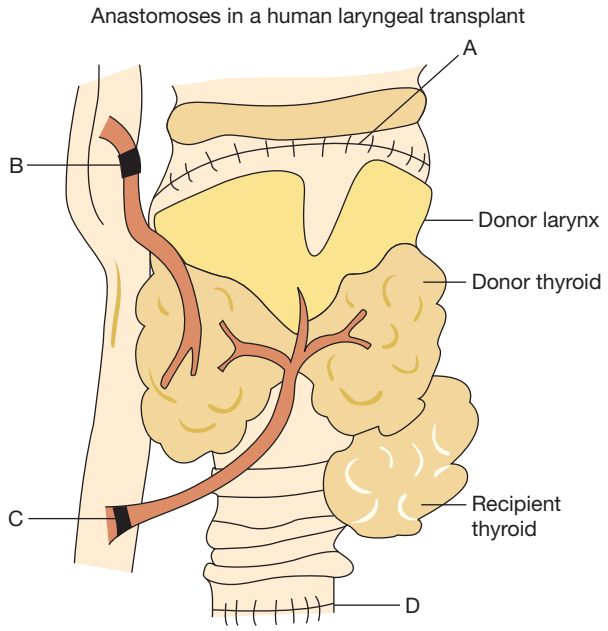
Clinical tracheal allotransplantation has been tried in humans, with success reported in one patient after 9 weeks.[52] The report was made 9 weeks after the actual allotransplantation, but unfortunately there were no follow-up reports. The donor trachea was first implanted heterotopically in the sternocleidomastoid muscle and pedicled orthotopically in 3 weeks. No immunosuppressive therapy was used. In another human, long-segment allograft with omental revascularization and immunosuppressive therapy, necrosis, and stenosis occurred, requiring a stent that could not be removed.[59] More recently, the Leuven Tracheal Transplant Group have reported successful tracheal allotransplantation after withdrawal of immunosuppressive therapy.[60] Indirect revascularization of the graft was achieved by first placing the graft in a heterotopic position (the recipient's forearm fascia). However, the membranous posterior wall of the allograft underwent avascular necrosis. Its 'success' must be questioned.

Kluyskens and Ringoir attempted the first human laryngeal transplantation (subtotal or partial laryngeal transplant) in

1969 in a patient who underwent incomplete laryngectomy for cancer.[61] The graft was unmatched and episodes of rejection were treated with azathioprine, prednisolone, actinomycin C, and antilymphocyte serum. Rapidly fatal recurrence of cancer secondary to the immunosuppression overshadowed graft survival, and further transplantation attempts in humans were abandoned for decades. In retrospect, the long-term viability of Kluyskens and Ringoir's graft would have been unlikely, as no vascular or neural anastomoses were performed.

Strome *et al.*[62] described fresh laryngeal nonvital organ transplantation with complete HLA matching, which included a five-ring segment of trachea, thyroid, and parathyroids, and a portion of attached pharyngeal wall, plus both superior laryngeal nerves and right recurrent nerve, to replace a totally scarred larynx secondary to previous trauma in a 40-year-old male. The donor was a 40-year-old male who had died from a ruptured cerebral aneurysm. Arterial, venous, and neural anastomoses were done, and perfusion was established early in the procedure. Over time, the patient regained vocal cord function and normal deglutition. Despite one episode of rejection, health and function were good at 40 months, with continued immunosuppressive therapy. To date, the patient continues to speak with a good voice and swallow without difficulty[63] (**Figure 1**).

This experience has been expanded substantially by Tintinago *et al.*, in Columbia, who have reported a series of 20 clinical laryngeal and tracheal transplants.[64] The Columbian group reports high-quality functional outcomes and peer-reviewed published reports of this series are awaited with great interest. However, it was reported at recent meetings in Washington and Rome that although the tracheal recipients are doing well, two of three laryngeal recipients, both with a primary laryngeal cancer operation, subsequently died.



A = hypopharynx and tongue base, B = superior thyroid artery end-to-end, C = inferior thyroid vein end-to-side to internal jugular vein, D = trachea. In addition, the recurrent laryngeal nerves may be repaired directly or by use of ansa cervicalis.

Figure 1 Anastomoses in human laryngeal allotransplantation. Reproduced from Birchall, M. *Lancet* **1998**, *351*(9102), 539–540, with permission from Elsevier.

Although these cases have shown that human laryngeal transplantation is now technically possible, several issues need to be resolved before the operation can be introduced into routine clinical practice. For a start, success in making severed laryngeal nerves work again has proved elusive. In addition, loss of a larynx because of trauma is rare. Most people who would merit a laryngeal transplant would have a present or past history of laryngeal carcinoma, and such patients would have to be subjected to a lifelong immunosuppressive therapy to prevent rejection, with the increased risk of rapid tumor recurrence. This is not only what happened to the 1969 patient, but also to the world's first tongue transplant recipient, who also had advanced squamous cell cancer, in 2004.[61,65]

5.536.3. Tissue-Engineered Trachea: Basic Sciences to Clinical Application and Transplantation

Given that no predictable and dependable replacement had yet been found, attention turned to tissue engineering. Tissue engineering implies formation of tissue by cultivated cells introduced into a framework of biodegradable synthetic polymer, which guides the shape and size of a macrostructure, such as a tube. Although it is widely assumed to be a relatively new field, the first report of tissue engineering was published in 1933, when tumor cells were implanted into a pig, wrapped in a polymer membrane to protect them from immune attack.[66] However, the modern era of tissue engineering could be said to have begun at the start of the 1980s with the development and clinical use of skin replacements. The field continues to expand and tissue bioengineering has already provided functional human organ replacements elsewhere[67,68] (**Figure 2**).

Tissue engineering applies the principles of engineering, material science, and biology toward the development of biological substitutes that restore, maintain, or improve tissue function. The three major approaches to tissue engineering include guided tissue regeneration using engineered matrices alone, the injection of isolated cells alone, or the use of cells seeded on or within matrices (cell matrix construct). The latter two methods are the most common. Using isolated cells or cell substitutes avoids potential surgical complications and allows cell manipulation prior to injection/infusion (such as gene therapy), but has the drawbacks of possible rejection or loss of function.[69]

Tissue engineering requires cells, a matrix/scaffold on which to seed them, and a means of providing sustenance and blood supply. Scaffolds without cells take many months to repopulate,[8,9] and, without blood supply, all but the smallest, thinnest grafts will ultimately fail. A tissue-engineering technique that maximizes cell growth, adhesion, and structural integrity is required. A major advance in tissue engineering has been the recognition of the huge advantages offered by stem cells; these include primarily their ability to self-renew, providing a theoretically inexhaustible supply, and to differentiate to any cell type when grown under the appropriate conditions.

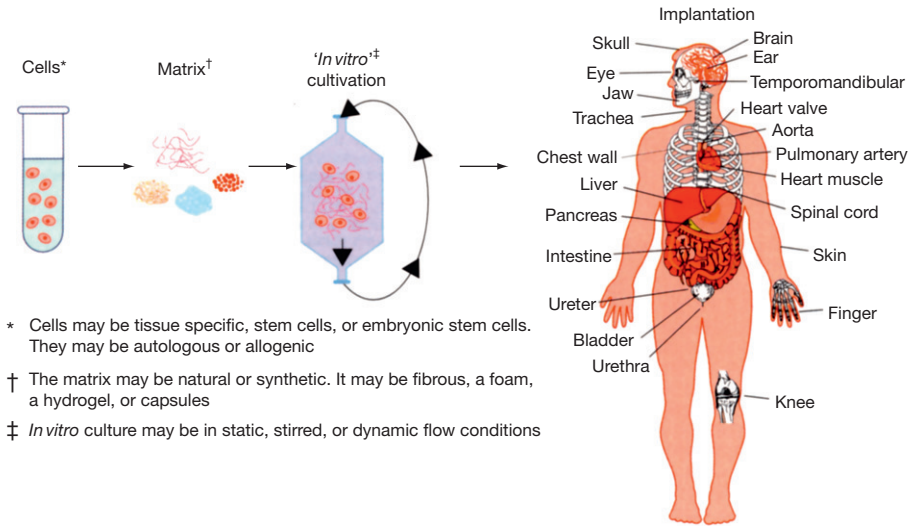


Figure 2 The tissue-engineering process. Reproduced from Vacanti, J. P.; Langer, R. *Lancet* **1999**, *354*(Suppl. 1), S32–S34, with permission from Elsevier.

5.536.3.1. Suitable Scaffolds (Natural, Synthetic)

The prime requirements for any scaffold in tissue engineering are biocompatibility, nonimmunogenicity, the capacity to sustain and/or promote the growth of the relevant cells/tissue, and provision of a template for tissue growth in three dimensions. Many different materials (natural and synthetic, biodegradable and permanent) have been investigated.

Scaffolds constructed from natural materials have been studied to evaluate their ability to support cell growth. They are usually composed of particular derivatives of the extracellular matrix (ECM) (and as such would possess natural interactive properties such as cell adhesiveness). Proteic materials, such as collagen, alginate or fibrin, and polysaccharidic materials, like glycosaminoglycans (e.g., hyaluronic acid derivatives), have all proved suitable in terms of cell compatibility, but some issues with potential immunogenicity still remains. In addition, there are obvious limitations associated with biological materials, including lack of consistency, biodegradability, and structure malleability.

The developments in materials science that have occurred in recent years, particularly in relation to the generation of bioactive materials, have provided a major advance in tissue engineering. The use of synthetic scaffolds, as used by the Wake Forest group,[67] has the advantage that structures can be tailored to the size and shape required for a particular patient. In addition, material properties such as strength, degradation time, porosity, and microstructure can be more easily controlled. Furthermore, there are no issues related to a limited donor pool. There are many potential materials under investigation for this application, including peptides, collagen, and ceramics. They lack the 'natural' macro- and microanatomic qualities of decellularized scaffolds. However, by studying the way cells and stem cells migrate and differentiate *in vitro* and within scaffolds, it should be possible to determine which combinations of molecules may be added to give optimal cell performance and angiogenesis.

The most commonly used polymers in synthetic matrices are biodegradable aliphatic polyesters. These polymers degrade through nonenzymatic hydrolysis of the ester bonds. The degradation products are nontoxic, natural metabolites and are eliminated from the body in the form of carbon dioxide and water. A synthetic material in common use is polylactic acid (PLA). This is a polyester that degrades within the human body to form lactic acid, a naturally occurring chemical that is easily removed from the body. Similar materials include polyglycolic acid (PGA) and polycaprolactone (PCL); their degradation mechanism is similar to that of PLA, but they exhibit a faster and a slower rate of degradation, respectively, compared to PLA. Polymers of PGA (first developed as Dexon, a synthetic biodegradable suture material) were first shown to be effective as matrices for new tissue formation,[70] and subsequently found to be adaptable in creating highly specific shapes such as that seen in structural cartilage.[71]

These polymers can be produced in a number of shapes and physical forms, including meshes, sponges, and films with a biodegradation rate that can be changed through copolymer proportions (e.g., altering chemical composition by varying the ratio of lactic to glycolic acid in the poly(lactic-*co*-glycolic acid), or PLGA, copolymers). Over the past decade, new synthetic materials and material-processing techniques have provided matrices, which, used in combination with chondrocytes, have produced high-quality tissue-engineered cartilage in a variety of different shapes, including the human ear,[72] nasoseptal implants,[73] a temporomandibular joint disk,[74] as well as joint resurfacing[75] and meniscal replacement[76] (**Figure 3**).

5.536.3.2. Decellularized, Nonimmunogenic Matrices (Allogenic, Xenogenic)

In the last decades, increasing evidence has enlightened that acellular, nonimmunogenic matrices, obtained with the detergent–enzymatic method, act as scaffolds and can stimulate

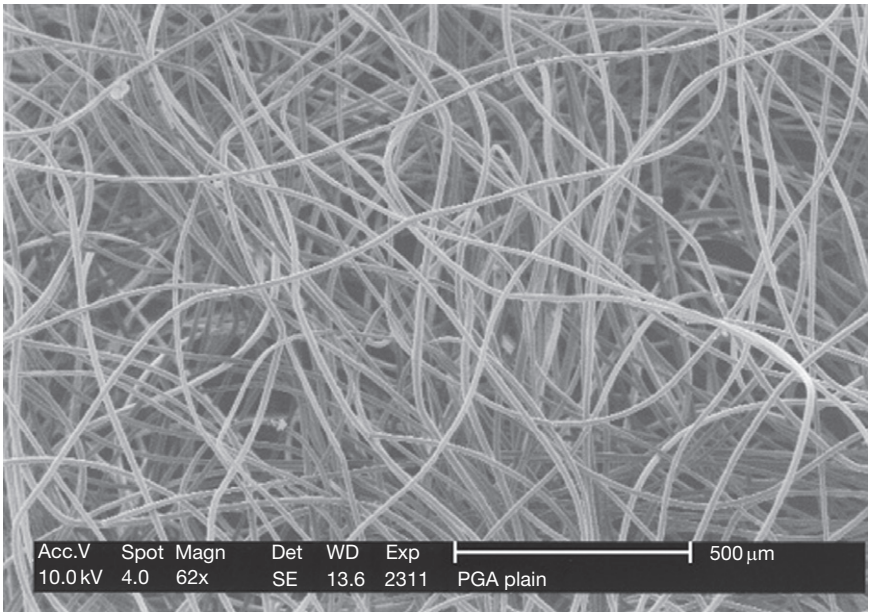

Figure 3 Scanning electron microscopy of a fiber-based polymer scaffold consisting of a nonwoven mesh of polyglycolic acid fibers.

in vivo the ingrowth of host cells, matrix formation, and the binding of new cells and matrix to host tissue.[58,77] Those characteristics would eventually prevent the formation of stenosis. Scaffolds derived from decellularized tissues have been used successfully in both preclinical animal studies and in human clinical applications.[78]

Behrend *et al.*[79] addressed the challenge of treating nonhuman tissue such that low immunogenicity on transplantation is achieved while preserving the tissue's structural integrity. Results showed that trypsin/EDTA tissue preparation caused a substantial reduction in the tensile strength of the trachea, making this an unsuitable method for preparing tracheal tissue intended for transplantation. In an *in vitro* study by Conconi *et al.*,[80] porcine tracheal matrices were treated with 18 cycles of a detergent–enzymatic method to reduce the antigenicity of matrices, thus better supporting adhesion of both chondrocytes and tracheal epithelial cells when compared with formalin, thimerosal, and acetone preparations.

In another experiment, autologous costal chondrocytes, smooth muscle cells, respiratory epithelium, and endothelial progenitor cells were cultured *in vitro* and then seeded on acellularized jejunal segments that served as a vascularized matrix.[81] Chondrocyte growth and extracellular cartilaginous matrix production were observed within 2 weeks, and thus, this experiment yielded the fundamental elements for a tissue-engineered trachea. This study also addressed the need for a three-dimensional (3D) scaffolding to mimic the native trachea.

Macchiarini *et al.*,[82] created a tissue-engineered tracheal patch using autologous muscle and fibroblasts seeded on a collagen matrix from a decellularized porcine proximal jejunum segment. After incubating for 3 weeks in a bioreactor, the bioartificial construct was used to close the tracheal defect in a 58-year-old man who had undergone a right completion carinal pneumonectomy. Postoperative endoscopies confirmed that the graft was airtight and covered with autologous ciliated respiratory epithelium. After 12 weeks, the bioartificial patch was functionally and morphologically integrated into the adjacent airway without signs of chronic inflammation, infection, or the growth of granulation tissue. This case report shows promise that tissue engineering may be the solution when therapeutic interventions are limited (**Figure 4**).

However, the bioengineering process in these previous experiences was labor intensive and required too many steps to gain wide clinical acceptance. Jungebluth *et al.*[83] demonstrated that the *in vitro* detergent–enzymatic method, described previously, used to generate short, but vital, tracheal matrices[80] is also a simple and effective method to bioengineer *in vivo* tracheal matrices of sufficient length to have potentially useful clinical application. Such matrices lack any MHC antigens and were shown to maintain structural and functional integrity, similar to that of native tracheas. Seventeen cycles, or around 35 days of detergent–enzymatic treatment, were necessary to bioengineer a tracheal tubular matrix that was structurally and mechanically similar to native trachea, but lacked sufficient immunogenicity to avoid rejection in animal models. A higher number of cycles led to worsening of the mechanical properties of the tracheal matrices to such an extent that implantation could be jeopardized. Interestingly, the immunologic and mechanical characteristics of the matrices remained unaffected by a 2-month storage in phosphate-buffered saline (containing 1% antibiotic and antimycotic, at 4 °C).

To confirm the nonimmunogenic properties of the decellularized matrices, the group went on to implant them in HLA-unmatched pigs and mice, mimicking allotransplantation and xenotransplantation settings, respectively. Implants were left over a period of 30 days without immunosuppression. They displayed no histological signs of local or graft rejection and significantly less inflammatory reaction and activation of

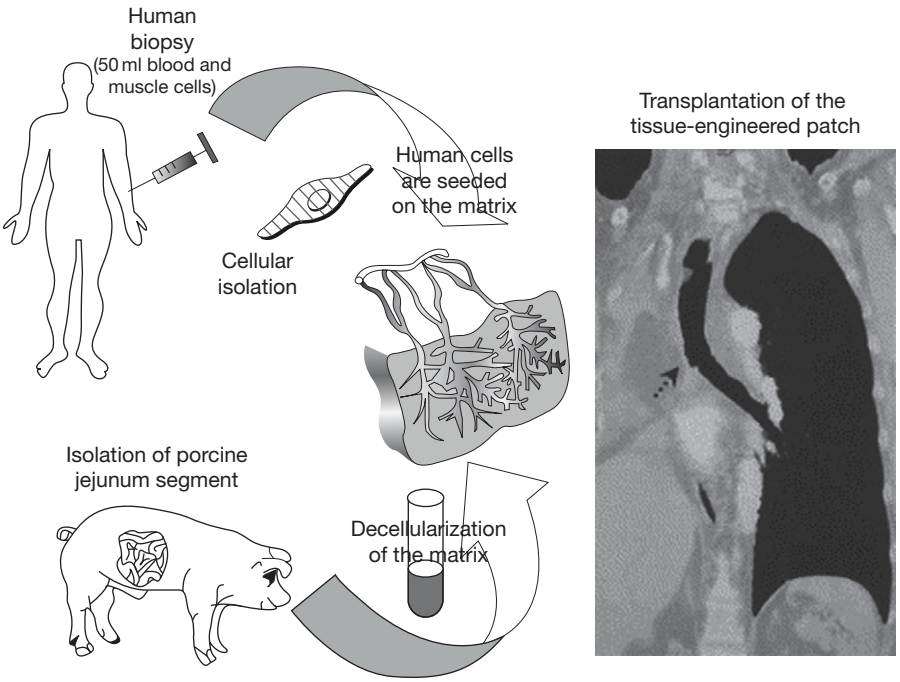

Figure 4 Process of engineering the bioartificial patch. Muscle cells and fibroblasts are isolated from a biopsy specimen obtained from the patient. These cells are seeded on a biologic matrix representing a collagen network generated from a decellularized porcine jejunal segment. During the incubation period, the cells start to remodel the xenogenic matrix and replace it with autologous connective tissue. Within 4 weeks, this autologous bioartificial implant can be clinically used. The computed tomographic scan of the chest 6 weeks after graft implantation shows the site (arrow) where the tissue-engineered patch was transplanted. Reproduced from Macchiarini, P.; Walles, T.; Biancosino, C.; Mertsching, H. *J. Thorac. Cardiovasc. Surg.* **2004**, *128*(4), 638–641, with permission from Elsevier.

adhesion molecules (e.g., P-selectin), or expression of swine leukocyte antigen antibodies, when compared with control or untreated tracheas during the study period.

A technique similar to the one described by Jungebluth *et al.*,[83] Go *et al.*,[84] and Conconi *et al.*[80] was employed by Macchiarini *et al.*[58] to decellularize a human trachea that was then seeded with autologous cells and used to replace a long-segment stenosed airway secondary to tuberculosis in a 30-year-old patient. The graft immediately provided the recipient with a functional airway, improved her quality of life, and had a normal appearance and mechanical properties at 4 months. The patient had no antidonor antibodies and was not on immunosuppressive drugs. At 1 year postimplantation, the graft is still functioning well and there are no signs of rejection.[85] The results show that we can produce a cellular, tissue-engineered airway with mechanical properties that allow normal functioning, and which is free from the risks of rejection.

The potential strengths of the decellularized scaffold approach lie in the similarity to normal anatomy and biomechanics that can be achieved. To this may be added observations of improved angiogenesis and cell migration, hypothetically via residual peptides left on the scaffold by the washing process, and by the presence of mesenchymal stem cells (MSCs). In other words, the decellularized scaffold seemed to fulfill the properties of an 'ideal matrix,' namely biocompatibility, bioabsorbability, nonimmunogenity, support of cell attachment and growth, and an ability to induce angiogenesis.

Compared with biodegradable synthetic scaffolds, natural decellularized xenogenic and allogenic scaffolds maintain the natural ECM composition, do not produce toxic biodegradation products, do not induce inflammation, and have already been successfully used for tissue engineering of heart valves, blood vessels, and urinary bladder.[86] A potential drawback, however, is the need for cadaveric donors. Still, tissue can be banked for later use and is nonallogenic, thereby increasing the potential donor pool compared to conventional transplanted organs.

5.536.3.3. Seeding with Stem Cells

Cells used in tissue engineering can be derived from numerous sources, including primary tissues and cell lines. Cells may be allogenic, xenogenic, syngeneic, or autologous. Ideally, the cells should be nonimmunogenic, highly proliferative, and easy to harvest and should have the ability to differentiate into a variety of cell types with specialized functions.

The single most important element to the success of tissue engineering is the ability to generate sufficient numbers of cells that maintain the appropriate phenotype and perform the required biological functions. For example, cells must produce ECM in the correct organization, secrete cytokines and other signaling molecules, and interact with neighboring cells/tissues. Immediately, this raises a number of potential problems, not least of which is obtaining appropriate cell numbers to promote repair.

To tissue engineer the trachea, the key components are reproducible cell lines with tracheal characteristics and a synthetic scaffolding to reproduce the structural requirements. Tissue preparations and culture media have been compared to find a combination that supports high levels of cell differentiation and maintains cellular structure and strength. Sachs *et al.*[87] found that primary human tracheal epithelial cells cultured in media with high concentration of retinoic acid produced better cell differentiation when compared with media with low or no retinoic acid. Primary human laryngeal epithelial cells from normal individuals have also been isolated and characterized, and it has been shown that they can be cultured *in vitro*.[88]

Although autologous cells are most desirable compared to allogenic and xenogenic cells, with regards to immunological compatibility and pathogen transmission, in general, they are differentiated and postmitotic. This can also be compounded by the tendency of some cell types to dedifferentiate during *ex vivo* cultivation and express an inappropriate phenotype. Although primary, especially autologous, cells are still used in tissue engineering,[89–91] yields and proliferation rates tend to be low and for some phenotypes, harvesting from a patient or donor is not an option. In particular, the standard approach of harvesting autologous cells (e.g., cartilage) for surgical reconstruction of the trachea has disadvantages such as donor site pain and limited tissue availability. These limitations have stimulated studies to find and develop alternative cell sources for tissue-engineering strategies and stem cells are already providing solutions to some of the problems encountered using primary cells released from explanted tissues.

Stem cells play a crucial role in the development and regeneration of human tissues. They are defined as cells that continuously renew themselves, while maintaining the ability to differentiate into various cell types.[92] The flexibility of stem cells, whether adult, embryonic, or induced embryonic, is an important component of this future. Embryonic stem cells, which have the capacity to develop into all three germ layers, have an immense regenerative capacity in animal models. However, use of embryonic stem cells comes with ethical dilemmas and concerns over immunological rejection of tissue, infection risks (including transmission of prions) and risks of tumor formation. Amniotic fluid is also a rich source of stem cells and these can be induced to differentiate into cell types representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neuronal, and hepatic lineages. In addition, they were found to be nontumorigenic.[93]

The recent discovery that adult cells can be persuaded to take on all the antigenic and behavioral characteristics of embryonic stem cells (inducible pluripotent stem cells) opens up a whole new vista for regenerative medicine,[94,95] although their clinical safety in terms of virus infection or tumorigenicity has not been established. Recently, however, it has been shown that the generation of inducible pluripotent stem cells is possible without any genetic alteration of the adult cell (so-called protein-induced pluripotent stem cells). A repeated treatment of the cells with certain proteins channeled into the cells via polyarginine anchors was sufficient to induce pluripotency.[96] Meanwhile, adult MSCs have already proven their versatility and safety in a number of phase I/II human clinical trials (e.g.,[97]).

The use of adult MSCs as a cell line is advantageous for several reasons. First, bone marrow aspirates can be done under local anesthesia, averting the risks associated with general anesthesia in critically injured patients. Second, in combination with *in vitro* tissue culturing, it is possible to obtain large numbers of each of the cell types from MSCs, sparing the patient from multiple procedures. In theory, therefore, these cells could be removed from a patient, incorporated into a tissue construct, and put back into the same individual when repair becomes necessary, thereby removing the need for immunosuppression (**Figure 5**).

Nakamura's group have designed acellular, biosynthesized prostheses with a porous polypropylene framework to mimic the cartilaginous mechanical properties of the native trachea, conjugated with a lyophilized collagen layer (collagenous sponge), which enables host cells to migrate and proliferate. This has been applied to canine models and human studies.[8,9,98] Their work in animal models and clinical studies with acellular scaffolds showed that epithelialization of the luminal surface is rather slow. They argue that cell-seeding approaches should be considered in terms of epithelialization speed, as both the study by Macchiarini *et al.*[58] and further animal experiences by the same group show.[99–101] However, recently Go *et al.*[84] have shown that both epithelial and mesenchymal stem-cell-derived chondrocytes are necessary for optimal survival of tissue-engineered airway transplants in pigs.

5.536.3.4. Bioreactors

Most of the early work in tissue engineering relied on the use of standard static cell-culture conditions for the *in vitro* fabrication of tissue before implantation. Producing a dynamic *in vitro*

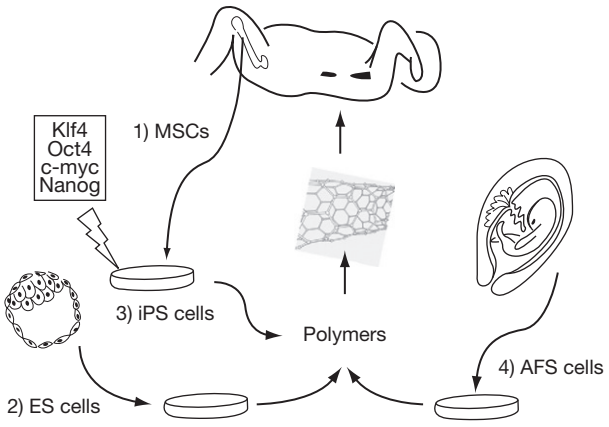

Figure 5 Sources of stem cells. Mesenchymal stem cells (MSCs) can be derived from the bone marrow of a patient and expanded *in vitro*. The same cells can be either directly seeded onto a polymer or transfected as to express stemness genes (Klf4, Oct4, c-myc, Nanog), hence becoming induced pluripotent stem (iPS) cells. iPS will then be expanded *in vitro* and seeded onto a polymer. Alternatively, embryonic stem (ES) cells can be derived from a donor blastocyst, expanded *in vitro*, and finally seeded onto a polymer. Amniotic fluid stem (AFS) cells can be collected from the amniotic fluid of a donor, or patient, prenatally, expanded *in vitro* and seeded onto a polymer. The polymer seeded with either cell type will finally be transplanted to replace the native organ. Adapted from Zani, A.; Pierro, A.; Elvassore, N.; De Coppi, P. *Semin. Pediatr. Surg.* **2009**, *18*(1), 57–62.

microenvironment culture system (bioreactor) for tissues may be an important aspect in guiding the formation of tissue with certain structural and functional characteristics. The use of bioreactors enables the *in vitro* culture of greater volumes of cells than could be obtained with conventional tissue-culture techniques. Furthermore, the use of bioreactors allows the investigator the opportunity to control flow and mixing, which can enhance mass transfer of nutrients, gases, metabolites, and regulatory molecules.

Bioreactors can also provide mechanical regulatory signals, such as directly applied compression, to stimulate the cells to produce specific biomolecules. Vunjak-Novakovic *et al.*,[102] for example, have shown that hydrodynamic conditions in convective-flow tissue-culture bioreactors can improve the quality of cartilage produced in comparison to standard static culture conditions and can modulate the composition (matrix components), morphology, mechanical properties, and electromechanical function of tissue-engineered cartilage. Hydrodynamic stimulation of the cartilage resulted in the production of greater amounts of ECM components such as glycosaminoglycans and collagen, leading to improved biomechanical properties. Mechanical stimulation is needed to favor cellular proliferation, maintenance of cellular differentiation, ECM production, and tissue organization with overall maturation of the cell construct.

Major challenges in functional airway bioengineering require uniform and highly efficient cell seeding on both the outer and inner surfaces of the 3D tubular matrix, coculturing different cell types, and optimum mass transport between the culture medium and the growing tissues. To address these issues, a novel double-chamber, rotating bioreactor has been developed, suitable for *in vitro* engineering of long airway grafts.[58] Early on, it was realized that the two different cell types (epithelial cells and chondrocytes) required different culture conditions. Therefore, the prototype bioreactor created for preclinical work was designed to provide two separate sterile compartments, each with a rotating air-medium interface. Viability of cells in both compartments was maintained and the dynamic culture environment in the bioreactor was controllable and reproducible; an essential requirement for the nutrient supply and waste removal needed to sustain large 3D constructs. The rotation provides the hydrodynamic shear stress necessary to promote metabolic activity and proper differentiation of the seeded cells.

Currently, the major limitation of the rotating bioreactor is the low level of automation of the system. An automatic medium conditioning and exchange system is desirable in order to minimize contamination risks and protect homeostasis. This would operate unattended over a period of days or weeks, while permitting intermittent, sterile evaluation of pH, nutrient, or waste concentration. A system controller would also be useful to manage the tissue-engineering process. Monitoring the data provided by sensors, allied to closed-loop feedback, will allow more control and, thereby, reproducibility of expansion, differentiation and migration of cells within the scaffold.[85]

The group has confirmed the persistence of viable chondrocytes, and a layer of viable epithelial cells at 2 months post-surgery.[85] However, the epithelial layer, whilst macroscopically intact and clearing mucus by this time, was microscopically discontinuous. Thus, further work to improve epithelial cell coverage of the internal surface of the graft preoperatively is necessary, and this is an important design consideration for further refinements of the bioreactor. In addition, the application of flow stimuli to the internal compartment of the bioreactor may encourage appropriate alignment, orientation, and function of cilia prior to implantation, thereby initiating appropriate clearance of mucus from the first postoperative day (**Figures 6** and **7**).

5.536.3.5. Transplantation in Animal Models and Humans

Langer and Vacanti's[69] review seemed to boost the trend of tissue-engineering approaches in this field. In 1994, epithelial tissue was first induced on a tissue-engineered trachea.[103] In that study, tracheal epithelial cells were isolated from newborn lambs in advance to induce an epithelial lining on the reconstructed site. These epithelial cells were injected into a previously manufactured cylindrical cartilage tube made from cells harvested from calves. These *in vitro* formed tubes were then implanted into subcutaneous pockets of ten nude mice, aged 6 weeks. Four of the ten implanted tubes were found to develop an epithelial lining on the inner surface, whereas the other six tubes became infected.

Development of tracheal cartilage has also been studied in rats by means of tissue engineering.[104] Kojima *et al.*[105] ambitiously tried to create cartilage with a biodegradable sheet of PGA and chondrocytes from the nasal septa of sheep. They prepared two bioabsorbable PGA mesh sheets, which were separately seeded *in vitro* with fibroblasts and chondrocytes. The two sheets were formed into a tube and implanted under the sternocleidomastoid muscle before tracheal replacement. Disappointingly, their attempt gave poor results; their animals survived only 2–7 days after surgery because of malacia and stenosis. The graft degenerated and was unable to maintain the mechanical properties required of a functional trachea.

Okamoto *et al.*[106] have made tracheal cartilage using bone morphogenetic protein 2 in dogs. In their canine model, a 1×5 cm slit defect of the tracheal cartilage was created in the trachea in advance, while carefully preserving the tracheal mucosa. Subsequently, regeneration of the cartilage was recognized around the stumps of the resected cartilages. Although these tissue-engineering trials have met with some limited success, achievement of a long-term durable tracheal cartilage with mechanical properties similar to those of native tracheal cartilage still seems a long way off.

Although there are previous reports of generation of small volumes of tracheal cartilage and clinical application,[81,82] progress with long-segment grafts up until recently has been limited by lack of an ideal scaffold, well-established epithelial and chondrocyte culture techniques, and an appropriate bioreactor environment. The approach of Macchiarini *et al.*[58] differed from that of Vacanti's group in that, instead of regenerating cartilage from chondrocytes, they used a cadaveric trachea with a cartilage backbone as a matrix. The group removed cells and MHC antigens from a human donor trachea using the detergent–enzymatic technique described previously in animal studies,[80,83] in order to create a nonimmunogenic, decellularized matrix.

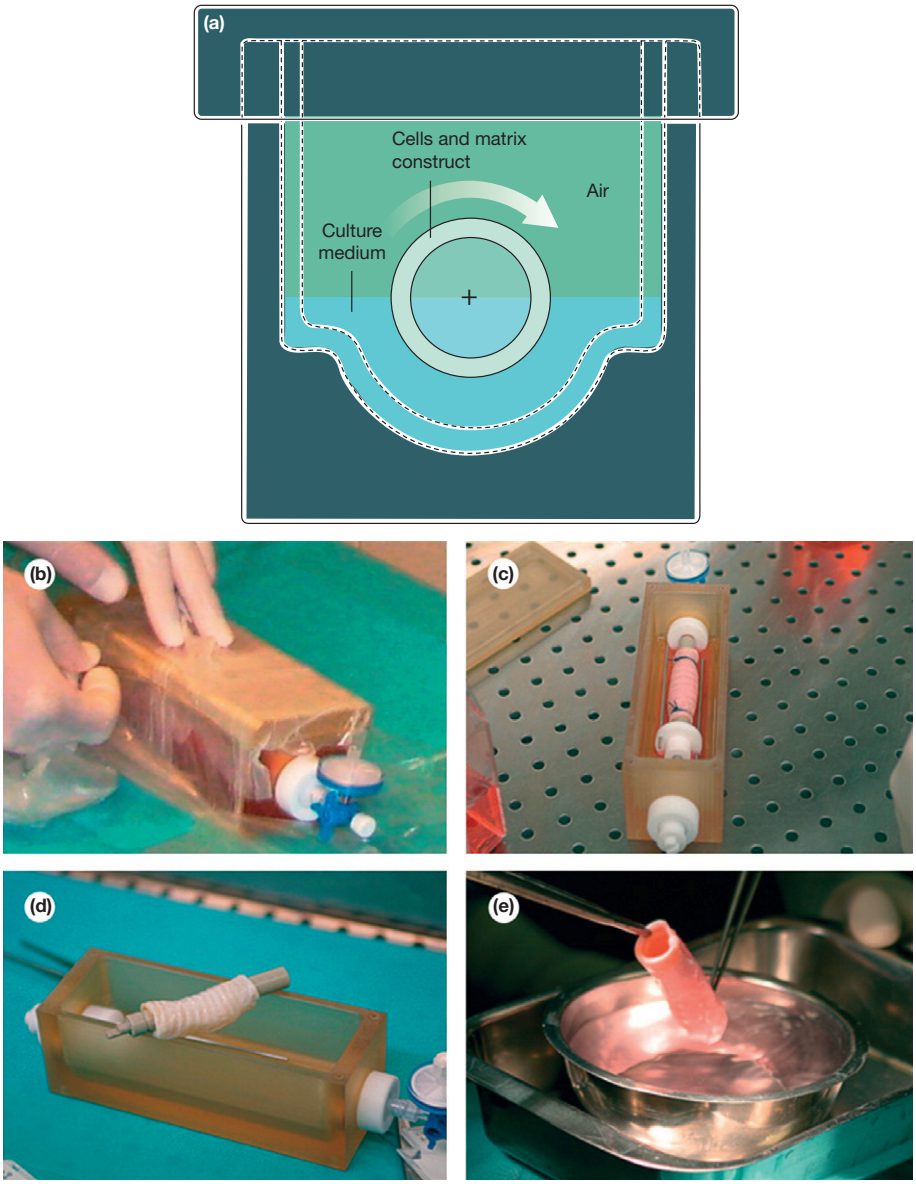

Figure 6 Bioreactor developed for airway tissue engineering. Reproduced from Macchiarini, P.; Jungebluth, P.; Go, T.; *et al*. *Lancet* **2008**, *372*(9655), 2023–2030, with permission from Elsevier.

Twenty-five cycles were required to remove nearly all HLA-positive cells from the tracheal matrices. This was then readily colonized by autologous epithelial cells and mesenchymal stem-cell-derived chondrocytes that had been cultured from cells taken from the recipient (a 30-year-old woman with end-stage bronchomalacia). This tissue-engineered graft was successfully implanted in order to replace the recipient's left main bronchus. The tissue-engineered airway remained patent 4 months after the operation and the patient had an improved quality of life. Importantly, the patient had no anti-donor antibodies and was not on any immunosuppressive drugs. The graft is still functioning well and there is no sign of rejection at 1 year postimplantation[85] (**Figure 8**).

Although the graft in the above study was completely covered with viable mucosa at 1 month, it is still not clear whether these epithelial cells originated from the seeded cells, or whether they grew in from an adjacent healthy airway. Previous studies have suggested that early on, it is the implanted cells that are important, and later on, they may grow in from the adjacent recipient site.[54,55,107]

A longer follow-up interval is required prior to a full-scale clinical trial, to fully assess the tissue-engineered airway's efficacy and safety. In particular, longer follow-up is necessary to assess the long-term retention of the graft's biomechanical properties, whether new chondrogenesis (or osteogenesis) occurs from the seeded chondrocytes, and to monitor for

signs of restenosis, rejection, or the presence of antidonor antibodies.

5.536.4. Tissue-Engineered Larynx for Total Laryngeal Replacement and Transplantation: The Ultimate Goal

The replacement of movement, as would be necessary to replace larynx or esophagus, introduces another order of magnitude of complexity. Nevertheless, progress toward these goals is starting to bear fruit.

5.536.4.1. Generation of Muscle

One of the challenges in developing a fully functional tissue-engineered larynx suitable for total laryngeal replacement is being able to generate muscle as would be required to reproduce normal vocal cord movements to allow laryngeal speech and breathing and to protect the airway from aspiration. *In vitro* engineering of functional skeletal muscle tissue would also be a very important issue in reconstructive surgery, particularly for the repair of congenital defects, and when a large amount of muscle is lost following trauma, oncological resection, or prolonged denervation.

Adult mammalian muscle cells are terminally differentiated and cannot replace themselves. Muscle regeneration, through cell transplantation, has long been explored as a potential therapeutic approach for muscle disorders such as Duchenne muscular dystrophy (DMD). At present, in addition to the obvious need to modulate the immunological, inflammatory response, two major concerns need to be addressed: what are the best muscle progenitors and what is the most efficient way of delivering them?

Different cell sources have been tested to find the optimal cell type that would proliferate and integrate into the regenerating muscle. The most well-known muscle progenitor cells are satellite cells. Satellite cells, first described in 1961,[108] are dormant progenitors located at the periphery of skeletal myofibers that can be triggered to proliferate for both self-renewal and differentiation into myogenic cells. In adult skeletal muscle, satellite cells reside beneath the endomysium (basal lamina) of muscle, closely juxtaposed to muscle fibers, and make up 2–5% of the nuclei associated with a particular fiber. Satellite cells are normally mitotically quiescent, but are activated (i.e., enter the cell cycle) in response to stress induced by weight bearing, or by trauma such as injury.

Two general approaches are adopted to engineer artificial skeletal muscle tissue. One way is to regenerate autologous satellite cells by biopsy, expand and differentiate cells *in vitro* in a 3D-defined environment (such as an artificial bioreactor), and reimplant the neotissue after differentiation has taken place (*in vitro* tissue engineering). The second approach involves the generation of satellite cells, expansion of cells *in vitro*, and reimplantation of donor cells using a transport matrix, which allows differentiation into myotubes to occur *in vivo* (myoblast transfer therapy). In the latter scenario, implanted myoblasts might also serve as vehicles for the delivery of recombinant proteins and/or growth factors (*in vivo* tissue engineering).

Myoblast transplantation (also known as myoblast transfer therapy) is a possible treatment for congenital and acquired muscular disorders, including several muscular dystrophies, and has been piloted for the treatment of vocal fold paralysis.[109] The initial demonstration that myoblast transplantation could restore the expression of dystrophin in nude/mdx mouse muscle fibers (an animal model of DMD) came as early as 1989.[110] However, the clinical trials that followed produced either negative or very limited positive results. Allogeneic myoblasts transplanted into DMD patients have been largely inefficient owing to immune rejection, rapid death, and limited intramuscular migration.

An important and poorly understood limitation of the satellite cell is its *in vitro* proliferative capacity.[111] After isolation, satellite cells can only divide a small number of times, and *in vitro* expansion reduces *in vivo* differentiation potency.[112] On the other hand, a small amount of tissue-resident satellite cells, *in vivo*, is sufficient to regenerate large parts of muscle tissue.[112–114] Collins *et al.*,[113] for example, showed that transplantation of single, intact myofibers with their attached satellite cells led to high levels of cell integration and proliferation. The inability to recapitulate the proliferative capacity *in vitro* is probably due to loss of the highly specific niche that normally surrounds these cells. In addition, satellite cells lack the ability to cross the muscle endothelium when delivered systemically (i.e., intravenous or interarterial), and because of this limited migration, they must be injected intramuscularly.

In the past few years, attention has focused on the myogenic potential of other stem cells. In addition to muscle-committed satellite cells, multilineage stem cells encountered in embryonic, as well as adult, tissues exhibit myogenic potential in experimental conditions and have been able to form skeletal muscle myofibers. These multilineage stem cells include bone marrow-derived MSCs, skeletal muscle side population cells, muscle-derived stem cells (MDSCs), $CD133^+$ ($AC133^+$) stem cells, mesoangioblasts, and pericytes, in addition to embryonic stem cells, amniotic fluid stem cells, and umbilical cord stem cells.[93,115–123]

One of the main obstacles in the formation of new muscle tissue is the lack of an adequate support for expanded satellite cells. To overcome this obstacle, many groups are trying to develop adequate synthetic and biological matrices to act as delivery systems for implanted cells.[124–133] Current studies on the optimal biochemical and physical conditions of the scaffolds to support myoblast survival and differentiation are aimed at improving this therapeutic platform. The studies are based on the premise that the environment should resemble the natural recipient environment as much as possible to fully support differentiation and maturation of myoblasts into adult skeletal muscle. Growth factors could also be employed and absorbed in the polymer prior to cell seeding. This could be released *in vivo*, with time-promoting proliferation, integration, and differentiation of the transplanted myoblasts.

5.536.4.2. Reinnervation

The main barrier to successful laryngeal transplantation is restoration of normal laryngeal speech and breathing functions. The larynx has the most complex motor function of

any muscular-based system in the human body as may be appreciated by listening to high-performance singing. This complexity is reflected by the comparatively high density of motor fibers in the recurrent laryngeal nerve, as compared to the small size of the muscles it innervates. While sensation is certainly important in eliciting cough, restoration of near-normal mobility of the arytenoids, and hence of the vocal cords, is essential.

Peripheral branches of cranial nerves are thought to regenerate more easily than nerves of the central nervous system. Indeed, damaged peripheral axons usually extend even through the gap caused by the injury. Functionally, however, some peripheral branches of cranial nerves, such as the oculomotor, facial, and recurrent laryngeal nerves regenerate as poorly as those of the central nervous system. Indeed the recurrent laryngeal nerve is known to be one of the peripheral branches of cranial nerves least likely to regenerate functionally once it is cut. At present, however, it is not clear why this may be the case. Major reasons for failure are thought to be failure of the regenerating axons to reach the original target organs, degeneration of the vocal cord muscles, and aberrant simultaneous innervation of antagonistic muscles caused by misdirection of regenerating axons.[134]

Unfortunately, direct repair of the recurrent laryngeal nerve results in synkinesis (mass movement) of muscles as repair in adult animals fails to recapitulate the successful axonal pathfinding of embryogenesis.[135] Thus, although recent electromyography of the patient from the Strome *et al.*[62] study has confirmed some recurrent nerve reinnervation on the right side,[136] the significant abduction that would be required to allow closure of his tracheostomy is still lacking.

A second way of replacing recurrent nerve function is anatomical reinnervation. There is only one muscle that causes laryngeal abduction and posterior motion of the arytenoids, the posterior cricoarytenoid muscle. The unique position of this muscle in laryngeal function, particularly breathing, has given its reinnervation greater prominence than that of the other intrinsic muscles. Fex[137] was the first to show that the phrenic nerve could be rerouted in animals to drive the posterior cricoarytenoid, although reports also suggest that the technique (and related rerouting techniques using other motor nerves such as the ansa cervicalis) may still result in aberrant reinnervation of adjacent muscles, as well as the target abductors with functionally suboptimal results.

The use of laryngeal pacemakers that are triggered on inspiration to stimulate abductor (opening) muscles has been explored by Zealear *et al.*[138] Implantation of a device based on a cardiac pacemaker allowed the removal of a tracheostomy in three of six patients with bilateral recurrent nerve damage implanted, five of whom were reported to have good cord movement. Although the reported system was bulky, groups in the USA and Europe are presently obtaining encouraging results with refined models. These devices may ultimately either provide short-term function and retention of muscle bulk while nerve regeneration proceeds (the so-called 'baby-sitting' effect), or be used as a permanent solution. However, these systems are still far from ideal and do not affect the process of regeneration itself.

Another, complementary, possibility is to work in partnership with peripheral nerve biologists to achieve faster, more accurate reinnervation of a laryngeal graft. Nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4) have all shown promise in speeding up peripheral nerve repair and are presently being applied in models of laryngeal reinnervation.[139] The application of insulin-like growth factor-1 (a potent myotrophic stimulus) to laryngeal muscles, using a viral vector, is also being tried as a means of retaining end-organ function when reinnervation eventually occurs.[140] Important areas to be investigated are which growth factors to use when, and how to retain them at the repair site.[141]

A tissue-engineered approach to recurrent laryngeal nerve reinnervation has been tried by Kanemaru *et al.*[134] Using a biodegradable artificial nerve conduit constructed of PGA tube coated with collagen, they were able to functionally regenerate four out of six recurrent laryngeal nerves across a 10-mm gap in adult dogs. No functional regeneration was observed where the recurrent laryngeal nerves were reconstructed with an autologous nerve graft (greater auricular nerve). On the other hand, misdirection of regenerated axons to inappropriate muscles was still seen. Perfect recovery of vocal cord movements requires that regenerating axons find the appropriate path leading to their target muscles and reinnervate them accurately.

5.536.4.3. Revascularization

A major potential problem with bioengineered organs is the provision of a functional blood supply. Vascularization is an essential factor for successful implants of bioengineered tissues, and a tissue of more than a few millimeters in volume cannot survive by diffusion and requires formation of new blood capillaries to supply essential oxygen and nutrients. Without revascularization, tracheal grafts of substantial length will possibly undergo necrosis.

Several approaches have been used to induce angiogenesis to a target site, including wrapping a graft with a pedicled omental flap, incorporation of angiogenic factors into the bioengineered tissue, seeding endothelial cells with other cell types and prevascularization of matrices prior to cell seeding.[142]

The use of angiogenic factors is a popular approach to induce neovascularization in engineered tissues. However, bolus injection of recombinant angiogenic proteins such as vascular endothelial growth factor (VEGF) or basic fibroblast growth factor (bFGF) has limitations due to the inherent instability of these proteins *in vivo* and the possibility of uncontrolled effects at distant sites. In order to overcome these problems, investigators designed systems of biodegradable polymers that provided localized and sustained growth factor release.

The embedment of angiogenic proteins inside different material-based implant devices has been actively pursued and several polymeric systems, both natural (alginate, fibrin, hydroxyapatite and chitosan, agarose, collagen, and gelatin) and synthetic (polyethylene glycol, PLA/glycolic acid, silica gel) have been investigated in order to facilitate the development of vascular-inductive tissue-engineering matrices.[126]

An alternative method for angiogenic factor delivery uses naked (plasmid) DNA and viral vectors for recombinant expression of angiogenic factors to the engineered tissue.[143] Matrices of poly(lactide-*co*-glycolide) (PLG) were loaded with plasmid, which was subsequently released over a period ranging from days to a month *in vitro*. Sustained delivery of plasmid DNA encoding PDGF from the matrices led to transfection of large numbers of cells, resulting in enhanced matrix deposition and blood vessel formation in the developing tissue. In another study, De Coppi *et al.*[129] combined the isolation and genetic engineering of myoblasts, with tissue transplantation, in an attempt to create well-vascularized muscle tissue. Rat myoblasts were transfected with a bicistronic plasmid encoding VEGF and green fluorescent protein (GFP), or with a plasmid encoding a nonfunctional VEGF–alkaline phosphatase (AP) fusion protein. The transfected cells were suspended in collagen type I and injected subcutaneously into nude mice. Neovascularization and muscle tissue mass significantly increased with functional VEGF-transfected cells, compared with nonfunctional VEGF-transfected cells.

Microfabrication technology, having largely arisen out of biomedical microelectromechanical systems (MEMS), is a rapidly emerging science with many applications including biomedical engineering.[144–146] It was originally developed for the circuit industry, and allows complex branching patterns at the 1-μm level to be imprinted onto silicon or Pyrex wafers using photolithography and a series of subtractive etching techniques. These templates can be used as molds to replicate their branching patterns onto bioresorbable polymer films, which can then be seeded with endothelial cells to form endothelialized microvasculature networks. The technique allows for a resolution that is required to form templates at the microcirculation level (i.e., the capillaries), which are of the order of 10 μm in diameter. Additionally, micromagnetic resonance imaging and microcomputerized tomography may provide detailed 3D images of the microvasculature for mathematical modeling of flow, branching angles, and resistance to optimize template design (**Figure 9**).

Macchiarini *et al.*[58] did not use any specific measures to aid revascularization in their graft. Nevertheless, they observed rapid recovery of blood flow and luminal mucosal appearance. Indeed, laser-Doppler measurements showed a healthy, adjacent microvascular bed from postoperative day 4 and active mucosal bleeding at 30 days, indicating successful revascularization.

Jungebluth *et al.*[83] have shown that angiogenic cytokines (bFGF, transforming growth factor β) might be present within decellularized matrices, and postulated that similar expression might contribute to timely revascularization. In support of this view, when they implanted sections of detergent–enzymatic method-treated pig trachea into a Balb/c mouse dorsal skin pouch, graft neovascularisation was seen by 2 weeks.

Another possibility is that the seeded epithelial cells and chondrocytes in the biological prosthesis before the implantation may have induced early revascularization. However, it is still unclear whether the seeded cells regenerated any tissue, including the cartilage and mucosa. Until the functions of the seeded cells are more clearly elucidated, it remains unclear whether the results should be regarded as a fully tissue-engineered replacement, or an allotransplantation of the trachea.

5.536.4.4. Immunogenicity

By contrast with solid organ transplants, which take place in sterile mesenchymal environments (e.g., kidney, liver, heart), the airway represents an interface between the internal and external environment. Unsurprisingly, the airway mucosa has immunologically active cells playing a key part in airway transplantation,[53] and these contribute to acute allograft rejection, which requires high-dose immunosuppression. Unlike other transplants, airway replacement is rarely a life-saving procedure, so a completely nonimmunogenic allograft with preserved functional and mechanical characteristics is the minimum target for organ replacement.

Using multiple color immunofluorescence histology, Birchall's group has described a dense, organized network of immunologically active cells, including many dendritic cells in pig[147–150] and human[151] laryngeal mucosae. Human laryngeal epithelial cells also express MHC molecules.[88] Thus, all the indications are that at least the mucosal element of the larynx will represent a strong graft.

In support, Genden's studies of murine tracheal grafts have shown that replacement of the epithelium by host epithelial cells completely prevents rejection after withdrawal of immunosuppression.[56] As re-epithelialization therefore appeared as an attractive strategy for airway grafts, Genden's group went on to show that subsequently the process could be significantly speeded up with the application of VEGF carried by a fibrin matrix to the mucosa.[152]

These observations suggest that tissue (mucosa) specific interventions may be highly effective in preventing laryngeal (or other mucosal organ) allograft rejection and thus removing the need for conventional immunosuppression. Such strategies would also open the door to transplantation for the large pool of potential recipients with laryngeal cancer. This view is tempered somewhat, however, by the observation that rat and mouse laryngeal grafts appear to exhibit early rejection throughout all tissues, not just the laryngeal mucosa,[63,153] and other 'compartments' within the larynx also contain antigenic tissue.[154]

Conconi *et al.*,[80] Macchiarini *et al.*,[58] and Jungebluth *et al.*[83] have developed a technique to generate decellularized tracheal matrices by detergent–enzymatic methods (containing sodium deoxycholate/deoxyribonuclease lavations). They are able to generate decellularized tracheal matrices of sufficient length to be clinically useful, with functional and mechanical properties similar to native tracheas, but without the problems of immunogenicity. The immunologic ignorance resulting from this procedure avoids allorejection and xenorejection in animal models[83] and humans,[58] and therefore there is no need for immunosuppression. One possible contributory factor to avoidance of hyperacute and acute rejection is the lack of an immediate dedicated blood supply, although vessels were seen to grow into the implanted tissue with time. This protocol opens the door to the creation of clinically functional, fully tissue-engineered airway and organ replacements in the near future.

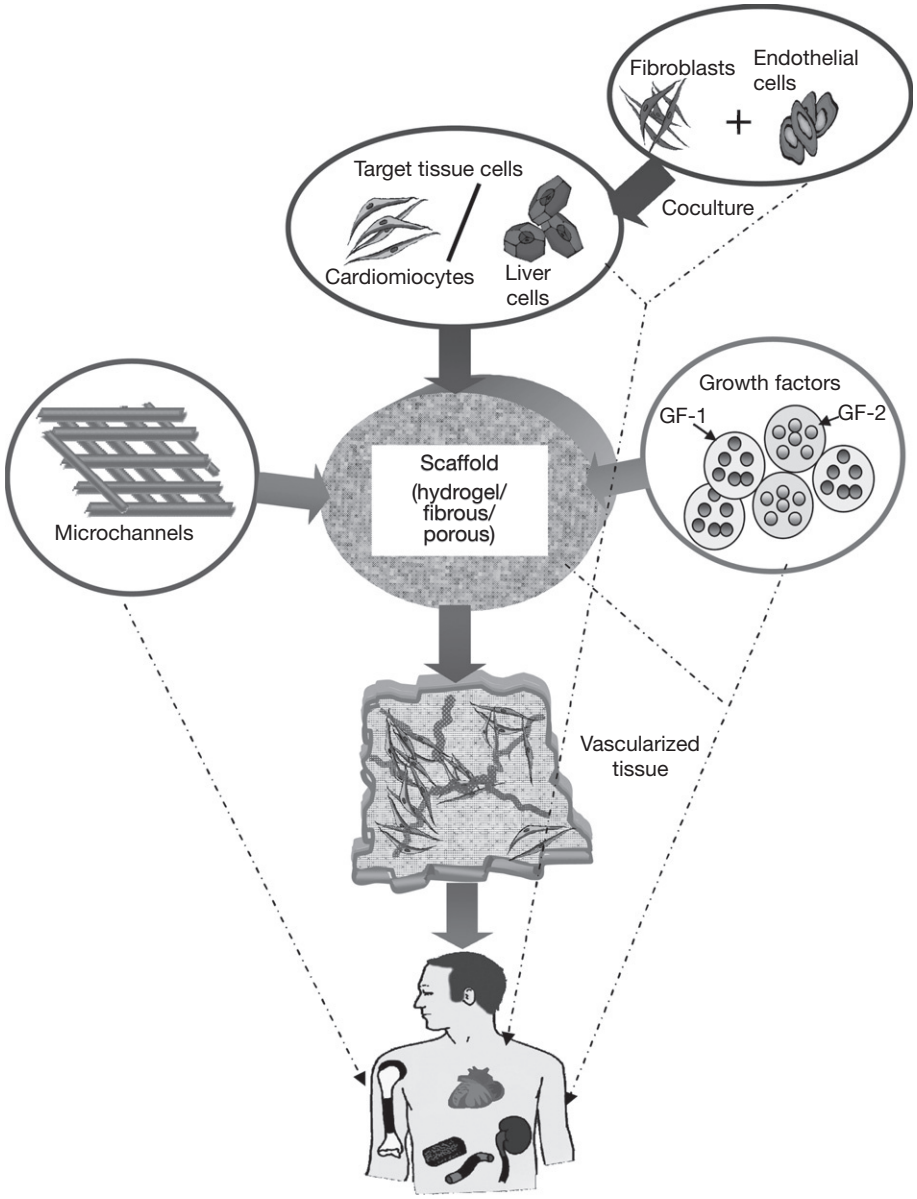

Figure 9 Vascularization strategies for tissue engineering. Independently, each approach can be directly applied *in vivo* for angiogenesis support and enhancement–schematic view. Solid arrows denote integration of the approaches *in vitro* and implantation of vascularized tissue construct. The dashed lines denote direct application *in vivo* of one or several of the approaches. Adapted from Kaully, T.; Kaufman-Francis, K.; Lesman, A.; Levenberg, S. *Tissue Eng. B Rev.* **2009**, *15*(2), 159–169.

5.536.5. Future Challenges and Goals

5.536.5.1. Tissue Engineering the Esophagus: A Preliminary Step Toward Generating a Tissue-Engineered Larynx

Esophageal cancer is a difficult gastrointestinal malignancy to treat, and esophagectomy is often a highly morbid procedure with significant postoperative complications. The stomach, jejunum, or colon are often used in reconstruction procedures, and the patient may suffer from malnutrition postoperatively secondary to poor functioning of the substitute or loss of length and function of the gastrointestinal tract that is being used. Additionally, the treatment of long-gap esophageal atresia often poses a challenge for pediatric surgeons. Current surgical therapies include stretching, circular myotomy, and colonic interposition. These procedures, although often successful, can be complicated by leakage, stricture, and elongation of the interposed colon.

The history of reconstructive surgery of the esophagus dates back to the beginning of the last century. As early as 1907, Bircher first reported the use of a tube of skin to substitute the esophagus.[155] Over the last 80 years, development of an artificial, and more recently a tissue-engineered, esophageal replacement has been investigated as a means to treat these esophageal diseases. Progress in this area may shed some light on the development of a tissue-engineered larynx, for total laryngeal replacement, when the larynx is diseased or dysfunctional.

The esophagus, like the trachea, is an epithelial-lined tubular structure, but tissue engineering of a myoepithelial tube presents additional challenges, namely generating functioning muscle, together with reinnervation and a supportive blood supply; the very same challenges that current investigators attempting to tissue engineer the larynx face. In addition, the esophagus is less rigid and therefore lacks the same support as the trachea.

Many attempts at creating a replacement for the esophagus using artificial materials including rubber, polyethylene, teflon, and polypropylene, among others have been investigated.[156] Most of these materials were eventually extruded, and complications of leakage and stenosis in the long term often developed, as in the case of trachea. Additionally, autologous tissues and homografts have been used as esophageal substitutes. The skin, trachea, and fascia have been used, but complications such as anastomotic leakage and stenosis again often ensued.[156]

Sato *et al.*[157] have been investigating methods to create a tissue-engineered esophageal replacement. Their goal is to harvest a small amount of normal esophageal tissue from a patient with esophageal cancer before operation, culture the cells, and create a natural esophageal replacement *in vitro*. Then they propose to graft the replacement into the same patient at the time of operation.

Toward these goals, Sato *et al.*[157] cultured esophageal epithelial cells on the surface of collagen gels in which biodegradable PGA mesh was embedded. They then sutured the mesh to create a tubular structure lined with cultured cells and wrapped these tubes in the latissimus dorsi muscle flaps of athymic mice. The tubular structure was maintained *in vivo*, and appeared histologically similar to normal esophageal epithelium. A basement membrane was also identified by antilaminin staining. The same group also then embedded fibroblasts into the collagen gels as a feeder layer and repeated the experiment. They noted that the fibroblasts accelerated the proliferation and differentiation of the epithelial cells both *in vitro* and *in vivo*.[158]

Beckstead *et al.*[159] looked at the interaction of esophageal epithelial cells with natural and synthetic scaffolds. Parameters such as calcium concentration, scaffold composition and pore size, and epithelial behavior on synthetic and natural scaffolds were analyzed. The authors concluded that both decellularized human skin (AlloDerm) and degradable polyesters (PLA, PLGA, PCL) supported esophageal epithelial cell adhesion and proliferation. However, natural scaffolds proved to lead to architecturally superior epithelial organization and stratification, compared to synthetic scaffolds, with no need for induced modifications. Modification of the synthetic scaffold's pore size and surface properties (including identification of the proteins or growth factors within the natural matrices responsible) may be necessary to mimic epithelial behavior on natural scaffolds.

More recently, Marzaro *et al.*[160] produced esophageal substitutes composed of homologous esophageal acellular matrix and autologous smooth muscle cells, both isolated from the esophagus of newborn pigs. Acellular matrices obtained by detergent–enzymatic methods did not present any MHC markers, expressed bFGF (demonstrating angiogenic activity), and supported cell adhesion. The authors implanted acellular matrices, with and without cultures of autologous smooth muscle cells, *in vivo* after creating a porcine esophageal wall defect. Constructs containing autologous smooth muscle cells proved to have less severe inflammation and showed an early organization into small fascicules.

To overcome the issue of absent peristaltic contractility in an artificial esophagus, Watanabe *et al.*[161] developed nickel–titanium shaped memory alloy coils, which were placed in an annular manner on a Gore-Tex vascular graft. Interestingly, low-voltage electrical current passing through the coils generated peristaltic movements in the artificial esophagus implanted in a goat model.

5.536.6. Conclusions

The prospect of being able to build customized, nonimmunogenic tissues and organs from scratch, via tissue engineering, is an attractive one. The potential strengths of the decellularized scaffold approach lie in the similarity to normal anatomy and biomechanics that can be achieved, with the opportunities for improved angiogenesis and cell migration.

However, there are many questions that urgently need to be addressed before the technology is accepted and made universally available. Future research should focus on the functions and determining fates of the stem cells *in vitro* and *in vivo*, angiogenesis regulation, optimal bioreactor design and conditions, immunogenicity, and long-term clinical follow-up.

The trachea is an excellent model for addressing these critical questions in the wider picture of cell- and tissue-engineered organ replacements. The trachea is a luminal structure with a relatively thin wall through which nutrients, cells, and new blood vessels pass with relative ease. The replacement of movement, as would be required to replace the larynx, or the replacement of organs that perform similarly complex functions (such as esophagus), introduces another order of magnitude of complexity. Nevertheless, we are one step closer to fulfilling these goals.

Glossary

Adipocyte A mature fat cell.
Adipogenesis The process by which preadipocytes differentiate to become mature fat cells.
Autologous Derived from a patient's own body.
Biocompatible Material or substance that does not cause negative reaction with surrounding tissue or host upon implantation.
Expansion Increase in cell number, proliferation.
Natural biomaterial A material derived from natural sources used for biological applications.
Preadipocyte A precursor fat cell that has not yet matured.
Scaffold A substrate derived from natural or synthetic material that is intended to mimic tissue in the body and support cell growth while building new, healthy tissue.
Synthetic biomaterial A material manufactured or produced from synthetic polymers and used for biological applications.

Abbreviations

bFGF	Basic fibroblast growth factor
HA	Hyaluronic acid
IL-6	Interleukin-6
PAI-1	Plasminogen activator inhibitor-1
PEG	Poly(ethylene glycol)
PL	Poly(lactide)
PLG	Poly(lactide-*co*-glycolide)
Pref-1	Preadipocyte factor-1
TGF-β	Transforming growth factor-β
TNF-α	Tumor necrosis factor-α

5.537.1. Introduction

Cases of traumatic injury, congenital defect, or tumor resection often result in soft tissue defects, where loss or removal of volumes of adipose tissue, within the subcutaneous layer of skin, results in alterations of the skin's normal contour.[1] Soft tissue defects are repaired clinically using plastic and reconstructive procedures to restore the missing volume of adipose tissue. Clinical procedures used to repair such defects include autologous fat tissue grafts and tissue flap transfers, implants, or injectable fillers that reconstruct and fill the void space. While many options for soft tissue reconstruction are used in clinical application, there is, however, not one strategy that is useful for the wide range of defects that may exist. Additionally, the methods currently used for soft tissue reconstruction are limited in their success due to complications, such as tissue resorption, resulting in loss of tissue volume over time.[1–6] Researchers are, therefore, working to develop methods for

engineering autologous adipose tissue that may be used to fill soft tissue defects. This chapter will provide an overview of adipose tissue structure and function along with a discussion of specific biomaterials used in adipose tissue engineering strategies and a current review of the success and limitations of these strategies in the field of adipose tissue engineering.

5.537.2. Adipose Tissue Engineering

Tissue engineering methods are being investigated to develop a wide range of tissues, including bone, skin, cartilage, vascular, and adipose tissue for patients in need.[7,8] The development of natural, autologous engineered tissue using a patient's own cells will eliminate the need for tissue or organ transplants where immunological rejection is often of concern for patients receiving donor tissue.[7,9] Most tissue engineering strategies are based on the premise of taking healthy cells from a patient and culturing them in a laboratory setting to attain a larger quantity of cells sufficient for seeding onto scaffolds. Scaffolds for tissue engineering are support structures designed to facilitate cellular growth and proliferation upon implantation into the patient. As cells covering the scaffold increase in number and differentiate, the scaffold will degrade or absorb, resulting in newly formed autologous tissue.[10,11]

The development of tissue-engineered adipose tissue would ideally provide replacement tissue that is similar in texture and structure as the native soft tissue in need of reconstruction. Engineered adipose tissue has the potential to provide reconstruction options that are natural and that use the patient's own healthy cells. Additionally, the advent of minimally invasive technologies, enhanced by tissue engineering strategies, could provide reconstruction options better suited for plastic and reconstructive surgical patients.[12] Minimally invasive, tissue-engineered strategies could effectively reduce postsurgical trauma that patients would endure from the typically used open procedures required for implantation of tissue expansion devices, implants, and tissue transfers.[13]

Many factors must be considered to design the optimal adipose tissue engineering system. Attention must be paid to all key aspects of the tissue engineering process, including the cell source, scaffold material, cellular environment, and means of device delivery.[14,15] Logistically, the ideal cell source should be readily available, simply obtained, and easily expanded in culture.[2] The ideal scaffold material should provide a surface that facilitates cell attachment and proliferation, be esthetically similar in texture to native soft tissue, and also be biocompatible with host tissue upon implantation.

5.537.3. Adipose Tissue Structure and Function

In order to successfully engineer any tissue, it is first necessary to understand the natural physical and functional characteristics of the tissue of interest. Two forms of adipose tissue exist – white and brown. As white adipose tissue is the type found within the subcutaneous layer of soft tissues, our discussion will focus only on white adipose tissue. Adipose tissue is characterized as a viscoelastic material, possessing the characteristics of both viscous and elastic materials that are capable of resisting flow and also returning to their original shapes after deformation is applied.[16,17] The stiffness for viscoelastic materials has been shown to depend on the rate of strain applied. The reported values for the elastic modulus of adipose tissue range from 0.5 to 25 kPa. This wide range may be attributed to the source or *in vivo* location of the evaluated samples, in addition to the lipid and water content of the evaluated samples.[18–22]

Adipose tissue has many functions within the body, serving as a thermal insulator within the body and providing protective cushioning to the body's internal organs. Additionally, adipose tissue serves as an energy storage locale and secretory organ that produces hormones and cytokines that function in metabolic processes.[23,24] The multifunctional role of adipose tissue within the body means that there are many characteristics of adipose tissue that must be further understood in order to successfully engineer new adipose tissue.

5.537.3.1. Cellular Composition

Adipose tissue is characterized as a loose connective tissue composed primarily of lipid-filled, mature cells called adipocytes. The adipocytes are bound together by collagen fibers, primarily collagen type IV, which form the structural network.[23] In addition to adipocytes, other cell types within adipose tissue include smooth muscle cells, endothelial cells, fibroblasts, blood cells, and preadipocytes, which account for one- to two-thirds of adipose tissue composition and are found within the stromal-vascular fraction of the tissue.[25–29]

The intracellular space in an adipocyte is filled to approximately 90% with a single, unilocular, lipid droplet. The lipid within mature adipocytes fills the cell such that the cell's nucleus is pushed to the periphery of the cell membrane, forming a thin ring within the cell.[30,31] Mature fat cells can range in diameter from 10 to 200 μm depending on the size of the lipid droplets within the cell.[24,32] The lipid-filled nature of mature adipocytes leaves them fragile and sensitive to mechanical deformation. Mature adipocytes are obtained either through excision or liposuction, which may cause damage to the vascular supply or to the cell body, respectively. This cellular damage results in a large cell population that will not retain the desired cell volume *in vivo*.[5] Mature adipocytes in culture are limited in their proliferative capabilities and are not readily expanded. This characteristic is attributed to their terminally differentiated state, which further discourages their use in tissue engineering.[4,31,33]

Preadipocytes, which are precursor cells committed to the adipocyte lineage, are contained within the stromal-vascular fraction of enzymatically digested tissue. These cells are fusiform or fibroblast-like in appearance before they are differentiated.[5,31] Differentiation of these cells results in morphological and biochemical changes, where the cells become rounded in shape, and begin to accumulate triacylglycerol and form lipid vacuoles.[4,33] Preadipocytes are deemed more advantageous as a cell source than mature adipocytes because they are easily cultured, easily expanded, and easily obtained. They are capable of both proliferating to obtain larger cell numbers and of differentiating to build the tissue of interest.[26,34–36]

5.537.3.2. Adipogenesis

The process of adipogenesis, or the formation of fat, is a multistep process involving the proliferation and differentiation of preadipocytes. The steps involved in adipogenesis have been widely evaluated through the use of preadipocyte cell lines such as 3T3-L1 and 3T3-F442A.[37] During the proliferation stages of cell growth where cell number increases, preadipocytes morphologically resemble fibroblasts, as shown in Figure 1. This shape is maintained throughout the proliferation stages. At confluence, proliferation of the cells is inhibited by cell–cell contact and growth arrest occurs. The preadipocytes then enter the differentiation stage.[26,37–40] Once differentiation is induced, morphological changes in the cell occur. The preadipocytes become more spherical in shape and lipid is accumulated within the cell such that the cell forms a unilocular mature adipocyte.[37,39–47]

For differentiation of preadipocyte cell lines to occur, differentiation inducers consisting of insulin, dexamethasone, and 3-isobutyl-1-myethylxanthine (IBMX) are added to the cultures to initiate and accelerate the differentiation process.[37,41,42,48–51] The ability to isolate and culture primary preadipocytes from several species has been demonstrated. When studying differentiation of these cells, the use of primary cells offers several advantages. Primary preadipocytes can be obtained from adipose deposits in different locations on a wide variety of animals, which can provide information on species and tissue microenvironment variations. Additionally, it has been shown that primary cultures may differentiate in the presence of low concentrations of insulin when cultured in serum or with high concentrations of insulin in a serum-free medium.[37]

As preadipocytes progress through the differentiation process to become mature adipocytes, they not only undergo morphological changes, but also change at the genetic level where genes are expressed at different stages of development. One gene expressed by preadipocytes is growth arrest and DNA damage-inducible protein (GADD) 153, which is also known as CCAAT/enhancer-binding protein ζ (C/EBPζ) and CHOP-10.[40,42,52] GADD is responsible for blocking the G1 to S transition between phases of the cell cycle, which initiates growth arrest, and subsequently differentiation.[52] Another gene characteristic of cells of the adipose lineage is peroxisome proliferator activator receptor (PPAR)-γ, which is expressed early in the differentiation process at low levels.[37,53–55] As differentiation progresses, the level of PPAR-γ expression has been shown to increase.[37,54,56] PPAR-γ belongs to the family of nuclear hormone receptors and is key in the induction and maintenance of differentiated adipocytes. The expression of PPAR-γ has also been shown to induce growth arrest and to initiate adipogenesis in fibroblast cell lines.[37,57] The expression of adipocyte-specific fatty-acid-binding protein-2 can be detected in mature adipocytes[58]; this lipid-binding protein is expressed when cells accumulate lipid.[39,41,53,56,59] The expression of these transcription factors may be evaluated with reverse transcriptase polymerase chain reaction (RT-PCR) to assess the stages of preadipocyte differentiation. Assessment of the developmental stage of cells is particularly crucial for the analysis of primary adipose-derived tissue cultures.[37]

5.537.3.3. Secretory Function of Adipose Tissue

Long thought to function solely to cushion the organs of the body and store the body's fuel supply, white adipose tissue has now become recognized as an endocrine or secretory organ within the body. Adipocytes are capable of secreting many proteins and cytokines (termed adipokines) that may influence the behavior of other cells within the body.[60–62] Factors secreted by adipocytes have been categorized by function, including extracellular matrix (ECM) development, cell metabolism, immunological function, or other processes within the body.[60] Table 1 highlights several of the factors secreted by adipose cells and their function within the body. These secreted factors not only function to influence the behavior of surrounding tissues, but factors such as transforming growth factor-β (TGF-β) and preadipocyte factor-1 (pref-1) function in an autocrine manner to inhibit adipogenesis.[28,60,61,73,97–100] The factors secreted by the cells found within the adipose tissue play an important role in adipogenesis and may play a role in the development of tissue engineering strategies.

5.537.3.4. Adipose-Derived Stem Cells

More recently, adipose tissue has been identified as a source of multipotent cells that have the capacity to differentiate to cells of adipogenic, myogenic, chondrogenic, and osteogenic lineages when cultured with a specific stimuli.[101–114] These adipose-derived stem cells (ADSCs) may be obtained from liposuction aspirates or through abdominoplasty procedures and have been deemed advantageous for tissue engineering applications because of their ability to differentiate to multiple cell types. Additionally, adipose tissue is often available in an abundant, expendable amount within the body, which yields a readily available tissue source that is easy to harvest in

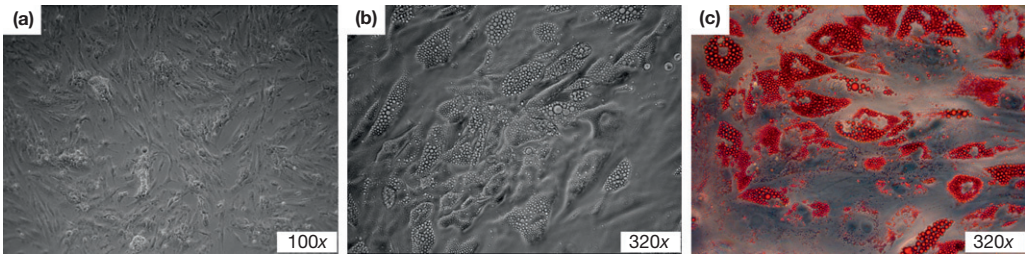

Figure 1 (a) Human preadipocytes isolated from fresh adipose tissue samples exhibit a fibroblast-like morphology. (b) Differentiation of human preadipocytes for 14 days results in the formation of intracellular lipid droplets and morphological changes characteristic of mature adipocytes. (c) Oil Red O staining of intracellular lipid shows the accumulation of lipid droplets within cells differentiated for 14 days.

Table 1 Common factors secreted from adipose tissue

Secreted factor	*Expressed by*	*References*
Role: Metabolic function		
Adiponectin	Adipocytes	63–65
Leptin	Adipocytes	66–71

comparison to bone marrow aspiration procedures that result in significant pain.[35,101,112,115]

5.537.4. Biomaterials for Adipose Tissue Engineering

When selecting a material for use as scaffolding in adipose tissue engineering, several aspects must be considered. Scaffold selection depends on the physical, mechanical, and chemical properties of the material.[116] Because the tissue that is being reconstructed is a 'soft' tissue, a scaffold material that imparts a natural feel is ideal, particularly for restoration of breast tissue in women.[33,117,118] Additionally, the cell type of interest will affect the material selected for use as a scaffold. Adipocytes and preadipocytes are anchorage-dependent cells, meaning that they require a surface, that is, substrate, of defined stiffness so that attachment, proliferation, and differentiation can occur.[1,4,34] The porosity of a scaffold surface can be selectively modified to both encourage cellular attachment and to allow the diffusion of nutrients and vascular ingrowth within a scaffold.[33,119] More specifically, it has been shown that dispersed, cultured fat is difficult to maintain on two-dimensional (2D) surfaces in static flow,[57] perhaps attributable to the fact that mature adipocytes are capable of a phenomenon known as dedifferentiation, where the cells lose accumulated lipid and revert to a previous fusiform state observed in preadipocytes.[58,120] Moreover, culturing anchorage-dependent cells on appropriate substrata will result in increased proliferation and ultimately the presence of a greater number of cells with the potential to differentiate in culture.[3]

Scaffolds used in tissue engineering may be implanted either by surgical incision or by injection. The materials used for constructing the scaffolds, whether intended for injection or implantation following incision, must possess several essential properties. These materials should be biocompatible, biodegradable, easily manufactured and sterilized, and easily managed during surgical procedures, and should guide the differentiation, migration, and proliferation of cells.[3,9,10,121–123] Additionally, the materials should possess mechanical properties in line with that of natural tissue and have nontoxic by-products. In order to allow adequate cellular growth, the scaffold design should be porous to allow the permeation, both inflow and outflow, of nutrients and waste products.[9] Thus, the size of the scaffold should also be taken into consideration, not only with respect to the method of implantation, but also with respect to cellular nourishment throughout the scaffold. Of the implantable materials that are available for use in tissue engineering, those most widely used have been porous biodegradable polymers, which include poly-L-lactide, poly(glycolide) (PG), and copolymers of the two.[9,124] Injectable hydrogels, such as alginate and chitosan, appear to have the ideal implantation characteristics for use specifically in breast tissue regeneration; however, their low moduli often do not provide sufficient support for anchorage-dependent cells. Studies have been conducted using calcium alginate gels, as well as hyaluronic acid (HA) gels, where the interactions of preadipocytes with the gel material have been investigated.[3,4,27]

Additionally, the surface topography of the pores within a scaffold may be altered to influence cellular behavior. Pore size and shape has been shown to affect cellular attachment, by providing formed sites into which cells may grow. Scaffolds designed for adipose tissue engineering must have pores large enough so as not to inhibit the proliferation and differentiation of preadipocytes. As preadipocytes mature, they significantly increase in size because of an increase in cell number and an increase in volume associated with lipid formation.[6,36,39–41,43–45,47,125–127] Adequate sizing of pores is essential in scaffold design for adipose tissue engineering.

Biomaterials may be derived from natural or synthetic sources. Many natural and synthetic biomaterials have been researched to evaluate their potential use for engineering adipose tissue. The selection of a specific biomaterial for adipose tissue engineering will depend on the desired characteristics of the implant. **Table 2** presents a summary of the advantages and disadvantages associated with natural and synthetic biomaterials. Further discussion of specific natural and synthetic materials and their use in adipose tissue engineering is provided in the following text.

5.537.4.1. Natural Biomaterials

Natural polymeric biomaterials include collagen, gelatin, alginate, HA, and chitosan.[10,27,119,128] Natural materials are advantageous for use in tissue engineering because they are readily available and may be degraded by enzymatic activity. Additionally, natural materials are recognized by cells and are known to have high cell affinity. However, disadvantages when using natural materials are apparent. These materials have source variability, that is, they are derived from natural sources that can only be controlled to a limited extent, and they remodel relatively quickly and unpredictably *in vivo*. Natural materials have also been shown to elicit immunogenic reactions *in vivo*, which may limit their successful implantation.

5.537.4.1.1. Alginate

Alginate is a natural polysaccharide that is derived from brown seaweed and algae, and is commercially available as sodium salt or sodium alginate.[129] It is a copolymer made up of two monomer units: β-D-mannuronic acid (M blocks) and α-L-guluronic acid (G blocks) that are linked by a (1→4) glycosidic bond. The M and G blocks are arranged sequentially with either repeating or alternating blocks.[122,133] The amount and

Table 2 Comparison of natural and synthetic biomaterials

Natural materials	10,27,119,128,129
Advantages	
Readily available	
Degraded by enzymatic activity	
Recognized by cells leading to high cell affinity	
Disadvantages	
Source variability	
Remodeled quickly and unpredictably *in vivo*	
Synthetic materials	119,122,129–132
Advantages	
Controlled production, leading to controlled batches	
Ability to alter chemically and structurally to suit application	
Predictable degradation	
Disadvantages	
Cell affinity may be affected	
Biocompatibility	

distribution of each M or G block is dependent on the properties of the seaweed from which the alginate is derived. This distribution of M and G blocks also contributes to the mechanical properties of the alginate when it is gelled. Gelation of alginate occurs when a divalent cation, such as Ca^{2+}, Mg^{2+}, or Ba^{2+}, binds with the G blocks to form ion bridges between the polymer chains.[134] The degree of cross-linking correlates with the number of G blocks found in the molecule; the higher the content of G blocks, the stiffer the resulting gel.[135] The ability to manipulate the cross-linking density provides a means of controlling the mechanical and swelling properties of the alginate. Alginate has many uses in drug delivery, cell encapsulation, and in tissue engineering because it is biocompatible, low in toxicity, and relatively low in cost.[136] However, degradation of the gel is not directly controlled by enzymes. Rather, cross-linked chains are broken down upon the loss of divalent ions to the surrounding environment, and the smaller chains are then gradually carried from the body through normal kidney function.[137] Longer alginate chains are not degraded and released from the human body, as they are degraded by alginase, an enzyme not found in humans.[138] Also, because of the hydrophilic nature of alginate, protein adsorption is inhibited, thereby limiting the number of cells that will attach to and proliferate on alginate surfaces. It is for this reason that in many tissue engineering applications some form of surface modification is applied to promote cellular attachment.[27,118,139,140]

Indeed, alginate is a natural hydrogel material that is hydrophilic in nature, thereby discouraging the adsorption of proteins to its surface.[141] The inhibition of protein adsorption results in a diminished ability of anchorage-dependent cells to attach to the surfaces of the material.[27,118,134] Typically, for alginate hydrogels to support cell–surface interactions, the material is covalently modified by the addition of peptides, such as arginine, glycine, and aspartic acid (RGD), that create cell adhesion ligands to help the material support cell attachment.[27,117,118,134,139]

Early *in vivo* studies were performed by Loebsack and coworkers to determine the efficacy of using porous alginate beads coupled with RGD to stimulate the formation of adipose tissue within the subcutaneous space of rats. Long-term evaluation following 6 months of implantation showed that the porous alginate-RGD beads were biocompatible and did facilitate tissue ingrowth while remaining stable over time.[142]

Halberstadt and coworkers injected alginate-RGD fragments into the subcutaneous space of sheep necks to contrast the effect of chemically modified alginate versus unmodified alginate for adipose tissue engineering. Alginate-RGD fragments, approximately 500 μm in diameter, were seeded with sheep preadipocytes isolated from sheep omentum tissue. Following implantation for up to 3 months, it was found that the modifications to the alginate fragments did support cell adhesion and proliferation, resulting in adipose tissue formation in the sheep.[117]

Alginate scaffolds containing poly(lactide-*co*-glycolide) (PLG) microspheres loaded with basic fibroblast growth factor (bFGF) were evaluated for their ability to facilitate vascularization of implants for tissue engineering applications. Perets and coworkers showed that implantation of bFGF-releasing alginate–PLG composite scaffolds resulted in vasculature formation after only 5 days of implantation. Further evaluation of samples after 21 days *in vivo* revealed an increase in vasculature density over the course of time. The implantation of the bFGF-loaded microspheres within the alginate scaffold resulted in a controlled release of the bFGF that facilitated new vasculature formation.[143]

Modified forms of alginate gels have, therefore, been shown to remain stable over long periods of time *in vivo*, indicating that they may be useful for support scaffolds for adipose tissue engineering. Additionally, the ability to produce various shapes and forms of alginate scaffolds, that is, beads, thick gels, etc., may be advantageous in filling defects of various shapes and sizes. The use of alginate for adipose tissue engineering, however, appears limited by the apparent need to chemically modify the alginate surface for sufficient cellular attachment.

5.537.4.1.2. Chitosan

Chitosan is a natural biomaterial derived from the deacetylation of chitin (a copolymer of *N*-acetyl-glucosamine and *N*-glucosamine units linked by β(1→4) glycosidic bonds).[144–146] Behind cellulose, chitin is the second most abundant polysaccharide on earth and is typically found in the exoskeleton of crustaceans such as crabs and shrimp.[134,136,147] As a natural material, the source of chitin and derivation process used to obtain chitosan will result in products of varied molecular weight and degree of deacetylation (DD). Chitosan may range in molecular weight from 300 to more than 1000 kDa with DD values from 30 to 95%.[144,146] The degradation of chitosan, therefore, is based on the molecular weight and DD, where chitosan degradation of chitosan will decrease as the DD increases.[147] Chitosan is typically insoluble in water or basic pH environments, but is soluble in acidic environments. Degradation of chitosan *in vivo* occurs via lysozyme enzymatic activity and hydrolysis.

Chitosan has been widely investigated for biomedical applications such as wound healing, antimicrobial treatment of bacteria, and drug delivery.[146,148,149] The use of chitosan for biomedical applications is so extensive because it is readily available, cost-effective, biocompatible, biodegradable, and easily processed to form structures of varied shape and porosity.[145,149,150] As a result of these desirable attributes, chitosan

has been investigated for engineering skin, bone, cartilage, liver, nerve, and vascular tissues.[151–153]

Because of its low strength, chitosan is often blended with other materials such as alginate or HA to form scaffolds optimal for cellular attachment.[147] Chitosan has been combined with synthetic materials such as PLG to form fibrous scaffolds used for tissue engineering.[154] Additionally, chitosan–gelatin blends have been used to form films useful for additional biomedical applications.[155]

Wu and coworkers evaluated glutaraldehyde-cross-linked collagen–chitosan hydrogel scaffolds seeded with preadipocytes for adipose tissue engineering applications. Preadipocytes isolated from the epididymal fat pats of rats were shown to successfully attach and proliferate on the porous scaffolds *in vitro*. Further evaluation of the scaffolds was performed *in vivo* by implanting the preadipocyte-seeded scaffolds within the back musculature of Lewis rats for 7 and 14 days. Histological evaluation at the completion of the *in vivo* studies showed that animal tests proved that the scaffolds were biocompatible, induced vascularization, and formed adipose tissue.[156]

The use of chitosan for adipose tissue engineering has not been widely investigated by many researchers; however, great potential for chitosan in adipose tissue engineering applications exists. Chitosan is easily processed into scaffolds of various shapes and sizes. Fabrication of injectable microspheres that would be well suited for minimally invasive applications, such as those where adipose tissue engineering would be useful, has been reported by several researchers.[153,157] Preliminary evaluation of chitosan–gelatin beads for adipose tissue engineering, Yang and coworkers (Clemson University, unpublished data), has shown that chitosan–gelatin beads not only support the attachment and proliferation of adipose cells, but also facilitate the differentiation of preadipocytes to mature adipocytes *in vitro*. As shown in **Figure 2**, intracellular lipid droplets, characteristic of mature adipocytes, were observed from Oil Red O staining of cells bovine cells grown on chitosan–gelatin beads, following 21 days of culture *in vitro*. The ease of combining growth factors and therapeutics within chitosan may potentially provide scaffolds that will facilitate adipose cell attachment and differentiation to mature fat cells to form new tissue *in vivo*.

5.537.4.1.3. Collagen and gelatin

Collagen, the most abundant protein in the human body, has been widely regarded and used in tissue engineering strategies. As the major protein component of ECM, it is a major component of many bodily tissues, including bone, tendons, skin, and cartilage. Additionally, it provides the structural framework of tissues such as blood vessels and adipose tissue.[129,140,145,152] Numerous forms of collagen exist; however, type I is the most abundant and therefore the most widely used. Properties of collagen, such as its biocompatibility, its ability to degrade enzymatically, its ability to be processed into a variety of shapes and forms (sheets, sponges, injectable microspheres, etc.), and its ability to have tailored degradation and mechanical properties (due to cross-linking), have contributed to its wide use in tissue engineering applications. However, because collagen is often derived from animal tissues, specifically, bovine and porcine bone, skin, or tendon, concerns regarding its use have been raised. Additionally, collagen is quickly remodeled and, as a stand-alone scaffold, does not have the long-term mechanical integrity necessary to guide the formation of new tissue.

Gelatin, another natural biomaterial used in tissue engineering, is derived from denatured collagen proteins; the denaturation occurs as a result of processing collagen with acid thermal modification. Like collagen, gelatin is widely used because of its biodegradability and biocompatibility. Its denatured state results in relatively low antigenicity as compared to collagen of animal origin.[152] Gelatin scaffolds of various shapes are widely used in tissue engineering applications, particularly because gelatin has been shown to support cell attachment and proliferation.

Collagen sponges and meshes seeded with human preadipocytes were evaluated, by von Heimburg and coworkers, *in vitro* and *in vivo* to evaluate their utility for adipose tissue engineering.[127,158] Evaluation of the collagen scaffolds within nude mice showed that these porous structures support cellular ingrowth and matrix synthesis; however, high numbers of cells seeded onto the scaffolds are required for significant adipose tissue growth.[116,127,158]

Composite collagen scaffolds made of collagen fibers embedded within collagen gels have also been evaluated for use in adipose tissue engineering. Gentleman and coworkers incorporated short collagen fibers within collagen gels to minimize contraction of the gels, once cultured *in vitro* with cells, and to maintain the ability of nutrients to be transported throughout the gels.[159] Evaluation of the composite collagen scaffolds seeded with preadipocytes for 21 days *in vitro* showed that incorporation of fibers within the gels aided in maintaining the structural integrity of the gel, which in turn facilitated growth of viable cells throughout the gel. The preadipocytes

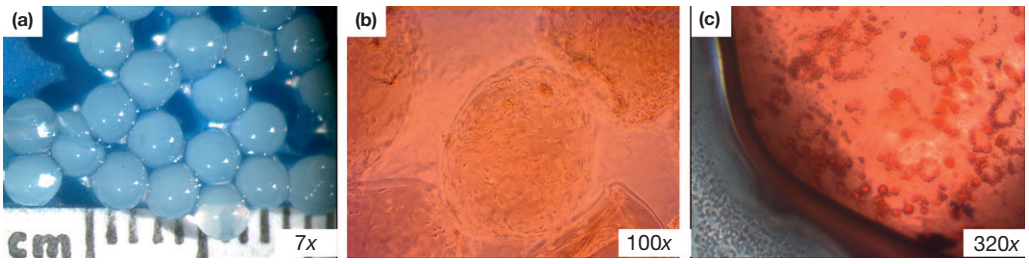

Figure 2 (a) Stereomicroscopic image of chitosan–gelatin beads. (b) Primary bovine preadipocytes seeded on chitosan–gelatin beads. (c) Oil Red O staining of primary bovine adipose cells, on the surface of chitosan–gelatin beads, showed the presence of intracellular lipid droplets characteristic of mature adipocytes following differentiation for 21 days. Images B and C courtesy of Dr. Chih-Chao Yang of the Institute for Biological Interfaces of Engineering at Clemson University.

were able to differentiate, as indicated by the lipid present within the gels. Composite collagen scaffolds, therefore, are potentially useful for maintaining implant shape while encouraging adipose tissue formation.[159]

Gelatin sponges have been used for culturing both preadipocytes and human mesenchymal stem cells (MSCs) for soft tissue engineering purposes.[127,158,160] Additionally, microspheres made of gelatin have been widely used for adipose tissue engineering. Masuda and coworkers evaluated photocured styrenated gelatin microspheres (SGMs) loaded with bFGF and insulin growth factor-1 (IGF-1) to stimulate angiogenesis and adipogenesis simultaneously. Implantation of the microspheres within Wistar rats resulted in new adipose tissue formation with associated vasculature; however, further evaluation of the system is needed to determine optimal concentrations of each growth factor to include in the system.[161–163]

Investigators have also studied collagen–gelatin combination scaffolds for adipose tissue engineering, including gelatin microspheres loaded with FGF and embedded within collagen gels or collagen sponges. Vashi and coworkers showed that collagen gels containing FGF-gelatin microspheres facilitated the formation of mature, vascularized adipose tissue after implantation in mice for 6 weeks.[164] Meanwhile, Hiraoka and coworkers and Kimura and coworkers demonstrated the ability to generate adipose tissue *in vivo* using scaffolds made of gelatin microspheres loaded with FGF, embedded within collagen sponges, and seeded with rat and human preadipocytes, respectively.[165–167]

Gelatin microcarriers have also been used for evaluating large animal models for adipose tissue engineering. Primary adipose cells isolated from fresh bovine tissue samples were seeded on gelatin microspheres by Gomillion and coworkers, as shown in **Figure 3**. Following implantation of the gelatin microspheres into Holstein heifers, histological evaluation showed that the gelatin microcarriers elicited a minimal inflammatory response while allowing tissue ingrowth. The formation of new adipose tissue deposits was not observed; however, the microcarriers were shown to be biocompatible within a bovine animal model.[168]

Like other natural biomaterials, chitosan and gelatin may be used to fabricate scaffolds of various shapes and sizes that may be useful for adipose tissue engineering applications. Studies to date evaluating collagen and gelatin scaffolds for adipose tissue engineering have yielded various methods that result in new adipose tissue formation. These methods, however, have not yet been successfully implemented to create larger volumes of adipose tissue.

5.537.4.1.4. Fibrin

Fibrin is the insoluble protein matrix formed by fibrinogen that plays a major role in blood clotting and wound repair. Fibrin glue is widely used clinically, and has proved useful as a cell delivery matrix for tissue engineering when combined with other biodegradable materials.[145] Additionally, fibrin gels have been used in tissue engineering applications, the structure of which is influenced by the concentration of fibrinogen along with pH and other factors.[152] Fibrin gel matrix alone has been shown to have poor mechanical properties and is unable to withstand forces produced during adipose tissue formation; however, the use of fibrin gel as a delivery medium for *in vivo* implantation of preadipocytes with related growth factors has proved sufficient for injectable delivery of adipose cells.[169,170]

5.537.4.1.5. Hyaluronic acid

HA, or hyaluronan, is a natural polysaccharide biomaterial commonly found in connective tissues such as articular cartilage, synovial fluid, and the umbilical cord.[152] This material can be derived from rooster combs and can be fabricated into a variety of shapes, including membranes, fibers, sponges, and microspheres.[129,140] The chemical structure of HA consists of disaccharide units of D-glucuronic acid and *N*-acetyl-D-glucosamine; it is water-soluble and forms viscous solutions.[171] As a biomaterial, HA is known to aid in tissue repair by promoting mesenchymal and epithelial cell migration, thus enhancing collagen deposition and angiogenesis.[116,129] Commercially available forms of HA, such as Restylane® and Juvederm®, are FDA-approved products used cosmetically as dermal fillers for wrinkle and other contour defects within soft tissue.[172–174] These injectable forms of HA-based materials are widely used because they provide similar structural and mechanical properties as natural soft tissue.[174]

For adipose tissue engineering applications, the angiogenesis-promoting characteristic of HA has proved very advantageous. Researchers, von Heimburg and coworkers, evaluated preadipocyte-seeded HA sponges or nonwoven carriers implanted in nude mice and found that pore size influenced the development of adipose tissue; increased vascularization was observed in larger-pore constructs, while greater adipose differentiation was observed with smaller pore constructs.[36,116,127] HA gels seeded with preadipocytes were also tested within pigs, resulting in the formation of mature adipocytes and blood vessels within the gel; however, only a minimal volume of tissue was produced that was not entirely stable following 6 weeks of implantation.[116]

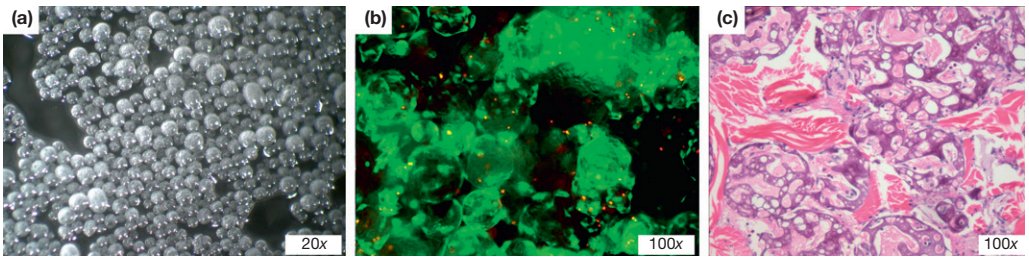

Figure 3 (a) Stereomicroscopic image of gelatin microspheres. (b) Results of LIVE/DEAD cell viability assay show viable primary bovine adipose cells (green) attached to the surface of the gelatin microspheres. (c) Following implantation within a bovine animal model to assess biocompatibility, histological analysis shows that the gelatin microcarriers elicit a minimal inflammatory response and allow ingrowth of collagen.

5.537.4.1.6. Matrigel™

Matrigel™ is a reconstituted basement membrane derived from extracts of Engelbreth-Holm-Swarm mouse tumors.[175] The basement membrane is structurally a thin layer of ECM sheets that consist primarily of collagen type IV, entactin, perlecan (heparan sulfate proteoglycan), and laminin. This laminin-rich mixture of Matrigel™ closely resembles the complex extracellular environment of the basement membrane and is used for cell-culturing model systems, particularly for evaluating angiogenesis and cellular differentiation.[175,176] Matrigel™ has been commercially available for licensing through the National Institutes of Health Technology Transfer Office since 1984 and has been used for cellular applications since that time.[175]

Matrigel™ has been evaluated for adipose tissue engineering applications. Early studies performed by Kawaguchi and coworkers evaluated injections of Matrigel™ with bFGF, both with and without preadipocyte cells, in a nude mouse model. Adipose tissue formation was observed not only within the cellular samples, but also within the samples containing only bFGF and Matrigel™. After comparison of all study samples, Kawaguchi and coworkers concluded that the combination of Matrigel™ with bFGF induced neovascularization, which in turn recruited adipose precursor cells to the implant site, which ultimately differentiated to form new adipose tissue.[177]

Additional studies to evaluate the ability of Matrigel™ to facilitate *de novo* adipogenesis were conducted by Tabata and coworkers. Gelatin microspheres loaded with bFGF were incorporated into Matrigel™ scaffolds to control the release of the bFGF *in vivo*. Evaluation within a nude mouse model showed that increased release of bFGF resulted in more adipose tissue formation; however, high levels of bFGF resulted in fibrous tissue formation caused by rapidly growing vasculature.[166,178] Characterization of cells that migrated into the Matrigel™ upon implantation showed that adipocyte precursors readily migrated into gels formed by Matrigel™, further suggesting that the ECM components, laminin and collagen type IV, found in Matrigel™, may play key roles in adipose tissue formation.[163]

Because it is derived from a tumor cell model, the exact components of Matrigel™ are not consistent or well defined. While neovascularization and adipose tissue formation are induced with Matrigel™ based implants,[29,179] use of Matrigel™ scaffolds within recovering cancer patients may not be recommended. Additionally, the use of Matrigel™ within humans will likely not be biocompatible due to its tumor cell origins. These facts should be taken into consideration before selection of Matrigel™ for adipose tissue engineering strategies. Perhaps, a more ideal solution would be to consider incorporation of the Matrigel™ components, laminin and collagen type IV, which have been hypothesized to play roles in adipogenesis, into scaffolding materials for engineering new adipose tissue,[180] or to derive new basement membrane gels from normal tissues such as tendon.[181]

5.537.4.1.7. Other naturally derived materials

Researchers have evaluated the potential of other naturally derived materials as scaffolds for adipose tissue engineering. In a study conducted by Masuda and coworkers, fragments of omentum tissue combined with rat preadipocytes were evaluated within a Wistar rat model. The omentum is a highly vascularized, fat-filled tissue extending from the stomach to below the colon and small intestine. Characterization of the omentum tissue shows that it possesses microvascular endothelial cells and produces significant amounts of vascular endothelial growth factor (VEGF). Implantation of the fragmented omentum with preadipocytes within rats for up to 3 months resulted in formation of adipose tissue masses with high triacylglycerol content. The outcome was thought to be attributed to the long-standing presence of VEGF from the omentum tissue that was instrumental in neovascularization and, ultimately, adipose tissue formation.[161,162]

An alternate method for adipose tissue engineering was investigated by Flynn and coworkers. Scaffolds made of placental decellular matrix (PDM) and cross-linked with hyaluronan were formed and evaluated for adipogenic potential. Human placental tissue was decellularized and primary ADSCs were either encapsulated within the PDM or seeded on the surface of the PDM that was then cross-linked with HA. *In vitro* evaluation of the scaffolds after 14 days of culture showed differentiating adipose cells within each scaffold; however, further analysis of these scaffolds is needed to more fully assess their potential in adipose tissue engineering.[182,183] Similarly, preliminary assessment of tendon-derived basement membrane material suggests potential use for this biomaterial in adipose tissue engineering.[181]

Additional adipose tissue engineering methods using scaffolds based on adipose tissue ECM have been investigated. Vermette and coworkers conducted a study to evaluate the potential of adipose-derived stromal cells to 'self-assemble' in the presence of ascorbic acid, forming their own ECM and ultimately forming sheets of all natural adipose tissue that produced lipid and expressed detectable quantities of leptin.[184]

Finally, more recent studies have evaluated the use of injectable ECM powders produced from fat tissue as scaffolding material for adipose tissue engineering. As shown in **Figure 4**, human adipose tissue obtained from liposuction patients was washed and processed until a gel-like suspension was formed. The suspension was then frozen, freeze-dried, and crushed to form ECM powders. *In vitro* evaluation of the adipose tissue ECM powders with human ADSCs showed that cells readily adhered to and proliferated on the ECM powder scaffolds. *In vivo* evaluation of the cellular ECM powders within a nude mouse model showed that the ECM powders supported adipogenesis when implanted with and without cells.[185]

5.537.4.2. Synthetic Biomaterials

Synthetic materials, such as poly(lactide) (PL), PG, and various copolymers, are also widely used in tissue engineering. For select applications, synthetic polymers can offer greater advantages than naturally occurring materials. Synthetic polymers can be produced under controlled conditions, which results in a uniform batch of material that may be altered chemically and structurally to suit a specific application. This reduction in variability also allows predictable degradation of synthetic materials, unlike their natural material counterparts.[10,119,130,132] Synthetic polymers may be modified to have high mechanical integrity, and they can also be produced in a variety of shapes, including meshes, sponges, films, and microparticles.[10]

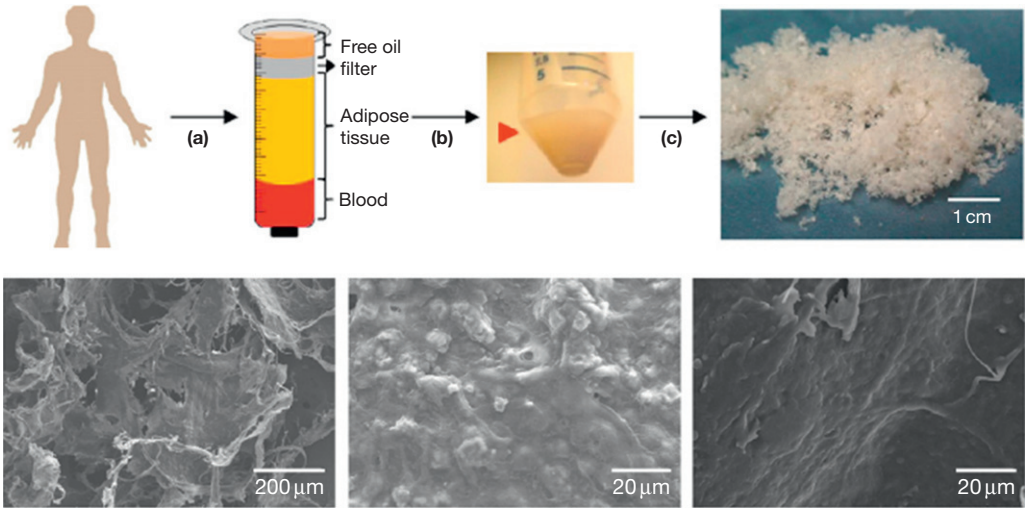

Figure 4 Injectable human ECM powders were prepared by Choi and coworkers from liposuction tissue (a) that was washed to separate blood and oil (b), then processed to form a gel-like suspension (c) that was freeze-dried to form the extracellular matrix powders. Scanning electron micrograph images show the resulting texture of the extracellular matrix powders. Reprinted from Choi, J. S.; Yang, H. J.; *et al. J. Control. Release* **2009**, *139*(1), 2–7, with permission from Elsevier.

5.537.4.2.1. Biodegradable polymers

Synthetic biodegradable polymers comprise a category of biomaterials that are widely used in tissue engineering applications. Uniform batches of materials that can be altered chemically and structurally may be produced under controlled conditions, specific to the application. Minimal batch variation allows predictable degradation of synthetic materials, unlike their natural material counterparts.[10,119,130,132] A variety of shapes, including meshes, sponges, films, disks, and microparticles, may be formed using these polymers.[10] The most commonly used polymers for adipose tissue engineering include PG and PLG, a copolymer of PG and PL.

PLG disks and foam scaffolds seeded with preadipocytes were used by Patrick and coworkers for *in vivo* implantation into rats. Mature fat cells with newly forming blood vessels were initially observed at early time points (2–5 weeks); however, longer implantation resulted in scaffold degradation with simultaneous tissue resorption.[1,186,187] In an effort to produce volume-stable adipose tissues, Cho and coworkers used a combination of PLG with fibrin matrix. Preadipocyte cells suspended in the fibrin matrix were injected into a dome-shaped PLG support placed within a subcutaneous pocket in nude mice. Over a 6-week period, adipose tissue of a stable volume was formed.[188] When PG meshes seeded with preadipocytes were used by Fischbach and coworkers, minimal cell spreading was observed and no adipose tissue was formed; however, the PG meshes, when used in 3D culture with preadipocytes, facilitated the production of viable adipose tissue.[48]

Injectable microspheres made of PLG were formed by Choi and coworkers and evaluated for adipose tissue engineering. Primary rabbit MSCs were seeded on PLG microspheres and implanted into nude mice. *In vivo* evaluation showed new adipose tissue formation when microspheres were seeded with rabbit MSCs that were differentiated with adipogenic medium before implantation.[189] Further analysis by Choi and coworkers evaluating the PLG microspheres seeded with human ADSCs, similarly showed new adipose tissue formation when implanted in nude mice.[190]

Another synthetic material that has been used for adipose tissue engineering strategies is poly(ethylene glycol) (PEG). Microspheres made of a PLG/PEG mixture were loaded with insulin and IGF-1, factors known to influence adipogenesis. The inclusion of PEG was shown to lead to the formation of microchannels on the surface of the microspheres. Following implantation for 4 weeks within a rat model, it was shown that deposits of adipose tissue formed within the samples of microspheres loaded with insulin, IGF-1, and the combination of insulin and IGF-1, but not within the plain microspheres. The release of the insulin and IGF-1 facilitated the recruitment of cells that formed new adipose tissue.[191]

Photopolymerizable PEG hydrogel systems were also evaluated by Patel and coworkers. Degradable and nondegradable forms of PEG hydrogels, with and without cell adhesion ligands, were produced and seeded with preadipocytes isolated from the epididymal fat pads of rats. *In vitro* analysis of cell adhesion and cell viability showed that preadipocytes readily attached to the PEG hydrogels with the cell adhesion ligand incorporated; cells, however, did not proliferate on the nondegradable hydrogels. Degradable PEG hydrogels with incorporated cell adhesion ligands proved most optimal for potential adipose tissue engineering applications.[192]

More recently, Stacey and coworkers evaluated diacrylated PEG (PEG-DA) and methacrylated HA (HA-MA) for potential use in providing an adipogenic culturing environment. Preadipocytes or freshly isolated adipocytes were encapsulated in PEG-DA and HA-MA scaffolds and cultured *in vitro* at specified conditions for up to 16 days. Adipogenesis was assessed by comparing levels of adipogenic-specific factors expressed by the cells in PEG-DA, HA-MA, and in 2D culture. Analysis at the completion of the study showed that the PEG-based scaffolds supported the greatest adipogenic differentiation. Further analysis of the system, however, is needed.[193]

5.537.5. Future Outlook

Efforts to engineer autologous adipose tissue have been widely researched for more than 10 years, and yet there still is not one method that has been implemented into clinical practice that yields volume-stable quantities of adipose tissue *in vivo*. While many strategies have been investigated, their success has been limited because of their inability to

- Maintain cell and tissue viability for long-term implantation
- Maintain implanted cell capacity to differentiate *in vivo*
- Facilitate neovascularization or angiogenesis for implants
- Treat large volume defects

With the current difficulties and limitations, the future for adipose tissue engineering is filled with great opportunity for novel ideas to address these problems. As several of the limitations surrounding adipose tissue engineering success stem from the cell basis used in these strategies, further investigation of the factors affecting adipogenesis and fat cell differentiation is required. Numerous factors have been shown to inhibit or enhance adipogenesis; therefore, fully understanding the key regulatory factors of adipogenesis and being able to use these factors to control adipogenesis could be significantly useful. The control of adipogenesis could potentially be accomplished using specific cell–cell interactions or culture medium additives specific for adipose development.[194] In developing successful adipose tissue engineering strategies, combination or composite devices may also be useful. Growth factors and fat differentiation inducing components could potentially be incorporated into scaffold materials and used to enhance the overall effectiveness of engineered adipose tissue implants. In conclusion, the relationship between cellular components and biomaterials plays a significant role in the efficacy of adipose tissue engineering strategies. Not until the appropriate combination of cellular and biomaterial components is found will a successful method for clinically engineering adipose tissue exist.

5.538.1. Introduction

In 1999, we began to explore the feasibility of phalangeal regeneration. A copolymer of biodegradable polyglycolic acid (PGA) and polylactic acid (PLLA) was shaped into a human phalanx with a periosteum wrapped around it. PGA sheets seeded with chondrocytes were subsequently attached to both ends of the phalanx for the regeneration of a phalanx with joint cartilage *in vivo*.[1] In this human phalanx model, however, the three-dimensional (3D) morphological characteristics of the human phalanx were not maintained, indicating that a copolymer of PGA and PLLA was an inadequate material for our purposes.[2–5]

To overcome this drawback, attention was directed to Poly(L-lactide-ε-caprolactone) (P(LA-CL)), a copolymer of PLLA and polycaprolactone.[6,7] P(LA-CL) is known to be a readily moldable and biodegradable copolymer with characteristics adequate for tissue regeneration.[8,9] The 3D morphology has been reported to be maintained over a long period when P(LA-CL) is used for the induction of cartilage tissue.[10] Furthermore, we developed a new osteoinductive biodegradable copolymer with improved mechanical strength and bone conduction capacity by incorporating hydroxyapatite (HA) particles[11] into the internal structure of P(LA-CL).

In this chapter, we describe our renewed attempts at phalangeal regeneration by applying an osteoinductive biodegradable 3D copolymer of P(LA-CL) with HA particles, shaped into a human phalanx. By combining a high-performance biodegradable copolymer with periosteum, we sought to achieve a better induction of phalangeal regeneration. Maintenance of joint cartilage after cartilage formation is functionally important. Periosteum has been suggested to play an important role in the regulation of joint cartilage, although the mechanism is not precisely known. An analytical study of the interaction between the periosteum and the joint cartilage in our model was undertaken. Periosteum was attached circumferentially around one half of a phalanx-molded biodegradable copolymer and the regenerative ability of bone between the periosteal and nonperiosteal sides was compared with respect to tissue-forming properties and 3D-maintained shape. Thus, our study was designed from both functional (human phalanx shape) and analytical

viewpoints. A basic knowledge and understanding of the developmental processes that occur in phalangeal regeneration are clearly necessary for future clinical applications.

5.538.2. Periosteum for Human Phalanx Model

The periosteum is known to have three roles: (1) a source of osteocytes/chondrocytes that differentiate from pluripotent undifferentiated mesenchymal cells, (2) a scaffold for the proliferation of osteocytes/chondrocytes, and (3) a source of growth factors.[12]

Histologically, the periosteum consists of a superficial thick fibrous layer and a deep thin cambium layer. In the cambium layer, a large number of osteoblasts (pleuripotent undifferentiated mesenchymal cells), which stain eosinophilically with toluidine blue, are present, and they differentiate into osteocytes and chondrocytes. The periosteum is involved in bone growth (appositional growth) through the proliferation and differentiation of osteoblasts, and increases bone thickness and strength.[13] Also, the thickness of the cambium layer and the number of cells in it are known to markedly reduce with age, with decreases in the capacity for bone growth.[12,14]

Recently, more detailed research has been conducted on the periosteum, and the structure of the periosteum has been reported to differ as regards the diaphysis and the metaphysis. The metaphysial periosteum has a thick cambium layer with a large number of cells in it, and shows no structural changes associated with aging. The diaphysial periosteum, on the other hand, is thinner than the metaphysial periosteum, and both the thickness of the cambium layer and the number of cells in it have been reported to decrease markedly with age.[15]

5.538.3. *In Vivo* Model for Phalanx

5.538.3.1. Biomaterials

P(LA-CL) was prepared by infusing a polymer solution (5% (w/w); 1,4-diaxane and P(LA-CL) mixed at 75:25) into casts prepared in advance from a human phalangeal specimen (17 mm long, 7 mm wide, and 5 mm high) using a pipette to avoid foam formation, and then mixed with HA particles of about 30 μm diameter (70:30 wt%). The casts into which each polymer was infused were transferred to a refrigerator and allowed to stand for 2 h at −40 °C. The polymers were removed from the casts and freeze-dried at 40 Pa and −40 °C over 12 h (TF10-80ATA, Takara Seisakusho, Tokyo). Finally, the monomers and the vehicle were removed by vacuum drying (60 °C, 12 h), and osteoinductive biodegradable 3D copolymer with the shape of a human phalanx was obtained. The prepared P(LA-CL) had a molecular weight of 367 000, an interior with a spongy structure, a pore size of 50–100 μm, and a porosity of 95%. It was biodegraded in 4–6 months *in vivo*. HA particles were incorporated into the spongy structure of P(LA-CL).

5.538.3.2. Techniques for Fabrication

5.538.3.2.1. Preparation of the phalanx

Fresh periosteum was elevated from the radial diaphysis of a calf (within 1 month after birth) using a periosteum elevator and collected. The collected periosteum was wrapped circumferentially around one half of a biodegradable copolymer molded after the human phalanx and fixed by suturing with an absorbable thread (5-0 Vicryl®, Ethicon, Somerville, NJ, USA). In suturing, the cambium layer was brought into direct contact with the copolymer surface to allow osteoblasts and undifferentiated cells released from the cambium layer to migrate into the copolymer. To the prepared periosteum–copolymer complex, a modified M199 culture medium (Gibco, Grand Island, NY, USA) supplemented in advance with 10% fetal bovine serum (FBS, Sigma-Aldrich, St. Louis, MO, USA), 50 μg ml^{-1} ascorbic acid, 100 units ml^{-1} penicillin G, 100 μg ml^{-1} streptomycin, and 0.25 μg ml^{-1} amphotericin B was added, and the complex was incubated at 37 °C and in 5% CO_2 for 6 days (**Figure 1**).

5.538.3.2.2. Preparation of the joint cartilage

Cartilaginous tissue was collected from the shoulder joint of a calf using a #10 scalpel according to the method of Klagsbrun.[16] After the collected tissue was minced into 5 × 5-mm fragments, it was treated with 0.3% collagenase type II (Worthington Biochemical, Freehold, NJ, USA) at 37 °C for 14 h. The mixture was filtered through a nylon mesh (pore size: 300 μm), and the enzyme reaction was stopped by adding a modified F12 culture medium (Gibco, Grand Island, NY, USA) supplemented with 10% FBS, 50 μg ml^{-1} ascorbic acid, 100 units ml^{-1} penicillin G, 100 μg ml^{-1} streptomycin, and 0.25 μg ml^{-1} amphotericin B. The chondrocyte suspension obtained was washed three times with Ca^{2+}- and Mg^{2+}-free phosphate buffer (PBS, Mediatech INC, Herndon, VA, USA) and centrifuged (4 °C, 400 G, 10 min). To this chondrocyte suspension, the modified F12 culture medium was added, the cell concentration was adjusted to 100 × 10^6 cells ml^{-1}, and the cell suspension seeded on PGA (Gunze Co., Ltd., Kyoto; Size: 10 × 10 × 2 mm). The cell–polymer complex was placed in an incubator (37 °C, 5% CO_2) and allowed to stand for 4 h to have the seeded cells adhere to the polymer surface. Then, the modified F12 culture medium was gently added, and the suspension was placed again in the incubator (37 °C, 5% CO_2) for 5 days.

5.538.3.2.3. Preparation of the human phalanx model in vitro

The chondrocyte–polymer complexes were sutured to both ends of the periosteum–copolymer complex using an absorbable thread. The human phalanx model thus prepared was incubated in the modified M199 culture medium at 37 °C in 5% CO_2 for 24 h.

5.538.3.2.4. In vivo *implantation of the human phalanx model*

As preanesthetic medications, atropine sulfate (0.04 mg kg^{-1}, atropine sulfate; Phoenix Scientific Inc., MO, USA) and tolbutamide (3 mg kg^{-1}, trobugesic N; Dodge Animal Health, IW, USA) were administered to the nude mice by subcutaneous injection. Under general anesthesia with isoflurane (Pittman and Moores, Mundelein, IL, USA), the backs of the nude mice were disinfected with povidone iodine (The Purdue Frederick Company, Stamford, CT, USA), and a skin incision about 2 cm long was made. A human phalanx model was inserted into the subcutaneous pocket, which was closed by suturing with a 5-0 nylon suture (Sigma, Tokyo).

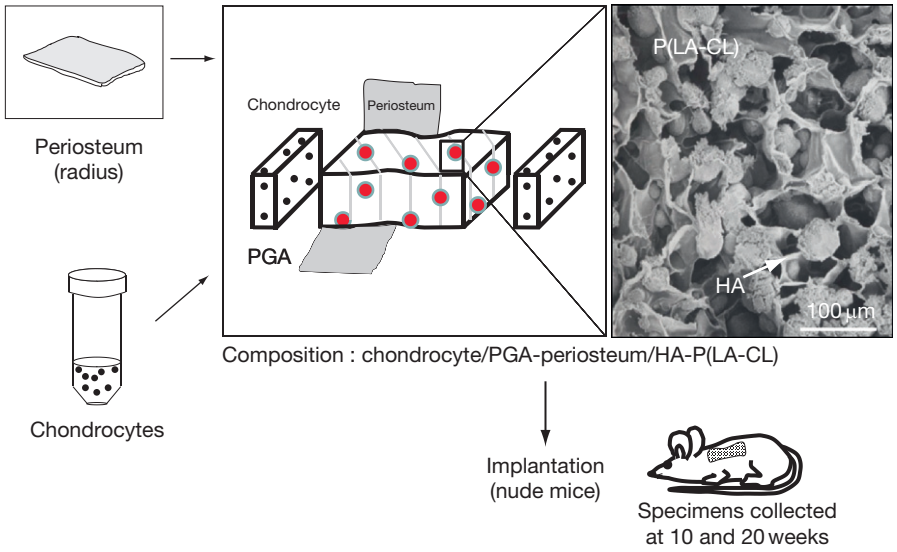

Figure 1 Experimental protocol.

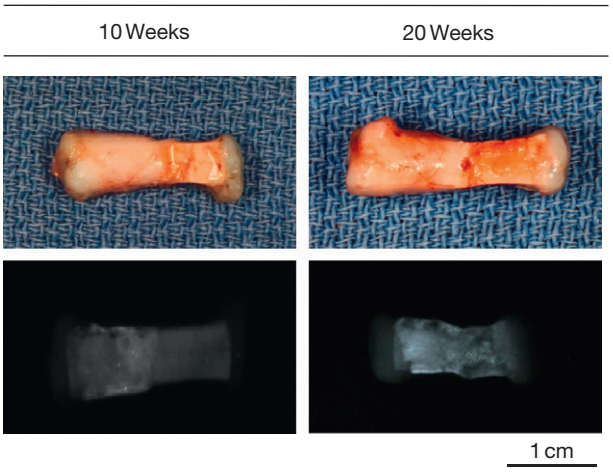

Figure 2 Gross morphology and X-ray. Calcification extending to the interior of the phalanx (10 weeks after implantation) and to the nonperiosteal side (20 weeks after implantation) was noted (bar = 1 cm).

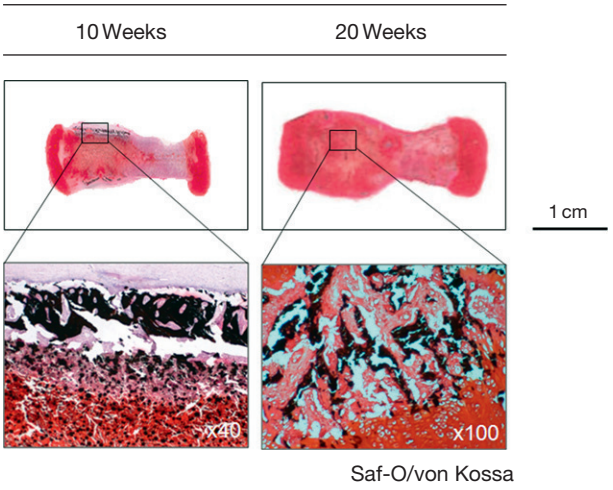

Figure 3 Histology of the human phalangeal models. Samples are from 10 to 20 weeks after implantation. Safranin-O and von Kossa staining (bar = 1 cm).

5.538.4. Development of the Human Phalanx Model

5.538.4.1. Gross Morphology

In the human phalanx models excised at 10 and 20 weeks after implantation, the phalangeal part to which the periosteum was attached (periosteal side) and the part to which it was not attached (nonperiosteal side) could be clearly distinguished by the presence or absence of white periosteum (Figure 2). On the periosteal side, the 3D structure of the phalanx was retained. On the nonperiosteal side, however, areas around the copolymer were slightly reddened and downsized. Significant elongation of the phalanx with time after implantation was noted, and it was more notable on the periosteal side. Joint cartilage was observed to be smooth, white, flexible, and markedly glossy at both ends of the periosteal and nonperiosteal sides of the samples removed 10 and 20 weeks after implantation. These findings suggest that satisfactory bone formation was induced by osteogenic cells that migrated from the periosteum into the interior of the copolymer on the periosteal side of HA-P(LA-CL), but adjacent blood vessels directly infiltrated into the interior of the copolymer and caused marked degradation and absorption of the copolymer on the nonperiosteal side.

5.538.4.2. X-Ray Findings

No clear calcification was noted on the nonperiosteal side after 10 weeks of implantation. On the periosteal side, an area of calcification extending to the interior of the phalanx could be noted after just 10 weeks, and radiopacity due to calcification decreased further and also extended to the nonperiosteal side after 20 weeks. These results suggest the high osteoinductive property of the copolymer with periosteum (Figure 2).

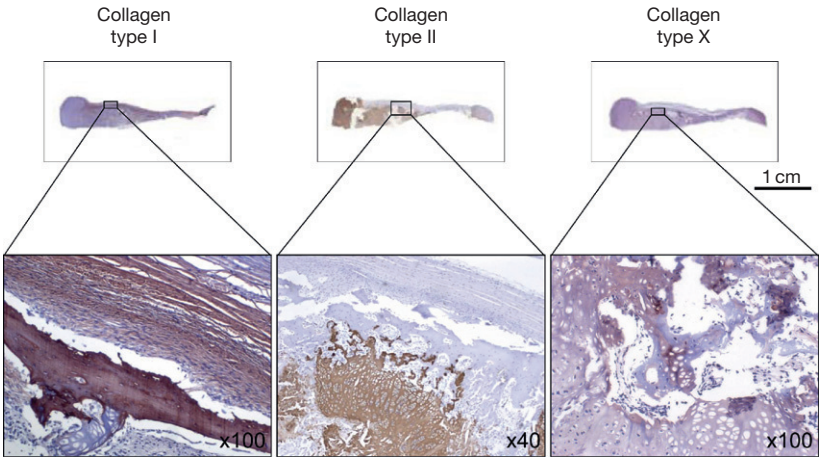

Figure 4 Immunohistochemistry to examine the mechanism of ossification. (Above) Cross-section (staining for type I, II, and X collagen, bar = 1 cm). (Below) Periosteal side (staining for type I collagen; × 100, staining for type II collagen; × 40, staining for type X collagen; × 100). Positive areas were observed below the periosteum for type I, and within the phalanx for type II. Areas stained for type X collagen were observed between the area stained for type I collagen and the area stained for type II collagen at 20 weeks after implantation.

5.538.4.3. Histology

In the groups of the human phalanx model excised 10 and 20 weeks after implantation, calcified areas that reacted positively with von Kossa staining were observed on the side to which the periosteum was attached (periosteal side). Positive areas were localized under the periosteum after 10 weeks, but extended to the interior of the phalanx after 20 weeks. On the nonperiosteal side, no area with positive reaction was noted. The periosteal sides showed intense positive responses to safranin-O over a wide area of the interior of the phalanx model at 20 weeks after implantation, indicative of proteoglycan in large amounts. These results suggest that calcified areas are initially localized under the periosteum but widen over the interior of the phalanx with time. Joint cartilages were positively stained for safranin-O staining at 10 and 20 weeks after implantation at both ends of the model (Figure 3).

5.538.5. Assessment of the Human Phalanx Model

5.538.5.1. Mechanism of Ossification

In order to examine the mechanism of ossification, immunostaining for type I, II, and X collagen was performed at 20 weeks after implantation. On the periosteal side, in particular, areas positive for immunostaining for type I collagen were localized under the periosteum, in which the trabeculae were formed. In the deeper areas of the trabeculae, large round chondrocytes were regularly arranged in a columnar pattern. This region corresponded to the area positive for type II collagen immunostaining. Areas positive for type X collagen were observed in the hypertrophic chondrocyte layer. This corresponded to the area between the type I collagen-positive and type II collagen-positive areas (Figure 4). These results suggest that bone formation occurs by endochondral ossification. On the nonperiosteal side, no area positive on immunostaining for type I, II, or X collagen was noted.

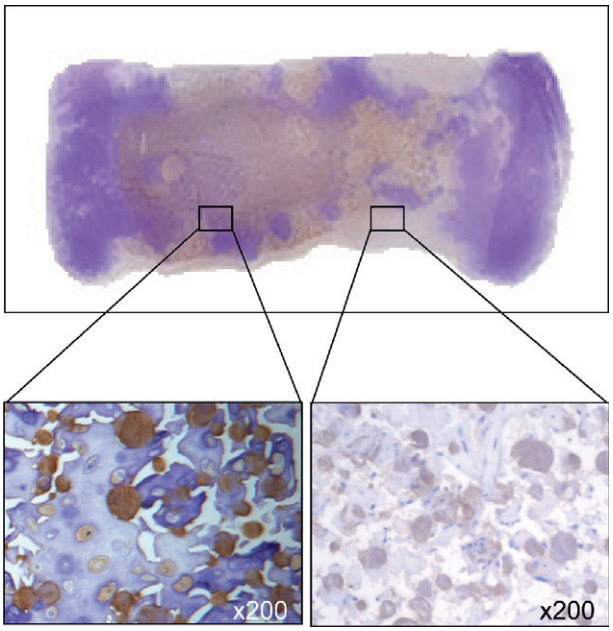

Figure 5 Immunohistochemistry to examine osteogenic capability of the copolymer. (Above) Cross-section (BSP staining). (Below) Periosteal and nonperiosteal parts (BSP staining, × 200). Bone sialoprotein (BSP) was performed to examine osteogenic capacity. An area positive for BSP that extended from the periosteal to the nonperiosteal side was markedly shifted to the nonperiosteal side at 20 weeks after implantation.

5.538.5.2. Osteogenic Capability of the Copolymer

Bone sialoprotein (BSP) has a molecular weight of 70 000–80 000 and is a protein almost specific to bone. It is synthesized by osteoblasts, promotes the adhesion of osteoblasts and osteoclasts to the matrix by the RGD (Arg-Glu-Asp) cell adhesion sequence, is adsorbed on the surface of HA by the continuous sequence of glutamic acid, and forms

plate-like HA.[17,18] According to recent reports,[19,20] BSP is considered to be distributed in newly formed osteoid, interact with collagen fibers of initial osteoid, and thus play an important role in the initial stage of bone formation. BSP also binds with calcium and HA and shows a marked bone-forming capability.[21]

On immunostaining for BSP, positive areas were observed over the entire side of the phalanx to which the periosteum was attached (periosteal side). On the side to which no periosteum was attached (nonperiosteal side), no area positive for BSP was noted. Moreover, BSP-positive areas extended from the periosteal to the nonperiosteal side, and the border between the positive and negative areas was markedly shifted to the nonperiosteal side (Figure 5). These results suggest that the expression of BSP is markedly promoted by the combination of the osteoinductive biodegradable 3D copolymer with periosteum.

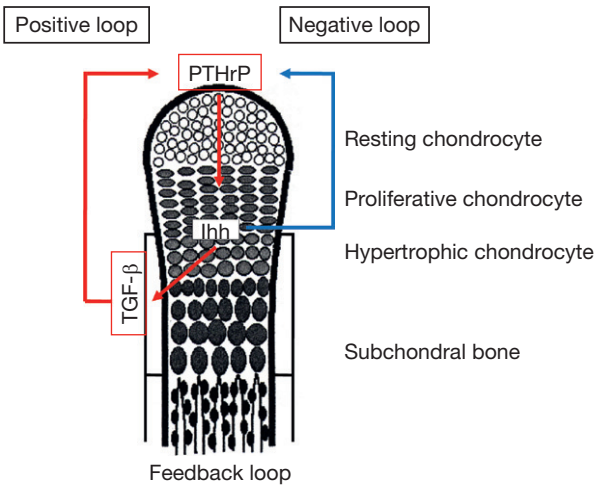

Figure 6 Signal pathway between periosteum and joint cartilage. Modified from Kronenberg, H. M. *Nature* **2003**, *423*, 332–336.

5.538.5.3. Signal Pathway Between Periosteum and Joint Cartilage

The periosteum releases various growth factors, including TGF-β, IGF-1, BMP-2, and integrins,[12] and has been suggested to be closely involved in the regulation and maintenance of the joint cartilage structure and extracellular matrix. Particularly, TGF-β released from the periosteum, PTHrP released from the resting layer present in the most superficial part of the joint cartilage, and Ihh released from the proliferative layer have been shown to form a feedback loop, leading to clarification on the control for signal pathway of joint cartilage by the periosteum (Figure 6).[22–30]

In the human phalanx model, cells were nonselectively captured by laser capture microdissection (LCM)[31] from three such areas as the side layer of the periosteum, the resting layers, and the hypertrophic layers of the joint cartilage (Figure 7). Then, serial changes in the expression of periosteum/cartilage-related genes (PTHrp, Ihh, TGF-β) were examined in the captured cells with RT-PCR to analyze the signal pathway between the periosteum and the joint cartilage. As a result, positive expressions of type TGF-β (side layer), PTHrp (resting layer), and Ihh (hypertrophic layer) were observed, and the positive feedback loop system was complete on the periosteal side, while it was incomplete on the nonperiosteal side (Figure 8).

5.538.6. Conclusion and Future Directions

In this study, a human phalanx model was prepared by attaching the periosteum to an osteoinductive biodegradable 3D polymer, which was P(LA-CL) with the incorporation of HA particles, in the shape of the human phalanx. Cultured chondrocytes seeded on PGA sheets were subsequently attached to both ends of the copolymer of P(LA-CL)with HA particles for the phalangeal regeneration. The model was implanted into nude mice, and the regeneration of phalanx and joint cartilage was induced. Areas with and without attachment of the

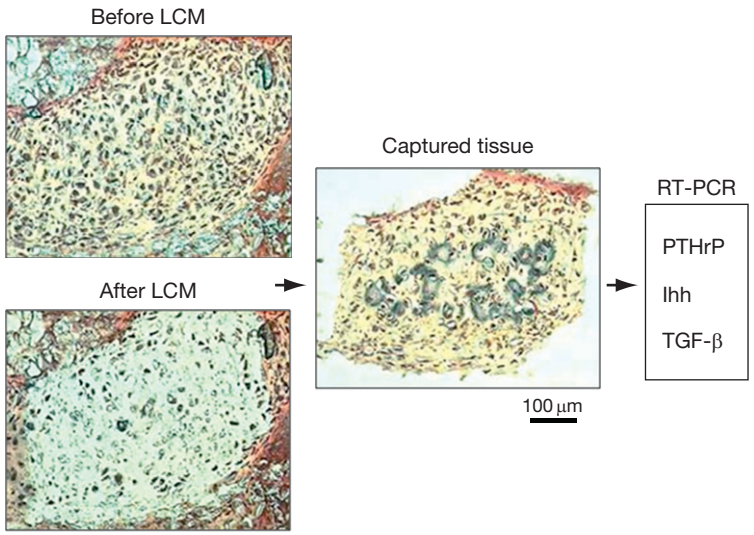

Figure 7 Method of laser capture microdissection.

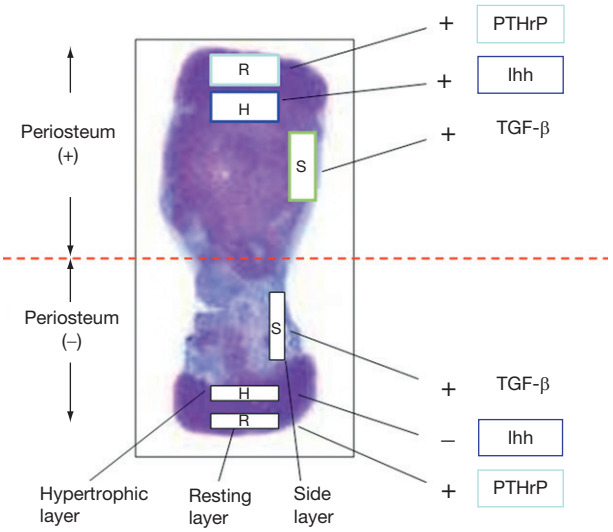

Figure 8 Gene expression using RT-PCR. Expression of PTHrp, Ihh, and TGF-β genes was examined at 20 weeks after implantation.

periosteum were prepared in each phalanx model (periosteal and nonperiosteal sides), and the involvement of the periosteum in the maturation process was evaluated. On gross examination, the 3D morphology of the phalanx was maintained more favorably on the periosteal side. On histological examination, bone formation was observed to proceed through an endochondral ossification mechanism. Expression of BSP on the periosteal side was remarkably higher than that on the nonperiosteal side. RT-PCR data suggested that expression of TGF-β, PTHrp, and Ihh was a central aspect of a feedback loop system that operated efficiently on the periosteal side, but incompletely on the nonperiosteal side.

From these results, it can be seen that the attached periosteum plays an important role in the induction of regeneration of the phalanx and joint cartilage in a human phalanx model. P(LA-CL) with the incorporation of HA particles promoted both osteogenesis and chondrogenesis with periosteum. Combination of the osteoinductive biodegradable 3D copolymer with periosteum was extremely useful for accelerating the human phalangeal regeneration. Future research will need to be directed at both donor and recipient transplantation sites in an autologous model. A functional network of blood vessels that can nourish the regenerated phalangeal tissue will need to be developed, either *in situ* at the defect site or in a donor site, which can be subsequently transferred as a 'free flap' using microvascular surgery. The latter approach will not only require good angiogenic development into the regenerated phalanx, but also need to have a primary pair of vessels of sufficient caliber for undertaking the microsurgical vascular connections. Further analysis of phalangeal regeneration techniques will allow functional and successful reproduction of the phalanx, with the goal of phalanx or phalangeal joint reconstruction for patients with phalangeal defects resulting from congenital or acquired diseases or traumatic injury.

Glossary

Acellular matrix Collagen-rich scaffolds prepared by removing all cellular components from a donor tissue.

Adult stem cell An undifferentiated cell found in postnatal tissues that can self-renew as well as produce progeny that can differentiate into the various cell types that comprise the tissue.

Amniotic fluid stem (AFS) cell A multipotent cell type found in the amniotic fluid surrounding an embryo; AFS cells may be mesenchymal in origin and differentiation to neural, hepatic, osteogenic, and chondrogenic lineages, among others, has been demonstrated.

Embryonic stem (ES) cell A broadly multipotent cell type found in the inner cell mass of a blastocyst; ES cells can differentiate into nearly every cell type in the body.

Induced pluripotent stem (iPS) cell A somatic cell that has been dedifferentiated to a stem cell-like phenotype via the introduction of functional gene products involved in maintaining pluripotency.

Reproductive cloning The use of cloning procedures to produce a live offspring that is a genetic copy of an adult animal.

Therapeutic cloning The use of cloning procedures to produce a blastocyst *in vitro* in order to obtain embryonic stem cells for cell therapy or tissue engineering applications.

5.539.1. Introduction

Patients suffering from diseased and injured organs may be treated with transplanted organs. However, there is a severe shortage of donor organs that is worsening yearly. As modern medicine increases the human lifespan, the aging population grows, and the need for organs grows with it, as aging organs are generally more prone to failure. Scientists in the field of regenerative medicine and tissue engineering apply the principles of cell transplantation, material science, and bioengineering to construct biological substitutes that can prolong life by reducing mortality from these diseases. Therapeutic cloning, where the nucleus from a donor cell is transferred into an enucleated oocyte in order to extract pluripotent embryonic stem cells, offers a potentially limitless source of cells for tissue engineering applications. The stem cell field is also advancing rapidly, opening new options for therapy. This chapter reviews recent advances that have occurred in regenerative medicine and describes applications of these new technologies that offer promise of a longer life.

The field of regenerative medicine encompasses various areas of technology, such as tissue engineering, stem cells, and cloning. Tissue engineering, one of the major components of regenerative medicine, follows the principles of cell transplantation, materials science, and engineering toward the development of biological substitutes that can restore and maintain normal function. Tissue engineering strategies generally fall into two categories: the use of acellular matrices, which depend on the body's natural ability to regenerate for proper orientation and direction of new tissue growth, and the use of matrices with cells. Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds, or by removing cellular components from tissues via mechanical and chemical manipulation to produce collagen-rich matrices.[1–4] These matrices tend to slowly degrade on implantation and are generally replaced by the extracellular matrix (ECM) proteins that are secreted by the ingrowing cells. Cells can also be used for therapy via injection, either with carriers such as hydrogels, or alone.

When cells are used for tissue engineering, a small piece of donor tissue is dissociated into individual cells. These cells are either implanted directly into the host, or are expanded in culture, attached to a support matrix, and then reimplanted into the host after expansion. The source of donor tissue can be heterologous (such as bovine), allogeneic (same species, different individual), or autologous. Ideally, both structural and functional tissue replacement will occur with minimal complications. The preferred cells to use are autologous cells, where a biopsy of tissue is obtained from the host, the cells are dissociated and expanded in culture, and the expanded cells are implanted into the same host.[4–12] The use of autologous cells, although it may cause an inflammatory response, avoids rejection, and thus, the deleterious side effects of immunosuppressive medications can be avoided.

Most current strategies for tissue engineering depend upon a sample of autologous cells from the diseased organ of the host. Aging itself is not a barrier to successful applications of engineered tissues, as cells can be expanded from young and old patients alike. However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, stem cells are envisioned as being an alternative source of cells from which the desired tissue can be derived. Stem cells can be derived from discarded human embryos (human embryonic stem cells), from fetal tissue, or from adult sources (bone marrow, fat, skin).

Therapeutic cloning has also played a role in the development of the field of regenerative medicine. This type of cloning, which has also been called nuclear transplantation and nuclear transfer, involves the introduction of a nucleus from a donor cell into an enucleated oocyte to generate an embryo with a genetic makeup identical to that of the donor. Stem cells can be derived from this source, which may have the future potential to be used therapeutically.

5.539.2. Biomaterials

For cell-based tissue engineering, the expanded cells are seeded onto a scaffold synthesized with the appropriate biomaterial. In tissue engineering, biomaterials replicate the biologic and mechanical function of the native ECM found in tissues in the body by serving as an artificial ECM. Biomaterials provide a three-dimensional space for the cells to form into new tissues with appropriate structure and function, and also can allow for the delivery of cells and appropriate bioactive factors (e.g., cell-adhesion peptides, growth factors), to desired sites in the body.[13] As the majority of mammalian cell types are anchorage-dependent and will die if no cell-adhesion substrate is available, biomaterials provide a cell-adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can also provide mechanical support against *in vivo* forces such that the predefined three-dimensional structure is maintained during tissue development. Furthermore, bioactive signals, such as cell-adhesion peptides and growth factors, can be loaded along with cells to help regulate cellular function.

The ideal biomaterial should be biodegradable and bioresorbable to support the replacement of normal tissue without inflammation. Incompatible materials are destined for an inflammatory or foreign-body response that eventually leads to rejection and/or necrosis. Degradation products, if produced, should be removed from the body via metabolic pathways at an adequate rate that keeps the concentration of these degradation products in the tissues at a tolerable level.[14] The biomaterial should also provide an environment in which

appropriate regulation of cell behavior (adhesion, proliferation, migration, and differentiation) can occur such that functional tissue can form. Cell behavior in the newly formed tissue has been shown to be regulated by multiple interactions of the cells with their microenvironment, including interactions with cell-adhesion ligands[15] and with soluble growth factors. Since biomaterials provide temporary mechanical support while the cells undergo spatial reorganization into tissue, the properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, while in late development, it should have begun degradation such that it does not hinder further tissue growth.[13]

In general, three classes of biomaterials are used for engineering tissues: naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa), and synthetic polymers such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-*co*-glycolic acid) PLGA). These classes of biomaterials have been tested with respect to their biocompatibility.[16,17] Naturally derived materials and acellular tissue matrices have the potential advantage of biological recognition. However, synthetic polymers can be produced reproducibly on a large scale with controlled properties such as strength, degradation rate, and microstructure.

5.539.2.1. Naturally Derived Materials

Collagen is the most abundant and ubiquitous structural protein in the body, and may be readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction.[18] Collagen implants, under normal conditions, degrade through a process involving phagocytosis of collagen fibrils by fibroblasts.[19] This is followed by sequential attack by lysosomal enzymes including cathepsins B1 and D. Under inflammatory conditions, the implants can be rapidly degraded largely by matrix metalloproteinases (MMPs) and collagenases.[19] However, the *in vivo* resorption rate of a collagen implant can be regulated by controlling the density of the implant and the extent of intermolecular cross-linking. The lower the density, the greater the space between collagen fibers and the larger the pores for cell infiltration, leading to a higher rate of implant degradation. Collagen contains cell-adhesion domain sequences (e.g., RGD) that may assist in retaining the phenotype and activity of many types of cells, including fibroblasts[20] and chondrocytes.[21]

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle[22] and a cell immobilization matrix[23] owing to its gentle gelling properties in the presence of divalent ions, such as calcium. Alginate is relatively biocompatible and approved by the Food and Drug Administration (FDA) for human use as wound dressing material. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of polygluronic block in the alginate chains.[22]

5.539.2.2. Acellular Tissue Matrices

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues. The matrices are often prepared by mechanical and chemical manipulation of a segment of tissue.[1–4] The matrices slowly degrade upon implantation, and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrowing cells.

5.539.2.3. Synthetic Polymers

Polyesters of naturally occurring α-hydroxy acids, including PGA, PLA, and PLGA, are widely used in tissue engineering. These polymers have gained FDA approval for human use in a variety of applications, including sutures.[24] The ester bonds in these polymers are hydrolytically labile, and these polymers degrade by nonenzymatic hydrolysis. The degradation products of PGA, PLA, and PLGA are nontoxic natural metabolites and are eventually eliminated from the body in the form of carbon dioxide and water.[24] The degradation rate of these polymers can be tailored from several weeks to several years by altering crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Since these polymers are thermoplastics, they can be easily formed into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion, solvent casting,[25] phase separation techniques, and gas foaming techniques.[26] Many applications in tissue engineering often require a scaffold with high porosity and ratio of surface area to volume. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(ortho-esters), can also be used to fabricate scaffolds for tissue engineering with controlled properties.[27]

5.539.3. Cells for Use in Tissue Engineering

5.539.3.1. Embryonic Stem Cells

Human embryonic stem cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated but pluripotent state (self-renewal), and the ability to differentiate into many specialized cell types.[28] They can be isolated by aspirating the inner cell mass from the embryo during the blastocyst stage (5 days postfertilization), and are usually grown on feeder layers consisting of mouse embryonic fibroblasts (MEFs) or human feeder cells.[29] More recent reports have shown that these cells can be grown without the use of a feeder layer[30] and can thus avoid the exposure of these human cells to mouse viruses and proteins. These cells have demonstrated longevity in culture by maintaining their undifferentiated state for at least 80 passages when grown using current published protocols.[31,32]

Human embryonic stem cells have been shown to differentiate into cells from all three embryonic germ layers *in vitro*. Skin and neurons have been formed, indicating ectodermal differentiation.[33–36] Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation.[37–39] Pancreatic cells have been formed, indicating endodermal differentiation.[40] In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers while in culture, and can form teratomas *in vivo*.[41]

5.539.3.2. Laboratory-Generated Stem Cells

In addition, stem cells for tissue engineering can be generated through cloning procedures. There has been tremendous interest in the field of nuclear cloning since the birth of Dolly in 1997, but frogs were the first successfully cloned vertebrates derived from nuclear transfer[42–45] but the nuclei were derived from nonadult sources. In the past 15 years, tremendous advances in nuclear cloning technology have been reported, indicating the relative immaturity of the field. Dolly was not the first cloned mammal to be produced via nuclear transfer; in fact, live lambs were produced in 1996 using nuclear transfer and differentiated epithelial cells derived from embryonic discs.[46] The significance of Dolly was that she was the first mammal to be derived from an adult somatic cell using nuclear transfer.[47] Since then, animals from several species have been grown using nuclear transfer technology, including cattle,[48] goats,[49] mice,[50] and pigs.[51,52]

Two types of nuclear cloning, reproductive cloning and therapeutic cloning, have been described, and a better understanding of the differences between the two types may help to alleviate some of the controversy that surrounds these technologies.[53,54] Banned in most countries for human applications, reproductive cloning is used to generate an embryo that has the identical genetic material as its cell source. This embryo can then be implanted into the uterus of a female to give rise to an infant that is a clone of the donor. On the other hand, therapeutic cloning is used to generate early stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body, and thus would be useful in tissue and organ replacement applications.[55] Therefore, therapeutic cloning, which has also been called somatic cell nuclear transfer, may provide an alternative source of transplantable cells. **Figure 1** shows the strategy of combining therapeutic cloning with tissue engineering to develop tissues and organs. According to data from the Centers for Disease Control (CDC), an estimated 3000 Americans die every day of diseases that could have been treated with stem cell-derived tissues[56,57] With current allogeneic tissue transplantation protocols, rejection is a frequent complication because of immunologic incompatibility, and immunosuppressive drugs are usually required.[55] The use of transplantable tissue and organs derived from therapeutic cloning may potentially lead to the avoidance of immune responses that typically are associated with transplantation of nonautologous tissues.[56]

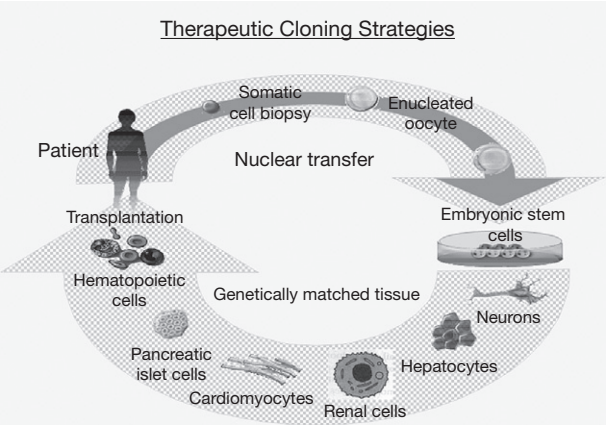

Figure 1 Strategy for therapeutic cloning and tissue engineering.

Although it looks promising, somatic cell nuclear transfer technology has certain limitations that require further improvements before therapeutic cloning can be applied widely in replacement therapy. Currently, the efficiency of the overall cloning process is low. The majority of embryos derived from animal cloning do not survive after implantation.[58–60] To improve cloning efficiency, further improvements are required in the multiple complex steps of nuclear transfer, such as enucleation and reconstruction, activation of oocytes, and cell cycle synchronization between donor cells and recipient oocytes.[61]

Recently, exciting reports of the successful transformation of adult cells into pluripotent stem cells through a type of genetic "reprogramming" have been published. Reprogramming is a technique that involves dedifferentiation of adult somatic cells to produce patient-specific pluripotent stem cells, without the use of embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus, the patient who donated these cells) and would not be rejected. Yamanaka was the first to discover that MEFs and adult mouse fibroblasts could be reprogrammed into an 'induced pluripotent state (iPS)'.[62] This group used MEFs engineered to express a neomycin resistance gene from the *Fbx15* locus, a gene expressed only in ES cells. They examined 24 genes that were thought to be important for embryonic stem cells and identified four key genes that, when introduced into the reporter fibroblasts, resulted in drug-resistant cells. These were Oct3/4, Sox2, c-MYC, and Klf4. This experiment indicated that expression of the four genes in these transgenic MEFs led to expression of a gene specific for ES cells. MEFs and adult fibroblasts were cotransduced with retroviral vectors, each carrying one of the four genes, and transduced cells were selected via drug resistance. The resultant iPS cells possessed the immortal growth characteristics of self-renewing ES cells, expressed genes specific for ES cells, and generated embryoid bodies *in vitro* and teratomas *in vivo*. When iPS cells were injected into mouse blastocysts, they contributed to a variety of cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to ES cells. Unlike ES cells, chimeras made from iPS cells did not result in full-term pregnancies. Gene expression profiles of the iPS cells showed that they possessed a distinct gene expression signature that was different from that of ES cells. In addition, the epigenetic state of the iPS cells was somewhere between that found in somatic cells and that found in ES cells, suggesting that the reprogramming was incomplete.

These results were improved significantly by Wernig and Jaenisch in July 2007.[63] Fibroblasts were infected with retroviral vectors and selected for the activation of endogenous *Oct4* or *Nanog* genes. Results from this study showed that DNA methylation, gene expression profiles, and the chromatin state of the reprogrammed cells were similar to those of ES cells. Teratomas induced by these cells contained differentiated cell types representing all three embryonic germ layers. Most importantly, the reprogrammed cells from this experiment were able to form viable chimeras and contribute to the germline-like ES cells,

suggesting that these iPS cells were completely reprogrammed. Wernig *et al.* observed that the number of reprogrammed colonies increased when drug selection was initiated later (day 20 rather than day 3 posttransduction). This suggests that reprogramming is a slow and gradual process and may explain why previous attempts resulted in incomplete reprogramming.

It has recently been shown that reprogramming of human cells is possible.[64,65] Yamanaka showed that retrovirus-mediated transfection of *OCT3/4*, *SOX2*, *KLF4*, and *c-MYC* generates human iPS cells that are similar to hES cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Thompson's group showed that retroviral transduction of *OCT4*, *SOX2*, *NANOG*, and *LIN28* could generate pluripotent stem cells without introducing any oncogenes (c-MYC). Both studies showed that human iPS were similar but not identical to hES cells.

Another concern is that these iPS cells contain three to six retroviral integrations (one for each factor), which may increase the risk of tumorigenesis. Yamanaka *et al.* studied the tumor formation in chimeric mice generated from Nanog-iPS cells and found 20% of the offspring developed tumors due to the retroviral expression of c-MYC.[66] An alternative approach would be to use a transient expression method, such as adenovirus-mediated system, since both Jaenisch and Yamanaka showed strong silencing of the viral-controlled transcripts in iPS cells.[66,67] This indicates that these viral genes are only required for the induction, not the maintenance, of pluripotency.

Another concern is the use of transgenic donor cells for reprogrammed cells in the mouse studies. Both studies used donor cells from transgenic mice harboring a drug resistance gene driven by *Fbx15*, *Oct3/4*, or *Nanog* promoters so that, if these ES cell-specific genes were activated, the resulting cells could be easily selected using neomycin. However, the use of genetically modified donors hinders clinical applicability for humans. To assess whether iPS cells can be derived from nontransgenic donor cells, wild-type MEF and adult skin cells were retrovirally transduced with Oct3/4, Sox2, c-MYC, and Klf4 and ES-like colonies were isolated by morphology alone, without the use of drug selection for *Oct4* or *Nanog*.[67] iPS cells from wild-type donor cells formed teratomas and generated live chimeras. This study suggests that transgenic donor cells are not necessary to generate iPS cells.

Although this is an exciting phenomenon, it is unclear why reprogramming adult fibroblasts and mesenchymal stromal cells have similar efficiencies.[62] It would seem that cells that are already multipotent could be reprogrammed with greater efficiency, since the more undifferentiated donor nucleus the better SCNT performs.[68] This further emphasizes our limited understanding of the mechanism of reprogramming, yet the potential for this area of study is exciting.

5.539.3.3. Amniotic Fluid and Placental Stem Cells

An alternate source of stem cells is the amniotic fluid and placenta. Amniotic fluid and the placenta are known to contain multiple partially differentiated cell types derived from the developing fetus. We isolated stem cell populations from these sources, called amniotic fluid and placental stem cells (AFPSC) that express embryonic and adult stem cell markers.[69] The undifferentiated stem cells expand extensively without feeders and double every 36 h. Unlike human embryonic stem cells, the AFPSC do not form tumors *in vivo*. Lines maintained for over 250 population doublings retained long telomeres and a normal karyotype. AFS cells are broadly multipotent. Clonal human lines verified by retroviral marking can be induced to differentiate into cell types representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neuronal, and hepatic lineages. In this respect, they meet a commonly accepted criterion for pluripotent stem cells, without implying that they can generate every adult tissue. Examples of differentiated cells derived from AFS cells and displaying specialized functions include neuronal lineage secreting the neurotransmitter L-glutamate or expressing G-protein-gated inwardly rectifying potassium (GIRK) channels, hepatic lineage cells producing urea, and osteogenic lineage cells forming tissue-engineered bone. The cells could be obtained either from amniocentesis or chorionic villous sampling in the developing fetus, or from the placenta at the time of birth. The cells could be preserved for self-use, and used without rejection, or they could be banked. A bank of 100,000 specimens could potentially supply 99% of the US population with a perfect genetic match for transplantation. Such a bank may be easier to create than with other cell sources, since there are approximately 4.5 million births per year in the United States.[69]

5.539.3.4. Adult Stem Cells and Native Progenitor Cells

One of the limitations of applying cell-based regenerative medicine techniques to organ replacement has been the inherent difficulty of growing specific cell types in large quantities. Even when some organs, such as the liver, have a high regenerative capacity *in vivo*, cell growth and expansion *in vitro* may be difficult. By studying the privileged sites for committed precursor cells in specific organs, as well as exploring the conditions that promote differentiation, one may be able to overcome the obstacles that limit cell expansion *in vitro*. For example, urothelial cells could be grown in the laboratory setting in the past, but only with limited expansion. Several protocols were developed over the past two decades that identified the undifferentiated cells, and kept them undifferentiated during their growth phase.[10,70–73] Using these methods of cell culture, it is now possible to expand a urothelial strain from a single specimen that initially covered a surface area of 1 cm^2 to one covering a surface area of 4202 m^2 (the equivalent of one football field) within 8 weeks.[10] These studies indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the donor in sufficient quantities for reconstructive purposes.[10,71–76] Major advances have been achieved within the past decade on the possible expansion of a variety of primary human cells, with specific techniques that make the use of autologous cells possible for clinical application.

5.539.4. Cell Therapy with Injectable Substances

5.539.4.1. Bulking Agents

Injectable bulking agents can be endoscopically used in the treatment of both urinary incontinence and vesicoureteral

reflux. The advantages in treating urinary incontinence and vesicoureteral reflux with this minimally invasive approach include the simplicity of this quick outpatient procedure and the low morbidity associated with it. Several investigators are seeking alternative implant materials that would be safe for human use.[77]

The ideal substance for the endoscopic treatment of reflux and incontinence should be injectable, nonantigenic, nonmigratory, volume stable, and safe for human use. Toward this goal long-term studies were conducted to determine the effect of injectable chondrocytes *in vivo*.[78] It was initially determined that alginate, a liquid solution of gluronic and mannuronic acid, embedded with chondrocytes, could serve as a synthetic substrate for the injectable delivery and maintenance of cartilage architecture *in vivo*. Alginate undergoes hydrolytic biodegradation and its degradation time can be varied depending on the concentration of each of the polysaccharides. The use of autologous cartilage for the treatment of vesicoureteral reflux in humans would satisfy all the requirements for an ideal injectable substance.

Chondrocytes derived from an ear biopsy can be readily grown and expanded in culture. Neocartilage formation can be achieved *in vitro* and *in vivo* using chondrocytes cultured on synthetic biodegradable polymers. In these experiments, the cartilage matrix replaced the alginate as the polysaccharide polymer underwent biodegradation. This system was adapted for the treatment of vesicoureteral reflux in a porcine model.[79] These studies showed that chondrocytes can be easily harvested and combined with alginate *in vitro*, the suspension can be easily injected cystoscopically, and the elastic cartilage tissue formed is able to correct vesicoureteral reflux without any evidence of obstruction.

Two multicenter clinical trials were conducted using this engineered chondrocyte technology. Patients with vesicoureteral reflux were treated at ten centers throughout the US. The patients had a similar success rate as with other injectable substances in terms of cure (**Figure 5**). Chondrocyte formation was not noted in patients who had treatment failure. It is supposed that the patients who were cured have a biocompatible region of engineered autologous tissue present, rather than a foreign material.[80] Patients with urinary incontinence were also treated endoscopically with injected chondrocytes at three different medical centers. Phase 1 trials showed an approximate success rate of 80% at follow-up 3 and 12 months postoperatively.[81] Several of the clinical trials involving bioengineered products have been placed on hold because of the costs involved with the specific technology. With a bioengineered product, costs are usually high because of the biological nature of the therapies involved. As with any therapy, the cost that the medical health care system can allow for a specific technology is limited. Therefore, the costs of bioengineered products have to be lowered for them to have an impact clinically. This is currently being addressed for multiple tissue-engineered technologies. As the technologies advance overtime, and the volume of the application is considered, costs will naturally decrease.

5.539.4.2. Injectable Muscle Cells

The potential use of injectable cultured myoblasts for the treatment of stress urinary incontinence has been investigated.[82,83] Myoblasts were labeled with fluorescent latex microspheres (FLM) in order to track them after injection. Labeled myoblasts were directly injected into the proximal urethra and lateral bladder walls of nude mice with a microsyringe in an open surgical procedure. Tissue harvested up to 35 days postinjection contained the labeled myoblasts, as well as evidence of differentiation of the labeled myoblasts into regenerative myofibers. The authors reported that a significant portion of the injected myoblast population persisted *in vivo*. Similar techniques of sphincteric derived muscle cells have been used for the treatment of urinary incontinence in a pig model.[84] The fact that myoblasts can be labeled and survive after injection and begin the process of myogenic differentiation further supports the feasibility of using cultured cells of muscular origin as an injectable bioimplant.

The use of injectable muscle precursor cells has also been investigated for use in the treatment of urinary incontinence due to irreversible urethral sphincter injury or maldevelopment. Muscle precursor cells are the quiescent satellite cells found in each myofiber that proliferate to form myoblasts and eventually myotubes and new muscle tissue. Intrinsic muscle precursor cells have previously been shown to play an active role in the regeneration of injured striated urethral sphincter.[85] In a subsequent study, autologous muscle precursor cells were injected into a rat model of urethral sphincter injury, and both replacement of mature myotubes and restoration of functional motor units were noted in the regenerating sphincteric muscle tissue.[86] This is the first demonstration of the replacement of both sphincter muscle tissue and its innervation by the injection of muscle precursor cells. As a result, muscle precursor cells may be a minimally invasive solution for urinary incontinence in patients with irreversible urinary sphincter muscle insufficiency.

5.539.4.3. Endocrine Replacement

Patients with testicular dysfunction and hypogonadal disorders are dependent on androgen replacement therapy to restore and maintain physiological levels of serum testosterone and its metabolites, dihydrotestosterone, and estradiol.[87,88] Currently available androgen replacement modalities, such as testosterone tablets and capsules, Depo-Provera injections, and skin patches may be associated with fluctuating serum levels and complications such as fluid and nitrogen retention, erythropoiesis, hypertension, and bone density changes.[89] Since Leydig cells of the testes are the major source of testosterone in men, implantation of heterologous Leydig cells or gonadal tissue fragments have previously been proposed as a method for chronic testosterone replacement.[90,91] These approaches, however, were limited by the failure of the tissues and cells to produce testosterone.

Encapsulation of cells in biocompatible and semipermeable polymeric membranes has been an effective method to protect against a host immune response as well as to maintain viability of the cells while allowing the secretion of desired therapeutic agents.[92,93] Alginate–poly-L-lysine-encapsulated Leydig cell microspheres were used as a novel method for testosterone delivery *in vivo*.[88] Elevated stable serum testosterone levels were noted in castrated adult rats over the course of the study, suggesting that microencapsulated Leydig cells

may be a potential therapeutic modality for testosterone supplementation.

5.539.5. Tissue Engineering of Specific Structures

Investigators around the world, including those in our laboratory, have been working toward the development of several cell types and tissues and organs for clinical application.

5.539.5.1. Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA without cells[94,95] or with cells[96] were used to regenerate urethras in various animal models. Naturally derived collagen-based materials such bladder-derived acellular submucosa,[1] and an acellular urethral submucosa,[97] have also been tried experimentally in various animal models for urethral reconstruction.

The bladder submucosa matrix[1] proved to be a suitable graft for repair of urethral defects in rabbits. The neourethras demonstrated a normal urothelial luminal lining and organized muscle bundles. These results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction wherein the urethral defects were repaired with human bladder acellular collagen matrices (**Figure 2**).[98] The neourethras were created by anastomosing the matrix in an onlay fashion to the urethral plate. The size of the created neourethra ranged from 5 to 15 cm. After a 3-year follow-up, three of the four patients had a successful outcome with regard to cosmetic appearance and function. One patient who had a 15-cm neourethra created developed a subglandular fistula. The acellular collagen-based matrix eliminated the necessity of performing additional surgical procedures for graft harvesting, and both operative time and the potential morbidity from the harvest procedure were decreased. Similar results were obtained in pediatric and adult patients with primary urethral stricture disease using the same collagen matrices.[99] Another study in 30 patients with recurrent stricture disease showed that a healthy urethral bed (two or fewer prior urethral surgeries) was needed for successful urethral reconstruction using the acellular collage-based grafts.[100] More than 200 pediatric and adult patients with urethral disease have been successfully treated in an onlay manner with a bladder-derived collagen-based matrix. One of its advantages over nongenital tissue grafts used for urethroplasty is that the material is "off the shelf." This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time, as well as the potential morbidity due to the harvest procedure.

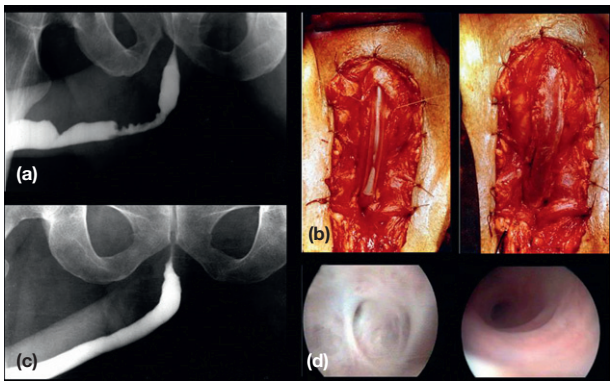

Figure 2 Tissue engineering of the urethra using a collagen matrix. (a) Representative case of a patient with a bulbar stricture. (b) During the urethral repair surgery, strictured tissue is excised, preserving the urethral plate on the left side, and matrix is anastamosed to the urethral plate in an onlay fashion on the right. The boxes in both photos indicate the area of interest, including the urethra, which appears white in the left photograph. In the left photograph, the arrow indicates the area of stricture in the urethra. On the right, the arrow indicates the repaired stricture. Note that the engineered tissue now obscures the native white urethral tissue in an onlay fashion in the right photograph. (c) Urethrogram 6 months after repair. (d) Cystoscopic view of urethra before surgery on the left side, and 4 months after repair on the right side.

The above techniques, using nonseeded acellular matrices, were applied experimentally and clinically in a successful manner for onlay urethral repairs. However, when tubularized urethral repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved, and complications ensued, such as graft contracture and stricture formation.[101] Autologous rabbit bladder epithelial and smooth muscle cells were grown and seeded onto preconfigured tubular matrices. Entire urethra segments were resected and urethroplasties were performed with tubularized collagen matrices either seeded with cells, or without cells. The tubularized collagen matrices seeded with autologous cells formed new tissue that was histologically similar to native urethra. The tubularized collagen matrices without cells lead to poor tissue development, fibrosis, and stricture formation. These findings were confirmed clinically. A clinical trial using tubularized nonseeded SIS for urethral stricture repair was performed in eight evaluable patients. Two patients with short inflammatory strictures maintained urethral patency. Stricture recurrence developed in the other six patients within 3 months of surgery.[102] Other cell types have also been tried experimentally in acellular bladder collagen matrices, including foreskin epidermal cells and oral keratinocytes.[103,104] Vascular endothelial growth factor gene-modified urothelial cells have also been used experimentally for urethral reconstruction.[105]

The normal wound healing response to injury has been studied extensively, and this knowledge has been helpful in maximizing success for the engineering of tissues. At the time of tissue injury, cell ingrowth is initiated from the wound edges in order to cover the tissue defect. The cells from the edges of the native tissue are able to traverse short distances without any detrimental effects. If the wound is large, more than a few millimeters in distance or depth, increased collagen deposition, fibrosis, and scar formation ensue. Matrices implanted in wound beds are able to lengthen the distances that cells can traverse without initiating an adverse fibrotic response. However, these distances are also limited. The maximum distance that adjacent cells from the wound edge have to travel to create normal tissue over a biologic matrix is approximately 1 cm.[106] Tissue defects greater than 1 cm, that are treated with a matrix alone, without cells, usually have increased collagen deposition, increased fibrosis, and scar formation. Cell-seeded matrices implanted in wound beds are able to further lengthen the distance for normal tissue formation, without initiating an adverse fibrotic response.

Studies in the field of regenerative medicine have shown that very large defects, greater than 30 cm, can be successfully treated using cell-seeded scaffolds. This explains the described experimental and clinical results noted with urethral repair. Nonseeded matrices are able to replace urethral segments when used in an onlay fashion because of the short distances required for tissue ingrowth. However, if a tubularized urethral repair is needed, the matrices need to be seeded with autologous cells in order to avoid the risk of stricture formation and poor tissue development.

5.539.5.2. Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, whereas bladder tissue is designed for the excretion of solutes. Due to the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative materials and tissues for bladder replacement or repair.

Over the last few decades, several bladder wall substitutes have been attempted with both synthetic and organic materials. Synthetic materials that have been tried in experimental and clinical settings include polyvinyl sponge, Teflon, collagen matrices, Vicryl (PGA) matrices, and silicone. Most of these attempts have failed because of mechanical, structural, functional, or biocompatibility problems. Usually, permanent synthetic materials used for bladder reconstruction succumb to mechanical failure and urinary stone formation, and use of degradable materials lead to fibroblast deposition, scarring, graft contracture, and a reduced reservoir volume overtime.[7,107] Because of this, there has been an increase in the use of various collagen-based matrices for tissue regeneration. Nonseeded allogeneic acellular bladder matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue.[3,4,108–110] The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident. However, in multiple studies using various materials as nonseeded grafts for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully developed.[4,108,109,111–113] Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted.[114] With continued bladder research in this area, these matrices may have a clinical role in bladder replacement in the future.

Cell-seeded allogeneic acellular bladder matrices were used for bladder augmentation in dogs.[4] The regenerated bladder tissues contained a normal cellular organization consisting of urothelium and smooth muscle and exhibited a normal compliance. Biomaterials preloaded with cells before their implantation showed better tissue regeneration compared with biomaterials implanted with no cells, in which tissue regeneration depended on ingrowth of the surrounding tissue. The bladders showed a significant increase (100%) in capacity when augmented with scaffolds seeded with cells, compared to scaffolds without cells (30%). The acellular collagen matrices can be enhanced with growth factors to improve bladder regeneration.[115]

It has been well established for decades that the bladder is able to regenerate generously over free grafts. Urothelium is associated with a high reparative capacity.[116] Bladder muscle tissue is less likely to regenerate in a normal fashion. Both urothelial and muscle ingrowth are believed to be initiated from the edges of the normal bladder toward the region of the free graft.[117,118] Usually, however, contracture or resorption of the graft has been evident. The inflammatory response toward the matrix may contribute to the resorption of the free graft. It was hypothesized that building the three-dimensional structure constructs *in vitro*, before implantation, would facilitate the eventual terminal differentiation of the cells after implantation *in vivo* and would minimize the inflammatory response toward the matrix, thus avoiding graft contracture and shrinkage. The dog study demonstrated a major difference between matrices used with autologous cells (tissue-engineered matrices) and those used without cells.[4] Matrices implanted with cells for bladder augmentation retained most of their implanted diameter, as opposed to matrices implanted without cells for bladder augmentation, in which graft contraction and shrinkage occurred. The histomorphology demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in the matrices implanted without cells. Epithelial-mesenchymal signaling is important for the differentiation of bladder smooth muscle.[119]

The results of initial studies showed that the creation of artificial bladders may be achieved *in vivo*; however, it could not be determined whether the functional parameters noted were caused by the augmented segment or by the intact native bladder tissue. To better address the functional parameters of tissue-engineered bladders, an animal model was designed that required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ.[11] Cystectomy-only and nonseeded controls maintained average capacities of 22% and 46% of preoperative values, respectively. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements. These findings were confirmed radiographically (**Figure 3**). The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% total compliance). The compliance of the cell-seeded tissue-engineered bladders showed almost no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle. Immunocytochemical analyses confirmed the muscle and urothelial phenotype. S-100 staining indicated the presence of neural structures.[11] These studies, performed with polyglocolic acid based-scaffolds, have been repeated by other investigators, showing similar long-term results in a large number of animals.[111,120] The strategy of using biodegradable scaffolds with cells can be pursued without concerns for local or systemic toxicity.[121] However, not all scaffolds perform well if a large portion of the bladder needs replacement. In a study using SIS for subtotal bladder replacement in dogs, both the unseeded and cell-seeded experimental groups showed graft

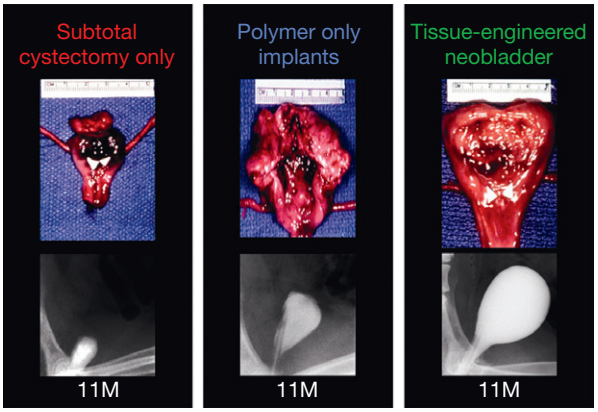

Figure 3 Gross specimens and cystograms at 11 months of the cystectomy-only, nonseeded controls, and cell-seeded tissue-engineered bladder replacements in dogs. The cystectomy-only bladder had a capacity of 22% of the preoperative value and a decrease in bladder compliance to 10% of the preoperative value. The nonseeded controls showed significant scarring with a capacity of 46% of the preoperative value and a decrease in bladder compliance to 42% of the preoperative value. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements and the compliance showed almost no difference from preoperative values that were measured when the native bladder was present (106%).

shrinkage and poor results.[122] The type of scaffold used is critical for the success of these technologies. The use of bioreactors, in which mechanical stimulation is started at the time of organ production, has also been proposed as an important parameter for success.[123]

A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was conducted starting in 1998. A small pilot study of seven patients was reported, using a collagen scaffold seeded with cells either with or without omentum coverage, or a combined PGA-collagen scaffold seeded with cells and omental coverage (**Figure 4**). The patients reconstructed with the engineered bladder tissue created with the PGA-collagen cell-seeded scaffolds with omental coverage showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods overtime (**Figure 5**).[124] It is clear from this experience that the engineered bladders continued their improvement with time, mirroring their continued development. Although the experience is promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional bladders. This was a limited clinical experience, and the technology is not yet ready for wide dissemination, as further experimental and clinical studies are required. FDA Phase 2 studies have now been completed.

An area of concern in the field of tissue engineering in the past was the source of cells for regeneration. The concept of creating engineered constructs involves initially obtaining cells for expansion from the diseased organ. However, it was not known until recently whether the cell population obtained for later autologous implantation was normal and would lead to normal tissue formation. For example, would the cells obtained from a neuropathic bladder lead to the engineering of another neuropathic bladder? Cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells *in vitro*, as demonstrated by growth assays, contractility, adherence tests, and microarray analysis.[125–127] However, when neuropathic smooth muscle cells were cultured *in vitro*, seeded onto matrices and implanted *in vivo*, the tissue-engineered constructs

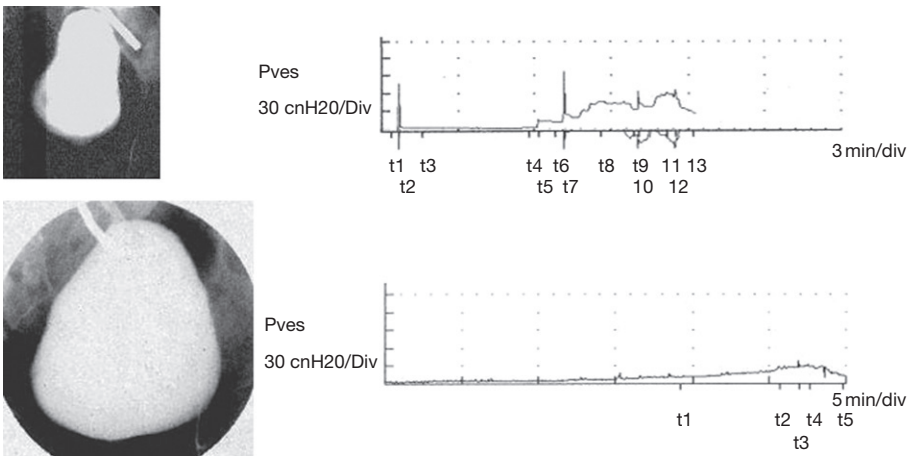

Figure 5 Cystograms and urodynamic studies of a patient before and after implantation of the tissue-engineered bladder. (a) Preoperative results indicate an irregular-shaped bladder in the cystogram (left) and abnormal bladder pressures as the bladder is filled during urodynamic studies (right). (b) Postoperatively, findings are significantly improved.

showed the same properties as the tissues engineered with normal cells.[128] The progenitor cells, which reside within stem cell niches within each organ, are responsible for new cell differentiation and tissue formation during the normal process of tissue regeneration due to natural turnover, aging, and tissue injury. It is known that genetically normal nonmalignant progenitor cells, which are the reservoirs for new cell formation, are programmed to give rise to normal tissue regardless of whether the niche resides in either normal or diseased tissues.[128–130] Therefore, although the mechanisms for tissue self-assembly and regenerative medicine are not fully understood, it is known that the progenitor cells are able to "reset" their program for normal cell differentiation. The stem cell niche and its role in normal tissue regeneration remains a fertile area of ongoing investigation.

5.539.5.3. Kidney

The kidney is a complex organ with multiple cell types, derived from combining anlagen and a complex functional anatomy that renders it one of the most difficult to reconstruct.[5,131] While the metanephros is responsible for the development of the proximal section of the nephrons, the ureteric bud forms the collecting ducts and distal structures. The large vessels of the kidney are induced from extrarenal tissues. Divergent embryologic origin converges to produce at least 26 distinct functional cells in the kidney.[132] Previous efforts in tissue engineering of the kidney have been directed toward the development of extracorporeal renal support systems made of biological and synthetic components[133–141] and these *ex vivo* renal replacement devices are known to be life-sustaining. However, there would be obvious benefits for patients with end-stage kidney disease if these devices could be implanted long term without the need for an extracorporeal perfusion circuit or immunosuppressive drugs.

We have explored the possibility of seeding an implantable biomaterial with a heterogeneous population of renal cells to evaluate function and viability. Atala *et al.* plated donor rabbit kidney cells, including distal tubules, glomeruli, and proximal tubules *in vitro* and after expansion, these were seeded onto biodegradeable PGA scaffolds and implanted subcutaneously into athymic mice. The implants consisted of individual cell types and a mixture of all three. When examined histologically, progressive formation and organization of the nephron segments within the polymer fibers was noted. Additionally, BrdU incorporation into the renal cell DNA was confirmed.[142] It was unclear if the tubular structures found on the scaffolds occurred *de novo* from the implanted cells or if they merely represented fragments of donor tubules that had survived intact the original dissociation and culture process. To further investigate this question, mouse renal cells were harvested and expanded in culture. Subsequently, a single cell suspension was created from the isolated cells, and these were seeded on biodegradable polymers and implanted into immunocompetent synergic hosts. In this experiment, renal epithelial cells reconstituted tubular structures *in vivo*. The analyses of the retrieved implants indicated that the renal epithelial cells first organized into a structure with a solid center. Next, canalization into a hollow tube could be seen at 2 weeks. Histologic examination with nephron-specific lactins revealed successful reconstitution of proximal tubules, distal tubules, loops of Henle, collecting tubules, and collecting ducts. These results clearly showed that single cell suspensions grown *in vitro* are capable of reconstituting tubule structures. The tubules contained homogenous cell types within each tubule.[143]

Further investigations by our group have demonstrated that renal tubular development from digested renal units is possible in the murine model as well. Joraku *et al.* developed an *in vitro* method for cultivation of renal cells that allowed for development of tubular structures. This technique involves digestion of the entire murine kidney followed by cultivation of the resulting cells in a specific renal media. Immunohistochemistry revealed cells expressing proximal and distal tubule markers as well as markers for glomerular and endothelial cells. When these cells were allowed to grow on rat-tail type 1 collagen, cells from the thick ascending loop of Henle stained positive for Tamm–Horsfall protein in an architectural pattern reminiscent of natural tubules.[144]

Yoo *et al.* evaluated whether murine renal cells grown *in vitro* could produce functional results *in vivo*. They harvested the cells, expanded them in culture and seeded them onto a tubular device constructed from polycarbonate. At one end of the tubular device was a silastic catheter, which terminated into a reservoir. The device was subcutaneously implanted into athymic mice. The implanted device demonstrated extensive vascularization in addition to glomerular formation and highly organized tubular architecture. Immunohistochemistry for alkaline phosphatase showed positivity in the proximal tubule-like structures. Osteopontin, which is secreted by the proximal and distal tubular cells and the cells of the thin loop of Henle, was found on immunocytochemical staining of the tubular sections. In addition, the ECM of the newly formed tubules stained uniformly positive for fibronectin. Importantly, fluid collected in the reservoir of the device. This fluid was yellow and the uric acid concentration was 66 mg dl^{-1} (as compared to 2 mg dl^{-1} in plasma). The creatinine concentration of the fluid (27.91 ± 7.56 mg dl^{-1}) was 8.2 times higher than that found in the serum (4.49 ± 0.08 mg dl^{-1}).[145] These studies demonstrate that single cells can form multicellular structures, become organized into functional renal units, and are capable of unidirectional excretion of solutes through production of a urine-like fluid.

Next, we applied the principles of both tissue engineering and therapeutic cloning in an effort to produce genetically identical renal tissue in a large animal model, the cow (*Bos taurus*).[146] Bovine skin fibroblasts from adult Holstein steers were obtained by ear notch, and single donor cells were isolated and microinjected into the perivitelline space of donor enucleated oocytes (nuclear transfer). The resulting blastocysts were implanted into progestin-synchronized recipients to allow for further *in vivo* growth. After 12 weeks, cloned renal cells were harvested, expanded *in vitro*, then seeded onto biodegradable scaffolds consisting of polycarbonate membranes and three collagen-coated cylindrical silastic catheters (**Figure 6(a)**). The ends of the three membranes of each scaffold were connected to catheters that terminated into a collecting reservoir. This created a renal neoorgan with a mechanism for collecting the excreted urinary fluid (**Figure 6(b)**). These devices were transplanted subcutaneously into the same steer from which the genetic material originated, and then retrieved 12 weeks after implantation.

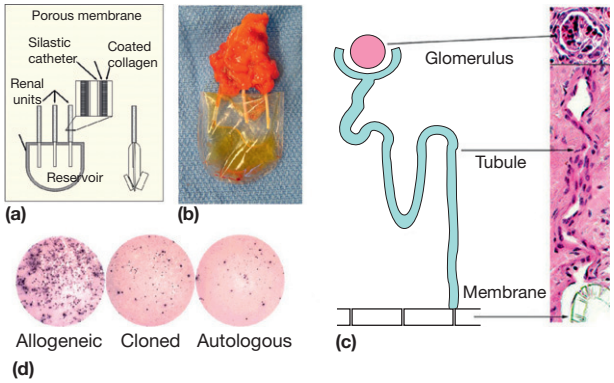

Figure 6 Combining therapeutic cloning and tissue engineering to produce kidney tissue. (a) Illustration of the tissue-engineered renal unit. (b) Renal unit seeded with cloned cells, 3 months after implantation, showing the accumulation of urine-like fluid. (c) Clear unidirectional continuity between the mature glomeruli, their tubules, and silastic catheter. (d) Elispot analyses of the frequencies of T cells that secrete IFN **FX** after stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts. Cloned renal cells produce fewer IFNγ spots than the allogeneic cells, indicating that the rejection response to cloned cells is diminished. The presented wells are single representatives of duplicate wells.

Chemical analysis of the collected urine-like fluid, including urea nitrogen and creatinine levels, electrolyte levels, specific gravity, and glucose concentration, revealed that the implanted renal cells possessed filtration, reabsorption, and secretory capabilities. Histological examination of the retrieved implants revealed extensive vascularization and self-organization of the cells into glomeruli and tubule-like structures. A clear continuity between the glomeruli, the tubules, and the silastic catheter was noted (**Figure 6(c)**). Immunohistochemical analysis with renal-specific antibodies revealed the presence of renal proteins, RT-PCR analysis confirmed the transcription of renal-specific RNA in the cloned specimens, and Western blot analysis confirmed the presence of elevated renal-specific protein levels.

Since previous studies have shown that bovine clones harbor oocyte mitochondrial DNA,[147–149] the donor egg's mitochondrial DNA (mtDNA) was thought to be a potential source of immunologic incompatibility. Differences in mtDNA-encoded proteins expressed by cloned cells could stimulate a T cell response specific for mtDNA-encoded minor histocompatibility antigens when the cloned cells are implanted back into the original nuclear donor.[150] Maternally transmitted minor histocompatibility antigens in mice have been shown to stimulate both skin allograft rejection *in vivo* and cytotoxic T lymphocytes expansion *in vitro*[150] that could prevent the use of these cloned constructs in patients with chronic rejection of major histocompatibility matched human renal transplants.[151,152] We tested for a possible T cell response to the cloned renal devices using delayed-type hypersensitivity testing *in vivo* and EliSPOT analysis of interferon-γ secreting T cells *in vitro*. Both analyses revealed no evidence of a T cell response, indicating that rejection of cloned renal cells will not necessarily occur in the presence of oocyte-derived mtDNA (**Figure 6(d)**). This finding may represent a step forward in overcoming the histocompatibility problem of stem cell therapy.[152]

These studies demonstrated that cells derived from nuclear transfer can be successfully harvested, expanded in culture, and transplanted *in vivo* with the use of biodegradable scaffolds on which the single suspended cells can organize into tissue structures that are genetically identical to that of the host. These studies were the first demonstration of the use of therapeutic cloning for regeneration of tissues *in vivo*.

Investigations into the possibility of using other cell types to produce renal tissue have also been promising. Perin *et al.* have been able to induce AFPSC to differentiate into renal tissues. They labeled human AFPSC with a green fluorescent protein and microinjected the cells into developing murine embryonic kidneys. They found that the labeled cells assisted in forming both C- and S- shaped bodies, and the cells expressed RNA for early markers of renal development.[153] This study demonstrates that AFPSC can differentiate into renal lineages when cultured *in vitro* with renal precursors. Although it looks promising, further *in vivo* studies and functional assays are required prior to clinical applications with AFPSC. For more information on renal tissue engineering strategies, please see **Chapter 5.540, Kidney Tissue Engineering** in this book.

5.539.5.4. Male Reproductive Organs

Reconstructive surgery is required for a wide variety of pathologic penile conditions, including penile carcinoma, trauma, severe erectile dysfunction, and congenital conditions such as ambiguous genitalia, hypospadias, and epispadias. One of the major limitations of phallic reconstructive surgery is the availability of sufficient autologous tissue. Nongenital autologous tissue sources have been used for decades. Phallic reconstruction was initially attempted in the late 1930s, with rib cartilage used as a stiffener for patients with traumatic penile loss,[154,155] but this process produced unsatisfactory functional and cosmetic results. Silicone rigid prostheses were popularized in the 1970s and have been used widely.[156,157] However, biocompatibility issues have been a problem in selected patients.[158,159] Tissue transfer techniques with flaps from various nongenital sources such as the groin and forearm have been used for genital reconstruction.[160] However, operative complications such as infection, graft failure, and donor site morbidity are not negligible. Phallic reconstruction with autologous tissue, derived from the patient's own cells, may be preferable in selected cases.

One of the major components of the phallus is corporal smooth muscle. Initial experiments have shown that cultured human corporal smooth muscle cells may be used in conjunction with biodegradable polymers to create corpus cavernosum tissue *de novo*.[161] In a subsequent study, human corporal smooth muscle cells and endothelial cells seeded on biodegradable polymer scaffolds were able to form vascularized cavernosal muscle when implanted *in vivo*.[162] Later, in order to minimize any immune reactions that a synthetic biomaterial might cause, naturally derived acellular corporal tissue matrix with the same architecture as native corpora was developed. Acellular collagen matrices were derived from processed donor rabbit corpora using cell lysis techniques. Human corpus cavernosal muscle and endothelial cells were derived from donor penile tissue, and the cells were expanded *in vitro* and seeded on the acellular matrices. The matrices were covered with the appropriate cell architecture 4 weeks after implantation.[163]

In order to look at the functional parameters of the engineered corpora, acellular corporal collagen matrices were obtained from donor rabbit penis and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on the matrices. An entire cross-sectional segment of protruding rabbit phallus was excised, leaving the urethra intact. Cell-seeded matrices were interposed into the excised corporal space. Functional and structural parameters (cavernosography, cavernosometry, mating behavior, and sperm ejaculation) were followed, and histological, immunocytochemical, and Western blot analyses were performed up to 6 months after implantation. The engineered corpora cavernosa achieved adequate structural and functional parameters.[164] This technology was further confirmed when the entire rabbit corpora was removed and replaced with the engineered scaffolds. Most interestingly, mating activity in the animals with the engineered corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating, and was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora and they conceived and delivered healthy pups. These studies demonstrate that penile corpora cavernosa tissue can be engineered. The engineered tissue is able to achieve adequate structural and functional parameters sufficient for erection, copulation, ejaculation, and conception in rabbits. Further studies will be needed to confirm the long-term functionality of these organs. In addition, further studies are needed to show that comparable human structures can also be engineered.

Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment for testicular dysfunction consists of periodic intramuscular injections of chemically modified testosterone or, more recently, skin patch applications. However, long-term nonpulsatile testosterone therapy is not optimal and can cause multiple problems, including excessive erythropoiesis and bone density changes. To address the problem, a system was designed in which Leydig cells, which produce most of the testosterone in the male, were microencapsulated in an alginate–poly-L-lysine solution and injected into castrated animals. Serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term.[165] These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present. Microencapsulated Leydig cells offer several advantages. For example, the encapsulation process creates a semipermeable barrier between the transplanted cells and the host's immune system, and it allows for the long-term physiologic release of testosterone.

Other studies have shown that testicular prostheses created with chondrocytes in bioreactors could be loaded with testosterone, and that these prostheses could provide controlled testosterone release into the bloodstream when implanted. The prostheses were implanted in athymic mice with bilateral anorchia, and testosterone was released long term, maintaining the androgen level at a physiologic range.[166] One could envision combining the Leydig cell technology described above with engineered prostheses for the long-term functional replacement of androgen levels.

5.539.5.5. Female Reproductive Organs

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue present for future reproduction. We investigated the possibility of engineering functional uterine tissue using autologous cells.[167] Autologous rabbit uterine smooth muscle and epithelial cells were harvested, then grown, and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval 6 months after implantation, histological, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Similarly, several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging due to the paucity of available native tissue. The feasibility of engineering vaginal tissue *in vivo* was investigated.[168] Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunocytochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered specimens, while the noncell-seeded structures were noted to be stenotic.[168]

5.539.5.6. Blood Vessels

Xenogenic or synthetic materials have been used as replacement blood vessels for complex cardiovascular lesions. However, these materials typically lack growth potential, and may place the recipient at risk for complications such as stenosis, thromboembolization, or infection.[169] Tissue-engineered vascular grafts have been constructed using autologous cells and biodegradable scaffolds and have been applied in dog and lamb models.[170–173] The key advantage of using these autografts is that they degrade *in vivo*, and thus allow the new tissue to form without the long-term presence of foreign material.[169] Application of these techniques from the laboratory to the clinical setting has begun, with autologous vascular cells harvested, expanded, and seeded onto a biodegradable scaffold.[174] The resultant autologous construct was used to replace a stenosed pulmonary artery that had been previously repaired. Seven months after implantation, no evidence of graft occlusion or aneurysmal changes was noted in the recipient.

5.539.5.7. Heart

In the United States, over 5 million people currently live with some form of heart disease, and many more are diagnosed each

year. While many medications have been developed to assist the ailing heart, the treatment for end-stage heart failure still remains transplantation. Unfortunately, as with other organs, donor hearts are in short supply, and even when a transplant can be performed, the patient must endure the side effects created by lifelong immunosuppression. Thus, alternatives are desperately needed, and the development of novel methods to regenerate or replace damaged heart muscle using tissue engineering and regenerative medicine techniques is an attractive option.

Cell therapy for infarcted areas of the heart is attractive, as these methods involve a rather simple injection into the damaged area of a patient's heart, rather than a rigorous surgical procedure, to complete. Various types of stem cells have been investigated for their potential to regenerate damaged or dead heart tissue in this manner. Skeletal muscle cells, bone marrow stem cells (both mesenchymal and hematopoietic), amniotic fluid stem cells, and embryonic stem cells have been used for this purpose. In this technique, cells are suspended in a biocompatible matrix that can range from simple normal saline to complex yet biocompatible hydrogels depending on the type of injection to be performed. The cells are either injected into the damaged area of the heart itself, or they are injected into the coronary circulation with the hope that they will home to the damaged area, take up residence there, and begin to repair the tissue. However, injectable therapies have been shown to be relatively inefficient, and cell loss is quite substantial. Newer methods of tissue engineering include the development of engineered "patches," which comprise cells adhered to a biomaterial that can theoretically be used to replace the damaged area of the heart. These techniques hold promise, but require further research into the optimal cell types and biomaterials for this purpose before they can be used extensively in the clinic (see Jawad *et al.*[175] for an excellent review of these methods).

However, the methods described above could only be used in cases where a relatively small section of heart muscle was damaged. In cases where a large area or even the whole heart has become nonfunctional, a more radical approach may be required. In these situations, the use of a bioartificial heart would be ideal, as rejection would be avoided and the problems associated with a mechanical heart (such as thromboembolus formation) would be abolished. To this end, Ott *et al.* recently developed a novel heart construct *in vitro* using decellularized cadaveric hearts. By reseeding the tissue scaffold that remained after a specialized decellularization process with various types of cells that make up a heart (cardiomyocytes, smooth muscle cells, endothelial cells, and fibrocytes) and culturing the resulting construct in a bioreactor system designed to mimic physiologic conditions, this group was able to produce a construct that could generate pump function on its own.[176] This study suggests that production of bioartificial hearts may one day be possible.

5.539.5.8. Liver

The liver can sustain a variety of insults, including viral infection, alcohol abuse, surgical resection of tumors, and acute drug-induced hepatic failure. The current therapy for liver failure is liver transplantation. However, this therapy is limited by the shortage of donors and the need for lifelong immunosuppressive therapy. Cell transplantation has been proposed as a potential solution for liver failure. The fact that the liver has enormous regenerative potential *in vivo* suggests that in the right environment, it may be possible to expand liver cells *in vitro* in sufficient quantities for tissue engineering.[177] Many approaches have been tried, including development of specialized media, coculture with other cell types, identification of growth factors that have proliferative effects on these cells, and culture on three-dimensional scaffolds within bioreactors.[177]

Extracorporeal bioartificial liver devices that use porcine hepatocytes have been designed and applied. These devices are designed to filter and purify the patient's blood as would the patient's own liver, and the blood is returned to the patient in a manner similar to kidney dialysis. Another cell-based approach is the injection of liver cell suspensions. This has been performed in animal models. Intraportal hepatocyte injection has also been used in patients with Crigler–Najjar Syndrome Type 1[178]; however, complications such as portal vein thrombosis and pulmonary embolism are major concerns, especially when large cell numbers are used.[179] Finally, cells including stem cells, oval progenitor cells, and mature hepatocytes have been seeded onto liver-shaped biocompatible matrices to engineer artificial, implantable livers. These have been tested in various animal models;[180,181] however, the transplantation efficiency as well as the functionality of these constructs must be improved substantially before the technology can be moved into the clinic.

5.539.5.9. Articular Cartilage and Trachea

Full-thickness articular cartilage lesions have limited healing capacity and thus represent a difficult management issue for the clinicians who treat adult patients with damaged articular cartilage.[182,183] Large defects can be associated with mechanical instability and may lead to degenerative joint disease if left untreated.[184,185] Chondrocytes were expanded and cultured onto biodegradable scaffolds to create engineered cartilage for use in large osteochondral defects in rabbits.[186] When sutured to a subchondral support, the engineered cartilage was able to withstand physiologic loading and underwent orderly remodeling of the large osteochondral defects in adult rabbits, providing a biomechanically functional template that was able to undergo orderly remodeling when subjected to quantitative structural and functional analyses.

Few treatment options are currently available for patients who suffer from severe congenital tracheal pathology, such as stenosis, atresia, and agenesis, due to the limited availability of autologous transplantable tissue in the neonatal period. Tissue engineering in the fetal period may be a viable alternative for the surgical treatment of these prenatally diagnosed congential anomalies, as cells could be harvested and grown into transplantable tissue in parallel with the remainder of gestation. Chondrocytes from both elastic and hyaline cartilage specimens have been harvested from fetal lambs, expanded *in vitro*, then dynamically seeded onto biodegradable scaffolds.[187] The constructs were then implanted as replacement tracheal tissue in fetal lambs. The resultant tissue-engineered cartilage was noted to undergo engraftment and epithelialization, while maintaining its structural support and patency. Furthermore, if native tracheal tissue is unavailable, engineered

cartilage may be derived from bone marrow-derived mesenchymal progenitor cells as well.[188]

5.539.6. Summary and Conclusion

Regenerative medicine efforts are currently underway experimentally for virtually every type of tissue and organ within the human body. As regenerative medicine incorporates the fields of tissue engineering, cell biology, nuclear transfer, and materials science, personnel who have mastered the techniques of cell harvest, culture, expansion, transplantation, as well as polymer design are essential for the successful application of these technologies to extend human life. Various tissues are at different stages of development, with some already being used clinically, a few in preclinical trials, and some in the discovery stage. Recent progress suggests that engineered tissues may have an expanded clinical applicability in the future and may represent a viable therapeutic option for those who would benefit from the life-extending benefits of tissue replacement or repair.

Glossary

Acellular matrix Collagen-rich scaffolds prepared by removing all cellular components from a donor tissue.

Adult stem cell An undifferentiated cell found in postnatal tissues that can self-renew as well as produce progeny that can differentiate into the various cell types that comprise the tissue.

Amniotic fluid stem (AFS) cell A multipotent cell type found in the amniotic fluid surrounding an embryo; AFS cells may be differentiated to hepatic, pancreatic, renal, cardiac, osteogenic, and chondrogenic lineages, among others.

Distal tubule The final segment of the nephron in the kidney, located between the loop of Henle and the collecting duct; regulates serum concentrations of potassium, sodium, and calcium as well as pH.

Embryonic stem (ES) cell A broadly multipotent cell type found in the inner cell mass of a blastocyst; ES cells can differentiate into nearly every cell type in the body.

Erythropoietin A glycoprotein cytokine hormone produced by the peritubular capillary endothelial cells in the kidney that controls erythropoiesis, or red blood cell production.

Glomerulus The basic filtration unit of the kidney; composed of a capillary tuft surrounded by Bowman's capsule and performs the first step in filtering blood to form urine. The rate at which blood is filtered through all of the glomeruli, and thus the measure of the overall renal function, is the glomerular filtration rate (GFR).

Loop of Henle The portion of the nephron that leads from the proximal straight tubule to the distal convoluted tubule; functions to create concentrated urine for excretion by forming an area of high sodium concentration deep in the medulla of the kidney, so that water present in the filtrate flows through aquaporin channels out of the collecting duct and is reabsorbed.

Metanephros An embryonic structure that becomes the permanent kidney in reptiles, birds, and mammals; develops by the tenth week of gestation in human embryos.

Nephron The basic structural and functional unit of the kidney; regulates the concentration of water and soluble substances like sodium salts by filtering the blood, reabsorbing what is needed, and excreting the rest as urine. The nephron also regulates blood volume and blood pressure, controls levels of electrolytes and metabolites, and regulates blood pH. In humans, a normal kidney contains 800 000 to 1 million nephrons.

Podocyte A cell with branching tentacle-shaped extensions that constitutes the barrier through which blood is filtered in the glomerulus of the kidney.

Proximal tubule The portion of the nephron of the kidney that leads from Bowman's capsule to the loop of Henle; regulates the pH of renal filtrate by exchanging hydrogen ions in the interstitium for bicarbonate ions in the filtrate; also responsible for secreting organic acids, such as creatinine and other bases, into the filtrate.

5.540.1. Introduction

Patients with renal disease were the first to benefit from transplantation, as the kidney was the first human organ to be replaced in 1955.[1] This transplant was performed from one identical twin to another. In the early 1960s, Murray, who later received the Nobel Prize for his work, transplanted a kidney from a nongenetically identical patient into another. This transplant, which overcame the immunologic barrier, marked a new era in medical therapy and opened the door for the use of transplantation as a means of therapy for different organ systems. Despite this, the problems that plagued early transplant surgeons still create difficulties today. Immunosuppressive medications are still required to prevent complications, their monitoring and controlling graft rejection can be difficult, and there is still a shortage of donor organs. These challenges have led physicians and scientists to seek alternatives in the relatively new fields of tissue engineering and regenerative medicine, and progress in these fields has paved the way for the development of new technologies for renal replacement therapy.

The difficulty in applying regenerative medicine techniques to the kidney is inherent in the complexity of the organ. Functionally, the kidney is responsible not only for waste elimination; it has endocrine properties as well. The primary role of the kidney is hemofiltration. The blood is filtered through a complex architectural system. The resulting ultrafiltrate is then concentrated in the renal tubules, which allow for the absorption and secretion of specific ions and water, thus maintaining appropriate intravascular concentrations of these components. In addition, the kidney produces erythropoietin (EPO), which is responsible for red blood cell production and adequate oxygenation of tissues. Renin is also secreted by the kidney and is a major factor in regulating blood pressure. The kidney activates vitamin D by converting the circulating 25-hydroxycholecalciferol into 1,25-dihydroxycholecalciferol, and it releases prostaglandins into the circulation. Attempts at complete renal tissue regeneration must provide these important functions in addition to filtration.

Embryologically, the kidney is derived from the integration of several primordial structures. While the metanephros is responsible for the development of the proximal section of the nephrons, the ureteric bud forms the collecting ducts and distal structures. The large vessels of the kidney are derived from extrarenal tissues. These divergent embryologic origins converge to produce at least 26 distinct functional cells in the kidney.[2] This heterogeneity creates difficulty with *in vitro* culture and in identifying potential renal stem or progenitor cells.

Despite these hurdles, there are several techniques currently being investigated for renal regenerative therapy. Some of these are based on embryology/developmental biology and others depend upon the identification of renal progenitor cells that could eventually be used for clinical applications. Still other techniques for renal regeneration or replacement are based on cell therapies. These include both the direct injection of certain cell types and the use of biomaterial scaffolds seeded with cells. This chapter will focus largely on the current status of cell-based therapies in renal regeneration, but it will also provide a brief overview of the other techniques.

5.540.2. Developmental Techniques

In mammalian embryonic kidney development, there are two successive steps leading to development of the metanephros. Initially, the ureteric buds are formed at the caudal end of the Wolffian ducts and subsequently the metanephric mesenchyme, induced by the ureteric buds, and the ureteric buds themselves interact with one another to produce the metanephros. The metanephros becomes the permanent kidney. These structures originate at day 11 of development (E11) in mice, at day 12 in rats (E12), between days 21 and 28 in pigs (E21–28), and during the fifth week of gestation in humans. Outgrowths arising from the distal end of the ureteric bud push radially into the surrounding metanephric mesenchyme. The metanephric mesenchyme differentiates into all tubular structures of the adult nephron, with the exception of the collecting system, which is derived from the ureteric bud.

To develop viable renal tissue for clinical application and tissue regeneration, transplantation of metanephroi has been attempted. Transplantation of metanephroi appears to have two significant promising factors promoting its future clinical usage. First, metanephric tissue appears to have decreased immunogenicity. Extensive literature has documented the lack of antigenicity and cotransmitters in metanephric tissue. Secondly, transplanted metanephroi have been successful in developing complex vascularization induced from host tissue. This would promote cellular survival in the host and allow development of tissues *in vivo*.

Renal anlagen transplanted into a host have demonstrated differentiation into renal tissue and functional capabilities including production of urine. In addition, the transplant was able to improve survival in anephric rodents. Initial studies demonstrating the feasibility of metanephroi transplantation were conducted by Woolf, who implanted pieces of E13–16 metanephroi into cortical tunnels fashioned in newborn mice.[3] Abrahamson was able to demonstrate survival and function of metanephroi transplanted subcapsularly in rats.[4] Rogers *et al.* were able to not only implant metanephroi outside the renal capsule in the omentum, but also performed a ureteroureterostomy, allowing for quantification of urine production.[5] Rogers *et al.* were also the first to demonstrate improved survival associated with metanephros transplantation. They implanted E15 rat metanephroi into the omentum of rats concurrent with a unilateral nephrectomy. Three weeks later, they performed ureteroureterostomy between the host ureter and the transplanted metanephroi in some of the rats. At 20 weeks following initial transplantation, they performed contralateral nephrectomy, forcing animals into end-stage renal disease (ESRD). They demonstrated a significant prolongation of life in the animals with the reconstructed excretory urinary tracts versus controls or those who received transplants without ureteroureterostomy.[6] Marshall and colleagues successfully transplanted rat metanephroi into the omentum and patches of retroperitoneal fat in the renal bed, adjacent to the circumflex iliac vessels and adjacent to the aorta/vena cava. They were able to demonstrate the presence of urinary cysts in all locations at 21 days posttransplantation. In renal units with urinary cysts, ureteroureterostomy was performed at this time point. When inulin clearance was measured 130 days

following ureteroureterostomy, the transplanted units contributed up to 11% of the total glomerular filtration rate (GFR).[7]

Integration of new nephrons into a diseased kidney could obviate the need for renal replacement therapy. Investigations into this possibility in an animal model have been promising. Woolf *et al.* implanted embryonic tissue into the renal cortex of newly born mice. They found that the donor tissue integrated into the host and generated new nephrons. In addition, the glomeruli of the donated tissue were vascularized by the host. Mature tubules and tubular extensions into the medulla were seen; however, it could not be confirmed that these nephrons connected to a collecting duct.[3] Rogers and colleagues performed a similar experiment, placing E15 rat metanephroi in adult male mice. They also found that nephron development and creation of a chimeric kidney occurred.[5] However, like Woolf, they could not verify that these nephrons connected to the collecting duct despite transplantation of a portion of the ureteric bud.[3,5]

5.540.3. Renal Progenitor Cells

Owing to the diverse nature of the kidney, identification of a single progenitor cell responsible for generating all of the cell types in the kidney is unlikely. However, because the majority of renal dysfunction results from disorders of either the tubules or the glomeruli, identifying the progenitor cells responsible for generating these structures could produce the most significant clinical impact. One method for identifying progenitor cells includes the recognition of specific cell surface markers. Bussolati and colleagues chose to determine whether CD133+ cells reside in the adult human renal parenchyma.[8,9] CD133 is expressed in hematopoietic and progenitor cells, and also in the embryonic kidney. This group observed that a CD133+ population was present and comprised approximately 0.8% of the total cell population within the renal cortex. These cells expressed Pax-2 but not CD-45 (a marker of the hematopoietic lineage) and cKit and CD90 (stem cell markers).[8] *In vivo*, these cells formed tubular-like structures following implantation into immunocompromised mice.[8] Following enzymatic digestion of rat kidneys, Plotkin and associates identified a single clone which expressed Sca-1, CD44, and CD34, the transcription factors Pod-1 and BF-2, and receptors for sonic hedgehog, BMP and retinoic acid. When these cells were injected subcapsularly following an ischemia/reperfusion injury, the isolated cells integrated into the peritubular capillaries and periphery of the papillae.[10] Gupta *et al.* enzymatically digested 4-week-old rat kidneys and cultured the resulting cellular suspension using culture methods similar to those used for bone marrow-derived cells. They identified a population of cells that were capable of >200 population doublings without senescence, and these cells expressed vimentin, Oct-4, and Pax-2, but did not express markers of either MHC class or markers of differentiated cells. When labeled cells from this study were reintroduced *in vivo*, they demonstrated integration into the renal architecture, but did not improve renal function following ischemia reperfusion injury.[9] The identification of renal cells, which can integrate into the renal parenchyma has implications for future therapies based on the replacement of nephrons. Integration of nephrons is especially promising for patients with progressive renal dysfunction to prevent ESRD.

Podocytes also present a novel model for understanding and identifying potential renal progenitor cells. Podocytes are postmitotic cells that lack the ability to reproduce, but are routinely found in the urine even in healthy individuals.[11] The number of cells lost in the urine exceeds that which would be expected for renal survival of 80 years. Therefore, it has been hypothesized that an inherent population of progenitor cells resides in the kidney and that these cells are capable of regenerating podocytes. Several groups have investigated the role of progenitor cells that may be involved in podocyte regeneration. Sagrinati and colleagues found a population of CD133+CD24+ cells that were localized opposite the vascular pole of Bowman's capsule. These parietal epithelial cells (PECs) were between 0.5% and 4% of the total cellular population, were maintained up to 90 population doublings, and expressed Oct-4 and BmI-1. When introduced *in vitro* following glycerol-induced rhabdomyolysis acute renal injury, these cells attenuated renal injury as measured by lower BUN levels 7–10 days following injection.[12]

Further investigations of the PEC by this group identified three subpopulations of these cells. A subset of undifferentiated cells only CD133/24+ was located at the urinary pole. A second transitional population of cells expressing CD133/24 and also nestin, complement receptor 1 (CR1), and podocalyxin (PDX) (all podocyte markers) were located between the urinary and the vascular pole. Continuous with the podocytes was a subset of cells that no longer expressed CD133/24, but were positive for nestin, CR1, and PDX.[13] *In vitro*, the only cells capable of differentiating into tubular cells were those that were CD133/24+ but not PDX+. To evaluate *in vivo* properties of these cells, an FSGS model of renal dysfunction was created with adriamycin infusion. The CD133/24+PDX− cells were able to reduce albuminuria and decreased glomerular and tubular quantitative injury in this model.[13] In another series of experiments, Appel *et al.* evaluated the CD133+ PECs and concluded that the PECs were capable of migration along the glomerular tuft to replace podocyte populations. They examined the cells at the base of the vascular pole adjacent to the podocytes and noted that only these cells were able to be stained with both PEC markers (claudin-1) and podocyte-specific markers (nestin, DDPIV, aminopeptidase A). A PEC-specific promotor (PDX) was identified which could be used to trace the migration of cells, and this experiment pointed to the recruitment of PEC by podocytes.[14]

Identification of renal progenitor cells is a substantial step forward in the understanding of the inherent regenerative capacity of the kidney. The ability to identify the subset of cells responsible for endogenous renal repair and expand these cells *in vitro* could have future therapeutic implications. Care must be taken in referring to these identified cells as renal stem cells, however. Currently, no group has demonstrated a population of cells which satisfy the strict definition of a 'stem cell,' which includes the ability to form clonal populations *in vitro*. In addition, this technology still needs refinement prior to clinical usage.

5.540.4. Cellular-Based Therapies

The functional heterogeneity and complex cellular architecture within the kidney present many challenges in the development of cellular therapies. These include the need to ensure precise

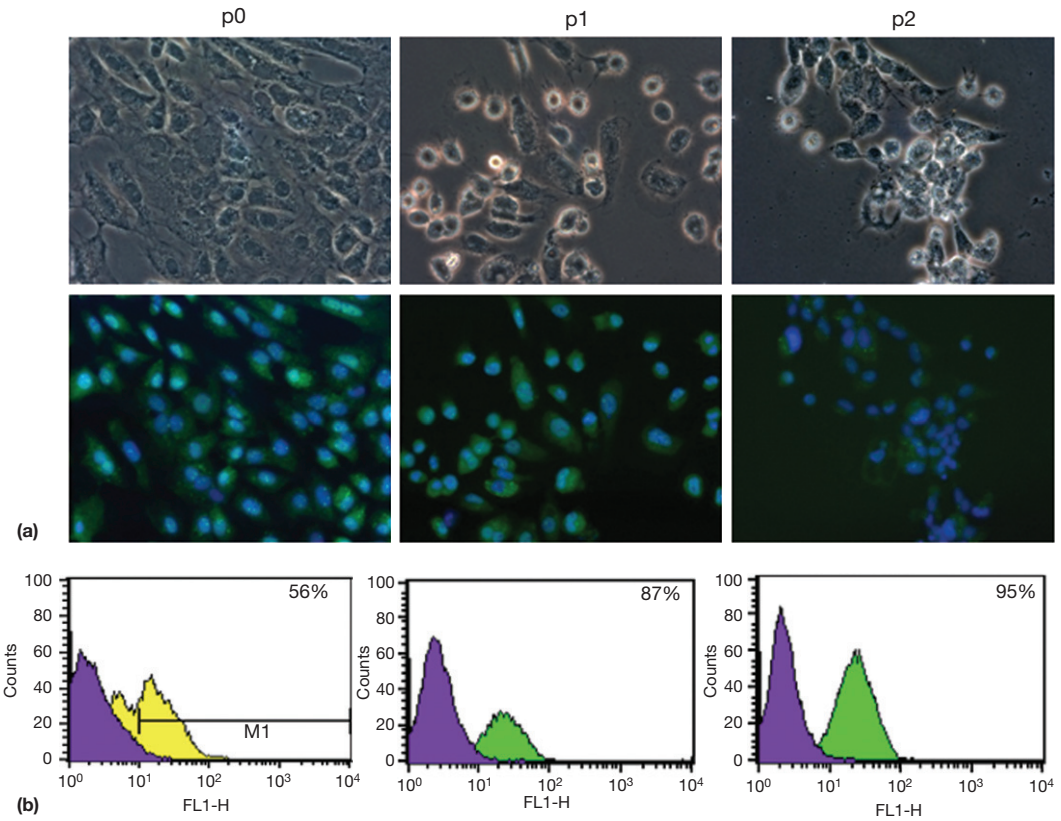

Figure 1 Isolation and characterization of EPO-producing cells. Rat primary renal cells were cultured according to previously established methods. (a) Subcultures through passage 2 and corresponding immunofluorescent staining with an anti-EPO antibody (400×). (b) FACs analysis of EPO expression through passage 2.

delivery of the cells, which allows homing to the necessary location, and the need to define exactly what type of cell should be delivered. While some groups have evaluated the possibility of using stem cells from various lineages, others have focused on the use of differentiated renal cells to improve function.

Isolation of a single cell type for reintroduction to the kidney may be an initial step in providing cellular therapies for renal dysfunction. One example of this type of therapy is the treatment of anemia associated with chronic renal dysfunction. Currently, patients with ESRD often require recombinant EPO injection in order to increase red blood cell counts, and recent research into alternatives to these injections has presented a novel platform for future clinical applications for cellular therapy. Isolation and culture of EPO-producing renal cells has been described by Aboushwareb *et al.*[15] The cells demonstrate increased EPO expression when exposed to hypoxic environments (Figures 1 and 2) (unpublished data, Aboushwareb *et al.*). These cells represent a potential lineage for future treatments of renal dysfunction-associated anemia. In another study on this topic, Bathlolomew and colleagues transfected baboon mesenchymal stem cells (MSC) with human EPO vectors and evaluated whether these cells were capable of *in vivo* EPO production. These cells could successfully produce EPO for up to 28 days in SCID mice and 137 days in baboons.[16] Targeting of anemia associated with renal dysfunction or other singular functions of the kidney may provide pathways to introduce cellular therapies for renal dysfunction.

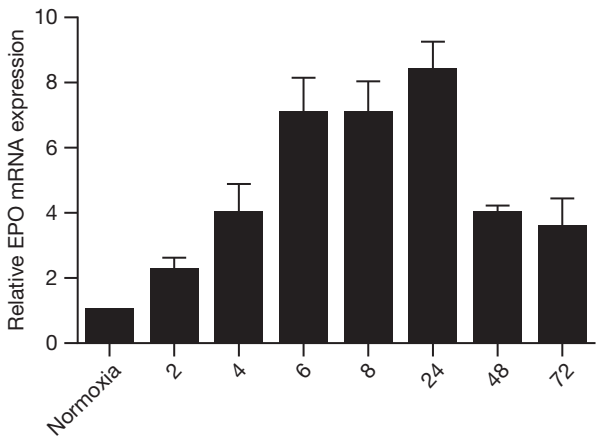

Figure 2 Time course of EPO gene expression in rat primary renal cells under 1% O_2 continuous hypoxia. Cells were allowed to grow in culture to 70% confluency. Following washing the cells and changing the medium, the culture plates were placed in continuous hypoxia from 2 up to 72 h. At the end points shown, total RNA was isolated from the cells relative EPO gene expression was quantified using real-time PCR. All the results were expressed relative to gene expression levels in normoxic samples. Result is expressed as mean ± SEM ($n = 5$).

Targeting of specific cells in the nephron could provide disease-specific cellular therapy. Patients may have either tubular dysfunction or podocyte dysfunction, and thus, each

patient requires a specific therapy based on pathology. Han and colleagues have found that primary rabbit proximal tubule cells are able to produce functional tubular units. Following enzymatic digestion of the cortex and removal of glomeruli, tubules were formed *in vitro* with luminal formation. Function was demonstrated with lucifer yellow, a fluorescent substrate of the *p*-aminohippurate (PAH) transport system transport.[17] In patients with tubular dysfunction, introduction of cultured tubules could direct therapy at the specific pathology of the disease.

Development of heterogenous populations of renal cells could also represent a potentially viable option for cellular therapy of renal disease. Joraku *et al.* developed an *in vitro* method for cultivation of mixed renal cells which allowed for the development of tubular structures (**Figure 3**). This technique involves digestion of the entire murine kidney, followed by cultivation of the resulting cells on rat-tail type 1 collagen. Upon histologic examination, cells from the thick ascending loop of Henle stained positive for Tamm–Horsfall protein.[18] This work was followed up by Souza *et al.* (unpublished data), who demonstrated the same phenomenon of self-assembly with isolated human kidney cells. These results further support the potential use of isolated and culture-expanded kidney cells for reassembling functional renal units within diseased kidneys. However, the published reports involving reintroduced adult renal cells have not yet demonstrated improvements in renal function resulting from this treatment, and the barrier of immune recognition has not been overcome either.[19]

5.540.5. Stem Cells for Use in Renal Tissue Regeneration

The cells used in regenerative medicine techniques can be autologous or heterologous in origin, and they can be either native cells or stem cells. In general, there are three broad categories of stem cells obtained from living tissue that are used for cell therapies. Embryonic stem (ES) cells are obtained through the aspiration of the inner cell mass of a blastocyst or, more recently, a single cell from this mass. Fetal and neonatal amniotic fluid and placenta may contain multipotent cells that may be useful in cell therapy applications. However, adult stem cells are usually isolated from organ or bone marrow biopsies. Stem cells are defined as having three important properties: the ability to self-renew, the ability to differentiate into a number of different cell types, and the ability to easily form clonal populations (populations of cells derived from a single stem cell). Many techniques for generating stem cells have been studied over the past few decades. Some of these techniques have yielded promising results, but others require further research.

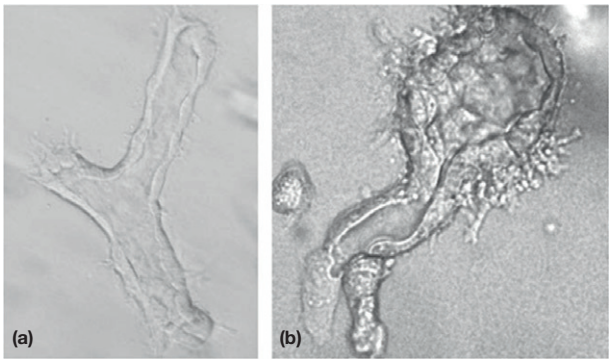

Figure 3 Murine primary renal cells form kidney-like structures *in vitro*. Primary murine renal cells were isolated, expanded in culture, and suspended in collagen. After 7 days of growth in the collagen matrix, the cells developed into three-dimensional structures that resemble tubules (a) and glomeruli (b).

5.540.5.1. ES Cells

In 1981, pluripotent cells were found in the inner cell mass of the human embryo, and the term 'human embryonic stem cell' was coined.[20] These cells are able to differentiate into all cells of the human body, excluding placental cells (only cells from the morula are totipotent, i.e., able to develop into all cells of the human body). These cells have great therapeutic potential, but their use is limited by both biological and ethical factors. The political controversy surrounding stem cells began in 1998 with the creation of human ES (hES) cells derived from discarded embryos. hES cells were isolated from the inner cell mass of a blastocyst (an embryo 5 days postfertilization) using an immunosurgical technique. Given that some cells cannot be expanded *ex vivo*, ES cells could be an ideal resource for regenerative medicine because of their fundamental properties: the ability to self-renew indefinitely and the ability to differentiate into cells from all the three embryonic germ layers. Skin and neurons have been formed, indicating ectodermal differentiation.[21–23] Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation.[24–26] Pancreatic cells have been formed, indicating endodermal differentiation.[27] In addition, as further evidence of their pluripotency, ES cells can form embryoid bodies, which are cell aggregations that contain all the three embryonic germ layers while in culture, and can form teratomas *in vivo*.[28] These cells have demonstrated longevity in culture and can maintain their undifferentiated state for at least 80 passages when grown using current published protocols.[29,30]

Various researchers have shown that ES cells may be useful in renal regenerative medicine.[31] Schulinder *et al.* were able to induce differentiation of hES into cells that produce the renal-specific products renin and WT-1 using culture media including activin-A and HGF.[32] Kim and Dressler have evaluated whether murine ES cells could be cultured *in vitro* to renal precursor cells and mesoderm. By culturing the ES cells in activin-A, retinoic acid, and Bmp7, they were able to induce genetic expression of Pax-2 (a marker of intermediate mesoderm from which the renal epithelial cells arise), WT-1 (seen in high levels in podocytes), cadherin 6 (an early marker for proximal tubules), and lim1 (seen in intermediate mesoderm). These cells also formed tubule-like structures when introduced *in vivo* to cultured kidney rediments from 12.5-day embryonic mice.[33]

Vigneau and colleagues showed that ES expressing brachyury, an embryonic nuclear transcription factor, which possibly denotes mesoderm, may differentiate into renal progenitor cells in the presence of activin-A. When these cells were injected into a developing metanephros, they were incorporated into the blastemal cells of the nephrogenic zone. Additionally, after only

a single injection into the kidneys of live newborn mice, the cells were capable of integration into proximal tubules. At 7 months, there was no evidence of teratoma formation, and the cellular morphology and polarization appeared normal.[34]

In addition to the ethical dilemma surrounding the use of ES cells, their clinical application is limited because they represent an allogenic resource and thus have the potential to evoke an immune response. New stem cell technologies such as somatic cell nuclear transfer (SCNT) and induced pluripotent stem (iPS) cells promise to overcome this limitation.

5.540.5.1.1. Single-cell embryo biopsy

One major objection to hES cell research is that it results in the destruction of embryos. Thus, a method of isolating these cells without destroying the embryo would be advantageous. In 2006, Chung *et al.*[35] were the first authors to report the generation of mouse ES cell lines in this manner. Their method was based on a technique used to obtain a single-cell embryo biopsy for preimplantation genetic diagnosis. Cells were taken from eight-cell blastomeres rather than from blastocysts. The cells differentiated into derivatives of all the three embryonic germ layers *in vitro* and into teratomas *in vivo* as well. In addition, the mouse embryos that resulted from the biopsied blastomeres developed to term without a reduction in their developmental potential.

5.540.5.1.2. Obtaining cells from arrested embryos

hES cell lines can also be derived from arrested embryos.[36] During *in vitro* fertilization, only a small proportion of zygotes produced will develop and progress successfully to the morula and blastocyst stages. Over half of the embryos stop dividing[37,38] and are therefore considered dead embryos.[39] Such embryos have unequal or fragmented cells and blastomeres and are usually discarded. Not all the cells within these arrested embryos, however, are abnormal,[36,40] and these embryos might be a source of hES cells. More studies are needed to characterize the full proliferation and differentiation potential of ES cells derived from arrested embryos.

5.540.5.1.3. Therapeutic cloning (SCNT)

SCNT, or therapeutic cloning, entails the removal of an oocyte nucleus in culture, followed by its replacement with a nucleus derived from a somatic cell obtained from a patient. Following nuclear transfer, the gene expression pattern of the transferred nucleus must be reprogrammed to that similar to an early embryo. This is accomplished through DNA modifications including histone protein modification, cytosine methylation, and chromatin remodeling, and reengineering the framework of the normal methylation patterns. This is accomplished *in vitro* through a series of chemical signals or introduction of electric potentials.

At this point, it is extremely important to differentiate between the two types of cloning that exist – reproductive cloning and therapeutic cloning. Both involve the insertion of donor DNA into an enucleated oocyte to generate an embryo that has identical genetic material to its DNA source. Following this point, however, there are important differences in the ethical and scientific implications of the techniques. In reproductive cloning, the embryo that is produced using SCNT is implanted into the uterus of a pseudopregnant female to produce an infant that is a clone of the donor. A world-famous example of this type of cloning resulted in the birth of a sheep named Dolly in 1997.[41] However, there are many ethical concerns surrounding such practices, and as a result, reproductive cloning has been banned in most countries.

While therapeutic cloning also produces an embryo that is genetically identical to the donor, this process is used to generate blastocysts that are explanted and grown in culture, rather than *in utero*. ES cell lines can then be derived from these blastocysts, which are only allowed to grow up to a 100-cell stage. At this time, the inner cell mass is isolated and cultured, resulting in ES cells that are genetically identical to the patient. It has been shown that nuclear transferred ES cells derived from fibroblasts, lymphocytes, and olfactory neurons are pluripotent and can generate live pups after injection into blastocysts. This shows that the embryos generated from cells produced by SCNT have the same developmental potential as blastocysts that are fertilized and produced naturally.[42–47] In addition, the ES cells generated by SCNT are perfectly matched to the patient's immune system, and no immunosuppressants would be required to prevent rejection should these cells be used in regenerative medicine applications.

Although ES cells derived from SCNT contain the nuclear genome of the donor cells, mitochondrial DNA (mtDNA) contained in the oocyte could lead to immunogenicity after transplantation. To assess the histocompatibility of tissue generated using SCNT, Lanza *et al.* microinjected the nucleus of a bovine skin fibroblast into an enucleated oocyte.[48] Although the blastocyst was implanted (reproductive cloning), the purpose was to generate renal, cardiac, and skeletal muscle cells, which were then harvested, expanded *in vitro*, and seeded onto biodegradable scaffolds. These scaffolds were then implanted into the donor steer from which the cells were cloned to determine if cells were histocompatible. Analysis revealed that cloned renal cells showed no evidence of T cell response, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mtDNA. This finding represents a step forward in overcoming the histocompatibility problem of stem cell therapy.

However, although promising, SCNT has certain limitations that require further improvement before its clinical application in addition to the ethical considerations regarding the potential of the resulting embryos to develop into clones if implanted into a uterus. In addition, this technique has not been shown to work in humans to date. The initial failures and fraudulent reports of nuclear transfer in humans reduced enthusiasm for human applications,[49–51] although it was recently reported that nonhuman primate ES cell lines were generated by SCNT of nuclei from adult skin fibroblasts.[52,53] In addition, before SCNT-derived ES cells can be used as clinical therapy, careful assessment of quality of the lines must be determined. For example, some cell lines generated by SCNT have contained chromosomal translocations and it is not known whether these abnormalities originated from aneuploid embryos or if they occurred during ES cell isolation and culture. In addition, the low efficiency of SNCT (0.7%) and the inadequate supply of human oocytes further hinder the therapeutic potential of this technique. Still, these studies renew the hope that ES cell lines could one day be generated from human cells to produce patient-specific stem cells with

the potential to cure many human diseases that are currently untreatable. Studies suggesting new uses for this technology are being published frequently, and these open the door for the development of many potential therapies related to these cells.[54]

5.540.5.1.4. Altered nuclear transfer

Altered nuclear transfer is a variation of SCNT in which a genetically modified nucleus from a somatic cell is transferred into a human oocyte. This embryo, which contains a deliberate genetic defect, is capable of developing into a blastocyst, but the induced defect prevents the blastocyst from implanting in the uterus. This process has the potential to generate customized hES cells from the blastocyst stage.[55] Human embryos with this genetic defect might lack the capacity to develop into viable fetuses, as a result of their inability to implant, thus providing a source of stem cells without destroying viable embryos. Proof of concept was obtained in mice by Meissner and Jaenisch[56] in 2006 using embryos lacking the *Cdx2* homeobox gene.

The viability of human embryos lacking the *CDX2* gene is unclear, as is whether this mutation restricts human developmental potential into certain lineages. While much research must be done before therapeutic strategies based on this technique could ever enter the clinic, at this time, hES cells derived from altered nuclear transfer can provide opportunities to study pluripotency in hES cells, without the need for destruction of viable embryos. The exact effects of CDX-2 gene knockout on the development of human embryos are not well known. The effects of this gene, however, have been thoroughly investigated in the gastric and intestinal epithelium.[57,58]

5.540.5.2. Reprogramming (iPS Cells)

Recently, reports of the successful transformation of adult cells into pluripotent stem cells through a type of genetic 'reprogramming' have been published. Reprogramming is a technique that involves dedifferentiation of adult somatic cells to produce patient-specific pluripotent stem cells. The advantage of this technique is that it obviates the need for creation of embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus, the patient who donated these cells) and would not be rejected. Yamanaka initially discovered that mouse embryonic fibroblasts (MEFs) and adult mouse fibroblasts could be reprogrammed into an 'induced pluripotent state (iPS)'.[59] These iPS cells were capable of immortal growth similar to the self-renewing characteristics of ES cells, expressed genes specific for ES cells, and generated embryoid bodies *in vitro* and teratomas *in vivo*. When iPS cells were injected into mouse blastocysts, they differentiated into several cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to ES cells. Unlike ES cells, chimeras made from iPS cells did not result in full-term pregnancies. Gene expression profiles of the iPS cells showed that they possessed a distinct gene expression signature that was different from that of ES cells. In addition, the epigenetic state of the iPS cells was somewhere between that found in somatic cells and that found in ES cells, suggesting that the reprogramming was incomplete.

Wernig and Jaenisch significantly improved these results in July 2007.[60] In this study, DNA methylation, gene expression profiles, and the chromatin state of the reprogrammed cells were similar to those of ES cells. Teratomas induced by these cells contained differentiated cell types representing all mesoderm, ectoderm, and endoderm. Most importantly, the reprogrammed cells from this experiment were able to form viable chimeras and contribute to the germline like ES cells, suggesting that these iPS cells were completely reprogrammed.

It has recently been shown that reprogramming of human cells is possible.[61,62] Yamanaka generated human iPS cells that are similar to hES cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Thompson's group showed that retroviral transduction of the stem cell markers *OCT4*, *SOX2*, *NANOG*, and *LIN28* could generate pluripotent stem cells. However, in both studies, the human iPS cells were similar but not identical to hES cells. Recent efforts by several researches have demonstrated successful creation of iPS in more than one animal model.[63,64] The porcine model is the most important of these due to its similarity to the human kidney. They each published retroviral transfection of cells with expression of stem cell markers. These are exciting potential preclinical models for future therapeutic direction.[65] Although reprogramming is an exciting phenomenon, our limited understanding of the mechanism underlying it currently limits the clinical applicability of the technique, but the future potential of reprogramming is quite exciting.

5.540.5.3. Amniotic-Fluid and Placenta-Derived Stem Cells

The amniotic fluid and placental membrane contain a heterogeneous population of cell types derived from the developing fetus.[66,67] Cells found in this heterogeneous population include MSC.[68,69] In addition, the isolation of multipotent human and mouse amniotic-fluid and placental-derived stem (AFPS) cells that are capable of extensive self-renewal and give rise to cells from all the three germ layers was reported in 2007.[70] AFPS cells represent approximately 1% of the cells found in the amniotic fluid and placenta. The undifferentiated stem cells expand extensively without a feeder cell layer and double every 36 h. Unlike hES cells, the AFPS cells do not form tumors *in vivo*. Lines maintained for over 250 population doublings retained long telomeres and a normal complement of chromosomes. AFPS cell lines can be induced to differentiate into cells representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neural-like, and hepatic lineages. In addition to the differentiated AFPS cells expressing lineage-specific markers, such cells can have specialized functions. Cells of the hepatic lineage secreted urea and α-fetoprotein, while osteogenic cells produced mineralized calcium. In this respect, they meet a commonly accepted criterion for multipotent stem cells, without implying that they can generate every adult tissue.

Amniotic fluid stem (AFS) cells represent a new class of stem cells with properties somewhere between those of embryonic and adult stem cell types, probably more agile than adult stem cells, but less so than ES cells. Unlike embryonic and iPS cells, however, AFPS cells do not form teratomas, and if preserved for self-use, avoid the problems of rejection. The cells

could be obtained either from amniocentesis or chorionic villous sampling in the developing fetus, or from the placenta at the time of birth. They could be preserved for self-use and used without rejection, or they could be banked. A bank of 100 000 specimens could potentially supply 99% of the US population with a perfect genetic match for transplantation. Such a bank may be easier to create than with other cell sources, since there are approximately 4.5 million births per year in the United States.

Since the discovery of the AFPS cells, other groups have published on the potential of the cells to differentiate to other lineages such as cartilage[71] and lung.[72] Perin and colleagues investigated if AFPS could differentiate into renal structures by labeling human cells and injecting them into murine embryologic renal tissues. The anlagen were cultured *in vitro* using a novel method to allow embryologic survival through 10 days in culture. The AFPS integrated in renal structures including C and S bodies. Reverse transcriptase polymerase chain reactions (rtPCR) demonstrated zona occludens-1, claudin, and glial-derived neurotrophic factor, all of which are early markers for renal differentiation and were not seen in AFPS not injected into the anlagen.[73] This study demonstrates that AFPS can differentiate into renal lineage when cultured *in vitro* with renal precursors. While this is promising, further *in vivo* studies and functional assays are required prior to clinical applications with AFPS.

5.540.5.4. Adult Stem Cells

Adult stem cells, especially hematopoietic stem cells, are the best understood cell type in stem cell biology.[74] However, adult stem cell research remains an area of intense study, as their potential for therapy may be applicable to a myriad of degenerative disorders. Within the past decade, adult stem cell populations have been found in many adult tissues other than the bone marrow and the gastrointestinal tract, including the brain,[75,76] skin,[77] and muscle.[78] Many other types of adult stem cells have been identified in organs all over the body and are thought to serve as the primary repair entities for their corresponding organs.[79] The discovery of such tissue-specific progenitors has opened up new avenues for research.

A notable exception to the tissue specificity of adult stem cells is the MSC, also known as the multipotent adult progenitor cell. This cell type is derived from bone marrow stroma.[80,81] Such cells can differentiate *in vitro* into numerous tissue types[82,83] and can also differentiate developmentally if injected into a blastocyst. Multipotent adult progenitor cells can develop into a variety of tissues, including neuronal,[84] adipose,[78] muscle,[78,85] liver,[86,87] lungs,[88] spleen,[89] and gut tissue,[81] but notably not bone marrow or gonads. There has been considerable research into the identification, characterization, and expansion of the renal multipotent progenitor cell.

5.540.6. *In Situ* Kidney Development

An attractive potential renal regenerative therapy would be a combination of several of the individual therapies discussed earlier. The ability to create a segment of functional kidney tissue *in vitro* and subsequently implant this into a patient with renal dysfunction would obviate the need for lifelong dialysis and for obtaining a suitable donor kidney. In addition, if such a construct could be seeded with autologous cells derived from the patient to be treated, there would be no need for immunosuppression. Previous studies have demonstrated that a bladder scaffold seeded with autologous cells can be transplanted *in vivo* with excellent results, even after 5 years of follow-up. While the kidney represents a more ambitious endeavor in terms of its more complex architecture and function, the promising results of the bladder regeneration study open the door for clinical use of this type of therapy for renal dysfunction.

One potential method for *in vitro* growth of kidney tissue involves the use of both biomaterial scaffolds and kidney cells. Heterogeneous cell populations could be seeded on an implantable biomaterial, and this construct could be cultured *in vitro* for some time to allow for cellular attachment and growth. Autologous cell populations for this purpose could be obtained with a renal biopsy. Atala *et al.* demonstrated the feasibility of this approach by plating donor rabbit kidney cells, including cells from the distal tubules, glomeruli, and proximal tubules *in vitro*. After expansion, these cells were seeded onto biodegradable polyglycolic acid (PGA) scaffolds and implanted subcutaneously into athymic mice. The implants consisted of either individual cell types or a mixture of all the three. When examined histologically, progressive formation and organization of the nephron segments within the polymer fibers was noted. Additionally, BrdU incorporation into the renal cell DNA was confirmed. However, it was unclear if the tubular structures found on the scaffolds formed *de novo* from the implanted cells or if they merely represented fragments of donor tubules which had survived the original dissociation and culture process intact. To further investigate this, mouse renal cells were harvested and expanded in culture. Subsequently, single isolated cells were seeded on biodegradable polymers and implanted in immune-competent synergic hosts. In this study, it was shown that renal epithelial cells reconstituted tubular structures *in vivo*. The analyses of the retrieved implants demonstrated that renal epithelial cells first organized into a structure with a solid center. Subsequently, canalization into a hollow tube could be seen at 2 weeks. Histologic examination with nephron-specific lactins revealed successful reconstitution of proximal tubules, distal tubules, loops of Henle collecting tubules, and collecting ducts. These results clearly showed that single-cell suspensions grown *in vitro* are capable of reconstituting into tubule structures. The tubules contained homogenous cell types within each tubule.

Yoo *et al.* evaluated murine renal cells grown *in vitro*.[90,91] They harvested the cells, expanded them in culture, and seeded them onto a tubular device constructed from polycarbonate. At one end of the tubular device was a silastic catheter, which terminated into a reservoir. The device was subcutaneously implanted into athymic mice. The implanted device demonstrated extensive vascularization in addition to glomerular formation and highly organized tubular architecture. Immunohistochemistry staining for alkaline phosphatase showed positivity in the proximal tubule-like structures. Osteopontin, which is secreted by the proximal and distal tubular cells and the cells of the thin loop of Henle, was found on immunocytochemical staining of the tubular sections. The extracellular

matrix of the newly formed tubules stained uniformly positive for fibronectin. The fluid collected from the reservoir was yellow and the uric acid concentration was 66 mg dl^{-1} (as compared to 2 mg dl^{-1} in plasma). The creatinine concentration of the fluid (27.91 ± 7.56 mg dl^{-1}) was 8.2 times higher than that found in the serum (4.49 ± 0.08 mg dl^{-1}). This demonstrates that single cells can form multicellular structures, become organized into functional renal units, and are capable of unidirectional excretion of solutes through a urine-like fluid.

Ross and colleagues have used a combination of renal scaffold and ES cells to induce *in vitro* formation of a kidney. Using a series of detergents, and following an intricate protocol to preserve physiologic pressure, they successfully decellularized a rat kidney as evidenced by histologic examination. At this point, ES cells from a GFP-labeled mouse were injected through either the ureter or renal artery, and the tissue was cultured *in vitro*. Without the use of differentiation agents, immunostains and rtPCR demonstrated Pax-2 (a critical factor in branching morphogenesis and is expressed in both the ureteric bud and induced metanephric mesenchyme) and Ksp-cadherin (an adhesion protein expressed by distal nephron tubular cells at later developmental stages).[92] Here, the decellularized extracellular matrix induces the differentiation of ESC and raises the possibility of using decellularized porcine kidneys, which have similar architecture to human kidneys, as a future clinical intervention.

To determine whether renal tissue could be formed using an alternative cell source, SCNT was performed to generate histocompatible tissues, and the feasibility of engineering syngeneic renal tissues *in vivo* using these cloned cells was investigated.[48] Renal cells from the cloned embryos were harvested, expanded *in vitro*, and seeded onto three-dimensional renal devices (Figure 4). The devices were implanted into the back of the same steer from which the cells were cloned and were retrieved 12 weeks later. This process produced functioning renal units. Urine production and viability were demonstrated after transplantation back into the nuclear donor animal. Chemical analysis suggested unidirectional secretion and concentration of urea nitrogen and creatinine. Microscopic analysis revealed formation of organized glomeruli and tubular structures. Immunohistochemical and RT-PCR analysis confirmed the expression of renal mRNA and proteins. These studies demonstrated that cells derived from nuclear transfer can be successfully harvested, expanded in culture, and transplanted *in vivo* with the use of biodegradable scaffolds on which the single suspended cells can organize into tissue structures that are genetically identical to that of the host. These studies were the first demonstration of the use of therapeutic cloning for regeneration of tissues *in vivo*.

5.540.7. Renal Tubular Assist Devices

Development of a renal tubular assist device (RAD) to attenuate hemofiltration has been another avenue of cellular therapy investigated. Humes and colleagues have designed an extracorporeal device, which works in concert with hemofiltration units. Here, proximal tubule cells are seeded in confluent monolayers in a multifiber bioreactor. When used for dialysis, blood is pumped through a conventional hemofilter. Following processing through this filter, the ultrafiltrate is again processed through the RAD. The filtered blood exiting the hemofilter enters the RAD through the extracapillary space port and then disperses throughout the fibers of the device. The hollow fiber membrane protects the cells lining the inner surface from immune-related attacks. The purpose of these devices is to supplement hemofiltration and attempt to replace the physiologic functions of the kidney that are not addressed with hemofiltration. Initial studies using porcine tubular cells demonstrated significantly improved ammonia excretion and elevated plasma levels of 1,25-dihydroxyvitamin D3 in dogs with acute uremia. Cells on the RAD demonstrated replicative capacity as they returned to baseline function 2 weeks following usage.[93]

A phase I/II trial of the RAD was performed in 10 ICU patients with acute renal failure associated with acute tubular necrosis. Proximal tubule cells for the RAD were derived from

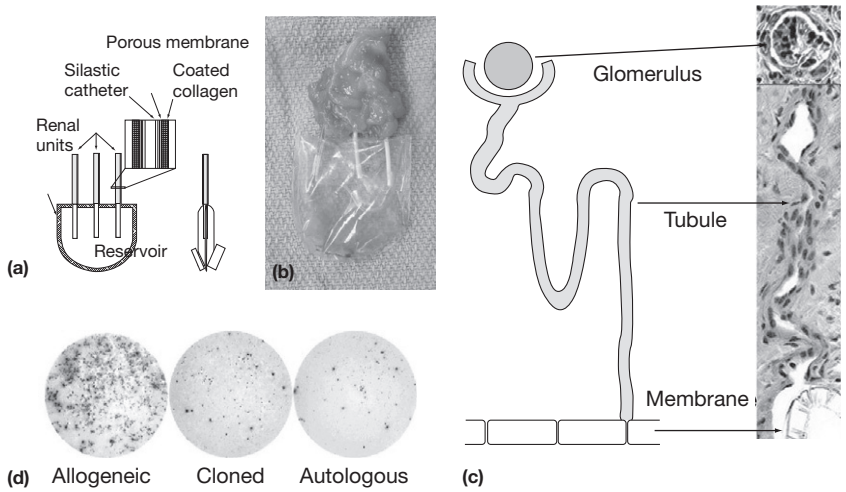

Figure 4 Production of kidney tissue by therapeutic cloning and regenerative medicine. (a) Illustration of the tissue-engineered renal unit. (b) Renal unit seeded with cloned cells, 3 months after implantation, showing the accumulation of urine-like fluid. (c) There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. (d) ELISPOT analyses of the frequencies of T cells that secrete IFN-γ after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

the human kidney tissue that was intended for transplant but discarded due to anatomic or fibrotic concerns. These patients had significant other comorbidities with multiple concomitant illness and multiple organ failures. The most common adverse effects were hypovolemia, thrombocytopenia, and hyperglycemia. The RAD did appear to have an immunomodulatory effect, as there was a significant decline in IL-6, IL-10, and G-CSF. Despite high predicted 30-day mortality rates, 60% of patients survived for 30 days.[94] It is difficult to interpret efficacy from a phase I/II trial, so the results from a phase III, multicenter, randomized, controlled, open-label trial were reported recently. Here, 58 patients were randomized into two groups: 40 patients were treated with the RAD and hemofiltration versus 18 patients with hemofiltration alone. With a median treatment duration of 35.9 h, there was only one malfunction of an RAD. Patients receiving RAD renal supplementation were found to have an earlier recovery of renal function, although this was not statistically significant. Survival was significantly improved at 180 days in patients with RAD support. Using subgroup analysis, higher survival rates were noted for RAD patients for all sets of organ failure.[95] It is important to recognize that the patients enrolled in these studies are critically ill patients in the intensive care unit. Despite this, a substantive effect on survival and renal recovery was noted, paving the way for future investigations.

5.540.8. Summary and Conclusions

Renal regenerative therapy is an exceedingly complex endeavor due to the multiple functions of the kidney. However, as there is a shortage of donor kidneys and more patients progressing to ESRD, there is true hope for a significant clinical application. Through the use of methods described here, the future for renal regenerative therapy has great potential for clinical impact in the future.

Glossary

Acute liver failure Rapid development of severe complications after the first signs of liver disease, which indicates that the liver has sustained severe damage.
Bioartificial liver (BAL) device Artificial extracorporeal device designed to provide temporary support for liver functions during acute liver failure.
Chronic liver failure Diseased state of liver that involves progressive destruction of the liver parenchyma leading to fibrosis and cirrhosis.
Orthotopic liver transplantation Replacement of a diseased liver with a healthy allogenic organ.

Abbreviations

BAL	Bioartificial liver
DLM	Decellularized liver matrix
ECM	Extracellular matrix
ESC	Embryonic stem cell
hESC	Human embryonic stem cell
iPS cell	Induced pluripotent stem cell

5.541.1. Introduction

5.541.1.1. Liver Structure and Function

The liver is the largest solid organ of the body, constituting ~2–5% of the adult body weight. It is a dark reddish brown organ shaped like a cone. It lies below the diaphragm on top of the stomach in the thoracic region of the abdomen. It has two main and two accessory lobes conforming to peritoneal attachments and surface fissures. According to the functional vascular anatomy of the organ, it is divided into eight sectors and segments with independent afferent and efferent blood supply and biliary channels within collateral circulation within the segments. Structurally and histologically, the liver can be divided into four tissue systems[1]: intrahepatic vascular system, stroma, sinusoidal cells, and hepatocytes.

The intrahepatic vascular system comprises the hepatic artery, portal vein, hepatic vein, and biliary system. Because of its location in between the digestive tract and the rest of the body, the liver is provided with dual blood supply from portal vein and hepatic artery.[2,3] The portal blood passes through the periportal limiting plate of hepatocytes and enters into the sinusoids through venous inlets. Arterial blood in terminal branches of the arteries also flows into the sinusoids and gets mixed in with the portal blood. The outflow of the sinusoidal blood (75% portal, 25% arterial) is into the central hepatic vein. The hepatic vein emerges from the central hepatic vein within each lobule. Hepatic veins collected from different segments of the liver drain into the inferior vena cava at the posterior surface of the liver below the diaphragm.[4,5] The biliary system emerges from the biliary canaliculus, which is a bile capillary formed by intercellular space bound by two adjacent hepatocytes. The

canaliculi are interconnected and form an extensive polygonal network. The network of canaliculi reaches an ampulla-like extension called the Hering's canal, which is considered as the end of canaliculi and the beginning of the ductules. The ductules are followed by bile ducts, which gradually increase in size and collect to form the common bile duct exiting the liver.[6]

The stroma of the liver is differentiated as four different structures: liver capsule, perivascular connective tissue, Glisson's portal track, and reticular network. The liver extracellular matrix (ECM) is composed of collagens type I and III (large fibrils), IV (net structure), V and VI (small fibrils), glycoproteins (laminin and fibronectin), elastins, glycosaminoglycans and proteoglycans.[7] The capsule of the liver has an endothelial cell coating and a network of collagen and elastin fibers. The capsule has connections to the blood and lymph vessels as well as the bile duct. It is also closely connected to the liver parenchyma. The perivascular connective tissue, also called the Glisson's capsule, starts at the portal vein and extends into the parenchyma surrounding the interlobular vessels. The reticular network consists of lattice fibers, which lie on the hepatic cell plates and provide mechanical support to the sinusoids. In the portal tract, the perivascular connective tissue terminates in the connective tissue covering of the perivascular fibrous capsule. The continuous line of hepatocytes bordering the portal tract is called the limiting plate.

One of the cellular components of the liver are the sinusoidal cells (also called the nonparenchymal cells). These cells include endothelial cells, Kupffer cells, Ito cells, and Pit cells. Although they take up a smaller portion of the liver volume (6.5%), they constitute 30–40% of the total cell number. Endothelial cells form a large portion of the sinusoidal cells and they form the lining of the sinusoids. They are interspersed with pores that control filtering of components from the blood and regulate exchange of fluid and compounds between the sinusoidal blood and the hepatocytes. Endothelial cells also form and secrete cytokines and ECM as well as vasoactive substances and growth factors. Kupffer cells, also considered as liver resident macrophages, are found randomly distributed in the sinusendothelium. Their main function is phagocytosis. Other functions include pinocytosis, secretion of signaling molecules such as cytokines, and clearance of toxins.[8–11] Ito cells are also called fat-storing cells or stellate cells and they lie in the space of Disse. They are involved in regulation of the sinusoid width, and they regulate and secrete ECM. Pit cells are resident lymphocytes that are natural killer cells and they destroy tumor cells and foreign cells, as well as necrosed cells.

Hepatocytes are the parenchymal cells of the liver that are responsible for the functions of the liver. They are polygonal epithelial cells that are highly polarized. About 37% of the cellular surface area is sinusoidal surface and performs absorptive and secretory functions. About 12% of the cellular membrane faces the bile canaliculi and this area is the secretory pole of the cells. The remaining 50% of the cellular membrane is the smooth intercellular fissure, that is connected to the space of Disse. The space is sealed from bile canaliculi by tight junctions only allowing the exchange of water and cations. The rest of the junctions are intermediate junctions and desmosomes between adjacent hepatocytes. They contain gap junctions that facilitate intercellular exchange.

There are several descriptions of a functional liver unit due to the lack of defined appearance of structural lobules in a human liver. A classical central vein lobule resembles a hexagon with portal tracts in the corners. It consists of radially arranged plates of 15–20 hepatocytes between the central vein and the limiting plate. The hollow spaces between the liver cells plates form a network of sinusoids and space of Disse. In the central vein lobule, blood flows from the branches of hepatic artery and hepatic portal vein through liver sinusoids and it flows out to the central vein.

A portal vein lobule also resembles a hexagon, where the periportal region is in the center and the central veins form the limiting points. Blood flow is from the center to the periphery, and the bile flow is from the periphery to the center.

Liver acinus is defined as the functional unit of the liver determined by the microcirculatory architecture. At the center of the acinar unit, there is the portal vascular bundle with the terminal branches of the hepatic artery and portal vein. The central vein is at the periphery of the acinus towards which the sinuoids extends radially and drains off the blood. An acinus is also a secretory unit for the transport of the bile. Three or more acini form a complex acinus and constitute different metabolic zones arranged radially around the vessels. Each zone differs in the contents of their blood supply such that zone 1 hepatocytes, closest to the vessels, are exposed to the highest oxygen and nutrient supply. The toxic compound content of the blood in zone 1 is also the highest and damaging to the cells. Zone 2 has an intermediate blood supply and zone 3 being nearest to the central vein has the least oxygen and nutrient supply. The zonal variation of the blood supply brings about the zonal heterogeneity of hepatocyte metabolic functions.[12–14]

The liver performs many metabolic functions that are essential for the maintenance of the health of the human body. Due to its location between the digestive tract and the rest of the body, its two blood supply channels import a large variety of endobiotics and xenobiotics, including nutrients and toxic substances from the digestive system. The major role of liver is the regulation of metabolism at molecular, cellular, and organ level. This brings about a complex set of functions that are carried out by the liver. There are about 70 different functions made possible by approximately 500 reactions that take place in hepatocytes.[1]

The major metabolic functions of the liver can be categorized in 12 different areas. These include bilirubin metabolism, porphyrin metabolism, uptake of amino acids, carbohydrates, lipids, and vitamins and their subsequent storage, metabolic conversion, and release into the blood and bile. Part of its metabolic regulation activity comes from hormone production. Alcohol degradation, acid base balance, and trace element metabolism form another group of functions. Finally, biotransformation and detoxification of substances that enter the body by the liver is another essential liver function.

5.541.1.2. Liver Failure

The structural and functional integrity of the liver is vital to the health of the human body. Even though a healthy liver may regenerate from one-third of its volume, any major insult to the organ may result in liver failure that must be corrected

immediately. It is usually associated with increased levels of endogenous substances such as bilirubin, ammonia, lactate, glutamine, aromatic amino acids, free fatty acids, phenol, mercaptans, benzodiazepines, and proinflammatory cytokines.[1] The overload of toxins saturates detoxification pathways in the liver; which subsequently leads to accumulation of new toxins and progressively leads to liver failure.[15] Furthermore, accumulation of toxins may impair liver function due to hepatic necrosis and apoptosis. The liver failure may be acute or chronic, which may be due to several reasons. Hepatic encephalopathy, coagulopathy, jaundice, sepsis, kidney failure, and cholastasis are major complications of liver failure. In acute liver failure, the liver function decreases abruptly for which the most common reasons are intoxications (e.g., acetaminophen), viral infections, and hepatic ischemia.[16] Chronic liver failure occurs in the context of cirrhosis which happens due to chronic viral infections of the liver, excessive alcohol intake, or hereditary or autoimmune liver disorders. In the United States alone, about 30 million people undergo a liver disorder, with roughly 27 000 deaths due to liver disease being registered annually. Metabolic disorders of the liver such as nonalcoholic steatosis due to obesity will likely increase this number in the future.

5.541.1.3. Strategies for Replacement of Hepatic Function

Currently, the only definitive treatment for severe hepatic failure is orthotopic transplantation. However, a critical shortage of organs causes a growing deficit of ~4000 livers per year.[17] Extracorporeal liver support systems are intended for the support of liver functions during liver failure until a suitable donor is found. However, they are still in the experimental stage and have not yet made it to the bedside. Hepatocyte transplantation is an alternative way to treat patients with liver diseases[18–20] and years of laboratory and clinical studies have demonstrated its efficacy.[21–24] However, limited cell supply and minimal engraftment efficiency have traditionally limited this approach.[18,25,26] Finally, tissue engineering approaches offer tools to create implantable tissue systems, which is another alternative to organ transplantation. Each of these approaches will be discussed further in the text.

5.541.2. Extracorporeal Liver Support Devices

Extracorporeal liver support devices are intended for use to bridge liver failure patients for transplants and provide hepatic support until the liver recovers from an acute liver failure.[27] It can provide artificial or bioartificial support depending on whether or not cells are included in the design of the device. An artificial liver support device aims to replace the detoxification functions of the liver by using membrane separation techniques that involve adsorption by charcoal, anion, or cation exchange resins. The separation selectively removes toxins and regenerates the dialysate. Such devices that have been tested clinically include the liver dialysis device,[28,29] Molecular Adsorbent Recirculating System (MARS),[30,31] and The Prometheus.[32,33] However, these devices are still considered experimental because their efficacy has not been demonstrated in large clinical trials.[34]

A bioartificial liver (BAL) device aims to replace not only the detoxification functions but also the synthetic functions of the liver by incorporating cells into the design of the device. The device consists of a housing unit called the bioreactor where the cells are cultured. The two important factors that determine the efficacy of the device include the bioreactor design and the source of the cells used in the system. These two factors will be discussed in detail next.

5.541.2.1. Bioreactor Design

The bioreactor design in a BAL device is an important factor as it directly affects the function of the cells cultured in the BAL.[35,36] (see **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design**.) The design parameters for an ideal bioreactor include reduction of mass transfer resistances and elimination of substrate limitations so that the device can function at maximum efficiency and minimize the dead volume within the device, thereby reducing the effects of plasma dilution in the patient.[37] The general operation of a BAL device is such that hepatocytes are seeded in the bioreactor and the patient's blood or plasma is circulated through the device. The ideal bioreactor design should maximize mass transfer to the hepatocytes hence maximizing the delivery of oxygen, nutrients, and toxins from patient's blood to the hepatocytes. The treated blood or plasma is then returned to the patient. This task requires large surface area for mass transfer as well as uniform hepatocyte and flow distribution. Various design configurations have been used to achieve these goals.

Most devices tested clinically utilize hollow fiber cartridges in which the cells are loaded inside the cartridge and the patient's plasma or blood is circulated in the lumen.[38–40] Due to the large diameter of fibers used in these designs as well as the resistance to mass transport through the fibers, hollow fiber bioreactor design is associated with issues related to substrate limitations.[41–45] Hepatocytes are highly metabolically active cells with very high demand for oxygen. The design limitations described above for hollow fiber bioreactors necessitates the enhancement of oxygen delivery to the cells for survival and optimal function. Earliest attempts to enhance oxygen delivery to the cells involved incorporating hollow fibers as conduits for oxygenation that were shown to help hepatocytes express differentiated function over several weeks.[46–49] Later studies focused on increasing the oxygen delivery to the cells through the use of oxygen carriers in the perfusate such as red blood cells[50] or perfluorocarbons.[51,52]

Another bioreactor design in BAL devices is based on flat surface geometry in which the hepatocytes are attached on a flat surface. In such a design, it is easier to control the internal flow distribution and to adequately perfuse and oxygenate the cells. However, one problem with such a design is achieving a sufficient concentration of cells without increasing the dead volume in the bioreactor beyond what is physiologically possible. In a flat plate bioreactor, the chamber volume is directly proportional to the channel height, and decreasing the channel height to decrease the volume increases the shear stress exerted by the flow on the hepatocytes. In an attempt to adequately oxygenate pig hepatocytes and protect the cells from shear stress in a flat plate bioreactor, de Bartolo and coworkers cultured liver cells between two gas-permeable membranes

and showed that the cells maintained differentiated functions for 18 days under flow conditions.[53,54] A comparison of a radial flow flat plate design to a hollow fiber bioreactor revealed that cells achieved polarity faster and expressed higher hepatic functions in the radial flow flat plate bioreactor due to the maximal contact of hepatocytes with the fresh perfusate in the radial flow configuration. The radial flow design also permits scale up without sacrificing the survival and the function of the cells.[55]

Using microfabrication techniques, we developed a microchannel flat plate bioreactor with an internal gas permeable membrane through which oxygen is supplied (**Figure 1**).[56] The oxygen distribution was found to be sufficient to maintain high hepatocyte survival, and albumin and urea functions for 4 days of perfusion.[57–59] In addition, such a BAL device with an internal membrane oxygenator was shown to rescue animals undergoing fulminant hepatic failure induced by D-galactosamine.[60] Further improvement to this design was made by incorporating microgrooves on the substrate plate. Hepatocytes were seeded in the microgrooves to protect them from detrimental shear stress (**Figure 2**). With the microgroove design, the cell viability was much higher resulting in a more stable production of albumin and urea over a 4-day culture period when compared to the flat substrate bioreactors.[61] In order to increase the cellular capacity of the bioreactor without introducing oxygen deprivation, stacked microgrooved plates in a radial configuration were used in later studies.[62]

5.541.2.2. Cell Source

The cell mass required to support an animal model of hepatic failure has not been systematically determined. Prior studies have shown significant improvements in various parameters using as low as 2–3% of the normal liver mass of the animal.[54,63] Devices that have undergone clinical testing have used 6×10^9–1×10^{11} porcine hepatocytes[47,48,64] or 4×10^{10} C3A cells.[65] Recently, in a pig model of hepatic failure, a BAL containing as few as 6×10^8 pig hepatocytes (about 3–5% of the liver mass) significantly improved survival.[66]

Clinical improvements have also been seen in hepatocyte transplantation studies using less than 10% of the host's liver mass. Intrasplenic transplantation of 2.5×10^7 allogeneic rat hepatocytes (~5% of the rat liver mass) prolonged the survival and improved the blood chemistry of anhepatic rats.[67] In another study using reversibly transformed human hepatocytes, 5×10^7 cells were injected intrasplenically into 90% hepatectomized rats.[68] In a recent study on humans with acute liver failure, intrasplenic and intraarterial injections of human hepatocytes (ranging from 10^9 to 4×10^{10} per patient, i.e., 1–10% of the total liver mass) transiently improved blood chemistry parameters and brain function after a lag time of about 48 h, but did not improve survival.[69] The lag time before any benefit is observed may reflect the time required for the engraftment of the cells in the host liver. Better survival of the injected cells may be possible if they were seeded in prevascularized polymeric scaffolds.[70] The relatively low number of hepatocytes needed

L.; Tilles, A. W. *Biotechnol. Bioeng.* **2005**, *90*, 632–644, with permission from Wiley.

for a therapeutic benefit suggests the possibility that the exogenously supplied hepatocytes may aid the regeneration of the native liver.[63] Considering that the cells in BAL devices do not survive for extended periods of treatment, cell sources chosen for BAL devices should be readily available in large numbers (see **Chapter 5.507, Tissue Engineering and Selection of Cells**).

Most clinically applied BAL support devices use primary porcine hepatocytes.[71] They are relatively easy to prepare in large quantities and show many of the differentiated functions of the primary adult human hepatopcytes.[72] Even though the safety and the efficacy of BAL devices using porcine hepatocytes have been demonstrated in preclinical trials,[55,60,73,74] significant improvement in patient survival has not been seen yet.[38,71,75] One disadvantage of using porcine hepatocytes is related to the immunological problems. Sustained exposure to xenogenic cells might result in anaphylactic reaction after 1 week.[76–78] In addition, there is also the risk of zoonosis including the transmission of porcine endogenous retrovirus (PERV), associated with the use of xenogeneic cells.[79]

An ideal cell type for use in a BAL device is the adult primary human hepatocyte because of the high number of differentiated liver functions demonstrated by this cell type. Primary adult human hepatocytes are isolated from discarded organs that are not found suitable for transplantation; hence they are usually in low supply and of low quality. In addition, primary adult hepatocytes are postmitotic and have no capacity to expand in culture to obtain sufficient numbers for use in a BAL device. Therefore, the shortage and the low quality of primary adult human hepatocytes limit the use of these cells in BAL devices.[80]

One alternative cell type is the human hepatocellular carcinoma cell line, HepG2. It is commonly used in the study of hepatocyte biology and has been shown to produce liver proteins including α-fetoprotein, albumin, α2-macroglobulin, α1-antitrypsin, transferrin, α1-antichymotrypsin, haptoglobin, ceruloplasmin, plasminogen, complement (C4), C3 activator, fibrinogen, α1-acid glycoprotein, α2-HS glycoprotein, β-lipoprotein, and retinol-binding protein.[81] A clonal derivative of HepG2, C3A cell line, is also used in BAL devices. It is selected for its strong contact inhibition of growth and increased albumin production in confluent cultures.[82,83] The ease of expansion to sufficient numbers and the display of a number of hepatic functions made them an attractive source of cells for use in bioartificial devices.[84] However, the low expression of phase I drug metabolizing enzymes compared to primary adult human cells makes them less attractive in detoxification properties desired in BAL support devices.[85,86]

Human fetal hepatocytes are an alternative source of human hepatocytes for use in BAL devices. Fetal hepatocytes, usually isolated from 22 to 24-week-old fetuses, still have the capacity to proliferate and, hence, they offer the possibility of being obtained in sufficiently high numbers for use in BAL devices. If the population doubling is not adequate, it is also possible to immortalize human fetal cells by SV40 or hTERT transformation.[87,88] Several studies report culture techniques to maturate fetal hepatocytes to display differentiated hepatic functions, which make them an attractive source for use in cell-based therapies for liver failure including BAL suppot.[89–92] However, ethical issues related to the use of fetal tissue as

well as the low availability of such a source necessitates the clonal expansion and generation of fetal hepatocyte cell lines that can match the functional capacity of adult primary hepatocytes.

An attractive cell source for generating human hepatocytes is the use of embryonic stem cells (ESCs). Human embryonic stem cells (hESCs) are pluripotent and they have the capacity for indefinite self-renewal when maintained under appropriate cell culture conditions. Given appropriate cues, they can form all three germ layers,[93–95] so they present as an invaluable cell source for cell-based therapies. ESC lines are derived from the inner cell mass of blastocyst stage embryos[93,96,97] and cultured on various types of feeder cells or suitable ECM under feeder-free conditions.[98,99] The pluripotency of hESCs is maintained in culture with knockout serum replacement and supplemental basic fibroblast growth factor.[100,101] The ethical issues related with the derivation and use of ESCs led to the generation of induced pluripotent stem (iPS) cells.[102] Generation of iPS cells involves introduction of pluripotency factors into adult somatic cells. The first studies used four transcription factors, Oct4, Sox2, c-Myc, and Klf4, which were introduced into adult mouse fibroblasts through retroviral transfection.[102] Through unknown mechanisms, these transcription factors reprogram the somatic cells into the pluripotent stage. Like hES cells, iPS cells have compact colony morphology and can be maintained in culture for prolonged periods. They express pluripotency markers such as Oct4, Nanog, SSEA-1, and they can differentiate *in vitro* and *in vivo* into three germ layers. One of the concerns about the use of iPS cells in cell therapies was the use of oncogenes, c-Myc and Klf4, to induce pluripotency. However, later studies showed that replacing c-Myc and Klf4 with Nanog and Lin-28 was also successful.[103] The use of small molecules such as valproic acid, a histone deacetylase inhibitor, instead of c-Myc and Klf4, has also been successful in inducing pluripotency in human fibroblasts.[104] Another concern about the use of iPS cells involves the use of viral transfection, which integrates viral genome into the recipient genome to deliver the pluripotency genes.[102] Recent studies have shown that gene delivery could be achieved by using the nonintegrating adenoviruses[105] or episomal vectors.[35,36] Given that the directed differentiation of iPS cells into the cell type of interest can be efficiently achieved, iPS cells are considered a safe and promising alternative to hESCs.

During recent years, there have been a number of reports on the hepatic differentiation of human ESCs. Protocols for directing the differentiation of ESCs into hepatocytes are usually based on signaling events in the early embryo, known to initiate specification of definitive endoderm.[106–108] Based on this understanding, treatment with growth factors in determined sequence has shown to direct ESCs to differentiate toward endoderm and further hepatic progenitors with some of the molecular characteristics of hepatocytes.[109–122] In the majority of settings, the resultant cells have morphological features similar to those of primary hepatocytes and most of the cells express liver-associated proteins. Our group's studies have contributed to this contemporary body of knowledge by showing that definitive endoderm can be produced through formation of embryoid bodies or by culturing mouse ESCs with collagen-sandwiched hepatocytes[123] and a more sophisticated coculture system, which has been demonstrated to differentiate ESCs into hepatocyte-like cells. However, existing concerns about these cells include the expression of many genes also expressed in the extra embryonic yolk sac. α-Fetoprotein, for example, is expressed in both the liver and the yolk sac.[108] To date, the majority of ESC hepatic differentiation protocols have produced cells with relatively immature hepatic characteristics despite rigorous enrichment protocols. Despite these issues, human ESCs are the most attractive cell type for the generation of hepatocytes with adult phenotype for use in BAL devices and other tissue engineering applications.

5.541.3. Implantable Hepatic Support Systems

The ultimate replacement of a failing liver is done by orthotopic transplantation. However, the shortage of available transplantable organs necessitates the search for other options to replace hepatic function. One straightforward alternative to organ transplantation is hepatocyte transplantation where the cells from a healthy donor are transplanted to a recipient with the failing organ with the expectation that the healthy cells will engraft in the recipient organ and provide the function of the failed organ. Besides the limited availability of healthy and functional hepatocytes, one major problem in cell transplantation is the low engraftment and survival of transplanted hepatocytes.[124] In order to overcome this issue, hepatocytes are transplanted within a carrier material in the form of encapsulation, microcarriers, or biodegradable scaffolds, which can protect the cells from the immune response of the recipient tissue by providing their own microenvironment; hence, increase their survival.[125] Furthermore, considering that the hepatocytes are highly metabolically active cells, there have been attempts to mimic the native liver architecture using tissue engineering and microfabrication techniques with the aim of providing perfusion for nutrient delivery and waste removal to enhance their survival and function.[126,127] Finally, development of a transplantable organ graft has been made possible by the use of a perfusion decellularized organ matrix as the scaffold which can be repopulated with liver cells.[128]

5.541.3.1. Direct Cell Transplantation

The first clinically successful case of hepatocyte transplantation was shown to treat Crigler–Najjar syndrome Type I, a metabolic liver disorder.[23] Crigler–Najjar syndrome results from the absence of uridine diphosphoglucuronate (UDP) glucuronosyltransferase activity, which is essential for the conjugation and excretion of bilirubin. Since hepatic architecture and function otherwise is normal in this metabolic syndrome, transplantation of hepatocytes was considered to be a safe and less invasive alternative to liver transplantation. Since that first clinical success, the clinical outcome of hepatocyte transplantation for acute and chronic liver failure and other metabolic diseases has been disappointing except when intended as a bridge to organ transplantation for patients with liver failure.[18,22,129,130] Several factors play a role in this poor outcome, including limited availability of high-quality cells and lack of suitable transplantation sites that can accommodate the required number of cells. Furthermore, the fate of transplanted

cells is dependent on their interactions with the microenvironment including the ECM, soluble factors such as cytokines and growth factors, and the immunological response of the host.[131] Hepatocyte engraftment is a low-efficiency process, transplantation of 3–5% host liver mass resulting in 0.5% engraftment of the host liver. The quality of the transplanted cells, the host liver architecture and ECM,[132] and the regeneration capacity of the host liver affect the engraftment efficiency.[133] Immune rejection by the host is another factor that affect the survival of the transplanted cells.[134]

5.541.3.2. Microcarrier and Encapsulated Systems

Hepatocyte attachment to microcarriers prior to transplantation is an alternative strategy to the direct injection of cells. The microcarriers offer ECM features on which the cells can attach and effect their survival and function. One of the earliest studies that report microcarrier-attached hepatocyte transplantation used collagen-coated microcarriers to host hepatocytes and their transplantation into Gunn rats, experimental models of Crigler–Najjar syndrome. The study showed the survival of hepatocytes for up to 2 months and display of function for 1 week.[135,136] When hepatocytes were attached to microcarriers made of chitosan/gelatin composite material, hepatocyte function was found to be at least 50% higher than those found in collagen-coated microcarriers.[137] The survival of C3A cells attached to porous collagen-coated polyethersulfone microcarriers into rats was about 95%, offering the possibility of transplantation of high concentrations of cells.[138]

A more promising approach in matrix-based hepatocyte transplantation is hepatocyte encapsulation. Encapsulation uses a thin spherical membrane around the cells that protects the cells from the immune response of the host tissue while creating a microenvironment that enhances the function of the transplanted cells[139] (see **Chapter 5.509, Cell Encapsulation**). Encapsulation also opens up the possibility of transplantation of xenogeneic cells due to the immunoprotection it provides.[140] An early study used a calcium–alginate–polylysine matrix to microencapsulate primary rat hepatocytes and transplanted the microcapsules in animal models of Crigler–Najjar syndrome. The microencapsulated cells were as effective as naked hepatocytes in lowering the bilirubin levels in the animals at 20 days of transplantation and the cells were not rejected.[141] Later animal studies also showed the immunoprotection of hepatocytes upon transplantation when the cells were encapsulated.[138,142–145] Another advantage of encapsulation is the possibility of cotransplantation of hepatocytes with nonparenchymal cells. The microenvironment created by the interactions between the hepatocytes and nonparenchymal cells within the capsule supports the function of hepatocytes and effects the long-term survival of the cells. Examples of such an approach include coculture of hepatocytes with bone marrow mesenchymal stem cells[146–148] and with Sertoli cells.[146–149]

5.541.3.3. Polymer Scaffolds

The ultimate goal of tissue engineering is to create structures that mimic the native organ architecture. Polymer scaffolds are tools of tissue engineering that provide the volume required to grow sufficient numbers of cells to recreate tissue architecture while featuring the ECM cues required for tissue organization. The polymer scaffold is desirably biodegradable so that the tissue may grow to replace the scaffold and support itself overtime.

Scaffolds have been used in the engineering of several tissues including, but not limited to, cartilage, bone, heart, blood vessels, and skin. Scaffolds used for liver tissue engineering serve as a vehicle for the delivery of hepatocytes, while allowing perfusion for nutrient delivery and waste removal to sustain the viability of the hepatocytes seeded inside. Moreover, it should be permissible to the growth of new blood vessels once transplanted for similar reasons.

One of the first examples of liver tissue engineering was shown using prevascularized polyvinyl alcohol discs. The discs were repopulated rat hepatocytes transplanted into animals for up to 1 year. Promisingly, even though initial cell engraftment was low, the discs contained viable cells after 1 year of transplantation.[150,151] Later studies focused on demonstrating optimal hepatocyte function and viability *in vitro* using tissue engineering culturing techniques. The first biomaterials that were tested for liver tissue engineering include those that are already approved for use in biomedical applications, such as polylactic acid (PLA), polyglycolic acid (PGA), and copolymers of lactic and glycolic acid (PLGA).[152] These materials are biodegradable, biocompatible, and can be fabricated into highly porous structures that may accommodate highly oxygen demanding hepatocytes.[153,154] Improved hepatocyte function due to spheroid formation has been shown in PLA-based discs[155–157] and PLA-based scaffolds.[158] A natural biopolymer, chitosan, has been the focus of several liver tissue engineering studies (see **Chapter 2.213, Chitosan**). Chitosan is a linear polysaccharide with randomly distributed β-(1-4)-linked D-glucosamine and *N*-acetyl-D-glucosamine units. It is a desirable material for biomedical applications because it is biodegradable, biocompatible,[159] and easy to chemically modify for manipulating its biological and mechanical properties.[160] Chitosan-based biomaterials that have been tested for hepatocyte culture and function so far include chitosan/alginate and chitosan/collagen blends,[161] galactosylated chitosan/alginate and galactosylated chitosan/alginate/heparin blends,[162,163] chitosan/galactosylated hyaluronic acid composites,[164] and nanofibrous galactosylated chitosan.[165] Recently, peptide-based biomaterials have drawn interest in tissue engineering applications. A well-defined synthetic hydrogel forming peptide, PuraMatrix™, was investigated for its capacity to support hepatocyte functions in a three-dimensional environment for rat[166] and porcine hepatocyte cultures.[167] Even though albumin and urea production as well as cytochrome P450 activities in PuraMatrix™ cultures were similar to those observed in collagen sandwich and Matrigel cultures, the advantage of using PuraMatrix™ was the possibility of achieving high functional capacity through the high-density cell cultures.[166] It also serves as a delivery vehicle for cell transplantation for which it has been shown to be highly effective in a number of animal models of liver failure.[168]

5.541.3.4. Microfabrication for Liver Tissue

Microfabrication techniques offer the skills to control the cellular microenvironment in cell culture and cocultures to mimic native tissue microarchitecture and subsequent cell

function in tissue engineering. Microfabrication techniques have thus far been used to create patterned cultures for cellular control and coculture[169–173] and molding for the construction of microvascular networks,[174] and for the assembly of three-dimensional networks for organ reconstruction[175–177] and development of microscale multiorgan systems for drug testing purposes.[178]

The leading work of Bhatia *et al*. revealed that the micropatterned coculture of hepatocytes with 3T3-J2 fibroblasts significantly improved the hepatocyte functions and the long-term maintenance of differentiated function using microfabrication techniques to create micropatterned surfaces for selective cell adhesion.[169–171] This work led to the fabrication of microscale culture systems of primary adult human hepatocytes that display highly differentiated drug metabolism functions (**Figure 3**).[173]

A successful culture of hepatocytes depends on the efficiency of nutrient delivery and waste removal in a tissue-engineered construct; which necessitates the presence of a vascular bed within the construct. One approach to reconstruct the artificial liver tissue is to build the tissue from ground up using microfabrication techniques. Even though it has not been realized so far, this promising approach involves a silicone or pyrex platform seeded with endothelial cells, with microchannels that allow continuous perfusion to form a well-sealed vascular network. Once the vascular network is established, the system is expected to be repopulated with hepatocytes and biliary epithelial cells to form the liver tissue.[179]

5.541.3.5. Whole Liver Tissue Engineering

The first generation tissue engineering materials have found limited use as they had limited ability to modulate the repair and regeneration of the host tissue. Consequently, material and host tissue interactions became an important consideration in the design of new materials such that the new generation materials should harness elements that regulate tissue regeneration by different mechanisms, such as controlling specific cell-binding interactions and responding to environmental cues.[180] In addition, since material microstructure has been found to play an important role for tissue morphogenesis,[181–183] three-dimensional aspects such as pore structure, surface area to volume ratio, texture, and surface topography that define material architecture have become other important design parameters.[184] Considering these design constraints, decellularized ECM represents an ideal material for tissue engineering applications as it retains the relevant aspects of the complex structure and chemical composition of the ECM[185] (see **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration** and **Chapter 2.221, Decellularized Scaffolds**). Moreover, using a decellularization technique described recently for heart,[128] the native three-dimensional structure of the organ can also be preserved which will most likely provide the necessary architecture for optimal cell distribution and subsequent tissue morphogenesis. In addition, the scaffold obtained via perfusion decellularization will contain a perfusable vascular tree that facilitates *in vitro* perfusion and reconnection to the blood torrent – which has been observed in skin grafts –[186,187] and this can greatly enhance nutrient delivery and waste removal in the tissue-engineered construct.

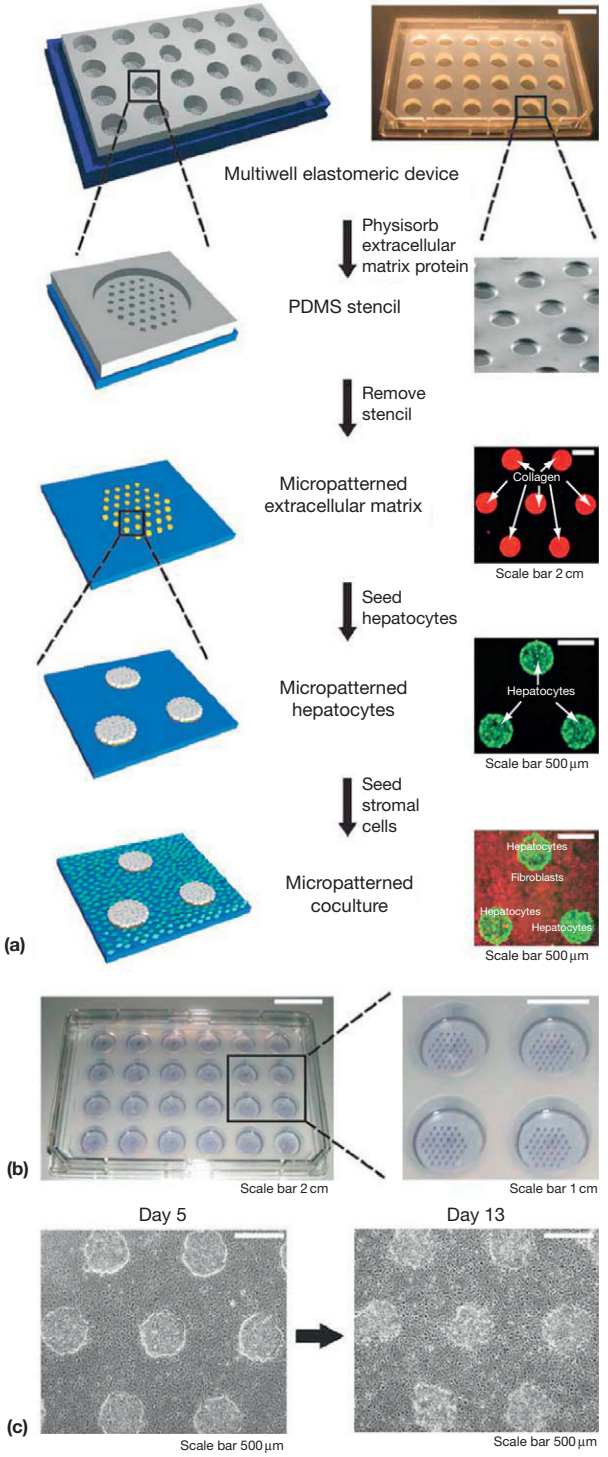

Figure 3 Preparation of microscale hepatocyte culture system. (a) Soft lithography process was used to fabricate microscale liver hepatocyte cultures in a multiwell format. A schematic of the process flow is shown next to the photomicrographs taken at each step (b) Photograph of a 24-well device with repeating hepatic microstructures (37 colonies of 500-μm diameter in each well), stained purple by 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (c) Phase-contrast micrographs of micropatterned cocultures. Primary human hepatocytes arranged in ~500 μm collagen-coated islands surrounded with fibroblasts. Reproduced from Khetani, S. R.; Bhatia, S. N. *Nat. Biotechnol.* **2008**, *26*, 120–126, with permission from Nature Publishing Group.

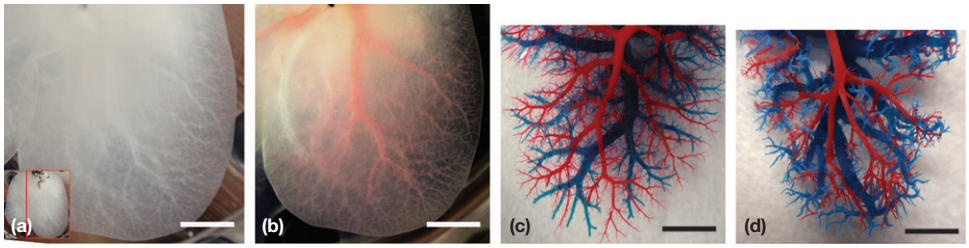

Figure 4 Decellularized liver matrix (DLM) scaffold retains intact lobular structure and vascular bed upon perfusion decellularization. (a) Representative photograph of decellularized left lateral and median lobes of rat liver, with the vascular tree visible. (b) The vascular tree, after perfusion with Allura Red AC dye. Corrosion cast model of left lobe of (c) a normal liver and (d) the DLM, portal (red) and venous (blue) vasculature. Scale bars (a and b) 10 mm (c and d) 5 mm. Reproduced from Uygun, B. E.; Soto-Gutierrez, A.; Yagi, H.; *et al*. *Nat*. *Med*. **2010**, *16*, 814–820.

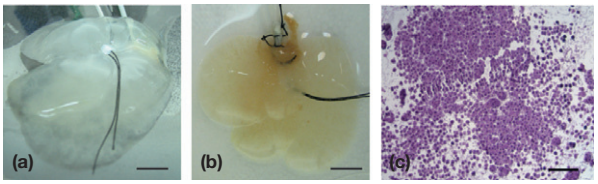

Figure 5 Repopulation of decellularized liver matrix (DLM) with adult primary hepatocytes. (a) Decellularized whole liver matrix, (b) the same liver after recellularization with about 50 million hepatocytes. (c) Hematoxylin and eosin staining of hepatocyte repopulated DLM. Scale bars, (a,b) 20 mm, (**c**) 100 μm. Reproduced from Uygun, B. E.; Soto-Gutierrez, A.; Yagi, H.; *et al*. *Nat*. *Med*. **2010**, *16*, 814–820.

Furthermore, traditional tissue engineering approaches for the development of transplantable liver grafts have, so far, been limited by oxygen and nutrient diffusion to thin two-dimensional structures, which are engrafted in highly vascularized regions.[166,167,188–190] Practical consideration of primary hepatocyte oxygen consumption requires that any hepatic mass, which is sufficient to provide metabolic function, should contain an extensive microvascular network and be connected to the blood supply; otherwise, the internal mass of the cells will suffer ischemic damage.[127,191,192]

Decellularization is an attractive technique for scaffold preparation in tissue engineering as the resulting material can potentially retain the architecture of the original tissue including the functional aspects of the native microvasculature.[193] The potential applications of decellularized matrix in tissue engineering have been demonstrated for a number of tissues including bladder,[194] artery,[195] esophagus,[196] myocardium,[197] skin,[187] and trachea[198] (see **Chapter 5.534, Skin Tissue Engineering**; **Chapter 5.539, From Tissue to Organ Engineering**; and **Chapter 5.527, Cardiovascular Tissue Engineering**). More recently, the Taylor group reported the decellularization of an entire heart through perfusion, preserving the original architecture and original microvascular network allowing for extensive recellularization.[128]

We have recently developed a transplantable liver graft using perfusion decellularized liver matrix (DLM).[199] The decellularization process preserved the structural and functional characteristics of the native microvascular network as shown by dye perfusion and corrosion cast molding (**Figure 4**). The preserved vasculature allowed subsequent recellularization with adult rat hepatocytes with over 90% efficiency (**Figure 5**). The *in vitro* perfusion culture of the recellularized liver graft showed that the graft supported liver-specific function at approximately 30% functional capacity of normal liver, including albumin secretion, urea synthesis, and cytochrome P450 expression *in vitro*. Furthermore, the recellularized liver grafts were transplanted in rats, supporting hepatocyte survival and function with minimal ischemic damage.

5.541.4. Conclusions and Future Directions

Liver is a highly metabolically active organ that has high oxygen and nutrient demands. Even though a healthy liver has the capacity to regenerate, damage to the organ may result in mortality if the hepatic function is not supported. As the current treatment methods for liver failure are limited, tissue engineering has offered tools for the development of alternative treatment options such as the provision of temporary support in terms of BAL devices, techniques to sustain long-term differentiated function of adult primary hepatocytes, and development of biomaterials as delivery vehicles of hepatocytes for cell transplantation. Furthermore, the tissue engineering tools have facilitated development of transplantable liver grafts from a wide range of synthetic and biological materials. Liver tissue engineering has also made use of microfabrication techniques to establish culture conditions that support long-term hepatic functions and it has led to studies to reconstruct liver tissue from ground up. However, so far, development of a transplantable liver graft using ground up techniques has not been successful mostly due to the complexity of the liver tissue architecture. Recently, use of whole organ scaffolds obtained by perfusion decellularization has drawn interest. The whole organ scaffold has the composition and the architecture of the native organ, which alleviates the need for reconstruction of the scaffold. It has already been shown that the hepatocytes display sustained function within the scaffold, and the presence of the vascular network facilitated its reconnection to the blood torrent *in vivo*. Future work in the development of a transplantable liver graft requires the addition of the nonparenchymal component of the liver, such as endothelial cells and the biliary epithelial cells, into the DLM scaffold.

5.542.1. Introduction

5.542.1.1. Novel Scaffold Fabrication Methods in Tissue Engineering

Any discussion on the development of tissues and organs requires an understanding of current tissue engineering approaches to fabricate porous three-dimensional (3D) scaffolds. The commonly adopted tissue engineering paradigm generally involves the seeding and culturing of cells in 3D porous scaffolds. The scaffold pore architecture plays an important role in cell seeding and tissue development, promoting homogenous cell spreading, cell differentiation, and host tissue ingrowth upon implantation. Traditional techniques to prepare such scaffolds include porogen leaching, phase separation, and gas foaming. Although parameters such as porosity and average pore size can be influenced by controlling processing parameters, the overall control of the scaffold architecture and its pore network is low. Most polymers used for tissue engineering scaffolds are hydrophobic, which particularly impedes the penetration of aqueous cell suspensions. Furthermore, foams fabricated using traditional techniques generally have low permeabilities and, therefore, slow diffusion of medium. This limits development of *in vitro* tissues to grafts of small cross-sections in static culture.[1,2]

These facts have driven the development of novel fabrication techniques for the preparation of tissue engineering scaffolds that provide more control over the scaffold design. One of these techniques is solid freeform fabrication (SFF), a computer-controlled additive fabrication of designed 3D constructs in a layer-by-layer process. Originally, SFF fabrication techniques were developed to create prototypes for purposes of designing new parts or products. Traditional prototyping methods involve laborious mould making and casting steps, while the ability to create an object within hours from a computer design by rapid prototyping (RP) significantly speeds up the development of products. In the biomedical field, these developments have led to the fabrication of aids for complex surgery[3] and patient-specific models for mould-assisted implant fabrication.[4] More recently, SFF techniques have been adopted for the preparation of medical implants, such as scaffolds for tissue engineering and regenerative medicine applications. The use of SFF is an attractive approach to producing scaffolds with customized external shape, and predefined and reproducible internal morphology. **Figure 1** gives a snapshot of techniques that have been applied in the preparation of porous scaffolds for tissue engineering – particularly polymer scaffolds – including SFF techniques. It also includes the characteristics of each method including the range of porosity and pore size that can be obtained, as well as the particular advantages and disadvantages of each technique, and a typical image of the scaffold microstructure.

Using SFF techniques, scaffold designs can be optimized with respect to mechanical properties and nutrient transport.[5] As SFF technologies are continuously evolving, fabrication costs are decreasing, and the properties of the manufactured parts are improving. For high-end applications, such as regenerative medicine, the relatively high cost per fabricated item justifies the use of SFF for the preparation of usable parts rather than prototypes. Following the early work of Sachs *et al.*[6,7] in 3D printing of biodegradable parts and, later, porous scaffolds, many SFF techniques have been used, modified and developed for tissue engineering over the last decade.[8] This has led to a significant improvement in the control over the design of 3D tissue engineering scaffolds.[9,10] Using SFF methods, it was shown that scaffold architecture influences mechanical properties,[11] oxygen gradients in culture,[12] engineered tissue composition,[13–15] and *in vivo* tissue ingrowth.[16] Although preparing scaffolds using SFF techniques has proven to be beneficial, major limitations still continue to hamper their application in tissue engineering. For example, the use of prefabricated scaffolds for tissue engineering does not allow for the precise placement of cells that is required to mimic the complex structural organization of natural tissues. Furthermore, seeding and culturing of prefabricated scaffolds is a very laborious process, and (pre)vascularization of the structures is a major challenge (see **Chapter 5.503, Biomaterials and the Microvasculature**).

5.542.1.2. Organ Printing

Organ printing adopts the principles of SFF fabrication to prepare tissue-engineered constructs (TECs) in an automated manner, but aims to include cells in the fabrication process itself. After pioneering experimental work on inkjet printing of biomaterials and cells by Boland *et al.*[17,18] and Derby *et al.*,[19,20] the term organ printing first appeared in 2003, being defined as "a rapid prototyping computer-aided 3D printing technology, based on using layer-by-layer deposition of cell and/or cell aggregates into a 3D gel with sequential maturation of the printed construct into perfused and vascularized living tissue or organ."[21] Additive manufacturing translates computer-aided design (CAD) to virtual cross-sections and then creates successive layers of cell-laden matrices with robotic computer-aided manufacturing (CAM) until the model is complete, with the aim of creating living tissue equivalents (**Figure 2**). The fundamental difference between organ printing and the preparation of cell-free tissue engineering scaffolds using SFF fabrication lies in the rationale that tissue formation is directed by the spatial placement of the cells themselves, rather than by the spatial architecture of a solid support structure.

	Scaffold name	Porosity and size	Schematic	Advantage and disadvantages	Image
Conventional scaffolds	Particulate leaching	Porosity < 90% Pore size 5–600 μm		Adv: Simple and user friendly method, suitable with a range of biomaterials and no special equipment is needed. Disadv: Density differences result in nonuniform pore size distribution. Difficult to achieve full interconnectivity and large pore interconnections. Skinning effect on outside surfaces of scaffolds. Organic solvents typically required.	
	Thermally-induced phase separation (TIPS)	Porosity < 90% Pore size 5–600 μm	Homogeneous solution; Temperature; Spinodal decomposition; Polymer concentration	Adv: Simple method, suitable with a range of biomaterials and no special equipment is needed fully interconnecting pores and large pore interconnections can be fabricated if spinodal decomposition is achieved. Disadv: Skinning effect on outside surfaces of scaffolds. Organic solvents typically required.	
Nano-scale scaffolds	Electrospinning	Porosity < 90% Pore size <1–10 μm	High voltage; Polymer jet	Adv: Inexpensive method to produce nano-microfibers from a wide range of polymers. Excellent cell and tissue compatability for mesenchymal cells. By using ice crystals as a collector, scaffolds with large pores and significant volume may be fabricated.	
	Electrospinning onto ice crystals	Porosity < 95% Pore size 20–200 μm	High voltage; Polymer jet; Ice crystals	Disadv: Organic solvents often required, scaffolds with volume, and large pore size or thickness are difficult to manufacture except by using ice crystal technique which has the disadvantage that sublimation required that increases complexity of manufacture. Mechanical properties of electrospun fibers is generally poor.	
	Self-assembling nanofibers	Porosity < 95% Pore size 200–800 μm		Adv: Self-assembling system, typically in water and can be formed in the presence of cells, with bioactive functionality. Disadv: Relatively expensive to manufacture in significant quantities. Weak mechanical properties probably restrict this type of scaffold to soft tissues.	
Solid freeform fabrication (SFF) scaffolds	3D printing (3DP)	Porosity < 45–60% Pore size 45–1600 μm	Ink-jet head; Roller; Liquid adhesive; Powder bed; Powder delivery	Adv: SFF techniques have accurate control over pore size and interconnectivity over conventional/nanoscale approaches. The layer-by-layer process allows fabrication of complex and anatomically shaped structures. Disadv: Expensive machinery required, resolution limitations at lower pore sizes. Biomaterials need to come in powder form with controlled particle size.	
	Stereolithography	Porosity < 90% Pore size 20–1000 μm	Scanner system; Laser; Object being fabricated; Photopolymer	Adv: Accurate control over pore size and interconnectivity. Layer-by-layer process allows fabrication of complex and anatomically shaped structures. Disadv: Expensive machinery required. Polymers compatible with UV curing is required.	
	Selective laser sintering (SLS)	Porosity < 40% Pore size 30–2500 μm	Laser; Scanner system; Powder bed; Roller; Powder delivery; Fabrication piston	Adv: Accurate control over pore size and interconnectivity. Layer-by-layer process allows fabrication of complex and anatomically shaped structures. Disadv: Expensive machinery required. Resolution limitations at lower pore sizes. Biomaterials need to come in powder form with tight controlled particle size, mainly applicable to ceramic materials.	
	Fused deposition modelling/3D plotting	Porosity < 80% Pore size 100–2000 μm	x–y–z stage; Extrusion nozzle; Polymer melt or filament; Table	Adv: Accurate control over pore size and interconnectivity. Layer-by-layer process allows fabrication of complex pore architectures and anatomically shaped structures with good resolution. Disadv: Since the technique uses polymer melts, it is limited to thermoplastics. Low pore sizes difficult to achieve while maintaining high porosity.	
	Direct writing	Porosity < 90% Pore size 5–100 μm		Adv: Accurate control over pore size and interconnectivity. Layer-by-layer process allows fabrication of complex architectures with excellent resolution. Disadv: Expensive machinery required. Biomaterials used need to be able to form polyelectrolyte inks. Significant times are required to manufacture scaffolds with suitable thickness.	

Figure 1 Snapshot of techniques for preparing porous polymer scaffolds for tissue engineering, including some characteristics of each technique. Reproduced with permission from Dalton, P. D.; Woodfield, T.; Hutmacher, D. W. *Biomaterials* **2009**, *30*, 701–702.

5.542.1.2.1. Rationale for developing organ-printing techniques

Cell-based tissue engineering research may profit from design strategies that mimic the anatomical organization of cells, matrix, and bioactive molecules more closely than allowed for by currently used techniques. Such arrangement could contribute to graft functionality and achieve suitable mechanical properties for the engineered tissue.[22,23] For example, the complex zonal organization of articular cartilage is believed to be one of the reasons why over 20 years of cartilage tissue engineering research have not resulted in the consistency and effectiveness required for widespread clinical use.[24,25] The traditional concept of tissue engineering involves the seeding of cells into porous scaffolds, which are cultured *in vitro* to form new tissue. This strategy has proven to be unsuccessful, particularly for large vascularized tissues such as bone. The diffusion of nutrients into large tissue-engineered bone constructs and the slow rate of vascular growth, that is, 2 mm per month,[26] mean that the approach has limited chance of success as cell death occurs well before any blood supply can be established.

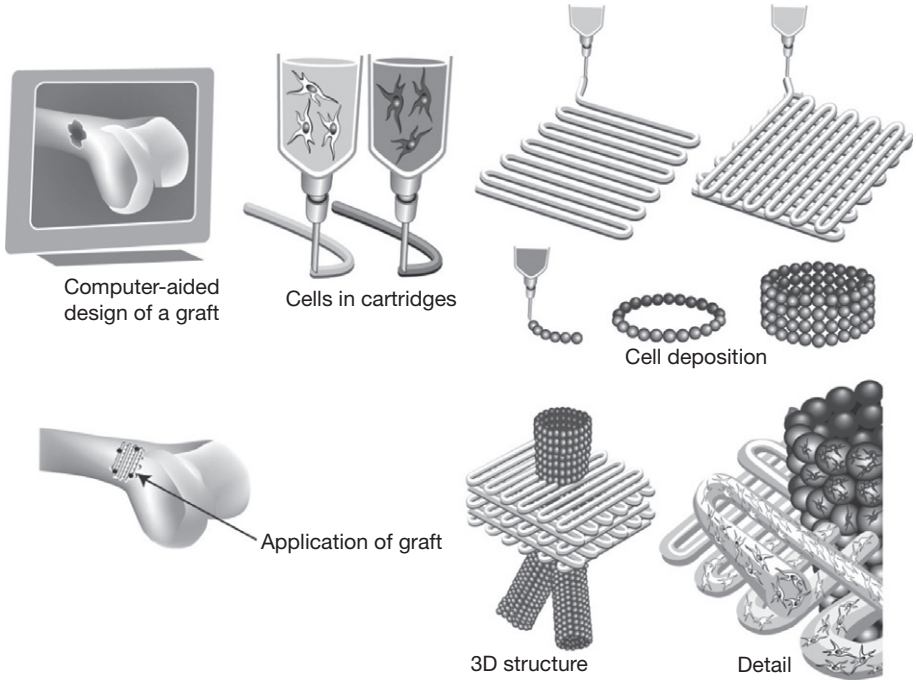

Figure 2 Approach to 3D organ printing. A designed graft is fabricated using a computer-controlled printing device from gels with structurally organized cells of different cell types. Reproduced with permission from Fedorovich, N. E.; Alblas, J.; De Wijn, J. R.; Hennink, W. E.; Verbout, A. J.; Dhert, W. J. A. *Tissue Eng.* **2007**, *13*, 1905–1925.

These findings, in combination with the relatively poor clinical translation of cell-based repair strategies to date, indicate that the current tissue engineering paradigm may have to be revised if more advanced progression toward creating tissues and organs is to take place. The four main justifications for pursuing an organ-printing approach are as follows.

First, the geometry and dimensionality of the cellular environment have a large influence on cell behavior. A number of studies have demonstrated the importance of a 3D structure on the behavior of cells in culture. For example, hepatocytes cultured as a monolayer on a collagen gel lose many of their liver-specific functions within a few days. However, when these same cells are overlaid with another layer of collagen gel to mimic the 3D structure of the liver, they retain many of their liver-specific functions for weeks in culture.[27] Also, it has been long known that chondrocytes dedifferentiate when cultured on flat surfaces,[28] whereas they retain their phenotype in 3D cultures. Although prefabricated porous scaffolds are 3D structures, seeded cells usually spread on scaffold walls or surfaces as they do on flat two-dimensional (2D) surfaces. So in practice, porous scaffolds often provide a 2D environment for cells, albeit with a high surface area in a 3D volume. In organ-printing techniques, the aim is to embed cells in a 3D artificial ECM to preserve phenotype and function, aiming to recreate the *in vivo* niche.

Secondly, traditional cell seeding techniques do not account for the spatial cellular organization of native tissues. Although cellular distributions and tissue formation can be influenced to some extent by controlling the scaffold architecture,[15] neither local variations in cell density, nor relative placement of different cell types can be well controlled when seeding prefabricated scaffolds. However, these parameters strongly influence cellular behavior and functionality of the engineered tissue. For example, stratified layers of chondrocytes harvested from different zones of native articular cartilage showed an increase in ECM production when compared to mixed controls.[22,29] Moreover, the chondrocytes in each layer retained their specific phenotypes. In another study, layered cartilage populations exhibited mechanical profiles that resembled the profile of native cartilage.[30] Hence, the relative placement of different cell types can modulate the way cells interact and influence each other's behavior. For example, there is evidence that endothelial cells promote differentiation of osteoprogenitors and osteoblastic cells. This was presented by many coculture studies,[31–34] wherein direct contact between the endothelial cells and osteoprogenitors was necessary for the increase in alkaline phosphatase activity and type I collagen synthesis to take place.[35] Cotransplanted endothelial cells enhanced bone marrow stromal-cell-mediated bone regeneration in an osseous defect.[36] In turn, bone marrow stromal cells influence endothelial cells by stabilizing blood vessel network formation *in vitro*.[33,37,38] For the formation of adequate blood vessels, stabilization of endothelial cells with other cell types is essential: smooth muscle cells[39,40] or fibroblasts[41] are indispensable, as long-term stabilization is ensured by association of the two cell types.[42–44]

This brings us to the third argument for using organ-printing techniques in making TECs. Neovascularization is a critical step in tissue engineering applications. Because diffusion enables sufficient supply of oxygen only over distances up to 100–200 μm, implantation of voluminous grafts of clinically relevant size without sufficient vascularity results

in hypoxic cells and cell death in the center of tissues.[45] Spontaneous vascular ingrowth of implants does occur, but at low speeds of typically tens of micrometers per day.[46] This has led to the successful use of TECs currently being limited to millimeter-scale or avascular tissues, such as skin or cartilage, in which postimplantation neovascularization from the host is sufficient to meet the demand for oxygen and nutrients.[47] Several strategies for enhancing vascularization are being investigated, including scaffold design, the inclusion of angiogenic factors, *in vitro* prevascularization, and *in vivo* prevascularization.[48] Organ-printing approach can be applied to each of these strategies, or a combination of them. Compared to tissue engineering using prefabricated scaffolds, the organ-printing approach has more potential for overcoming the problem of vascularization in thick tissue constructs through printing of an integrated vascular tree within the bioprinted tissue construct.[49,50] Endothelial cells can be deposited in a specific pattern between the cells that make up the engineered tissue, and the physiological fabrication conditions enable integration of patterned growth factors, such as vascular endothelial growth factor, without their being denaturated.

A fourth argument for following the organ-printing approach is one of logistics and economics. This is often disregarded by scientists but is a very important reason for the implementation of tissue engineering in clinical practice. Despite the widespread hype and significant investment, cell-based therapeutics have largely failed from both a clinical and financial perspective.[51] The developed tissue engineering products were not necessarily inferior to previous alternatives, but the improvement was not sufficient to justify the associated increase in costs.[52] It is critically important that newly developed tissue engineering products establish profitability to ensure continued investment from both the public and private sectors. A method for quantitatively estimating the chance of success of tissue engineering products is the headroom method, in which the effectiveness gap between the current best treatment and that which the new technology might plausibly achieve, is estimated.[53] The use of prefabricated scaffolds involves manual cell seeding and culturing processes. Such nonautomated tissue assembly is laborious and might be economically and logistically infeasible for clinical application on a large scale.[54,55] As organ printing is a fully automated tissue assembly process, it opens up a route to scalable and reproducible mass production of tissues and organ precursors.[56] Furthermore, implementing good manufacturing practices (GMP), quality control, and legislation are facilitated by the use of automated processes.

These arguments are a plea in the endeavor to develop organ-printing techniques for tissue engineering. Here, we present an overview of techniques and studies that support this development. This includes approaches that achieve defined cell organization, such as patterning of substrates and cells in 2D, and 3D assembly of cell-containing constructs.

5.542.2. 2D Patterning and Cell Printing

5.542.2.1. Introduction

Ultimately, for any pioneering work in cell printing, it is inherently easier to demonstrate proof-of-principle in 2D as opposed to 3D. Printing techniques that were initially developed in 2D and are now progressing toward 3D application are discussed in Section 5.542.3. Here, we discuss patterning and cell manipulation techniques that have been performed only in 2D so far.

Working in 2D has several specific advantages. Generally, higher resolutions and accuracies can be achieved, one has more control over the chemical and physical properties on a small scale, and imaging and characterization are easier. Patterning technologies can spatially control surface chemistry and topography at the micrometer level or even below. They can be designed to mimic the natural surroundings and regulatory microenvironments of cells *in vivo*, or to modify the microenvironment to study the cellular response (see Chapter 3.315, Biological Microelectromechanical Systems (BioMEMS) Devices).[57–59]

5.542.2.2. State of the Art

Numerous techniques can create cell patterns, either indirectly via patterning cell culture substrates or directly by patterning cells.

5.542.2.2.1. Techniques for patterning cell culture substrates

Photolithographic methods enable biomaterial scientists to alter surface properties at very high resolutions, at submicron scales. A well-developed set of tools, first developed for the electronics industry, has been translated and expanded to allow for studying cellular behavior on small scales on a variety of materials[60] with well-defined surface topographies[61] and spatially patterned proteins.[62] A scheme of how photolithography works is shown in Figure 3. First, a mask is created from a CAD on a chromium coated quartz (glass) plate by laser

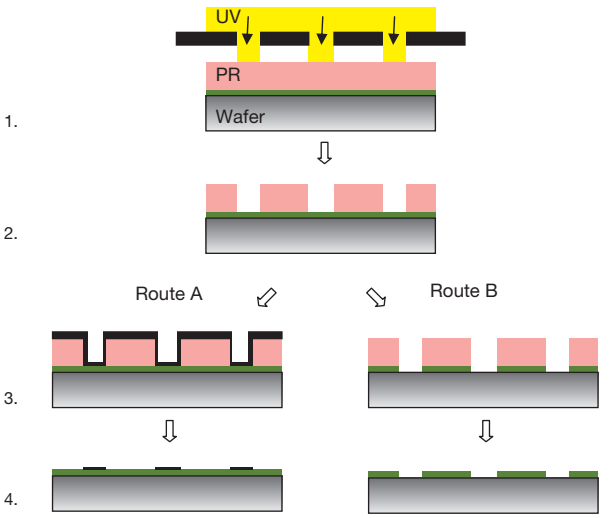

Figure 3 The photolithography process. 1. A flat substrate coated with photoresist (PR) is irradiated with UV light through a mask. 2. Developing of the wafer removes the (un)irradiated PR, leaving a pattern. In route A, the whole surface is coated with a (bio)active solution, and the pattern is exposed after lift-off of the remaining PR. In route B, a deeper layer of the substrate is etched with the pattern, after which the remaining PR is removed.

ablation. This mask is then used to illuminate a substrate spin-coated with a photosensitive polymer formulation – termed a photoresist (PR) – in a patterned manner. The UV-activated wafer is then 'developed' to dissolve either the illuminated parts (in the case of a negative-tone PR) or the not illuminated parts (for a positive-tone PR), thereby partly exposing the substrate. Then, two general routes can be followed. One is the etching-procedure, in which a layer on the substrate is removed by means of an etching solution, plasma or some kind of irradiation. Subsequently, the protected pattern is revealed by dissolution of the PR. In the other route, the total surface is first covered by a functional layer of metal or proteins for example. Then, the PR with the associated part of the functional layer is removed during a so-called 'lift-off ' process, leaving a patterned surface. The choice of the procedure to follow is often dictated by the chemistry of the substrate and functional patterning molecules.[63]

In the electronics industry, silicon is mostly used as the substrate material due to its finely tunable semiconductor properties and because it is atomically flat. For the purpose of imaging, transparent surfaces such as glass, tissue culture polystyrene (TCPS), and some (thin coatings of) metal oxides are preferred for cell studies. The applied patterned layers are often cell adhesive proteins or synthetic molecules containing cell adhesive peptide sequences. Several metal oxides show very different cell adhesive properties and have, therefore, also been used for patterned cell–substrate interaction studies.[64] The nonpatterned surface is usually backfilled with a second (passivating) solution. The passivation step is essential to limit the biofunctionalization to the printed areas.[63] Many passivating systems have been developed, most of them based on poly(ethylene glycol) (PEG). Photolithography can also be performed by direct writing with a laser beam, instead of by total irradiation using masks. Although the resolution is not as high and it takes more time to pattern a surface than can be done in a parallel fashion with a mask, this technique does have specific advantages. Heterogeneous patterns can be created by varying the exposure time, thereby influencing the ligand density.[65]

Photolithography gives researchers a set of tools to manipulate surfaces at very high resolutions, conferring on researchers the unique ability to study cell–substrate interactions on single cells in confined areas. A specific disadvantage of photolithography is the high cost associated with the necessary equipment and clean-room facilities. By transferring a pattern from a photolithography-fabricated silicon wafer to a polydimethylsiloxane (PDMS or silicone rubber) film, one can create a stamp to pattern material surfaces indirectly. This set of techniques, each of which uses stamps or channels fabricated in an elastomeric ('soft') material for pattern transfer, is referred to as soft lithography.[66] As one master wafer can be used to fabricate a large number of PDMS stamps, and the stamps can be reused, it greatly reduces costs. Furthermore, the stringent environmental requirements of photolithography do not apply. Also, the range of materials that can be patterned without the direct use of photoresists and UV irradiation is extended, particularly to delicate ligands such as peptides. Several techniques based on the soft lithography approach exist, of which the most commonly adopted is microcontact printing. As shown in **Figure 3**, a PDMS stamp is initially prepared by casting and curing of a prepolymer on a master, which usually is a silicon wafer, patterned using conventional photolithography. The stamp is inked with a solution containing the bioactive molecules to be printed, which (usually after drying) are transferred to the substrate. The nonprinted surface is then backfilled with a passivating solution. In many cases, the printed molecules are cell adhesion promoting proteins, such as fibronectin. As with photolithographic methods, here too the passivation step is essential to limit the biofunctionalization to the printed areas. An alternative soft lithography-based technique is microfluidic printing, which is also depicted in **Figure 4**. First, a stamp is brought into tight contact with the substrate, after which the patterning solution is introduced in the open channels (usually through capillary forces). After adsorption the stamp is removed, and the backfilling takes place. Although the patterns using this technique are restricted to continuous networks, it does have the advantage that simultaneous patterning with different molecular solutions is possible.[67] **Figure 4** gives an overview of the soft lithography-based techniques discussed above, while **Figure 5** shows an example of the application of microcontact printing to generate cell adhesive patterns on a cell non-adhesive background.

A strategy that bypasses the fabrication of silicon wafers in the clean room altogether and enables patterning in a very

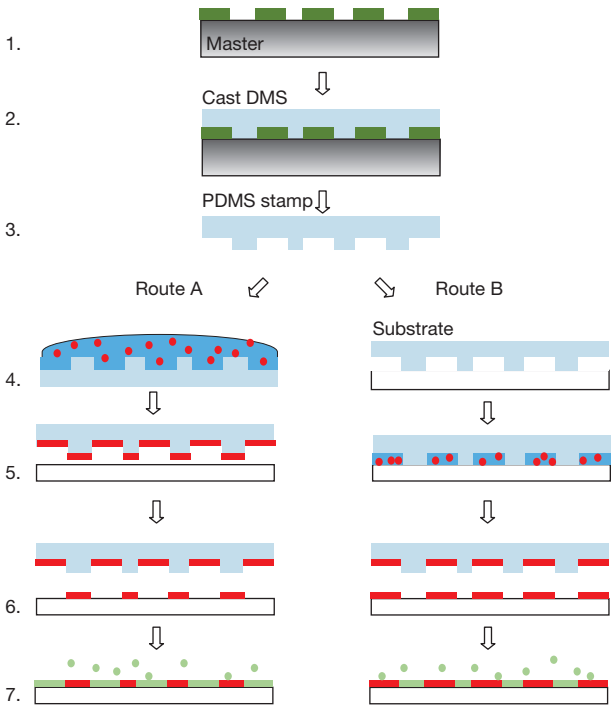

Figure 4 Principles of microcontact printing and microfluidic patterning. First, a 'master' wafer is created with conventional photolithography (1). DMS is cast on the master (2) and cured to create a PDMS stamp (3). In microcontact printing (route A), the stamp is coated with a bioactive compound (4 and 5), and the pattern is transferred to the substrate (6). In microfluidic printing (route B), the solution with the bioactive compound is introduced into the channels (6) after bringing the stamp in close contact to the substrate (5). For both methods, the final step is the backfilling of nonfunctionalized area with a cytophobic layer (7).

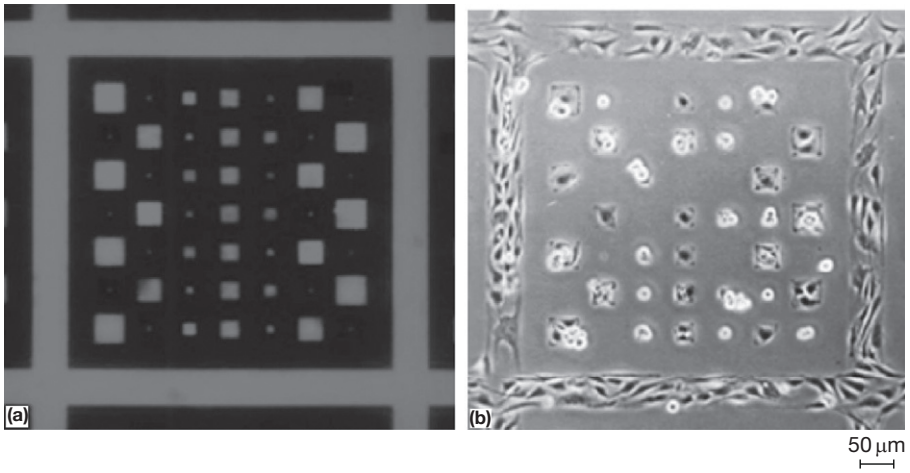

Figure 5 Example of microcontact printing. A gold surface was patterned into hydrophobic regions of alkanethiolate and hydrophilic regions of tri(ethylene glycol) terminated alkanethiolate. Fibronectin adsorbed specifically on the hydrophobic patches as visualized in (a) by antibody-bound fluorophores. (b) Bovine capillary endothelial (BCE) cells specifically bind to the fibronectin coated regions. Reproduced with permission from Kane, R. S.; Takayama, S.; Ostuni, E.; Ingber, D. E.; Whitesides, G. M. *Biomaterials* **1999**, *20*, 2363–2376.

inexpensive manner, is transparency-based photolithography. In this technique, the mask is generated by simply printing a pattern on a transparent overhead sheet, using a commercial inkjet or laser printer. Although the minimum feature size that can be accomplished is approximately 2 orders of magnitude larger than with conventional photolithography, it is still small enough (down to tens of micrometers) to make a valuable tool in fundamental cell biology studies[68], given that cells are typically 10–20 μm in size.

Yet another light-based patterning technique that allows for some control in the *z*-direction, makes use of two-photon polymerization to functionalize specific regions inside a transparent gel. In two-photon polymerization, the photoinitiator is excited by the (nearly) simultaneous absorption of two photons of relatively low intensity, which together introduce enough energy to initiate a chemical reaction. As a result, two-photon polymerization is a nonlinear optical process in which the reaction rate is proportional to the square of the laser intensity in contrast to a linear relationship, as in the case of single-photon polymerizations. This leads to more localized reactions. With this technique, Hahn *et al.*[69] locally modified a PEG-diacrylate (PEG-DA) hydrogel with acryl-PEG-peptide moieties, creating 3D cell-adhesive islets. Alternatively, they showed that low-molecular weight PEG-DA can be used to alter local cross-link density and, hence, transport and mechanical properties.

5.542.2.2.2. Examples of 2D substrate patterning studies for tissue engineering

As described previously, patterning technologies can spatially control surface chemistry and topography at the micrometer level and, therefore, they have the ability to control spatial cell distribution and study the effects of geometrical cues and spatial confinement on cellular behavior. Spatial concentration gradients prepared by modulating the spacing or width of photopatterned cell-adhesive peptide moieties influence cell alignment, morphology and motility. For example, Ito *et al.*[70] used photolithography to pattern a gradient in immobilized heparin, and cultured NIH3T3 cells in the presence of basic fibroblast growth factor. The cell proliferation was enhanced in a heparin density-dependent manner. The specific advantage of the patterning technique here is that a range of heparin densities can be tested at once, with nonimmobilized regions as an internal control. Chen *et al.*[71] used a similar technique to graft the thermoresponsive polymer poly(*N*-isopropylacrylamide-*co*-acrylic acid) to TCPS in a patterned manner, enabling the selective detachment of cells by cooling as a stimulus. In the same group, studies have also been performed on (micropatterned) photografting of pH-responsive polymers,[72] growth factors such as epidermal growth factor[73] and vascular endothelial growth factor,[74] cell-adherent proteins such as gelatin[75] and sugars such as β-galactose,[76] and sulfated hyaluronic acid for antithrombogenicity.[77]

Hahn *et al.*[57] used the simple and inexpensive transparency-based lithography approach to pattern otherwise non cell-adherent PEG hydrogel surfaces with the cell-adhesive arginine-glycine-aspartic acid-serine (RGDS) peptide sequences. The transparency of the hydrogel also enabled the construction of multiple layers of the patterned material.

The studies described above demonstrate the wide range of possibilities of functionalizing surfaces in a patterned manner, thereby preferentially influencing spatial cell distributions. The strength of high-resolution patterning techniques in relation to organ printing is exploited particularly when the behavior of the cells itself is influenced by altering their microenvironment. For example, Sarkar *et al.*[78] showed that the orientation of vascular smooth muscle cells (VSMCs), their F-actin fibers, and deposited fibronectin fibrils can be influenced by growing them in small-sized channels. For channels up to 50 μm in width, the cells were nearly 100% aligned, with a high aspect ratio of 12. Above 50 μm channel width, the aspect ratio and fiber alignment are decreased, and no preferred orientation is observed on nonpatterned surfaces. The structural organization of VSMC and their ECM is believed to play a crucial

role in the functionality of blood vessels of small diameter. The geometry of the cellular environment not only affects cell orientation, but also influences cell motility and shape. A study in which single cells were cultured on small adhesive islands of different shapes revealed a preferential focal point adhesion at sharp edges.[79] The deposition of synthesized fibronectin also took place particularly from these edges. The shaped islands, each measuring 900 μm^2 surface area, were prepared by microcontact printing of an alkanethiol on a gold-coated glass coverslip, followed by coating with fibronectin. Before the fibronectin coating step, the nonprinted area was made non-cell-adhesive by binding with PEG-alkanethiolate. Another strong example of geometry-driven manipulation of cellular behavior was presented by McBeath *et al.*,[80] using surfaces microcontact printed with fibronectin to prepare islets of different sizes. They showed that the differentiation of mesenchymal stem cells can be triggered by geometrical cues. The degree of cellular adhesion regulated the switch in MSC lineage commitment; the activation of the RhoA–ROCK pathway appeared to be instrumental in this switch. High activation of RhoA and ROCK led to osteogenic differentiation while low activity resulted in adipogenic differentiation, independent of cell shape.

5.542.2.2.3. Direct manipulation of cells

While the techniques and examples described above focus on the patterning of surfaces for the indirect manipulation of cell behavior, some of these techniques can be used for direct manipulation of cells as well. The use of UV and organic solvents prohibits the direct use of cells with most lithographic methods, but soft lithography techniques (microcontact printing in particular) can be used with cells. Using PDMS stamps prepared by photolithographic methods, patterns of cells can be transferred to a substrate. This form of microcontact printing is often referred to as cell stamping.[81] Cell stamping has also been performed on the surface of porous hydroxyapatite scaffolds.[82] Agarose hydrogel stamps were used for their low cell adhesion properties. Moreover, the hydrated surface ensured that the viability of cells adsorbed on stamps during the patterning process was maintained.

Laser-induced optical forces can be used in several ways for noncontact manipulation of particles 100 nm to 10 μm in diameter. One of these techniques is referred to as laser-guided direct writing, in which individual cells in suspension are guided to be deposited onto solid surfaces.[83] The optical force arises from a difference in the refractive indices of the cell and the medium it is suspended in. A laser beam that is directed off-center to the spherical cell is partially reflected and partially refracted to a different path, thereby transferring an impulse to the cell. By moving the target surface relative to the laser beam, arrays of cells are deposited. Although this ability to manipulate single cells in a noncontact manner is impressive, it has a number of limitations. Perhaps the major limitation is the low cell numbers that can be deposited, which makes it very difficult to upscale this technique for organ-printing purposes. Furthermore, it will be a challenge to retain the assembly of written cells, as they are only brought in physical contact with the substrate and do not necessarily bind to it directly.

Another cell manipulation technique that is laser-based, but works in a totally different manner, is matrix-assisted pulsed laser evaporation direct write (MAPLE DW), or simply laser printing.[84] In this technique, a layer of cells in medium is absorbed on the lower side of a quartz glass plate (**Figure 6**). A microscope objective is used to focus a laser beam on the plate, which results in a highly localized sharp temperature increase. This causes a small volume of liquid to vaporize and expel a jet of cell-containing medium, which is then deposited on a substrate. The excessive temperature during droplet generation does not appear to compromise cell viability, nor do printed cells express significantly higher levels of heat shock protein than nonprinted controls.[85] For the moment, laser printing works with cell-laden strips in a batch-wise manner; therefore, to reach high-throughput rates, a feeding mechanism for the continuous dispensing of cells will have to be established. Another challenge is to introduce hydrogels, or

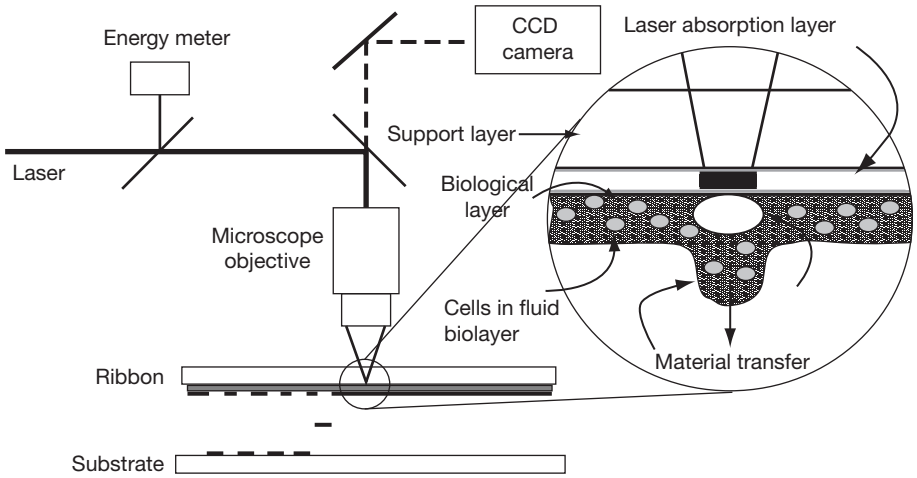

Figure 6 Schematic of a biolaser printing setup. A laser beam that is focused through a microscope objective heats up a small area on a metal or metal oxide absorption layer. The sudden localized temperature increase induces evaporation of a small volume of liquid in the biolayer, followed by expulsion of a drop of cell-containing liquid. Reproduced with permission from Barron, J. A.; Ringeisen, B. R.; Kim, H. S.; Spargo, B. J.; Chrisey, D. B. *Thin Solid Films* **2004**, *453*, 383–387.

Photopatterned gels with randomly encapsulated (multiple types of) cells. III, IV. Photopatterned gel with clustered encapsulated cells on a substrate (III) or free-floating (IV). V. Free-floating unpatterned hydrogel with encapsulated cell clusters. Reproduced with permission from Albrecht, D. R.; Tsang, V. L.; Sah, R. L.; Bhatia, S. N. *Lab Chip* **2005**, *5*, 111–118.

some other form of support structure, to enable printing of stacked layers for organ-printing purposes.

Another cell manipulation approach is based on cell organization by dielectrophoretic forces and subsequent entrapment in a UV-sensitive hydrogel.[86] This combination of patterning techniques makes it possible to fabricate layered 3D matrices with variable cell and gel organization (Figure 7). It makes it possible to study the effects of volumetric cell density, nutrient transport, and paracrine signaling (i.e., signaling between adjacent cells). Microorganization of bovine chondrocytes patterned with this technique was shown to have direct biological consequences with respect to their synthetic activity. The cumulative quantity of deposited glucosaminoglycan matrix proteins per cell decreased in a dose-dependent manner with increase in the size of cell clusters, indicating that homogenous cell distribution at high cell densities is indeed more desirable for adequate ECM formation.[87]

5.542.2.3. Translating 2D Approaches to 3D

Microfabrication tools make it possible to understand how spatial presentation of regulatory signals, such as adhesive molecules and growth factors, tailors cell microenvironment and regulates cellular responses,[57,88] and help to uncouple some of the regulatory signals involved in cell–matrix interactions.[87] Cellular patterning techniques can easily control the degree of interaction between the two cell populations and allow of studying cellular interactions of different ratios.[89]

Recent technical developments have made it possible to perform patterning of adhesive sequences in 2D+, for example, by micromolding and stacking layered 2D structures.[58,69,90] Other approaches to generating microcontrolled materials make use of a photolithographic technique to pattern bioactivity of desired dimensions into a preformed, existing material.[91] A similar technique uses a 3D focused laser with higher intensities, with the aim of removing material through photoablation.[92] Using PEG-fibrinogen hydrogels, this technique allows for the 3D patterning of patterns/channels to promote and direct cell migration and assembly of 3D networks of cells.

Not all the 2D patterning and cell manipulation techniques described above have the potential to be translated to make 3D cellular constructs. Limitations can be either the possibility to upscale to dimensions relevant for organ printing, or that the used technique is inherently 2D. The most straightforward way to translate a 2D technique to 3D is to perform the 2D fabrication process repeatedly in a layer-by-layer fashion. Most photolithographic techniques rely, however, on the modification of nondegradable substrates such as gold, silicon, or glass with biofunctional molecules on their surfaces rather than producing full layers of functional biomaterials. Translation of this technique therefore requires labor-intensive production and coalignment of individual parts to achieve multilayered structures.[93] Introducing intricate shape and porosity into these structures is very challenging. This renders these techniques unsuitable for fast and efficient development of 3D tissues.

Lithography of cell-containing gels seems more promising for 3D application, such as shown by Hahn *et al.*[69] using a computer-controlled laser and two-photon polymerization. A similar opportunity for translation to 3D is found for electropatterned cell-containing hydrogels such as those presented by Albrecht *et al.*, by stacking prefabricated gel layers. In mask-based photolithography, particularly, the use of printed transparent overhead sheets is promising as these provide an easy and inexpensive way of making masks with dimensions relevant to organ printing. Actually, automated 3D photolithography has already been developed and first steps are being taken to apply stereolithography to organ printing, which is described in **Section 5.542.3.2.3**.

For the possibility of continuous cell deposition techniques to be used in 3D, the structural integrity of the cell layer is the main determinant. Other important factors are the throughput rate and the accuracy of positioning each layer in line with the previous one. Often, there is a trade-off between these two factors. Laser-guided direct writing has a very high accuracy as cells can be manipulated individually, but the throughput rates and scale of the application are far from being applicable to organ printing. Another obstacle is that cells need to be suspended in nonviscous media, which impedes the use of hydrogels. Finally, for making larger multilayered constructs, there will have to be a mechanism to fix the organization of cells being deposited by the laser. For the biolaser printing technique, upscaling seems to be less of a problem, but that could go at the cost of accuracy. The challenges here are the continuous feeding of the liquid film, fixation of a printed layer, and accurate printing of subsequent layers.

Many approaches have been attempted in 2D to investigate a proof-of-principle for the process, with the aim of translating it to 3D. In reality, however, very few approaches have been translated to 3D, or they have a number of limitations or shortcomings that impede their application in organ printing. Still, these developments may be suited to alternative tissue engineering and regenerative medicine applications on smaller tissues, or for drug screening.

5.542.3. 3D Organ-Printing Processes

5.542.3.1. Organ Printing Versus Book Printing

Cell and organ printing are often compared to the traditional book printing technique invented by Johannes Gutenberg in the fifteenth century.[56] In this analogy, five essential components are needed, which are summarized in **Table 1**

Although the analogy between traditional printing and organ printing stretches far, it is incomplete in the sense that traditional printing is only a 2D process, whereas the third dimension is essential for printing organs. Organs consist of multiple tissues, each having complex 3D architectures with spatial differences in cell types, cell densities, and composition of the ECM. Taking into account the 3D character of organ printing, the comparison of cell support structures to paper, particularly, is an imperfect one. Whereas paper is a preformed support structure for the printing of text, the support structure for cells in organ-printing applications has to be, in most cases, prepared in the printing process itself. Organ-printing techniques should therefore rely on the simultaneous dispensing or assembling of cells or cell aggregates and support materials, mostly hydrogels. This can be achieved using techniques based on a number of operating principles, which are introduced in the following sections.

5.542.3.2. Overview of 3D Techniques

Earlier, we discussed techniques for the direct manipulation of cells in 2D. Although some of these techniques could be, or have been, used to make multilayered constructs, many of them cannot be upscaled to fabricate large, 3D living structures. Most of the techniques to date that have shown potential to actually prepare such 3D structures can be roughly divided into two categories. They are jet-based techniques and robotic dispensing techniques, as summarized in **Table 2**.

5.542.3.2.1. Inkjet printing

The idea of being able to print live organs using a desktop printer is truly fascinating. The application of low-cost, everyday use Hewlett-Packard (HP) inkjet printers in the early studies of bioprinting perhaps added to the vision of a revolution at

hand.[17,18] Inkjet printing refers to the spatially controlled dispensing of a jet of small drops of liquid material through a small orifice (Figure 8). In thermal inkjet printing, small volumes of the printing fluid are vaporized by a microheater to create the pulse that expels droplets from the print head.[112] This could explain the significant cell death (26%) observed upon thermal inkjet printing of primary rat embryonic hippocampal and cortical cells,[113] although dehydration of the printed cells has also been suggested to have compromised the viability in this study. Alternatively, in piezoelectric-actuated inkjet printing, no heating is used for creating the pulse. Moreover, it allows for some control of the mechanical stress experienced by the cells during the printing process.[114] A recent thorough investigation of the influence of piezoelectric inkjet printing on the viability of a human fibroblast cell line reported no statistical difference in the viability of printed cell populations compared to unprinted controls, for optimized printing conditions.[100] Analysis of metabolic activity revealed no evidence for decreased functionality of printed cell populations.

To date, the predominant focus of studies in the literature related to inkjet printing of cells and gels is on 2D printing only. Generally, cells, either in culture medium or in a hydrogel precursor, are printed onto a sheet of collagen or a synthetic polymer that is used as biopaper.[17,18] A challenging barrier to overcome in translating inkjet printing to organ printing, is the fabrication of 3D structures. For this, a liquid-to-solid transition has to occur to make layering possible. The relatively low threshold for the viscosity of inkjet printing fluids, typically around 30 mPa s,[115] becomes a severe restriction. To date, the most commonly adopted system is that of sodium alginate and calcium ions (mostly from $CaCl_2$ solutions), which form a gel upon mixing. Boland *et al.*[94] have printed the less viscous $CaCl_2$ solution into a bath of sodium alginate to print the branched structure depicted in Figure 9. In their setup, a jet of $CaCl_2$ droplets is printed into a 100 μm liquid top layer, leading to local gel formation. After the printing of each layer, the object is moved down into the bath, leaving the next film of liquid exposed to the incoming jet. As the calcium ions diffuse into the surrounding sodium alginate solution to induce gelation outside the droplets, a characteristic hollow-shell structure is formed (Figure 9). Therefore, it is unlikely that this system could be used to print cell-containing gels.

Alternatively, Xu *et al.*[99] followed the opposite approach and printed drops of the more viscous alginate solution into a $CaCl_2$ solution. As the same phenomenon takes place in this situation, but in the opposite direction, it has proven a promising method to form alginate beads with encapsulated cells. Nishiyama *et al.*[98] followed the same approach to print alginate beads and rings containing viable cells. However, the

typical gelling behavior of the alginate/calcium system makes it impractical for printing robust, well-fused gel structures with encapsulated cells.

Although inkjet printing was the first technique reported to be associated with organ printing, it has shown limited development in the construction of organs since the introduction of the organ-printing concept. In their attempts to increase the chance of success of inkjet printing of complex 3D TECs, materials scientists are facing the difficult challenge of turning low-viscous solutions into strong, biocompatible materials.

5.542.3.2.2. Robotic dispensing systems

Although organ printing was first proposed to become a jet-based platform,[21] the most successful attempts to prepare cell-containing constructs have been via the use of dispensing-based systems (Table 2). Perhaps the simplest setup used so far has been one composed of a gantry robot with a syringe-based deposition tool.[103] Using this system, predesigned shapes were fabricated from alginate hydrogels, and cells could be printed in the hydrogels with a viability of $94 \pm 5\%$. Although external geometries of an intervertebral disk and a meniscus could be well reproduced with this system, the 1.2 mm diameter of the deposited strands provides only limited spatial control for placing cells and materials. Higher spatial resolutions are usually achieved by pneumatically actuated dispensers. Figure 10 provides an example of the accuracy of patterned pneumatic dispensing of a 3% sodium alginate solution into a 5% calcium chloride solution, causing instant gelling. The figure shows a stable alginate hydrogel structure built up from 0.2-mm-thick strands.

Khalil *et al.*[102] have combined several dispensing techniques in one multinozzle dispensing system, allowing dispensing of materials with a large range of properties. Table 3 summarizes the characteristics of the four different nozzle systems. Interestingly, a piezo-actuated inkjet dispenser is included in the system, enabling direct comparison of this technique with others. Here, the particular disadvantages of inkjet-based systems discussed earlier (low viscosity threshold and droplet-based dispensing) are reiterated. The solenoid-actuated micronozzle forms an attractive alternative as it provides the ability to deposit strands of material in a continuous method. Still, it has a much faster response and possibly more control over the dispensing than the pneumatic micronozzle. Finally, the pressurized miniextruder could be employed to deposit fibers of highly viscous materials such as thermoplastics. Unfortunately, the authors did not present a comprehensive study to compare the specific advantages and limitations of the dispensing systems. Theoretically, the combination of

extruding a thermoplastic (which is basically fused deposition modeling[11]) and plotting a cell-containing hydrogel in one structure could unite the favorable mechanical properties of prototyped solid scaffolds with the precise placement of cells seen in organ-printing techniques. So far, the employment of such a combination has not been reported.

In more recent years, several studies have been published on the robotic dispensing using pneumatic systems of gelatin-based formulations with encapsulated hepatocytes or neural cells,[97,104,105,107] and of several synthetic and natural hydrogels containing bone marrow stromal cells.[106] These successful attempts to encapsulate cells in structured hydrogels make it likely that pneumatic robotic dispensing systems will continue to play a large role in organ printing in the future.

5.542.3.2.3. Stereolithography

Stereolithography is another SFF technique that allows for creating computer-designed 3D hydrogel structures with encapsulated cells.[116] The working principle of stereolithography is based on the spatially controlled solidification of a liquid resin by photopolymerization (Figure 11). It is a layer-by-layer form of photolithography, where the pattern is created by the use of either a computer-controlled laser beam or a digital light projector. In the latter case, the instant creation of a pixelated light pattern is achieved using an array of millions of mirrors, which can be individually and independently rotated to an on or off state. The pattern is illuminated on the surface of a resin, which is then solidified to a defined depth. After photopolymerization of each layer, the supporting platform is moved away from the surface and the built layer is recoated with liquid resin. A pattern is then cured in this second layer. By controlling the depth of curing through light intensity and exposure time, good adherence to the preceding layer is ensured.

Various research groups have used water-soluble di(meth) acrylated poly(ethylene glycol) (PEG-D(M)A) precursors to create structured, cell-containing hydrogels by stereolithography. The first reported successful cell encapsulation using stereolithography made use of Chinese hamster ovary cells and PEG-DMA precursors.[108] Later, PEG-DMA constructs containing

encapsulated human dermal fibroblasts,[109] and PEG-DA gel structures containing marrow stromal cells[110] were reported. In all the cases, cells could be encapsulated at high densities: several millions of cells per milliliter. The cells showed good survival after fabrication of the construct, especially when peptides containing RGD sequences were incorporated in the gels.[109] In cell encapsulation based on photopolymerization, factors such as the choice of photoinitiator and its concentration, wavelength and intensity of the light source, and pH, all play a critical role.[117] Besides cells, ligands, ECM components, growth factors, and controlled release particles can also be patterned inside a single scaffold using stereolithography.[118]

Stereolithography is the SFF technique with the highest accuracy and precision; it is also the most versatile with respect to freedom of design. Additionally, the automated process and scale of application make it a promising technique for organ printing. Perhaps the major limitation of the technique is that to date, fully automated fabrication is possible with only one type of resin (or cell suspension) at a time. The ability to pattern multiple resins in a construct or even within a single layer has been demonstrated, but complex sequential polymerization and rinsing steps were required for each layer built.[109,118] A major technological challenge lies in developing an automated system to feed different resins and remove uncured resin,so that eventually different cell types can be patterned in specific locations in 3D.

5.542.3.2.4. Robotic assembly

A possible route to fabricate 3D TECs that is still in an early stage of development is via robotic assembly of designed microparts. This approach is based on the same concept as assembling a structure using small building-block units as in Lego.[10] By combining parts with different designs, porous structures with controllable pore sizes and porosities can be assembled, thereby influencing local mechanical and transport properties as well. An example of an assembly setup with four degrees of freedom and a shape-memory alloy-based microgripper is depicted in Figure 12.

Suitable microparts have been accurately fabricated by photolithography from SU-8 photoresist resin.[119] Although not biodegradable and therefore of limited use for tissue engineering purposes, cured SU-8 is a suitable cell substrate with mechanical properties comparable to poly(L-lactide) and therefore apt for proof-of-principle and *in vitro* cell culture studies. A second set of nondegradable microparts was fabricated using an acrylic resin with a rapid microproduct development (RMPD) process based on stereolithography. Since then, many stereolithography resins have been developed for the direct fabrication of biodegradable tissue engineering scaffolds.[116] It can therefore be expected that in the future, biodegradable microparts for robotic assembly with a wide range of physical properties will be fabricated for the engineering of a wide range of tissues.

The ability to seed the microparts with cells prior to scaffold assembly is what makes this technique particularly interesting for tissue engineering following the organ-printing approach. Different parts could be seeded with different cell types, or multiple cell types could be seeded on the microparts in a patterned manner using cell stamping techniques, as described in Section 5.542.2.2.3. The patterning of proteins on the microparts is another possibility. In these ways, cellular constructs can be fabricated with a controlled cellular organization. The biggest difference when comparing robotic assembly to inkjet or robotic dispensing systems is the 'biopaper' being solid parts as opposed to hydrogels in which cells are encapsulated. This makes the approach particularly interesting for the engineering of hard tissues, where load-bearing scaffolds are desirable. The robotic assembly of TECs is a complex process that requires the combined use of advanced technologies. It involves the use of precise robots, image analysis, and force feedback systems, different feeds of microparts preseeded with cells, and a sterile environment under physiological conditions. Perhaps this complexity is why it is less established than hydrogel-based printing and dispensing systems. Nevertheless, it is a promising approach for organ printing that deserves the attention of tissue engineers in the future.

5.542.3.3. Developmental Phases and Components Associated with 3D Organ Printing

5.542.3.3.1. Preprocessing: design

In order to fabricate organ constructs of anatomical shape and size, blueprints of the organ in the form of a CAD are the first requirement. Medical imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) can be used to get a digital image of an organ, or of a defect that is

to be tissue engineered. These digital images can be manipulated to serve as building instructions for the organ-printing process. Over the last few years, the combination of medical imaging and SFF techniques has found its way into the tissue engineering field. In the first reported uses, the fabricated parts served as moulds to prepare anatomically shaped implants.[120–122] Woodfield *et al.*[123] used CT data to directly fabricate anatomically shaped rabbit knee scaffolds using fused deposition modeling and a biodegradable polymer. The implants showed congruent articulation after a 5 week culturing period and subsequent *in vivo* implantation for 6 weeks. Cohen *et al.*[103] showed that they could fabricate a solid meniscus-shaped hydrogel structure designed from a CT scan, using the same device and hydrogel, as was used for cell-laden constructs. It is expected that the use of medical imaging will become standard practice in designing constructs to be fabricated by organ printing.

5.542.3.3.2. Printing cell-laden 3D hydrogel constructs

Printed cells are encapsulated homogeneously in printed hydrogel strands and overcome the current drawbacks of heterogeneous tissue development caused by inhomogeneous cell seeding and dispersion (see **Chapter 5.509, Cell Encapsulation**).[106] The cells, localized to separate layers by interlayered cross-linking, retain the printed architecture.[124] Furthermore, printing sustains high cell viability, and cells retain the ability to differentiate after printing.[106]

Most published studies on the automated printing of cell-laden hydrogel show proof-of-principle of construct fabrication and cell viability (see **Table 4**, **Section 5.542.3.3.3**). The first steps have now been taken to further develop these systems and understand the parameters that govern the processes. Smith *et al.*[125] studied the influence of processing parameters such as printing pressure and pen speed, and environmental factors such as humidity and stage heating on printed line widths and cell viability.

Although most of the used systems are still custom-built, in the last few years several systems have become commercially available (**Figure 13**), and more have been announced. The technological development of such systems will play a key role in the functionality of printed tissue and organ constructs.

5.542.3.3.3. Hydrogels: gels used and criteria for developing hydrogel carriers for cell and organ printing

Hydrogels are extremely hydrated polymer networks. Due to their high water content, they are highly biocompatible and can act as 3D supportive matrices to embed cells in organ printing[126] (**Table 4**). Hydrogels are built up of water-soluble polymers, either synthetic or natural, which swell in water due to cross-links as opposed to dissolving, thereby maintaining structural integrity. The cross-links between the polymer chains are either physical interactions or covalent bonds.

Hydrogels based on ECM polymers provide an adhesive surface for the cells, but their composition is unpredictable, and their mechanical properties and degradation rates are difficult to control. Synthetic hydrogels offer a higher lot-to-lot uniformity with a more controllable and reproducible scaffold structure, gel formation dynamics, degradation rates, and mechanical properties. Stimulus-responsive hydrogels are well suited for organ printing because gel formation can be controlled during and after the printing process. These types of materials form a gel in response to changes in their environment. Cross-linking can be initiated using physical stimuli such as changes in temperature, pH, and ionic environment, or can be chemically induced via enzymatic reaction, or exposure to UV light in the presence of a photoinitiator (photopolymerization). In general, hydrogels have good cytocompatibility. They can homogeneously incorporate and suspend cells, growth factors, and other bioactive compounds while allowing rapid diffusion of nutrients to, and metabolites from, incorporated cells. A major disadvantage of hydrogels is their low mechanical strength, which makes handling and *in vivo* application difficult. The low strength is because hydrogels consist predominantly of water, held in place by a relatively fragile polymer network.[127] Therefore, a popular approach in biofabrication is the improvement of the mechanical stability by modification of hydrogels with photosensitive sequences that result in covalent cross-linking. [128] Alternatively, various methods exist to prepare hydrogels with greatly improved mechanical properties and toughness, in particular. Among these are the use of slide-ring gels, double-network gels, and nanocomposite gels.[129] Future studies will show how, deriving advantage from the extraordinarily improved mechanical

properties, these novel approaches can be used for organ printing, in conjunction with cell encapsulation and printing techniques.

Unmodified synthetic hydrogel matrices commonly lack suitable binding sites for the cells to adhere to, and these gels are also limited in their ability to support cell differentiation. Modifications that have been applied to target cell functioning include incorporation of adhesive sequences (e.g., RGD; heparin-binding sites), and peptides coding for growth factors.[130,131]

Cell migration through extracellular matrices is a key step in morphogenesis and tissue regeneration. As hydrogels are molecular mazes with mesh sizes typically below 1 μm, the migration, and therefore proliferation and functioning of embedded cells as well, can be severely restricted by the polymer chains in hydrogels. Particularly, in covalently cross-linked hydrogels, embedded cells can remain viable, but show little proliferation.[106] Wang *et al.*[132] cultured hepatocytes in glutaraldehyde cross-linked 3D gelatin structures for as long as 3 months, without observing an increase in cell number. Cell proliferation functions could still be detected by the multiple nuclei and nearly separated cytoplasts, but full mitosis and proliferation were arrested by chemical cross-links induced by the glutaraldehyde treatment. For the engineering of some tissues, cell proliferation is indeed not desired. For example, chondrocytes tend to either proliferate (in a dedifferentiated state) or deposit matrix (in a differentiated state). Cartilage is a tissue containing only a low density of cells and in which functionality is derived mainly from its matrix composition.[24] Therefore, for the engineering of cartilage, differentiation and matrix production are preferred over proliferation.

In other cases, cell migration and proliferation are important for tissue formation. Cell migration often becomes possible after degradation of the polymer backbone in natural hydrogels. Migrating cells manipulate the balance of collagenase and inhibitors of collagenase to maintain a proteolytic environment that is localized near the cell but is inhibited farther away from the cell surface. PEG-based hydrogels with proteolytically sensitive cleavage sites have been developed that allow embedded cells to migrate through a synthetic hydrogel.[133,134] Alternatively, physically cross-linked hydrogels exist that enable nonproteolytic cell migration and outgrowth of fibroblast aggregates.[135] For successful organ printing, the suitability of the hydrogels used for cell migration, proliferation, differentiation, and tissue formation should be better addressed in the future.

5.542.3.3.4. Scaffold-free assembly: aggregates and cell-sheets

Directed self-assembly by inkjet printed cell-aggregates has been investigated, demonstrating assembly of cell aggregates into tubular structures upon printing in hydrogel matrices (see **Chapter 5.530, Medical Applications of Cell Sheet Engineering**).[136–138] Some researchers speculate that as long as the boundary conditions are met, the self-assembly potential of cells will organize tissue from homogeneous cellular mixtures. Therefore researchers (especially in vascular tissue engineering) have focused on scaffold- and template-free approaches to

engineer tissues composed of only cells and the secreted matrix. Scaffold- and template-free approaches state that initially strong material properties are nonessential and may even impede efficient organ biofabrication. In order to support cell or tissue spheroid fusion, many of these techniques rely on the use of supportive hydrogel matrices to sustain the spheroids,[49,50,136] which, by definition, implies that these approaches are not entirely scaffold-free. Current drawbacks of cell-sheet technology and aggregate printing are the low resolution and tissue thickness limitations. Furthermore, it is technically challenging to remove biopaper postfusion, and fusion of spheroids may take as long as a week, which can lead to nonuniform surfaces.[50]

Using an alternative multilayered cell-sheet approach, Lee *et al.*[124] investigated the effects of printing resolution on outgrowth and connectivity of neural cells dispensed in collagen gels. After 15 days of culture, neurons printed at 250 μm interdispensing distance still showed more sparsely distributed cell clusters with low neural connectivity through neurite outgrowth, compared to neurons printed at 150 μm interdispensing distance. For astrocytes, an increase in growth rate and influence on morphology was observed with decreasing interdispensing distance, with a minimum printing resolution of approximately 400 μm required for sufficient growth rate and morphology.

5.542.3.3.5. Printing of multiple cell populations and tissue equivalents

By incorporating several cell types at predetermined locations, cell-seeded implants that further mimic native tissues can be generated. It remains to be seen however whether printed tissues that follow native anatomy with respect to anatomical geometry and spatial organization are relevant for *in vivo* tissue formation. To validate this issue, tissue formation by distinct cell populations printed at defined locations within one construct was tested *in vitro* and *in vivo*. Recent data on the generation of such constructs underlines the potential feasibility and impact of this technology. For example, as a model for osteochondral grafts, chondrocytes and osteogenic multipotent stromal cells were printed, yielding a dual heterogeneous construct. Distinct ECM formation was observed in the different regions of the construct, which was associated with the type of cells deposited.

5.542.3.3.6. Postprocessing

The design characteristics of the scaffold have a major impact on nutrient delivery (see **Chapter 3.309, Fluid Mechanics: Transport and Diffusion Analyses as Applied in Biomaterials Studies**). The use of SFF techniques allows for the preparation of more regular scaffolds with increased permeability compared to the use of conventional techniques such as salt-leaching, phase separation/freeze-drying, and gas foaming processes. Furthermore, they enable the inclusion of some form of an artificial vascular system in the scaffold design.[5] Printed interconnected pores form channels through which the nutrients can diffuse, resulting in a significant increase in cell survival in the core of the graft. However, the use of SFF fabrication methods alone does not guarantee long-term cell survival as the transport of nutrients and oxygen can be compromised by tissue growth over time. This is where organ printing provides a fundamentally different strategy compared to solid-scaffold tissue engineering. In solid-scaffold tissue engineering, cells are seeded in the pore space of a scaffold. As the cells in the periphery of the scaffold are exposed to higher nutrient and oxygen concentrations, they proliferate more compared to cells seeded inside. In this way, they block pores and thereby reduce the transport of nutrients to the core of the scaffold, leading to hypoxia and, eventually, apoptosis, and necrosis.[139–141]

In the cell–gel structure printing approach, however, cells are embedded in the strands of the printed scaffold itself, and pore channels remain open for transport of medium. In this way, throughout a printed gelatin construct, hepatocytes have shown to remain 98% viable after 3 months of static culture.[105] It should be noted, however, that in this case, proliferation did not occur. Obviously, when cells proliferate and start growing outside the hydrogel strands also, blocking of pores could occur. However, if the right hydrogel material is chosen, cells will probably prefer to colonize the strands first.

In order to further optimize the architecture and encapsulate the cells inside the scaffold material itself, bioreactors that improve the transport of nutrients and oxygen in the maturation phase can be used. In particular, perfusion systems improve nutrient and oxygen delivery to the cells inside the engineered tissue (see **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design**).[142,143]

Furthermore, the printed construct should have sufficient mechanical properties to allow handling as well as maintenance of its integrity once implanted in the host. Mechanical properties are often disregarded in organ-printing studies; in many cases, 'handibility' is the only used measure. As stated earlier, a very large improvement is possible with the use of specific types of hydrogels. It has been shown that the mechanical properties of cell–gel constructs improve upon maturation, due to the production of ECM. The concert of mechanical loading and supplementing growth factors during bioreactor culture significantly enhances the quality and mechanical properties of the tissue formed.[144] Probably, the mechanical properties of as-printed cell–gel constructs have to be improved in order to allow for mechanical loading.

The increasing availability of predictive mathematical and physical models of cell and tissue behavior will provide further insight into the effects of nutrient limitation and mechanical stimulation.[142,145,146]

5.542.4. Future Directions

5.542.4.1. Current Limitations in Organ Printing

At the moment, it is still impossible to print a tissue or organ. The technology of organized deposition of cells by 3D plotting has just evolved toward fabrication of centimeter-scaled tissues. The *in vivo* performance of such constructs containing multiple cell types after implantation at ectopic and orthotopic locations will provide further answers to the quality and quantity of tissue formation within the printed grafts. It is especially important to investigate whether the imposed cell organization actually contributes to functional tissue formation once implanted. Other points of concern are the nature of tissue formation in the transition zone between different tissues, for example, the development of osteochondral constructs consisting of articular cartilage and bone, and

the interaction between implanted and host tissue. Many aspects of cellular behavior in printed constructs are dictated by the nature of the support matrix, and our understanding of cell–matrix interactions is still rather limited, making it difficult to predict cellular outcomes.

5.542.4.2. Scale of Application

Before the printing of whole organ substitutes is achieved, many hurdles will have to be overcome. One aspect will be the gradual upscaling of printed constructs. Going from the tens of millimeters scale that current work is focused on to the tens of centimeters scale of organs implies an increase by a factor of 1000 in material volume, numbers of cells, and construction time. With such upscaling, transport limitations and vascularization become increasingly difficult as well as important.

However, printing of millimeter-sized living constructs is already proving to be very useful as it provides model systems in the development of 3D tissue strategies for tissue regeneration.[23] The possible combinations of materials, cell types, bioactive molecules, other additives, and processing conditions are innumerable, and cell- and organ-printing techniques can provide a method for high-throughput screening similar to the screening of biomaterial–cell interactions, as reported earlier.[147] Presumably, upscaling will be of little use before such optimization studies have yielded specific conditions for the engineering of specific tissues. Moreover, the mechanisms of cell aggregate fusion and tissue morphogenesis will require more detailed studies on a small scale before being applied in the engineering of artificial organ constructs. Furthermore, printed 3D microtissues can be used as models for drug testing purposes or for studying disease processes. A printed 3D environment can provide a better model than 2D environments, which might make drug screening faster and more selective. Such printed microtissues can provide a valuable extra step in the development of drugs, by yielding extra information before expensive and complex preclinical and clinical trials are initiated.

5.542.4.3. Tissue Complexity and Vascularization

Whether tissue engineers can precisely recapitulate the most essential structure and functional features of natural tissues and organs, and how far they must try to imitate developmental morphogenesis are a matter of debate.[138] Organ printing is a powerful tool to study the effects of 3D organization and will further help to provide answers to whether anatomical tissue design is necessary to achieve more functional grafts.

Much of the future success in this field will relate to the types of tissues and organ structures that are targeted for regeneration. It is unclear whether tissue engineers will ever be able to have sufficient control over the cell and tissue assembly processes to recreate the extreme complexity observed within the human body, where the level of tissue organization ranges from nanoscale up to tens of centimeters. The major assumption in the current strategies is that the cells themselves will still be primarily responsible for generating the necessary ECM. While cell and organ printing provide a mechanism to potentially arrange cells, tissues, and support structures in an optimal 3D environment, with the necessary nutrients, growth factors, and ECM cues to support growth and regeneration, it is unlikely that even the most simple of tissues or organs could be completely regenerated *in vitro* or *in vivo* within the near future. Clearly, the development of bioreactor systems to provide a sufficient and controlled environment for nutrient supply and mechanical stimulus to mature tissue prior to implantation will go hand in hand with the development of organ-printing strategies.[148]

One of the major challenges in tissue engineering is the vascularization of constructs. Insufficient vascularization can lead to improper cell integration or cell death in TECs, and this might be one of the reasons why the extent of clinical applications in the field of tissue engineering is still limited.[48] The difficulty in achieving such vascularization in constructs engineered following the traditional approach of seeding prefabricated scaffolds is one of the main reasons to develop organ-printing techniques.[149]

5.542.5. Conclusions

Organ-printing techniques enable the production of living constructs with spatial variations along multiple axes with high geometric complexity. The level of control offered by these technologies in the development of printed tissues will allow tissue engineers to better study factors that modulate tissue formation and function, and provide them with a valuable tool to study the effect of anatomy on graft performance.[80,89] Different biofabrication technologies function at different scales of organization. Precise 2D microscale patterning techniques may help answer an increasing demand for *in vitro* models that capture more of the relevant tissue complexity than do traditional tissue engineering systems.[150] Cellular micropatterning has already been useful in the study of many diverse biological phenomena, including spatial control over cell attachment, spreading, influence of cell shape, and outgrowth of blood vessels.[72,77] Potentially, *in vitro* printed constructs will display important structural and functional characteristics of a natural tissue, and could be used as a model system to study tissue-level responses to molecular, mechanical, or genetic manipulations, or as a tool to study diseased cells and tissue development in pharmacological/toxicological screens[1,151] However, micropatterning tools are much too small to ultimately function as tissue equivalents for *in vivo* implantation. Organ-printing techniques, such as 3D printing and dispensing, are too crude for facilitating the microscale cell organization, but can, nevertheless, enable fast and efficient cell-laden scaffold formation. They are potentially the favored strategy for the construction of grafts for *in vivo* applications and their clinical translation. The current state of the art in the robotic fabrication of cell and tissue constructs is still very far from creating complex functional organs, but progress in this direction is being made. These developments can provide solutions to other problems and give answers to fundamental questions on tissue morphogenesis and cell functioning as well.

NIS	Nationwide inpatient sample
THA	Total hip arthroplasty
THR	Total hip replacement
TJA	Total joint arthroplasty
TKA	Total knee arthroplasty

6.601.1. Introduction

Hip and knee joint replacement surgery is currently the standard of care for treating degenerative joint disease around the world. The prevalence of hip and knee arthroplasty in the United States has grown substantially since the 1990s.[1] Arthroplasty may involve total replacement of a diseased joint, or in the case of a hip fracture or single compartment knee arthritis, only one side of the joint may be surgically replaced by a partial joint prosthesis. The first time a joint is replaced, it is referred to as a primary procedure, but in the case of a failed surgery, it is necessary to perform a revision joint replacement. Considering both primary and revision procedures, over 1 million Americans benefited from partial and total joint replacement surgery in 2007. The different categories of primary and revision joint arthroplasty thus represent an established major platform for ongoing biomaterials advancement.

Because the cost, complications, and outcomes of revision joint replacement are generally worse than in primary surgery, there is great incentive to increase the longevity of joint replacements and to reduce the incidence of revisions. As a result, starting in the 1970s, orthopedic registries were developed in Scandinavia to track revisions on a national basis as a function of surgeon, patient, and implant characteristics.[2] In recent years, orthopedic registries have expanded across Europe, Canada, Australia, and New Zealand. Efforts to create a national orthopedic registry are still in the early stages in the United States. The sense of urgency surrounding a US arthroplasty

registry is compelling due to the anticipated future demand for joint arthroplasty. In the absence of a validated joint registry, administrative health care data in the United States represent a crucial resource in understanding the current and projected utilization of hip and knee replacements.

The purpose of this chapter is to provide a comprehensive review of the utilization of joint replacements and to discuss the implications of the future demand for surgeries in the field of biomaterials. As they are the earliest source of utilization data for joint replacement, international joint registries and validated administrative databases are first summarized and compared. The projected demand for joint replacements between 2010 and 2030 is also addressed. Finally, we review the limitations of the projection techniques and outline the economic implications of an escalating demand for joint replacement surgery in the future.

6.601.2. International Total Hip and Knee Implant Registries

International registries represent a well-established source of data regarding the current use of total joint replacement in Canada, Europe, and Australasia (Table 1). A registry is not merely a data repository containing basic clinical, patient, and implant data regarding the implantation and revision of total joint replacements. In countries in which an implant registry has been established, the data is also used as a tool to drive health care improvement by providing continuous feedback to the clinical community about procedure outcomes.

Orthopedic implant registries were first established in the 1970s in Sweden and later spread throughout Europe, Australia, and New Zealand. For example, the Swedish knee registry chronicles the growth of knee arthroplasty since the very beginnings of the procedure in the country (Figure 1). From the example of growth in Swedish total knee arthroplasty (TKA) utilization it may be appreciated that the characteristics and usage patterns of joint replacement vary considerably as a function of time. The temporal dimension greatly complicates comparisons among registries, which were established at different time periods and contain varying follow up. Thus, in the evaluation of clinical failure modes and their relationship to biomaterials across and between different registries, appreciation of the temporal variable is important.

If the long-term goal of a registry program is to improve the overall process of joint arthroplasty, tracking hospitalization outcomes (revisions, complications) is but the starting point

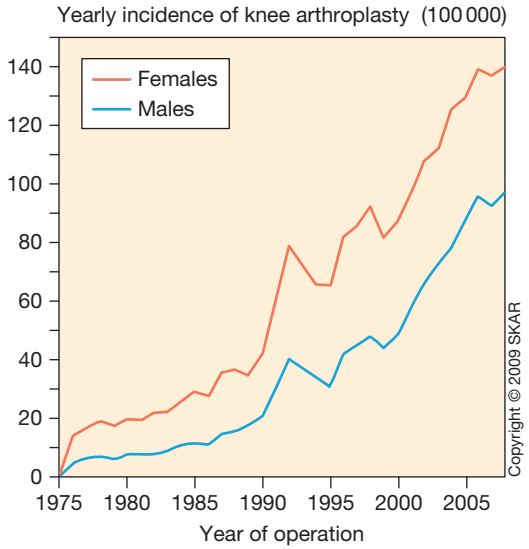

Figure 1 Annual incidence of knee arthroplasty in Sweden per 100 000 persons. Source: Swedish Knee Arthroplasty Register, Lund, Sweden.

for tracking the contribution joint arthroplasty makes to society. In its first 22 years of operation the Swedish hip registry focused on clinical metrics of surgery outcomes. However, since 2001, this registry has placed increasing emphasis on documenting improvement of the patients' quality of life following the surgery as well as the societal cost of performing the procedure. In many countries with a socialized health care system, including Sweden and Canada, the waiting time for surgery can be substantial. In Sweden, the mean wait time for total hip arthroplasty (THA) surgery was 312 days in 2007, whereas in Canada, the mean wait time was 182 days for THA. According to an economic analysis conducted by the Swedish hip registry, the societal cost for 1 year of wait time, incorporating lost productivity, is equivalent to the inpatient procedure cost of the surgery itself. Thus, the data from hip registries may be developed to drive changes in health care policy (e.g., reducing wait times in Sweden and Canada). Differences in health care delivery and access to joint replacement surgery cause wide variations in THA access between countries, as well as within countries over time. For example, within a country shifts in policy toward reducing wait times may increase the rate at which surgery is performed, even for a pool of patients that is not rapidly changing. Thus, policy shifts are but one example of the need for care

in extrapolating the current and projected utilization of hip and knee surgery outside of its national health care system.

Registries represent an important tool to evaluate the current use of total joint replacements in various countries, but they are by no means the only source of data regarding the utilization of surgical procedures. Large countries such as Germany and the United States currently do not have an operating hip and knee registry. Nationally representative administrative databases of countries without an operational registry are covered in the following section of this chapter. These databases can provide valuable and otherwise unavailable data regarding the current use of total hip and knee arthroplasty in the absence of a formal registry.

6.601.3. Public Data Sources for Orthopedic Implant Utilization in the United States

Even in countries with an established registry, administrative databases represent an important data source for total joint replacements. An administrative database may comprise a sampling of electronic hospital discharge records, or in the case of Medicare, the entire insurance claim history for individual patients. Total hip and knee procedures are identified in these databases according to the codes from the 9th Revision of the International Classification of Diseases, Clinical Modification (ICD-9-CM; see Table 2). Three public sources of administrative claims data for the United States are summarized in the following subsections.

6.601.3.1. National Hospital Discharge Survey

The National Hospital Discharge Survey (NHDS)[3] is an annual survey conducted by the National Center for Health Statistics (NCHS). Started in 1965, this survey program has continuously compiled a statistically representative sample of hospitalization from non-Federal and non-military short-stay community hospitals throughout the United States. As such, it is the oldest and most well-established inpatient discharge database in the country. Over the past decade, the number of hospitals included in NHDS has ranged from 430 to 490, with ~300 000 discharge records sampled per year. Information collected by NHDS includes patient demographics (e.g., age, gender), disease diagnosis, type of procedure performed, institutional characteristics, and resource utilization. Based on the information collected by the survey, national and regional estimates of characteristics of patients and surgical and nonsurgical procedures in hospitals of various bed sizes and types of ownership can be estimated using the provided sampling weights.

6.601.3.2. Nationwide Inpatient Sample

The Nationwide Inpatient Sample (NIS) is a larger and more recent database of inpatient discharge data in comparison with the NHDS.[4] Established in 1988 by the Healthcare Cost & Utilization Project (HCUP) of the Agency of Healthcare Quality and Research (AHRQ), the NIS has a far larger sample size in terms of both discharge records and number of hospitals. Compared to the NHDS, the NIS has 25 times more records with 5–8 million records per year and also includes twice the number of hospitals. The sampling of NIS captures 20% of inpatient hospital visits each year in the United States, and thus is well suited for studying national trends for rare diseases or for examining the epidemiology of diagnoses or procedures within minority subpopulations. The NIS also captures patient, payer, and hospitalization factors, as well as charges and cost information for the hospitalization, which can be used to evaluate the economic impact of procedures and diagnoses.

Table 2 Summary of ICD-9-CM codes for primary and revision total hip and knee replacement procedures

ICD9-CM-Code	*Description*	*Comments*
81.51	Primary total hip replacement	The type of bearing surface is coded, if known (00.74–0.77)
81.52	Partial hip replacement	This includes unipolar and bipolar hip prostheses; the type of bearing surface is coded, if known (00.74–0.77)
81.53	Revision of hip replacement, not otherwise specified	The type of bearing surface is coded, if known (00.74–0.77)
81.54	Primary total knee replacement	This code includes bicompartmental, tricompartmental, and unicondylar knee arthroplasty
81.55	Revision of knee replacement, not otherwise specified	
00.70	Revision of hip replacement, both acetabular and femoral components	Introduced 1 October 2005
00.71	Revision of hip replacement, acetabular component	Introduced 1 October 2005
00.72	Revision of hip replacement, femoral component	Introduced 1 October 2005
00.73	Revision of hip replacement, acetabular liner and/or femoral head only	Introduced 1 October 2005
00.74	Hip bearing surface, metal-on-polyethylene	Introduced 1 October 2005
00.75	Hip bearing surface, metal-on-metal	Introduced 1 October 2005
00.76	Hip bearing surface, ceramic-on-ceramic	Introduced 1 October 2005
00.77	Hip bearing surface, ceramic-on-polyethylene	Introduced 1 October 2006
00.80	Revision of knee replacement, total (all components)	Introduced 1 October 2005
00.81	Revision of knee replacement, tibial component	Introduced 1 October 2005
00.82	Revision of knee replacement, femoral component	Introduced 1 October 2005
00.83	Revision of knee replacement, patellar component	Introduced 1 October 2005
00.84	Revision of total knee replacement, tibial insert (liner)	Introduced 1 October 2005

6.601.3.3. Medicare

The 5% Medicare so-called Limited Data Set (LDS) is available from the Center for Medicare and Medicaid Services (CMS). The complete 5% dataset consists of seven components: hospital inpatient, hospital outpatient, home health agency, skilled nursing facility, hospice care, physician carrier (Part B), and durable medical equipment. A denominator file is also available that tracks the date of death or (more rarely) withdrawal by Medicare beneficiaries from the program. In the LDS, patients are uniquely identified by an encrypted Medicare beneficiary identification number that remains consistent across all parts of the database as well as over time. In this way, the utilization of healthcare resources by a patient can be tracked in different health care settings (i.e., both inpatient and outpatient), as well as in home hospice care, and during physician office visits.

6.601.4. Current Utilization of Total Joint Replacements

The number and prevalence of primary hip and knee replacement procedures have increased substantially in the United States between 1993 and 2006, most notably for primary TKA (Figure 2). The number of primary TKA and primary THA increased by 148% and 66%, respectively, during this period, corresponding to compound annual growth rates of 7.2% and 4.0%. The number of revision TKA and THA grew by 142% and 29%, respectively, with corresponding compound annual growth rates of 7.0% and 2.0%. Even after adjusting for population changes, the increase in procedure rates since 1993 was also evident, along with the slowdown in the prevalence of primary and revision THA and primary TKA between 2005 and 2006 (Figure 3).

To normalize the incidence of revision surgery, previous researchers from the Scandinavian registries have introduced the concept of a national revision burden, which is the ratio of revisions performed in a year to the total number of procedures (primary + revision). Using the 1993–2006 NIS dataset, the US mean revision burden of 16.2% (range 13.9–17.8%) for THA was approximately twice that for TKA (7.9%; range 7.3–8.4%; see Tables 3 and 4). The greater revision burden for THA compared to TKA is consistent with the relative revision burden in Canada which is 2.1 times greater than primary[6] and Finland which is 2.2 times greater.[7] The US mean revision burden for THA is also 65% greater than for TKA in Australia[8] and 78% greater than for Norway.[9]

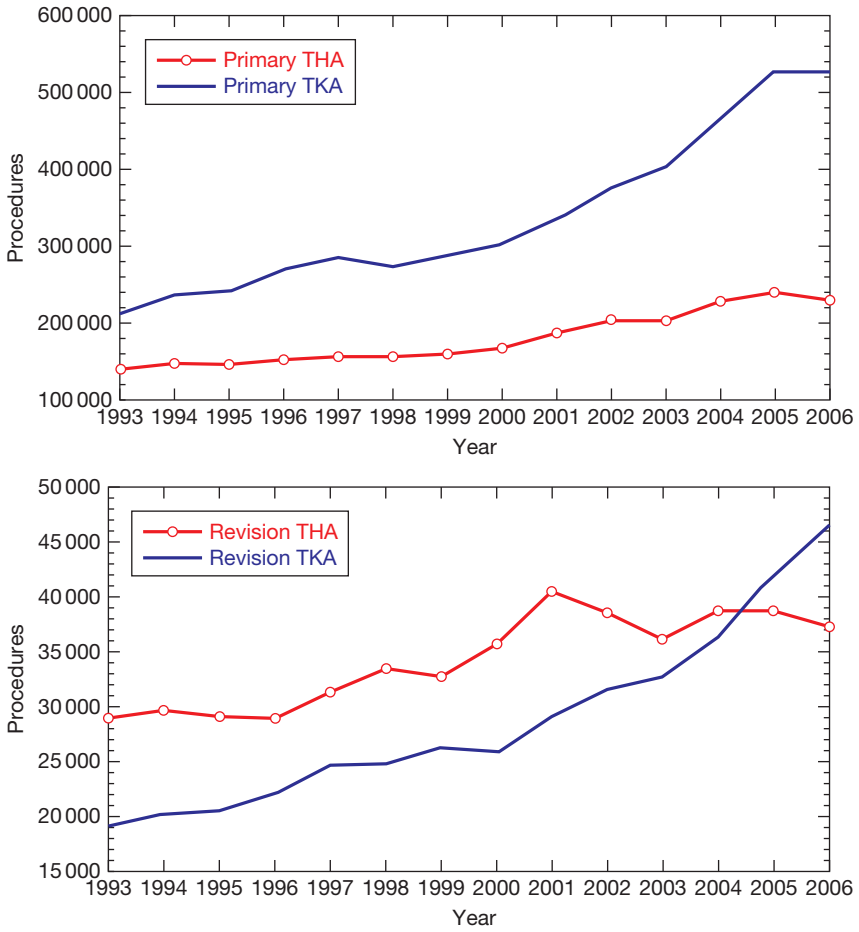

Figure 2 Annual number of primary (top panel) and revision (bottom panel) total hip arthroplasty and total knee arthroplasty in the United States. Note difference in *y*-axis scales.

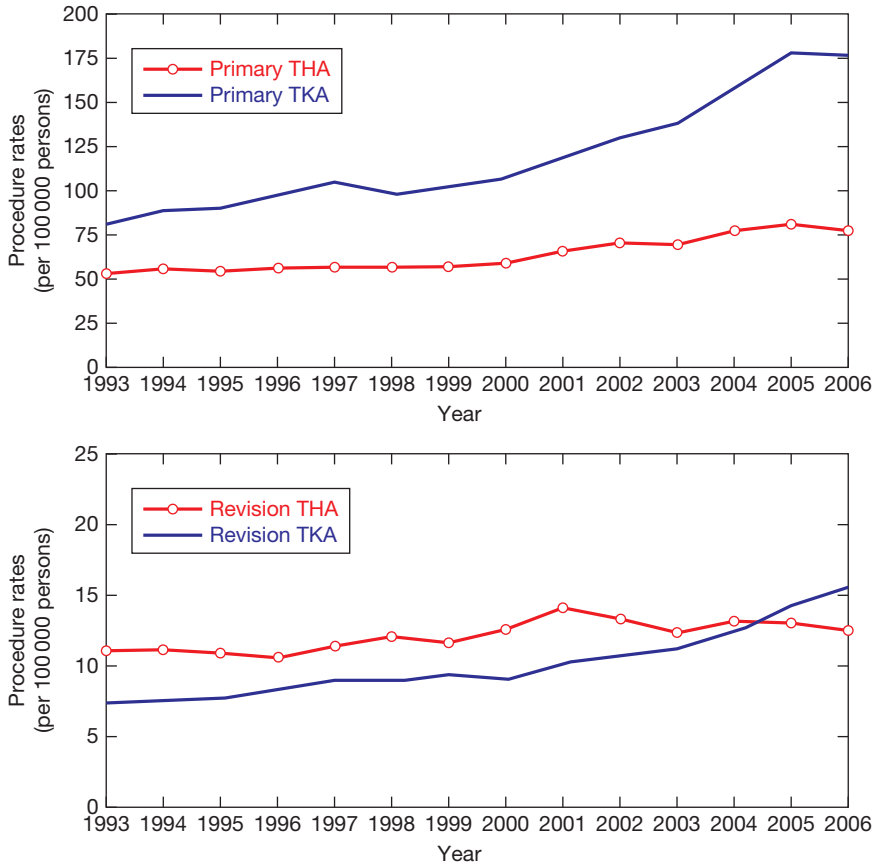

Figure 3 Annual incidence of primary (top panel) and revision (bottom panel) total hip arthroplasty and total knee arthroplasty in the United States per 100 000 persons.

Table 3 Mean revision burden for THA

Country	*Period*	*Revision burden (%)*	*Reference*
United States	1993–2006	16.2	Nationwide Inpatient Sample
Australia	2003–2007	15.7	Australian Orthopaedic Association – National Joint Replacement Registry
Canada	2002–2006	12.4	Canadian Institute for Health Information
Finland	1997–2006	17.3	National Agency for Medicines
Norway	1993–2007	14.6	The Norwegian Arthroplasty Register
Sweden	2003–2007	10.1	Swedish Hip Arthroplasty Register

Table 4 Mean revision burden for TKA

Country	*Period*	*Revision burden (%)*	*Source*
United States	1993–2006	7.9	Nationwide Inpatient Sample
Australia	2003–2007	9.5	Australian Orthopaedic Association – National Joint Replacement Registry
Canada	2002–2006	6.1	Canadian Institute for Health Information
Finland	1997–2006	7.9	National Agency for Medicine
Norway	1993–2007	8.2	Norwegian Arthroplasty Register
Sweden	1991–2003	4–7	Robertsson[5]

Overall, the THA revision burden in the United States is comparable to Australia[8] and Finland[7] (**Table 3**). Compared to the United States, the mean revision burden in Norway,[9] Canada,[6] and Sweden[10] are all lower. For TKA (**Table 4**), the US mean revision burden is comparable with the revision burdens of Norway[9] and Finland.[7] Compared to the United States, the knee revision burden is slightly lower in Canada[6] and in Sweden,[5] and slightly higher in Australia.[8]

In addition to revision procedures, the level of specificity in the ICD-9-CM codes makes it possible to perform national epidemiologic studies of postoperative complications in the US population. In a study by Kurtz *et al.*,[11] of periprosthetic infection between 1990 and 2004, the incidence of infection for both hip and knee arthroplasties in the United States nearly doubled from about 0.6% to 1.2%. The odds of infection increased annually at a rate of ~5% (odds ratio: 1.049; 95% confidence intervals (CI): 1.04–1.06). The length of stay (LOS) for infected TJAs was close to twice as long as for uninfected TJAs (2.21 times longer for THA, 95% CI: 2.18–2.23 times longer; and 1.87 times longer for TKA, 95% CI: 1.85–1.88 times longer) ($p < 0.0001$ for both). Furthermore, the ratio in LOS between infected and uninfected TJA has been on a widening trend between 1990 and 2004, with a rate of increase at 1.15% from year to year. The corresponding charge ratio for infected TJAs was also significantly greater ($p < 0.001$). This study highlighted an increasing trend of infected hip and knee arthroplasties in the United States. As demonstrated by the greater LOS and hospitalization charges/costs for infected TJA in this study and others,[12] the economic impact of deep infection is substantial. This infection research illustrates how administrative data from the NIS can be effectively used to quantify the national burden of specific total joint arthroplasty (TJA) complications, in addition to revision.

Recently, additional specificity provided in the ICD-9-CM procedure and diagnosis codes has greatly strengthened administrative databases as tools to examine national trends of TJA failure modes and revision strategies. In October 2005, based on a request from a group of orthopedic and health services researchers, the CMS and the NCHS implemented a series of changes to the ICD-9-CM diagnosis and procedure codes[13] (**Table 2**). These changes included new procedure codes that specify the THA bearing type, as well as new diagnosis and procedure codes to specify the cause of failure (e.g., dislocation, loosening, etc.) and type of component revised (e.g., acetabular component only, femoral component only, etc.) for revision THA. The availability of new bearing surface codes, revision diagnosis codes, and revision procedure codes provides an unprecedented opportunity to evaluate the comparative effectiveness of Total hip replacement (THR) bearing surfaces using administrative data.

Based on the new revision diagnosis and procedure codes, the epidemiology of revision THA was evaluated using the NIS database.[14] Based on a sample of 51 345 revision THA procedures spanning 1.25 years from October 2005 to December 2006, instability/dislocation was the most commonly reported cause of revision THA (22.5%), followed by mechanical loosening (19.7%) and infection (14.8%). All component revisions were most frequently reported (41.1%), followed by femoral component revision (13.2%), acetabular component revision (12.7%), isolated femoral head and acetabular liner exchange (12.6%), and arthrotomy (9.1%). Despite the increasing adoption of large diameter heads for THA over the recent years, this analysis indicated that dislocation remains the primary diagnosis reported for revision THA.

In summary, it can be seen that, based on data from administrative databases and national total joint registries, the current utilization of total joint replacements has been increasing over time. Despite the recognized success of these procedures, the number of revision procedures continues to increase for both THA and TKA. Minimizing revisions and complications continues to be a clinical concern and a major financial need.

6.601.5. Projected Utilization of Total Joint Replacements

Projections are important for guiding health care policy. In 2002, the American academy of orthopedic surgeons (AAOS) published projections of primary total hip and total knee replacement surgery through 2030, based on surgery rates calculated from the 1996 to 1999 hospitalization data from the NHDS and US Census projections for the next 30 years.[15] It is now clear that these projections by the AAOS underpredicted the expected utilization of primary TJA because the estimates of the surgery rates assumed a constant prevalence based on the average rate over the 4 years of the 1996–99 NHDS dataset and did not account for any year-to-year change in the rate itself. Thus, the projected growth in the number of hip and knee replacements in the AAOS model was fueled solely by the anticipated growth of the US population and was also limited to primary TJA without consideration for revision procedures. Since revision procedures place extensive additional demands on hospitals and surgeons and on medical costs, these should be considered in an analysis of projected future rates and population-based costs of arthroplasty procedures to the US health care system.

Motivated by the limitations in the prior projections, the authors used a much larger data source in the form of the NIS data, which has ~25 times more discharge records than the NHDS.[16,17] These projections[16] were based on 1990–2003 NIS data and the historical trajectory of surgery rates. They estimated the demand for primary THA to grow by 174%, from 208 600 in 2005 to 572 000 by 2030. The demand for primary TKA was also projected to grow more than sixfold, from 450 000 (95% prediction interval: 425 000–477 000) in 2005 to 3.48 million procedures (95% prediction interval: 2.95–4.14 million) by 2030. Revision TJA were also estimated to grow substantially from 40 800 to 96 700 for THA (an increase of 137%) and from 38 300 to 268 200 for TKA (an increase of 601%) between 2005 and 2030.

Following these initial projections, three additional years of NIS data (2004–2006) became available, allowing the comparison of previous projections with the recent NIS data, updating of the previous projections, and further demographic analysis of the projections. The previous projections[16] provided reasonably accurate estimates of the primary and revision TJA trends between 2004 and 2006,[17] particularly for revision TJA procedures, which were within the 95% CI of the previous projections. However, the previous projections underestimated the historical number of primary TJA procedures. Based on the additional 2004–2006 NIS data, the projections were reanalyzed, incorporating a 'variable rate' and a 'constant rate' approach to provide upper and lower prediction bounds, respectively. The 'variable rate' approach was consistent with the previous analysis, which allowed both the population and prevalence of surgery to vary over time. Conversely, the

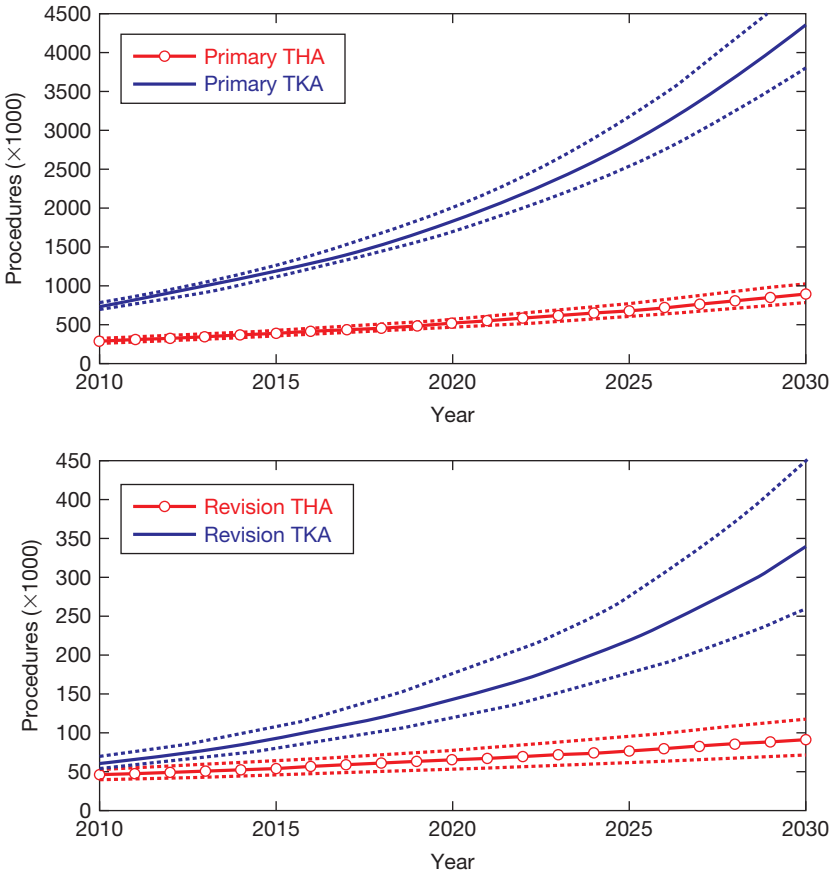

Figure 4 Projected annual demand for primary (top panel) and revision (bottom panel) total hip arthroplasty and total knee arthroplasty in the United States through the year 2030.

'constant rate' approach allowed the population to vary over time, but assumed that the future prevalence of surgery was constant, which was based on the average rate between 2004 and 2006.

Based on the updated projections,[17] the number of primary THA was predicted to increase from 229 900 procedures in 2006 to between 345 700 (constant rate) and 891 800 (variable rate) procedures in 2030 (Figure 4). Primary TKA was also predicted to increase from 524 600 procedures to between 792 200 (constant rate) and 4.34 million (variable rate) procedures over the same time period (Figure 4). Due to the relatively stable historical revision burden rates, the predicted demand for revision TJA is expected to be driven primarily by the increase in demand for primary procedures. Revision THA and TKA were projected to increase from 37 200 and 46 400 to 59 000 (constant rate)–91 400 (variable rate) and 64 600 (constant rate)–339 000 (variable rate), respectively, between 2006 and 2030. If the trajectory of surgery prevalence were to continue into the future, the demand for primary THA and TKA among younger patients, that is, patients <65 years old, will be projected to exceed 50% of all THA and TKA patients by 2011 and 2016, respectively. Younger patients will also be projected to exceed 50% of the revision TKA patient population by 2011. By 2030, the demand for TJA by younger patients aged <65 years will comprise 52% of primary THAs and 55–62% of primary or revision TKAs.

Based on the projected demand for primary and revision TJA, the corresponding economic impact in terms of hospitalization cost was also computed. By using the cost-to-charge ratio files provided in the NIS dataset to convert hospitalization charges to costs, the historical changes in average procedure costs were then projected for 2030. By combining the projected number of procedures and the projected costs for each procedure, the overall cost projections for primary and revision TJA were estimated. If the historical growth trajectory of procedure demand and costs continues, the overall cost for primary THA and TKA were projected to increase from $3.5 to $25.1 billion (95% CI: $14.9–40.4 billion) and from $7.0 to $92.9 billion (95% CI: $58.8–$144.6 billion), respectively (Figure 5). The economic burden for revision THA and TKA was also projected to increase from $712 million to $2.9 billion (95% CI: $1.1–$5.8 billion) and from $718 million to $13.9 billion (95% CI: $6.6–$27.1 billion), respectively.

6.601.6. Summary

In summary, the analyses of current and projected utilization for joint arthroplasty predict a massive anticipated demand for these procedures in the coming decades. However, the current economic and regulatory climate for health care

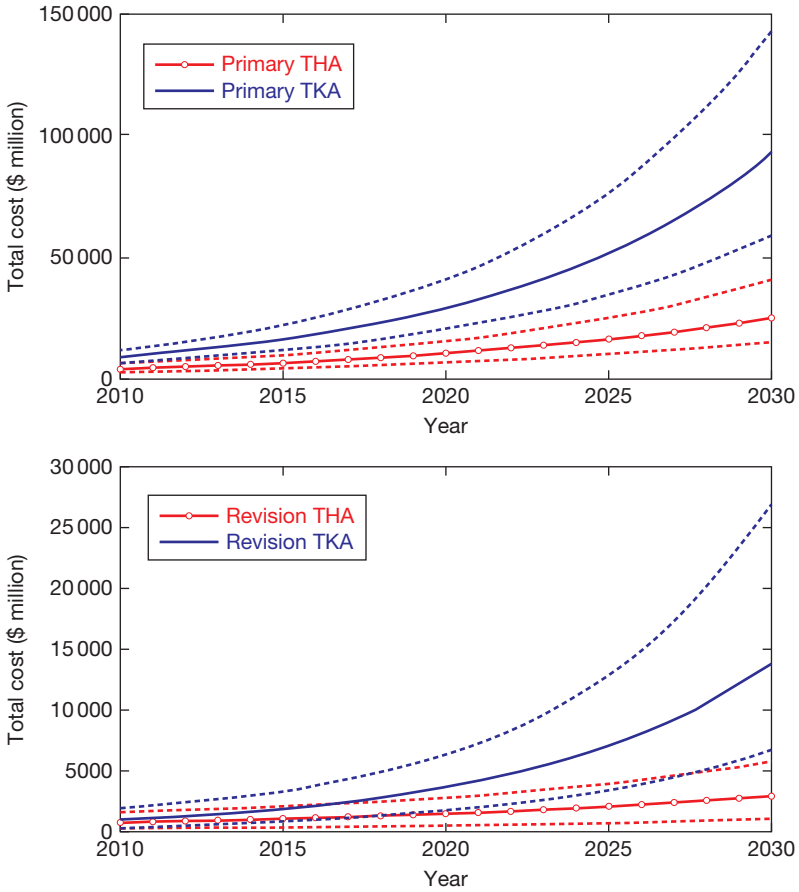

Figure 5 Projected annual cost of primary (top panel) and revision (bottom panel) total hip arthroplasty and total knee arthroplasty in the United States through the year 2030.

innovation is more challenging than ever before. New biomaterials for total joint replacement must be engineered to reduce widely recognized current complications such as loosening, dislocation, and infection for existing patient populations and to provide new functional capabilities to younger and more active patients. Technologies that only provide improved outcomes at 10+ years of service will require increased health economic justification. As scientists develop new biomaterials for the future joint replacement market, it is essential for commercial success that the studies to prove the cost effectiveness of these new technologies be designed and fully appreciated at the onset of the research and development phase in the product lifecycle.

Glossary

Arthroplasty Surgery to relieve pain and restore range of motion by realigning or reconstructing a joint.

Bone cement A substance commonly used to hold implants in bone.

Curing Toughening or hardening of a polymer material by cross-linking of polymer chains.

Initiator A substance that initiates a chemical reaction.

Monomer A molecule that can combine with others to form a polymer.

Radicals Atoms, molecules, or ions with unpaired electrons on an open shell configuration.

Abbreviations

ASTM	American Society for Testing and Materials
HA	Hydroxyapatite
LVC	Low viscosity cement
MMA	Methylmethacrylate
MW	Molecular weight
OR	Operating room
PMMA	Poly(methyl methacrylate)
SEM	Scanning electron microscopy
UCS	Ultimate compressive strength
UHMWPE	Ultrahigh molecular weight polyethylene
UTS	Ultimate tensile strength

Symbols

E_t	Tensile modulus of elasticity, or Young's modulus
G	Energy release rate
J	Energy release rate
J_{Ic}	Critical energy release rate
K	Stress intensity factor
K_c	Fracture toughness
K_{Ic}	Mode I (opening mode) fracture toughness
M_n	Number average molecular weight
M_v	Viscosity average molecular weight
M_w	Weight average molecular weight
N	Number of cycles
S, σ	Stress

6.602.1. Introduction

The advent of acrylic bone cement, adapting dental acrylics to fix artificial hip joints in human bone, is certainly a watershed moment in the history of modern biomaterials. Total joint replacement has become one of the most successful, cost-effective operations in all of surgery.[1] In *The Well-Cemented Total Hip Arthroplasty: Theory and Practice*, Malchau and Breusch[2] write

> [Cemented total hip arthroplasty (THA)] is a method – if performed well – which is highly successful, reproducible and cost effective … a well-performed cemented THA still remains the treatment of choice for the average patients with osteoarthritis of the hip over the age of 60–65 with average activity. Younger patients and those with high demand activity will have to accept a higher chance of earlier failure irrespective of the mode of fixation and choice of implant.

The collaboration between Dr. Dennis Smith and Sir John Charnley that resulted in the first cemented prostheses revolutionized orthopedic surgery by enabling a long-term fixation of the metal and plastic components used as a treatment for arthritis that was previously unachievable.[3] Bone cement has been the most common means of fixation of artificial joints DiMaio.[4] The successful implementation of long-lasting internal devices, made from nonbiological materials, for example, artificial hips, was one of the inspirations for succeeding generations of biomaterials scientists and engineers that opened the doors to the myriad devices and strategies to replace the function of human tissue and organs that the world of biomaterials now offers.

Bone cement is made from a common polymer – poly (methyl methacrylate) (PMMA) – that is sold commercially under names like Plexiglas®, Perspex®, and Lucite®. It is not expensive and is available in many preformed geometries (e.g., sheets and rods). The main difference between the Plexiglas® we buy at the local home improvement store and orthopedic PMMA (bone cement) is how the material achieves its final form. Commercial acrylic pieces are generally formed under heat and pressure, in controlled conditions, and are homogeneous. Bone cement is formed by mixing prepolymerized beads and a liquid methyl methacrylate (MMA) monomer (**Section 6.602.2**). The combination of the two components results in a viscous, doughy mass that cures to the point of mechanical stability in 7–10 min. The cured bone cement is responsible for maintaining the integrity of the fixation of the prosthesis and transferring stresses from one side of the joint to the other. Thus, it is one of a very small group of load-bearing materials that are created directly in their service environment, and must maintain mechanical integrity from that time. Concrete is another example of such a material. (We might consider adhesives in this group as well, as most adhesives – glues, epoxies, etc. – are also formed '*in situ*.' Adhesives, however, have the specific purpose to hold structural materials together; admittedly, they are load-bearing, but without the accompanying structural materials, adhesives would have no structural role. Concrete and bone cement are independent structural materials.)

6.602.2. Bone Cement Chemistry

Acrylic bone cement is a form of PMMA, with essentially the same chemical composition as the commonly used 'industrial' transparent acrylics, known by the trade names Plexiglas®, Lucite®, or Perspex®. Bone cement is formed by the bulk polymerization of a liquid methyl methacrylate monomer (MMA – the liquid phase) and PMMA, or MMA copolymer-based beads (the powder phase). The process begins the creation of free radicals from the liquid MMA, by an initiator that is added to the powder phase (usually, dibenzoyl peroxide) and an activator that is added to the liquid phase (usually, *N*,*N*-dimethyl-*p*-toluidine). When the powder and liquid are mixed together, the initiator and activator react to form free radicals (eqn [I]), which then link to the MMA (eqn [II]), and generate polymer chains from the MMA (eqn [III]):

$$\mathrm{PMMA(C_6H_5COO{-}OOC_6H_5)} \rightarrow 2\mathrm{C_6H_5\text{-}(R^*)} + 2\mathrm{CO_2} \quad [\mathrm{I}]$$

$$R^* + \mathrm{MMA\,(CH_2{=}CCH_3)} \rightarrow R\text{-}\mathrm{MMA}^* + \mathrm{Heat} \quad [\mathrm{II}]$$

$$R\text{-}\mathrm{MMA}^* \rightarrow R\text{-}\mathrm{MMA\text{-}MMA}^* + \mathrm{Heat} \quad [\mathrm{III}]$$

where R^* is the free radical from the initiator. The polymerization reaction is exothermic, and the heat generated, and subsequent peak temperatures, depend on the cement composition, the cement mass, and the starting temperature of the components.[5–7] For additional details on the polymerization chemistry of bone cement, see Kuhn,[8] Lautenschlager *et al.*,[6] and Park.[5]

It is important to note that the polymerization of bone cement is really the polymerization of the liquid phase (MMA), which creates a solid matrix that binds the beads of the powder phase.[9,10] Often, an inorganic material is added to render the cured bone cement radiopaque, generally, $BaSO_4$ or ZrO_2. The radiopacifier is a component of the initial powder phase and also becomes embedded in the polymerized liquid. Air bubbles or voids may also form during the polymerization process, and thus, fully cured bone cement often consists of four distinct material phases: two polymer phases (prepolymerized beads and the polymerized monomer), the

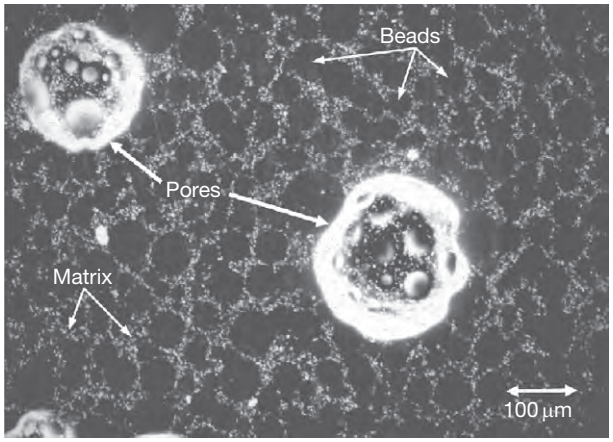

Figure 1 A polished cross-section of cured poly(methyl methacrylate) bone cement. The four major phases are present: Beads – which are from the original polymer powder, pores, polymerized monomer, and radiopacifier, in this case, $BaSO_4$. The polymerized monomer and radiopacifier are both contained in the matrix. The radiopacifier appears as tiny white specks that surround the dark circular cross-sections of the beads. The spherical beads are also seen lining the surfaces of the pores. Adapted from Topoleski, L. D. T.; Ducheyne, P.; Cuckler, J. M. *Biomaterials* **1993**, *14*(15), 1165–1172, used with permission.

radiopacifier, and voids (Figure 1). The mechanical and failure behavior of bone cement is likely to depend on the distribution and interaction of the phases within the bone cement mass.

The flow properties of bone cement change as the curing process progresses. Once the monomer has fully wetted the powder, the cement is in a predough stage and is in the least viscous state of curing. In the predough stage, the cement will stick to surgical gloves. The bone cement transforms into a nonsticky dough phase, as the surface monomer evaporates or polymerizes, and finally sets. Depending on initial temperature, bone cement may become solid in 7–12 min.[7] A user can control, to some extent, the length of the 'working time,' that is, time before the cement has hardened, by controlling the initial temperatures of the components (e.g., by storing them in a freezer or refrigerator). The fact that the bone cement has solidified, however, does not mean that the polymerization process is complete. Additional polymerization may continue for several weeks, and even then, not all of the monomers would have been converted.[11–16]

6.602.3. Bone Cement Applications

6.602.3.1. Bone Cement in Surgery

Bone cement is generally mixed in the operating room on an 'as needed' basis. Because the curing time is fast, the bone cement is usually not prepared until the whole surgery needed to permanently place a component of an artificial joint has been completed. The techniques used to introduce the bone cement into the bone depend on the location or component that is to be fixed, and the surgeon's preference and experience. The presence of voids, mentioned earlier, for example (Figure 1), was shown to reduce the fracture resistance of bone cement.[17,18] Therefore, most bone cement is subjected to a mixing environment that reduces the porosity. Initially, this was accomplished by centrifuging the liquid cement to separate the air from the polymer.[17] Mixing the cement in a bowl designed to create a vacuum proved to be a more favorable option;[18] it does not require transfer of the cement, the process takes place during mixing, not separately, thus giving the surgeon more time to work with the material, and eliminates the need for a centrifuge in the operating room (OR) (Figure 2).

Currently, to reduce porosity, most bone cement is mixed using various vacuum mixing systems. Many of the vacuum mixing systems are designed to release the mixed cement into a cartridge, which is then placed in what is essentially a caulking gun. If the cement is to be placed in a femur to fix the femoral component of an artificial hip joint, for example, the cement can be injected into the femoral canal. (This is generally done in a 'retrograde' fashion. The nozzle of the cement gun is placed into the distal or far end of the femoral canal, and the gun is withdrawn as the cement is injected distally to proximally.) The surgeon may opt to 'hand pack' the cement, as in the case of a tibial component of an artificial knee. In this case, the cement can be ejected from the cement gun onto the surgeon's hand and manipulated into the appropriate site. The state of the bone cement (predough, dough, etc.) when applied to the bone depends on the site of use, surgeon's preference, etc.

Once the cement is in place, the surgeon has a limited time to insert the device into the bone cement and ensure that the device is correctly placed and aligned. Although the time may be short, the surgeon must also ensure that the device does not move once it is in place, and must maintain a stable position until the bone cement is fully cured. The time from when the components of the bone cement are mixed until it is not possible to further manipulate either the prosthesis or bone cement is sometimes called the 'working time.' Once the cement has cured, its job is primarily structural – to hold the device in place permanently and facilitate load transfer from the device into the remaining bone. Bone cement fracture and/or loosening of the device within the cement mantle can lead to failure of the artificial joint and require a revision surgery. Thus, we discuss the mechanical properties of bone cement in detail in this chapter.

Radiographic examinations of patients with loosened prostheses may reveal a radiolucent line in the bulk of the cement, indicating that the cement has fractured. In the 15-year follow-up study by Kavanagh *et al.*,[19] cement fracture was identified as the 'most frequent mode of failure.' There are examples where cement fracture was indicated on a radiograph, yet the patient retained function of the prosthesis for over 3 years. A subsequent examination revealed that the extent of the cement fracture had escalated, the prosthesis had loosened, and revision surgery was necessary (Figure 3).[20]

The long-term success of a total joint prosthesis depends on the continued function of, and interaction between, each of the components comprising the prosthetic system. In a cemented total hip prosthesis, for instance, stress transfer from the pelvis to the femur is a function of the materials between the two bones (bone–PMMA–metal–UHMWPE–metal–PMMA–bone) and the interfaces between the materials. PMMA exhibits the lowest fracture toughness and ultimate tensile strength (UTS) of the materials.[21,22] (UHMWPE (ultra-high molecular

Figure 2 Elements of commercially available bone cement. Left: cement in the packaging, a case and single dose. Figure 3 A set of radiographs of the same artificial hip joint taken ~3 years apart. (a) Fractures in the poly(methyl methacrylate) bone cement are evident (f), but at this point are not symptomatic. (b) The same patient 3 years later, where the progression of the fractures is evident. Bone cement fragments are penetrating the bone. Following this radiograph, the artificial hip was revised. Adapted from Topoleski, L. D. T.; Ducheyne, P.; Cuckler, J. M. *J. Biomed. Mater. Res.* **1990**, *24*, 135–154, used with permission.

weight polyethylene) is used as a low friction articulating surface, generally to prevent metal from articulating on metal, for example, as part of the acetabular component of a total hip prosthesis, or the tibial component of a total knee prosthesis.)

The relationship between interfacial integrity (stem/PMMA or bone/PMMA) and cement fracture is not well understood.[23] It has been postulated that maintaining the load-bearing capabilities of the metal stem–PMMA interface is critical to preventing fracture of the bone cement mantle,[24] or conversely, that the irregularity of the bone–PMMA interface is responsible for cracking of the bone cement.[25] The initiation of *in vivo* bone cement fractures remains an important topic of fundamental interest in orthopedic biomaterials.

Although we are concerned in this chapter with the use of bone cement, it is valuable to briefly discuss alternative means of fixation (which are discussed in more detail elsewhere in this text). As bone cement has been called the 'weak link' in artificial joint fixation, methods to fix joint components without cement have been used for some time.[26] Porous coatings on device surfaces provide a scaffold for bone to grow into the coatings and create a biological fixation, sometimes referred to as 'bone ingrowth.' Hence, not all artificial joints use bone cement fixation. Artificial joints may rely solely on bone ingrowth, may have some components cemented and others that are fixed by ingrowth, or may be completely cemented. The fixation method(s) may depend on the health of the patient's bones, the type of device implanted, and the surgeon's background and preferences. Therefore, we must recognize that not all artificial joints make use of cemented fixation.

6.602.3.2. Potential Adverse Effects of Bone Cement

There are a number of possible adverse effects from bone cement exposure, and the patient, the clinician, and the laboratory researcher working with bone cement are potentially susceptible. For example, methylmethacrylate exposure can cause skin reactions.[4] Surgical gloves do not protect the skin from MMA; in fact, MMA apparently easily penetrates the gloves.[27] When bone cement is delivered to the bone, there are potential thermal and chemical effects on the

contacting tissue.[28,29] The heat of the polymerizing bone cement, along with the release of MMA, may affect the tissue contacting the bone cement. There have been several reports of toxic effects from the MMA in humans and animals.[29–34]

Methylmethacrylate monomer may be released from the polymerizing cement into the surrounding tissues during mixing, manipulation, insertion, and curing of the bone cement.[28,29,35] The monomer release depends on the available monomer, which, in turn, depends on the polymerization rate.[5] For a given polymerization rate, the monomer release depends on the surface area of the cement mass. The cement mantle thickness does not affect the monomer release.[29] The adverse effects usually occur during or shortly after polymerization and, presumably, result from the availability of a relatively large amount of free monomer available before the reaction is completed.[15] The monomer may cause peripheral vasodilatation and hypotension when directly absorbed into the circulation.[35]

McLaughlin *et al.*[34] studied the mechanisms of MMA clearance from blood in dogs when the monomer was introduced by both simulated hip procedures or injection. They discovered that the monomer was almost completely cleared from the blood in <20 min. A measureable physiologic effect occurred only when the MMA exposure was between 30 and 40 times the amount available during total hip replacement. No foreign material was visible in the lungs of dogs receiving a low dose of injected monomer; dogs that received higher doses showed signs of pulmonary edema. The liver and spleen showed no evidence of monomer damage. Although monomer quantities released during surgery appear to be much lower than dangerous doses, reducing the amount of monomer released into a patient would seem to be advantageous in the long run.

6.602.3.3. Bone Cement as an Antibiotic Delivery System

One of the great advances in the application of biomaterials has been the use of materials, especially polymers, as drug delivery systems. Because total hip arthroplasties are susceptible to infection, one avenue to provide sustained delivery of antibiotics at the internal site of the operation is via the bone cement. Antibiotic-impregnated bone cement (also referred to as antibiotic-loaded bone cement) releases the antibiotic agent(s) into the surrounding tissue. There is some controversy as to the most effective use of antibiotic-loaded bone cement.[4,36–39] Furnes *et al.*[40] state that antibiotics in the bone cement give an added protection against infection over conventional antibiotic regimens. In revisions due to infection, for example, Gehrke[41] advocates the use of antibiotic-loaded bone cement.

Different investigators reached different conclusions on the effect of antibiotic loading on the mechanical properties of bone cement. One pivotal factor in how antibiotics may affect mechanical properties is how the antibiotic is mixed into the cement.[42] There are commercially available cements with the antibiotics premixed by the manufacturer; conversely, the antibiotic may be added and mixed during the cement preparation. Frommelt and Kühn[43] suggest that only the premixed cements retain appropriate mechanical properties. DeLuise and Scott[42] found that hand-mixing the antibiotic decreased the strength of the bone cement. In contrast, Lewis *et al.*[44] tested several mechanical properties of antibiotic-loaded bone cements mixed during preparation, and found no difference attributed to mixing method. Lewis and Bhattaram[45] examined the mechanical properties of three commercially available bone cements, available from the manufacturers both with and without antibiotics. They found that the addition of antibiotics did not affect the properties measured. Askew *et al.*[46] found no differences in bending modulus because of antibiotics, and also found that, after vacuum mixing, the antibiotics increased the porosity of the cement. Leone *et al.*[47] found that the reduction or increase in modulus depended on the type of antibiotic. Lewis[48] presents an excellent review of the literature on antibiotic-loaded bone cement, including compositions of commercially available cements and modeling of the elution kinetics, as well as details on the effect of antibiotic additives on the mechanical properties.

6.602.4. Mechanical Properties of PMMA–Bone Cement

6.602.4.1. Overview

The main function of bone cement is to transfer body weight under various service conditions (walking, standing, stair climbing, etc.) from the prosthesis to the bone. Therefore, the mechanical properties of bone cement will determine its success as a sold, structural material. In addition, as mentioned previously, bone cement is formed *in situ*, and its function will also depend on the properties when bone cement is in its nonsolid phase. The properties of bone cement in both its nonsolid and solid phases have enabled bone cement to perform its function admirably.[49]

6.602.4.2. Properties in the Nonsolid Phase

6.602.4.2.1. Viscosity

Polymerizing bone cement is a non-Newtonian fluid, which means that the viscosity is not constant as a function of time and shear rate. Viscosity cannot be determined independent of test method, and thus, for non-Newtonian fluids, the property 'viscosity' has no meaning. Viscosity calculations applied to fluids such as bone cement result in values termed the 'false-apparent viscosity' or 'apparent viscosity.' Because bone cement generally solidifies in about 10 min or less, apparent viscosity values depend on time, mass (volume), and test fixture geometry.[7,50]

Lewis[49] describes the 'ideal' bone cement as having a low and consistent value of apparent viscosity during the working time and, once the prosthesis was in its final location, polymerizes in a very short time. He provides a 'rule of thumb' that at 3 min after mixing, η should be $<100\ \text{Pa s}^{-1}$. Different cement formulations will achieve this viscosity at different strain rates.[49] Compositional factors that can influence the flow behavior of bone cements include the liquid monomer to powder ratio, the size of the solid polymer beads, the amount of radiopacifier, the amounts of initiator and accelerator, etc.[5,6]

The flow properties of bone cement can also be controlled to some extent by controlling the initial temperatures of the components before mixing. In general, chilling either or both the liquid and powder phase will lower the initial apparent viscosity and increase the working time[7] (**Figure 4**).

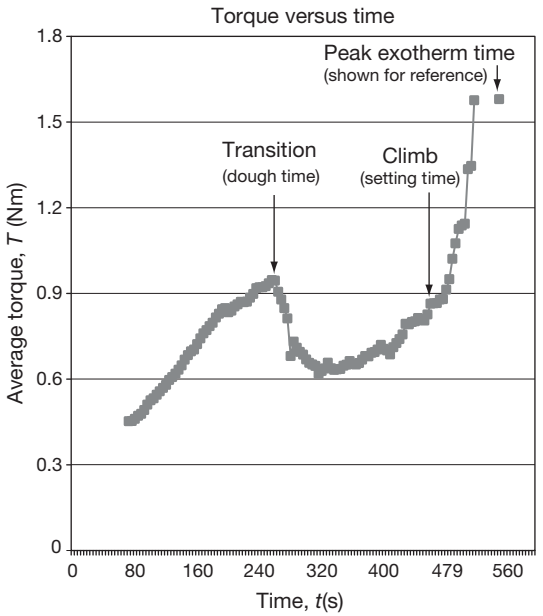

Figure 4 Torque versus time graph for curing poly(methyl methacrylate) (PMMA) bone cement. In this test, the torque resistance represents the changing viscous state of the curing bone cement. A relatively linear increase in resistance from the onset of testing (~80 s after mixing) reaches a peak at the Transition point, marking the onset of the dough phase. The torque values decrease because the material adheres less and less to the test chamber walls during the dough phase. The torque then increases again as the material starts to set. The point marked Climb indicates that the PMMA is completely set (the Setting Time) and the rapid torque increase occurs as the cement becomes solid. The setting time as determined by the peak exotherm temperature is shown for reference. From Sullivan, S. J.; Topoleski, L. D. T. *J. Biomed. Mater. Res. B Appl. Biomater.* **2007**, *81*(1), 224–230, used with permission.

6.602.4.3. Structure of Solid Bone Cement

6.602.4.3.1. Overall composition

The final solid bone cement generally consists of four distinct phases (if the cement is radiopaque): (1) The prepolymerized beads (from the powder component), (2) the polymer matrix (from the polymerization of the liquid MMA), (3) the radiopacifier, and (4) porosity (Figure 1). Pores may not be a material phase in the thermodynamic sense, but as a microstructural element, they contribute to the mechanical behavior of bone cement, and the designation 'phase' will be extended here to include porosity in bone cement. The relative amounts of each phase, and their distributions, will affect the properties of the bone cement.

6.602.4.3.2. Molecular weight

The molecular weight (MW) of a polymer can have a significant effect on its mechanical properties.[51–53] The two polymer phases of bone cement are polymerized under drastically different conditions – the prepolymerized beads are created under controlled factory conditions, and the matrix polymerizes within the bone. There is no reason to believe *a priori* that the MW or molecular chain entanglement of the two polymers is the same.

Lautenschlager *et al.*[6] reported several determinations of average MWs for bone cement: a number average (M_n) of $4.5–5.1 \times 10^3$ and a weight average (M_w) of 2.42×10^5 for cured bone cement. The number average for the powder (prepolymerized bead component) alone was $3.21–4.40 \times 10^4$. There was an apparent increase in the average MW during curing. This implies that the interbead matrix has a higher average MW than the prepolymerized beads. The result is unexpected as the polymerization of the matrix occurs through a 'run away' reaction, where an overabundance of initiator is added to the MMA (the initiator is mixed in with the powder). Many PMMA chains are initiated and they grow. For a fixed quantity of monomer, higher MWs are generally achieved by decreasing the number of polymer initiation sites. By saturating the monomer with initiators, the average MW is expected to stay low. Apparently, the interbead matrix manages to polymerize with a high average MW. It is possible that the interbead matrix polymer chains could raise the average MW, and yet not contribute extremely long chain polymers (MW of 1000 000 or greater) to the bulk polymer.[54] No attempt has been made to characterize the influence of the MW of each of the two polymer components on the fracture characteristics of bone cement.

In their discussion on the polymerization of bone cement, Lautenschlager *et al.*[6] noted:

> A most (desirable) feature in the context of set cement strength is a nearly complete interpenetration (entanglement) of preformed and newly formed chains after powder and liquid components are mixed. Boundaries of poor molecular interpenetration, created by the specific course of chemical events, are not necessarily visible in electron micrographs of set cement. Such defects can occur not only at undissolved bead/matrix interfaces, but also within what a typical scanning electron micrograph reveals as matrix material. The importance of weak molecular boundaries in the mass of the cement is their possible role in inducing localized microfractures.

Little is known about how the interaction between the two polymer phases affects the overall performance of bone cement, which would seem most relevant in the fracture properties. Numerous studies of fracture surfaces report observing bead 'pull-out' from the matrix polymer.[55,56] However, studies have shown that a decrease in MW in the beads (as the result of γ-irradiation) can lead to a decrease in the fracture resistance.[57] Other studies indicate that differences in MW can lead to differences in creep behavior.[58,59]

6.602.4.3.3. Porosity

We can roughly distinguish the types of pores found in fully polymerized bone cement as macropores (with a pore diameter >1 mm) or micropores (with a pore diameter <1 mm).[60] The pores may initiate, for example, from air initially adsorbed on powder constituents, including the radioopacifier, air trapped during mixing of the bone cement, evaporation of unreacted liquid monomer, and polymerization shrinkage.[12,20,49,56,61,62]

Centrifugation or vacuum mixing leads to a substantial reduction in porosity.[17,18] Centrifugation separates the air bubbles from the cement mass because of the different densities of the bubbles versus the cement material, and vacuum mixing eliminates or reduces the gasses in the cement environment by maintaining a vacuum. The amount of porosity

remaining in the solid cement mass depends on the mixing method and the initial temperature of the liquid monomer prior to mixing.[49]

The presence of pores in the cement may have an effect on the integrity of the cement mantle and hence on the life of the arthroplasty. The role of porosity in cement has been studied from different aspects, from reports of no effect on fracture toughness from reduced porosity,[25] to an optimum porosity content for fracture toughness,[63] to increased fatigue life in pore-reduced cements.[10,17,64,65]

From a mechanics point of view, spherical pores act to increase the local stresses by a factor of about 2.[66] Thus, pores may become initiation sites for fractures, and it follows that reducing porosity would reduce the likelihood of bone cement fracture. It is also possible that pores may play a role in blunting or diverting propagating cracks, thereby prolonging the life of the cement mantle by forming a larger damage zone and thus dispersing energy localized at the crack tip. Wang and Pilliar[63] indicated, based on maximizing the fracture toughness and plasticity effects, that an optimum pore density for bone cement could be defined; that is, there may be an effect of porosity on the fracture toughness of aged bone cement that is related to plasticizing effects of the aqueous aging. Topoleski *et al.*[20] showed that the porosity within the bone cement mass can interact with the propagating crack, but the link between the fracture mechanisms in bone cement and porosity has not yet been determined. Nonetheless, the current consensus is that the life of the cemented artificial joint will be extended by substantially reducing porosity.[49]

6.602.4.3.4. Radiopacifiers

Acrylic bone cements are invisible on radiographs, and hence, a radiopaque material is added to render the bone cement visible. Bone cements with radiopaque additives are termed radiopaque, and bone cements without such additives are termed radiolucent.

There are two commonly used radiopacifiers in commercial bone cement, $BaSO_4$ and ZrO_2. In general, $BaSO_4$ particles are roughly egg-shaped, ~1 μm or less in size. In contrast, ZrO_2 particles are larger and resemble cauliflower heads. In Charnley's[3] original paper introducing bone cement, he suggested using ~25% by weight $BaSO_4$ as a contrast agent. Currently, bone cements for total joint arthroplasty contain 10–15% by weight of either $BaSO_4$ or ZrO_2. More recently, applications of bone cements in spinal corrective surgery, such as kyphoplasty or vertebroplasty, use bone cements with up to 30% $BaSO_4$.[67–69]

Early studies on the effect of $BaSO_4$ addition on fracture toughness were inconsistent.[70] Beaumont[61] and Sih and Berman[71] attributed a decrease in bone cement fracture toughness to the addition of $BaSO_4$. Both Beaumont[61] and Wright and Robinson[56] indicated that $BaSO_4$ may act as a void initiator and therefore reduce the fracture performance of bone cement. Figure 5 illustrates voids that apparently nucleated around $BaSO_4$ particles.[20]

Barium sulfate is found in the interbead matrix phase of bone cement only, thus as much as one-sixth of the total matrix weight is $BaSO_4$. If $BaSO_4$ particles are essentially equivalent to pores, then the 'microporosity' of the PMMA matrix could be substantial, and may thus lead to reduced fracture toughness.

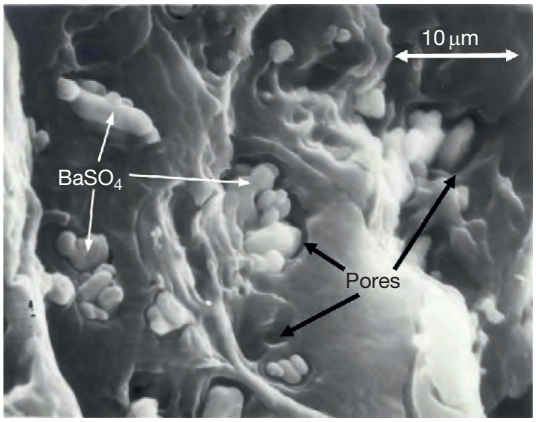

Figure 5 Scanning electron micrograph of a section from a fracture surface of cured PMMA bone cement. $BaSO_4$ particles, on the order of 1μm are not embedded in the polymer matrix, but rather appear to sit inside small pores. Adapted from Topoleski, L. D. T.; Ducheyne, P.; Cuckler, J. M. *J. Biomed. Mater. Res.* **1990**, *24*, 135–154, used with permission.

It is interesting that in one of the few studies to address the effect of testing environment on the fracture toughness of bone cement, Freitag and Cannon[70] noted an increase in fracture toughness for specimens tested in bovine serum, in contrast to specimens tested in air. The increase occurred only for bone cement containing $BaSO_4$. For bone cement without $BaSO_4$, fracture toughness was the same in both environments.

As the radiopacifier is added to the bone cement in the powder phase and ends up in the interbead matrix polymer, the distribution of the particles will depend on the mixing technique and the propensity for the particles to either disperse or to agglomerate. The radiopacifier will thus affect any mechanical processes that are influenced by the interbead matrix, especially fracture. Agglomerations of poorly dispersed $BaSO_4$ may reduce the fracture resistance of the bone cement by acting as crack initiation sites.[72] Molino and Topoleski[73] showed that $BaSO_4$ decreased fatigue crack velocity by creating a more favorable and longer crack propagation path through the interbead matrix polymer, resulting in longer fatigue lifetimes than in radiolucent cements of the same composition. Alternative methods to render bone cement radiopaque, such as reducing the size of the radiopaque particles,[74] may further allow researchers to improve the mechanical properties of cement while retaining the essential radiographic properties.

6.602.4.4. Properties in the Solid Phase

6.602.4.4.1. Overview

An artificial joint is subjected to a complex loading environment, and the ability of the bone cement to transfer loads from the prosthesis to the bone depends on the static or quasistatic responses to those loads. Similar to designing a bridge, the artificial joint system can best be designed when the mechanical properties of the constituents are well known and controlled. Bone cement generally behaves as a linear elastic material and tends to exhibit brittle fracture characteristics. Many of the common mechanical properties of bone cement have been determined for various conditions. Static or

quasistatic properties of materials are generally determined from the results of stress–strain tests. (Strictly speaking, most such mechanical tests measure load, or applied force, and deflection, or change in length. Stress and strain are calculated from the load and deflection data.) For a linear elastic material, the slope of the elastic portion of a stress–strain curve, whether the material is under compression, tension, or shear, is called the elastic modulus or Young's modulus. The highest stress the material attains before failure is called the ultimate stress. Note that the ultimate stress is not the fracture toughness, discussed below. Static compressive, tensile, and shear properties are generally obtained on regularly shaped specimens (cylinders, dog bones, etc.), using standard mechanics methods. There are at least two particularly valuable summaries of the mechanical properties of bone cement, those by Lewis[49] and Saha and Pal.[21,22] These excellent summaries lead to the same conclusion – that the reported properties of bone cement depend on how those properties were measured, from the formulation and mixing of the cement to the creation of test specimens and to the physical testing parameters. In a recent paper, Nottrott[75] showed that the environment in which test specimens were aged could have a significant effect on properties over the course of several years. Therefore, in comparing the results from different studies, we must take the testing procedures under consideration.

6.602.4.4.2. Static compressive properties

The values of the ultimate compressive strength (UCS) and Young's modulus (or modulus of elasticity, E_c) depend on the type of cement, and mixing, curing, and storage or aging conditions. The UCS values vary from 72.6 to 117.0 MPa and E_c varies from 1940 to 3180 MPa, as summarized in Lewis.[49] As the stress distribution in a cemented artificial joint depends, at least in part, on the properties of the constituent materials, the wide variations in UCS and E_c (over 60%) imply that the stress distribution in an artificial joint will depend on how the bone cement is created.

For a given mixing method, the bone cement formulation has the greatest influence on the results. As Lewis[49] states:

> The key parameters are: the quantities of stabilizers, initiators, and radiopacifiers; the presence or absence of a copolymer; the powder size and distribution; the ratio of bead to milled prepolymerized particles; and the rate of change of viscosity with time.

Lewis[49] also postulates that, for a given brand of cement, the mixing method has an important influence on the mechanical properties through its effect on the porosity. Clearly, the more porous the cement, the lower the density, and while the UCS increases with decreasing porosity, there is no clear relationship with compressive modulus.

6.602.4.4.3. Static tensile properties

Artificial knees and hips are subjected to compressive forces that arise from maintaining body weight in a variety of activities. At first glance, it would appear that no tensile stresses are obvious in an artificial joint system. Tensile stresses arise, for example, from bending forces, and also from the effects of local geometry (e.g., the irregular bone surface). As with the compressive properties, the values of the UTS and tensile modulus of elasticity (E_t) depend on the type of bone cement, the mixing and handling conditions, and the test procedures.

For a given cement type, whether or not the cement was mixed using a pore reduction method (centrifugation or vacuum mixing) was significant, with the UTS increasing as porosity decreased. UTS values vary from 23.6 to 49.2 MPa and E_t varies from 1583 to 4120 MPa, again as summarized in Lewis.[49] The variation in UTS is over 100%, and the variation in E_t is over 160%. The strain to failure ($\varepsilon_{max,t}$) ranged from 0.86 to 2.49, a change of 190%. The wide range of reported values again indicates that, because of variations in cement parameters, the stress distribution in an artificial joint system may be highly variable.

6.602.4.4.4. Shear strength

Shear strength of bone cement has not received as much attention as other properties. A summary of the results presented in Lewis[49] shows that the ultimate shear stress values range from 32 to 69 MPa, and are, as other static properties, influenced by cement type and preparation and testing parameters. Funk and Litsky[76] showed that the cement's shear modulus can have an effect of the shear stresses at the cement–bone interfaces, which will have a pivotal role in stress transfer to the bone, and thus, for example, bone remodeling.

6.602.4.4.5. Creep

Creep, and the related phenomenon of stress relaxation, are the results of the viscoelastic response of materials under either a prolonged load or deformation. Creep of a material can lead to a permanently altered geometry, and hence an altered stress environment. PMMA–bone cement, as an amorphous polymer, exhibits measurable creep, and its viscoelastic behavior will affect the overall structural behavior in an artificial joint system.[77]

Several studies have observed the creep behavior of bone cement both with static and dynamic loads. The creep of bone cement depends on the type of cement, preparation procedures, environment, and the testing conditions, including stress level and test type (i.e., static or dynamic, compressive of tensile).[77–79] A higher stress level will result in a higher creep rate, as will a higher temperature. Verdonschot and Huiskes[78] showed that bone cement creeps more readily under tensile loading than under compressive loading. Additional phases or additives may reduce the creep behavior of bone cement by effectively dividing the cement mass into smaller continuous segments. Both Pal and Saha[80] and Chwirut[77] showed that carbon-reinforced cement exhibits less creep deformation than nonreinforced cements.

Some researchers believe that some amount of creep may be beneficial to the implant, although an optimum creep level has not been established. Bone cement creep can result in subsidence of a femoral stem, effectively wedging the stem into the cement, and also reduce stress peaks in the cement mantle.[78,81,82] At some point, creep is no longer beneficial to the implant and may cause fracture of the cement mantle from excessive plastic deformation, which may result from microcracking around the pores.[77] Different cement parameters, such as the amount of porosity or residual monomer, the bead size in the powder phase, or cement formulation (such as adding an MMA-styrene copolymer or cross-linking agents)

can affect the creep of PMMA, as can test conditions, like temperature. For example, reducing porosity or increasing the bead size can increase creep resistance.[59,75,77,81,83,84]

6.602.4.4.6. Fracture toughness

The previous discussion of bone cement properties has addressed how the mechanical strength (UTS, UCS) is influenced by the environment, microstructure, and the method of curing. Stiffness or strength considerations, however, are not the only important factors in the bone–bone cement-prosthesis system. The ability of a material to resist crack growth requires the study of fracture mechanics.[71]

Although bone cement *in vivo* is subjected to a fatigue loading environment, the principles that govern static fracture, or the fracture toughness, of a material can be used to gain insight into the fatigue behavior. Thus, while improving the fracture toughness of bone cement may not directly translate to an improved fatigue resistance, studying the fracture mechanisms and material behavior during fracture toughness tests can guide future fatigue studies. In addition, the same fracture mechanics considerations that are used to predict and describe static fracture also apply to fatigue.

Two properties are generally used to describe the fracture resistance of a material: the energy release rate, G, and stress intensity factor, K. The energy release rate takes into account the energy involved in crack propagation and can be obtained from the work done on a cracked specimen. The stress intensity factor describes how the stress field is modified near the crack tip. The value of K is a function of the nominal stress, σ, and also the crack length, a. The general equation that describes the stress intensity factor is

$$K = Y\sigma\sqrt{a} \qquad [1]$$

where Y is a function of the crack size and geometry of the specimen. The equation states that the larger the flaw, or current crack length, the lower the stress needed to cause fracture. The value of the stress intensity factor at fracture is called the critical stress intensity factor, or fracture toughness, K_c. The fracture toughness is a simple relative value of the material's ability to resist crack propagation given the existence of an already sharp crack. Fracture toughness can therefore be characterized as a material's ability to resist further crack propagation or crack extension.[85] Another interpretation of fracture toughness is that it is a measure of the energy absorbed by a material prior to crack extension and is thereby related to the energy necessary for crack propagation. The Griffith[86] crack propagation criteria are based on the postulate that a crack can grow only if there is enough energy available to create a new crack surface area. It is important to understand that the presence of a critical quantity of energy is not a guarantee for crack growth. It is not correct to state that, given the energy necessary for crack growth, a crack *will* grow, only that a crack *can* grow; it may not.

Expressions for Y have been determined for many specimen geometries, making K_c usually straightforward to define.[87,88] The remarkable result of eqn [1] is that a material's fracture toughness value is independent of loading conditions, crack size, and specimen geometry, thus making fracture toughness a material property.

It is well known that the MW of a polymer, or the grain size in metals, affects fracture toughness.[53,87]

Fracture toughness tests require specimens with certain minimum dimensions (see, e.g., Broek[87] or ASTM E399) and that a sharp crack be introduced into the specimen (**Figure 6**). Different specimen geometries can be usedas, if the test requirements are met, the resulting data yield a material property that is independent of geometry. It is possible, therefore, to directly compare the published values of fracture toughness of various bone cements determined by different investigators. In his review paper, Lewis[49] reviewed the fracture toughness results from several different studies, conducted under a variety of conditions. The studies encompassed six different types of commercially available bone cements. The fracture toughness of the bone cements ranged from 1.03 to 2.32 MPa $m^{1/2}$. As a benchmark, the fracture toughness of commercial PMMA is roughly between 1 and 1.5 MPa $m^{1/2}$.[55,89] Thus, PMMA is not noted for its resistance to fracture. Fracture toughness tells only a part of the failure story; however, it is a starting point that must be augmented by a subsequent discussion of fatigue failure.

6.602.4.4.7. Fatigue fracture

Possibly, the most critical consideration for the integrity of the bone cement mantle itself is the fatigue behavior. Although other behaviors, like creep, may influence the overall success of the prosthesis, the artificial joint construct is subjected to fatigue loading, and gross or even undetected fatigue can cause failure of the prosthesis.[20,90] For example, microcracks that develop under cyclic loading can alter the modulus of the cement mantle, even if no gross fracture is present, and hence affect the stress transfer to the bone. The fatigue properties of bone cement received increased attention as researchers postulated and showed that fatigue was a primary cause of cement failure. Lewis[90] gives an excellent review of the details of different fatigue studies, with an emphasis on comparing/contrasting preparation methods, testing methods, and cement brands. It is difficult to compare/contrast fatigue results performed by different researchers, because there are many ways to conduct fatigue tests, and there is no material property, like fracture toughness, that completely characterizes the fatigue crack resistance of a material (**Figure 7**).

Few authors have examined specimens of PMMA that were retrieved from actual *in vivo* service. Williert *et al.*[91] examined only PMMA–bone interface surfaces of retrieved PMMA specimens to study the interface morphology of the bone cement. Topoleski *et al.*[20] performed a fractographic analysis of retrieved bone cement specimens, which failed *in vivo*, and compared and contrasted fracture surfaces created under known, controlled conditions. Rapid fracture surfaces, such as those created during a fracture toughness experiment, have a distinctly flat morphology, which was notably absent from the *in vivo* fracture surfaces. The identifying characteristic irregularity of the fatigue surfaces observed on both the controlled fractures and the retrieved specimens is the consequence of the fatigue crack damage zone characteristic of PMMA–bone cement.

There is a need for continued pursuance of bone cement fatigue knowledge. A brief summary of important concepts for consideration in fatigue testing of bone cement is presented in order to guide unfamiliar readers. The overview by

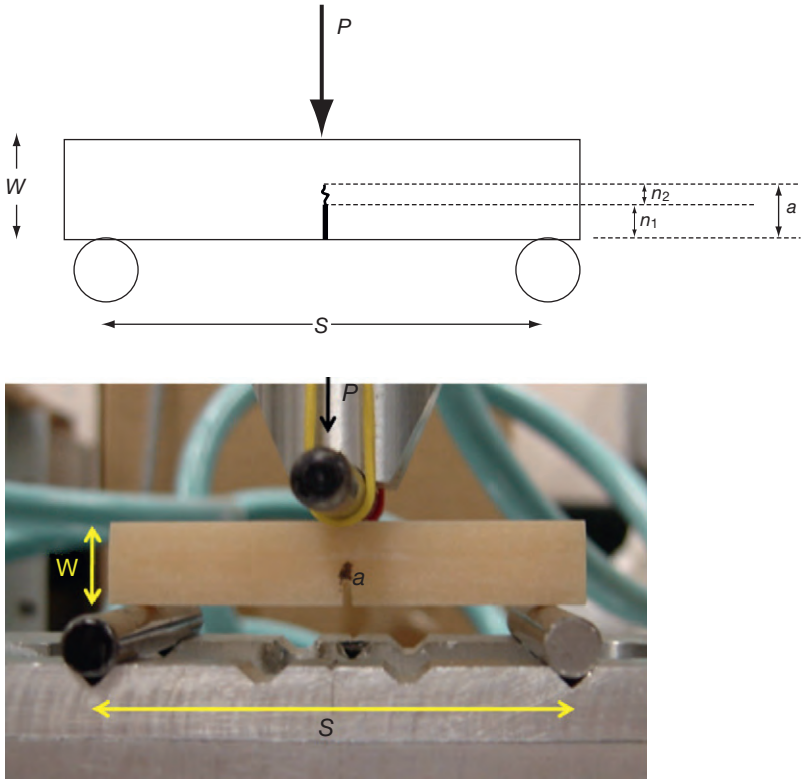

Figure 6 Top – a schematic of a three-point bending specimen for fracture toughness testing. A load (P) is centered between the two supporting fixtures, separated by span (S). An initial notch (n_1) is cut into the specimen, and then a further extension of the notch may be created by 'prefatiguing' a longer crack (n_2) from the initial notch. The total initial crack length (a) is the sum of the cut notch and the prefatigued crack ($n_1 + n_2$). The load at failure P, support span S, specimen height W, specimen depth B, and initial crack length a, are used to calculate the fracture toughness (K_{IC}) of the specimen using the equation $K_{IC} = \frac{PS}{BW^{3/2}}\left[2.9\alpha^{1/2} - 4.6\alpha^{3/2} + 21.8\alpha^{5/2} - 37.6\alpha^{7/2} + 38.7\alpha^{9/2}\right]$ where $\alpha = a/W$.[87] Broek[87] also gives an excellent summary of other potential geometries for fracture toughness testing, as well as the appropriate equations for calculating fracture toughness. Bottom – a photograph of a poly(methyl methacrylate) bone cement three-point bending specimen prior to loading for a fracture toughness test.

Krause *et al.*[92,93] or a text devoted specifically to fatigue analysis, such as Collins,[94] are more detailed sources of fatigue testing methodologies.

The fatigue or endurance limit of a material is defined as the stress level at which the material may undergo an infinite number of cycles, that is, may never break. An enormous amount of time is required to estimate the endurance limit of a material at a low testing frequency. A reliable model of stress (or strain) versus cycles to failure for bone cement, based on low cycle to failure testing, can reduce the time and expense of fatigue characterization. Krause *et al.*[92,93] present suggestions for statistical analysis of fatigue tests that may be useful for estimating the fatigue limit, by concentrating fatigue testing on failures that occur at <1 million cycles, and extrapolating to longer lifetimes. Fatigue data may be presented as lifetime, or cycles to failure for a given initial stress (based on the S–N or stress vs. cycles to failure curves), as probability of failure after a given number of cycles, or as crack growth rates (using, e.g., the Paris relationship[95]).

Because of the extensive time required to perform fatigue studies on any material, the loading frequency must optimize data production. Human gait analysis shows that the femur is loaded twice during each step, once at heal strike, and once at toe push-off, and the two loading peaks occur in a span of about 0.4 s.[96] The physiologic loading rate, therefore, for each step is two cycles per 0.4 s, or ~5 Hz. The twin loading peaks repeat with the next heal strike of the same foot, ~1 s later. A single fatigue test to 1 million cycles, at 5 Hz, requires ~2.5 days. A comprehensive series of fatigue tests would involve an inordinate amount of time. Higher frequencies may not be appropriate, however, because the fatigue properties of many polymers are sensitive to fatigue testing frequency, due primarily to thermal effects. Consideration of frequency sensitivity, service loading rates, and economics must be balanced. The highest frequency allowable, without changing the nature of the fatigue failure from that found *in vivo*, is the test frequency of choice.

Pilliar *et al.*[97] investigated the effect of test frequency on the results of fatigue tests in bone cement. They measured the effect of frequency on the temperature of the bone cement, and noted that below 10 Hz, there was no measured change in temperature with a change in test frequency; therefore, below 10 Hz, fatigue behavior of bone cement appears to be independent of thermal effects associated with increased test frequency.

Johnson *et al.*[98] published a study of the effect of test frequency and environment on the results of bone cement fatigue experiments. They performed tension fatigue tests at one stress level only, and their results, therefore, cannot be

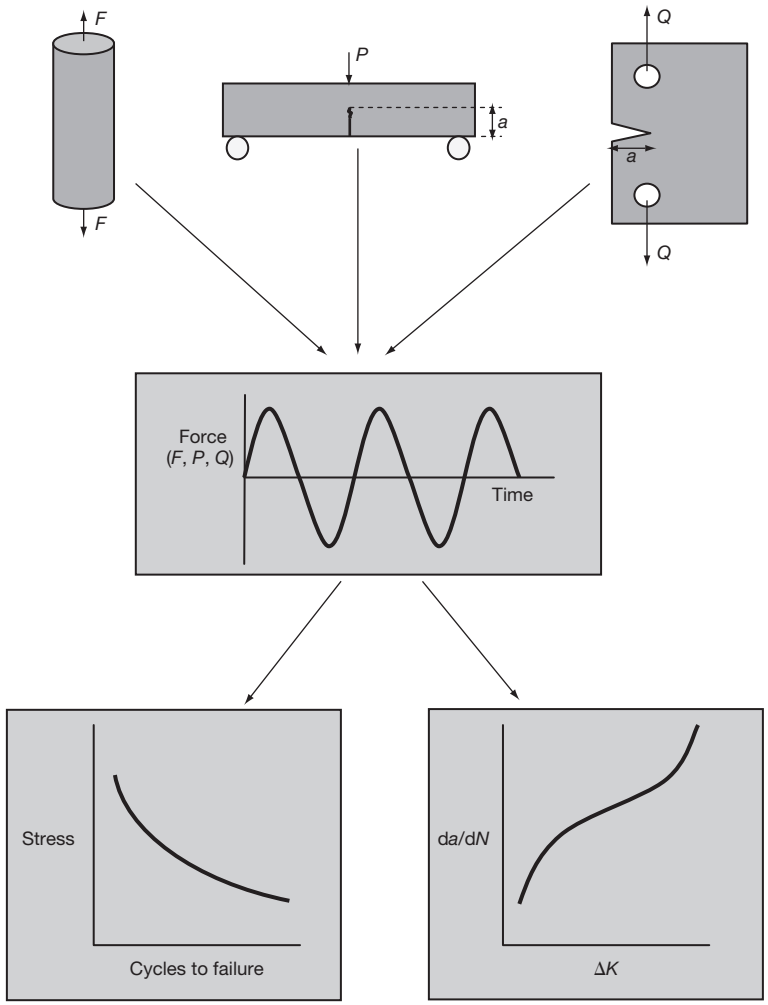

Figure 7 Fatigue specimens can take many forms, depending on the nature or amount of material available. The top row shows three commonly used specimens and test configurations. From left to right, simple tension (or compression), three-point bending, and compact tension (CT) specimens. Fatigue, or cyclic, loading is applied to the specimen, schematically depicted in the center row. The nature of the load cycle – maximum load, tension–tension versus tension–compression, loading frequency, etc. – depends on the goals of the particular study. The bottom row shows two common presentations of the fatigue data: (left) the stress versus cycles to failure, or *S–N*, curve, (right) and the crack velocity/cycle versus change in stress intensity (K), or da/dN versus ΔK, curve.

generalized. They reported an increase in fatigue life with increased testing frequency. They also reported a decrease in fatigue life in 37 °C saline versus an air and room temperature environment. Krause and coworkers[92,93,99] addressed the issue of consistency in fatigue testing of PMMA–bone cement. In their review, they state that comparisons between different studies are often difficult because of the myriad varieties of test conditions, cement preparation methods, test specimen geometry, and test methodology. They explicitly warn Krause *et al.*[92]:

> Readers of fatigue papers should be cautioned that conclusions presented are only valid for the parameters and test conditions tested. It is extremely dangerous and can be misleading to extrapolate test data conducted under one set of conditions to general conclusions. . .

In an effort to address this issue, Lewis and Nyman[100] suggested that standardized test conditions may be useful. For direct comparison of results for different conditions, especially for fatigue tests, the same test methods must be used; however, we must also recognize that different situations or scientific questions may require specific methods to determine an answer.

6.602.4.4.7.1. Effect of environment, differences between industrial PMMA and bone cement, and $BaSO_4$ addition

Jaffe *et al.*[101] investigated the effects of storing Simplex® and CMW® bone cements in bovine serum for up to 2 years on compressive fatigue life. They performed compression fatigue tests at 30 Hz, and determined the effect of storage to be negligible. Only one specimen of each storage treatment was tested at a given stress, however, and as fatigue testing is plagued by data scatter, it is difficult to extract fundamental conclusions from their work.

Beaumont and Young[55] compared the slow crack growth in both commercial PMMA (Perspex®) and PMMA–bone cement.

They did not perform dynamic fatigue studies, but measured instead the time to failure as function of a single, sustained load (static fatigue), at 20 °C in air and in water. Their data indicated that bone cement had better crack propagation resistance (lower crack velocities for a given stress intensity)and a higher fracture toughness than Perspex®. They also noted an environmental effect: an increase in propagation resistance for bone cement specimens tested in water versus bone cement tested in air.

The superior fracture properties of bone cement compared to Perspex® may be at first surprising, as Perspex® is generally polymerized under well-controlled conditions, and MWs can be high. In contrast, bone cement polymerization is uncontrolled and MWs are low compared to the industrial PMMA. For most polymers, including PMMA, fatigue fracture is dependent on MW,[51] and in the absence of MW information, fatigue data comparisons between the two forms of PMMA are difficult.

Beaumont and Young[55] also performed scanning electron microscopic fractography on their failed specimens. From observations of the bone cement fracture surfaces, they identified 'pull-out' of bead phase polymer from the surrounding matrix. The bead pull-out may explain the lower crack propagation velocities, and higher fracture toughness, of bone cement compared to Perspex®. Bead pull-out from the matrix requires energy that would otherwise be available to propagate a crack. As commercial PMMA is homogeneous, that is, there is no bead phase to pull out, that specific energy dissipation mechanism is absent.

Freitag and Cannon[89] performed the earliest cyclically loaded, tension-compression fatigue studies on bone cement. They investigated bone cement with and without the addition of 10% by weight $BaSO_4$. Their tests were performed at body temperature (37 °C) in a bovine serum bath and in air at room temperature. They showed that testing at 37 °C in serum increased the values of both fracture toughness and fatigue life over the respective values obtained in air at the ambient temperature. Their data relating the effect of $BaSO_4$ addition to the fracture properties of bone cement were inconclusive. Depending on the type of cement and the environment, the addition of $BaSO_4$ either increased or decreased the fracture toughness, but there was *no* observed effect on the fatigue behavior of the cement.

Wright and Robinson[56] compared fatigue crack propagation behavior in three different bone cements: a standard viscosity cement, a low viscosity cement (LVC), and carbon fiber-reinforced cement. They determined that there was no difference in crack propagation rates for standard bone cement compared to LVC. The addition of carbon fibers, however, reduced the crack propagation rate by an order of magnitude. Fractographic analysis of the standard and LVC cements indicated the separation of matrix and bead phases after fracture.

Krause *et al.*[93] performed an extensive series of fatigue tests examining three commercially available bone cements: Simplex P (Howmedica, Inc. Rutherford, NJ), Zimmer Regular (Zimmer, Inc. Warsaw, IN), and Zimmer LVC. They showed that there was no difference in the endurance limit between Zimmer Regular and Simplex P bone cements, but both had a significantly higher endurance limit than Zimmer LVC. They noted that the endurance limits estimated by their study were between 7 and 11 MPa. They reported that their endurance estimations were comparable to *in vivo* stresses for bone cement predicted by other investigators.

6.602.4.4.7.1.1. Porosity reduction Several studies have concentrated on the effect of porosity on the fatigue life of bone cement. Centrifugation and vacuum mixing are two techniques used to reduce the porosity inherent in bone cements hand mixed in the operating room. Burke *et al.*[17] (as well as Davies *et al.*[102,103]) showed that reduction of porosity in bone cements by centrifugation increased ultimate tensile strain, ultimate tensile stress, and fatigue life.

Rimnac *et al.*[25] argued that the fatigue life of a material encompasses the time for crack initiation plus the time for crack propagation through the material. Wright and Robinson[56] speculated that cracks in bone cement are readily initiated *in vivo*, and therefore, Rimnac *et al.*[25] suggested that crack propagation testing is more pertinent to the fatigue performance of bone cement than a test that does not differentiate between propagation and initiation. They based conclusions concerning fatigue crack propagation resistance of bone cement on fracture toughness test results. Fracture toughness is indeed a measure of a material's ability to resist crack growth or propagation, given a fully formed crack. A qualitative relationship between the fracture toughness and the fatigue life of a material generally exists; that is, materials with high fracture toughness tend to exhibit greater fatigue lives than materials with a lower fracture toughness, although there is no consistent functional relationship between fracture toughness and fatigue life of materials.[104] Rimnac *et al.*[25] found no difference in the fracture toughness of centrifuged (pore-reduced) and noncentrifuged bone cements.

The study by Rimnac *et al.*[25] motivated a series of 'Letters to the Editor' of *The Journal of Bone and Joint Surgery* written by Harris, Burke, Harrigan, Wixson and Lautenschlager, and Rimnac[105] in response. The controversy centered not on the results of the Rimnac *et al.*'s[25] study, but on the interpretation of the data and subsequent conclusion that porosity reduction in bone cement is inconsequential, as it does not affect crack propagation as measured by fracture toughness testing. Rimnac, in reply, maintained that because of the irregular surface of bone cement *in vivo*, cracks were readily initiated, and thus, fracture toughness is a relevant measure of failure resistance in bone cement.

6.602.4.4.7.1.2. Effects of notches and surface irregularities Davies *et al.*[102] began to address the question of the effect of surface irregularities on the fatigue life of porous (i.e., noncentrifuged) and centrifuged bone cements. They introduced surface flaws via composites of bovine trabecular bone or the addition of a 'sharp' notch, 0.25 mm deep. Their results indicated that the reduction of porosity was the dominant factor influencing the fatigue life of the specimens and not the introduction of surface irregularities. It is interesting that they reported an improvement in the fatigue life of both the centrifuged and noncentrifuged notched specimens over their nonnotched counterparts. Hamati *et al.*[106] also compared notched versus nonnotched specimens. They found that the notched specimens had a lower fatigue life at a given apparent applied stress.

An important concept of fracture testing is that stress intensity, a measure of energy available for crack propagation,

is the driving quantity in the fracture mechanics analysis of notched specimens. Notched and nonnotched specimens cannot be compared directly when tested at the same nominal stress, because stress may have no meaning in the case of the notched specimen if the notch is assumed to be a crack. The stress at a crack tip is theoretically infinite, regardless of the applied stress. The use of a notched specimen, in contrast to a nonnotched or smooth specimen, changes the condition of the test, and the comparison of notched and nonnotched specimens on the basis of a 'nominal stress' is inappropriate. At the very least, consideration of a stress concentration factor must be included in the analysis.

Topoleski *et al.*[10,65] presented results of the fatigue analysis of plain, pore-reduced, fiber-reinforced, and pore-reduced-fiber-reinforced bone cements from both nonnotched and notched specimens. The nonnotched specimens required both crack initiation and propagation time for failure, and were evaluated on the basis of nominal applied stress. The notched specimens required only the crack propagation time before failure, and were evaluated on the basis of nominal stress intensity. For both the nonnotched and notched cases, the pore-reduced cements exhibited higher fatigue lives at each stress level or stress intensity. Because the porosity reduction increased even the fatigue lives of the notched specimens, it was concluded that porosity enhances fatigue crack propagation resistance in bone cement; however, the effect of porosity reduction on the notched specimens decreased with decreasing nominal stress intensity and eventually vanished. It is therefore important to know the *in vivo* stresses and stress intensities in order to measure the efficacy of porosity reduction.

6.602.4.4.7.1.3. Porosity reduction: how does it work? It is reasonable to conclude from the published studies that porosity reduction does indeed enhance the fatigue life of bone cement. Two questions remain: (1) how? and (2) for actual *in vivo* stresses, is porosity reduction effective? Analytical and numerical approaches have been used to advance the answer to the second question, and have been summarized briefly[99]; however, the *in vivo* bone cement stresses remain an elusive piece of the cemented prosthesis puzzle and a potentially fruitful course for mechanics research.

The first question, how does porosity reduction enhance the fatigue performance of PMMA, is also unsettled; however, several investigators have begun to build a picture of the material mechanisms of porosity influence on bone cement fracture. Gharpuray *et al.*,[107] Gilbert *et al.*,[12,64] and Topoleski *et al.*[20] observed small cracks emanating from pores in bone cement during fatigue crack propagation. Lu and Topoleski[108] showed that the microcracks (to differentiate them from the primary crack) comprise part or all of the process zones associated with the propagating crack. Because fatigue crack propagation depends on the formation of microcracks, the way that ductile metals form a "plastic zone," or ceramics and concrete also form a process zone comprised of microcracks, then the apparent dependence of fatigue life on porosity content is explained: pores are sites where microcracks easily nucleate. As fatigue fracture is a low-energy phenomenon, the stress concentration effect of porosity may have a substantial effect compared to the stress intensity at the crack tip. Timoshenko and Goodier[66] give the solution for the maximum local stress around a spherical cavity, under uniform tension, as 45/22 $\sigma_{nominal}$. In the vicinity of a slowly advancing crack front, the stress concentration effect of the pore increases the material's stress and microcracks form in response. For the rapidly advancing crack, such as that in a fracture toughness test, the crack moves too fast to allow the development of microcracks; the crack tip fracture energy overwhelms the stress concentration contribution of the pores.

Topoleski *et al.*[20] showed that the fracture surfaces from fatigue cracks were irregular, due to microcracking in the process zone, and that the fracture surfaces formed during a fracture toughness test (rapid fractures) were flat, indicating that no microcracking occurred. The effects of porosity, therefore, may not be manifested during a test that produces a rapidly moving crack, like the fracture toughness test.

6.602.4.4.7.2. Failure mechanisms

There has been little work performed toward the understanding of crack growth mechanisms in bone cement. A fundamental procedure for investigating the fracture processes of a material is to examine fractured surfaces. Direct observation of the fracture surface characteristics or the microstructure of bone cement is rarely reported. The fracture surfaces from both slow and rapid fracture of industrially cured PMMA, conversely, have been studied in detail.[55,109–114] The surfaces of slow or fatigue fractured Plexiglas® are generally smooth, although Döll[110] showed that there is a smooth to rough transition in the surface appearance as the viscosity average MW (M_v) is decreased below about 163 000.

Few comparisons of the fracture surfaces of industrial PMMA and bone cement are documented. Beaumont and Young[55] showed that the slow fracture surface of Plexiglas® (high MW) had a smooth appearance, while the slow fracture surface of bone cement (lower MW), was irregular. Beaumont and Young[55] also noted that bone cement fatigue surfaces were 'rough,' but the Perspex® fatigue surfaces were 'smooth.' The contrast in fatigue surface morphology between the two forms of PMMA indicated that different mechanisms occurred during fatigue fracture. They mentioned possible fracture mechanisms, including particle pull-out and noting 'bunches of crazes' at the crack tip of Perspex®, indicating the nature of the process zone of the industrial form of PMMA. Kusy and Turner[113] examined the rapid fracture morphology of industrial PMMA specimens with varying MWs. They noted an absence of crazing below an M_v of 90 000, and observed glassy surfaces on specimens with $M_v < 60\,000$. The fracture surface morphology is highly dependent on MW, and hence the fracture mechanisms depend on MW also. The number average MW (M_n) of Simplex cement was reported as 89 700 by Rimnac *et al.*[25] ($M_v = 1.9\ M_n$, Kusy and Turner[113]), which would place bone cement above the M_v to form crazes proposed by Kusy and Turner.

Fatigue crack propagation, as well as quasistatic fracture properties, depends on MW.[109,110,114] Fracture toughness becomes independent of MW when $M_v > 40\,000$[109,111]; however, Kim *et al.*[111] showed that fatigue crack propagation continues to be influenced by MW even when $M_v > 1000\,000$. The morphology of fatigue fracture surfaces also likely depend on MW. Although bone cement is known to behave differently from industrial PMMA, and direct comparisons

between the two materials may not be relevant, the differences may be rooted in the different microstructures. Within each of the polymer phases of bone cement, the PMMA may be homogeneous like industrial PMMA. It follows that the surface morphology of fatigue fracture surfaces in bone cement are likely to be dependent on the MW of the two polymer phases.

The morphologies of fatigue and fast fracture surfaces of bone cement are distinct, and Freitag and Cannon[89] were able to identify the extent of a fatigue crack before catastrophic failure by observing the rough to smooth transition of the fracture surface. They reported that the fatigue surface of bone cement was 'textured,' as did Beaumont and Young,[55] and postulated a fracture mechanism based on the initiation and propagation of several 'microcracks,' leading to an irregular fracture surface. Fractographic studies support a simple generalization for PMMA–bone cement fracture surfaces: slow fractures (fatigue) produce rough or irregular fracture surfaces, while rapid fractures (produced during fracture toughness tests) produce smooth or cleaved fracture surfaces.[17,56,61,91,97,115]

The difference in fracture morphology indicates a different mechanism of failure. Topoleski *et al.*[20] and Lu and Topoleski[108] also investigated the damage zone of bone cement and observed that microcracking or a 'microcraze' shower preceded the crack tip. Microcracking can occur in PMMA (nonbone cement) if the MW is not high enough to develop crazes.[113,116] The coalescence of the microcracks is a mechanism for crack extension and the irregularity of the fatigue surface.

Because so little is known, fundamental research on the nature of bone cement fatigue failure mechanisms is crucial. Knowledge of the failure mechanisms is the tool to understand the role of bone cement in total joint failures, and is essential for applying creative alternate bone cement formulations with the intent to prevent failures.

6.602.4.5. Summary

Bone cement fracture can at least be linked to, if not directly responsible for, failures of total joint arthroplasties. There are two ways of evaluating the fracture properties of bone cement, fracture toughness measurements, and fatigue testing. Fracture toughness tests are, in general, an easier way to establish a quantitative evaluation of material fracture properties than fatigue tests because (1) fracture toughness is a material property, and independent of test protocol or specimen geometry; fatigue tests do *not* result in a unique material property, but are dependent on test methodology; (2) fewer specimens are required to characterize the fracture toughness of a material than to characterize the fatigue properties; and (3) fracture toughness tests do not require nearly as much time as fatigue. Fracture toughness embodies only one aspect of the fracture characterization of a material, however, and is related to a fast propagating, high energy crack. Fatigue, or subcritical, fracture is a lower energy phenomenon and requires a more extensive and sophisticated series of experiments than fracture toughness. If a material fails under fatigue or subcritical loading conditions, then fracture toughness alone is inadequate to understand or predict the failure behavior of the material; fatigue characterization is necessary.

6.602.5. Improving PMMA–Bone Cement

6.602.5.1. Introduction

Increasing the *in vivo* longevity of PMMA by improving the resistance to failure of the polymer has received some, albeit surprisingly little, attention. To improve bone cement, one can either replace current bone cements with new bone cements, that is, alter the chemical composition to create a better cement via an 'internal' modification, or modify existing bone cements using an additive 'external' force or agent. (Modifications of existing bone cement can also be applied to new bone cements, or new bone cements may be formulated to better take advantage of 'external' modifications; however, an understanding of any modification, internal or external, is fundamental to predicting efficacy of treatments, and has not yet been achieved.) Porosity reduction is an example of an external modification that has the apparent result of increasing the fatigue life of current cements.

To follow the discussion of bone cement failure, we will examine approaches to improving the failure resistance. First, a brief outline of two initial studies on chemically alternative cements, and second, a more extensive review of an external modification: the addition of a fiber-reinforcing phase to existing cements.

6.602.5.2. Chemical ('or Internal') Modifications

Weightman *et al.*[117] formulated a bone cement based on an *N*-butyl methacrylate monomer, replacing MMA. They noted that the *N*-butyl methacrylate-based material showed a higher ductility, a higher apparent fracture toughness, and a greater fatigue life. The concept of using butyl methacrylate was also investigated by Litsky *et al.*[118] They replaced the PMMA powder component of bone cement, rather than the liquid monomer component, with butyl methacrylate beads, and retained the MMA monomer. Their hypothesis was that local contact stresses are responsible for the initiation of total joint loosening, and reducing the cement modulus reduces the local contact stresses. Litsky *et al.*'s[118] preliminary studies showed clinical promise, but mechanical and failure characteristics are unknown and require further investigation.

There has been much research on replacing PMMA-based bone cements with other materials, for example, cements that contain hydroxyapatite (HA) that may allow the bone to biologically interact with the cement. A review of alternative cement materials is found elsewhere in this text. The reader of this chapter will find excellent reviews of the potential 'new' bone cements by Kenny and Buggy[119] and Lewis.[120]

6.602.5.3. Fiber Reinforcement

Different reinforcing fibers have been added to bone cement to try to improve the fracture resistance. Fibers include carbon,[22,97,121–126] Kevlar®,[127,128] PMMA,[129] polyethylene,[130,131] stainless steel,[61,132–134] titanium,[54,135] and zirconia.[136] At least one formulation, a carbon fiber-reinforced cement, was commercially available,[126] but its availability was short-lived.

An understanding of the interaction between the different materials in a total joint replacement is essential for success.

As fundamental understanding increases, and prostheses are used to facilitate a wider variety of patient needs and service functions, more exactly engineered materials will be required to ensure prosthesis longevity. Advances in fiber-reinforced composite engineering materials are indicative of the potential for tailoring material properties, and total joint fixation is ideal for composite materials applications. The addition of a reinforcing phase to bone cement, generally short fibers or whiskers, has been investigated only sporadically in the past. One advantage of adding a reinforcing fiber to bone cements is that currently used cements can be potentially reinforced with little or no alteration.

Knoell *et al.*[123] added between 0.67% and 5.87% by volume content (1–10% by weight. The percent fiber contents are reported as volume percents for consistency. Where the original source reports percent by weight, a conversion has been made from wt% to vol%, using the following values for densities: PMMA 1.2, carbon 1.75, and aramid (Kevlar®) 1.44 gm cm^{-3}) carbon fibers (~6 mm in length) to PMMA. They measured increases of up to 100% in the average Young's modulus for the reinforced PMMA. They were also among the first to report a decrease in peak curing temperature of the reinforced PMMA.

Pilliar *et al.*[97,124] incorporated 2% carbon fibers (6 mm length, 7 μm diameter) into bone cement. They measured a 50% improvement in tension–tension fatigue limit, an improved impact performance, and a 36% increase in UTS. Pilliar *et al.*[97,124] indicated that their reinforced PMMA had poor intrusion characteristics due to increased apparent viscosity and poor fiber distribution throughout the cement mass.

Wright and Trent[137,138] performed preliminary studies using PMMA reinforced with chopped aramid fibers. PMMA reinforced with 5.17% fibers (7% by weight) exhibited a 74% increase in fracture toughness over the plain PMMA. They were not able to produce reinforced PMMA with a fiber content >5% because of mixing and handling difficulties.

Beaumont[61] introduced glass beads into the PMMA mass. He measured a decrease in crack propagation velocity, as much as three orders of magnitude, with a 30% bead addition.

Very few investigators considered the use of metal fibers to reinforce PMMA. Metal fibers have an advantage over brittle carbon fibers because they can be ductile. Taitsman and Saha[139] used large diameter (0.5–1.0 mm) stainless steel and Vitallium *wires* as a reinforcing phase. Their concept was more like the inclusion of reinforcing bars in structural concrete than that of a fiber-reinforced composite material. They embedded 1, 2, or 3 wires in PMMA specimens and reported up to an 80% increase in tensile strength (with 3 embedded Vitallium wires), but noted that clinical applications of their wire reinforced cement were limited.

Fishbane and Pond[132] reinforced industrial grade PMMA (Plexiglas®) and PMMA–bone cement with stainless steel whiskers (0.5–1.0 mm length, 65 μm diameter; or 3–6 mm length, 90 μm diameter). They determined that the addition of fibers up to 6.5% improved the compressive strength of Plexiglas® by nearly 100%, but for the surgical grade PMMA realized only a 25% increase. Fishbane and Pond[132] postulated that the reason for the decreased performance of the surgical PMMA was "...due to limitations imposed by the (surgical) methacrylate preparation technique."

Kotha *et al.*[133] also reported an increase in the fracture toughness using stainless steel fibers. Kotha *et al.*[134] generated further improvements by treating the stainless steel fibers with a silane coupling agent. The increase was attributed to the enhanced adhesion between the coated fibers in contrast to the noncoated fibers.

Schnur and Lee[140] investigated the use of titanium (Ti) sheet, wire, mesh, and powder as a reinforcing phase. Their work is similar to that of Taitsman and Saha[139]; both investigated a system similar to reinforced concrete, rather than a composite bone cement. Schnur and Lee's goal was to increase the modulus of PMMA to that of cortical bone. An addition of 16%, 1 mm diameter wires (a total of 25 wires), increased the modulus of the PMMA by 380% and the maximum compressive stress by 75%. It is not clear, however, whether the modulus of PMMA must approach that of cortical bone for prosthesis success. Some bone cement researchers[118] have proposed the opposite, while others[71,140] argued that a reduction in PMMA modulus might be detrimental to the prosthesis.

Other studies of reinforced PMMA–bone cement have incorporated carbon/graphite or aramid fibers. Robinson *et al.*[141] tested both Zimmer Regular and Zimmer LVC reinforced with 2% volume of carbon fibers (1.5 mm in length, 10 μm diameter). Both reinforced cements exhibited an increase in fracture toughness of ~32% over their plain counterparts. Surface fractography revealed no evidence of fiber fracture, indicating that the increase in 'toughness' was due principally to fiber pull out. Subsequent work by Wright and coworkers[56,142] addressed fatigue crack propagation rates of carbon fiber-reinforced PMMA. An order of magnitude decrease in crack propagation velocity was measured for carbon fiber-reinforced cements.

Saha and Pal[22] tested PMMA reinforced with 0.67% carbon fibers (1% by weight; 6 mm length, 8 μm diameter) and PMMA reinforced with 1.61% and 3.82% aramid fibers (Kevlar-29®, 2 and 4% by weight; 12–13 mm length, unspecified diameter). The carbon fiber-reinforced PMMA showed a 20.5% increase in UCS, and the aramid fiber-reinforced cement showed increases of 19.5% and 28.7% for the 1.61 and 3.82 vol%, respectively. Saha and Pal emphasized two important consequences of the addition of fibers to PMMA: (1) the peak temperature of the reinforced PMMA was lower than the plain PMMA, which might help to reduce thermal necrosis of tissue surrounding the polymerizing PMMA, and (2) the addition of fibers decreased the workability of the cement. They noted, as did Pilliar *et al.*,[97] that uniform dispersion of fibers was difficult to obtain. Saha and Pal[22] machine-mixed carbon fibers with PMMA powder prior to the monomer addition in an attempt to improve fiber distribution in the reinforced PMMA. They claimed that the machine-mixed PMMA exhibited, in general, improved mechanical properties over their hand-mixed reinforced PMMA. The carbon fibers used in the two investigations were different, however. The fibers used in the machine-mixed study were 'dumbbell' shaped, contrasting with the cylindrically shaped fibers used in the hand-mixed study. The 'dumbbell' shape of the fibers probably increased the stress transfer between the fiber and the PMMA matrix, which led to an increase in the overall strength of the machine-mixed reinforced PMMA.

Ekstrand *et al.*[121] were able to fabricate carbon fiber-reinforced PMMA with fiber contents as high as 16.38% by volume (40% by weight) They used industrial composite fabrication techniques, however, which have limited or no clinical application. The primary contribution of their work showed that there was no contact between the carbon fibers and the PMMA after the composite was stored in distilled water for 30 days. They also showed that the ultimate flexural strength of the composite nearly tripled as the volume fiber content was increased from 5.87% to 16.38% (10–40% by weight).

Pourdeyhimi *et al.*[127] studied the effect of the fiber content on the fracture toughness of hand-mixed, reinforced, dental PMMA. They used aramid fibers from 0.82% to 5.17% by volume (1–7% by weight), and graphite from 0.67% to 5.87% by volume (1–10% by weight), and performed fracture toughness tests, calculating values for both K_{Ic} and J_{Ic}. (J_{Ic} is the critical value of a quantity J, calculated by the so-called J-integral, and is a measure of energy release rate for materials where plasticity effects at the crack tip are not negligible.[87]) For each type of fiber-reinforced cement, the fracture toughness increased with increasing fiber content. The aramid fiber specimens showed a greater increase than the carbon fiber specimens of the same volume fraction. The energy dissipated in the micromechanisms of failure was greater for the aramid fibers than for the carbon fibers. Dental PMMA is different from surgical PMMA, however. The dental PMMA may be heat-cured, and sometimes pressurized, before it is used. The techniques for creating a reinforced dental PMMA generally cannot be adopted to create a reinforced surgical PMMA. In a parallel study,[128] where reinforced dental and bone cements were both tested at 5.17% fiber content, the K_{IC} of the bone cement increased by 77%, and for the dental acrylic by 98% (the nonreinforced bone cement had a K_{IC} 33% greater than the nonreinforced dental acrylic).

Wagner and Cohn[143] and Pourdeyhimi and Wagner[130] investigated the performance of polyethylene (PE) fibers as a reinforcing phase. An increase in fracture toughness of about 24% was observed for 0.8%, 3.2%, and 5.6% fiber content (1%, 4%, and 7% by weight). Fracture toughness was not affected by fiber content after the initial addition of 0.8% fibers; the fracture toughness remained constant. They characterized the bonding between the fibers and the PMMA matrix as 'poor.' Their reported fractography showed fiber pull-out and fiber bending as energy absorption mechanisms contributed by PE fibers. It is difficult to explain why a fracture toughness plateau is reached, and fracture toughness does not improve with increasing fiber content. Yang *et al.*[131] also investigated PE fibers. They modified the surfaces of the PE fibers and determined that the treated fibers (with grafted MMA) produced a greater reinforcing effect than did the untreated PE fibers.

Topoleski *et al.*[10,54,65] determined the fracture toughness and studied the fatigue behavior of Ti-reinforced bone cement. They achieved >50% increases in fracture toughness with 5% fiber content. They also addressed the reinforced cement delivery and fiber distribution problems,[144] and were able to mix and deliver, with relative ease, a reinforced bone cement with a uniform fiber distribution. Fractography revealed fiber-matrix debonding, local fracture path change, and ductile fiber deformation and subsequent fracture as principal mechanisms of energy absorption. Analysis of the fatigue characteristics[10,65] revealed that for both notched and nonnotched reinforced specimens, the fatigue lives were increased by nearly an order of magnitude. The combination of porosity reduction *and* fiber reinforcement further increased the fatigue resistance.

Kotha *et al.*[134,135] also incorporated titanium fibers into bone cement. In their study, they heat-treated the fibers to produce a thin coating of titania on the fibers. They obtained an increase in fracture toughness of the reinforced bone cement of between 19% and 30%.

Gilbert *et al.*[129] reported an increase in the UTS and fracture toughness using PMMA fibers (a 'self-reinforced' cement). Their cement was a dental acrylic, however, and the fracture toughness of the reinforced acrylic was approximately equal to the fracture toughness of nonreinforced orthopedic bone cement. They claimed that the increase in fracture toughness was 50% for 'preferentially aligned fibers.' Further study is required to determine whether similar increases can be achieved in bone cement.

Very recently, Kane *et al.*[136] reported that the fatigue life of zirconia fiber-reinforced PMMA increased significantly over that of PMMA. They were able to incorporate up to 20% by the volume of zirconia fibers. The use of brittle ceramic fibers to reinforce bone cement is relatively new, and it will be interesting to pursue this avenue and investigate the reinforcing mechanisms.

6.602.6. Summary and Concluding Remarks

Artificial joints are an extremely successful medical treatment for people suffering from arthritis. Bone cement was one of the biomaterials essential to the success of artificial joints. There are many critical considerations to address to further improve bone cement and thereby improve cemented artificial joints. For instance, it is necessary to distinguish between fatigue crack initiation and fatigue crack propagation and their relative contribution to the fatigue life of bone cement. A greater understanding of the nature of bone cement, the material, is needed: how do the various phases influence failure? For instance, how does $BaSO_4$ alter bone cement properties and produce an apparent environmental interaction?; what are the material mechanisms contributing to fracture and can they be altered to increase failure resistance? The questions of where and why cement cracks initiate, whether an initiated crack must necessarily propagate to failure, and how bone cement interaction with other material components of the total joint prosthesis contributes to success or failure remain to be answered. By studying each component and then analyzing that component's contribution to the system behavior, a greater understanding of material-related mechanical failures of total joint prostheses is generated, and may eventually lead to failure elimination.

There is an ongoing effort to improve the fracture properties of bone cement, through both chemical modification, and the addition of a reinforcing phase, or to create bone cements with alternative formulations. Most of the published studies of fiber-reinforced bone cement involved measuring a material property with respect to the nonreinforced bone cement. Few of the papers have discussed the actual mechanisms of reinforcement. Among the material properties enhanced by the addition of a fiber-reinforcing phase are the ultimate strength,

fracture toughness, and fatigue crack propagation resistance of bone cement. To improve the properties of bone cement through the use of a fiber-reinforcing phase, it is clear that (1) a clinically workable cement must be engineered, and (2) the mechanisms of material property improvements in such a bone cement must be well characterized in order to produce the best possible bone cement. Advances in achieving both goals have received some recent attention; however, many aspects of fiber reinforcement remain unknown. Fiber material, dimensions, content, and delivery techniques must be further researched to produce reinforced cements with superior properties.

Acrylic bone cement appears to be a material that will continue to play a role in orthopedic treatments. Orthopedic research today is concentrated on several important avenues to improve artificial joint replacements, and relatively few investigators devote time to understanding and improving bone cement. The potential exists, however, to improve the performance of bone cement and thus continue to provide patients with better prostheses and higher quality of life.

6.603.1. Introduction

Joint arthroplasty, or the surgical reconstruction of diseased joints, has been practiced in the United States since the nineteenth century. It evolved from an osteotomy of the hip joint, performed by a physician from Pennsylvania

in 1826 to include the interposition of an implant material between the articulating surfaces of a reconstructed joint.[1] A variety of natural and metallic biomaterials were initially employed, including ivory, silver, rubber, wood, celluloid, and glass. By the early twentieth century, mold arthroplasties, in which an implant was molded over the surface of the femur to articulate against the natural acetabulum, were fabricated out of glass, ceramic, and metal including Vitallium™, a cobalt–chromium alloy.[2] The success of early arthroplasties was highly variable and spurred continuous innovations in surgical procedure, implant design, and biomaterials.

In contrast to hemiarthroplasty in which only one side of a diseased joint is surgically reconstructed, in total joint arthroplasty, both articulating surfaces of the joint are replaced. Contemporary total joint arthroplasty evolved from technology developed by McKee (in 1951) and Charnley (in 1958) for the artificial hip.[3,4] The most widely accepted implant configuration since this time comprises a metal component articulating against a polymeric component fabricated from ultra-high molecular weight polyethylene (UHMWPE). Although other bearing couples have been investigated during the past three decades, such as metal-on-metal or ceramic-on-ceramic total joint replacements, today metal-on-UHMWPE articulations are an international standard of care for degenerative joint disorders.[5] Worldwide, approximately 1.5 million UHMWPE components are implanted annually. In the United States alone, an estimated 800 000 total joint replacements are performed, representing healthcare costs of above 20 billion dollars.[6,7] Today, metal-on-UHMWPE total joint arthroplasty is an effective treatment modality providing immediate pain relief and remarkable restoration of mobility for patients with disabilities. Thus, UHMWPE is one of the most widely used biomaterials in the world.

Since the inception of metal-on-polyethylene joint implants in the 1960s, osteolysis (resorption of peri-prosthetic bone) triggered mainly by UHMWPE wear particles has been one of the major problems in total hip arthroplasty among instability/dislocation and infection.[8] Efforts to solve the wear problem in UHMWPE have spurred studies into the structure, morphology, and mechanical properties of the polymer. Among these developments, radiation cross-linking accompanied by thermal treatments to improve oxidative stability has successfully decreased wear in the first decade of service. Recently, several alternative antioxidant-stabilized UHMWPE bearing surfaces with improved mechanical properties have been introduced.

This chapter provides a review of the processing, manufacture, and sterilization methods and provides more detailed explanations of methods of cross-linking and the introduction of an antioxidant stabilizer in UHMWPE for total joint replacement. The first part of the chapter summarizes the structure and relevant properties of UHMWPE as well as processing conditions for total joint implants; the second part summarizes degradation mechanisms of UHMWPE; the third part reviews cross-linked UHMWPEs in clinical use. The final section reviews recently introduced and new UHMWPEs in development as alternative biomaterials for total joint arthroplasty.

6.603.2. General Properties and Processing of UHMWPE

6.603.2.1. Manufacture

Implant manufacturing process for implants fabricated out of UHMWPE starts with the resin powder. The resin powder, historically provided by only a handful of chemical manufacturers is converted to consolidated forms of stock either by bulk converters or on-site by medical implant manufacturers. Because the melt viscosity of UHMWPE is very low, it is not amenable to typical processing methods such as injection molding, and consolidation is done either by compression molding or ram extrusion.[9] Implants can then be machined from consolidated stock, or resin powder can be 'direct compression molded' into the final implant shape. In addition to direct compression molding and machining of converted stock material, there exists a hybrid UHMWPE manufacturing process used by Biomet known as HIP (hot isostatic pressing).[10] The multistep process begins with the manufacture of a cylindrical compact through cold isostatic pressing which expels most of the air. Subsequently, the compacted rods are sintered in a hot isostatic pressure furnace in a low oxygen pouch to prevent degradation. The resulting rod stock is essentially isotropic due to the hydrostatic sintering process and may be considered to be a compression molded form of the resin. Finished implants are then made by either turning or milling operations. In some cases, the resin converter may supply the stock in a shape that is a slight oversizing (preforming) of the finished implant. The mechanical and wear properties of UHMWPE may be significantly affected by the manufacturing processes, such as the temperature and pressure cycles during molding, and as such, these processes are proprietary.

The mechanical properties of consolidated UHMWPE vary as a function of the cooling rate,[11] which affects the crystallization kinetics and may lead to lower crystallinity at higher cooling rates. A slow cooling rate from 142 °C under nitrogen produced a compact that had a modulus of 475 MPa and a yield strength of 21.7 MPa, whereas water quenching from 200 °C produced a compact with a modulus of 213 MPa and a yield strength of 13.8 MPa. The variation in mechanical behavior with cooling rate of the melt may be attributed to differences in the quantity and morphology of the crystalline phase in UHMWPE. It is also known that while type 1 fusion defects (incomplete interparticle voids) can be removed by properly controlling the consolidation conditions, type 2 fusion defects (incomplete interparticle cohesion by self-diffusion) are common in UHMWPE. One major reason for the existence of structural defects in consolidated UHMWPE is the extremely slow diffusion of the ultra long polyethylene chains during consolidation. According to the Reptation Theory by[12] and the tube model of Doi–Edwards,[13] the motion of a single linear chain is described as restricted by the topological constraints ('tube') from the neighboring chains so that this chain can relax only along the tube axis. Dynamic thermal analysis of entangled UHMWPE (molecular weight, $3.6 \times 10^6\,g\,mol^{-1}$) showed a terminal relaxation time of 15 h at 180 °C,[14] much longer than the conventional processing time (usually less than 1 h at 190–250 °C). It was shown that prolonged exposure to high temperatures (~300 °C) can enhance the toughness of UHMWPE.[15]

The wear of UHMWPE components, which is a crucial clinically relevant macroscopic property for joint implants, depends upon surface roughness to an extent.[16] Off-the-shelf UHMWPE components vary in surface R_a from 0.28 to 0.89 μm. The polished metal counterfaces of orthopedic bearings, in contrast, vary in typical surface R_a from 0.01 to 0.02 μm. Because of the initial difference in surface roughness at the UHMWPE and metal counterfaces, the initial wear rate involves the removal of the larger 'macroscopic' asperities on the UHMWPE surface, whereas the long-term wear rate is governed by the 'microscopic' asperity size of the metal counterface. Thus, changes to the surface roughness of UHMWPE components may be expected to affect the initial wear rate.

6.603.2.2. Structure–Property Relationships

The nomenclature of UHMWPE has changed considerably in the past four decades, complicating the comparison and review of historical processing conditions. In the early 1960s, UHMWPE was classified as a form of high-density polyethylene (HDPE) among members of the polymer industry.[1] Thus, Charnley's earlier references to UHMWPE as HDPE are technically accurate for his time.[17] Today, HDPE is classified as linear polyethylene with a density $>0.940\,g\,cm^{-3}$ and having a molecular weight typically below $200\,000\,g\,mol^{-1}$, whereas UHMWPE is defined by ASTM D 4020 as a linear polyethylene with an average molecular weight >3.1 million $g\,mol^{-1}$[18] and >1 million $g\,mol^{-1}$ by ISO 11542. The two UHMWPE resins available today are designated GUR 1020 and GUR 1050 and have molecular weights of about 3.5 and 6 million $g\,mol^{-1}$, respectively.[19] Up until the early 1990s, this type of resin was produced only from what today we would consider the lower molecular weight UHMWPE (GUR 1020). To date, this compression molded low molecular weight UHMWPE is still the primary UHMWPE used in the European marketplace.

Two ram extruded resins, 1900 and 1900H, were supplied from Hercules Powder Company and Montell Polyolefins (Wilmington, DE, USA) until the disassembly of the production line in 2002. It has to be mentioned that the 1900 resin, which had a molecular weight in the range of 2–4 million $g\,mol^{-1}$, has a relatively high long-term success; implants that had been fabricated by direct compression molding of this resin showed higher survival rates because of their resistance to oxidation compared to implants fabricated from the conventional GUR resin of similar molecular weight.[20] As this resin was discontinued in 2002, implants fabricated from this material are not expected to be available for very long.

Variations between the material properties of consolidated Ticona and Montell resins have been explained by differences in the average resin particle size, the size distribution, and morphology of the resin particles.[21] GUR resins have a mean particle size of about 140 μm, whereas the mean particle size of Montell 1900 was around 300 μm. The subtle differences between the nascent particle morphology of the spheroid particles of the resin powders, when studied under a scanning electron microscope, revealed notably that the powder morphology in the Ticona resins was characterized by a fine network of submicron-sized fibrils which interconnected the microscopic spheroids.[1] These were attributed to the use of different catalysts and manufacturing processes, resulting in different polymer morphologies. For example, depending upon the processing conditions, the 1900 also exhibited spherulitic crystalline morphology,[22] whereas spherulites are not observed in Ticona resins, which have a lamellar crystalline morphology.[23] There is ongoing research at DSM (Netherlands) to reintroduce a Type 3 resin such as Himont 1900, a class of resin categorized by its molecular weight and catalyst residues.[19]

At the nanometer length scale, UHMWPE is a two-phase viscoplastic solid, consisting of crystalline domains embedded within an amorphous matrix (**Figure 1**). The crystalline phase of UHMWPE consists of folded rows of carbon atoms packed into lamellae, typically 10–50 nm in thickness and 10–50 μm in length. The crystalline morphology of UHMWPE encompasses a distribution of lamellar sizes within the polymer, although the typical interlamellar spacing is 50 nm, on the basis of small-angle X-ray scattering measurements.[24] The surrounding amorphous phase consists of randomly oriented and entangled polymer chains traversed by tie molecules which interconnect lamellae and provide resistance to mechanical deformation. Thus, at the nanometer length scale, UHMWPE is a complex composite material which can evolve over time in response to its mechanical, chemical, and thermal history.

The intrinsic viscosity (IV) of UHMWPE is related to the bulk impact strength and abrasive wear resistance after conversion to bulk form, although the relationships are nonlinear. The maximum impact strength was found to be between 16 and 20 IV, which is the equivalent to a molecular weight range of 2.4–3.3 million using the ASTM calculation for molecular weight.[1,19] As the IV increases, abrasive wear resistance increases, as measured by sand slurry testing, reaching a plateau for IV greater than 20. In *in vitro* wear studies using pin-on-disc (POD) apparatus, the wear of UHMWPE consolidated by compression molding varied between 7 and 10 mg million^{-1}-cycles of testing.[25,26]

Despite the successful use of additives such as antioxidants in many polymers used in food packaging, consumer applications, and other medical devices, additives in UHMWPE total joint implants are not common. This is due to some serious negative effects of historically used additives. Calcium stearate, which was used as a scavenger for catalyst particles left in the polymer as well as a release agent, was found in the oxidized portions of retrieved tibias accompanied by white banding, suggesting its involvement in oxidation.[27] Fusion defects and

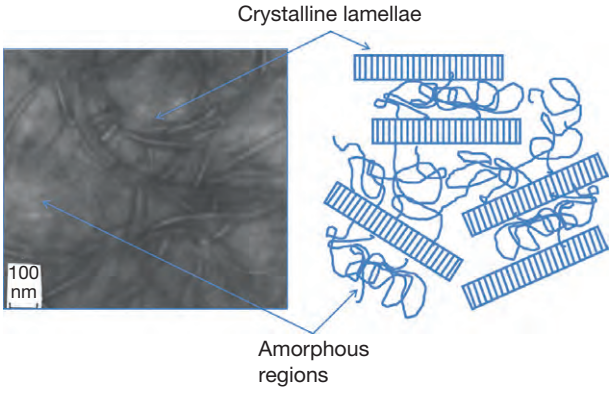

Figure 1 Polyethylene morphology.

internal microvoids could serve as stress concentrations and promote the nucleation of cracks and general reduction in the mechanical properties of the material, with deleterious consequences for the fatigue wear commonly observed in tibial bearings for total knee arthroplasty as a result of oxidation.[28–30] While the effects of consolidation parameters and the presence of calcium stearate at the grain boundaries on fusion defects could not be clearly identified, manufacturers opted to use resins with lowered calcium stearate concentrations (i.e., GUR 1020 and 1050). Another additive that was included in a modified UHMWPE in the 1970s was carbon fiber in an attempt to increase the modulus and mechanical strength of UHMWPE, thereby improving its longevity.[1] Despite showing some promise in the laboratory in terms of increased strength and pitting resistance, this carbon-reinforced UHMWPE (Poly II™) failed completely after short-term implantation *in vivo*.[31] It was revealed that carbon fibers, which were not well bonded to the polymer matrix, acted as crack nucleation sites and cracks propagated much faster in this material than in unreinforced polymer. Recently, the lipophilic natural antioxidant vitamin E was introduced in UHMWPE to improve its oxidation resistance in the long term.[32] This additive does not appear to affect the wear and mechanical properties of UHMWPE detrimentally, and we discuss the properties of vitamin E-stabilized UHMWPE in detail in the following sections.

6.603.3. The Effects of Sterilization and Early Developments

During the first three decades of UHMWPE as a joint arthroplasty material and as recently as 1995, UHMWPE was typically sterilized with a nominal dose of 25–40 kGy of gamma radiation in the presence of air. However, it was clearly shown that this sterilization process led to increased oxidation, accompanied by recrystallization, embrittlement, and general degradation of the mechanical integrity of the implant (**Figure 2**).[33] By 1998, all of the major orthopedic manufacturers in the United States were either sterilizing UHMWPE using gamma radiation in a reduced oxygen environment or sterilizing without ionizing radiation, using ethylene oxide or gas plasma. Today, gamma sterilization in inert atmosphere is a standard for implants using radiation sterilization. Implants, which are produced with reduced or no free radicals, as we discuss later, use nonionizing techniques of gas plasma or ethylene oxide gas sterilization. Gamma sterilization in inert gas has reduced the rate of oxidation of the implants in the high oxygen environment on the shelf before implantation.[34]

Sterilizing by ionizing radiation introduces oxidation potential into UHMWPE because of free radicals caused by the irradiation, and these radicals remain trapped in the material in the long term (**Figure 3**). The mechanism of generation and methods of reducing, eliminating, or stabilizing these free radicals are discussed in detail later in the chapter; however, the benefit of ionizing radiation over nonionizing sterilization methods should briefly be mentioned here. While increasing oxidation potential, radiation also induces cross-linking in the polymer, which significantly reduces the wear of UHMWPE as a function of increasing radiation dose.[35–37]

The need to compare the oxidative stability of UHMWPEs with different free radical and oxidation burdens brought about the development of *in vitro* preconditioning and accelerated aging methods.[1] From a variety of accelerated aging studies involving increased temperature, oxygen partial pressure, and in some cases, the addition of oxidizing media such as hydrogen peroxide, two testing methods have emerged as 'standard' preconditioning techniques. The first preconditioning method,[38] relied on thermally aging specimens in a standard air furnace at 80 °C for up to 23 days. The validation of the protocol was with gamma-sterilized UHMWPE (in air) prior to accelerated oxidation or shelf aging for up to 10 years. After 23 days of thermal aging, the maximum oxidation index in the specimens corresponded to that of 7–9 years of shelf aging. In the second method,[39] specimens were preconditioned under 5 atm of pure oxygen at 60 and 70 °C for up to 7 days.

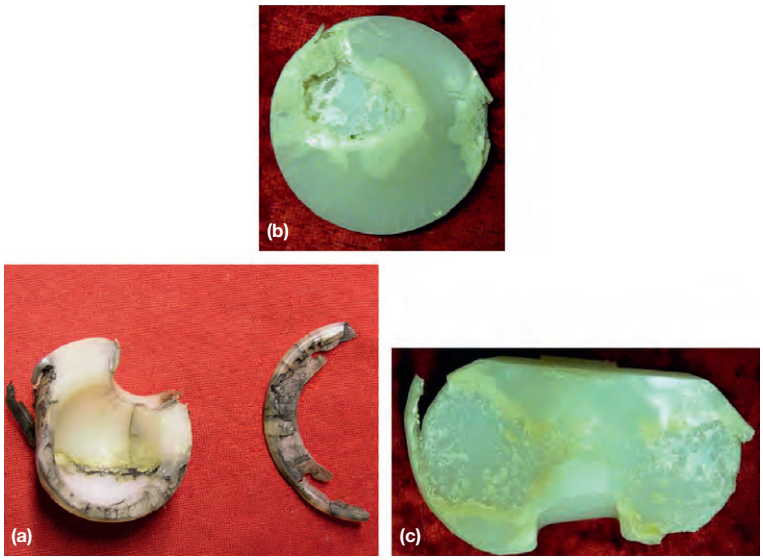

Figure 2 Examples of oxidative damage in hip (a), patella (b), and knee (c) components.

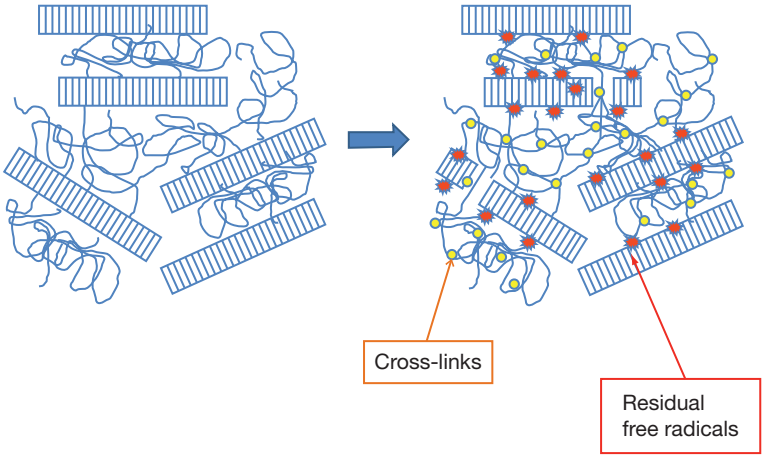

Figure 3 Induction of free radicals and cross-link in UHMWPE on irradiation.

The specimens preconditioned at 70 °C exhibited a subsurface oxidation peak, similar to that observed in retrieved components. Using this method, 1 week of preconditioning at 70 °C and 5 atm of pure oxygen resulted in oxidation equivalent to 5–10 years of ambient shelf aging. In subsequent research, 2 weeks was adopted as a 'standard' aging duration at 70 °C and 5 atm of oxygen.[9,40]

These early developments in accelerated aging protocols were designed to differentiate UHMWPE with and without the oxidative burden of residual free radicals from irradiation. These methods do not produce any difference between the newer generations of UHMWPE materials without free radicals or with substantially reduced oxidation potential. Oxidation-resistant materials have been introduced clinically relatively recently (irradiated and melted UHMWPEs since 1999, and vitamin E-stabilized and irradiated UHMWPEs since 2007); therefore, it is yet somewhat early to compare new *in vitro* accelerated aging methods to *in vivo* results. Nevertheless, several *in vitro* methods, including real-time aging in aqueous environment at body temperature,[41–43] thermal aging combined with cyclic loading,[44,45] and thermal aging combined with lipid absorption,[46] are being developed to differentiate between oxidatively more resistant UHMWPEs. These methods also attempt to better simulate the chemical and mechanical environment of the implants *in vivo*.

The level of oxidation in UHMWPE components can be determined using spectroscopic techniques. The oxidation cascade initiated by radiation-induced free radicals results finally in polymer degradation products, which are mainly carbonyl-containing species such as ketones, esters, and acids (Brach del Prever[47]; Costa[48]). Therefore, the area under the IR absorbance of the peak(s) in the 1680–1800 cm^{-1} range is used to quantify oxidation normalizing to an internal standard.[49]

Cross-linking polyethylene by using irradiation doses higher than sterilization dose (>40 kGy) was introduced to decrease the abrasive/adhesive wear of UHMWPE to decrease the incidence of peri-prosthetic bone loss, directly caused by UHMWPE wear debris. In the next section, we describe different cross-linking technologies and also the treatments addressing the oxidation burden introduced by radiation cross-linking.

6.603.4. Cross-linking Technologies

6.603.4.1. Early Experience with Cross-linking

In early developments, cross-linking of UHMWPE was performed by two different methods: radiation cross-linking and chemical cross-linking.[50–52] In the early 1970s, Oonishi *et al.* implanted UHMWPE acetabular cups that were cross-linked in the solid state using 1000 kGy of gamma radiation in the presence of air.[53–58] Oonishi implanted acetabular components made from this material and compared the wear rate to that in patients implanted with control UHMWPE, which were sterilized by ethylene oxide. The radiographic wear measurements showed average rates of steady-state linear head penetration of 0.006 mm $year^{-1}$ for 600 kGy-irradiated UHMWPE, compared to 0.098 mm $year^{-1}$ for ethylene oxide sterilized conventional UHMWPE.[59] In the 1970s, Grobbelaar *et al.* also investigated cross-linking of UHMWPE using up to 800 kGy of gamma radiation in the presence of a sensitizing environment such as acetylene.[60] They observed a 30% increase in the abrasion resistance of the cross-linked UHMWPE as measured by the sand-slurry method.

The use of polyethylenes cross-linked by silane chemistry was first proposed with the hypothesis that cross-linked UHMWPE would exhibit less creep and would contribute to decreased penetration in the early stage of implantation.[50,51,61] They showed a slightly improved creep resistance as well as improved wear resistance at high sliding velocities under unidirectional motion in cross-linked UHMWPE compared to un-cross-linked UHMWPE. They did not show any significant difference between the wear rates of uncross-linked and cross-linked UHMWPEs, but this was because of the lubrication and dynamic conditions they used, which were not in their more clinically relevant form at the time.[62–66,52,67] reported on the wear behavior of 22 mm diameter, silane cross-linked acetabular components, which were actually injection molded HDPE,[1] similar to the material described by Atkinson and Cicek.[50,51] Wroblewski's clinical and joint simulator studies showed remarkable agreement in the wear rates of the cross-linked polymer. After an initial 'bedding-in' penetration of 0.2–0.41 mm at 2 years, the subsequent average penetration rate (or wear rate) was 0.019 mm $year^{-1}$.

Clinical follow-up was at a minimum of 15 years with a maximum of 18.1 years with a total of 17 patients.[68]

Despite the evidence of improved wear resistance also with peroxide-cross-linked UHMWPE, its oxidative stability was of concern.[10,36] While these developments introduced cross-linking as a means of decreasing wear and creep in implant components, the large-scale use of cross-linked UHMWPE in joint implants started in 1999 after development of cross-linking and oxidative stabilization methods using radiation cross-linking.

6.603.4.2. Radiation Cross-linking Followed by Thermal Treatment

6.603.4.2.1. Formation of cross-links and wear reduction through cross-linking

Radiation cross-linking combined with thermal treatment emerged in the late 1990s as a technology to improve the wear and oxidation resistance of UHMWPE acetabular components.[35,36,69] The development of this technology during the past decade led to a series of new alternate UHMWPE bearing materials, including irradiated and melted, irradiated and annealed, sequentially irradiated and annealed, and irradiated and mechanically annealed UHMWPEs.

Understanding the wear mechanism of UHMWPE became central to the aim of improving the wear resistance of this polymer. The analysis of acetabular components retrieved during an autopsy or a revision operation showed that the highly worn areas were polished to a glassy finish on gross examination.[70] Upon investigation under a scanning electron microscope, numerous multidirectional scratches along with fine, drawn-out fibrils with a diameter of 1 μm or less oriented parallel to each other became apparent on the worn articular surfaces. These fibrils were thought to be the most likely source of the wear particles observed in periprosthetic osteolytic tissue.[71] Thus, wear appeared to occur mostly through the breakup of fibrils formed by large-strain plastic deformation and orientation of the surface. The fibrils were weakened in the transverse direction and subsequently ruptured during multidirectional motion of the hip. These *in vivo* findings were later reproduced *in vitro*[65,71,72] using wear testing devices. These researchers showed that the wear rate of UHMWPE increased markedly when the articulation was switched from a unidirectional to a multidirectional motion. The underlying mechanism in the orientation of the surface fibrils is the direction of motion. This orientation increases the strength of the fibrils in this direction and weakens them in the transverse direction. Hence, debris generation occurs easily when the direction of motion is altered.

During ionizing irradiation of UHMWPE, free radicals are formed, the most prevalent of which are the carbon free radicals resulting from the breakage of the C–H bonds[73] and these radicals are found in three forms: the alkyl, allyl, and polyenyl free radicals.[74–76] The polyenyl free radicals are formed especially at higher radiation doses.[77] Most of these free radicals recombine in the amorphous portion of the polymer,[78] where the chains are highly mobile. The reaction of a free radical generated by the cleavage of a C–H and C–C bond results in long-chain branching or Y-linkages by reacting with terminal vinyl groups (**Figure 4**). The recombination of two free radicals formed by the cleavage of C–H bonds on separate chains

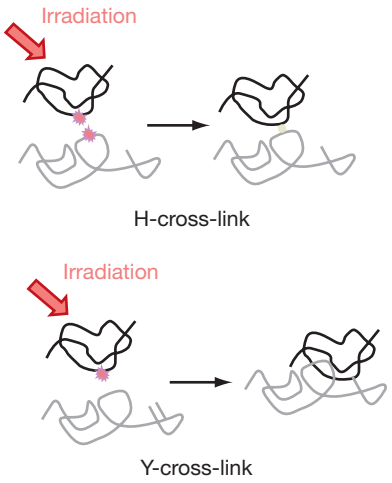

Figure 4 Schematics of cross-linked structures.

results in cross-linking through an H-linkage. The remaining free radicals are trapped in the highly ordered crystalline lamellae.[79,80] As the interchain distance is fixed at 4.1 Å between polyethylene chains in a crystal and the C–C bond distance is 1.5 Å,[81] interchain or intrachain cross-linking is highly unlikely. Therefore, free radicals travel along the crystal chains and encounter other free radicals to form a double bond or encounter the crystalline–amorphous interface. The decay of free radicals in the crystalline phase, therefore, is extremely slow, taking as long as several years.[82]

When oxygen is present in irradiated polyethylene, it reacts with the primary free radicals to form peroxy free radicals.[73,83–86] These peroxy radicals abstract a hydrogen atom from other polyethylene chains, creating primary free radicals, which can then react with oxygen to further this cascade.[87,88] When peroxy free radicals get hydrogenated, they form hydroperoxides, which are not stable and over time degrade into oxidation products, mainly ketones, esters, and acids.[89–93] The formation of these oxidation products is accompanied by chain scission and a decrease in the molecular weight of polyethylene, leading to deterioration of mechanical properties[94–96] (**Figure 5**).

Increasing the entanglement density of UHMWPE through melt-annealing was the first proposal to decrease the extent of surface deformation during articulation. However, quenching of the molten UHMWPE was not effective in maintaining what was thought to be a higher entanglement state of the polymer in the melt. This method was later modified by adding radiation cross-linking at above the melt temperature to lock in the entanglements in place. Later, it became clear that the increase in wear resistance of the polymer was not necessarily due to the increase in entanglement density but was due to the cross-linking. Hence, cross-linking was advanced as a means to impede the formation of surface fibrils and reduce the wear of UHMWPE. Cross-linking of UHMWPE molecules would decrease the chain mobility needed for the large-scale plastic deformation and hence slow down the surface fibril formation.

6.603.4.2.2. The effects of thermal treatment during or after irradiation on oxidation and wear

In first-generation cross-linked UHMWPEs widely available for clinical use,[97] postirradiation thermal treatment was used

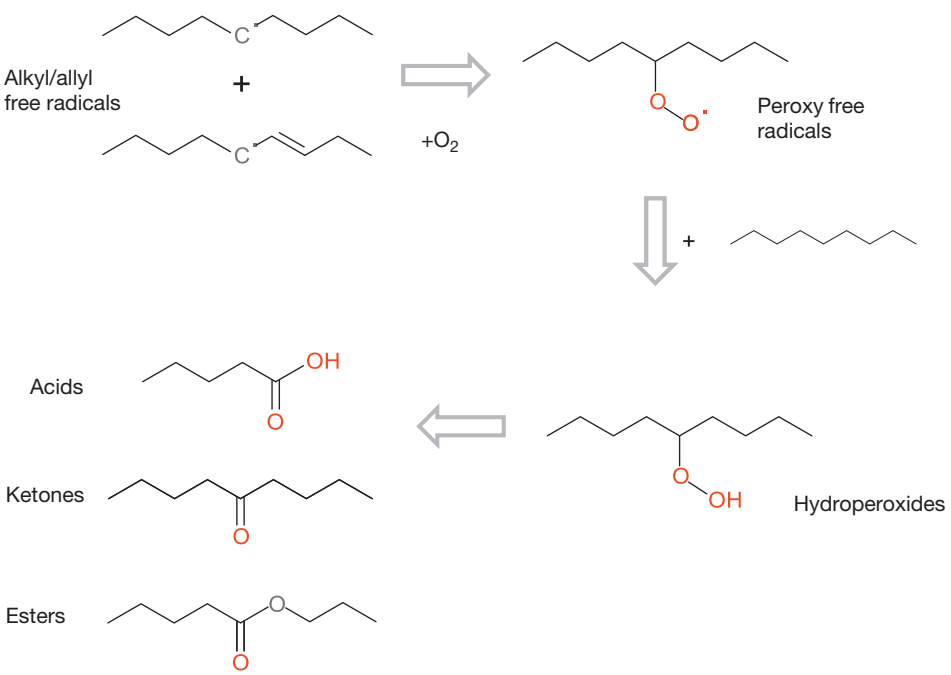

Figure 5 Oxidation cascade in polyethylene.

to increase the oxidation resistance to reduce or eliminate the residual free radicals trapped in the crystalline domains. One approach was to anneal the irradiated UHMWPE below its peak melting point,[98] reducing the free radical concentration by providing more energy to the free radicals and allowing them to recombine to some extent.[99] The free radicals were reduced by annealing, but the implant was also terminally gamma sterilized, which introduced additional free radicals. In the long term, there was significant oxidation in irradiated and annealed UHMWPE *in vivo*.[100–102] In spite of this, at intermediate follow-up (up to 8 years), the *in vivo* femoral head penetration rates with irradiated and annealed UHMWPE are less than those for conventional UHMWPE[103,104] and the clinical effects of this elevated oxidation are not yet manifested.[101] One study showed fatigue damage at the oxidized rim of explanted irradiated and annealed UHMWPE acetabular liners, although none was revised because of rim damage.[100]

The second approach was postirradiation remelting of the crystals to allow for the free radicals to recombine completely. This method reduced the radiation-induced residual free radical concentrations to undetectable levels as measured by electron spin resonance and resulted in very low measurable oxidation in accelerated aging tests.[105] At the same time, recrystallization was hindered by the newly formed cross-links, the crystallinity was reduced, and therefore, the fatigue strength of radiation cross-linked UHMWPE was further reduced.[106] The *in vitro* wear rate[36] and the penetration rates of remelted UHMWPE in the intermediate term (5–7 years) have been very low,[107] but there are some concerns about the increased incidence of rim fracture under impingement and adverse loading conditions because of the lowered fatigue strength of this material.[108–110]

Both gamma and electron beam (e-beam) irradiation have been used to cross-link UHMWPE.[35,105] While the cascade of events that leads to the formation of cross-links and residual free radicals are similar for both gamma irradiation and electron beam irradiation, there are still important differences between the two methods, specifically in terms of penetration of the effects of radiation and radiation dose rate achieved. Gamma irradiation sources are commonly on the basis of the artificial isotope of cobalt (^{60}Co) that generates gamma photons. While the penetration of gamma source into UHMWPE has no practical limitations, the activity level of the gamma source limits the radiation dose rate. With an electron beam, the radiation is in the form of accelerated, charged particles. The penetration of the effects of e-beam radiation is limited by the kinetic energy of the electron beam, measured in million electron volts (MeV). With a 10 MeV electron beam incident on a UHMWPE surface, radiation penetrates about 4–4.5 cm. The radiation dose rate that a commercial e-beam accelerator provides is about two orders of magnitude larger than that from a commercial gamma source.

Because of the high dose rate of irradiation to which the UHMWPE is exposed, adiabatic heating of UHMWPE is common during electron beam irradiation. Electron beam radiation offers a greater control of dose rate, which presented a means to control the temperature rise in UHMWPE during irradiation during the development of highly cross-linked UHMWPEs. This also meant that the polymer could be melted during irradiation. It was also shown that the rate of formation of H-linkages increased with increasing irradiation temperature, thus leading to increased cross-linking.[111] Radiation dose is energy per unit mass of the material being irradiated and it is measured in kGy units, or $kJ\,g^{-1}$. The specific heat of UHMWPE is $\sim 2.5\,kJ\,g^{-1}\,^{\circ}C$; using a radiation dose of 100 kGy, UHMWPE needs to be heated to at least 120 °C to achieve near complete melting of the crystalline domains

during irradiation. The efforts on using e-beam to melt the UHMWPE led to the development of warm irradiated UHMWPE, now used in the fabrication of some total hip and total knee components.[97] In the large-scale manufacturing of warm irradiated UHMWPE, a terminal melting step in an air convection oven is used to ensure that complete melting is achieved and that residual free radicals are eliminated. Surprisingly, warm irradiation of UHMWPE resulted in some unusual properties: Warm irradiated UHMWPE displays two distinct peak melting points, one near 115 °C and the other at 137 °C. This is an indication of a bimodal lamellae thickness distribution. Transmission electron microscopy of warm irradiated UHMWPE corroborated this finding, showing thick lamellae embedded in a matrix comprising smaller and thinner lamellae and the amorphous phase.[69] Warm irradiation and melting of UHMWPE also results in higher ductility and lower strength in comparison with irradiation without preheating and melting.[69]

As the absorbed radiation dose increased, the cross-link density increased with saturation behavior starting at around 100 kGy, beyond which increases in cross-link density decreased rapidly.[36] The multidirectional wear rate of UHMWPE was also shown to decrease with increasing radiation dose, also showing asymptotic behavior with saturating cross-link density. Studies of damaged surfaces of retrieved implants[70] showed that there exists a plasticity-induced damage layer on the articulating surface of implants.[112] As discussed above, increased plasticity results in orientation in the principal direction of motion with weakening in transverse directions. Radiation cross-linking decreases chain mobility and chain stretch; as a result, it decreases the plasticity of the polymer.[106,113–115] This is presumably a major mechanism by which wear was decreased through radiation cross-linking (**Figure 6**).

Investigations on the wear behavior of highly cross-linked UHMWPE on functional joint simulators followed the initial preclinical testing using pin-on-disc wear testers. To obtain more clinically relevant results, simulators have been designed for wear testing.[116–119] Simulators have been designed to match the *in vivo* wear rate, wear debris size, and shape of UHMWPE as well as the surface morphology observed in explanted components by replicating *in vivo* attributes such as component positioning, temperature, loading, and kinematics of normal gait,[120–124] all of which are known to affect the wear rate of UHMWPE. The simulator tests are typically carried out at 1–2 Hz, in bovine serum at 37–40 °C to simulate joint temperature. Wear is assessed gravimetrically and can be measured also by a volumetric method using a coordinate measuring machine, which can measure the three-dimensional shape of the articular surface. When measuring wear volumetrically, creep deformation of UHMWPE has to be separated from wear; this can be done by melting the component after testing is completed as UHMWPE has excellent shape memory and creep deformation can be eliminated by remelting the component (**Figure 7**[125]). Limitations of simulators are the choice of kinematics, which is usually limited to normal gait kinematics in contrast to a complex variety of activities of daily living. Another factor affecting wear in the simulator is the testing environment. While bovine serum is the accepted analog for synovial fluid, dilution of bovine serum with water to obtain protein concentrations relevant to *in vivo* conditions is commonly used. However, wear of conventional (gamma-sterilized) UHMWPE has been shown to increase with bovine serum dilution.[66] At high water concentration, nonphysiological wear mechanisms can dominate the wear process.[63] Other factors that may affect the outcome are surface finish of the metallic counterface, stress levels, and loading mode (dynamic vs. constant).[126]

Hip simulator studies of various designs with irradiated and melted UHMWPE all showed significantly improved wear resistance (60–90% decrease) in comparison with conventional UHMWPE. Some studies used gamma in air-sterilized UHMWPE and others used ethylene oxide or gas plasma-sterilized UHMWPE as controls. Note that the gamma-sterilized controls would have some cross-linking and thus would also have a lower wear rate than the controls sterilized by nonionizing methods. The hip simulator studies explored the influence of long-term use, artificial aging, presence of third-body particles, femoral head size, and, later, component

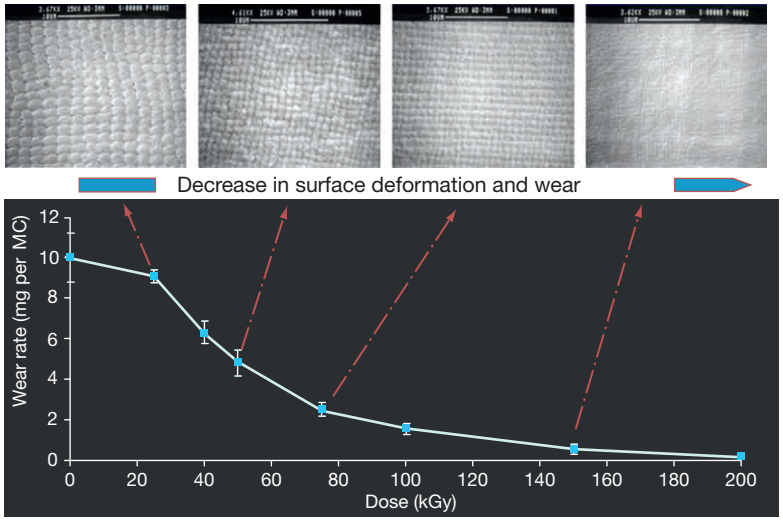

Figure 6 The effect of cross-linking on surface features and wear.

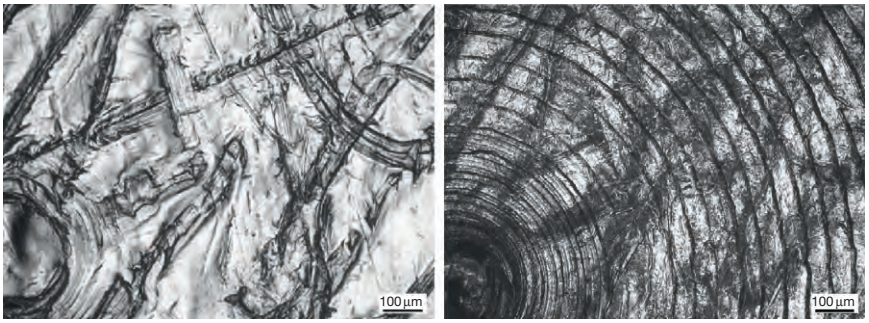

Figure 7 The recovery of surface deformation of cross-linked UHMWPE by melting.

placement on the wear of irradiated and melted UHMWPEs. Some studies were carried out to 30 million cycles, corresponding to 15–30 years of *in vivo* service of an average total hip patient.[35,66,69,125,127,128] These studies showed that the marked reduction in wear was not affected by the long-term testing and that there was no fatigue-induced wear. The addition of third-body particles, in the form of bone cement, increased the wear of both conventional and highly cross-linked UHMWPEs; yet the latter still exhibited better wear resistance. Standard artificial aging protocols did not oxidize the irradiated and melted UHMWPEs appreciably because of the improved oxidation resistance and as a result did not affect their wear rate.

The femoral head size is an important effect in that with larger heads the wear rate of conventional UHMWPE acetabular liners increases.[128] Even though there is an increase in the contact area and hence a reduction in contact stress, wear increases with head size because of the dominant increase in the distance traveled at every gait cycle. Historically, smaller heads, 22 to 28-mm-diameter femoral heads, had been used to minimize the wear of the liners. Yet, the disadvantage of smaller heads is the decrease in the stability and the range of motion of the joint.[129] Hip simulator studies also showed that interestingly, there was not any significant increase in the wear rate of UHMWPE when tested against larger femoral heads and the wear rate of an acetabular liner with an inner diameter of 46 mm and fabricated with irradiated and melted UHMWPE was lower than that of a 22-mm conventional UHMWPE acetabular liner.[128]

There have been a number of clinical trials comparing the *in vivo* performance of irradiated and melted UHMWPE to that of conventional UHMWPE acetabular liners.[130–132] Radiographic examination of the patients allows the measurement of femoral head penetration into the acetabular liner. The penetration for the first 1–2 years is mostly due to creep and wear, and beyond the second year of follow-up, penetration is attributed to mostly wear alone. All of these studies are showing markedly reduced wear rate with highly cross-linked UHMWPE beyond the second year of follow-up compared to the respective controls (regardless of sterilization method), corroborating the laboratory evidence of reduced wear.[69,128]

6.603.4.2.3. Development of highly cross-linked total knees

The development of highly cross-linked UHMWPE for use in tibial knee inserts followed the introduction of this material in total hips. Knee simulator studies on the wear behavior of irradiated and melted UHMWPE tibial knee inserts have been widely published.[133–139] These investigations focused on the effect of long-term testing, artificial aging, presence of third-body particles, implant design, and most importantly on malpositioning of the implants. The studies uniformly showed improved adhesive/abrasive wear with irradiated and melted UHMWPE in comparison with conventional gamma-in-air or -in-nitrogen sterilized UHMWPE tibial knee inserts of either cruciate retaining or posterior stabilized designs. Artificial aging of the test components was used to simulate long-term oxidation in the conventional UHMWPE and the testing of these components on the knee simulators showed delamination damage. When the irradiated and melted UHMWPE components were subjected to identical accelerated aging conditions and tested on the knee simulator, they showed no delamination or pitting.[138] In the presence of third-body particles, the highly cross-linked UHMWPE components still showed lower wear rate than conventional UHMWPE. Investigations also showed that the highly cross-linked UHMWPE exhibits better wear performance when it is articulated against surgically explanted femoral components that had been extensively damaged during *in vivo* service.[137]

In total knees, the malpositioning of components can seriously compromise not only the knee function but also the performance of the UHMWPE components used because of the altered stress state.[136] The highly cross-linked UHMWPE tibia inserts were also tested under certain worst-case scenarios. One is the circumstance of a tight posterior cruciate ligament (PCL), which would increase the roll back of the femoral component during flexion and apply high stresses to the posterior edge of the tibial component. Under these conditions, accelerated aged conventional UHMWPE tibial inserts showed massive delamination in less than 50 000 cycles of stair climbing, while the aged highly cross-linked components showed no delamination up to 500 000 cycles.[136]

Backside wear is another important factor that could affect long-term performance of total knees. Knee simulator studies also showed that the extent of backside wear decreases markedly with irradiated and melted UHMWPE in comparison with that observed in conventional UHMWPE.[138]

There have been a number reports on the *in vivo* performance of irradiated and melted UHMWPE based on changes observed on surgically explanted components.[140,141] Interestingly, the articular surfaces of the first retrievals were very

highly scratched and discolored. Plastic deformation due to third-body particles was the culprit despite an initial fear that the scratches were due to wear and the discoloration due to oxidation. We used the shape memory property of UHMWPE and showed by melting of the explants the elimination of the scratches and recovery of the original machining marks.[140] The discoloration was not due to the oxidation of the components but simply due to the absorption of the lipids from the synovial fluid.[140] While wear polishes the articular surface and removes the scratches and discoloration, in irradiated and melted UHMWPE scratches and discoloration accumulate, which points to the lack of wear in these components. Similar observations were also made with surgically retrieved tibial knee inserts that were made from irradiated and melted UHMWPE.[141]

While there have not been any published prospective, randomized clinical studies looking at highly cross-linked UHMWPE knees, one retrospective, case-matched series of 200 patients compared highly cross-linked knee implants with conventional knee implants at a follow-up of 6–7 years[142] and showed that there was a significant reduction in cases showing radiolucency (2 compared to 20 for control), and no revisions due to osteolysis in the highly cross-linked cohort. The irradiated and melted UHMWPE has been in clinical use around the globe for the past decade with more than two million implantations.[97]

6.603.4.2.4. Mechanical and fatigue properties

There are compressive and shear forces on UHMWPE during articulation, and there may be residual tensile stresses that arise from accumulated stress during repeated load cycles.[143] The reversal of stress direction causes fatigue cracks to initiate causing delamination, especially in total knee implants.[144,145] Therefore, besides wear, the second most important property change in UHMWPE induced by irradiation is its fatigue resistance. Fatigue testing is performed in cyclic tension on a compact tension specimen,[146] which is designed to concentrate applied stress at a notch tip with an existing crack. A stress factor at crack inception (ΔK_i) is calculated as a measure of fatigue crack propagation resistance. This is the stress factor range (dependent on the load ratio, sample geometry, and crack length), at which the crack growth rate exceeds 10^{-6} mm per cycle. The ΔK_i of unirradiated UHMWPE is reported as 1.6–2.0 MPa $m^{1/2}$.[26,147] The temperature at which the testing is performed (25 vs. 40 °C), the frequency used in the test, testing environment (air vs. water), and the crack initiation method are some factors that account for the variation in the results obtained from different laboratories.

With increasing cross-link density, the fatigue crack propagation (FCP) resistance decreases.[106,148] On the other hand, crack initiation resistance increases with cross-linking.[149] While irradiation alone decreases the FCP resistance, melting subsequent to irradiation further decreases the FCP resistance.[106] This decrease is again related to the decrease in the ductility of the materials and is also manifested in other mechanical properties such as the elongation to break. The tensile mechanical strength of UHMWPE is mainly dependent on its crystallinity and therefore, irradiation by itself does not adversely affect the strength. On the other hand, melting after or during irradiation decreases the crystallinity and therefore decreases the strength.[106] Recrystallization of the polymer chains is hindered by the presence of cross-links, and chain mobility and reptation needed for the lamellae to form are limited. However, the decrease in crystallinity results in an increase in compliance of the polymer, which is desirable in load-bearing applications as it decreases the contact stress.[150]

The fatigue strength may be decreasing with cross-linking and melting, but understanding the effects of these changes on implant performance is complicated by the design and use of the implants. Fatigue failures reported with irradiated and melted UHMWPE acetabular liners are rare; however, when they occur, these failures are primarily at the rim and almost always occur with steep shell placement.[108,109] While some occurrences of fracture were reported with acetabular liners,[110] none was reported with highly cross-linked tibial knee inserts.

Orthopedic implant manufacturers chose different radiation dose levels as the optimum for irradiation and melting. The debate continues between 100 kGy and 50 kGy as being the optimum dose levels. As we explained above, the beneficial effects of radiation cross-linking in terms of increasing the wear resistance decrease rapidly above 100 kGy. Thus, the optimum radiation dose rate for increasing wear resistance is around 100 kGy. At 50 kGy, some of the mechanical properties, such as toughness and elongation at break, are higher with a lower wear resistance compared to that at 100 kGy. The argument between 50 and 100 kGy is mainly how much reduction in wear is needed to prevent periprosthetic osteolysis. While there have been cases of osteolysis in 50 kGy irradiated and melted UHMWPE[151] clinically, we need long-term (beyond 10 years) clinical studies to determine the comparative incidence of periprosthetic osteolysis and loosening while using this and conventional UHMWPE.

6.603.4.3. Sequential Irradiation and Annealing

While the clinical significance of measured oxidation levels in highly cross-linked UHMWPE is not clear, it is clear that oxidized conventional UHMWPE gamma sterilized in air caused high incidence of wear and damage on total joint implants. It is also clear that a UHMWPE with residual free radicals has high oxidation and thus degradation potential. Therefore, a sequentially irradiated and annealed UHMWPE (X3™) was also developed to replace the irradiated and annealed UHMWPE (Crossfire™), which showed oxidation *in vivo*.[100,102] The hypothesis was that smaller doses of irradiation (30 kGy) followed by high temperature annealing below the melting point (at 130 °C) would lead to more effective reduction of free radicals and less oxidation potential. Also, in contrast to the original material, this annealed UHMWPE is sterilized by nonionizing gas plasma sterilization in order not to introduce an extra oxidative burden on the material. In one study, where X3 UHMWPE was compared to conventional, gamma-sterilized UHMWPE and 90 kGy irradiated and thermally annealed UHMWPE, the free radical content of X3 was low but detectable (9×10^{15} mg MC^{-1}).[152] In a separate test performed in our laboratory, the free radical content of two never implanted X3 acetabular liners from two different lots showed a substantial free radical signal. The free radical concentration of X3™ was 1.12×10^{15} spins per gram in comparison to 2.6×10^{15} and 4.3×10^{15} spins per gram for

conventional and Crossfire™ acetabular liners. The oxidation rate of this material *in vivo* and the effects of this oxidation in the properties are yet to be determined.

Hip simulator wear testing of 32 and 36 mm unaged X3 acetabular liners was performed for 10 million cycles in 50% fetal substitute alpha calf serum diluted by deionized water.[99,153] The wear rate of X3 was substantially reduced compared to gamma-sterilized UHMWPE tested for 5 million cycles. This study showed that the wear behavior of X3 is substantially better than that of conventional UHMWPE in its unaged state.

The main advantage of irradiation followed by annealing below the melting point is the retention of the crystallinity of radiation cross-linked UHMWPE as melting of the crystals is avoided. Thus, the mechanical properties and fatigue strength of this material would be substantially changed from that of the cross-linked state in contrast to irradiated and melted UHMWPE, whose fatigue strength is decreased around 30% by postirradiation melting. The crystallinity of X3 UHMWPE was reported to be about 62% before and after accelerated aging in a pressure vessel at 70 °C at 5 atm oxygen for 2 weeks, compared to 61.3% and 70.8%, respectively for conventional UHMWPE.[153] These suggest that the crystallinity of X3 is close to that of conventional UHMWPE. The ultimate tensile strength of X3 UHMWPE before and after aging was 56.7 and 56.3 MPa compared to 54.8 and 29.9 MPa, respectively, for conventional UHMWPE.[153]

The need to develop a wear- and oxidation-resistant cross-linked UHMWPE with improved fatigue properties led to the development of a second-generation cross-linked UHMWPE with antioxidant stabilization. The rationale behind the development of this material was that the residual free radicals from the radiation cross-linking could be stabilized by the antioxidant vitamin E, thus eliminating the need for postirradiation melting for oxidative resistance. This would lead to the retention of crystallinity and fatigue resistance. The next section is devoted to vitamin E-stabilized highly cross-linked UHMWPE.

6.603.5. Vitamin E-Stabilized, Radiation Cross-linked UHMWPE

6.603.5.1. The Rationale and Incorporation Methods

Vitamin E stabilization of UHMWPE was introduced as an alternative method to provide oxidation resistance without sacrificing some of the fatigue strength.[32] There are two methods by which vitamin E can be incorporated into radiation cross-linked UHMWPE. The first is blending of the liquid antioxidant with UHMWPE resin powder, consolidating the mixture by compression molding, and irradiating the consolidated blend for cross-linking.[154–157] Because vitamin E can act as a free radical scavenger during irradiation as well, the cross-linking efficiency of UHMWPE is lowered in the presence of vitamin E[156,157] and the vitamin E concentration in the blend is limited to less than about 0.3 wt%.[158] In addition, the radiation dose has to be optimized as it is necessary to expose a vitamin E blend to a higher dose irradiation than virgin UHMWPE to obtain a desired cross-linking or wear rate. Nevertheless, this vitamin E-stabilized UHMWPE is promising in decreasing oxidation of irradiated UHMWPE[155,159] and can have low wear rates if the vitamin E concentration and radiation dose are optimized.[156,158] Recently, medical grade UHMWPE resin supplier Ticona (Florence, KY) has announced its large-scale production of vitamin E-containing resin for various ultimate applications and a 0.1 wt% vitamin E-containing, 91-kGy irradiated UHMWPE acetabular cup was implanted in Switzerland in 2009.[160] The second approach, which we describe in detail in this chapter, is diffusing vitamin E into already consolidated and radiation cross-linked UHMWPE. Using this method, the amount of incorporated vitamin E is not limited by the cross-link density, but the saturation limit of the cross-linked polymer at body temperature, which is approximately 0.7 wt%. Total hip implants manufactured from 100-kGy irradiated, vitamin E-diffused, and terminally gamma-sterilized UHMWPEs have been clinically used since 2007. Prospective, randomized clinical studies, including an RSA study based at our institution, are underway.[161]

6.603.5.2. Mechanism of Action Against Oxidation

Vitamin E is the most abundant and effective chain-breaking antioxidant present in the human body.[162] The major physiological role of vitamin E is to react with free radicals in cell membranes and protect polyunsaturated fatty acids from degradation due to oxidation.[163] Oxidation of polyunsaturated fatty acids results in active free radicals (LOO•, LO•). The antioxidant activity of vitamin E (RRR-α-tocopherol *in vivo*) is due to hydrogen donation from the phenolic OH group on the chroman ring to a free radical on the oxidized lipid chain. Hydrogen abstraction results in a tocopheryl free radical, which can combine with another free radical. Therefore, tocopherol can theoretically prevent two peroxy free radicals from attacking other fatty acid chains and producing more free radicals.[164–166] Therefore, the cascading nature of oxidation is stopped, and oxidative damage can be prevented.

Oxidation reactions in polyethylene, which has a lipid-like molecular structure, also follow a similar mechanism of oxidation as lipids do *in vivo*.[87,91,167] In irradiated UHMWPE, the carbon free radicals resulting from the breakage of the C-H bonds are prevalent.[73] When oxygen is present in irradiated polyethylene, it reacts with the primary free radicals to form peroxy free radicals.[83–86] These peroxy radicals, in the absence of an antioxidant such as vitamin E, abstract a hydrogen atom from other polyethylene chains, creating new primary free radicals, which can then react with oxygen to further this chain of reactions.[87,88] When peroxy free radicals react with hydrogen, they form hydroperoxides, which are not stable, and degrade into oxidation products, mainly ketones, esters, and acids.[89,90,92,93] The formation of these oxidation products is accompanied by chain scission and a decrease in the molecular weight of polyethylene, deteriorating its mechanical properties.[94–96] In an irradiated polyethylene containing vitamin E, peroxy free radicals presumably abstract a hydrogen atom from vitamin E, forming hydroperoxides without the formation of new free radicals. Vitamin E is also effective in reacting with alkyl radicals,[168] but the reaction rate with peroxy free radicals is higher than that with any other radical.[164,166] The oxidation cascade in irradiated polyethylene is, therefore, hindered in the presence of vitamin E.

6.603.5.3. Diffusion of Vitamin E in UHMWPE

For vitamin E to be able to protect UHMWPE against oxidation, the antioxidant has to be distributed throughout the entire thickness of the component.[169] Polyethylene can be doped with vitamin E simply by allowing it to remain in a bath of pure or diluted vitamin E (**Figure 8(a)**). Because vitamin E is highly hydrophobic, it diffuses readily into polyethylene, especially at elevated temperature; however, on the application of this concept, there are several factors to be considered.

First, it is important not to melt the sample substantially during the diffusion process and thereby to avoid the loss of crystallinity during postirradiation melting, which causes a decrease in mechanical strength.[106] The melting range of UHMWPE starts at 100 °C with a peak melting point of about 140 °C; more crystallinity is lost as the diffusion temperature nears the peak melting point. Increased temperature also increases the surface concentration and the saturation concentration of vitamin E at the surface of UHMWPE.[170,171] Dimensional changes can occur both due to the thermal release of residual stresses from previous processing steps and due to the swelling of the surface with vitamin E. A slightly oversized preform can be processed and machined as a terminal step before sterilization to overcome changes in dimensions.

To obtain a uniform vitamin E concentration profile throughout components of various thicknesses, a two-step diffusion process at elevated temperatures below the melting point was developed involving doping of UHMWPE by soaking in vitamin E with subsequent homogenization at an elevated temperature below the melting point.[170] The doping step was restricted to 120 °C because there were significant volumetric and weight changes above this temperature. When a high surface concentration of vitamin E had been obtained, the homogenization of the surface vitamin E throughout the irradiated component could be achieved at a higher temperature below the melting point because there was no additional diffusion of vitamin E into the component.

A secondary effect of exposing the polyethylene to high temperature during doping and homogenization would be to decrease the amount of residual free radicals caused by radiation cross-linking. But, a terminal sterilization by gamma irradiation is used currently in clinically available implants prepared using this method, resulting in substantially detectable free radicals in this material (3.5×10^{16} spins per gram compared to 11.7×10^{16} spins per gram for 100-kGy irradiated UHMWPE;[42]). Despite the presence of these free radicals, vitamin E-stabilized UHMWPE has shown great oxidative stability when subjected to accelerated aging as discussed later.

During irradiation, vitamin E hinders cross-linking in UHMWPE as a function of increasing concentration.[156,157] In fact, at vitamin E concentrations above 0.3 wt%, the incremental increase in cross-link density by increasing the radiation dose is minimal and it is not possible to cross-link vitamin E-containing UHMWPE to the same level as that of 100-kGy irradiated and melted UHMWPE even at irradiation doses as high as 200 kGy.[158] The terminal gamma irradiation for sterilization causes a very small increase in cross-link density. At the same time, some vitamin E is grafted onto the polymer chain by the postdiffusion irradiation, preventing elution out of components;[172] therefore, it may be desirable to graft some of the vitamin E in the material.

6.603.5.4. Oxidative Properties

A major factor limiting the maintenance of the wear and mechanical properties of irradiated UHMWPEs *in vivo* is oxidation.[33] Oxidation is determined by spectroscopic techniques measuring carbonyl moieties on UHMWPE formed as a result

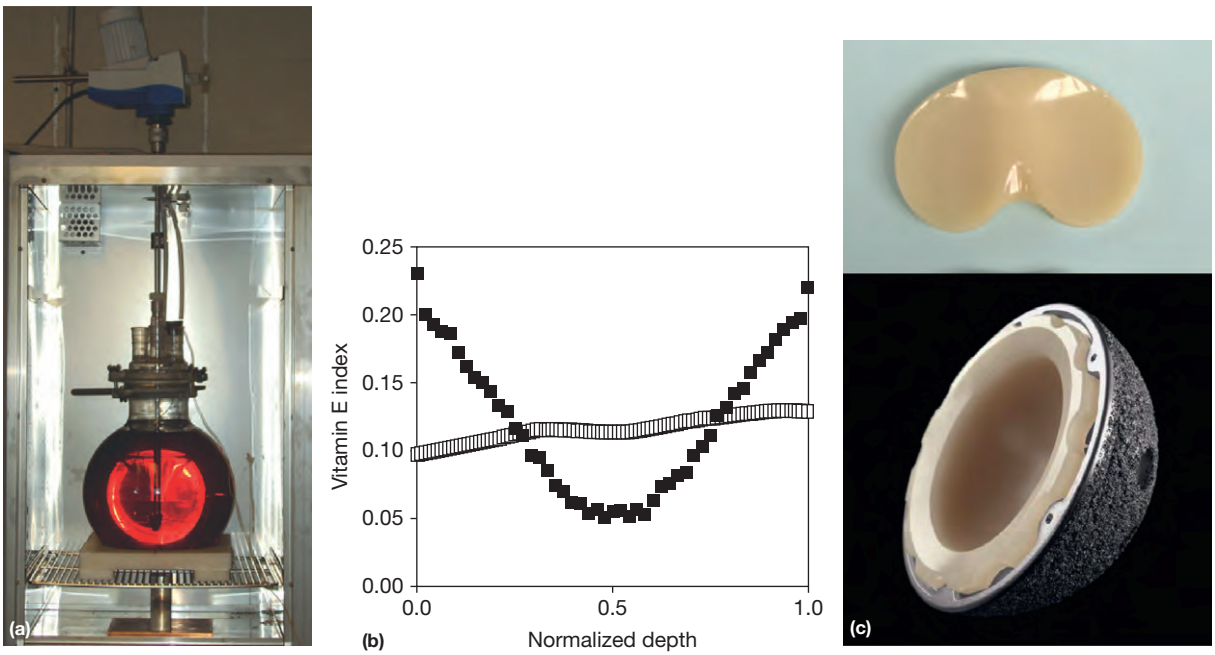

Figure 8 Benchtop pilot setup for vitamin E doping of UHMWPE (a); representative profiles of a component with a vitamin E-rich surface and a uniform vitamin E profile (b); vitamin E-diffused, radiation cross-linked joint implant components (c) (courtesy of Biomet).

of the decay of hydroperoxides.[173] Typically accelerated aging methods are used *in vitro* to compare the oxidative stability of various polyethylene formulations.[9] While accelerated aging is helpful in comparing the oxidation resistance and oxidation potential of different types of bearing materials, it cannot be used to predict the oxidation timeline or profile of a particular material *in vivo*.

Nevertheless, it has been shown in several types of accelerated aging studies, carried out at elevated temperatures and/or in the presence of pure oxygen under high pressure, that vitamin E-containing, irradiated polyethylene is more stable than gamma-sterilized or high-dose irradiated polyethylene.[32,106,154,155,159,174–176] It is proposed that this is due to the reaction of vitamin E with the primary free radicals on the polyethylene chains and also free radicals resulting from their reaction with oxygen. In a study looking specifically at the stabilizing effect of vitamin E in vitamin E-diffused, irradiated UHMWPE showed higher oxidative stability than unstabilized, irradiated UHMWPE over 7 months in air at room temperature and in water at 40 °C[42](showing similar trends at 36 months; **Figure 9**).[177]

As mentioned above, a cross-link density equivalent to that of 100-kGy irradiated and melted UHMWPE is desired because this material has been shown *in vitro* and *in vivo* to decrease wear significantly compared to conventional UHMWPE.[69,130] The studies discussed here were performed on UHMWPE with an initial radiation dose of 85–100 kGy and with a terminal gamma sterilization dose of ~25–40 kGy after vitamin E incorporation designed to obtain similar wear resistance to this predicate material.

6.603.5.5. Wear

Wear testing of vitamin E-diffused, 100-kGy irradiated UHMWPE on a custom-designed pin-on-disc tester in bovine serum showed that the wear rate was comparable to that of 100-kGy irradiated and melted UHMWPE.[32] In this study, accelerated aging at 80 °C for 5 weeks did not change the wear rate of this UHMWPE despite the fact that vitamin E was diffused only 0.5 mm into the surface of this sample and not throughout the entire thickness. This suggested that the wear region was within this surface layer protected by the vitamin E.

After the development of the diffusion method by doping followed by homogenization below the melting point, 5-mm thick acetabular liners were irradiated by 85-kGy gamma irradiation, doped with vitamin E, subsequently homogenized to obtain vitamin E throughout, and terminally gamma-sterilized. These acetabular liners (28- and 40-mm inner diameter) were wear-tested on a hip simulator against CoCr femoral heads using normal gait load and kinematics at 2 Hz in undiluted clean bovine serum for 5 million cycles and compared to conventional UHMWPE gamma sterilized in inert gas.[178] This study showed *in vitro* that under normal conditions, the wear reduction in vitamin E-diffused, highly cross-linked UHMWPE compared to conventional UHMWPE (**Figure 10**; 92% and 90% reduction in wear for 28- and 40-mm cups, respectively, compared to 28-mm conventional UHMWPE) was comparable to what was observed previously with irradiated and melted UHMWPE compared to conventional UHMWPE.[69,128] Similar results were observed when these liners were tested in undiluted bovine serum with third-body polymethyl methacrylate (PMMA) and barium sulfate particulate debris (72% and 75% reduction in wear for 28- and 40-mm cups, respectively, compared to 28-mm conventional). The results obtained from these hip simulator studies with vitamin E-diffused, irradiated highly cross-linked UHMWPE confirmed earlier studies that showed that the wear rate of highly cross-linked UHMWPEs was largely independent of femoral head size.[128]

There are concerns about the ability of highly cross-linked UHMWPEs to withstand especially two clinically adverse situations. One of these is the femoral neck impingement on the rim of an acetabular liner, most often because of the vertical placement of the shell with excessive anteversion.[109,110] There is increased concern for highly cross-linked UHMWPEs because of their initially lower fatigue strength than that of unaged conventional UHMWPE and the fact that larger head sizes with thinner polyethylene can now be used, thanks to the independence of the wear rate of highly cross-linked UHMWPEs from femoral head size.[128,179,180] In a clinically

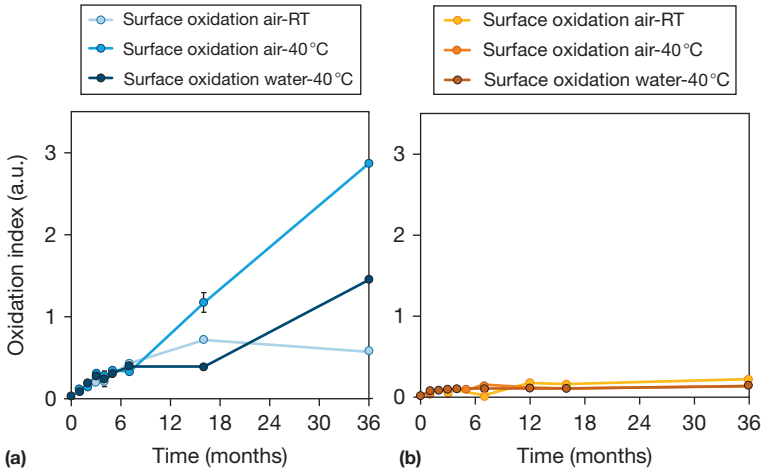

Figure 9 Oxidation levels of radiation cross-linked (unstabilized) (a) and vitamin E-diffused, radiation cross-linked UHMWPEs (b) after real-time aging for 3 years.

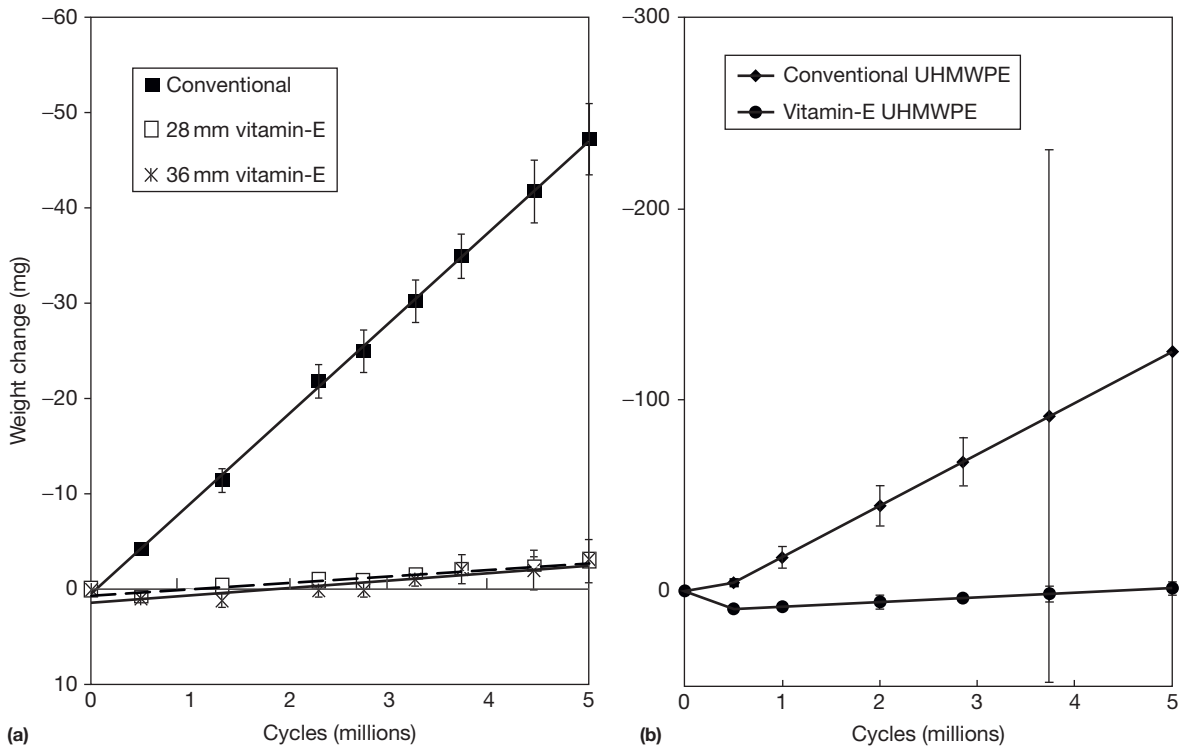

Figure 10 Hip (a) and knee (b) simulator wear data of unaged vitamin E-diffused, radiation cross-linked UHMWPE against conventional, gamma-sterilized UHMWPE in clean serum.

relevant device fatigue test involving the impingement of the rim of thin polyethylene liners by the neck of the femoral components, simulating the adverse case of vertical malpositioning of the implant, 3.7-mm-thick vitamin E-diffused, cross-linked acetabular liners with 28- and 40-mm inner diameter were loaded on the rim by the femoral neck for 2 million cycles. There were no fractures in any of the tested liners, including the conventional UHMWPE liners with 28 mm inner diameter used as controls. No apparent differences between unaged conventional UHMWPE and vitamin E-diffused, highly cross-linked UHMWPE were observed.[178]

6.603.5.6. Peri-Prosthetic Effects

Wear debris of conventional UHMWPE has been clearly associated with osteolysis and loosening of implants.[181,182] Currently, there is no conclusion on the differences in the biological activity of the wear debris from highly cross-linked UHMWPE compared to conventional UHMWPE. While the average particle size of highly cross-linked UHMWPEs appears to be smaller than that of conventional UHMWPE, the number of particles is also significantly lower. In addition, conventional UHMWPE has been associated with high oxidation not observed in irradiated and melted UHMWPE; therefore, the activity of the particles may not be the same.[183] In fact, there is recently one study showing that vitamin E-containing wear particles of uncross-linked UHMWPE reduced the biological response of cells *in vitro* as measured by tumor necrosis factor-α (TNF-α) production.[184] Vitamin E may also have a direct role in regulating immune response when associated with UHMWPE particles on the basis of an *in vitro* study indicating that vitamin E-stabilized unirradiated UHMWPE increased matrix metalloproteinase-9 secretion from granulocytes.[185]

Vitamin E is found in foods such as vegetable oils, nuts, seeds, whole grains, leafy green vegetables, and avocados.[186] The vitamin E commonly used for the stabilization of radiation cross-linked UHMWPE is produced synthetically and is certified to be at least 97% pure α-tocopherol. Both synthetic and natural vitamin E are regarded as safe for human consumption by the Food and Drug Administration as additives in prepared food in accordance with current good manufacturing principles.[187] There are no known adverse effects of the consumption of vitamin E naturally occurring in food. One major concern regarding vitamin E-stabilized UHMWPE involves its possible elution from the polymer *in vivo* and its local/ systemic effects. There was measurable elution of vitamin E from vitamin E-diffused UHMWPE aged in the laboratory in water at 40 °C for 3 years.[177] This was attributed to the surface vitamin E concentration being higher than the saturation concentration of vitamin E in early-phase vitamin E-diffused, irradiated UHMWPE at 40 °C. The concentration profile became uniform at a vitamin E level of ~0.7 wt% at 3 years, suggesting that this was the saturation concentration. Nevertheless, these components did not show any detectable oxidation at 3 years. To quantify the effects of complete elution on the oxidative stability of vitamin E-diffused cross-linked UHMWPE, a clinically irrelevant extraction procedure in boiling hexane was used,[172] after which some vitamin E remained in the samples. These samples were exposed to accelerated aging after extraction and did not

oxidize despite the removal of most of the vitamin E. This suggested that under clinically relevant conditions, the complete removal of vitamin E from the components was highly unlikely and that the components would be protected even under adverse conditions. In addition, currently clinically used components are prepared to have a more uniform concentration at around 0.7 wt% before sterilization, which would minimize the driving force for elution out of the components.

Regarding the peri-prosthetic effects of the elution of vitamin E from irradiated UHMWPE, Wolf *et al.*[188] have determined that there were no cellular cytotoxic or genotoxic effects of vitamin E extracted from a vitamin E-blended and terminally gamma-sterilized UHMWPE containing 0.8 wt% vitamin E *in vitro*. In a study investigating the local toxicity of vitamin E, an emulsifying agent (Tween 80™) was used to solubilize vitamin E in an aqueous solution, in order to simulate the mechanism of vitamin E transport conjugated to lipoproteins. In this study, 2 ml of this emulsion (10 mg of vitamin E) was injected to the knee joints of New Zealand white rabbits and the animals were sacrificed at 2 weeks ($n = 3$) and at 12 weeks ($n = 6$). The control knee was injected with the carrier solution without vitamin E. The findings were that regardless of the time *in situ*, the synovial tissue had a normal appearance at harvest and there were no signs of inflammation or sterile puss. The tissue of all control knees had the same unremarkable appearance.[189]

The effect of vitamin E on the device fixation of vitamin E-diffused, irradiated UHMWPE was investigated in a canine hip model.[189] A comparison between bony ingrowth (using histology) of cups with vitamin E-diffused, irradiated UHMWPE liners ($n = 14$) and irradiated, unstabilized UHMWPE liners ($n = 7$) showed no significant differences between the two groups after 3 months of implantation time.

6.603.5.7. Mechanical and Fatigue Properties

As mentioned above, there is a decrease in mechanical and fatigue strength of irradiated and melted UHMWPEs, caused both by cross-linking and the loss of crystallinity during melting, which quenches the residual free radicals.[105] The loss of crystallinity during postirradiation melting was avoided by doping irradiated UHMWPE with vitamin E.[106,178] Therefore, the ultimate tensile strength, yield strength, and fatigue crack propagation resistance were increased as well. The value for the ultimate tensile strength of 100 kGy irradiated and melted UHMWPE reported in the literature is ~35 MPa;[106] the ultimate tensile strength of vitamin E-diffused, irradiated UHMWPE was measured to be 46 MPa under the same testing conditions.[178]

The fatigue strength of surgical-grade UHMWPE is typically quantified by determining the resistance to fatigue crack propagation by cyclically loading a specimen designed to concentrate stresses at a crack tip (2008). The stress range that needs to be applied to propagate the crack at a rate of 10^{-6} mm per cycle is reported as a measure of the resistance to crack propagation. The values for unirradiated or gamma-sterilized UHMWPE, which has high fatigue resistance in its unaged state, have been reported as 1.4–2.0 MPa $m^{1/2}$.[32,149] In contrast, irradiated and melted highly cross-linked UHMWPEs had values of 0.55–0.69 MPa $m^{1/2}$ depending on the radiation dose.[32,149] The fatigue resistance of vitamin E-diffused, 100-kGy irradiated UHMWPE was 0.70–0.77 MPa $m^{1/2}$.[32,178] Also importantly, the strength of vitamin E-diffused, irradiated UHMWPE remained unchanged when exposed to accelerated aging, while that of conventional, gamma-sterilized UHMWPE deteriorated significantly.[106,178] While conventional UHMWPE has high fatigue strength in its unaged form before exposure to oxygen, its fatigue resistance is severely deteriorated due to oxidation, to as low as 0.19 MPa $m^{1/2}$.[106]

In summary, vitamin E-stabilized, highly cross-linked UHMWPE appears to be equivalent or better than irradiated and melted UHMWPE in terms of wear and oxidation resistance with improved fatigue resistance, as tested *in vitro*. Its clinical performance is yet to be determined.

6.603.6. Other UHMWPEs with Clinical Potential

The future goal of UHMWPE development is to remove the bearing surface material from being the bottleneck in the success and longevity of joint implants. While significant improvements have been made, the material can still be improved to allow for more anatomical designs and ease with more challenging surgery. Also, the average longevity of joint implants still falls short when it comes to a patient with degenerative joint disease requiring a primary joint replacement surgery in his or her 50s or younger age. Therefore, we would like to finally discuss some UHMWPEs that are still in laboratory development but have the potential of improving the outcome of joint surgery from a material perspective.

6.603.6.1. High-Pressure Crystallized UHMWPE with Stabilized Free Radicals

Polyethylene exhibits a hexagonal crystalline phase at elevated temperatures and pressures.[190] In this phase, which is only encountered at pressures in excess of 210 MPa, the individual chain stems are rotated at random phase angles with respect to each other, allowing for chains to slide past each other. The crystalline lamellae formed in this phase are called 'extended chain' crystals (ECC) and these crystals can grow to larger extent and also result in higher crystallinity.[190,191] This is believed to be a consequence of less hindered crystallization kinetics in the hexagonal phase compared with that in the orthorhombic phase.[190,191] High-pressure crystallization (HPC) of unirradiated GUR 1050 UHMWPE at above 160 °C and 300 MPa yielded ~70% crystalline UHMWPE, compared to 50–60% for conventional UHMWPE.[192] An increase in crystallinity of UHMWPE by HPC was shown to increase the resistance of UHMWPE to the propagation of fatigue cracks by about 25%[147] while no significant changes in ultimate tensile strength were observed.[193] Thus, HPC can be an important tool in improving the mechanical strength of wear and oxidation-resistant UHMWPEs.

It is believed that extended chain crystal growth occurs in the hexagonal crystalline phase. The stable hexagonal crystalline phase, as determined by *in situ* thermal analysis experiments, lies above about 210 °C and 340 MPa.[194,195] However, it has been shown that extended chain crystals can be obtained in a 'transitional' hexagonal phase above about 190 °C and

200 MPa.[196] In our studies with uncross-linked UHMWPE (GUR 1050, 6 Mg mol^{-1}), we were able to obtain extended chain crystals and increased crystallinity at 180 °C and 310 MPa.

In 1991, a high-pressure crystallized, gamma-sterilized UHMWPE known as Hylamer™ was marketed by the DePuy-DuPont Orthopaedics joint venture (Newark, DE, USA). Hylamer™ was prepared by hot isostatic pressing UHMWPE, leading to the formation of extended-chain crystallite morphology with thick (200–500 nm) lamellae and high crystallinity (65–71%).[197] Two members of this high-pressure crystallized UHMWPE family prepared by changes in the processing conditions included the Hylamer™ for use in acetabular liners and Hylamer™-M for use in tibial inserts. Because of increased crystallinity, the strength of Hylamer was higher than that of conventional UHMWPE, but its modulus was also increased, leading to increased contact stresses.[1,147] Wear simulation *in vitro* suggested that the wear rate of Hylamer was not significantly affected.[198] In contrast, the *in vivo* wear rates of Hylamer components turned out to be much higher than expected.[199–201] An analysis of the average wear rate, oxidation, and mechanical properties in retrieved Hylamer™ and conventional UHMWPE inserts of the same design[202] showed no statistically significant difference between the linear wear rates of the two materials, while the ultimate tensile strength and elongation to break appeared lower in the Hylamer™ components for a given level of oxidation, leading the authors to conclude that the impact of oxidation may be more detrimental to Hylamer™ than to conventional UHMWPE. This material was discontinued because of unacceptably high revision rates; however, the reason for this *in vivo* change in wear behavior was not clarified. Presumably, the highly crystalline Hylamer was more susceptible to oxidative degradation because it had less amorphous content and therefore, there was a greater percentage of tie molecules broken for a given level of oxidation.

On the basis of this hypothesis, we and others have continued working with HPC of UHMWPE as an alternative method for improving the fatigue strength of cross-linked UHMWPE. Our hypothesis was that if stabilized properly against oxidation, the HPC process could lead to improved strength without sacrifices in structural integrity. One approach was to high pressure crystallize UHMWPE first, and then increase its crystallinity and fatigue resistance.[192,203,204] The highly crystalline UHMWPE was then further irradiated for cross-linking. We found that despite obtaining satisfactory wear resistance with this material, the radiation dose rate had to be controlled to control crystalline population distribution and obtain improved mechanical properties.[205] This cross-linked UHMWPE with improved strength was then doped with vitamin E as described above for non-high-pressure crystallized UHMWPE for oxidative stability.[203]

A second approach was to high pressure crystallize cross-linked UHMWPE to improve its strength.[206,207] A third approach was to high pressure anneal cross-linked UHMWPE.[208] High-pressure annealing utilizes a pressurizing/heating route to the hexagonal phase without melting the irradiated UHMWPE. The mobility induced in the crystalline chains during the phase transformation allowed the recombination and elimination of residual free radicals. The increase in crystallinity and crystal size accompanying the hexagonal phase transformation was negatively correlated to increased cross-link density presumably because of increased cross-linking constraints decreasing the mobility of the chains. Nevertheless, there was a substantial increase in the strength of UHMWPEs cross-linked with 25–65 kGy.

Another idea was to induce mobility in UHMWPE chains during hexagonal phase transformation by using a plasticizer. Our hypothesis tested positive and vitamin E, which we used for this purpose, increased the crystallinity and fatigue strength of the resulting high-pressure crystallized UHMWPE.[26] Interestingly, there was a strong correlation between increased crystallinity and decreased wear for this material. A vitamin E-blended, radiation cross-linked UHMWPE showed significantly lower wear than conventionally cross-linked UHMWPE at similar cross-link density,[209] and it appears that there is a synergy between the presence of vitamin E during high-pressure crystallization and radiation cross-linking thereafter in preparing a crystalline and cross-linked amorphous structure leading to low wear and improved properties.

6.603.6.2. Vitamin E-Blended, Irradiated, and Mechanically Annealed UHMWPE

The mechanical deformation of irradiated UHMWPE followed by annealing below the melting point has been shown to eliminate detectable residual free radicals.[210,211] In addition, mechanical deformation can induce isotropic changes in UHMWPE where the mechanical strength in a preferred direction can be higher because of orientation.[212] Thus, a vitamin E-blended, radiation cross-linked, and mechanically deformed UHMWPE can have high oxidative resistance by two mechanisms: incorporation of vitamin E and decrease in the free radical burden by deformation. It can also have high mechanical properties. If it is used in its mechanically deformed state, these properties will be anisotropic, and if the original shape is recovered through a thermal treatment at the end (**Figure 11**[213]), they will be isotropic.

6.603.6.3. Surface Cross-linked UHMWPE

In uniformly cross-linked UHMWPEs, the mechanical properties are governed by the amount of cross-link density in the material. However, cross-linking is not needed all throughout the implant but at the articular surface. Therefore, it is desirable to limit cross-linking to a thin surface layer on the articular surface of the implant such that a majority of the implant remains at a low cross-link density and its mechanical properties remain unaltered. Surface cross-linking using controlled electron beam penetration has been reported.[214,215] However, this method is not feasible for use with curved surfaces and was not accurately controllable. Assuming a conservative *in vivo* linear femoral head penetration rate into highly cross-linked UHMWPE acetabular liners of 0.05 mm year^{-1},[130,216] it would take 40 years to wear through 2 mm of highly cross-linked UHMWPE surface. Thus, a surface cross-linked layer about 2 mm could be used for long-term wear resistance.

When UHMWPE is irradiated in the presence of vitamin E, its cross-linking is hindered with increasing vitamin E concentration[157] such that increased radiation exposure is necessary for vitamin E-containing UHMWPE to obtain wear resistance

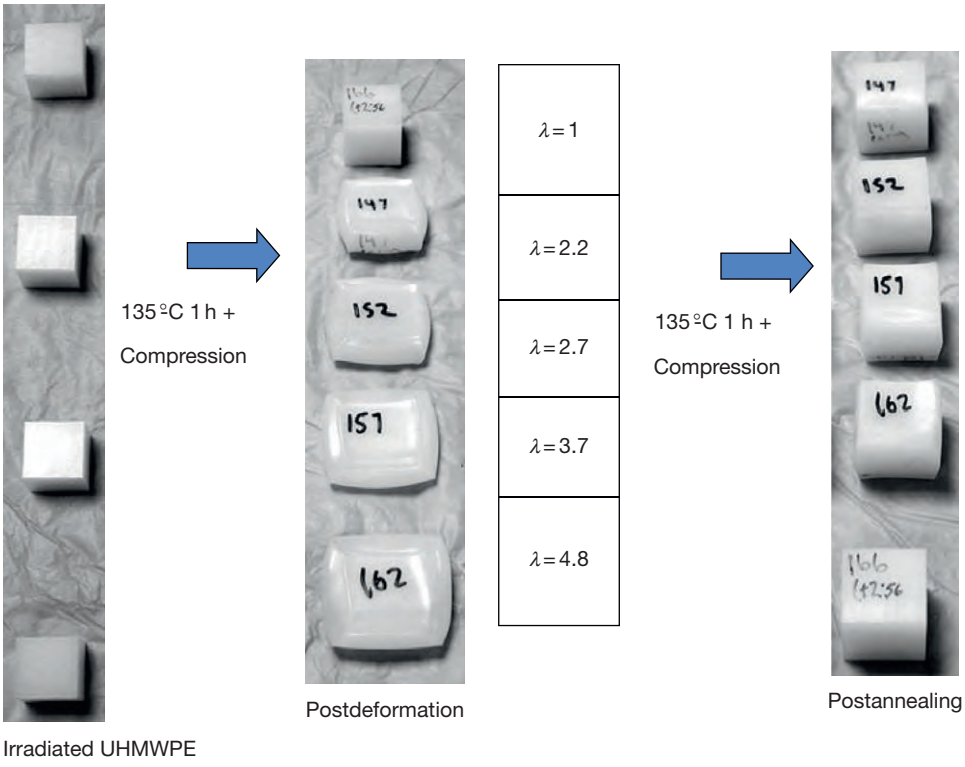

Figure 11 An example of the mechanical annealing process to eliminate residual free radicals.

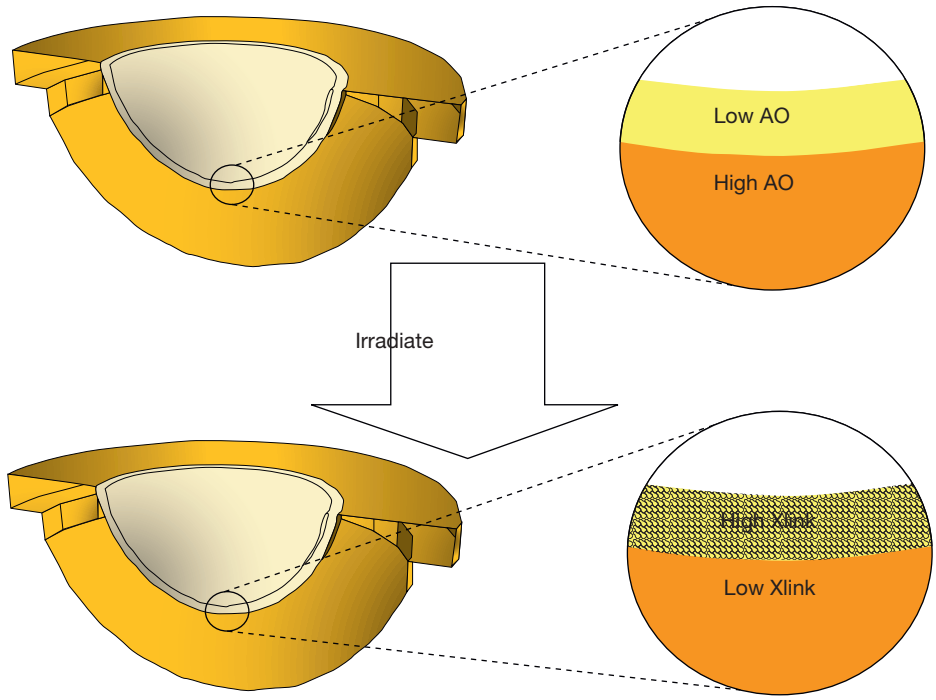

Figure 12 Surface cross-linked UHMWPE using a spatially controlled antioxidant (AO) concentration.

equivalent to that of virgin irradiated UHMWPE.[156,158] The advantage of this result is that cross-link density can be manipulated through spatially controlling vitamin E concentration during irradiation. On the basis of this result, we limited the cross-linking of the implant to the surface by using a low vitamin E concentration on the surface (~0.05 wt%) and a high vitamin E concentration in the bulk (~1 wt%) (Figure 12[217]).

Table 1 Comparison of the mechanical properties of radiation cross-linked UHMWPEs

	UTS (MPa)	*EAB (%)*	*WF (kJ m^{-2})*	*Impact strength (kJ m^{-2})*	*ΔK_i (MPa m$^{1/2}$)*
Conventional (25 kGy)	46 ± 2	376 ± 20	2237 ± 148	93 ± 3	1.19 ± 0.04
First-generation cross-linked (100 kGy + melting)	39 ± 3	225 ± 9	1206 ± 67	60 ± 2	0.54 ± 0.02
Second-generation cross-linked (100 kGy)	43 ± 2	256 ± 17	1240 ± 151	66 ± 2	0.72 ± 0.02
Third-generation surface cross-linked (2wt% + 100 kGy)	56 ± 3	422 ± 11	3091 ± 315	122 ± 1	1.24 ± 0.02

UTS, ultimate tensile strength; EAB, elongation-at-break; WF, work-to-failure; ΔK_i, stress factor range at fatigue crack inception.

This UHMWPE with a spatially controlled vitamin E concentration profile was prepared by either layered molding UHMWPEs with different concentration of vitamin E or by extracting the surface antioxidant from a UHMWPE molded with a uniform concentration of vitamin E. Using either method, we showed that high cross-linking could be achieved on the surface with low cross-link density in the bulk. This led, as expected, to higher overall fatigue strength. In fact, using a 2 wt% vitamin E blend in the bulk with 100 kGy subsequent irradiation resulted in impact strength and fatigue strength comparable to unaged, conventional, gamma-sterilized UHMWPE, virtually eliminating the effects of increasing the wear resistance by cross-linking from the mechanical properties (**Table 1**).

This material is promising as a bearing surface for all joints and can lead to reduced concern about the incidences of fracture of implants under high stresses. Another advantage of improving the fatigue resistance of UHMWPE is the ability to use thinner UHMWPE components, which may have the benefit of preservation of more bone stock and improving dislocation rates in hips by enabling the use of larger femoral heads.

6.603.7. Conclusions and Future Directions

Together with catheterization materials in cardiovascular surgery, UHMWPE is the most widely used biomaterial for long-term implantation. While joint replacement surgery is one of the most successful surgeries today, restoring function and quality of life to patients with debilitating degenerative joint disease, implant longevity is still wanting, especially for high-demand patients such as those with high BMI or young (age <55 years) patients with high activity levels. The development of UHMWPE technology is only one factor affecting clinical outcomes among those such as device design, patient comorbidity, and most notably, surgeon skill. However, the advances in UHMWPE technology are such that the material properties of UHMWPE are no longer the bottleneck in surgical outcome. Therefore, revisions due to UHMWPE-related failure such as particle-induced osteolysis or delamination-related instability are expected to decrease significantly in the coming decade. In the hip, highly cross-linked UHMWPEs have now become the standard-of-care as bearing surfaces.[5] It appears that radiation cross-linking has increased the wear resistance of UHMWPE[107,216] and is likely to decrease the incidence of osteolysis, at least in the first decade.[142] It also appears that using larger head sizes coupled with cross-linked UHMWPE has less of an effect in increasing wear rates than previously observed for conventional UHMWPE.[128,179,180] Combined with the belief that using larger head sizes results in less risk of dislocation,[129] there is a tendency to use thinner cross-linked UHMWPE components. This may increase the risk of adverse occurrences such as rim impingement, edge loading, and rim fracture, especially given the high prevalence of surgical malalignment in the hip (63%[218]). In the knee, the use of cross-linked UHMWPE is less common because of concerns of mechanical failure; therefore, there is still prevalent use of wear and oxidation-prone conventional UHMWPE. Improvements in the mechanical properties of wear-resistant cross-linked UHMWPEs would allow more widespread use of cross-linked UHMWPE[219] and presumably less incidence of wear, delamination, and instability.[135,220,221]

Furthermore, we are attempting to provide successful therapies for joint disease at progressively early stages of the diseases to maintain the health and function of the joint, as well as the quality of life of joint implant patients. Therefore, advance in polyethylene technology is expected to provide more flexibility in implant design such that more anatomical reconstruction of joints can be performed with the least amount of invasive interference.

Finally, the mechanical and tribological properties of UHMWPE favor its use as a bearing material in many joint replacement devices. This chapter has focused on acetabular liners for hip artroplasty and tibial bearings in knee arthroplasties because these comprise the largest number of joint implants and the improvements in bearing technology can be determined statistically in these two joints. However, UHMWPE is also used in buttons to resurface the patella in total knee arthroplasty, in sleeves to permit semiconstrained rotation in elbow and wrist arthroplasty designs, in counterfaces inserted into the glenoid in shoulder arthroplasty, and most recently, in total disc replacement surfaces in the spine. The discussion here is undoubtedly relevant for these devices as well, and developments in polyethylene technology are expected to positively affect the outcomes in these other joints albeit with some time lag.[222]

6.604.1. Introduction

Ceramics are inorganic, nonmetallic materials classified as bioresorbable, bioreactive, or bioinert based on *in vivo* characteristics. Bioinert ceramics, such as alumina and zirconia, have gained particular attention as orthopedic bearing materials with desirable *in vitro* and *in vivo* wear properties. The mechanical properties of ceramics – low wear and high stability – make their use especially suitable for high-demand applications such as total hip arthroplasty (THA).

During nearly four decades of clinical use, more than 6 million alumina orthopedic components have been implanted worldwide.[1] While promising clinical outcomes have been demonstrated in large-scale cohorts around the world, there have been concerns with regard to risks of fracture and audible squeaking.

The problem with ceramics, which has prevented higher surgeon adoption over the years, has been breakage. Issues with other bearings have resulted in continued improvements in ceramics. Breakage has been a historical problem with metallic components too; however, with improvements in manufacturing and metallurgy, this problem has been obviated in metals. Likewise, as successive generations of ceramic products are introduced to the market, the risk of fracture has been dramatically decreased, and the squeaking issue is now largely understood to be related to the total hip system used and not solely to a ceramic articulation.

Each successive generation of ceramics has seen improvements in manufacturing, quality control, and clinical application and utility. We spend some time detailing the history of ceramics and the subsequent improvements in the material over the years, to trace these sequential improvements in components. The fourth generation, the alumina matrix composite, has been available only for approximately 5 years now in any major capacity, and, with the increased use of this material, a clear reduction in the fracture rate has already been seen.

This chapter reviews the evolution of modern ceramics and concludes with the clinical experience worldwide, presenting a discussion of both outcomes and complications. Over the last decade, CeramTec AG (Plochingen, Germany) has emerged as the dominant manufacturer of medical-grade ceramics worldwide. Moreover, the vast majority of the world clinical results literature is based on ceramic materials manufactured by CeramTec. As such, and in the interest of space, we have decided to focus on the manufacturing data provided by CeramTec for this historical and manufacturing overview.

6.604.2. History

THA remains one of the most successful and durable procedures in orthopedic surgery. Yet, surgeons and engineers are continually seeking to improve this procedure, in both operative technique and implanted hardware/biomaterials.[2] Historically, it was the initial concern over catastrophic wear in early THA designs that prompted the introduction of ceramics in the early 1970s.

The first use of alumina (aluminum oxide, Al_2O_3) as a biomaterial in dental implants can be traced back to 1930.[3] The modern era of alumina ceramics was ushered in by Sandhaus in 1965, with the use of high alumina powder in dental implants.[4] The initial pioneering attempts to utilize ceramics as a means of reducing early problems of wear in THA were conducted in France under the direction of Dr. P.M. Boutin. Boutin first used alumina in orthopedic surgery in the early 1970s, when he successfully implanted total hip components made of alumina.[5] His efforts proved to be of limited success due to the difficulty in coupling alumina ceramics and metal components.

Like Boutin in France, the German government decided in the early 1970s to fund research focused on the development of alumina ceramic technology for the purpose of reducing wear in THA. This work resulted in the development of a medical-grade alumina ceramic material. Moreover, the project established modularity via the Morse taper concept: different materials could be matched according to function (e.g., alumina ceramic as a bearing material, and metal employed as a stem material).

Early pioneers selected alumina ceramics for a number of reasons. First, ceramics are extremely hard (over 2000 Vickers Pyramid units on the Smith and Sandland hardness scale[6]). In comparison, materials such as cobalt chrome and titanium exhibit hardness of less than 500 HV. Second, alumina ceramics are stable at high temperatures in aqueous environments. The hydrophilic surface in an aqueous environment allows for fluid lubricant to cover larger areas of the bearing surfaces than seen with metals. Finally, alumina ceramic has superior bioinertness in both bulk and particle scales when compared to metal and plastics materials in THA.

6.604.3. Early Clinical Results

Clinical results of the early high molecular weight polyethylene (HMWPE) cups against alumina ceramic ball heads were excellent.[7] The ceramic on plastic combination showed substantial reduction in wear debris over the traditional HMWPE cup on metal ball head systems.

Results of the early alumina-on-alumina ceramic designs were mixed, largely due to ceramic fractures and poorly designed acetabular and femoral components. Review of the French clinical series of 172 consecutive patients at more than 10 years follow-up included 15 acetabular cup revisions for aseptic loosening, as well as five component fractures.[8] A review of the German experience of 109 patients at minimum 10 years follow-up included 24 revisions for femoral component aseptic loosening and five fractured components.[9] The experience in the United States with monolithic cup and cementless stems (Mittelmeier design) was also unacceptable and led to the removal of the system from the market. Miller[10] (United States) followed the results of 102 patients and reported a 26% aseptic loosening rate for the femoral stem, with no fracture of any of the ceramic components in the first 3 years after implantation.

While early clinical experience with alumina ceramic components in THA had high rates of loosening, it is unclear whether it was directly related to the use of alumina ceramics. The first generation of alumina ceramics had a high incidence of fracture, partly related to the heterogeneity of industrial ceramic manufacturing processes and a lack of consensus standard for the materials. As a result of this early experience, a number of manufacturers who had entered the market discontinued their activities in the medical field. Nevertheless, the wear rate of these early alumina ceramic wear couples was low ($2.6\,\mu m\,year^{-1}$ for the cup; $5.4\,\mu m\,year^{-1}$ for the head) and showed promise when compared with metal against HMWPE; wear rates have only continued to improve over the last three decades.[11,12]

The problems of the 1970s became the focus of the orthopedic ceramic manufacturing efforts in the 1980s. Improved fixation of second-generation acetabular and femoral designs reduced the incidence of aseptic loosening; refinement of surgical indications, including implantation of ceramics in younger, active patients improved complication rates.[13] Finally, the aggressive efforts by the manufacturers to first standardize and then to continually improve alumina ceramics, coupled with improvements in THA design, were rewarded with lower fracture rates, decreased incidence of loosening, and improved implant survivorship.[13]

In the early 1990s, a separate effort in France centered upon zirconia ceramic (zirconium oxide) applications. Zirconia has improved strength and fracture toughness compared to alumina. Despite its improved mechanical properties over alumina, the material exhibits different degrees of stability depending on the conditions of use. Under the stress of high-temperature conditions in an aqueous environment, there can be transformation to a monoclinic phase from a tetragonal phase seen at room temperature. This phase transformation, accompanied by volume expansion of the transforming crystals, causes increased surface roughness and results in distinctly inferior wear characteristics. Furthermore, zirconia's inability to articulate against itself limits its versatility.[14] Accordingly, zirconia has now been largely abandoned in orthopedic surgery, including in THA systems.

6.604.4. Evolution of the Mechanical Properties of Alumina and the New Alumina Matrix Composite

In nearly four decades of ceramic use in THA, more than 6 million alumina ceramic components produced by CeramTec AG have been implanted in patients worldwide (CeramTec company data). The majority of these implanted components are alumina ceramic ball heads. The materials used in these alumina components have undergone improvements to enhance reliability *in vivo*. These improvements largely stem from the following: medical-grade processing conditions of the raw material, improved sintering techniques coupled with hot isostatic pressing, laser marking, and proof testing of finished components.[15]

In addition to these processing improvements, the development of ceramic materials to satisfy increasing physiologic demands, additional sizes, and increased longevity has resulted in higher strength composite ceramic materials. Recent iterations of ceramic components marketed in the United States include BIOLOX® *delta*, an alumina matrix composite produced by CeramTec AG. This product has improved upon biocompatibility, mechanical performance, and chemical and hydrothermal stability; importantly, it exhibits at least equivalent tribological characteristics when compared to the alumina ceramic materials currently in use.[16]

The basic foundation for this composite material dates back to the early 1970s, when companies began investigating transformation toughening to increase strength. The transformation, which involves addition of small zirconia particles homogeneously dispersed within the alumina matrix, presents a means to dissipate energy associated with a crack propagating in the microstructure. The compressive stress field generation in the vicinity of the transforming grain (due to volume increase) impedes crack propagation. This process increases the fracture toughness of the composite material. While this mechanism has been well known for many years, additional work was required before the zirconia-toughened materials could be reliably used as orthopedic load-bearing implants.

Subsequent work was carried out to enhance the long-term reliability of the zirconia-toughened alumina composites.[17] In addition to modified toughening techniques (e.g., *in situ* formation of elongated oxide crystals), hardness may be improved by alloying the material with chromium oxide, creating a solid solution within the basic alumina matrix. The distribution of chromium inside the alumina atomic lattice activates a colorizing effect similar to natural ruby. Properties of the successive generations of alumina and alumina matrix composite ceramics are illustrated in Table 1. Higher Young's modulus translates to increased stiffness (i.e., small deformation), and hardness is related to lower wear, while a low wetting angle ensures increased lubrication. Smaller grain size provides increased strength, and a high density provides for better surface finish. Figures 1–3 present other key mechanical properties of ceramics – stiffness, hardness, and flexural strength, respectively – in comparison with commonly used materials in orthopedic surgery.

Table 1 Mechanical properties of alumina and the alumina matrix composite

	1970s alumina	*1980s alumina*	*1990s alumina*	*Alumina matrix composite*
Strength (MPa)	400	500	580	1250
Hardness (HV)	1800	1900	2000	1925
Bending strength (MPa)	>450	>500	>550	>950
Wetting angle (°)	<50	<50	<50	<50
Microstructure (μm)	≤4.5	≤3.2	≤1.8	≤1.0
Density (g cm^{-3})	3.94	3.96	3.98	4.37
Young's modulus (GPa)	380	380	380	350
Laser marking	No	+	+	+
Hipped	No	–	+	+
Proof-tested	No	–	+	+
100% control	+	++	+++	+++
Suitable for ceramic–ceramic	+	++	+++	+++

6.604.5. Proven Long-Term Clinical Stability

The long-term stability of alumina ceramic components relates to both biocompatibility and bioinertness. Long-term retrieval analysis of 32 mm BIOLOX® ball heads against cemented polyethylene cups at more than 20 years confirmed a majority compliance with the original manufacturing specifications.[18,19] These analyses demonstrated no fretting corrosion

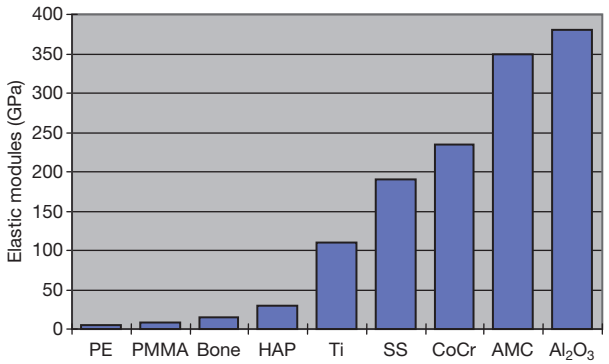

Figure 1 Comparison of stiffness. PE, polyethylene; PMMA, polymethylmethacrylate; HAP, hydroxyapatite; Ti, titanium; SS, stainless steel; CoCr, cobalt-chrome; AMC, alumina matrix composite; Al_2O_3, alumina. Source: CeramTec AG company data.

or corrosion in the bore of the BIOLOX® heads and the tapers of their corresponding metal stems, and no degradation in strength. These findings contrast with the clinical findings of retrieved metal ball heads[20,21] and *in vitro* wear testing.[22] Consequently, the superior wear rates *in vitro* and stability *in vivo* of alumina ceramic ball heads have proven to be valuable characteristics in the quest for improved bearings in arthroplasty.

6.604.6. Biocompatibility

The search for alternative bearings is not new, and it is certainly not limited to ceramic couples. Alterative bearings include ceramic-on-ceramic/polyethylene, as well as metal-on-metal. Experimentation with these couples dates back over decades. Metal-on-metal couples, purported to be linked to malignancy and teratogenicity, have been under recent scrutiny for metal hypersensitivity, blood ion levels, and animal studies.[23] These concerns seen with metal couplings have not been borne out in ceramic bearings, making ceramics a more biocompatible option.

The testing of all materials to be used for permanent implants in the body has been standardized for several years. International Standards Organization (ISO) regulation 10993 outlines specific tests to be carried out depending on the intended use of the material. Because all ceramic components produced are permanent orthopedic implants, they are subjected to rigorous protocols: cytotoxicity testing of both solid and particulate material; sensitization, genotoxicity, chronic toxicity, and carcinogenicity evaluations; and short- and long-term implantation animal studies.

The particles generated by the different wear couples in orthopedic implants today have different levels of biological activity in the body. Ceramic wear debris has the lowest level of reactivity due to the size, shape, and chemical composition of the particles. This fact results in significantly lower osteolytic potential when compared to polyethylene, cross-linked polyethylene, and metal.[24–33] When this is combined with the lower volumetric wear rate of the ceramic-on-ceramic wear couple, a 100-fold reduction in biological activity and osteolytic potential is seen.[34] Even under microseparation conditions (contact of ball head/cup rim), the wear rate of the alumina ceramic-on-ceramic was 50 times less than that of metal-on-crosslinked polyethylene.[27,35] The concentration of wear particles in the periprosthetic tissues of loosened implants was 2–22 times lower with alumina ceramic than with metal-on-polyethylene.[25] Long-term clinical results with ceramic-on-ceramic THA confirm the excellent biocompatibility and reduced wear rate of ceramic-on-ceramic bearings.[24,25,36–38] The proven biocompatibility data are based largely on the track record of the largest alumina manufacturer, CeramTec AG, and the over 6 500 000 alumina and nearly 1 000 000 alumina matrix composite components implanted globally since 1973.

6.604.7. Current Manufacturing State of the Art

The quality of either alumina or the alumina matrix composites is defined by key processing parameters, and governed by regulations established by the American Society for Testing and Materials (ASTM) and by the ISO. These processes include obtention of high-purity raw material, medical-grade processing conditions, improved sintering techniques and hot isostatic pressing, laser marking, and proof testing. All these factors enhance the reliability of the ceramic components *in vivo*.[1]

Removal of impurities such as silicates and alkali oxides reduces glassy phases at the grain boundaries, improving corrosion resistance, mechanical strength, and fatigue properties. Sintering temperature is optimized to establish ideal grain size and distribution. This, in combination with hot isostatic pressing, provides a higher density. Laser marking is used to establish smoother surface conditions and prevent stress risers. Finally, proof testing is now carried out by most manufacturers of ceramic components around the world. This, along with verification of the chemical composition, grain size, density, surface finish, sphericity, dimensional compliance, and surface inspection using a dye penetrant, ensures the reliability of the components.

6.604.8. Ceramic Component Failure

There remain inherent risks of alumina ceramic use *in vivo*. While *in vitro* studies seek to minimize these risks, *in vivo* conditions can be quite different. For example, abnormally high loads may be placed on the component on account of trauma. Poor placement of the components, such as vertical cup placement, may impose abnormal loading conditions. Patient-related factors, such as poor bone density, high activity levels, and obesity can undermine component stability. Patient-related factors, as well as surgeon and material factors, can significantly affect the reliability and expected service life of the component.

In addition to individual components (e.g., acetabular cup, ball head, and femoral stem), the taper mating surface and its proper function are important to the eventual service life of present-day alumina ceramic components. Components must have identical mating taper surfaces, and mating surfaces must be protected during surgery, to prevent damage, and impacted properly in adequate axial alignment. **Table 2** captures the incidence of *in vivo* fractures of ceramic components reported historically **Table 2**.

Complications data demonstrate several trends. In the early years, two companies (Rosenthal and Friedrichsfeld) experienced unusually high failure rates on their products as a result of which they do not presently produce ceramic components. Overall, breakage of an alumina ceramic component is rare and actually lower than that of other procedural complications (e.g., stem breakage).[67] Furthermore, improvements in manufacturing process, surgical technique (i.e., cup position and minimizing impingement), and improved acetabular component design (i.e., elimination of lipped liners) have over time continually decreased the rate of catastrophic failure. Nevertheless, while they are rare, there are still instances when even modern ceramic bearings fail. Therefore, more study is needed to stratify specifically the breakages related to trauma, surgical technique, and a number of other conditions.

The higher mechanical properties of zirconia in ball heads did not translate into a lower rate of breakage, as had

been originally anticipated. Even though there are only two series reported in the literature, the zirconia fracture rate is higher than that reported for current-day alumina.[64,65] The Callaway series, of note, used femoral stems produced by the Hospital for Special Surgery Dana Center, which has been criticized for a high breakage rate secondary to a substandard connecting taper.

6.604.9. Recent Clinical Reports of the Use of the Latest Generation of Alumina Ceramics

Several reports have described the clinical outcomes of THA implanted with current generation implants, fixation technology, surgical techniques, and modern alumina bearings. In over 61 644 cases reported from 2000 to 2008 in the medical literature, there have been a total of 21 fractured components (~0.034% fracture rate). In alumina-on-alumina THA cases in several clinical series, with follow-up of 3–20 years, no alumina bearing failures were encountered (Table 3). Thus, modern alumina THA bearings appear to be safe and reliable if used with implants of proven design and durability.[1,39,46,57]

6.604.9.1. United States Experience

D'Antonio and Capello presented a review of the 52 000 ceramic–ceramic hips implanted since the 2003 Food and Drug Administration (FDA) approval of Stryker ceramic hip arthroplasty products[68]: four acetabular fractures (0.008%) and nine head fractures (0.017%) were seen in the group. Further Stryker data comparing metal-on-polyethylene and ceramic–ceramic couples at greater than 7 years follow-up found a 7.5% revision rate in the control group (metal-on-polyethylene) versus a 2.7% revision rate for ceramic-on-ceramic.[69] There were no fractures in the ceramic cohort, while the control group experienced osteolysis and revisions attributable to wear. Capello *et al.* reported on 475 hips at an average 8 years of follow-up. Cortical erosions were less seen in the ceramic-on-ceramic hips than in the metal-on-polyethylene

Table 3 Clinical outcomes of total hip arthroplasty with alumina bearings since the year 2000

group, and there was no aseptic loosening in the ceramic group. Overall, there was a <1% fracture rate requiring reoperation in the ceramic-on-ceramic hips.[70]

Garino cited no fractures at 3 years follow-up in 333 cases.[71] Murphy *et al.*, in a report on the Wright IDE trials, included 1709 hips in 1484 patients across 12 centers.[72] Minimum follow-up was 2 years after implantation of Transcend cups and various femoral stems. At average 8-year survival, there were four ceramic liner fractures (0.27%) and two reoperations for instability. While breakage issues have historically forced ceramics to lag with respect to head size, Murphy concluded that the relative lack of neck and liner options did not impede safe surgery with these components. Murphy *et al.* also reported no osteolysis and no dislocations at mean 4.3 years in 194 hips implanted with alumina-on-alumina bearings.[73] In a study looking at both Biolox Delta ceramic-on-ceramic and Biolox Delta ceramic on moderately cross-linked polyethylene, Hamilton *et al.* cited two ceramic liners that were chipped during insertion and two acetabular liner failures in the ceramic-on-ceramic group.[74]

6.604.9.2. European Experience

The reported European experience with an alumina-on-alumina combination showed a mean wear rate of 0.025 μm $year^{-1}$ and limited osteolysis up to 10 years after arthroplasty.[8,48,75–77] Hamadouche *et al.* saw no evidence of wear and no fractures at 18.5 years minimum follow-up.[78] When comparing 28 bilateral arthroplasties (one ceramic–ceramic and the others contralateral ceramic–polyethylene) at 20-year revision-free follow-up, Hernigou *et al.* saw more osteolysis/wear in the alumina-on-polyethylene hip than the alumina-on-alumina hip.[79] Aldrian *et al.* reviewed the mid-term results of Biolox ceramic-on-ceramic and Alpha Cera Fit Alphanorm (Lassnitzhohe, Austria) uncemented components in 107 hips at minimum 7 years follow-up[80]: three ceramic head fractures were seen; there were no radiographic signs of lysis or loosening. Nau *et al.* in Germany reported no osteolysis or loosening in 199 Cera Fit THA at mean follow-up time of 42 months.[81] Fenollosa *et al.* in Spain saw no osteolysis or component fracture in their series of 74 patients below the age of 50 years.[82] At greater than 7 years' survival, Lazzaro *et al.* reported no clinical or radiographic signs of loosening of the femoral component, and seven cases of acetabular cup loosening.[83]

6.604.9.3. Asian Experience

Poor results were seen with early Kyocera ceramic components in the Japanese population: 10-year survival rates of 75% for the acetabular component and 86% for the femoral component, and a mean polyethylene linear wear rate of 0.10 mm $year^{-1}$, radiographically.[84] Koo *et al.* cited five alumina head fractures for a 1.4% fracture rate.[85] Kawanabe *et al.* reported no fractures at 7–21 years' follow-up in 215 THAs.[86] Park *et al.* found two fractures in 357 patients at 4–7 years' follow-up.[87] Sugano *et al.* reviewed the use of navigation in performing cementless ceramic-on-ceramic THA in 59 hips at a mean of 6 years postoperatively.[88] The results were compared with 111 hips implanted without navigation: two revisions were performed in the group without navigation (one aseptic acetabular loosening and one ceramic liner fracture). Zhou *et al.* compared ceramic-on-ceramic with metal-on-polyethylene implants for cup migration; they found no increased cup migration in the ceramic-on-ceramic implant compared with the metal-on-polyethylene.[89]

As of December 2009, the US FDA had approved seven Pre-Market Approval applications and one Product Development Protocol submitted by orthopedic implant manufacturers who presently market alumina THA bearings within the United States (**Table 4**). Alumina-on-alumina THA bearings in the United States are classified by the FDA as class III devices.

Therefore, annual follow-up is required of all patients for a minimum of 5 years postsurgery, and a selected postmarket surveillance group must be followed for 10 years.

At the conclusion of 2009, more than 5500 patients were enrolled in clinical studies with alumina-on-alumina ceramic THA, with some follow-ups reaching the 10–12 year mark. Ongoing clinical studies in the United States show the improvements made in manufacturing and design over the years, which feature the use of cemented or cementless components (stem and acetabular shells) in conjunction with alumina ball heads with either an UHMWPE or an alumina shell insert. The alumina acetabular insert design is used in conjunction with a metal shell design with a taper that locks the ceramic insert in place. Both the insert and ball heads have no unsupported alumina ceramic edges, and all exposed alumina ceramic surfaces are polished. The only variable in the material design is the acetabular insert (either UHMWPE or alumina ceramic). This mating of current-day stem and shell designs with different wear couples is the basis for future designs.

6.604.10. Statistical Observations of the Largest Ceramic Manufacturer Clinical Report Database (January 2000 to September 2009)

An analysis of the CeramTec database related to the BIOLOX® family of ceramic components (January 2000 to September 2009) offers important insights into the complication rates related to implanted ceramics products. However, product failure data reported to CeramTec AG Medical Products Division may not accurately capture all failures, as not all events are reported to the manufacturer. Similar company databases were not able to capture unexpectedly high failure rates, such as with the yttrium-stabilized zirconia femoral heads made by the French company DesMarquest.[11] Nevertheless, it is important to evaluate large-scale company database reports for emerging trends. Conclusions from data analysis of the CeramTec database are given below:

Alumina bearing failures in THA are uncommon. A total of 2 420 000 alumina THA bearing components were manufactured from January 2000 to September 2009 (**Figure 4**). Based on the clinical reports received by the manufacturer, a clinical fracture rate of 0.020% occurred[100]; the overall probability of a ceramic component failure *in vivo* was therefore about 2 in 10 000.

Alumina failures can be related to specific adverse events. In the database, there were only 58 failed components files that contained sufficient information from which to draw firm conclusions as to the reason for failure. In each of these cases, the components failed after a single adverse event that might not ordinarily be associated with routine primary THA. These adverse events included trauma, cold immersion of the component after autoclaving, mismatch between the femoral head diameter and the acetabular insert, recurrent hip dislocations, and gross mal-positioning

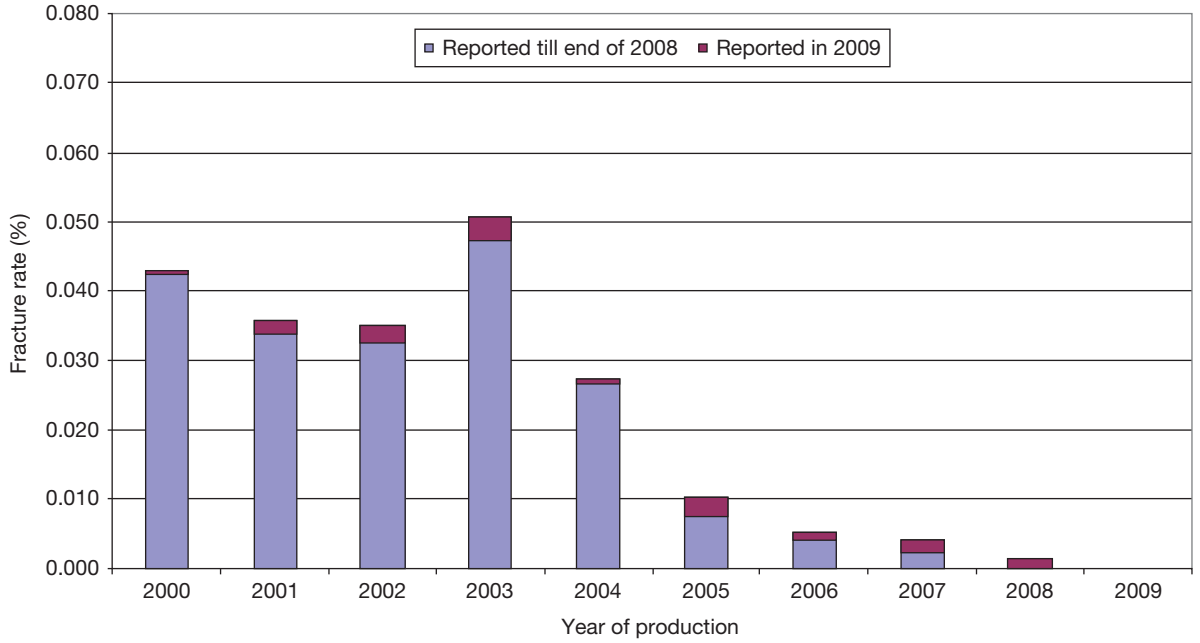

Figure 4 Fracture rate in CeramTec database according to year. Source: CeramTec AG company data.

of THA implants. While there may be an inherent risk of component fracture with routine conditions, it is clear that these components often fracture clinically, as a result of some event creating an overload condition.

Most in vivo failures of alumina THA occur early after implantation. Femoral heads manufactured from the historical alumina material and the new alumina matrix composites tend to fracture relatively early after surgery. Forty percent of the fractures had failed within 12 months of surgery; 60% had failed within 24 months, and 75% had failed within 36 months following implantation. These data suggest that, after 3 years, the risk of an alumina femoral head fracture *in vivo* is only 25% of the 0.02% overall incidence of failure (i.e., 0.004%) (**Figure 5**).

Alumina matrix composite is more reliable than previous alumina (in the short- to midterm). Future material improvements may continue to reduce the risk of failure of alumina components. Alumina matrix composites have even greater fracture toughness values and resistance to crack propagation when compared to traditional alumina.[8] The improvement in reliability offered by this new composite ceramic material is quite promising. In a comparison of the *in vivo* fracture rate between the alumina components (2.42 million implanted) and the alumina matrix composite components (570 000 implanted), the fracture rate reported to the manufacturer was reduced from 0.020% to 0.002% (CeramTec company data). This increase in short- to mid-term reliability is quite promising and requires further follow up.

Increasing femoral head diameter reduces the risk of fracture. The failures reported to CeramTec suggest that the risk of alumina femoral head fracture declined with increase in femoral head diameter. Larger diameter femoral heads were associated with a reduced risk of failure *in vivo* (**Figure 6**).

Alumina femoral head fracture rates can vary with the neck size. Among the 28 mm diameter alumina femoral heads, the fracture rate was influenced by the neck length design in the taper bore. The lowest risk of fracture was associated with a medium neck size, while the short and long neck lengths were associated with higher femoral head fracture rates (CeramTec company data).

The risk of failure of an alumina acetabular insert is quite small. One of the reported early issues with ceramic acetabular inserts involved the chipping of ceramic inserts intraoperatively when an alumina acetabular insert was seated into a metal shell. If it is not properly aligned with the metal shell, a piece of ceramic can chip off the insert edge.[40,52] This problem is technique related and associated with eccentrically placed insert impacted into a metal shell.[1,46,55] While only a small part of the edge is damaged by chipping, a significant stress riser is created in the material, and the chipped insert must be replaced with a new one. The rate of alumina insert damage during surgery as reported to CeramTec was relatively stable at 0.026% from January 2000 to September 2009 (CeramTec company data).

Implant design affects the performance of alumina bearings. Optimal load transfer from an alumina bearing to either a metallic femoral stem or an acetabular shell depends upon the load transfer area design, its material composition, roughness, morphology, and many other factors. At the present time, variables related to the design of these load transfer areas vary between the various implant manufacturers. The specific design of a given THA implant can influence the reliability of the alumina bearing components. The extent to which implant design variables contributed to the failures is unknown.

6.604.11. Ceramic Component Squeaking

Complications such as articulation noise and, in particular, squeaking can create a degree of concern and discomfort in the patient. Much research has been devoted to clarify the mechanisms involved. Present data conclusions are as follows:

All hard-on-hard bearings are susceptible to the generation of articulation noises. The incidence of articulation noise is not unique to ceramic-on-ceramic bearings. Articulation noises have also been associated with metal-on-metal bearings and metal-on-metal resurfacing systems: for example, Back *et al.* noted a 3.9% rate of transient squeaking with metal-on-metal resurfacing replacements.[101]

The cause of squeaking may be multifactorial. Patient factors, such as muscle tension, weight, and height may be contributing factors. Taller and heavier patients tend to have a higher incidence of articulation noises. Surgical-related issues, such as placement of the implants and bone or tissue impingement, are also found to be important factors. Implant design issues – femoral stem and neck geometry, implant material, implant range of motion to mechanical impingement, the number of interfaces in a given design, shell deformation, and locking mechanism – all play a role.

The frequency of occurrence appears to be design related. A substantial difference in the frequency of these noises appears to be related to component design differences. Squeaking in ceramic taper locking modular shells with flush mounted ceramic insert designs has a reported incidence of less than 1%. In contrast, a design utilizing titanium encased and recessed ceramic liner appears to have a much higher incidence (2.7% to more than 11%). There appears to be a direct relationship between the type of femoral stem, the design of the neck, and the material used in the stem, and the incidence of squeaking. In one study, surgeons using one specific femoral stem design had a significantly higher incidence of squeaking when compared to other surgeons in the group who used the same acetabular modular system but with a femoral stem of a different design.[102]

Squeaking may be a temporary condition. Komistek analyzed under fluoroscopy a group of patients with documented complaints of squeaking following C–C hip replacements, and found that he could not reproduce squeaking in the audible range in any of these patients, under a variety of conditions mimicking activities of daily living.[103] Furthermore, in another study, Lee and Garino reported on a group of squeakers followed prospectively for a minimum of 5 years and found that, after the minimum follow-up period, 50% of patients had either had complete cessation of squeaking or had significant diminution of symptoms.[104] Thus, this type of acoustic phenomena following ceramic THA continues to be poorly understood and its clinical significance remains uncertain.

Squeaking has not been shown to be a predictor of clinical performance. There is no data available that indicates that one type of articulation noise, such as squeaking, compromises the mechanical integrity and clinical longevity of the implanted system. In most clinical studies, reports of squeaking following THA comprise a small portion of the patient population.

Studies utilizing the Ti alloy (TAl6V) with a C-taper include a 0.3% squeaking rate cited by Lusty *et al.*,[99] and a 0.97% rate in Mesko *et al.* in a report of 930 consecutive ceramic-on-ceramic hips.[105] According to D'Antonio, the highest reports of squeaking have involved the use of a femoral stem made of titanium–molybdenum–zirconium–iron with a V-40 tapered neck geometry.[102] These reports include the following: Restrepo *et al.*[106] at a 2.7% incidence; four of these Trident Stryker components underwent revision, and stripe wear was observed. Keurentjes in the Netherlands[107] reported a 20.9% incidence, and Jarrett *et al.* cited a 32.8% incidence of all noises and 10.7% squeaking incidence (4 of 14 reproducible squeaking).[108]

Walter *et al.* in Australia reported a 0.6% rate,[109] and Capello saw 0.8% squeaking rate in Stryker components.[70] Jarrett *et al.* also reported a 19.5% squeaking rate at less than 3 years.[110] Chang *et al.* in Korea described no squeaking in revision THA using third-generation CoC components

at average follow-up of 5.4 years.[111] Hamilton reported no squeaking at minimum 2 years follow-up in either Delta ceramic-on-ceramic or Delta ceramic on moderately cross-linked polyethylene.[74] Mai *et al.* reported a 17% rate of patient-perceived hip noise, with 10% rate of 'squeaking.'[112]

While squeaking is noted as a nuisance by most patients, few reports have linked nontraumatic squeaking to impending failure of the hip system. Our institutional experience on squeaking has been that most patients report squeaking as a waxing and waning condition that occurs during the first few years following THA, with eventual disappearance or diminution of symptoms. Most patients complained of no pain with this condition and had high levels of function postoperatively. Consequently, one must weigh the risks and benefits of revision for squeaking alone.

The indications for THA have been extended into younger age and/or high activity groups. These patients will place more rigorous environmental demands, both occupational and recreational, upon their THA. As a result of this, the longevity of existing THA systems in the market today is being redefined, and biomechanical testing has been useful in exploring this complication.[113,114] Articulation noises are not new phenomena; however, it appears that the specific noise described as 'squeaking' is the result of a number of factors. Proper classification of the sounds may be helpful in diagnosing their origin and clinical implication.

Table 5 Clinical wear rates of various wear couples

Material combination	*Annual wear (mm)*
Metal/UHMWPE[11]	0.2
Alumina/UHMWPE[11]	0.1
Alumina/Alumina (1980s)[32]	0.005
Alumina/Alumina (1990s)[115]	0.001

UHMWPE, ultra-high-molecular-weight polyethylene.

6.604.12. The Beneficial Wear Properties of Alumina Ceramics Outweigh the Risk of Fracture

While metal on UHMWPE has been the traditional benchmark for clinical wear, alternative bearings have positively influenced wear rates and offer options in the high-demand or young populations. Justification for ceramic bearings is made in the face of a relatively constant revision rate of THA in the United States despite advancing surgical techniques.[7] It is possible that the new generation of UHMWPE may be more sensitive to abrasive wear and might be 'protected' against this type of wear by the use of a ceramic ball head. Table 5 illustrates the difference between the bearing couple wear rates. It is important for the operating surgeon to carefully balance the risk of alumina ceramic complications against the gains achieved by the reduction of wear debris, particularly when the patient is younger and more active.

6.604.13. Clinical Use of Ceramics in the Global Community

The use of ceramics ball heads varies greatly by region (Figures 7 and 8). Perhaps the most important issue relates to the price differential between metal and ceramic ball heads. As an example, in the United States, the ceramic ball head list price is often greater than four times that of the same ball head sold in Europe, while metal ball head prices are more equivalent. This price differential may be the largest single contributing factor accounting for the different usage rates around the world. Another important factor that influences usage relates to the educational programs for orthopedic surgeons: some

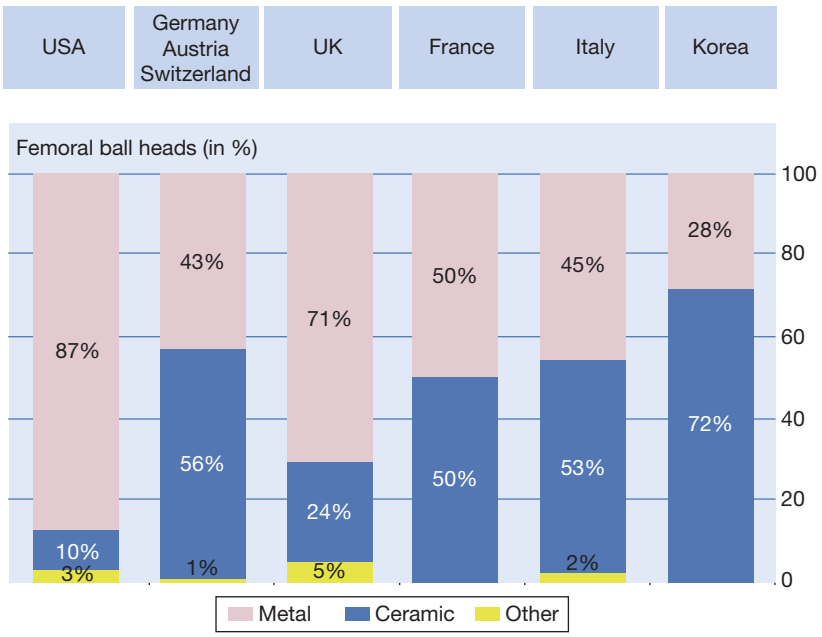

Figure 7 Femoral ball head usage by region. Source: Avicenne, BVmed, Eucomed, Global Markets Direct, and CeramTec (2007).

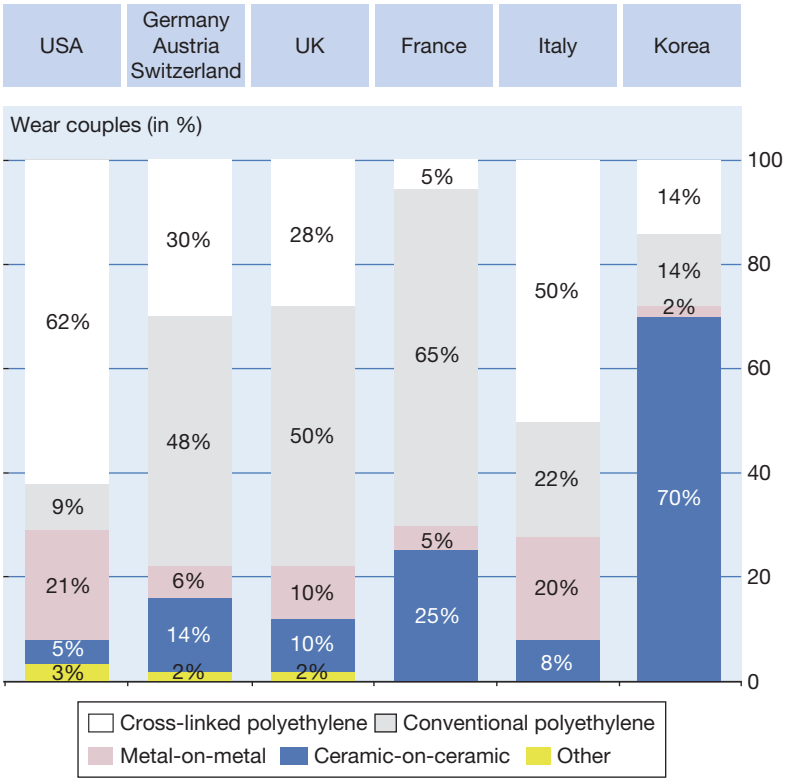

Figure 8 Wear couples by region. Source: Avicenne, BVmed, Eucomed, Global Markets Direct, and CeramTec (2007).

countries have endorsed usage of ceramics for many years, whereas in other areas, a rebirth of ceramics has been recognized only in the last decade or so.

6.604.14. Ceramics Allow Large Diameter Wear Couple with Little Wear Debris

The use of ceramic-on-UHMWPE or ceramic-on-ceramic articulation offers the possibility of large diameter wear couples. The use of these large wear couple sizes provides enhanced stability and range of motion with a negligible increase in the amount of wear debris. For example, a change of a 28-mm wear couple to a 32-mm wear couple in the same system (assuming a 2–1 head-to-neck ratio) provides an increase of nearly 7° in arc range of motion. The use of a 36-mm wear couple improves the range of motion by a total of 14° from the 28-mm couple (Figure 9).

The next generation of CeramTec ceramic components, the Delta Ceramax system manufactured by the Smith and Nephew company, is presently an investigational device and pending approval in the United States. No claims regarding safety and efficacy can be made, and preliminary data regarding excellent burst testing and wear properties must be fully evaluated in clinical trials. For example, burst testing for 28 mm ceramic inserts reveals inserts that exceed testing capacity at >247 kN; likewise, 36 mm inserts exceed testing capacity at >285 kN. The FDA requires a minimum of 46 kN.[116] As ceramics perform well under compression, the factory-assembled titanium band for the ceramic insert preloads the liner in a compressive manner; this feature significantly increases burst strength.

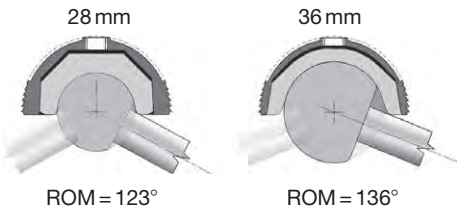

Figure 9 Implanting a larger wear couple diameter improves arc range of motion, and range of motion to impingement. Source: CeramTec AG company data.

6.604.15. Conclusions

Alumina THA bearings are the result of extensive improvements to the material, manufacturing processes, and implant design. Clinical experience during the last three decades has demonstrated the wear advantages of the alumina family of ceramics in reducing debris in THA, as well as the reliability and safety of modern alumina bearings. As an alternative to metal-on-polyethylene and metal-on-metal bearings in THA, modern alumina is safe, durable, reliable, and provides substantial benefits in wear reduction. Low *in vitro* and *in vivo* wear rates may outweigh the small risks of ceramic-associated complications.

The surgeon has to balance these risks of alumina failure and audible noise generation against the proven advantages of alumina. Reductions in wear have been seen when ceramics are coupled with UHMWPE or alumina ceramic. These may have long-term implications in the reduction of revision rates

in THA. Furthermore, the applications of THA in young, more active, and high-demand patients may be extended. Ceramics have permanently changed the alternative bearings options, both in the United States and worldwide.

TCP	Tricalcium phosphate

6.605.1. Introduction

6.605.1.1. Objectives of Joint Replacement

The clinical objectives of joint replacement are to relieve pain and increase mobility. To meet this objective, material choice and design decisions must provide as physiologic a strain as possible to the bone surrounding the prosthesis so that the integrity and functionality of the bone and implant are maintained over an expected service life of 10–15 years. Materials suited for joint replacements are those that are well-tolerated by the body and can withstand cyclic loading on the order of 10^7 cycles in an aqueous, protein enriched environment.

Total joint replacements are categorized by the mechanism of fixing the implant to the surrounding tissue. In general, implants are either cemented or cementless, referring to whether the implant is stabilized with a grouting agent or by direct contact between tissue and the implant surface. Problems with cemented implants, especially in younger patients, inspired cementless implants in which fixation is dependent upon tissues' ability to bond with the implant and maintain this bond over time.[1–5]

The design of joint replacements is geared toward maximizing interfacial bonding and stress transfer across the implant/tissue interface, within the constraints of using materials that can meet the mechanical demands and be tolerated biologically. Parameters dictating the success of porous-coated joint replacements (Figure 1) include the mechanical properties of the implant, coating, and implant/coating interface[6–10]; mechanisms of tissue attachment to the implant, including

the surface state of the implant and coating, and size, shape, and distribution of surface porosity[11–18]; the mechanical properties of the tissue, including stress and strain magnitude and distribution[19–21]; the elastic properties of the implant, coating and tissue, especially with respect to mediating relative motion and tissue adaptation[22–27]; initial stability and strategies to stimulate tissue ingrowth[28–34]; implant design[35–37]; and the biological response to the implant materials.[38,39]

6.605.1.2. Objectives of Biological Fixation Using Porous Materials

Cementless fixation is achieved by establishing an interference fit between the implant and surrounding tissue. Cementless implants are designed to minimize the time necessary for tissue integration and maximize interfacial stability. Ideally, the implant materials should elicit the formation of normal tissue at the surface and establish a continuous interface capable of supporting service loads over time.[40]

Cementless fixation may be achieved via surface active materials, surface textured materials, or porous-coated materials. Surface active materials lead to fixation through a chemical reaction between tissues and a bioactive implant surface.[41] With surface textured materials, bone grows onto the surface of a grooved or textured implant.[6,42,43] With porous-coated materials, bone grows into the pores of a three-dimensional (3D) porous or porous-coated material.[13,18]

Porous-coated prostheses provide fixation to bone by creating an interdigitation between bone and a porous 3D surface.[12,13,44] Porous-coated systems can lead to a higher bone/implant shear strength than other types of fixation,[12,45] resulting in a better stress transfer from the implant to the surrounding bone, a more uniform stress distribution between the implant and bone, and lower stresses in the implant.[44,46]

6.605.2. Materials Used for Porous Coatings

Porous coatings have been fabricated from polymers – polytetrafluoro-ethylene,[47,48] polysulfone,[43,49] polyethylene,[50] and poly(methylmethacrylate),[51] ceramics – calcium aluminate[52] and alumina,[53,54] and metals – stainless steel,[55] cobalt-based alloys,[18] titanium-based alloys,[13] and tantalum.[56]

6.605.2.1. Metals

Implant materials may corrode and/or wear leading to the generation of particulate debris, which may elicit local and systemic responses. Although metals exhibit high strength and toughness, they are more susceptible to electrochemical degradation than ceramics or polymers. Therefore, a fundamental criterion for choosing a metallic implant material, especially one that will be used as a porous coating with a high surface area, is that the biological response it elicits is minimal. Because of the combined mechanical and environmental demands, metals currently used for porous coatings in orthopedics are limited to three classes: cobalt-based alloys, titanium-based materials, and tantalum. Each of these materials is well-tolerated by the body because of its passive oxide layer.

Porous metal coatings are manufactured from powdered microspheres,[18] fibers,[13] wires,[55] foams,[57] or other porous conglomerates,[58] which are mechanically or chemically bonded onto a dense metallic substrate to produce periodic or inhomogeneous porous surface geometries that vary in porosity and degree to which the porous medium is open or closed (**Figure 2**).

6.605.2.1.1. Cobalt-based alloys

Three cobalt alloys are used as orthopedic implants: Co–28Cr–6Mo, which is cast (ASTM F75), forged (ASTM F799), or wrought (ASTM F1537); Co–20Cr–15W–10Ni, which is wrought (ASTM F90); and Co–35Ni–20Cr–10Mo, which is wrought (ASTM F562) or forged (ASTM 961) (Table 1). The requirements for powdered coatings conform to those of cast Co–28Cr–6Mo (ASTM F1377).

Co–28Cr–6Mo alloys are cast at 1350–1450 °C and exhibit an inhomogeneous, large-grained, cored microstructure. The dendritic regions are Co-rich and the interdendritic regions are a combination of a Co-rich γ-phase, a Cr-rich $M_{23}C_6$ phase, where M is Co, Cr, or Mo, an M_7C_3 phase, and a Cr and Mo-rich σ-phase.[59] Co–28Cr–6Mo alloys exhibit a eutectic point at 1235 °C.[59] At temperatures above the eutectic, local melting of the solute-rich zones occurs. Cooling to below the eutectic yields a microstructure consisting of grain boundary σ, γ, and $M_{23}C_6$, which embrittle the alloy. Since the interdendritic phases reduce ductility and corrosion resistance, Co–28Cr–6Mo is solution annealed at 1225 °C, resulting in the transformation of σ to $M_{23}C_6$ and partial dissolution of the $M_{23}C_6$ phase.[60]

Wrought Co–Cr has an austenitic microstructure. Forging above 650 °C results in elongated grains, without recrystallization of the austenitic structure, whereas cold-working below 650 °C results in the formation of an ε-phase. Forging results in a smaller grain size and finer distribution of the block carbides than casting.

Co–35Ni–20Cr–10Mo also has a fine-grained austenitic microstructure. This alloy undergoes an allotropic phase transformation, from an HCP to an FCC structure at 650 °C. Similar to Co–28Cr–6Mo, the low-temperature FCC phase is retained upon cooling, with the transformation product existing only within narrow HCP bands. Aging within the two-phase field leads to the formation of a Co_3Mo precipitate in the HCP regions.

Porous-coated Co–Cr–Mo alloys are created by sintering powdered Co–Cr–Mo microspheres, 100–300 μm in diameter onto a Co–Cr–Mo substrate at 1200–1300 °C for 1–3 h. Alternatively, some coatings are formed by plasma-spraying irregular particles onto a substrate. Since sintering temperatures are above the eutectic point,[59] localized melting accelerates particle bonding. However, processing at temperatures in this range results in the formation of eutectic phases and grain boundary carbides, reducing ductility.

6.605.2.1.2. Titanium-based materials

The combination of high strength, resistance to electrochemical degradation, benign biological response, and relatively low modulus make titanium-based materials attractive for load-bearing applications. Commercially, pure titanium does not possess sufficient strength for orthopedic load-bearing applications, but it is used for porous coatings. Several titanium alloys provide sufficient strength and corrosion resistance: Ti–6Al–4V, wrought (ASTM F136) or cast (ASTM F1108); Ti–6Al–7Nb, wrought (ASTM F1295); Ti–13Nb–13Zr, wrought (ASTM F1713); Ti–15Mo, wrought (ASTM F2066) (Table 2). Several new Ti alloys have also been investigated: Ti–5Al–2.5Fe,[61] Ti–12Mo–6Zr–2Fe, and Ti–35Nb–7Zr–5Ta.[62] Of these alloys, Ti–6Al–4V is the most extensively characterized and used. Porous coatings are comprised of commercially pure Ti or Ti–6Al–4V (ASTM F1580).

At room temperature, Ti–6Al–4V is a two-phase α + β alloy. Above the β-transition temperature (975 °C), an allotropic phase transition occurs, transforming the microstructure to a single-phase body-centered cubic (BCC) β-alloy. Heat treating Ti alloys varies the relative amounts of α- and β-phases and morphologies, resulting in a variety of microstructures and

range of mechanical properties, depending on whether heat treatments were performed above or below the β-transition temperature and cooling rate.

Thermal treatments below the β-transition temperature produce recrystallized equiaxed microstructures, characterized by small (3–10 μm), rounded α-grains with aspect ratios near unity. This type of microstructure is recommended for Ti–6Al–4V implants (ASTM F136). Thermal treatments above the β-transition temperature lead to a variety of microstructures, depending on cooling rate in the $(\alpha+\beta)$ field. Slow cooling produces a lamellar microstructure, similar to that produced by casting and high-temperature sintering of porous coatings, and characterized by coarse (5–20-μm thick) parallel α-platelets. Lamellar microstructures may be refined via solution treatments above the β-transus and subsequent aging at a temperature high in the $(\alpha+\beta)$ phase field.[7,63,64] Titanium microstructures may also be refined by chemical alloying,[65–68] resulting in microstructures with α-grain sizes <1 μm, aspect ratios near unity and discontinuous grain boundary α, microstructural attributes which increase fatigue strength.

To produce sufficient energy to bond Ti microspheres or particles to a substrate, sintering temperatures in the range of 1200–1400 °C are necessary.[5] At these temperatures, bonding of titanium occurs by solid state diffusion. Temperatures in the 1200–1400 °C range are above the β-transition temperature of most Ti alloys used in medicine, leading to coarse lamellar microstructures. The notch-sensitivity of titanium, along with the lamellar microstructure and surface changes created by high-temperature sintering, lead to a significant reduction in fatigue strength of porous-coated Ti implants versus noncoated implants.

Fiber or wire mesh coatings may be bonded to the substrate using a combination of temperature and pressure. The use of pressure allows for lower sintering temperatures. Therefore, Ti–6Al–4V can be sintered at temperatures below the β-transition temperature,[69] resulting in the retention of an equiaxed microstructure. Other porous coatings, such as ones formed from powdered microspheres, become too dense when subjected to pressure, reducing the porosity below the minimum level necessary for bone ingrowth.

On average, bone only grows into 30% of the total available pore spaces in porous-coated implants and is limited to outer regions of porous coatings.[70] To provide porous surfaces with a higher degree of porosity, without compromising mechanical properties, open cell foams, some mimicking the architecture of trabecular bone, have been developed.[57] Starting with an organic foam shell precursor, metal, typically titanium or tantalum, is coated onto the pore surfaces using vapor deposition and sintered to the bulk implant, resulting in porosities of 60–80%.

6.605.2.1.3. Tantalum

Porous tantalum foams are developed from pyrolysis of an organic precursor into a vitreous carbon skeleton.[57] Subsequently, crystalline tantalum is deposited into the foam via chemical vapor deposition.[56] Modifying the thickness of the Ta layer controls stiffness, strength, and porosity. Nominally, physical properties of Ta foams are in the range of trabecular bone properties: stiffness 3 GPa, compressive strength 60 MPa.[71,72] The larger, more open and regular porosity can lead to bone ingrowth through the full thickness of the coating, filling as much as 80% of the pores and leading to higher fixation strength.[56] Applications of porous Ta include hip and knee arthroplasty, especially revision cases, treatment of osteonecrosis of the femoral head, spinal fusion cages, and use as a structural bone graft substitute.[73,74]

6.605.2.2. Ceramics and Ceramic-Coated Metals

Ceramics were originally used in medicine and dentistry because of their relative biological inertness compared to metals. Over time, emphasis has shifted toward bioactive ceramics, or ceramics that can form a chemical gradient and chemical bond with bone through surface dissolution and ion exchange. In addition to having the ability to bond to bone, ceramics are also used to deliver cells, proteins, and genes.

The most common bioceramic used in orthopedics is hydroxyapatite (HA; $Ca_{10}(PO_4)_6(OH)_2$). The motivation for using synthetic HA as a biomaterial stems from the hypothesis that a biomaterial with a composition similar to the mineral phase in bone will bond to bone. The crystal structure of HA is modified by ionic substitutions, which influence bone bonding. Most synthetic HA implants contain substitutions for the PO_4^{3-} and/or OH^- groups and vary from the ideal stoichiometry and Ca/P ratio of 1.67. For example, oxyhydroxyapatite, tricalcium phosphate, tetracalcium phosphate, and octocalcium phosphate have all been detected in commercially available apatite implants (**Table 3**).[75–78]

Bioactive ceramics exhibit low tensile strength and fracture toughness. Therefore, their use in bulk form is limited to applications in which only compressive loads are applied. Bioactive ceramics may be implanted in anatomic sites subjected to tensile stresses if they are used as a coating on a metal or ceramic implant[29] or strengthened via crystallization or reinforcing with a second phase.[79–82]

Calcium-phosphate coatings have been deposited onto porous metal implants to accelerate bone ingrowth, increase the strength of the prosthesis/bone interface, and shield tissues from metallic corrosion products.[29,70,83] The amount of bone ingrowth, strength of the ceramic/bone interface, degree of improvement in bond strength relative to noncoated metals and Ca-P solubility are variable, suggesting material and processing induced variance in the ceramic and metal, in addition to biological variability.[76,84]

Calcium-phosphate coatings are bonded to metallic implants via several techniques: sintering[75,76,85]; plasma-spraying[77,86]; ion beam and other sputtering techniques[87,88]; electrophoretic deposition[75,76]; sol–gel techniques[89]; pulsed laser deposition[90]; chemical vapor deposition[91]; and solution techniques.[92–95]

Table 3 Calcium-phosphate phases with corresponding Ca/P ratios

Name	*Formula*	*Ca/P ratio*
Hydroxyapatite (HA)	$Ca_{10}(PO_4)_6(OH)_2$	1.67
Fluorapatite	$Ca_{10}(PO_4)_6F_2$	1.67
Chlorapatite	$Ca_{10}(PO_4)_6Cl_2$	1.67
A-type carbonated apatite (unhydroxylated)	$Ca_{10}(PO_4)_6CO_3$	1.67
B-type carbonated hydroxyapatite (dahllite)	$Ca_{10-x}[(PO_4)_{6-2x}(CO_3)_{2x}](OH)_2$	$\geq$1.67
Mixed A and B-type carbonated apatites	$Ca_{10-x}[(PO_4)_{6-2x}(CO_3)_{2x}]CO_3$	$\geq$1.67
HPO_4-containing apatite	$Ca_{10-x}[(PO_4)_{6-x}(HPO_4)_x](OH)_{2-x}$	$\leq$1.67
Monohydrate calcium phosphate (MCPH)	$Ca(H_2PO_4)_2{\cdot}H_2O$	0.50
Monocalcium phosphate (MCP)	$Ca(H_2PO_4)_2$	0.50
Dicalcium phosphate dihydrate (DCPD)	$Ca(HPO_4){\cdot}2H_2O$	1.00
Tricalcium phosphate (TCP)	α- and β-$Ca_3(PO_4)_2$	1.50
Octacalcium phosphate (OCP)	$Ca_8H(PO_4)_6{\cdot}5H_2O$	1.33

Adapted from Segvich, S. J.; Luong, L. N.; Kohn, D. H. In *Biomaterials and Biomedical Engineering*; Ahmed, W., Ali, N., Öchsner, A., Eds.; Trans Tech Publications: Zurich, 2008, with permission.

During plasma-spraying, powder is sprayed onto the metal implant, with plasma temperatures as high as 10 000 °C. The ceramic particles form a loosely bonded coating on impact. Due to the rapid cooling of the particles, the temperature of the metal does not exceed 150 °C and the structure and properties of the bulk metal do not change. However, porosity and phase changes are induced in the ceramic, and mixtures of HA, TCP, and tetracalcium phosphate evolve from stiochiometric HA.[77]

During ion sputtering, an ion beam sputters off atoms from a target to form a thin coating on the porous metal. With electrophoretic deposition, the Ca-P coating is precipitated out of suspension onto the metal implant. Electrophoretic deposition is more conducive to coating the internal surfaces of a porous metal. Both sintering and electrophoretic deposition of apatite on titanium result in a phosphate-rich interfacial layer.[75] The interior of the coating is phosphate-depleted, resulting in a higher Ca/P ratio, the formation of tetracalcium phosphate and increased solubility.

An apatite layer can also be formed on an implant surface *in vitro* under STP conditions.[92,93,95–99] The use of biomineralization strategies to form 'bone-like mineral' *in vitro* is based on the concept that bioactive ceramics can bond to bone through a layer of bone-like apatite, which forms on some ceramic surfaces *in vivo* and is characterized as a carbonate-containing apatite with nanoscale crystallites.[100–103] It is therefore hypothesized that a requirement for a biomaterial to bond to bone is the formation of a biologically active bone-like apatite layer.[100–103]

The deposition of apatite onto an implant surface from solution is guided by the pH and ionic concentration of the microenvironment. Conditions conducive to heterogeneous nucleation will support epitaxial growth of mineral. To drive heterogeneous precipitation of mineral nuclei, the net energy between a nucleated precursor and the substrate must be less than the net energy of the nucleated precursor within the ionic solution.[93] The surface energy of an implant may be altered and functional groups that can chelate calcium ions may be created by grafting, self-assembled monolayers, irradiation, alkaline treatment, or hydrolysis.[95,97,99,104,105] Biomimetic strategies have been used to coat metals to accelerate osseointegration,[92,96,98,104,106] as well as glasses, ceramics, and polymers.[95,97,99,105,107,108]

The self-assembly of apatite within the pores of a porous or porous-coated implant enhances cell adhesion, proliferation, and osteogenic differentiation, as well as modulates cytoskeletal organization and cell motility *in vitro*.[109] When progenitor cells are transplanted on these materials, a larger and more spatially uniform volume of bone is regenerated.[110] An additional benefit of the biomimetic processing conditions is that growth factors can be incorporated into the coating without denaturing, enabling a dual conductive/inductive approach.[111–113]

Regardless of the technique used to coat an implant with bioactive ceramic, long-term stabilization and fixation strength frequently do not depend on the ceramic coating. The primary benefit of ceramic-coated porous metals is to accelerate the achievement of a steady-state interfacial strength. In addition to characterizing the ceramic/bone interface under functional loading, the mechanical integrity of the metal/ceramic interface must also be considered as a design parameter.

Different structures and compositions of Ca-P coatings result from different processing techniques. Ion exchange reactions at the interface between a ceramic surface and biological environment depend on a comprehensive set of physical/chemical properties, including particle size and shape, pore size, shape and distribution, phases present, crystallinity, coating thickness, hardness, stiffness, roughness, and surface area.[114] Differences in ceramic chemistry and structure lead to differences in biological response both *in vitro* (e.g., cell attachment and proliferation, protein synthesis, RNA transcription)[109,115,116] and *in vivo* (e.g., cell differentiation, amount and rate of bone formation, intensity, or duration of inflammatory response).[117–119] The collective data from numerous animal and human studies are that calcium-phosphate coatings with Ca/P ratios in the range 1.5–1.67, tricalcium phosphate and HA, respectively, result in the most beneficial tissue response.[114]

6.605.2.3. Polymers

Because of stress shielding of bone with stiff metallic implants, it is hypothesized that an isoelastic femoral stem or coating, which has a modulus similar to that of bone, will result in a more uniform stress distribution and better stress transfer across the implant/bone interface, reducing mechanically mediated bone resorption. Since most polymers are not mechanically suitable to be used as bulk load-bearing implants porous polymers, including polytetrafluoro-ethylene,[47,48] polysulfone,[43,49] and polyethylene,[50] have been used as coatings.

Coating metal implants with polymers could circumvent problems arising with porous metal coatings, including reduction in fatigue strength, stress shielding, and release of dissolution products. For example, polymer coatings have a lower modulus, are sintered to Ti–6Al–4V at temperatures below the β-transformation, and decrease the surface area of metal exposed to body fluids.[49] These advantages, however, are outweighed by the inability of the metal–polymer interface to withstand the stresses resulting from functional loading.

Although polymer coatings are used less extensively than metal or ceramic coatings, bone will grow into many polymers that are sufficiently inert and have a suitable porosity. The extent and time course of ingrowth depends on the location of implantation and mode of loading, but, at least from qualitative observations, the integrity of the polymer/bone interface can be as mechanically stable as a metal/bone interface. With the interest in degradable materials for tissue regeneration, porous polymers have experienced a renewed interest.

6.605.3. Properties of Porous-Coated Implants

To achieve bone ingrowth into the surface of an implant, high surface area coatings are used. The surface area of porous-coated implants is five to ten times greater than the surface area of noncoated, nontextured implants. Porous coatings have the potential to provide advantages of biological fixation, increased bone/implant shear strength, better stress transfer from the implant to the surrounding bone, and a more uniform stress distribution. However, the increased surface area does lead to potential, mechanical, and electrochemical disadvantages and design of porous-coated implants requires an understanding of the mechanical and electrochemical consequences of higher surface area materials. Reductions in fatigue and degradation resistance have been implicated in the failure of porous-coated implants.[120–122]

6.605.3.1. Mechanical Properties

Due to the long service life requirements of total joint replacements, the most critical mechanical property is high cycle fatigue strength. For many materials, 90% of the fatigue life is spent initiating a fatigue crack.[123] Thus, microstructural and compositional parameters inhibiting crack nucleation produce good high cycle fatigue strength. However, for materials with voids and geometric irregularities, especially notch-sensitive materials such as titanium, resistance to crack propagation is also a critical design parameter. Because of the microstructural and geometric changes brought about by the deposition of a porous coating onto an implant surface, the high cycle fatigue strength of porous metal implants is approximately 75% lower than the fatigue strength of uncoated total joint replacements[7,8,10,124,125] (**Table 4**).

The high ultimate and fatigue strengths make Co–Cr–Mo alloys suitable for joint reconstruction. However, the fatigue strength of porous-coated Co–Cr–Mo is only 180–250 MPa.[5,60,125] The high-temperature (1200–1300 °C) sintering treatment required to bond the coating to the substrate results in a microstructure similar to the microstructure of cast Co–Cr–Mo, which exhibits porosity and eutectic phases. Noncoated implants subject to the same sintering treatment have similar low fatigue strengths.[5,125] The lower fatigue strength of porous-coated Co–Cr–Mo implants can therefore be attributed to sintering, and postsintering treatments sufficient to refine cast microstructures are also applicable to porous-coated Co–Cr–Mo implants.[60,125]

The fatigue strength of Co–Cr–Mo alloys is controlled by the ability of the solute atoms C, Cr, and Mo to inhibit dislocation motion.[60] Solution annealing increases strength and ductility due to a reinforcing effect of the transformed carbides. However, prolonged annealing, such as during sintering treatments, results in more complete carbide dissolution and a decrease in fatigue strength.[60] Hot isostatic pressing (HIP-ing) increases the fatigue strength by reducing porosity and eliminating grain boundary carbides.[125]

The mechanical properties of $(\alpha+\beta)$ titanium alloys are dictated by the amount, size, shape, and morphology of the α-phase and the density of α/β interfaces.[114,126–128] Microstructures with a small α-grain size, a well dispersed β-phase, and a small α/β interface area, such as equiaxed and H_2-alloyed microstructures, resist fatigue crack initiation best and have the highest fatigue strengths (500–700 MPa),[8,67,127–129] because a small α-grain size decreases the slip length. Lamellar microstructures, which have a larger α/β surface area and more oriented colonies, have lower fatigue strengths (300–500 MPa), because slip is more easily transmitted from one plate to another. Hydrogen-alloying treatments break up the continuous grain boundary α and colony structure and produce a homogeneous microstructure consisting of refined α-grains in a matrix of discontinuous β, resulting in increased fatigue strength.[67]

Table 4 Fatigue strengths of porous-coated metals

Material	*Treatment*	*Fatigue strength (MPa)*	*Testing parameters*	*Authors*
Co–Cr–Mo	As cast	267	Reverse bending ($R=-1$); 167 Hz; $N=2\times10^7$	Georgette and Davidson[125]
	Sintered + HT[a]	177		
	Sintered + HIP + HT	255		
	Porous-coated, sintered + HT	193		
	Porous-coated, sintered + HIP + HT	234		
Ti–6Al–4V	Wrought	625	Reverse bending ($R=-1$); 50 Hz; $N=10^7$	Yue *et al.*[10]
	β-sintered	500		
	Porous-coated, β-sintered	200		
	Wrought	617	Reverse bending ($R=-1$); 167 Hz; $N=5\times10^7$	Cook *et al.*[124]
	β-sintered	377		
	Porous-coated, β-sintered	138		
	Wrought	668	Reverse bending ($R=-1$); 167 Hz; $N=5\times10^7$	Cook *et al.*[7]
	β-sintered	394		
	β-sintered + BAA-1[b]	488		
	β-sintered + BAA-2[b]	494		
	Porous-coated, β-sintered	140		
	Porous-coated, β-sintered + BAA-1	161		
	Porous-coated, β-sintered + BAA-2	162		
	Wrought	590	Reverse bending ($R=-1$); 100 Hz; $N=10^7$	Kohn and Ducheyne[8]
	β-sintered	497		
	β-sintered + HAT-1[c]	669		
	β-sintered + HAT-3[c]	643		
	β-sintered + BAA-3[b]	538		
	Porous-coated, β-sintered	218		
	Porous-coated, β-sintered + HAT-3	177		
	Porous-coated, β-sintered + BAA-3	233

[a]Proprietary postsintering heat treatment.

[b]BAA = postsintering beta annealing and aging treatment: BAA-1 = 1250 °C, 2 h, slow cool; BAA-2 = 1250 °C, 2 h, slow cool/Ar cool/(α + β) anneal, 4 h, Ar cool BAA-3 = 1030 °C, 20 min, Ar quench/540 °C, 4 h, Ar quench.

[c]HAT = postsintering hydrogen-alloying treatments: HAT-1 = 850 °C, 0.5 h in H_2/650 °C, 16 h in vacuum; HAT-3 = 850 °C, 0.5 h in H_2/590 °C, 4 h in Ar/775 °C, 4 h in vacuum.

Since the fatigue life of porous-coated titanium alloys is governed by both the initiation and propagation of fatigue damage, the design of porous-coated implants must also account for mechanisms of fatigue crack propagation, which differ from those governing fatigue crack initiation. Microstructures with large grains and α/β interfacial areas have lower fatigue crack propagation rates and higher threshold stress intensities than fine-grained microstructures.

The reduced fatigue strength of porous-coated Ti is due to a combination of three factors: stress concentrations at the porous coating/substrate interface and within the porous coating: local stresses can be as high as 6X the applied stress[130]; changes in microstructure due to high-temperature sintering: resulting lamellar microstructures have a fatigue strength 20–40% lower than the fatigue strength of wrought, equiaxed Ti–6Al–4V[8,10,67,124,131]; and surface contamination from sintering.[10] Of these three factors, stress concentrations are the most critical.

As the stress concentration in a porous coating increases, the controlling stage of fatigue changes from crack initiation to short crack propagation to long crack propagation (**Figure 3**). As the governing stage of fatigue changes, the microstructure which maximizes the resistance to damage accumulation during that particular stage also changes. At low stress concentrations, crack initiation is the governing stage of fatigue and microstructures with small grains have the highest fatigue strength. At high stress concentrations, fatigue is governed by long crack propagation and coarse microstructures have the highest fatigue strength. At intermediate stress concentrations, such as the stress concentrations at sinternecks, there is no effect of microstructure, since fatigue life is equally dependent on crack initiation and crack propagation. Current porous coating designs lie in the crack propagation region of **Figure 3**. Reducing the stress concentrations at the porous coating/substrate interface will enable postsintering treatments to increase the fatigue strength of porous-coated titanium implants.

6.605.3.2. Electrochemical Properties

Corrosion and wear of implants are undesirable because of potential biological reactions to the degradation products

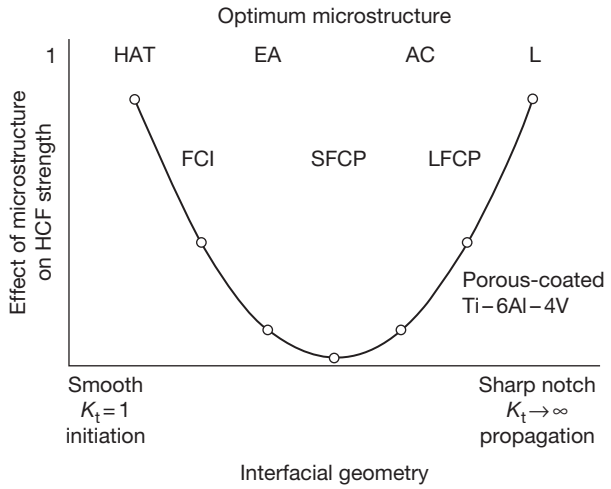

Figure 3 Schematic of Ti–6Al–4V high cycle fatigue (HCF) strength and governing stages of fatigue (FCI, fatigue crack initiation; SFCP, short crack propagation; LFCP, long fatigue crack propagation) as functions of microstructure (HAT, hydrogen alloy treated; EA, equiaxed; AC, acicular; L, lamellar) and interfacial geometry. and potential loss of implant structural integrity. For these reasons, metals used in implantology are in their passive state under typical physiological conditions and, theoretically, breakdown of passivity and transport of metal ions and electrons across the metal oxide should not occur.

Cobalt–chromium alloys are corrosion resistant because of their passive chromium oxide layer. Alloying with Mo further enhances corrosion resistance.[60] The inhomogeneous microstructure of cast Co–Cr–Mo makes it more susceptible to corrosion than the forged alloy,[132] due to the presence of Cr-depleted dendritic regions acting as the more anodic sites in a galvanic reaction. Wrought Co–Cr–Mo has a lower carbon content than cast Co–Cr–Mo and, as a result, a lower corrosion resistance.[132] However, the rest potentials of Co–Cr alloys are below the breakdown potential, and the breakdown potential exceeds the potential of the oxygen reduction reaction.[133] In addition to the increased surface area of porous-coated Co–Cr alloys, sintering causes microstructural changes that also decrease corrosion resistance behavior. For example, in sintered Co–Cr, corrosion preferentially occurs at grain boundaries and regions adjacent to carbides.[134] Both c.p. Ti and Ti–6Al–4V possess excellent corrosion resistance for a full range of oxide states and pH levels. The low dissolution rate and near chemical inertness of titanium dissolution products allow bone to osseointegrate with titanium.[133]

Even in their passive condition, however, metals are not inert, and passive dissolution occurs from the surfaces of metals used in orthopedics. Corrosion of a metal (oxidation/reduction reactions and the rate of these reactions) is dictated by thermodynamic driving forces and kinetics. Corrosion may be an independent process or act in concert with wear. Even if uncoupled, neither corrosion nor wear operates via a single or spatially uniform mechanism. For example, corrosion may occur globally over a large region of an implant surface or locally at sites of different surface or solution concentration. Under functional loading, which can involve relative motion, fretting or wear between components, corrosion can be mechanically assisted. Fretting corrosion, corrosion fatigue and stress corrosion cracking can accelerate the release of metal ions or particulates. Dynamic metal-on-metal contact can occur in metal–metal wear couples and in tapered connections in modular prostheses and these junctions are especially prone to corrosion, with elevated amounts of corrosion products detected in surrounding tissues.[135–137] If wear particles are generated, then there also exists the potential for these higher surface area particles to undergo dissolution.

Although the biological consequences are unknown, increased concentrations of metal ions occur locally and systemically in patients with metal implants, especially loose implants.[39,138–141] While discolored tissues adjacent to titanium implants are due to metal debris, the elemental ratios in the tissue are similar to those in the bulk alloy, suggesting that the debris represent wear particles rather than corrosion products.[142] Although wear debris present a large surface area for corrosion, it is the presence of wear debris that is the major contributor to systemic increases in titanium.[140] Corrosion products are more prevalent in tissues adjacent to Co–Cr implants, although these products are also associated with modular implants or loosening.[39] During wear accelerated corrosion, Co–Cr alloys can release large amounts of dissolution product during repassivation, due to solution supersaturation at the metal surface. Titanium, on the other hand, repassivates almost instantaneously through surface controlled oxidation kinetics. Titanium ion release that does occur is a result of the chemical dissolution of titanium oxide.

The increased surface area of porous-coated implants increases the potential for passive dissolution or mechanically-assisted degradation. Metal oxide dissolution in porous-coated implants creates several questions that are important to investigate: What material is released? How much is released? What reactions are release products involved in? What percent of the release products is excreted versus retained? If retained, where do these products accumulate? What biological responses result from the retained fraction?[39,143–145]

6.605.4. Design and Characterization of Porous Materials

The complex 3D surface geometry and micromechanical environment within porous materials make the design and characterization of porous-coated implants challenging. The interfaces between the porous coating and implant and porous coating and tissue (hard and soft) also need to be well characterized as part of an effective design approach. Many of the design principles for porous-coated implants translate into the design of porous scaffolds for tissue engineering. The success of both technologies depends on the ability of the microenvironment to help organize cell function in 3D porous media and allow functional tissue to grow and adapt. Understanding the interaction between porous biomaterials and tissue at different dimensional scales is therefore important, and a variety of experimental and analytical approaches are available to characterize this complex microenvironment.

Porous coatings are formed from bonded microspheres, fibers, plasma-sprayed particles, or foams, and can be either open or closed systems of ordered or random architecture. Quantifying architectural parameters and developing structure–property relations is critical, especially considering competing design objectives of maximizing porosity for transport, cellular invasion, and bone ingrowth, but also maximizing strength.

Stereology is well established in metallurgy and stereological principles were adapted for analysis of trabecular bone and other porous and granular media.[146,147] Briefly, test lines oriented at an angle θ are superposed onto planar sections of a porous coating consisting of domains that are defined as either material or void space. The mean intercept length is the average distance between two material/void interfaces measured along a line. When mean intercept length is plotted against direction, the data fit the equation of an ellipse in 2D and an ellipsoid in 3D. From 2D measures of the ratio of material voxels to total voxels and the number of intersections a test line makes relative to its total length, architectural parameters, such as volume fraction, surface-to-volume ratio, thickness, density, and separation can be calculated. The ratios of mean intercept length in orthogonal directions can provide an estimate of the degree of anisotropy. Connectivity of a porous structure and determination of whether a structure is open (connected pores) or closed cell (pores not connected) can be quantified via the determination of an Euler number.

Characterizing the mechanical properties of porous materials is more complicated than for dense, spatially homogeneous materials. Three levels of dimensional scale should be considered: structural properties or properties of the whole domain of material and voids; material properties or properties of individual microspheres, fibers, or struts of trabecular metal; and nanoscale properties or properties on the same dimensional scale as features of the material that interact with cells.

Characterizing the stiffness of porous coatings is important because local stiffness controls cell spreading, cytoskeletal mechanics, and cell differentiation,[148] ultimately affecting bone ingrowth. The stiffness of a porous coating also controls stress transfer, bone adaptation, and stability of the porous coating/tissue interface.[149,150] Gradients in stiffness between porous coatings and the underlying dense implant also affect porous coating/substrate bonding. At the structural-level, porous coatings may be anisotropic, which necessitates testing in multiple directions. Structural-level stiffness–strength relations follow a power law relationship with structural density and, for idealized models of cellular solids, closed form relations for the stiffness of open and closed cell structures exist.[151]

Anisotropic elastic constants of a porous coating/tissue interfacial zone can be predicted via a number of analytical techniques that provide values bounded by load and displacement boundary conditions.[25] The amount and distribution of bone ingrowth into a porous coating and subsequent bone adaptation depend on local strains,[152,153] which are dependent on material and tissue architecture within the implant/tissue interfacial zone.[150,154] Coating design, loading history, and relative motion also affect the amount of bone ingrowth.[27,154,155] Developing relations between local strain magnitude and amount and distribution of ingrown bone is challenging. Most studies focus on bone adaptation to implants on a global level, not accounting for porous coating architecture. However, local tissue distribution surrounding individual microspheres within a whole implant interface is poorly correlated with global mechanical fields. Global models by themselves, unless highly refined and computationally intensive, model the porous coating/tissue interface as a homogeneous bonded interface, and omit local details. Local models of isolated regions of a porous coating are valuable for predicting local stresses and strains, but are typically not linked to an analysis of the whole implant. Scaling local strains to actual tissue strains in relation to physiological loading is needed to establish the relationship between local interface tissue strains and amount of bone ingrowth.

Local models idealize porous coatings into regular, periodic microstructures consisting of idealized shaped unit cells and, in hierarchical analyses, are coupled with global continuum models.[150] Coupled global/local modeling shows that with increased depth of bone ingrowth, stress concentrations in both metal and tissue are reduced, reducing potential mechanical failure at the porous coating/tissue interface.[150,156] Moreover, strain fields around individual microspheres are inhomogeneous and peak strains in the interfacial zone are more than triple the strains predicted by global analyses, demonstrating the need for local analyses.

Because of the stress intensification in porous metals, crack initiation life is not a valid predictor of fatigue life. Therefore, a technique of detecting fatigue crack initiation and monitoring fatigue crack propagation is important for characterizing the mechanical response of porous coatings. In implementing a technique of monitoring fatigue damage in porous materials, several material characteristics must be considered: the complex surface geometry, the potential for damage to occur simultaneously at multiple, unknown sites, and the possibility of irregular crack contours.[157]

A technique of monitoring the structural integrity of a porous material should fulfill the following criteria[157]: (1) detect damage at any location at any time; (2) detect damage at multiple sites that are unknown *a priori*; (3) measure the dimensions of damage; (4) be sensitive, accurate, free of artifact, easily calibrated and implemented; (5) monitor the material continuously during loading; (6) monitor in real-time; (7) be nondestructive; and (8) be applicable to all materials and in all environments. Nondestructive techniques of detecting material flaws and measuring damage may be defined with respect to the physical parameter(s) of the material that the defects alter, and include techniques that measure alterations in mechanical, electrical, magnetic, thermal, acoustic, chemical and optical properties, and particle and wave parameters (**Table 5**).

In summary, a combination of experimental and analytical techniques introduced into biomaterials has yielded insights into the behavior of porous coatings as structural materials and as components of a biomaterial/tissue composite that are critical to the clinical success of porous-coated prostheses.

6.605.5. Porous Coatings in Tissue Engineering

Many of the strategies used to design porous-coated implants can be transferred to the design of porous scaffolds used in

Table 5 Summary of techniques to monitor material damage

Technique	*Advantages*[a]	*Disadvantages*[a]	*Minimum detectable damage zone (μm)*
Acoustic emission	1, 2, 4–8	3, 4	10
Barkhausen noise	1, 2, 5–7	3, 4, 8	–
Compliance/ COD	3, 5–8	1, 2, 4	25
Computed tomography	1–3, 7, 8	4–6	50
Eddy currents	1, 2, 7	3–6, 8	220

[b]O = on the order of.

tissue engineering for controlling tissue growth. An ideal tissue substitute would satisfy the following design requirements, many of which are design requirements for porous-coated implants[94,158]: biocompatibility; osteoconductivity – it should provide an appropriate environment for attachment, proliferation, and function of osteoblasts or their progenitors, leading to the secretion of new bone; osteoinductivity – it should have the ability to incorporate factors that direct bone growth; sufficient porosity to allow transport and ingrowth of vascular tissue; mechanical integrity to support functional loads; controlled degradation into nontoxic species that are metabolized or excreted; and ability to be easily processed into irregular 3D shapes.

Bone regeneration can be achieved by culturing cells capable of expressing the osteoblast phenotype onto porous synthetic or natural materials that mimic structural and/or functional aspects of natural extracellular matrices. Materials that satisfy at least some of the design requirements for a bone substitute and support bone regeneration include titanium,[34,159] PLGA,[160] collagen,[161] polyphosphazenes,[162] polyurethanes,[163] polycaprolactone,[164] PEG,[165] poly-(propylene fumarate),[166] starch-based materials,[167] alginate,[168] silk,[169] bioactive glasses and glass ceramics,[115,116] HA, TCP, and coral,[119,161,170,171] HA/ and HA/TCP/collagen,[161] and polymer/apatite composites.[97,172–174] Analogous to the findings that the architecture and composition of a porous-coated total joint replacement control tissue ingrowth,[27,154] alterations in scaffold composition and structure can alter *in vitro* outcomes, including osteoblast or progenitor cell attachment and proliferation, collagen and noncollagenous protein synthesis and RNA transcription,[109,116,174–177] as well as *in vivo* outcomes, including progenitor cell differentiation to an osteoblast lineage, amount and rate of bone formation.[117,119,178]

In addition to their osteoconductive nature, porous and porous-coated biomaterials can be combined with inductive factors, to control cell proliferation, differentiation, and bone formation.[113,179,180] Osteoinductive properties can be integrated into a biomaterial by immobilizing proteins or peptides to the material surface via adsorption, cross-linking, covalent binding, or physical entrapment. Each of these immobilization techniques results in different loading efficiencies and different levels of protein retention, as well as influences the release profile of the molecule. Growth factors can be adsorbed to or dispersed over the surfaces of metal, ceramic, and polymer biomaterials, allowing these nonbiologically communicative materials to serve as delivery systems for molecules that can communicate with surrounding cells.[181,182] Although release kinetics are dependent on the material and protein, the general release profile of a surface adsorbed molecule is rapid release, followed by a slower release based on the chemical and/or physical attraction between the material and protein.[183,184] In some cases, a more sustained release or a pulsatile release is required for a growth factor to be effective. Controlled release of a growth factor can be achieved by incorporating the factor into the bulk of a polymer during polymerization and designing a release profile based on protein diffusion and/or material degradation.[185,186] Other means of incorporating proteins into the bulk of a material include using layer-by-layer assembly and adsorbing the protein into each layer deposited,[187] binding pellets together using a gel, with a growth factor adsorbed to the surface of the pellets,[188] using sol–gel techniques to create slow release protein carrier coatings,[189,190] and coprecipitating inorganic/organic coatings onto implants.[111,191]

In order to integrate drug delivery capabilities with other design variables for a porous-coated implant, methodologies that are amenable to encapsulating a drug to the surface of a material that can withstand mechanical loads would have the most impact. Growth factors and antibiotics have been incorporated onto titanium alloy implants by coprecipitating the proteins with calcium phosphate.[179,192] An important advantage to this approach is the ability to produce calcium-phosphate coatings at a physiological temperature, minimizing conditions that would change the biological activity of the factors. The mineral/protein coating can be as thick as 50 μm.[191] Biomolecules can be incorporated at different stages of calcium-phosphate nucleation and growth,[111,193] enabling spatial localization of the molecule through the apatite thickness and increasing protein loading. Coprecipitation therefore results in a more controlled release of biomolecules in comparison to adsorption, because the negatively charged protein has an affinity for the apatite matrix, rather than just a superficial association.[111,191] Techniques used to incorporate growth factors into bone-like mineral can also be used to incorporate genes.[112,194]

6.605.6. Summary and Future Directions

Over the past 40 years, porous-coated implants have been utilized clinically as an alternative to cemented implants, especially in younger and more active patients. In addition to total joint replacements, porous-coated implants are used for segmental defects and as spinal implants. Many of the design objectives learned over the last four decades may also be translated to tissue engineering. Conversely, tissue engineering strategies may come to fruition first when used to augment the function of an implant, rather than regenerate a tissue *de novo*.

The use of porous and porous-coated biomaterials is expected to expand and, although clinically successful, modifications to current technologies could increase the service life and expand the pool of patients with indications for use. There are several areas in which new materials, new designs, and new strategies of creating and maintaining tissue ingrowth could be achieved. New coating materials that have a combination of fatigue resistance and elastic match with bone, yet have sufficient porosity to facilitate transport and are biologically tolerable are needed. A second approach to improve mechanical integrity and cooptimize mechanical and transport properties to modify coating architecture. Architectural modifications include design of functionally graded materials, creation of open cell coatings, and development of optimization algorithms to design coatings in which material is distributed to meet dual objective functions of maximizing strength and maximizing permeability. Design and manufacturing of periodic, open microstructures can be achieved by solid free form fabrication methods, such as 3D fiber deposition, selective laser melting, 3D printing.[195–197]

Strategies to increase the magnitude and rate of bone ingrowth using material chemistry and biological approaches also parallel many strategies used in tissue engineering. In fact, advances in tissue engineering are likely to first arise in conjunction with established implantology approaches and materials. Use of nanomaterials, attachment of biological factors, and integration of drug delivery with implantology may each help enhance bone growth. A variety of cell functions, such as adhesion and intracellular signaling, are sensitive to surface features on the order of nanometers.[198] Creation of nanosized grains or nanoscale topologies on a microscale coating could therefore provide a porous-coated implant with the physical scale necessary to better influence biological function.

Attachment and delivery of proteins from implants is also being pursued.[189,190] Proteins, however, are subject to isolation and degradation. Proteins can also change conformation because they possess sections with varying hydrophobicities. Peptides can mimic the function of a protein while being smaller, cheaper, and less susceptible to degradation. Peptides have the potential for controlling initial biological activity, because they can contain specific target amino acid sequences and can permit control of hydrophilic properties through sequence design. Peptide sequences have been designed to mimic sections of ECM proteins,[199] and material-specific peptides have been discovered.[200]

Modifying surface chemistry and integration of biological molecules with materials to control cell function are important design modifications. By themselves, however, they are not sufficient for clinical function. A key to translating advances in nanotechnology, materials chemistry, and biomolecular surface engineering into the design of a clinically relevant implant is to integrate the nanoscale features needed to control cell function with a larger 3D implant that has the dimensions and bulk properties required to fulfill a desired clinical application.

Glossary

Osteolysis Lysis of bone, typically an active resorption of bone tissue by osteoclasts as part of an ongoing disease process.

Radiostereometric analysis A high precision method for measuring micromotions, such as the migration and wear, of orthopedic implants in the skeleton in three dimensions.

Single-nucleotide polymorphism A DNA sequence variation occurring when a single nucleotide, such as an A, replaces one of the other three nucleotide letters—C, G, or T in a certain stretch of DNA.

Synovitis Inflammation of the synovial membrane.

Synovium Synovium, also called synovial membrane, is the soft tissue that lines the non-cartilaginous surfaces of joints.

Abbreviations

ASGM1	Anti-asialo GM1 rabbit sera
BC	Bone cement
BSP	Bone sialoprotein
COX	Cyclooxygenase
hIL1Ra	Human interleukin-1 receptor antagonist
IL-1	Interleukin-1
ITAM	Immunoreceptor tyrosine-based activation motif
LPS	Lipopolysaccharides
mRNA	Messenger ribonucleic acid
M-CSF	Macrophage colony-stimulating factor
MSCs	Mesenchymal stem cells
NF-kB	Nuclear factor kappa B
NSAIDs	Nonsteroidal anti-inflammatory drugs
OCP	Osteoclast precursors
OPG	Osteoprotegerin
PAMPS	Pathogen-associated molecular patterns
PBMCs	Human peripheral blood monocytes
PGE2	Prostaglandin E2
RANK	Receptor activator of NF-kB
RANKL	Receptor activator of NF-kB ligand
RSA	Radiostereometric analysis
SCID	Severely combined immunodeficient
SNPs	Single nucleotide polymorphisms
TGF	Transforming growth factor
THR	Total hip arthroplasty
TiAlV	Titanium–aluminum–vanadium
TJA	Total joint arthroplasty
TJR	Total joint replacement
TKR	Total knee replacement
TLR	TOLL-like receptors
TNF-α	Tumor necrosis factor alpha
UHMWPE	Ultra-high-molecular-weight polyethylene
VEGF	Vascular endothelial growth factor

6.606.1. Introduction

Total joint replacement/arthroplasty (TJR/TJA) has been one of the most successful operations for patients with disabling arthritis. The 15-year survivorship of the total hip replacement (THR) and total knee replacement (TKR) is ~90% or higher using contemporary prostheses and techniques and judicious patient selection.[1] However, wear of TJRs is inevitable and as a result of excessive wear of the articulating surfaces, late failure has been the most common long-term complication of the procedure, which often requires revision surgery. On the other hand, the population is aging and the shifting demographics in the United States has prompted younger patients and those with more active life styles to undergo TJR. These facts have led to higher expectations of patients for the improved survivorship of TJR. Although technical advances have been associated with an increasing success rate of specific prostheses, the incidence of failures resulting from wear-related osteolysis requiring surgical revision may not be decreasing.[2] According to a recent report, a 10-year revision-free survival rate was observed in 90% of patients older than 70, but only 72% of patients younger than 50.[2] Wear between the primary bearing surfaces generally exhibits few clinical symptoms or signs until painful synovitis, fracture, structural failure, or loosening of the implant are noticed. Thus, when debris-associated chronic synovitis and osteolysis become notable, revision surgery including thorough debridement and replacement of worn and damaged components is indicated. At revision surgery, implant loosening is often accompanied by the formation of a fibrous chronic inflammatory membrane.[3] In this chapter, the characteristics of the bone–implant interface are reviewed, the biological effects of wear debris generated from wearing of TJRs are summarized, and the available nonsurgical treatments are discussed.

6.606.2. Orthopedic Wear Debris

Orthopedic implants must be integrated with host bone to function properly. However, formation of a fibrous membrane, as opposed to osseous integration is often accompanied by loosening of the implants.[4] Observation of the tissue surrounding loose prostheses has enhanced our understanding of the nature of the wear debris generated from the prosthesis. Histological observations show that retrieved periprosthetic tissue contains numerous particles of bone cement (BC), polyethylene, and metallic debris and that the generation of wear particles and the process of loosening are related[5,6] (**Figure 1**). The nature of the wear particles is dependent on the materials used in the prosthesis.[3,6,7] Studies in the 1980s and 1990s revealed that the majority of wear debris contained in the interface membrane of failed joint implants is polyethelene[8] and cementless prostheses generated more particles than cemented ones.[4] For a metal-on-polyethylene articulation, several hundreds of thousands of polyethylene particles may be generated during a single gait cycle.[9] Besides the quantity of generated particles, many factors influence the biological reactivity of particulates. *In vitro* studies established that the biologic response of the cells to wear particles is a function of the size, composition, surface roughness, and the quantity of particles.[8] The aspect ratio, the surface binding proteins may also influence the general biocompatibility.[8] Recently, alternative bearing surfaces designed to reduce the wear process have been introduced. These include highly cross-linked ultra-high-molecular-weight polyethylene (UHMWPE), ceramic-on-ceramic and metal-on-metal bearing surfaces. These new articulations have shown promise in reducing volumetric wear and it is hoped that the long-term complications of osteolysis will also be reduced.[8] However, recent analysis suggested that although the volumetric wear rate of highly cross-linked UHMWPE has been significantly decreased, the smaller sized highly cross-linked polyethylene particles may be more bioreactive.[10] When metal-on-metal wear is involved, the metallic particles are usually in the nanometer scale range and the resulting surface area of the particles is large.[11] In addition to generating particulate wear debris, metal-on-metal articulating surfaces can also produce other byproducts, mainly free metallic ions that can lead to chronic toxic and immune reactions such as a type IV T-cell-mediated immune response and pseudotumor formation.[8,12] In cases of ceramic wear debris, submicron-sized particulates of alumina and zirconia

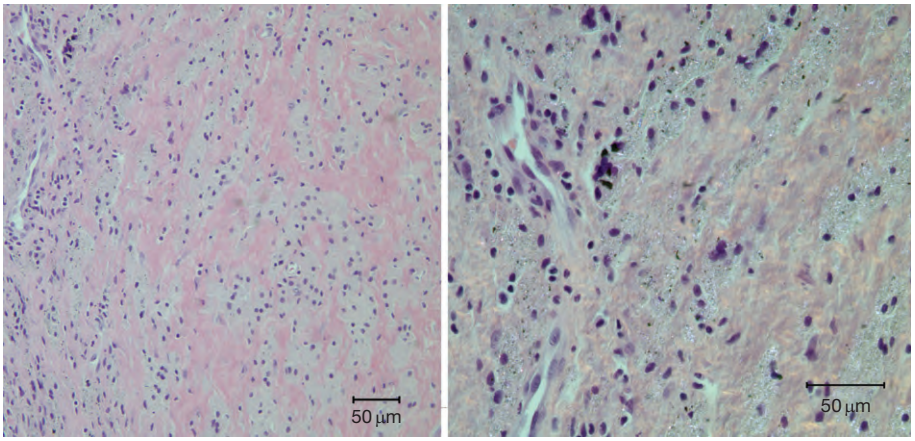

Figure 1 Photomicrograph of histological section from tissue retrieved from the granulomatous synovial capsular tissues demonstrating sheets of macrophages in a fibrovascular stroma. Left: Hematoxylin and eosin stain, light field and right: hematoxylin and eosin stain, polarized light field.
Note: Black metal particles and abundant granular white specks of polyethylene under polarized light can be seen.

can elicit a similar but usually less intense reaction to those seen with submicron-sized polymers and metal debris.[13,14] Overall, the wear rate of these newer bearing surfaces has been significantly reduced compared to conventional metal-on-polyethylene articulations. However, although the volumetric wear rates of the bearing surfaces are reduced, the characteristics of particles, including size, shape, and surface coating antigenic properties of the particles and host factors, all contribute to the complex process of osteolysis.[10,15–17]

6.606.3. Biologic Reactions of the Host to Wear Debris

The biological response of the host to wear debris occurs in a unique microenvironment in which a variety of host cells are exposed to continuously generated wear particles. The cellular response has been dominated by cells of the monocyte–macrophage lineage and many other cells are active participants. Cellular profiles from studying retrieved membranes surrounding the implant revealed the presence of macrophages, fibroblasts, lymphocytes, mesenchymal stem cells (MSCs), osteoblasts, and osteoclasts.[3,18,19] Current research has also identified molecules that are released by these cells that regulate the inflammatory processes elicited primarily by particles (**Figure 2**).

The role of the major cells implicated in the process of implant wear and the cellular response to wear debris and the biological factors involved in the regulation of these cells are reviewed in the following sections.

6.606.3.1. Macrophages

The presence of macrophages with phagocytosed wear particles has been universally reported in cases of failed TJR. To date, almost all the particles generated from wearing of prostheses, including metal particles, UHMWPE, PMMA, ceramics, and hydroxyapatite have been shown to activate macrophages.[20–23] Wear particles less than approximately 10 μm can be engulfed by macrophages,[24] which then become activated, and can activate other macrophages by means of autocrine and paracrine mechanisms. Furthermore, more macrophages are recruited to the site, thereby increasing the local macrophage population.[25,26] Activated macrophages release inflammatory mediators and disrupt the homeostatic balance between osteoclasts and osteoblasts. Activation of macrophages by particles can also occur without phagocytosis.[27] In the case of surface contact between particles and macrophages, multiple surface receptors (CD11b, CD14, TOLL-like receptors (TLRs)) on macrophages can interact with particles that are associated with specific proteins. The intracellular signaling transduction involves the activation of the mitogen-activated protein kinase cascade (JNK, MEK), leading to activation of transcription factor nuclear factor kappa B (NF-κB) and nuclear translocation, which upregulates gene expression mechanisms for proinflammatory cytokines and chemokines, the hallmarks of foreign body and chronic inflammatory reaction.[28] These cytokines and inflammatory mediators include interleukin-1 (IL-1), IL-6, IL-8, IL-11, prostaglandin E2 (PGE2), metalloproteinases, collagenase, receptor activator of NF-κB ligand (RANKL), macrophage

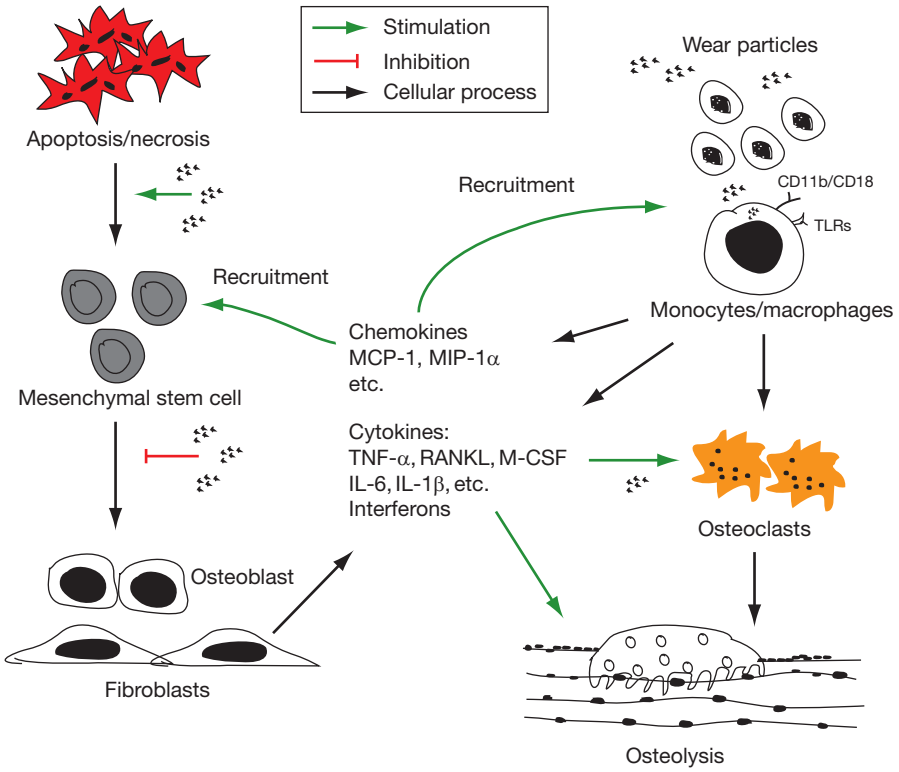

Figure 2 Diagram of the biological reactions associated with wear particles.

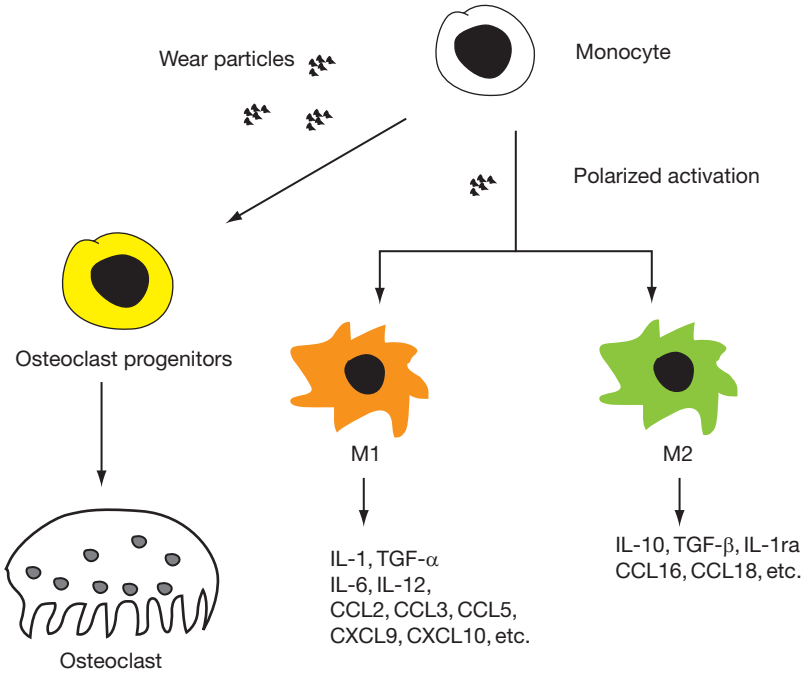

Involvement of monocyte/macrophages in periprosthetic osteolysis

Figure 3 Involvement of monocyte/macrophages in periprosthetic osteolysis. Monocytes are precursors to both macrophages and osteoclast precursors (OCPs). Wear debris induce the classically activated macrophages (M1) to secrete proinflammatory mediators and the release of reactive oxygen. In contrast, alternative activation of macrophages (M2) may contribute to granuloma fibrosis and bone remodeling.

colony-stimulating factor (M-CSF), vascular endothelial growth factor (VEGF), and tumor necrosis factor alpha (TNF-α).[8]

An emerging hypothesis for macrophage activation in osteolysis is that macrophages are heterogeneous cells and the heterogeneity of the undifferentiated circulating monocytes as well as the microenvironment may lead to polarized activation of macrophages. Following the initial exposure to wear particles, classically activated macrophages (M1) initiate a periprosthetic proinflammatory response, and this response subsequently transitions to a more prolonged, noninflammatory phase dominated by an alternative macrophage phenotype (M2) to form granulomas in an attempt to process nondegradable materials[29] (Figure 3). Studies comparing the periprosthetic tissue from revision TJR and synovium revealed elevated levels of chitotriosidase and CCL18, markers for alternative macrophage activation.[30–32]

6.606.3.2. Osteoblasts and MSCs

Osteoblasts are mainly responsible for the process of bone formation. Several studies have demonstrated reduced new bone formation in the presence of particles.[33] In cell culture studies, osteoblasts or osteoblast-like cells were able to phagocytose particles and release chemokines that trigger the migration of other cell types.[34] Particles also disrupt the osteoblast adhesive behavior, alter its gene expression profile, and induce apoptosis.[35,36] One mechanism by which osteoblasts communicate with osteoclasts is the production of cell membrane-associated RANKL and M-CSF. Interaction of RANKL with the receptor activator of nuclear factor κB (RANK) on mononuclear cells of the monocyte/macrophage lineage eventually leads to osteoclastogenesis. Particle-treated human primary osteoblasts produce high amounts of factors that induce osteoclastogenesis including RANKL and M-CSF-1.[10]

Recently, attention has shifted to the potential destructive effects of wear particles on osteoprogenitors as they differentiate to bone-forming cells. Adult MSC-like progenitor cells can be found in bone marrow as well as in adult trabecular bone.[37,38] During the life span of the prosthesis, bone marrow cells and the trabecula directly juxtaposed to bone are exposed to continuously generated particles. The biological function of these progenitor cells could be critically affected by increasing amounts of wear particles, potentially diminishing the pool of osteoblasts for bone formation and osseointegration. The mechanisms by which wear particles exert their impact on MSCs remain largely unknown. Recent studies showed that submicron-sized particles decrease the proliferation and viability of human MSCs, suppress gene expression of bone sialoprotein (BSP), and inhibit matrix mineralization.[39] Prolonged exposure of murine osteoprogenitor-like cells to titanium particles also reduced the viability of these cells by direct and indirect induction of apoptosis or necrosis.[40] With the diminished stem cell population and compromised stem cell function, the process of osseointegration and prosthesis fixation can be severely jeopardized.[41]

6.606.3.3. Osteoclasts

The differentiation, migration, and activation of osteoclasts have been implicated as the key step accelerating the degradation of bone.[3] Most inflammatory mediators released by macrophages and present at the bone–implant interface,

including PGE2, TNF-α, IL-1β, and M-CSF are potent stimulators of osteoclastogenesis.[42–44] The essential signaling for osteoclastogenesis is the interaction of RANKL and RANK. RANK, a member of the TNF receptor superfamily, is expressed on osteoclast precursors and mature osteoclasts. RANKL is expressed on the cell surface of osteoblasts, bone marrow stromal cells, fibroblasts, mammary epithelial cells, and activated T cells.[45] RANKL is active as a transmembrane molecule as well as a soluble monomer.[46] Following RANKL–RANK contact, multiple signaling molecules (TRAF6, NF-κB, AP-1, and NFAFc1) are activated. NFATc1 is absolutely required as the master regulator of osteoclasts.[47] Together with M-CSF, RANKL also activates the resorptive function and maintains the survival of mature osteoclasts.[48–50] RANKL or RANK deficient mice develop severe osteopetrosis as a result of complete deficiency in osteoclastogenesis.[49,51,52] Osteoprotegerin (OPG), a soluble decoy receptor of RANKL, blocks the RANKL–RANK coupling by competitively binding with RANK.[52–55] OPG is mainly produced by bone marrow stromal cells, dendritic cells, and monocytes/macrophages.[55,56] The molecular ratio of RANKL, RANK, and OPG expression has become an indicator for assessing bone remodeling. Studies using polyethylene and TiAlV wear particles and a human monocytic leukemic cell line showed that TiAlV and polyethylene particles induced the expression of RANK mRNA, and OPG mRNA expression increased transiently.[57] OPG levels in the joint fluid from failed total hip arthroplasty patients were much lower than those from patients with osteoarthritis.[58]

Osteoclastogenesis also requires costimulation via ITAM (immunoreceptor tyrosine-based activation motif) signaling receptors. When osteoclast precursors deficient of DAP12 and FcRγ, two ITAM-containing adaptor proteins were stimulated with RANKL and M-CSF, no multinucleated osteoclasts could be seen.[59,60]

Because osteoclasts have the ability to mobilize calcium from bone, initiate bone remodeling, and communicate with hematopoietic stem cells, they are referred as innate immune cells of bone by some researchers.[61–65] Murine osteoclast precursors express TLRs TLR1–TLR9 and *in vitro* studies showed that direct TLR stimulation inhibited osteoclast formation induced by RANKL.[66] Very little information is available on the role of TLRs on osteoclastogenesis *in vivo*. The interaction of osteoclasts and other innate immune receptors is currently an active research area.

6.606.4. Other Factors Modulating the Biological Activity of Wear Particles

6.606.4.1. Genetic Contribution

Clinical variation seen in patients with TJR suggests a potential genetic contribution. Minor variations in DNA sequence can result in subtle changes in gene expression, giving rise to altered susceptibility to osteolysis. Variation in specific genes for single nucleotide polymorphisms (SNPs) correlated with osteolysis after TJR in a cohort of 481 subjects (214 failed cemented THR, 267 radiologically intact implants).[67] A study conducted on a cohort of 609 subjects (268 patients with osteolysis, 341 nonosteolytic THR controls) suggested a positive association of the gene, FREZ, encoding a protein for Wnt signaling, with osteolysis.[68]

6.606.4.2. Endotoxin

The contribution of byproducts derived from bacteria to aseptic loosening has received considerable attention in recent years. Lipopolysaccharides (LPS), the classic endotoxin, has been shown to increase the biological activity of wear particles to induce osteolysis *in vitro* and *in vivo*.[69–75] Besides LPS, a collection of immunostimulatory molecules known as pathogen-associated molecular patterns (PAMPs) have been identified. The sources of PAMPs in patients with aseptic loosening and how crucial the PAMPs are to aseptic loosening remains unclear. Studies have suggested that one source of PAMPs could be the gram-positive bacteria containing biofilm attached to implants.[76,77] Other sources of PAMPs could be the systemic blood circulation[78] or the contamination of surgical implants.[79] Studies to evaluate the polymorphisms in the genes encoding the PAMP receptors and the risk of aseptic loosening will provide key information regarding this subject.[67,68]

6.606.4.3. Implant Instability

Recent studies have emphasized the importance of mechanical stability of implants in the generation of wear particles and aseptic loosening. Relative motion of the implant in bone triggers the formation of a fibrous membrane.[80,81] Such a membrane serves as a conduit for particles, cells, and other osteolytic mediators, inhibiting bone formation and enhancing bone erosion.[82–84] Clinical studies showed that cemented THRs with minor early subsidence rates (relative motion) using sensitive techniques such as radiostereometric analysis (RSA) will become loose clinically within 2 years.[85] However, whether relative motion of an implant precedes or follows the formation of a fibrous membrane is unknown.

6.606.4.4. Pressure

In general, cells can be perturbed by pressure in various manners. In the context of implant fixation, pressure can alter local bone remodeling, affecting new bone formation and osteolysis.[86] Clinically, when implants have subsided during loading, widening of the medullary canal, thinning of the cortex, and the presence of a bony pedestal distal to the implant can often be found as a result of profoundly altered distribution of mechanical forces. Under normal conditions, there is a thin layer of synovial fluid in the articulating surface that bathes the natural or replaced joint articulation. This fluid is distributed into the contiguous accessible areas of the joint, also known as the effective joint space, by each step during loading of the limb, much like a hydraulic piston. In the case of synovitis, increased fluid production within the joint causes increased intraarticular pressure during loading, which is transmitted to the joint space and contiguous areas. When synovitis occurs concurrently with increased numbers of wear particles, fluid containing wear particles, cellular infiltrates, proinflammatory factors, and other molecules can be introduced into the effective joint space.[87–89] This may be the reason for the observation of osteolysis remote from the source of particle generation, as seen in cases of polyethylene wear with widespread osteolysis around the femoral stem.

In vivo animal studies also confirmed that pressure alone can adversely alter bone remodeling.[90–93] In fact, particles and

mechanical forces such as hydrostatic pressure, cyclic stretch, or mechanical strain have been shown to be synergistic.[82,94,95] Although animal models are always somewhat different than the clinical situation, they do suggest that pressure can induce adverse bone remodeling in the absence of wear particles.

6.606.5. New *In Vivo* Models and Development of Particle-Induced Osteolysis

The ongoing production of wear debris may be asymptomatic clinically. When severe pain or other local symptoms such as swelling, poor function, or pathologic fracture are noticed long after joint replacement, periprosthetic osteolysis is often present to an extended degree. Newer alternative bearing surfaces are successful in reducing the particle load delivered to the local tissues, but to date, nonsurgical pharmacological methods to prevent or treat the adverse effects of wear particles are still not available. This fact has spawned new research efforts into the pathogenesis of particle disease in the hope that early nonsurgical intervention may prevent or delay the need for revision surgery. Several new *in vivo* models have emerged and information collected from these studies further pinpointed the biological pathways involved in wear particle disease (Table 1).

6.606.5.1. Models of Continuous Delivery of Particles *In Vivo*

Following THA, wear particles are generated continuously with usage of the joint. As a result, the local tissues are exposed to wear particles in an accumulative fashion over prolonged periods of time. For *in vivo* studies of particle disease, the majority of animal models have been applying one bolus/a single dose of particles, or multiple periodic injections of particles to an anatomical site, which is different from the clinical situation. Kim and colleagues made the first attempt to connect a diffusion pump with the knee joint containing an intramedullary femoral Kirschner wire in rats to deliver polyethylene particles to the knee joint continuously.[105,106,119] This novel model showed that continuous delivery of high-density polyethylene particles was associated with increased expression of TNF-α mRNA and radiographic osteolysis around the rod. Formation of an inflammatory periprosthetic membrane lined with osteoclasts was also found.

The group from Stanford University optimized and quantitated Kim's rat model using bench top experiments and converted and validated it into an *in vivo* murine model for studying the effects of continuous infusion of particles.[102–104,120] In the *in vitro* experiment, blue-dyed commercial polystyrene particles and retrieved clinically relevant UHMWPE particles were suspended in mouse serum at various concentrations and loaded into Alzet mini-osmotic pumps.[103] Pumps were attached to hollow titanium rods via vinyl tubing and the efflux from the rod was collected into a vessel. The number of particles contained in the collection vessel was quantitified at the 2- and 4-week time points. Delivery of both particle types was feasible when the pumps were loaded with concentrations of 10^9–10^{11} particles per pump, which are clinically relevant particle concentrations. Efficiency of delivery of polystyrene particles decreased with higher initial particle concentration; UHMWPE particle delivery increased slightly with increasing initial particle concentration. By the end of the 4 weeks, approximately one-third of the UHMWPE particles in the pump were delivered into the collection vessel. The same delivery system was then evaluated using explanted mice femora in organ culture to show that continuous intramedullary delivery of submicron-sized polymer particles using osmotic pumps is feasible.[102] Infusion of UHMWPE particles at concentrations of 2.60×10^{11} particles per ml for 2 weeks and 8.06×10^{11} particles per ml for 4 weeks both yielded significantly more bone loss radiographically compared to controls in which only mouse serum was infused. Finally, clinically relevant UHMWPE particles were infused to the femoral intramedullary space of live mice for 4 weeks using a subcutaneous implanted osmotic pump.[104] Continuous infusion of UHMWPE particles for 4 weeks led to reduced bone volume detected by microCT and altered alkaline phosphatase expression. The model has therefore proven useful in studying the biological processes associated with wear debris in a more clinically relevant scenario.

Table 1 Animal models currently used to study wear debris-induced inflammation

Species	*Model*	*Key references*
Mouse	Calvarial	96–98
Mouse	Air pouch	99–101
Mouse	Intramedullary implant with particles – femur	102–104
Rat	Intra-articular or intramedullary – femur	105–108
Rabbit	Intramedullary – femur	109–111
Rabbit	Harvest chamber – tibia	112–114
Dog	Pistoning implant – femoral condyle	82
Dog	Intramedullary – hip replacement	115–117
Sheep	Intra-articular injection – hip replacement	118

6.606.5.2. Cell Trafficking in the Presence of Wear Particles

Macrophages, foreign body giant cells, and osteoclasts are the primary cells carrying out phagocytosis and bone resorption. The common precursor of these cells are monocytes in the blood circulation. Whether the phagocytic cells/osteoclasts participating in osteolysis were derived from local monocytes population or migrated remote monocytes is an interesting question that pertains to the therapeutic strategy of particle disease. There have been a few recent studies to suggest that local wear debris may cause systemic migration of macrophages to the site of particle generation. One study injected the distal femora of nude mice with suspensions of Simplex BC or UHMWPE particles and delivered reporter murine RAW 264.7 macrophages, which stably expressed the bioluminescent reporter gene *fluc*, and the fluorescence reporter gene *gfp* intravenously through the tail vein. Trafficking of the labeled macrophages to the femora containing the particles was evaluated by bioluminescence imaging and compared to animals which only received saline in the femora.[121] Six to eight days after the animals were given the exogenous labeled macrophages in the tail vein, the bioluminescent signal of femora containing BC or UHMWPE particle suspensions increased significantly whereas the saline controls did not show this effect. Histological study confirmed the presence of large numbers of reporter macrophages within the medullary canal of

mice that also received the particles. Thus, BC and UHMWPE particles contained in the mouse femur were able to stimulate the systemic recruitment of macrophages. Manipulating the trafficking of systemic macrophages may be a therapeutic strategy to interfere with particle-induced periprosthetic osteolysis.

The trafficking of human peripheral blood monocytes (PBMCs) in the context of particle-associated periprosthetic osteolysis was also studied in a mouse–human (SCID-Hu) chimera model.[122] Human periprosthetic tissues harvested during revision surgery of aseptic periprosthetic loosening were placed into the quadriceps and paravertebral muscles of severely combined immunodeficient (SCID) mice. After a 30-day recovery period following the implantation, the engrafted tissue contained high levels of IL-1, TNF, and IL-6. Priming of the periprosthetic tissues before implantation with retroviruses encoding for human IL-1 receptor antagonist (hIL-lRa) decreased the total number of inflammatory cells and expression of IL-1 and TNF. In a separate study, the SCID mice underwent periodic intraperitoneal injection of anti-asialo GM1 rabbit sera (ASGM1) to deplete the mouse of the host macrophages and the human periprosthetic tissues harvested during revision arthroplasty surgery for aseptic loosening were placed the same way as previously described. Human PBMCs labeled with PKH2 fluorescent dye were then injected into the peritoneum of the same mice. Fourteen days later, the injected fluorescence labeled PBMC were found to traffic to the xenografts and were associated with increased expression of IL-1, IL-6, TNF-α, and RANK within the periprosthetic tissue.[123] This experiment once again confirmed that systemically administered blood monocytes can traffic to an area of particle-induced inflammation.

6.606.6. Therapeutic Strategies

Since aseptic loosening occurs in only a small fraction of patients who undergo TJR, current attempts for nonsurgical treatments has focused on existing pharmacologic approaches known to interfere with inflammation. Several candidate drugs are being considered based on their specific targets. Anti-inflammatory drugs, such as nonsteroidal anti-inflammatory drugs (NSAIDs), selective cyclooxygenase (COX) inhibitors (e.g., celecoxib), TNF antagonists (e.g., etanercept, infliximab, adalimumab), and IL-1 antagonists (e.g., Anakinra) may potentially have a role in curtailing the progression of osteolysis on a theoretical basis. However, the adverse effects of these drugs, especially the impairment to the immune system are of great concern. In this respect, one promising candidate for the nonsurgical treatment of osteolysis is the RANKL antagonist. This approach not only prevented wear-induced osteolysis in animal models,[124–127] but consistently demonstrated nonimmunosuppressive effects. Interestingly, a human recessive null mutation in RANKL led to clinical osteopetrosis but without adverse immunosuppressive effects, further demonstrating the potential of RANKL antagonists.

6.606.7. Conclusion

Wear particles from bearing surfaces and supporting materials of TJAs are inevitably generated with usage of the joint. The characteristics of the particles depend on the materials of the bearing surfaces and the overall design and function of the implant. These particles and their byproducts stimulate local and systemic biological reactions by the host to mount an inflammatory and foreign body reaction. Many cell types are active participants or modulators of these events. The cells communicate by the release of cytokines, chemokines, and other proinflammatory factors in a paracrine and autocrine fashion. Newer bearing couples reduce overall volumetric wear; however, the long-term clinical performance still needs to be evaluated. Newer pharmacological approaches may hold promise in mitigating osteolysis as an alternative nonsurgical treatment for selected patients if the prosthesis is still functioning well.

6.607.1. Introduction

Fretting corrosion, or mechanically assisted corrosion (MAC), occurs at modular junctions or connections of implant components and is produced by relatively small-scale (1–100 μm) motion between implant components induced by cyclic loading. This type of corrosion occurs in all types of alloys regardless of material couple (e.g., stainless steel/stainless steel, Co-alloy/Co-alloy, Co-alloy/titanium, titanium/titanium, etc.). Fretting of modular implant components commonly occurs in the modular connections of hip and knee implant in orthopedics.[1] Corrosion products are bioreactive and cause local inflammation that results in local bone loss (osteolysis), pain, and ultimately implant loosening. An in-depth analysis of this phenomenon is given elsewhere in this publication (see **Chapter 6.608, Implant Debris: Clinical Data and Relevance**). Inflammation from corrosion debris is proportional to the amount of debris and can thus occur slowly over time (decades) with little debris or can occur within months when there is aggressive fretting corrosion. This was the case in stainless steel (SS) intramedullary rods used for hip fracture fixation that demonstrated aggressive corrosion in the modular taper resulting in rapid bone loss and ultimately recall of the implant.[2] Fretting corrosion is dependent on amount of micromotion, the designs of modular connections, the alloy combination, and other factors that affect the mechanical or chemical environment of the implant, including surgical factors. For example, tibial inserts in total knee replacements have been shown to undergo over 100 μm of micromotion at low loads (<100 N) when 'locked' into place, creating an ideal site for the generation of fretting corrosion products.[3] Mechanical-load-induced motion results in increased rates of corrosion by deforming the protective oxide layer (which forms a barrier on the surface of metal implants) and thereby reducing the activation across the oxide. Furthermore, the oxide layer is also fractured and reformed (repassivation). Fretting corrosion is MAC at interfaces; if and when present, the mechanical abrasion of the oxide layer also leads to changes in solution composition at the interface, and may thereby further reduce the energy barrier for ion release and enhance corrosion.

The metals literature is clear: there is no 'crevice' corrosion with Co–Cr alloys and Ti alloys in the typical conditions of the body. Fretting corrosion is electrochemically determined in

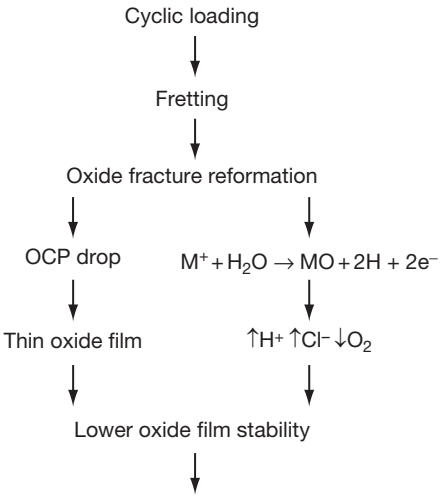

Figure 1 Schematic of the mechanically assisted corrosion (fretting corrosion) within modular junctions (connections) of implant components is shown. Upon repassivation of metal surfaces, a buildup of H^+ and Cl^-, and a lowering of the pH within the crevice environment occur.

that the oxidation reaction of the metallic species is energetically favored by the reduction in free energy associated with metal-oxide formation that results in the sequestration of O_2 from any available source (primarily H_2O). Repassivation of a metal surface at the interface environment results in a buildup of Cl^- and H^+ (lowers the pH). This MAC[4] model of modular junction fretting corrosion has been reported on and popularized by Gilbert *et al.*[1,4] and is schematically represented in Figure 1. An in-depth analysis of these phenomena is given elsewhere in this publication (see **Chapter 1.102, Metals for Use in Medicine**).

6.607.1.1. Orthopedic Alloys

While there are few new alloys that are designed to improve the fretting corrosion resistance of modular junctions (e.g., Zr–Nb alloys, Oxinium™ from Smith and Nephew, Memphis), the three principal metal alloys used in orthopedics over the past 25 years remain dominant, particularly in total joint replacement: (1) titanium alloys, (2) cobalt alloys, and (3) stainless steel alloys. Differences in strength, ductility, and hardness generally determine which of these three alloys is used for a particular implant component.

6.607.1.1.1. Stainless steel alloys

Orthopedic stainless steels, such as 316LV (i.e., ASTM F 138), include molybdenum to enhance the corrosion resistance of the grain boundaries, while chromium dissipated evenly within the microstructure allows the formation of chromium oxide (Cr_2O_3) on the surface of the metal. Stainless steels are surface treated (e.g., in nitric acid) to promote the growth and thickening of this passive oxide layer over the entire surface.[5–8]

6.607.1.1.2. Cobalt–chromium alloys

Cobalt–chromium implant alloys fall into one of two categories of biologic concern: those with nickel and those without; cobalt–nickel–chromium–molybdenum (CoNiCrMo), designated as ASTM F 562, and those without nickel, cobalt–chromium—molybdenum (CoCrMo), for example, ASTM F 75 and F 76.

6.607.1.1.3. Titanium alloys

While pure titanium is generally the most corrosion resistant of the implant metals, titanium alloy Ti–6Al–4V (ASTM F 136) is used for joint replacement components because of its needed superior mechanical properties in comparison to commercially pure titanium (cp Ti). The Ti–6Al–4V alloy microstructure is generally composed of a fine-grained HCP phase with a sparse distribution of the BCC phase to maintain strength and corrosion resistance.

6.607.1.2. Implant Junctions

6.607.1.2.1. Screw–plate interface

Corrosion is often observed in the connections of retrieved screw–plate interfaces and modular connections of joint replacement components. Investigations have shown that crevices formed at the screw plate junction are dependent on the geometry of the screw–plate interface and that preventing fretting corrosion may not be feasible through enhanced surgical technique. Screw–plate fretting is a common source of corrosion debris, although gross evidence of corrosion in screw–plate interfaces is rare.[9]

6.607.1.2.2. Modular junctions

Implant modularity is a primary design feature of modern total joint replacements. The vast majority of the >1 000 000 total joint replacements that are performed every year in North America are modular in design with components that press fit together using press-fit interlocking connections. These modular connections typically involve a tapered male–female junction between implant components, such as a Morse taper, consisting of a tapered shank and socket held together by interlocking ridges. In total hip replacement components, this connection is either metal to metal or metal to ceramic, with a tapered cone on the stem and a tapered bore in the head (Figure 2). This has been a mechanism of connection used in machine tooling for over a century and has been used in orthopedics for approximately 30 years. The more common forms of Morse taper modular junction in total hip replacements are made from cobalt–chromium–molybdenum (Co–Cr–Mo) alloys (ASTM F 75 or F 799) or titanium alloys (Ti–6Al–4V, ASTM F 136), and the heads which fit on these femoral stems comprise either Co-alloy, ceramic alumina (Al_2O_3), or ceramic zirconia (ZrO_2). Despite the geometry-specific interlocking mechanisms of these junctions, micromotion does occur. When body fluids penetrate this junction, MAC, that is, fretting corrosion, may occur, perturbing and disrupting the passive film layer.

Orthopedic alloys rely on the protective barrier of passive films to reduce oxidation (corrosion) from taking place. Since the electrical potential across the body-fluid–metal solution interface for these reactive metals can be 1–2 V and the distances are so small, the resulting electric field gradient across the oxide is very high, on the order of 10^6–10^7 V cm^{-1} (Figure 3). Particularly important to implants is the oxide film theory of Mott and Cabrera,[10] which states that oxide film growth depends on the electric field across the oxide. If the

Figure 2 Total hip replacement femoral components are shown where the head is press fitted onto the stem and secured only by tapping into place to form an interlocking at the 'Morse taper' modular junction. Courtesy of Bioengineering Solutions, Inc.

voltage potential across a metal–oxide–solution interface is decreased, then the oxide film thickness decreases by a reductive dissolution process resulting from electrochemical interactions that act to compensate and keep the electric field strength constant. Increasing the voltage across an interface will correspondingly increase the thickness of the film. In fact, oxide thickness is often determined by the 'anodization rate,' which is defined as the oxide thickness per volt.[11] If the interfacial potential of an implant interface is made sufficiently negative (or similarly if the pH of the solution is made low enough), then metal oxide films will no longer be thermodynamically stable and will undergo reductive dissolution, resulting in no barrier to active corrosion. These barrier oxide films are not flat, smooth, continuous sheets of adherent oxide covering the metal; they can be of needle[12] or dome[13] shapes. Several treatments are used to increase the barrier effect of protective oxide films, which include hot, concentrated nitric acid baths, boiling in distilled water,[14] and anodization. However, detailed investigations into how induced changes in oxide film structure maintain and protect the surface of orthopedic alloys *in vivo* remain incomplete.

6.607.2. Experimental Methods: Implant Fretting Corrosion

6.607.2.1. Methods: Oxide Layer Testing

Structural properties of protective oxide films intimately relate to the degree of fretting or corrosion resistance offered by metal surfaces. These structural properties include adhesion strength of the oxide to the substrate metal, hardness, thickness of the oxide, and the relative modulus of elasticity of oxide and substrate. One method to investigate these properties during and after oxide fracture is scratch testing. This technique has been extensively used by Gilbert *et al.*[15–17] to investigate oxide behavior where the components of a scratch test apparatus include piezoelectric actuators able to produce high-speed displacements of a nonconductive diamond stylus, all attached to a load cell to measure the force imposed on the diamond stylus (Figure 4). The stylus is lowered onto the specimen with a known force and displaces approximately 50 μm in 1–2 s to produce a controlled high-speed repeatable scratch. Both the force of the stylus and the potential voltage applied to the metal specimen can be varied and the resultant measured corrosion current(s) transients and repassivation time constants can be used to assess the repassivation behavior of various orthopedic alloys in different conditions (e.g., electrolytes). By scratching off a narrow band of oxide, the repassivation magnitudes and rates, the mechanical strength of the oxide layer, and the magnitudes and time constants associated with the potential and current transients created can all be studied on different materials and compared.

6.607.2.2. Methods: Modular Junction Fretting Testing

In vitro studies of modular junction fretting quantify the degree of fretting corrosion through electrochemical measurement and through measurement of weight loss of the implant under cyclic loading laboratory conditions (see Figure 4).[18] Fretting corrosion testing of modular junctions employs a combination of classical open circuit analysis and metal release immersion testing during mechanical loading.

6.607.2.2.1. Open circuit potential

Open circuit potential (OCP) analysis during mechanical loading represents the sum of thousands of chemical reactions at the interface, in the complicated environment of the multiple metals in an alloy/surface oxide and the proteinaceous serum electrolyte. An example of an experimental set-up for testing the head–neck junction of a total hip replacement is shown in Figure 5. The equilibrium external current (at 0 load) for this 'multielectrode system,' will reach steady state at near zero. Within an appropriate electrolyte (e.g., serum), one part of a modular component is used as a working electrode (WE) to measure the voltage (OCP) between the WE and a standard reference electrode (e.g., calomel or standard hydrogen electrode). A distal portion of the same component is sectioned or cut away from the area of interest to provide for an electron sink and is used as a counter electrode to measure the fretting corrosion current (I_{fret}). Alternatively, a similar material with equal surface area as the area of the implant that would have been in contact with the solution is often used. The testing chamber is filled with appropriate electrolyte (at 37 °C) and allowed to equilibrate for at least 24 h prior to loading. The electrolyte should fully cover the modular junctions to be tested but remain below any contact point(s) used to apply compression. Typically, the components may be wetted with electrolyte immediately prior to assembly, to simulate a worse case surgical scenario and facilitate fluid–crevice penetration within the period available for *in vitro* testing of the modular junctions.

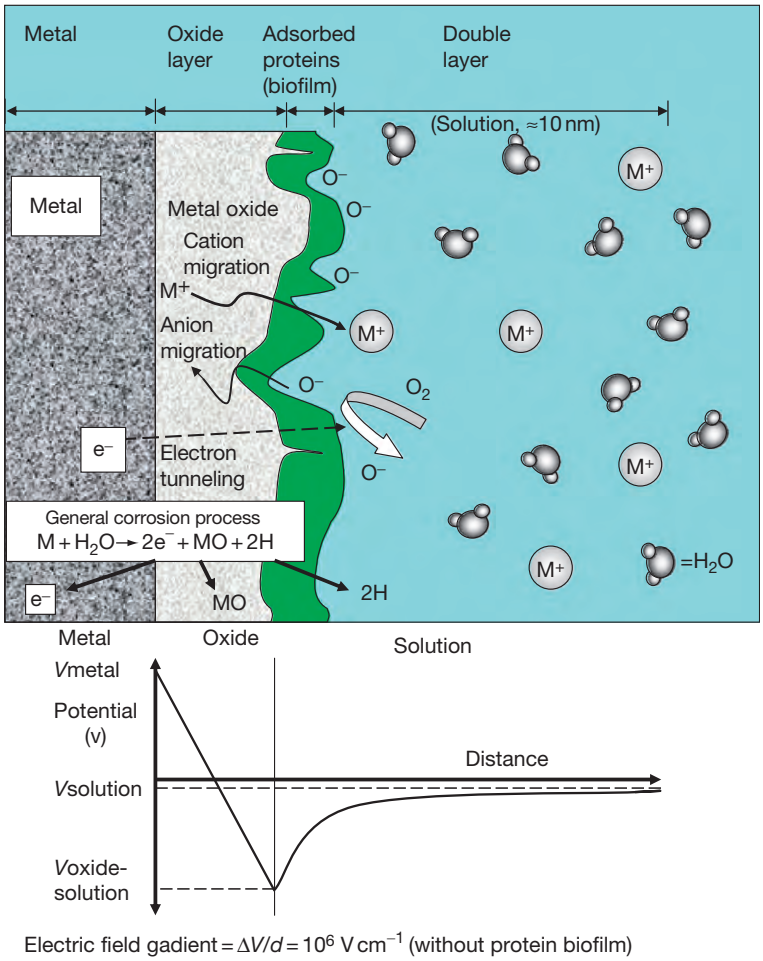

Figure 3 Orthopedic implant metal surfaces in contact with a biological environment are covered by an oxide layer followed by the adsorbed protein (biofilm) through which metal ions can pass into solution as shown.

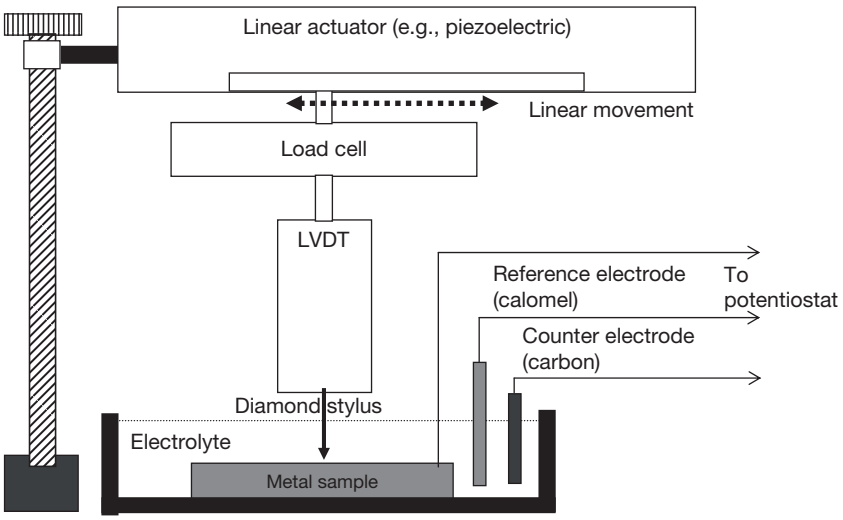

Figure 4 The components of a scratch test apparatus are shown that include piezoelectric, a nonconductive diamond stylus, a load cell to measure the force imposed on the diamond stylus, and a potentiostat to measure the voltage and current generated when the sample is scratched with a known force and displacement, for example, 50 μm in 1–2 s. The corrosion current(s) transients and repassivation time constants can be used to assess the repassivation behavior of various orthopedic alloys under different conditions (e.g., electrolytes).

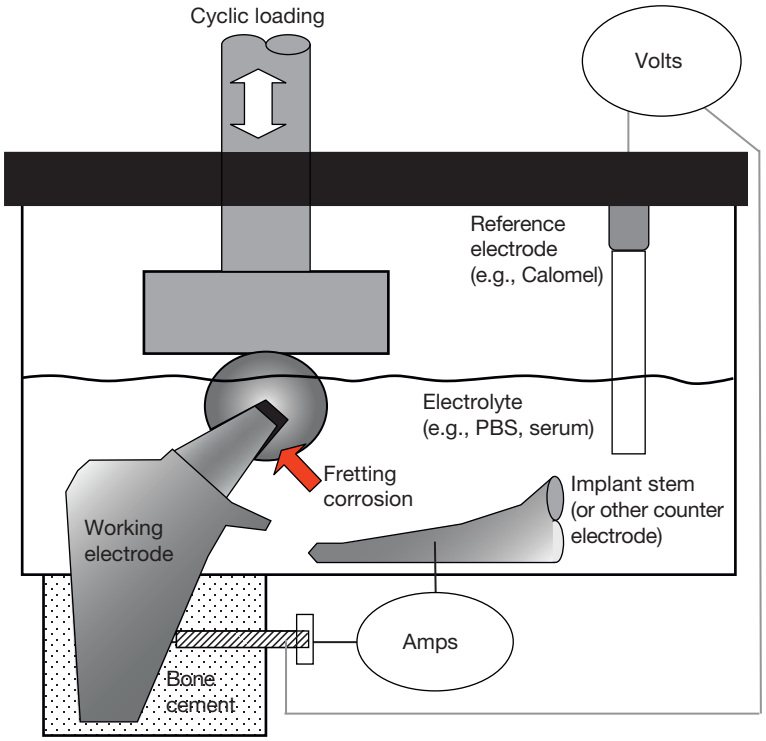

Figure 5 Fretting corrosion test chamber should ideally be air tight or have a 0.2 μm filtered connection to the environment to prevent bacterial contamination within the electrolyte. The modular component of the implant is embedded in bone cement and connected to a potentiostat for monitoring the (1) increase in current and (2) decrease in voltage that occur during fretting corrosion.

6.607.2.2.2. Metal release fretting corrosion testing

A direct test of metal released during fretting corrosion can be conducted using atomic absorption spectroscopy (AAS) and inductively coupled plasma atomic emission mass spectroscopy (ICP-MS) to quantify the concentration of ions released. These spectroscopic analysis techniques have high sensitivity (in parts per billion with proper experimental technique) but they cannot provide information about the valence state of the ions released.

6.607.2.2.3. Mechanical loading

Different mechanical loading environments can be used to simulate physiologic loading or to determine loading conditions at which fretting corrosion will start in different types of material couple or junction configurations. Sinusoidal loads are used to simulate cyclic *in vivo* loads. A typical loading environment for monitoring a total hip replacement modular junction involves simple uniaxial sinusoidal cyclic compression, with a 210 kg load (with a loading ratio of $R = 0.1$, 210–21 kg or 2060–206 N) applied at 1–5 Hz in a neutral anatomic position (following ASTM F 1404 guidelines) for $\sim 1 \times 10^6$ cycles. As a result of the muscle and weight balance biomechanics at the hip joint, a load of 210 kg simulates the average net physiologic load imposed on the femoral head by the cumulative muscle and weight component of a 70 kg individual.

6.607.2.2.4. Short-term testing

Short-term fretting corrosion tests are used to measure the initiation of fretting behavior. These tests are generally either scratch tests or actual mechanical loading of the implant junctions in a physiologically relevant electrolyte with electrochemical monitoring. Short-term testing is used to evaluate fretting associated with material design characteristics (such as alloy material, surface roughness, component tolerances, and surface treatments) and loading characteristics (such as load magnitudes, frequency, load pattern, etc).

6.607.2.2.5. Long-term testing

Long-term testing is used to evaluate how material design characteristics (such as alloy material, surface roughness, component tolerances, and surface treatments) and loading characteristics (such as load magnitudes, frequency, load pattern, etc.) affect fretting over the long term (i.e., typically >2 days of cyclic load testing at >1 Hz). Electrochemical monitoring of voltage drops and current increases associated with fretting induced by cyclic loading can be combined with other types of measurements of corrosion such as metal ion release within the electrolyte. Monitoring the voltage, current, and metal ion release requires state-of-the-art methods for assessing how specific designs and material affect modular and other types of implant junction fretting.

Longer term testing of fretting corrosion can involve the measurement of weight loss of the implant. This type of long-term testing is typically conducted by simulating a yearly loading regimen (>1 million cycles) and then measuring the subsequent weight loss and physical condition of the modular components. Past investigations involving the study of weight loss of modular head–neck junctions of total hip replacements

have indicated less than 5 mg of weight loss for a 5-million cycle test at average physiologic loads (e.g., 2100 N for a 70 kg person).[19,20] This matches the values of weight loss cycles measured in some Ti–6Al–4V alloy stem designs. This value of 1 mg year^{-1} likely represents the upper limit of what is physiologically tolerable without inducing inflammation, bone loss, and early loosening.[19,20]

6.607.3. Implant Fretting and Biocompatibility

6.607.3.1. Past Investigation of Fretting Corrosion Testing

Beginning in the late 1980s, there were reports of fretting corrosion occurring in the modular junctions of total hip replacement components, while concern about corrosion at connections of spinal rods began a little earlier.[21] Both mixed and similar metal couples were undergoing this type of corrosion attack, but there was greater modular junction fretting observed in hip replacements in mixed metal connections.[4,22]

While wear of articulating surfaces is the major source of released metal *in vivo*, many implant retrieval studies have implicated modular junction fretting as a significant source of released metal in total joint replacements that do not have metal-on-metal articulating bearings.[4,23–34] Some studies of implant retrievals have found some fretting corrosion in greater than 35% of cases where dissimilar metal junctions were used (e.g., Ti–6Al–4V to Co-alloy), and in only 7% of THA cases studied with same metal junctions (e.g., Co-alloy to Co-alloy).[28,34–36] Urban *et al*. reported that of 10 different taper designs in 25 retrieved hip arthroplasties, there was evidence of fretting corrosion in all 10 different taper designs (from six different manufacturers) with Co-alloy/Co-alloy, Co-alloy/Ti-alloy, and Co-alloy/$A1_2O_3$ couples.[25,37] Although less common, modular junction corrosion attack of titanium alloy stems also occurs. Thus, material type highly influences modular junction corrosion,[31] and this emphasizes the need to clearly evaluate new highly modular component materials (e.g., ceramic heads on highly modular stems in THA). It should be noted that the majority of heavily corroded modular junctions observed in past retrieval studies were so-called '6-degree taper' designs (see **Figure 6**), which have been phased out of modern implant designs.[28,34–36]

With the increasing popularity of highly modular implants and new types of materials used for articulating surfaces (such as ceramic heads in THA), the possibility of accelerated fretting corrosion requires further study (i.e., in Co-alloy heads).

Fretting corrosion is highly dependent on the composition of the electrolyte, that is, saline versus protein solutions.[18,38,39] While it has been generally established that decreased rates of fretting corrosion occur in protein solutions when compared to physiologic saline solutions, there are notable exceptions. In one study, serum proteins were shown to increase the corrosion (up to 61%, increasing anodic Tafel constants and decreasing cathodic Tafel constants) of stainless steel implant specimens, during electrochemical testing.[40] Similarly, the fretting corrosion of stainless steel plates and screws in protein solutions released increased amounts of Ni and Cr compared to that in saline.[41] Thus, the solubility of metals within the electrolyte media is intimately related to the electrolyte and the implant materials themselves.[42] Even small changes to the

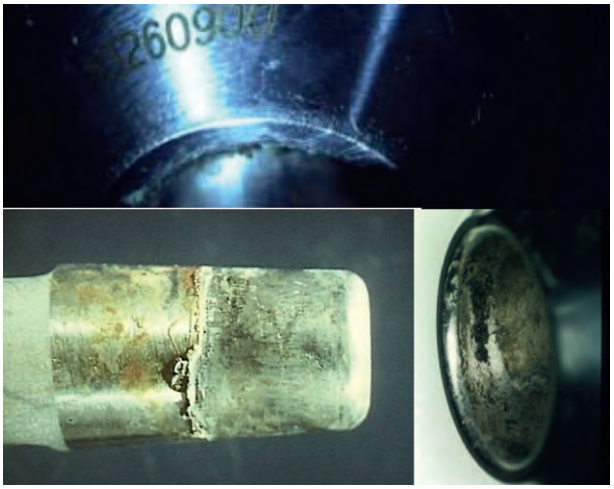

Figure 6 Previous generations of retrieved joint replacement components commonly showed corrosion around the rims of metal conical taper connections, that is, corrosion precipitates at the head–neck junction composed of $CrPO_4$ and other corrosion products. Courtesy of Prof. Robert Urban.

electrolyte can dramatically change fretting corrosion behavior; for example, rates of fretting corrosion in titanium alloy screw plates increased with the addition of soluble calcium to test electrolyte.[43] Generally however, testing in saline solutions (0.9% saline, Ringer's, Hank's Tyrode's, or 10% serum) provides identification of worst case environments even though they do not represent the 100% serum *in vivo* environment.

Both material-dependant surface chemistry and the surface roughness geometry (e.g., ridge design, tolerances, etc.) play a role in the amount of fretting corrosion. However, we have found that among femoral heads with similar geometrical/topographical characteristics (i.e., nearly identical *Ra* values, macroscopic geometry, and stem interface fit) material-dependent surface characteristics seem to dominate as a source of differential fretting corrosion behavior. When testing the fretting corrosion behavior of ceramic-to-metal and metal-to-metal modular junctions, we found that ceramic-to-metal modular junctions produce significantly less fretting and soluble metal debris than geometrically similar metal-to-metal modular junctions.[44] This was evaluated potentiodynamically where both a smaller voltage drop and recovery time were associated with the fretting of ZrO_2 heads on Co-alloy stems (compared to Co-alloy heads) (see **Figure 7**). However, there was little visual evidence of fretting corrosion after 5 million cycles at physiologic loads in serum (**Figure 8**).

6.607.4. Conclusions

Fretting corrosion of orthopedic implants remains a significant clinical problem that has yet to be mitigated in any targeted way. Currently, minimizing fretting corrosion involves (1) understanding the metallurgical processing variables, (2) minimizing the tolerances of modular connections, (3) understanding the surface chemistry and topography, and (4) using appropriate material selection. Surface treatments (e.g., nitriding,

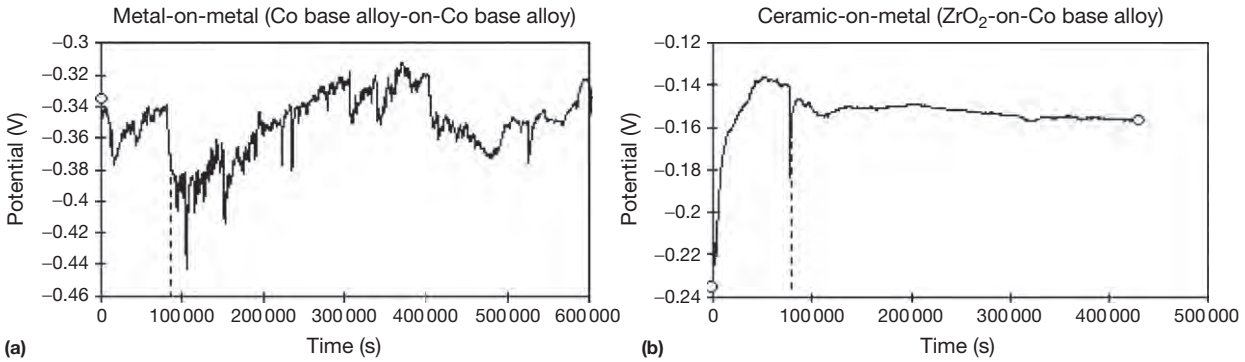

Figure 7 Potentiodynamic monitoring (open circuit potential, OCP) of (a) cobalt alloy and (b) zirconium oxide heads coupled to cobalt alloy stems (210 kg at 2 Hz). Dotted lines indicate onset of cyclic loading. Directly following loading, both configurations decreased in potential (voltage) by approximately 55 mV, indicative of fretting onset.

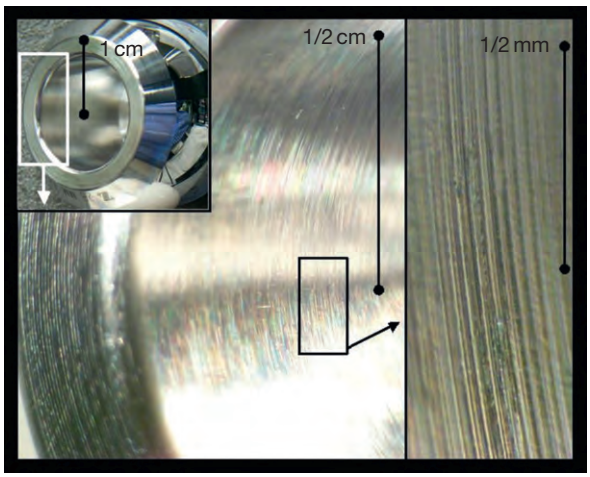

Figure 8 Photographs showing the inside of the modular connection of a Co-alloy femoral head (Zimalloy™, Zimmer, Inc., Warsaw, IN) after fretting corrosion testing for 5×10^6 cycles at 2200–220 N, 2 Hz. There was no observable damage at low magnification, but at high magnification slight degradation of some of the ridges within the taper are apparent. Note: Bars indicate scale.

ion implantation, etc.) can significantly reduce the magnitude of fretting corrosion of titanium alloys and other metal implant devices but to date have not been widely designed to specifically address fretting corrosion. There is an incomplete understanding of which corrosion mechanisms (electrochemical determinants), geometrical characteristics, and material alloy designs dominate *in vivo* fretting of current orthopedic implants. Modular junctions used in joint replacement components and internal fixation devices are now a pillar of modern orthopedic surgery and increasing in popularity. Thus, fretting corrosion is likely to grow as a problem associated with current orthopedic implant designs. Continued awareness of this issue within the orthopedic community and continued basic and clinical research to enhance our understanding of these phenomena are needed to engineer solutions targeted to eliminate implant micromotion or prevent mechanically aided corrosion, that is, fretting corrosion.

6.608.1. Introduction

Over 1 000 000 total joint arthroplasties (TJA) are performed each year in the United States and the projected demand is much higher for the next decade.[1,2] While TJAs typically function successfully for an average of 15 years, such implant procedures still fail in the longer term, and there remains a problem of lasting success.[2,3] Over the long term, all implant debris cause a local inflammatory response that eventually results in bone loss and loss of implant fixation.[4] This inflammatory reaction can occur in 10% of these individuals at 10 years postsurgery and results in marked bone loss around the implant. This phenomenon of bone loss is called 'aseptic osteolysis' and results in pain and premature loosening of the orthopedic implants.[5–7] However, aseptic osteolysis generally only refers to bone loss around an implant that is radiographically visible on an X-ray, Figure 1. The degradation products of the orthopedic biomaterials, generated by wear and electrochemical corrosion, mediate this adverse effect. How this debris is produced via fretting corrosion is discussed elsewhere in this publication (**Chapter 6.607, Fretting Corrosion of Orthopedic Implants**). Debris may be present as particulate wear, colloidal nanometer-size complexes (specifically or nonspecifically bound to protein), free metallic ions, inorganic metal salts/oxides, or in an organic storage form such as hemosiderin. Particulate debris have an extremely large and specific surface area for a given mass of debris, which is available for interaction with the surroundings. This can cause or further increase chronic elevations in serum metal content due to degradation of the implant. This chapter will focus on biomaterial degradation (through wear and electrochemical corrosion), dissemination of the debris, and the consequent local and systemic effects. General mechanisms are discussed elsewhere in this publication (**Chapter 6.606, Biological Effects of Wear Debris from Joint Arthroplasties**).

6.608.2. Implant Debris Types: Particles and Ions

The debris from all orthopedic implants can only be one of two basic types: particles or soluble debris (metal ions). The difference between particles and ions blurs as the size of the particles decreases to the nanometer range, and they become 'soluble.' Typically, particulate wear debris (metal, ceramic, or polymers) range from 40 nm to 1 mm in size, while the so-called 'soluble debris' is limited to metal ions or nanoparticles that are too small to be distinguished from ions, and are bound to plasma proteins.

Figure 1 Periimplant aseptic osteolysis above the acetabular cup of a metal-on-polymer bearing total hip replacement. Inset shows a granuloma surrounding acetabular fixation screw, which is a common site for bone resorption due to the ease with which particles can migrate and cause inflammatory soft tissue and osteolysis. 6.608.2.1. Particulate Debris

Different types of joint arthroplasty produce different amounts of wear debris. These can be of different sizes and shapes, and are implant and material specific. For instance, hard-on-hard bearing couples, such as metal on metal hips replacements, generally produce smaller sized (submicron), fairly round debris whereas the traditional metal-on-polymer bearings produce larger (micron sized) debris and is more elongated in shape (Figure 2).

Implants with metal-on-poly bearings comprise polymer particles that generally fall into the size range of 0.23 to 1 μm, with little metallic debris. Other sources of metal debris include corrosion at metal-to-metal connections between modular components of orthopedic implants. Ultra-high-molecular-weight polyethylene (UHMWPE) wear debris, in periimplant tissues, have shown that 70–90% of recovered particulates were submicron, with their mean size being approximately 0.5 μm.[8–10] Highly cross-linked polyethylene,

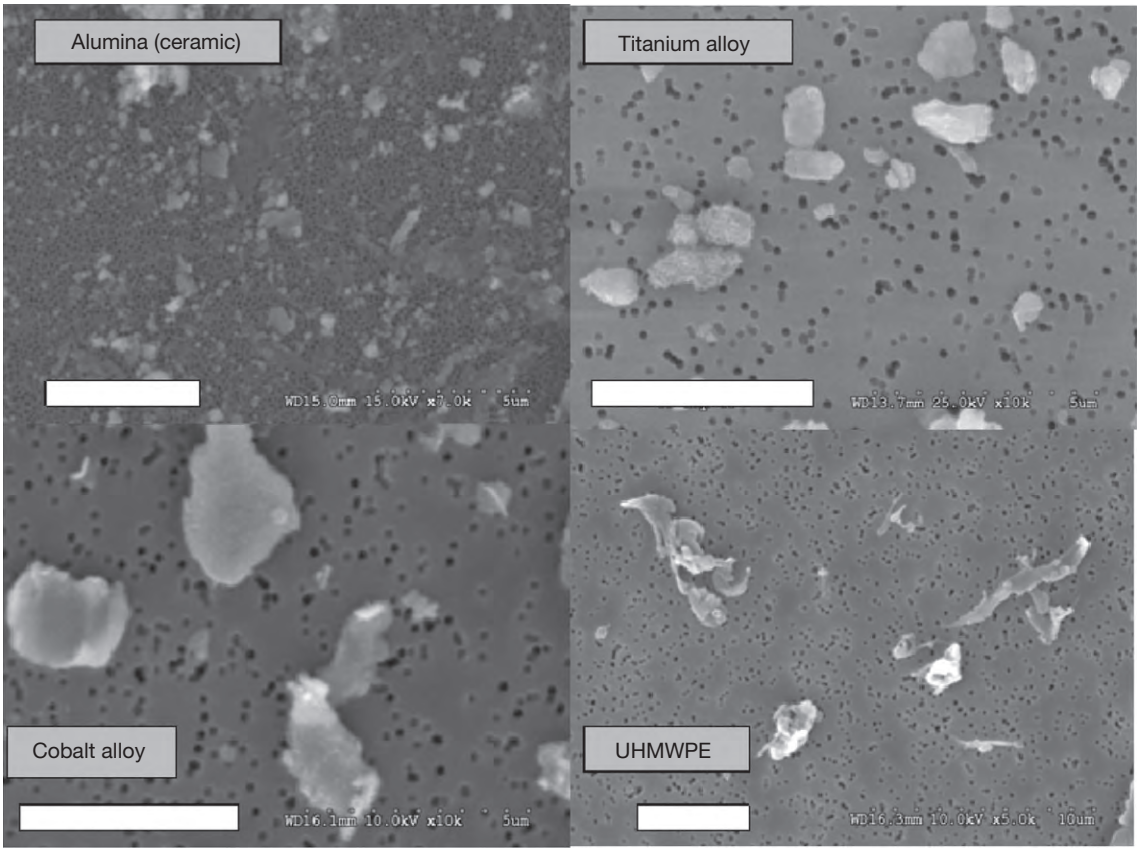

Figure 2 Implant debris from metal (cobalt alloy and titanium) and ceramic (alumina) debris are more rounded in comparison to polymeric (UHMWPE) debris which is more elongated in shape. Note: Bar = 5 μm. Courtesy of BioEngineering Solutions Inc.

used in current models of hip replacements, have demonstrated the production of smaller, and more rounded, debris in the submicron range and are as small as 0.1 μm in size.[11,12] Metal and ceramic bearings produce particles that are generally an order of magnitude smaller than the polymeric particles (at $\sim <0.05$ μm in diameter, i.e., in the nanometer range).

Histological analyses of periimplant tissues have identified different types and sizes of particles.[13–19]

Stainless steel: Stainless steel debris are found as closely packed, plate-like particle aggregates, occurring mostly at the steel screw–plate junctions. This debris contains particles of chromium compounds and range in size from 0.5 to 5.0 μm.[20]

Cobalt alloy: Cobalt alloy debris is a chromium–phosphate ($Cr(PO_4)\cdot 4H_2O$) hydrate-rich material termed 'orthophosphate,' and ranges in size from <1 to >500 μm.[20,21]

Titanium alloy: The degradation products observed in histologic sections of tissues adjacent to titanium-based alloys generally have the same elemental composition as the parent alloy, as opposed to the corrosion products of stainless steel and cobalt–chromium alloys used in implants.

6.608.2.1.1. Particle characterization

Traditionally, clinical analysis or particle characterization uses methods such as scanning electron microscopy (SEM) or transmission electron microscopy (TEM), both of which are number-based counting methods. These methods have biased our current understanding and have indicated that the majority of the wear (mass loss) from an implant comprises particles in the nanometer to submicron range. Such bias stems from the limited sampling of particles in tissues (100s–1000s) that are counted in image-based analysis techniques such as SEM. While newer analytical techniques, such as low-angle laser light scattering (LALLS) analysis, have the capability of sampling millions to billions of particles – as particles are counted as they pass in front of and scatter a laser light beam in proportion to their size – there is limited ability to use these more comprehensive assessments as a large amount of debris need to be analyzed. As millions of particles flow in front of a laser, in a LALLS analysis, the one-in-a-million large particle, which equals the mass of at least a million small particles, can be detected, and thus provides a more accurate accounting of the total debris.

The ability to comprehensively characterize implant debris is important as new designs and bearing surfaces are being used in both new and older implants. A multianalysis approach is necessary because a given amount of wear debris (weight loss from the implant) after a year of use could be attributed to the loss of a relatively few large particles, or hundreds of millions of small particles (e.g., $\sim 0.2\,mm^3$ volume loss after a million cycles of use could be from ~400 particles of 100 μm diameter or 400 million particles that are only 1 μm in diameter). The aforementioned bias of SEM techniques is limited to 'number-based' analysis, where, two very similar number-based distributions can look very different when analyzed on a 'volume-based' perspective. This is illustrated in **Figure 3**, a comparison of two samples A and B, where very different volume-based distributions are shown to look like very similar number-based distributions. Unfortunately, in the analysis of implant debris from tissues or simulator fluids there is usually <0.05 mg of debris which is insufficient for obtaining an accurate LALLS volume distribution and thus SEM and TEM analyses remain the standard methods used to characterize debris.

6.608.2.2. Metal Ions (Soluble Debris)

There is continuing clinical concern regarding the release of chemically active metal ions, which bind to proteins and remain in a solution and then disseminate to surrounding tissues, bloodstream, and remote organs. Normal serum levels of implant metals are as follows: 1–10 $ng\,ml^{-1}$ Al, 0.15 $ng\,ml^{-1}$ Cr, <0.01 $ng\,ml^{-1}$ V, 0.1–0.2 $ng\,ml^{-1}$ Co, and <4.1 $ng\,ml^{-1}$ Ti. These levels increase following TJA (**Table 1**). Particulate metallic wear debris contributes to this increase in metal concentrations in the serum because of the large surface area available for electrochemical dissolution.[14,17,18,20,21]

6.608.2.2.1. Metal ion release

Metal release from implants has always been of concern, because of both systemic and local effects. Increase in the levels of serum and urine Co and Cr are detected following successful total joint replacements of Co-alloy based components. Similarly, increased serum Ti and Cr concentrations are found in subjects with well-functioning Ti and/or Cr containing THR implants (**Table 1**).[14,22–25] An increase in Ni has been noted immediately following surgery; however, this increase is likely to be related to the use of stainless steel surgical instruments or the metabolic changes associated with the surgery itself.

Many factors can affect metal ion levels in the serum and urine of TJA patients, the most important of which is unintended metal wear. For example, increase in Ti levels, up to a hundred times higher than normal, has been reported in cases of failed metal-backed patellar components where unintended metal/metal articulation was the result of malpositioning of the implant or wear through of the polymer lining. However, in cases of excessive Ti-alloy wear and metal release, there was still no increase in the serum or urine levels of Al, V, or urine Ti levels. The second most important mechanism of metal release is mechanically assisted corrosion, or fretting corrosion, of the components of the modular implant that fit together, such as the head and neck junction of stems in a total hip arthroplasty, and has been associated with elevations in serum Co and urine Cr.[14,26,27] Another source of metal release is the general corrosion which takes place on any surface and increases in proportion to the surface area available, and where a porous coating on implant components gives rise to higher serum and urine chromium concentrations due to the larger surface area available for passive dissolution. Where does this metal circulate and accumulate? Homogenates of remote organs and tissue, obtained from people with living wills to donate their bodies for research upon death, have been found to have significant increases in Co and Cr concentrations in the heart, liver, kidney, spleen, and lymphatic tissue (**Table 1**). However, the majority of metal debris remains localized at the implant site and is most often 'kept' within the pseudocapsule that forms around a total joint implant which acts much like a joint capsule with pseudosynovial fluid in it as well. Increased levels of Ti, Al, and V in joint pseudocapsules have been found

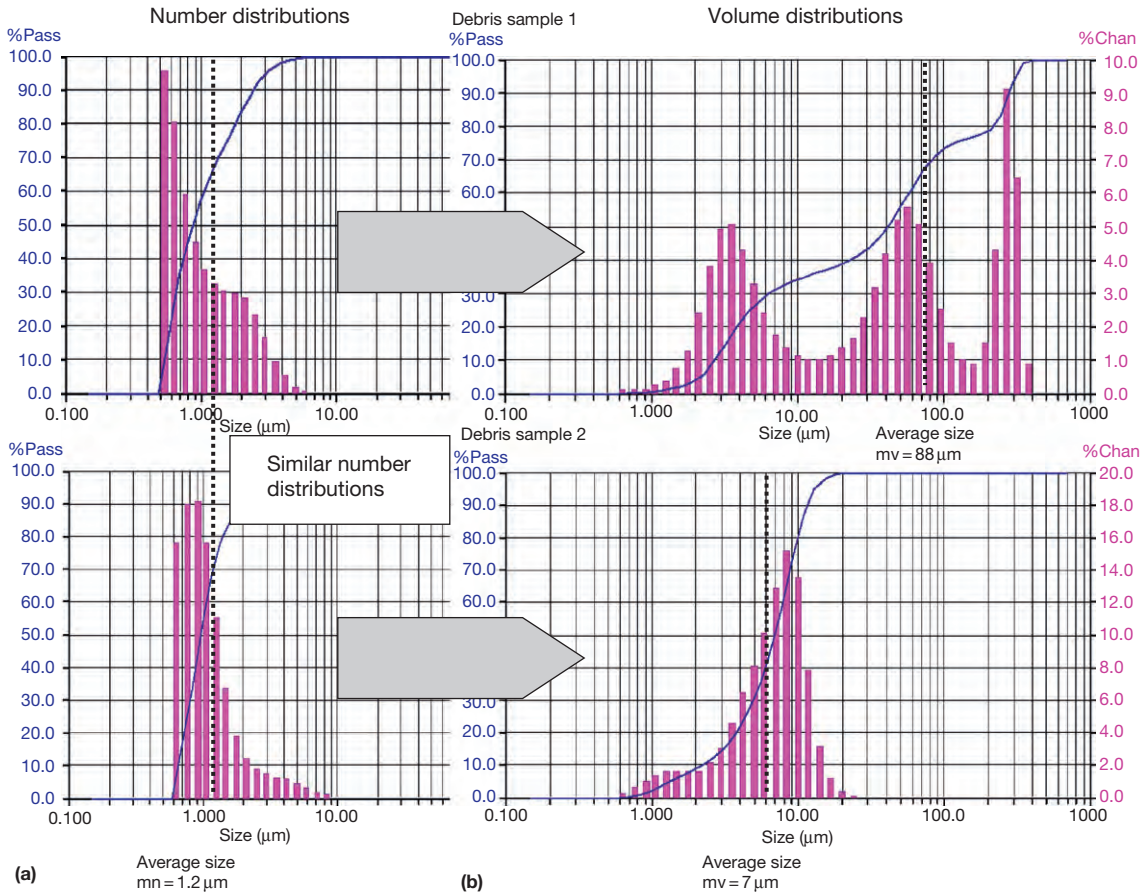

Figure 3 LALLS analyses of two implant debris samples using a (a) volume and (b) number distributions, demonstrates that similar number distributions and estimates of particle size can result from two very different sizes particles when analyzed using a volume distribution, which shows the size of the particle as a percent of the total volume. Note: The *x*-axis is particle diameter and the *y*-axis is (a) percentage of total number of particles in each size range and (b) the percentage of total mass in each size range. Courtesy of BioEngineering Solutions Inc.

with up to 200 ppm of Ti (six orders of magnitude greater than that of controls), 880 ppb of Al, and 250 ppb of V. Other filtering organs, such as the spleen, have been associated with increased Al levels and the liver has been found to contain enhanced Ti concentrations in people with failed titanium-alloy implants.[28]

6.608.3. Local Tissue Effects of Wear and Corrosion

Implant debris is the major determinant of the long-term performance of the implant because local inflammatory responses lead to bone erosion and implant loosening. The normal bone relies on the balance of bone formation and bone resorption forces (bone homeostasis), which involve the coordinated function of osteoblasts (bone building cells), osteoclasts (bone resorbing cells), and osteocytes (bone mechanotransduction and signaling network cells). If implant debris-induced inflammation causes a decrease in osteoblastic bone formation or an increase in osteoclastic bone resorption, the result will be a net loss of bone and osteolysis. Such bone loss (i.e., osteolysis) around an implant is the primary pathology that is associated with the local effects of the degradation of an orthopedic implant. This bone loss can occur as a diffuse cortical thinning or as focal cyst-like lesions. Particulate polymethylmethacrylate (PMMA) bone cement and old acetabular cups made of polytetraflouroethylene (PTFE) (Teflon) that produced massive amounts of implant debris were the first materials to be associated with osteolytic lesions. These were based on histological studies which demonstrated that the debris was associated with macrophages, giant cells, and a vascular granulation tissue. It is now known that osteolysis, in both loose and well-fixed uncemented implants, occurs due to particle debris generated by any material.[29,30]

Goldring *et al.*[31] were among the first to describe that the bone–implant interface in patients with loose total hip replacements is similar to the synovial-like membrane and that cells within the membrane have the capacity to produce bone resorbing factors such as prostaglandin E_2 (PGE_2) and collagenase. Such particle-induced osteolysis is less frequently associated with total knee arthroplasty than with total hip arthroplasty. It is unclear why this is so. However, factors such as implant/bone mechanical loading environment, differential mechanisms of hip and knee wear, and differences in interface barriers to migration of debris, have all been postulated to account for this apparent disparity.

[a]Data not available.

One unavoidable fact is that all implant debris cause low-grade inflammation that can ultimately lead to implant failure. Exactly how this happens is still unclear. Over the past 40 years we have learnt that implant debris-induced inflammation is largely caused by macrophages which react to implant debris by upregulating proinflammatory transcription factors (e.g., NFκβ) that signal the production and secretion of inflammatory cytokines such as interleukin-1β (IL-1β), tumor necrosis factor-alpha (TNF-α), IL-6, and IL-8[29] (**Figure 4**). Prostaglandins (e.g., PGE_2) are known to be important proinflammatory intercellular messengers that are involved in osteolysis due to implant debris. Anti-inflammatory cytokines such as IL-10 modulate the inflammatory process and are a part and parcel of this pathology, but the degree to which a lack of anti-inflammatory factors can contribute to particle-induced inflammation remains largely unknown. Other factors involved with bone loss include the enzymes responsible for the catabolism of the organic component of bone, such as the matrix metalloproteinases, collagenase and stromelysin. Activated immune and bone cells can produce several mediators that are known to be involved in the stimulation of osteoclast differentiation and maturation, such as the receptor activator of nuclear factor kappa beta ligand (RANKL) (also referred to as osteoclast differentiation factor).

Implant debris is relatively sterile, inert, and does not 'look' like a pathogen in any molecularly recognizable way. How then does implant debris provoke an inflammatory response? In other words, how can extra- and intracellular mechanisms sense and respond to sterile, nonbiological material such as implant debris? While this question has remained largely unknown for the past half century, new discoveries in immunology have implicated the 'inflammasome,' the danger signaling pathway (**Figure 5**).[32]

The first of these recent discoveries was that of the pattern recognition receptors (PRRs), which were discovered in 1996, and are present in the membrane and cytosol of human immune cells, such as macrophages. These are the toll-like receptors (TLRs) which recognize specific bacterial glycoprotein patterns and are now called 'pathogen-associated molecular patterns' or PAMPs. The types of identified PAMP receptors now include TLRs,[33] mannose receptors (MR), and NOD-like receptors (NLRs).[34] These PRRs initiate events that activate the cell and induce the secretion of proinflammatory cytokines which then lead to a broader inflammatory response.

Similar to PAMPs, nonpathogenic stimuli were found to activate immune cells via a novel danger signal pathway. The key molecular components in this pathway were called the

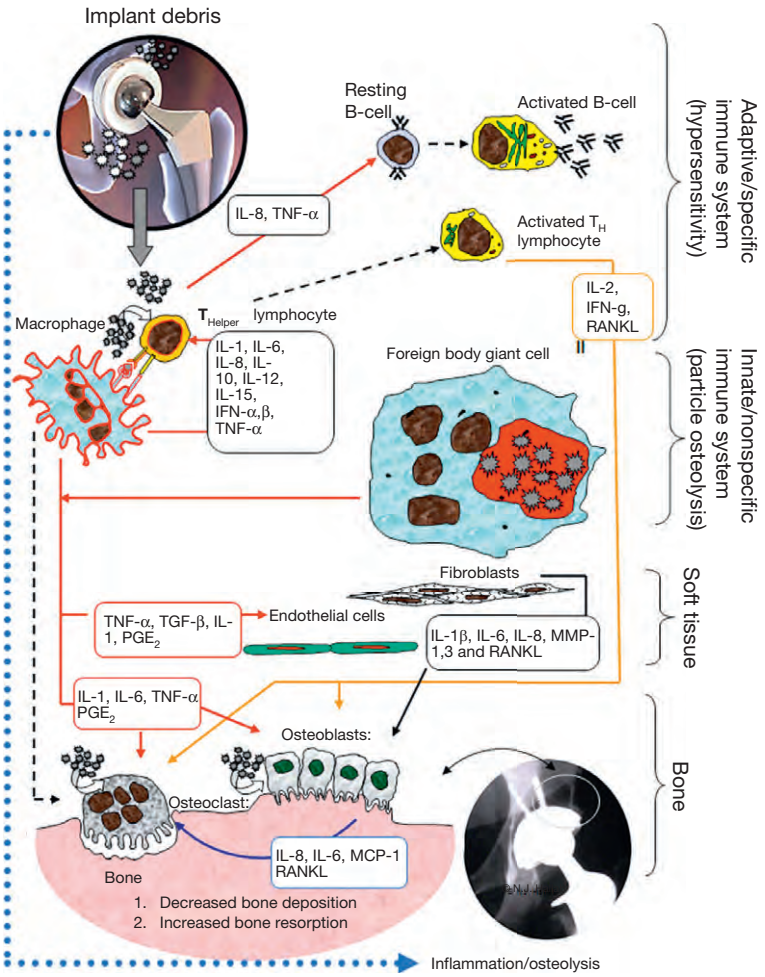

Figure 4 Numerous cytokines from periimplant cells reacting to implant debris can negatively affect bone turnover. IL-1, IL-6, and TNF-α are some of the most potent cytokines responsible for increasing bone loss and enhancing proinflammatory responses. Courtesy of BioEngineering Solutions Inc.

'inflammasome' and the signals that activate it were termed 'danger-associated molecular patterns,' or DAMPs.[35] So now there are PAMPs (pathogens) and DAMPs (something the cell recognizes as a danger signal that is causing or will most likely cause cell damage). Thus, this new paradigm for immune system activation now includes specific receptors that recognize both PAMPs and DAMPs.[36,37] This is important because the inflammasome pathway was the first pathway to explain how cells could transduce sterile, nonpathogen-derived stimuli (e.g., cell stress and cell necrosis) into an inflammatory response.[34,38] Other nonbiological-derived danger signals include such cell-damaging stimuli as UV light, particulate adjuvants present in modern vaccines[39,40] and, as it also turns out, implant debris.[41]

When particles activate the inflammasome pathway, cells release IL-1β, IL-18, IL-33, and other cytokines. This happens as follows:

Debris → Phagocytosis → Lysosome damage → ROS (reactive oxygen species) → Inflammasome (NALP3/ASC) → Caspase-1 → IL-1β (and other IL-1-family) cytokines (Figure 5).

Therefore, once ingested by immune cells, particles (or DAMPs, such as asbestos and implant debris, etc.) induce some degree of lysosomal destabilization. This lysosomal destabilization then causes an increase in NADPH (nicotinamide adenine dinucleotide phosphate-oxidase), and an associated increase in reactive oxygen species (ROS). This release comes from the protease- and acid-rich extreme environment inside lysosomes which is used to breakdown ingested particles/bacteria, etc. The release of the intracellular ROS species then activates the intracellular multiprotein 'inflammasome' complex which is composed of NALP3 (NACHT-, LRR-, and pyrin domain-containing protein 3) which is associated with ASC (apoptosis-associated speck-like protein containing a CARD domain).[34,42] This inflammasome activation then activates Caspase-1, which then converts cytokines such as IL-1β and IL-18 (and others) into their respective active forms. This illustrates the many steps that are involved in this relatively simple danger-signaling pathway and the many new potential points of pharmacological intervention to block this response to prevent particle-induced inflammation and osteolysis.

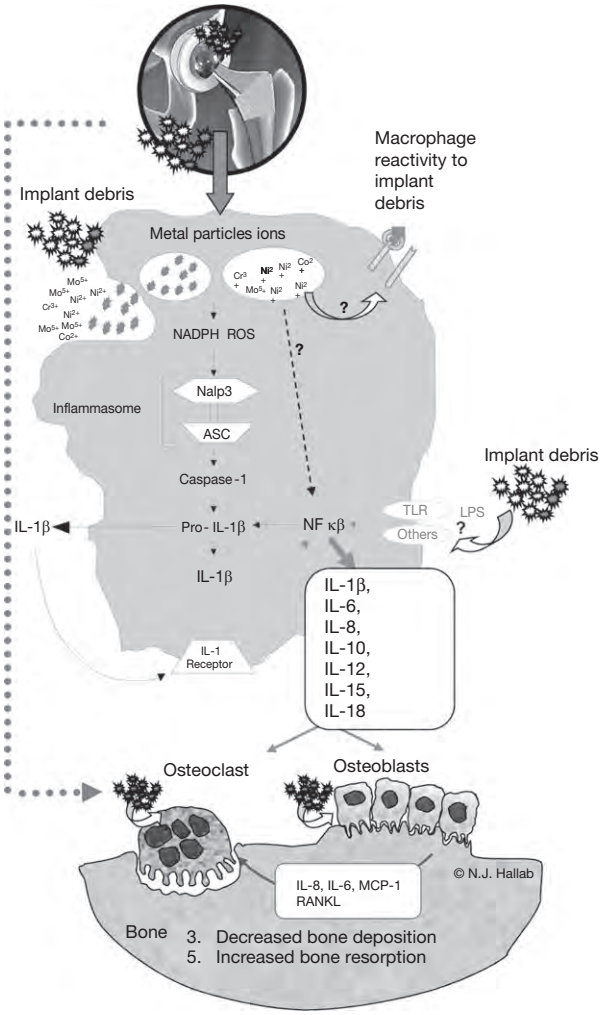

Figure 5 Metal-induced inflammasome activation occurs when soluble and/or particulate implant debris activate the Nalp3 inflammasome when chemicals inside intracellular compartments used to digest foreign material (such as phagosomal NADPH-induced reactive oxygen species and/or cathepsin B) leaks out of these compartments in an event called phagosomal destabilization. The inflammasome complex, Nalp3-ASC then induces the activation of caspase-1, which in turn allows mature IL-1β to be secreted. IL-1β is a very potent proinflammatory cytokine that exerts an autocrine and paracrine effect inducing a broader more potent inflammatory response (e.g., activation of NFκβ proinflammatory responses). 6.608.4. Systemic Effects of Wear and Corrosion

Implant surfaces and wear debris are always, to some degree, releasing chemically active metal ions into the surrounding tissues. While these metal ions, bound to serum proteins, may reside in local tissues, they are also transported via the bloodstream and the lymphatics to the remote organs. There is concern about this phenomenon because of the known, potential toxicity of the elements that are being used in modern orthopedic implant alloys: titanium, aluminum, vanadium, cobalt, chromium, and nickel. Metal toxicity can occur by altering (i) cell/tissue metabolism, (ii) host/parasite interactions, (iii) immunologic interactions, and (iv) by inducing chemical carcinogenesis.[43–47]

Cobalt and chromium are essential trace metals required for the normal function of some enzyme reactions. In excessive amounts, however, these elements are toxic. Excessive cobalt can lead to heart problems (cardiomyopathy), excess red blood cells (polycythemia), a decrease in thyroid functions (hypothyroidism), and to carcinogenesis. Excessive chromium has been linked to nephropathy, hypersensitivity, and carcinogenesis. Other metals such as nickel can cause skin rashes (eczematous dermatitis), hypersensitivity reactions, and cancer. Excessive vanadium exposure has been linked to heart and kidney dysfunction, hypertension, and depressive psychosis. Aluminum toxicity results in renal failure and anemia, bone softening (osteomalacia), and neurological problems. However, it is important to note that such effects generally apply only to excessively high levels of the soluble forms of these elements, and, most likely, do not apply to the levels of metals released due to implant degradation.

The association of metal release from orthopedic implants with any toxicity is conjectural since a cause-and-effect relationship has not yet been established. However, discovering any toxic effects is very difficult given the kinds of problems that are normally associated with the elderly, and thus, those expected to occur in any population of orthopedic patients.[48]

6.608.4.1. Systemic Particle Distribution

What determines the amount of wear debris accumulation in remote organs is not clearly understood. When there is an increase in the magnitude of particulate debris generated by a prosthetic device, there is a corresponding elevation in both the local and systemic burden of particles. Wear particles found systemically (found beyond the local environment of the implant periprosthetic tissue) are primarily in the submicron size range. There have been numerous cases where metallic, ceramic, or polymeric wear debris from hip and knee prostheses have been found in the regional and pelvic lymph nodes, along with gross dark staining by metallic debris, fibrosis (buildup of fibrous tissue), lymph node necrosis, and histiocytosis (abnormal function of tissue macrophages,). Metallic wear particles have been detected in the paraaortic lymph nodes in up to 70% of patients with total joint replacement components. It is unclear what the ramifications of this are, but traditional inflammatory responses to metallic and polymeric debris in lymph nodes includes the same responses that are seen locally, which are immune activation of macrophages and the associated production of cytokines.

Thus, lymphatic transport is, most likely, a major route for the dissemination of debris by which particles migrate via the perivascular lymph channels, either as free or phagocytosed particles within the macrophages. Within the lymph nodes, the disseminated particles are mostly submicron in size. However some metallic particles as large as 50 μm and polyethylene particles as large as 30 μm have also been found. These particles can travel further on to the liver and spleen where they are found within the macrophages or, in some cases, in nodules of inflammatory tissue granulomas throughout the organs. The size of these metallic particles is nearly an order of magnitude less in the liver and

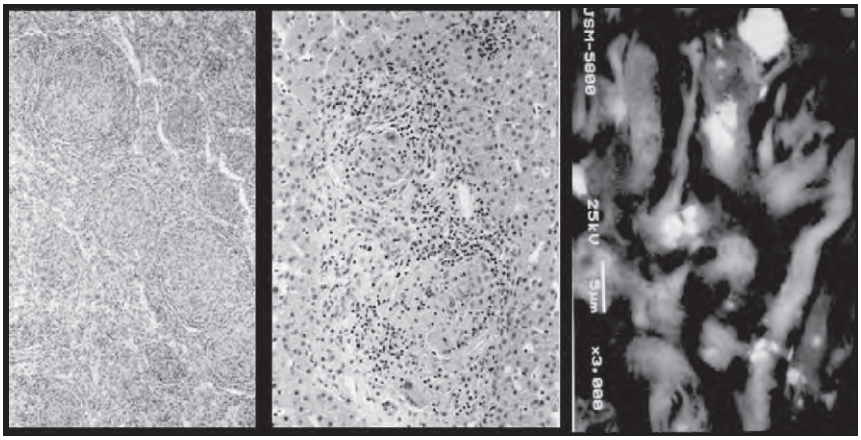

Figure 6 Soft tissue nodules of immune cells and tissue cells called epithelioid granulomas have been found to (a) occur within the portal tract of the liver (40×) and, (b) within the splenic parenchyma (15×). (c) The particles within these tissues have been identified as titanium alloy particles using backscattered SEM/EDS analysis of particles in a spleen (3000×). Courtesy of Prof Robert Urban.

spleen than that in lymph nodes, indicating that some additional filtration happens before the particles end up in the these organs. This is not alarming because the cells of liver, spleen, and lymph nodes normally accumulate small amounts of a variety of foreign materials without any apparent clinical manifestation. However, an excessive accumulation of particles can induce the formation of nodules of inflammatory tissue (granulomas) or granulomatoid lesions in the liver and spleen (Figure 6). The degree of reaction to these particles in the liver, spleen, and lymph nodes is probably modulated, as it is in other tissues by (1) the number of particles (dose), (2) their rate of accumulation, (3) the duration of their prescence, and (4) the biologic reactivity of the cells to these particles (size and materials composition). It is no surprise that metallic particles in the liver or spleen are more prevalent in subjects with previously failed arthroplasties compared to those with well-functioning primary joint replacements.

Diseases, which obstruct lymph flow through lymph nodes such as a metastatic tumor, or those which cause a generalized disturbance of circulation such as chronic heart disease or diabetes, may be expected to decrease particle migration to remote organs. Other pathologies, such as acute or chronic-active inflammation in the periprosthetic tissues may increase particle migration[29,48,49] by recruiting more immune cells to remove the debris.

6.608.4.2. Hypersensitivity

Some adverse responses to orthopedic biomaterials are subtle and continue to foster debate and investigation. One of these responses is 'metal allergy' or hypersensitivity to metallic biomaterials. Ions released from the implants, while not sensitizers on their own, can activate the immune system by forming complexes with native proteins. Polymeric wear debris is not easily chemically degraded *in vivo*, but has not been implicated in allergic type immune responses.[50–53] Metals that are accepted as allergens/sensitizers (haptenic moieties in antigens) include (but are not limited to) the following: beryllium, nickel, cobalt and chromium, tantalum, titanium, and vanadium. Nickel is the most common allergen in humans followed by cobalt and chromium, and nickel is still a prominent alloy in medical grade stainless steel (Table 2). Generally, there are more reports of hypersensitivity reactions associated with stainless steel and cobalt-alloy implants than with titanium-alloy components.[54–61]

Hypersensitivity to metals is common and affects about 10–15% of the population. Skin contact and ingestion of certain metals result in immune reactions such as eczema (skin hives, redness, and itching). Hypersensitivity reactions are associated with the adverse performance of metallic cardiovascular, orthopedic, and dental implants. Orthopedic implant associated hypersensitivity reactions (metal sensitivity or metal allergy) are generally associated with type IV delayed type hypersensitivity (DTH), a specific type of cell-mediated adaptive immune response. Over the past 20 years a growing number of case and group studies have linked immunogenic reactions with the adverse performance of metallic cardiovascular, orthopedic, and plastic surgical and dental implants, and clinical symptoms have lead directly to device removal. These symptoms include severe dermatitis (inflammation of the skin), urticaria (intensely sensitive and itching red round wheels on the skin), and/or vasculitis (patch inflammation of the walls of small blood vessels).

6.608.4.2.1. Incidence of hypersensitivity responses among patients with metal implants

The incidence of metal sensitivity among people with well-functioning implants is about twice as high as that of the general population at approximately 25% (vs. 10%, Figure 7). Moreover, the incidence of metal sensitivity in people fitted with a 'failing' implant (in need of revision surgery) or with a well-performing metal-on-metal articulating implant is approximately 50–60% (Figure 7). This increase in the prevalence of metal sensitivity among people with a failing metal-on-polymer prosthesis has prompted the speculation that such immunological processes may be a factor that contributes to implant loosening. Cohort studies over the past

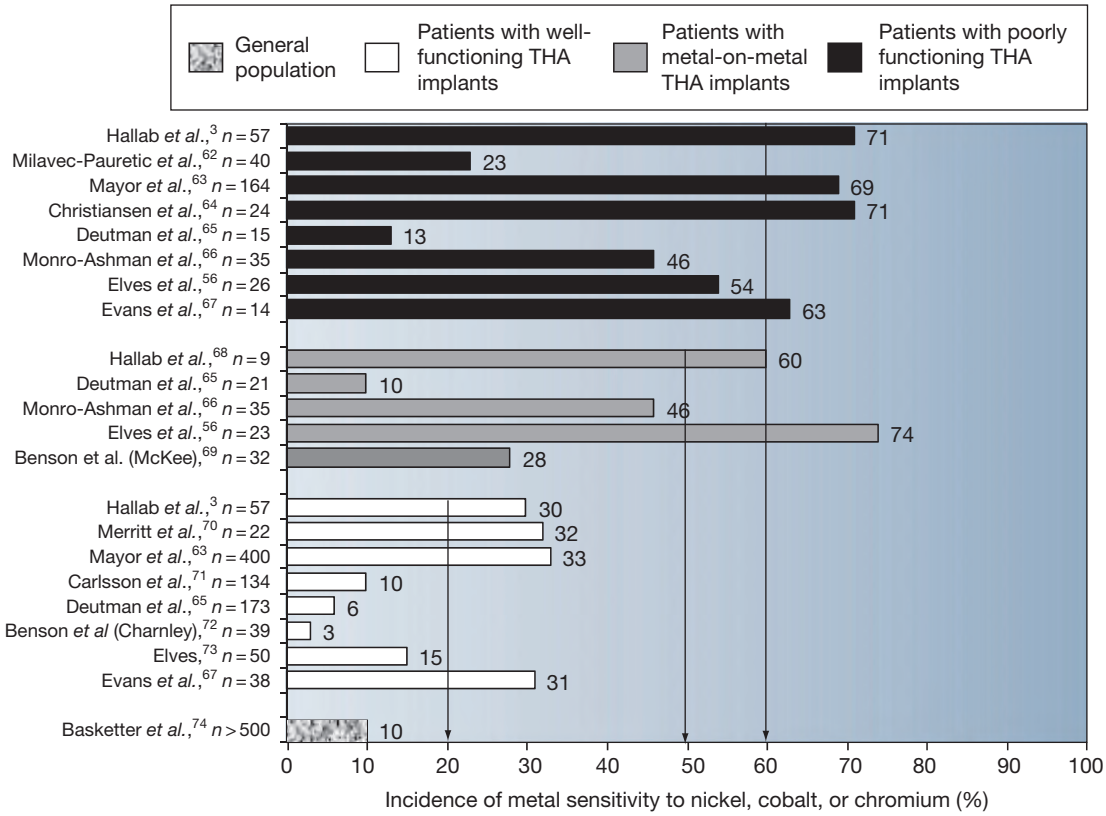

Figure 7 A compilation of investigations showing the averaged percentage of metal sensitivity among the general population, people with well-functioning implants, people with metal-on-metal implants, and people with failing implants (prior to getting them revised). Metal incidence rates include a positive response to allergy testing for nickel, cobalt, and/or chromium. All subjects were tested by means of a patch or metal-LTT (lymphocyte transformation test). Courtesy of Orthopedic Analysis LLC.

30+ years have, generally, indicated a correlation between metal implants and metal sensitivity,[50] clearly indicating that metal sensitivity can be a contributing factor to implant failure[60,75,76] (Figure 7).

Thus metal allergy testing ('metal-lymphocyte transformation test, metal-LTT') may be warranted in individuals with a history of metal allergy prior to receiving an implant. The importance of this line of investigation is growing, as the use of metallic spinal implants is increasing, as are the expectations of implant durability and performance.[77,78]

6.608.4.2.2. Testing for metal sensitivity

The time-related physical evidence associated with the symptoms of type IV allergic responses are severe enough to require

a revision of the arthroplasty in what is thought to be approximately 1–2% of all orthopedic patients. Diagnostic testing for metal allergy includes skin testing (i.e., so-called patch testing), and blood testing called metal-LTT. While patch commercial kits do exist for some metals,[76,79] there is continuing concern about sensitizing patients with patch testing[80] and doubts over how representative the dermal Langerhans cells are as proxies of periimplant antigen presenting cells.[81,82] The metal-LTT assesses the proliferative response of lymphocytes, obtained from peripheral blood by routine blood draw, to different metal antigens. Studies that have used both of these testing methodologies have shown similar incidence of metal sensitivity among patients with metal-containing total joint replacement implants.[53,83,84] This indicates that the adaptive immune system (i.e., lymphocytes) may be involved to a much larger degree in debris-induced inflammation than what has been previously attributed to the innate immune system alone (i.e., periimplant macrophages).

6.608.4.3. Carcinogenesis

The carcinogenic potential of implant debris remains an area of concern. Animal studies have documented that implant metals can act as carcinogens. Small increases in the incidence of rat sarcomas were found to correlate with high levels of serum cobalt, chromium, or nickel released from the metal implants. Additionally, lymphomas with some form of bone involvement were also more commonly found in rat models with metallic implants. Although not common, implant site tumors in dogs and cats – primarily osteosarcoma and fibrosarcoma – have been associated with stainless steel internal fixation devices.

Some epidemiological studies have implicated orthopedic implants in causing cancer 10–20 years after total hip replacement. However, recently, larger studies have found no significant increase in cancers such as leukemia or lymphoma, although these studies did not include individuals with higher serum concentration of metals such as those with a metal-on-metal prosthesis. The many differences between populations with and without implants that do not depend on the implant itself confound the interpretation of any epidemiological investigations.

It is still not known if metal release from orthopedic implants is carcinogenic because causality has not been established in human subjects, and, in fact, testing by the authors found that periimplant cells became toxic, prior to any DNA strand breaks, when tested with increasing concentrations of the metal ions found in implants.[85,86] The actual number of cases of tumors associated with orthopedic implants is probably underreported due to the frequency of tumors in the population that receive metal implants. However, compared to the number of devices implanted on a yearly basis (over 1 million), the incidence of cancer at the site of implantation is relatively rare. Continued monitoring and large long epidemiological studies are required to fully understand the associated risk.[87–90]

6.608.5. Conclusions

Total joint implants are a miracle of modern medicine, returning mobility, independence, and quality of life to millions of individuals every year. Implant debris is unavoidable and results in activation of the innate immune system, which in turn results in local inflammation that, over time, causes more bone loss than homeostatic mechanisms can keep up with. All of these lead to implant loosening, via aseptic osteolysis (**Figure 8**). When this reactivity is excessive, it may activate the adaptive immune system and result in an allergic response involving T-cells. New kinds of 'alternative' bearings that are being used in total joint implants, such as metal-on-metal articulating components, have resulted in new types of biological responses including lymphocyte-dominated granuloma-like lesions in the bone (termed ALVAL, for aseptic lymphocyte vasculitis-associated lesion), being found around some implants. This type of response seems to encompass the features of both the innate and the adaptive immune response,[91,92] and demonstrates that both innate (macrophage) and adaptive (T-lymphocyte) immune system reactivity can act to limit the lifetime of the current total joint replacement implants. Advances at the molecular and cellular level have increased our understanding of inflammatory bone loss. Treatment options ranging from diagnosing preexisting conditions of metal allergy (metal-LTT), general management of inflammation (e.g., NSAIDS) to selective blocking of cellular mediators (e.g., anti-IL-6, anti-TNF-α, IL-1β-receptor antagonist, etc.) are all part of the modern arsenal that is being used to help fight the problem of implant debris-induced inflammatory bone loss. There is increasing need for clinical studies to define the role of metal allergy, genetic susceptibility to particle-induced inflammation, general biological variability, and prosthesis-related factors in the pathogenesis of nonspecific and specific biological responses to implant debris.

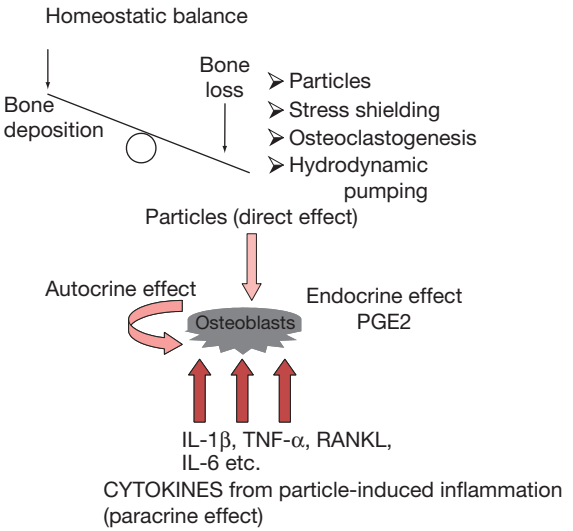

Figure 8 A number of factors can tip the scales away from bone homeostasis and towards net bone loss. Particle-induced inflammation is one of these factors and induces the release of potent cellular messages (inflammatory cytokines) which causes bone depositing cells called osteoblasts to stop producing bone and causes bone resorbing cells called osteoclasts to start increasing resorption. Over time, this results in a net bone loss and loosening of implants.

MESS	mangled extremity severity score
MIC	Minimum inhibitory concentrations
MRI	Magnetic Resonance Imaging
MRSA	Methicillin-resistant *S. aureus*
NSAID	Nonsteroidal Antiinflammatory Drug
PCR	Polymerase chain reaction
PET	Positron emission tomography
PIA	Polysaccharide intercellular adhesin/ hemagglutinin
RGD	Argineglycine-aspartate
sub-MIC	Subminimal inhibitory concentration

6.609.1. Orthopedic Implants

6.609.1.1. New-Generation Biomaterials

The age of bionic human beings is not too distant as implants are being popularized throughout the different areas of medicine.[1–3] The old system or tissue-based conservative approaches to treatment is slowly being phased out and replaced with aggressive surgical interventions that include the increasing use of biomolecular artificial implant components.[4–6] Implants, drugs, and innovative procedures have improved life expectancy from 49.2 years a century ago to over 78 years now.[7] In fact, according to recent data from a physician survey, the hip and knee replacement operation has been ranked number 10 on the list of most important medical innovations, ahead of NSAIDs, cardiac enzymes, and laparoscopic surgery, yet behind balloon angioplasty and MRI or CT scans.[8] Most implants in medicine are associated with orthopedics, with some form of fixation device in 40% and artificial joints in 12% of the people with implants.[9] Annually, over 800 000 new hip arthroplasties are performed worldwide, with 120 000 in the United States alone[10] and 43 000 in Canada.[11] Additionally, over 300 000 total knee replacements are performed per year in the United States,[12] adding up to over 1.5 million total joint replacements performed worldwide.[13]

The rapidly aging population has driven the demand for implants even higher. Specifically, in the United States during 1900s, only 3.1 million people were over 65 years of age; there are over 35 million people in that population group in 2006,

with a projected 60 million by 2020.[7] Currently, more than 3.2% of the population over 55 have an artificial joint and at least another 2% require one.[14] These numbers are only expected to increase as the aging population shows a high prevalence of osteoporosis, osteoarthritis, and degenerative bone conditions that promote the higher implant demand.[15] In addition to implant demand associated with aging, more than 35 million people experienced trauma in 2004, resulting in over 6 million fractures that required an implantable fixation device, with an estimated cost of $58.5 billion in 2004.[16,17] These numbers, when combined with the 200% increase in joint utilization between 1999 and 2002 alone,[18] suggest that implant applications will skyrocket over the next few decades.[19]

The $23 billion US medical implant industry is a witness to the sophistication and extensive research in implant engineering and design.[20] Implant designs have evolved with surgical experience and are now radically different from the original Charnley low friction hip.[21–23] Orthopedic implants are manufactured from a variety of materials that show biological compatibility and mechanical performance, good interface responses, and long-term reliability of the surface.[24] Industrial designs use stainless steel, titanium, polyethylene, ceramics, bioglass, and carbon, often in combination, to create a complex total joint replacement with separate components serving specific biomechanical and biological functions.[25–28] Of these, titanium and its alloys have often been a preferred material in orthopedic and dentistry applications as they possess great biocompatibility and exhibit minimal toxicity to host tissues.[29–34] Through the history of biomedical implants, simple, unprocessed alloys were used to create an implant that was relatively inert to the physiological milieu. Modern implants undergo blasting, coating, and modification of both surface topography and chemical characteristics in order to best adapt to the target tissue environment.[35–39] Additional surface modifications often focus on introducing biological agents directly onto the surface. Hydroxyapatite, calcium phosphate, arginine-glycine-aspartate (RGD), bone morphogenetic proteins (BMPs), or albumin have been used to further improve the specific functions of different implants.[35,40–44]

A drawback to these sophisticated implants, however, is the increase in research and development costs as well as the higher cost of implant production. Together, these result in the overall increase in joint replacement costs.[45] In 2003, the total cost of joint replacement amounted to over $1.4 billion for total hips and over $2.59 billion for total knees.[46–50] When considering that 15% of the US gross domestic product is allocated to health care, the rising costs of orthopedic implants affects everybody,[51] with more than 2/3 of the costs of joint replacement and 22% of trauma reimbursed through either Medicare or Medicaid.[17,52] A simpler, smarter design is necessary to decrease both costs and complications.

6.609.1.2. Orthopedic Complications

Joint replacement has been called the orthopedic success story by the American Academy of Orthopaedic Surgeons[53] with over 85% of patients satisfied with the results of surgery.[54] Perioperative mortality is less than 0.5% and prosthesis failure is about 10% at 10 years.[54,55] Despite that visible success, the rate of failure and the need for revision procedures have been increasing faster than the rate of primary replacement.[18] An obvious cause is that, as implants become more popular, both the number of patients and surgeons involved with joint replacements has been increasing rapidly. On the patient side, the inclusion of both younger and older patients has expanded into population groups that have an increased rate of complications.[45] The overall incidence of these complications appears to be gender dependent, with higher risks in the male patient population.[54] More importantly, prior revisions lead to a threefold increase in complications as compared to outcomes after the first revision.[56] Nevertheless, most comorbidities and preoperative function do not substantially change arthroplasty outcomes at 5 years.[57] Still, some, including obesity, are important patient-dependent factors that lead to additional complexity and even premature failure of the implant.[57–60] On the other side of the surgical table, the surgeon's experience and technique are crucial to the final outcome of surgery. Medicare data suggest that surgeons who themselves perform less than 12 operations a year and are in hospitals that see less than 25 joint replacements per year see the highest complication rates.[54,61,62] The rate of complications decreases as the number of surgeries increases and remains inversely proportional to the surgeon's experience.[63] In retrospect, over 17.5% of hips and 8.2% of knee implants are currently being revised due to complications, leading to substantial costs, disability, and patient discomfort.[18,52]

Most patients come back for revision due to pain (66%), dislocation or instability of the prosthesis (14%), infection (11%), trauma (5%), or immobility (4%).[64] Ultimately, the implant is a foreign body and is inextricably associated with complications due to foreign body reaction, inflammation, and poor host integration. The most common prosthesis-associated long-term complications of arthroplasty include aseptic loosening (30–40%), infection (0.5–7%), and osteolysis (5%).[65–70] Other nonsurgical complications after joint replacements include pulmonary embolism, pneumonia, myocardial infarction, cerebrovascular accidents, deep vein thrombosis, and others.[71] All these complications are currently being addressed in the clinic by improved technique and better indications for joint replacement. Still, no ideal or simple solution exists and such complications are only partially solved through treatments like peri- and postoperative antibiotics or stringent limitations imposed on the patient.[72–74]

Aseptic loosening produces pain and instability affecting the patient's quality of life. Improving implant design may significantly lower the incidence of aseptic loosening and osteolysis,[75–77] especially in cases where inflammation and immune system response may be the causative agents of loosening.[13] Specifically, the implant may erode to produce metal particles both surrounding the implant and also within phagocytosing immune cells to provide a mechanism for osteolysis and failure of the implant to integrate.[78,79] Once ingested into the cells, the lysozomes are unable to enzymatically degrade metals, leading to a cascade of cytokine release. Such release elicits a continuous inflammatory response that affects the immediate periprosthetic environment, endosteum, and bone tissue.[13] Several approaches from plasma coating to nanoscale surface fabrication attempt to decrease the amount of particulate matter and debris produced by the implant and thus decrease the cytotoxic effects of joint prosthesis.[80,81]

6.609.2. Periprosthetic Infection

The complications of aseptic loosening are minor when compared to another major problem associated with implant placement – an infected prosthesis. Over 2 million cases of hospital-acquired infection are reported annually in the United States, with more than half associated with implants.[82] Periprosthetic infection, one of the most dreaded complications in orthopedics, often results in repeat surgeries, patient distress and disability, and increased cost and utilization of medical resources.[83,84] Infection, despite being less prevalent than aseptic loosening, can lead to chronic systemic spread, osteomyelitis, possible tissue necrosis or amputation, and, in particularly difficult cases, even death.[85] It is important to realize that, at the end of the day, periprosthetic infections do not affect just the patient, but this dreadful complication impinges on society at large. As far back as 1989, the annual cost of infection exceeded $200 million.[85] More recent data show that joint revisions due to infection cost more than $50 000 per case; revision due to aseptic loosening is only about $16 000 and primary arthroplasty, about $8500. Financial analysis estimates that as little as 1% decrease in revision rate for total joint arthroplasty would save as much as $211 million in US health care costs.[18] Considering the costs of revisions, the additional hospital time and disability and the loss of the workforce due to sick leave, the costs of periprosthetic infection easily surpass $1 billion, with much higher costs to society at large.

6.609.2.1. Prevalence and Etiology

Despite the apparently decreasing incidence of infection from almost 7% in Charnley's experience[21] to less than 1% in high volume institutions,[86–88] recent data suggest that infection rates are greatly underestimated.[89–91] The inadequate reporting is related to the difficult diagnosis in the clinical setting.[89,92] Classically, microbiological sampling of the tissue was used to differentiate between aseptic and septic loosening. However, as our knowledge of infection has increased, it has become apparent that bacteria can escape detection either because they are not present in large enough numbers for diagnosis or they remain strongly adherent to the implant and thus are difficult to sample through ordinary microbiological methods.[91,93,94] Because of these difficulties, there is no gold standard test for diagnosis of periprosthetic infection and most physicians struggle with a combination of clinical and biochemical markers that inconsistently detect or misdiagnose infection. Data based on DNA detection using the polymerase chain reaction (PCR) suggest the possibility of infection presence in as many as 73% of revision cases. However, PCR is overly sensitive to contamination or proteic material and, thus, often produces a high rate of false positives.[89,95,96] Nevertheless, multiple studies have also found bacteria, bacterial components, and infection-associated immune responses associated with a disproportionately large number of implants retrieved during revision surgery.[89,97–100] Furthermore, the fact that antibiotic prophylaxis improves the outcomes of joint replacements and decreases the overall rate of complications including aseptic loosening and osteolysis supports the current understanding that infectious organisms may play a larger role than initially thought.[101]

Certain comorbidities further increase the risk of infection. Rheumatoid arthritis, diabetes mellitus, obesity, sickle-cell disease, psoriasis, poor diet, and a compromised immune system, as well as previous surgeries in the affected limb, are often linked to higher risks of implant-associated infection.[85,102–104] Rheumatoid arthritis, for example, is associated with a 2.6-fold increase in infection rates compared to osteoarthritis.[105] Also, revision surgeries lead to an almost threefold increase in infection risk.[55,106] Most of these conditions are associated with a depressed or compromised immune system which allows any chance contamination to develop into an overt infection. However, on the other side of the surgical table, as is the general case for complications, surgeon experience, antibiotic timing and dosing, surgery duration, especially if over 2.5 h,[106] operating-room traffic, and the complexity of reconstruction are all important factors determining the probability of infection.[85] Finally, in trauma, compound open fractures are at increased risk of deep wound infection and osteomyelitis, which is further compounded by the fact that over 30% osteosynthetic materials have a high risk of infection. In fact, virtually 100% of patients who undergo external fracture fixation develop pin tract infections.[107–110]

Periprosthetic infection is caused by the same infectious organisms that are found in hospital intensive care units or associated with trauma.[111] Most of these organisms are natural flora and become pathogenic by being introduced into deep tissues, thus bypassing skin defenses. Coagulase-negative staphylococci are the most prevalent organisms in orthopedic infection and are the causative organism in 30–67% of cases.[88,112,113] These include *Staphylococcus epidermidis*, *S. haemoliticus*, and over 30 other species of gram-positive bacteria. *S. aureus* is isolated in 12–23% of the cases, with other mixed flora found in 10–11%, streptococci in 9–10%, gram-negative bacilli in 3–6%, enterococci in 3–7%, and anaerobes in 2–4%[88,113]; these organisms are common contaminants on all indwelling implants, including heart valves, dental prosthesis, or catheters.[114–117] Interestingly, the prevalence of coagulase-negative staphylococci in orthopedic infection has been constantly decreasing with *S. aureus* slowly taking prevalence.[113] Even more importantly, *S. aureus*, *S. epidermidis*, and *Pseudomonas aeruginosa* are inherently efficient at adhering to and colonizing implant surfaces through expressing specific genetic elements for both quorum sensing and ultimately, biofilm formation.[118–122] The adherence and colonization of the implant surface greatly increases the recalcitrance of infection to treatment and thus, any implant that could inhibit adherence would decrease periprosthetic infection and its associated disability and cost. However, in devising such an implant, better understanding of the etiology and pathophysiology of infection is necessary to best map the angle of attack against the ravages of periprosthetic infection.

6.609.2.2. Mechanisms and Routes of Infection

Infection originates from bacterial contamination of the implant either during surgery or later through hematogenous transfer or local dissemination.[110] Each mechanism of infection initiation is important, even though surgical contamination is the most common route. Infection associated with surgical contamination manifests itself within the first 3 months after

surgery.[110,123] The importance of surgical contamination is documented by an infection rate of 1–5% that drops to less than 0.5–1% after improved prophylactic measures and superior sterility.[106,110,124] For that reason, the more stringent operating procedures in high-volume centers could be part of their success, while smaller centers without such capabilities tend to struggle.[55,125–127]

Late, acute onset of periprosthetic infection, often one year or more after surgery is attributed to hematogenous transfer/contamination.[128] Such transfer can occur during a urinary tract infection, dental work, or other minor surgery where bacteria can be introduced into the bloodstream. The possibility of infection through this route has led to a debate as to the use prophylactic antibiotics during minor surgery or dental procedures in patients with a previous implant.[129,130] Minor bacteremia that initiates in patients after such procedures may lead to contamination of the implant, which becomes a safe haven for the infectious organisms. Thus, current practice recommends prophylactic antibiotics in urological or extensive dental procedures for high-risk patients with artificial joints.[131,132]

In addition to hematogenous transfer, local dissemination from a contiguous focus is another important, yet often overlooked, mechanism of infection. When multiple prior surgeries or procedures are being performed on a limb,[106] bacterial contamination, even if not associated with an implant, may produce local chronic infectious foci.[108,133,134] Bacteria can remain encapsulated in a biofilm within the endosteum crevices without clinical manifestation.[135,136] Such biofilms, when disturbed by another surgical intervention, generate the seeders necessary for implant contamination.

In order to estimate the overall distribution of infection, recent data from 146 patients showed 70% of infection cases were chronic, 17%, acute postoperative; and 13%, acute hematogenous.[137] One study saw 45% of infections presenting early, 23% delayed, and 32% expressing late onset of periprosthetic infection,[138] with an average time from primary joint arthroplasty to diagnosis of infection of about 30–35 months.[137,139] In conclusion, no matter which mechanism bacteria use to get to the implant, bacterial colonization resulting in biofilm formation is an important culprit in infection survival and propagation that leads to the final implant failure. By preventing this colonization and inhibiting biofilm formation, implant infection could be inhibited, and thus the occurrence of periprosthetic infection strongly curtailed.

6.609.2.3. Biofilms in Pathogenesis of Infection

Implant-associated infection invariably involves the interplay between the infectious organism, the implant, and the host. Gristina *et al.* have formulated a 'race for the surface' hypothesis, where infection development competes with normal osseointegration, with the ultimate success of the implant dependent on the prevalent process.[140–142] Generally, with a successful sterile surgery and a host balance between integration and immune system response, arthroplasty is quite successful. However, the events that occur within bone to adapt to the presence of a new implant are also those that predispose the implant to bacterial colonization. In fact, the presence of an implant decreases by more than 10^5-fold the minimal dose of *S. aureus* that is necessary to create an abscess.[123] When the implant provides this safe heaven for bacterial colonization, osteomyelitis can be initiated with only 10–100 bacteria; normal bone would require millions of bacteria to induce the same degree of infection and bone destruction.[143,144] Thus, the presence of a foreign body allows other foreign organisms to mitigate their own existence in the shadow of a much larger intruder like the implant.

The physiological response to the introduction of the implant into tissue environment challenges the host immune system, which may further trigger a foreign body reaction.[78,145] During implantation, the prosthetic surface becomes coated with physiological fluids, serum, and tissue fragments, as well as fibronectin, vitronectin, and albumin.[123] Albumin has been shown to inhibit the activation of the immune system and prevent extracellular matrix deposition on the implant.[146,147] Local granulocytes in the immediate periimplant environment tend to be degranulated and lack superoxide production due to wear particle ingestion, and, thus, are unable to kill bacteria.[123,148] The lack of an efficient immune system in the presence of abundant extracellular proteins provides an advantage for bacterial adherence.[149–152] In fact, the coating proteins support successful bacterial colonization. Studies have shown that over 90% of *S. aureus* express either fibronectin binding proteins, fibrinogen binding proteins, or collagen binding proteins, with almost 60% of bacteria expressing a combination of all the three.[153] More worrisome, these genes were significantly more common in methicillin-resistant *S. aureus* (MRSA) than in susceptible strains.[153] Thus, bacteria introduced to the site of the implant can undergo rapid, yet reversible surface adhesion.

Specific signals are required for successful bacterial colonization and biofilm formation. These include biofilm-associated protein (BAP) in *S. aureus* and polysaccharide intercellular adhesin/hemagglutinin (PIA), which is encoded by the *ica* operon in *S. epidermidis*.[123,154] This colonization and biofilm formation are not random, but molecular decisions take place in response to the suitability of the local environment, availability of nutrients, and the relative absence of bactericidal agents.[133] As the decisions are made, the adherent bacteria either release from the surface in search of a new habitat or initiate proliferative cascades and matrix production. This proliferation and subsequent accumulation of bacteria on the biomaterial surface is specific to biofilms, so, for example, *S. epidermidis* strains not capable of biofilm formation will adhere to the surface but fail to accumulate.[123,155,156] Once attached and proliferating, production of signaling and quorum sensing molecules leads to communal regulation of signaling cascades, specific patterns of geometric organization, and housekeeping.[110,123,133,152]

In the biofilm, a variety of microbial strains and species can coexist in close proximity and exist in areas of widely varying metabolisms, both rich and poor nutrient environments, and bordering aerobic and anaerobic pockets.[152,157] Bacteria within biofilms, originally thought to maintain a low metabolic state, are, in fact, more active than free-floating planktonic organisms. This high metabolism is necessary for producing extracellular polysaccharides, signaling proteins, and toxins.[154] For example, *S. aureus* produces over 40 toxins including enterotoxins, coagulase, proteases, and hemolysins.[158,159]

Many of these toxins work alongside the inflammatory antibodies and cytokines released locally from immune cells to further augment the damage to the periprosthetic host environment.[160,161] Other components in the extracellular polysaccharide matrix include proteins and nucleic acids, making it hard to differentiate the remnants of matrix from live bacterial populations.[154]

The abundant extracellular polysaccharide production results in a 'sludge' that comprises 85% of the biofilm with cells accounting for only 15% content by volume.[133] This composition makes biofilms difficult to detect and differentiate from surface debris. Furthermore, the usual treatment strategies fail to penetrate this sludge. Despite its seeming simplicity, such structural arrangement confers superior functional complexity. Developed biofilm communities form mushroom-like structures that are able to extend into the surrounding environment, sense fluid movement, and respond to the bathing environment, similar to the higher eukaryotic organisms from phylum Cnidaria or Porifera that include sponges and Hydrozoa. Furthermore, such structures can actually migrate in response to shear stress along the material surface, or propagate by either separation of entire biofilm fragments or dispersion of single free-floating planktonic bacteria.[133] Such cycles of propagation lead to the chronicity of biofilm infections.

Infection associated with biofilms remains subclinical for extended periods of time, with only mild fever and slight bacteremia, as the planktonic bacteria are killed by the immune system. Local damage results in loosening of the prosthesis and osteolysis, but such symptoms are often difficult to identify and differentiate from aseptic loosening or associated foreign-body reaction. Ultimately, if undiagnosed, the growing and expanding biofilm may lead to osteomyelitis and life-threatening complications. More importantly, the biofilm can confer multidrug resistance that makes the infection difficult to eliminate, often requiring radical interventions.

6.609.2.4. Biofilms and Multidrug Resistance

Biofilms are notoriously difficult to treat and common antibacterial treatment strategies often fail. Antibiotics are often successful at killing cultures extracted from biofilms, yet the same antibiotics have minimum effect on bacteria adherent onto implants and hidden within the biofilm.[162,163] Several factors are commonly thought to be responsible for biofilm resistance, including (1) decreased fluid flow and antibiotic penetration, (2) varied metabolism across the biofilm structure and thus decreased susceptibility, and (3) possible resistance genes within the often heterogeneous bacterial population with rapid interchange of plasmids.[164] The usual theory invokes the slow penetration of antibiotics into the sludge that kills only the surface bacteria. Fluid channels that are abundant within the biofilm are limited in pore size and capillary movement, forcing antibiotics to only slowly diffuse and not equilibrate. The resulting concentration gradients create zones of stress for cells deeper in the biofilm, without reaching the MIC for the antibiotic.[133,150,165,166] Simultaneously, the same slow diffusion creates nutrient gradients within the biofilm with areas of nutrient depletion and starvation.[164,167–169] These niches result in bacteria with low metabolic rates that fail to respond to the sub-MIC concentration of antibiotic.[164,170,171] The microbial organisms are given time to adapt and survive, inducing genetic modification or gene transfer to acquire resistant phenotypes.[169,172] Despite this theorized propensity to acquire resistance, bacteria within biofilms are not normally more resistant to antibiotics than planktonic bacteria.[164]

Specifically, antibiotic resistance is usually developed when long-term selective pressure on a bacterial population provides a competitive advantage to those organisms able to survive in the presence of the antibiotic. This survival and hence resistance results from genetic mutation or gene acquisition from other organisms of the same or different species. The specific mechanism involves either (1) drug inactivation by specific enzymes as in β-lactamases, (2) alteration of the antibiotic target site such as change in the D-ala-D-ala sequence for vancomycin binding, (3) alteration of metabolic pathways as in common resistance to sulfonamides, or (4) reduced accumulation of the drug such as in acquisition of efflux pumps.[173] Typically, resistance is manifested only when the cells are exposed to increasing sub-MIC concentrations of an antibiotic that do not produce killing. The antibiotic then introduces a new selective pressure in the population and stimulates adaptation and evolutionary changes toward resistance. However, quite often, due to manipulation of normal metabolic machinery, resistant organisms are slow growers and thus are at a disadvantage under normal circumstances.[163,169,171,174]

However, recent data with floroquinolones question the assumed origin of biofilm resistance to antibiotics. Floroquinolones, in contrast to aminoglycosides, have been shown to quickly penetrate and equilibrate throughout the entire biofilm, killing most cells.[164] Paradoxically, the biofilm survives and regenerates.[164] To explain that phenomenon, Lewis *et al.* have proposed the concept of 'persisters,' that is, bacteria within the biofilm that may have altered metabolism and resist killing by drugs.[172] Persisters, in fact, have similar susceptibility to growth inhibition, but cannot be killed by normal antibiotic dosing.[164] As a result, biofilms would not be theoretically resistant in a microbiological assay as they would maintain similar MIC to normal flora. This phenomenon only emphasizes that MIC reflects a measurement of growth rather than killing. In the usual host environment where the bacteria are planktonic and the drug eliminates the bulk of the infectious population, the immune system is capable of eliminating the few persisters.[164] This scenario changes in biofilms where the sludge prevents immune cell penetration. Antibiotics eliminate the bulk of the biofilm and successfully inhibit further growth. However, a few persisters, though, manage to survive and, upon discontinuation of the drug, are then responsible for biofilm regeneration and long-term survival.[175] Very high antibiotic doses are usually required to eliminate persisters; such doses are often impossible to prescribe due to host toxicity. In fact, we have previously shown that antibiotics given at doses as high as 10× the MIC have minimal effect on preventing bacterial growth and colonization of titanium surfaces.[176] Other studies on urinary catheters have found the need for over 1000 times the MIC to eliminate colonizing bacteria.[177] Thus, to address the very foundation to the problem, bacterial adhesion must be inhibited as we have suggested in a proposed novel implant design that has a self-protective surface to inhibit bacterial colonization, inhibit biofilm

formation, and ultimately address the problem of periprosthetic infection, treatment, and prevention. The success of an implant with these properties can only be judged based on the current criteria for infection detection.

6.609.3. The Diagnostic Dilemmas

Despite extensive progress in implant designs, the diagnosis of periprosthetic infection remains the most elusive part of the entire clinical process. No universal criteria exist to determine and differentiate infection from aseptic loosening and osteolysis, and the entire process is based on the integration of clinical presentation, laboratory data, imaging modalities, and good, old-fashioned, judgment. The ultimate evidence of infection includes the identification of the infecting organism and morphological determination of biofilms on the implanted surface,[161] however, such evidence is often only obtained after the failure and removal of the implant. Modern serological tests, molecular techniques, and imaging modalities have varying sensitivities and specificities that depend on the individual laboratory, hospital, and chosen cutoff values for positive diagnosis. Parvizi *et al.* have previously proposed a diagnostic algorithm that includes both pre- and intraoperative tests and thus shows reasonable success in diagnosing periprosthetic infection.[92] However, improved predictive tests are needed with easier and earlier diagnosis and more specific differentiation between infection and aseptic conditions.

Clinical history and physical examination are critical for determining the risk of periprosthetic infection. A good history identifying the specific presentation, duration and localization of symptoms, predisposing factors, and response to treatments may render an early diagnosis. In fact, a diagnosis can be almost always confirmed in cases presenting with severe joint pain, fever, poor wound healing, erythema, drainage, sinus formation, and early implant failure.[89,178,179] Such presentation is more common for an early onset of infection occurring within the first few months after surgery.[123] Early short-term antibiotics may ameliorate the symptoms but leave a nidus of infection that ultimately leads to chronicity, premature implant failure, and delayed infection. As such, delayed infection, due to the chronic subclinical nature of biofilms on implant surfaces, presents in more than 75% of cases with nonspecific symptoms including minor hip pain, instability, and local inflammatory responses.[180] Owing to various presentations, clinical suspicion is an important factor in the ultimate diagnosis of periprosthetic infection, but confirmation of infection requires additional testing.

6.609.3.1. Markers of Infection

Radiographic studies allow for additional information that would not be easily obtained on physical examination. Radiographs can provide some nonspecific information about the local environment around the prosthesis; in cases of overt infection, periosteal reaction, bone cysts, and resorption may be visible (**Figure 1**). Even though radiographs complete another aspect of the clinical scenario, more specific tests are required for a better differential diagnosis. Another aid to diagnosis is serologic testing that is often easy to perform and provides preoperative information to aid in the diagnostic algorithm. Specifically, blood leukocyte count and differential is not sensitive or specific to periprosthetic infection,[123,181] whereas synovial fluid leukocyte count and differential is a rapid and accurate assay for predicting periprosthetic infection.[123] In fact, a knee synovial fluid leukocyte count of more than $1.7 \times 10^9\,l^{-1}$ and a differential of more than 65% neutrophils produced a sensitivity of 94% and 97%, with specificities of 88% and 98%, for detecting periprosthetic infection, respectively.[182] Erythrocyte sedimentation rates (ESR) and C-reactive protein have become very popular as an initial screening test of infection due to their high negative predictive values, even though they are generally nonspecific markers of inflammation.[92] Both of these markers normally rise after arthroplasty, with C-reactive protein returning to normal within 3 weeks; ESR, however, takes up to 6 weeks to reach normal values with some diurnal variation present even at that time.[89] Elevation of these markers after 3 months is considered abnormal and may indicate the development of periprosthetic infection. ESR values of more than $50\,mm\,h^{-1}$ produced a sensitivity of at least 79%, with a specificity of 78%.[183] Even values over 30 mm/Hr in some studies produced 82% sensitivity and 85% specificity.[184] C-reactive protein is generally a better predictor of infection, with levels of 1 mg/dL considered more than 96% sensitive and 92% specific for periprosthetic infection.[184] However, these predictive values have to be evaluated alongside the clinical history, eliminating other inflammatory conditions like inflammatory arthropathies, psoriasis, and gout that also produce elevated ESR and C-reactive protein. More recently, serum levels of interleukin-6 (IL-6) have been shown to correlate with infection.[89] IL-6 is produced by monocytes and macrophages, and serum levels above $10\,pg\,ml^{-1}$ have consistently predicted infection with a sensitivity of 100%, specificity of 95%, positive predictive value of 89%, negative predictive value of 100%, and accuracy of 97% against positive histopathology and culture.[185] Such results are superior to both ESR and C-reactive protein with the caveat that this was a limited study that examined only 17 patients with infection out of a 58-patient case–control study.[185]

6.609.3.2. Microbiology Assays

High clinical suspicion combined with elevated serological values provide a clear indication for joint aspiration and culture.[92] Microbiological culture of the aspirate is the most direct preoperative method to detect and identify the infectious organism.[186] The presence of bacteria after culture is thought to have high specificity for infection even though possibly low sensitivity. The test is flawed by the low retrieval rate of bacteria from culture when compared to more sensitive methods like PCR or other biomolecular techniques.[95,96,187,188] However with proper technique and sterile handling, the chance of contamination is very low and allows clear delineation of the patient population. The presence of bacteria correlates with periprosthetic infection with a predictive value for knees of 85%.[91,189] In fact, in the Rothman Institute experience, such culture of aspirated fluid showed 100% specificity and 100% positive predictive value.[92] The predictive value is much lower for hips, mainly due to the different anatomy and pathways of communication between the peri-implant space and the joint

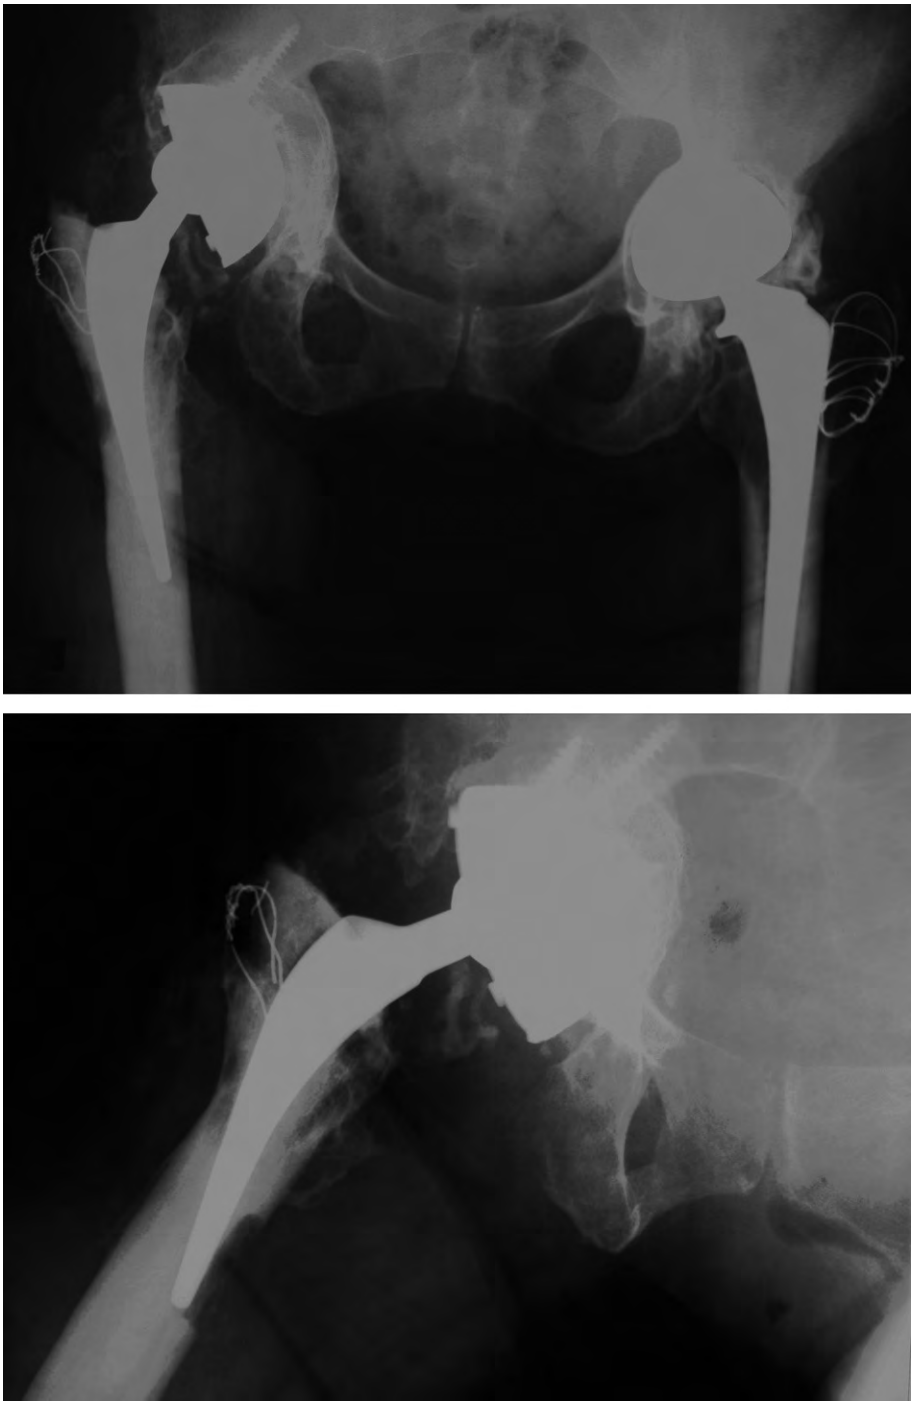

Figure 1 Failed implant. The patient presents with persistent hip pain, ESR 118 and CRP 4.3. Imaging (AP pelvis and hip shown) shows periosteal reaction, bone cysts, and implant loosening. The subsequent hip aspirate showed leukocytosis with a WBC count of 15 600 and a predominance of polymorphonuclear neutrophils (92%). The patient was taken to the OR with gross purulence observed upon opening the capsule and subsequent cultures were positive for *S. aureus*. A two-stage approach was taken with an antibiotic spacer initially and subsequent revision reimplantation.

synovium. Overall however, microbiological culture is not recommended as the single test for periprosthetic infection. Most authors agree on the utility of culture as a confirmatory test after clinical suspicion and serological tests have already indicated the probability of infection.[89,92,189] As a caveat to all of this, negative tests sometimes yield positive results when repeated, while antibiotic therapy within 2–3 weeks of aspiration drastically change the results, severely decreasing the chance of detecting true infections.[89,91,186,190] Therefore, in the presence of a strong clinical suspicion and positive serological test with no culture, advanced radionuclide imaging may provide another option.

More and more orthopedic surgeons employ radionuclide studies in their diagnostic algorithm by combining bone scintigraphy, technetium-99m, indium-111 scanning, or 18F-fluorodeoxyglucose (18F-FDG) imaging. Three-phase bone imaging by itself showed only 33% sensitivity and 86% specificity, with poor predictive value.[191] When using more specific antigranulocyte scintigraphy with monoclonal antibodies, a meta-analysis of over 522 implants showed a sensitivity as high as 90% and a specificity of 80%.[192] Technetium-99m sulfur colloid indium-111-labeled leukocyte bone scintigraphy gave a sensitivity of over 50% and a specificity of 95% in diagnosing infection.[193]

By comparison, fluorodeoxyglucose (FDG) positron emission tomography (PET) showed 95% sensitivity and 93% specificity for hip prosthesis-associated infection.[193] Yet another study showed 91% sensitivity and 72% specificity for diagnosing infection around the knee and 90% sensitivity, and 89% specificity around the hip.[194,195] Areas of infection involve inflammation and increased metabolism, especially relevant to glucose consumption. Immune system cells uptake the fluorodeoxyglucose which gets phosphorylated to deoxyglucose-6-phosphate and trapped in the cell long enough to be imaged by PET. However, again, PET is generally nonspecific and inflammatory conditions have to be ruled out in order to have any predictive value in the diagnosis of infection. Overall, radionuclide imaging is an exciting test but requires extensive resource utilization which is not easily available at most centers. Intraoperative tests and frozen sections represent a much more important component in the operating room.

Gram stain is probably the most common test performed intraoperatively that provides a specificity close to 100% but a sensitivity as low as 12–19%.[184,196,197] Unfortunately, bacteria, if in relatively low numbers, may escape the microscopic field and provide a false negative result. Intraoperative culture provides a better sensitivity, even though contamination during sampling may lead to a high rate of false positives.[89,198] More importantly, sampling techniques vary from surgeon to surgeon and the subsequent results confirm a high variability. Even with multiple samplings, sensitivity ranges from 65% to more than 94% with a high specificity of 96–100%.[92,184,196] Like gram stain, albeit having a slightly better sensitivity, cultures allow a high positive predictive value, and isolation of a single organism from multiple specimens almost always indicates a positive diagnosis of periprosthetic infection.

6.609.3.3. Intraoperative Diagnosis

When the culture results fail to confirm the presence of infection, frozen sections provide the last resort for ruling between the diagnosis of periprosthetic infection and aseptic loosening. Frozen sections associated with infection show the presence of inflammation and neutrophils. Because sampling and sections differ, sometimes lymphocytes or plasma cells are the only ones found, with few if any neutrophils.[89] For frozen sections with a polymorphonuclear lymphocyte count of more than 5 per 40x field, sensitivity reached 84–93% with a specificity of 77–96%.[199,200] By increasing the threshold to 10, specificity goes up to 85–98% at the cost of sensitivity dropping to 86%.[199,200] In the hands of other labs, though, 5 polymorphonuclear lymphocytes per field were associated with only 67% sensitivity and over 97% specificity in diagnosing infection.[201] Other inflammatory conditions may produce false-positive results and further skew the picture. Like other diagnostic tests, despite the fact that the criteria and thresholds for frozen sections are quite heterogeneous, five neutrophils per microscopic field combined with clinical suspicion is a good predictor of periprosthetic infection.

Therefore, after all tests, the final diagnosis is dependent on the complete picture and good clinical judgment. For instance, a strong clinical picture combined with less than three neutrophils per microscopic field is a strong indicator of infection, despite not exactly fulfilling the typical criteria in the literature. Many of the available tests are confirmatory or provide a good screening method, while none of them can be used as a single ultimate test for infection. Specific algorithms for diagnosis are helpful but do not apply to every patient.[92] Thus, a safe diagnosis relies on a combination of tests, science, judgment, and good predictive values.

6.609.4. An Interjection on Orthopedic Trauma

A diagnosis of infection is more direct in the orthopedic trauma setting and often can result in nonunion. Many times we see patients coming into the emergency department with complex open fractures and grossly contaminated wounds where the question of infection is brought up right at onset and a treatment protocol is automatically initiated before clinical decisions even start formulating themselves.

Trauma presents a unique situation wherein multiple biological systems are often affected and play an important role in final outcomes. The basic trauma assessment, even though superficially unrelated to a peripheral open fracture, has important details that direct subsequent management solutions and the specific approach. Basics of airway, breathing, and circulation provide information on the overall severity of trauma, initial mechanisms, and the energy of impact. Pending the stability of the patient, damage control orthopedics with external fixation in the operating room or even the trauma bay may take precedence over a fully orchestrated intervention. Various works have been done on assembling algorithms to direct initial trauma management.

The mangled extremity severity score (MESS)[202] attempts to combine patient information with the mechanism of injury and stability at presentation in order to predict the success of salvaging an injured extremity (**Table 1**). A younger patient with a simple fracture who is hemodynamically stable will typically do quite well compared to an elderly trauma victim with severely contaminated wounds and hemodynamic instability. A MESS score greater than 7 accurately predicts amputation in 100% of cases based on both prospective and retrospective data.

Gustilo and Anderson[203] have attempted to classify open fractures based on size, soft tissue characteristics, and overall contamination (**Table 1**). All these parameters usually play an important role in healing as well as infection complications. Grade I fractures are usually simple with a bone fragment breaking skin integrity but for all intense purposes they often act as close fractures (**Figure 2**). In contrast, grade III open fractures involve extensive soft tissue injury and sometimes

Table 1 Trauma classification of open fractures and mangled extremities

Gustilo classification of open fractures[a]		*Mangled extremity serverity score*[b]	
Type I		*Skeletal/soft tissue injury*	
Size	<1 cm	1. Low energy	Stab/simple fracture
Quality	Clean	2. Medium energy	Open fracture/dislocation
Soft tissue	Normal	3. High energy	Crush injury/close shot wound
Fracture	Typically simple	4. Very high energy	Includes gross contamination
Type II		*Limb ischemia (double if >6 h)*	
Size	>1 cm	1. Asymmetric pulse	
Quality	Clean-to-moderate contamination	2. Pulseless with diminished capillary refill	
Soft Tissue	Moderate crush	3. Cool, paralyzed, insensate	
Fracture	Usually comminuted	Shock	
Type III		1. Transient hypotension	
Size	>1 cm	2. Persistent hypotension	
Quality	Often high degree of contamination	Patient age	
Soft tissues	A. Adequate soft tissue coverage	0. Age <30 years old	
	B. Need for local or free flap	1. 30–50 years old	
	C. Arterial injury regardless of soft tissue injury	2. Age >50 years old

associated vascular injury. 24–70% of open fractures show growth based on derived microbiology data, even though likely 100% of open fractures are contaminated by bacteria, either foreign or normal skin flora. In the experience of Patzakis *et al.*,[204] simple fractures showed a rate of infection of 1.4% compared to 22.7% infection in grade III fractures, which mimics the data presented by Gustilo and Anderson[203] wherein up to 24% of complex open fractures were complicated by infection. Dellinger *et al.* supported that work through the finding that local fracture, requirement for blood transfussions, or polytrauma.[205] Antibiotic prophylaxis is nowadays initiated as soon as possible with cefazolin and augmented by gentamycin in grade III open fractures with addition of metronidazole in the case of soil/farm contamination. The duration of antibiotic treatment is less important, but 24–48 h seem appropriate. Radical debridement is usually as important as antibiotics, with all nonviable or potentially devascularized tissue being removed to minimize the necrotic area and therefore safe zone for bacterial growth.[206] Vascularity is the most important factor in determining infection and other complications after open fractures.[207]

Once infected, the presence of a foreign body, be it the intramedullary nail or the plate and screws, presents a unique and usettling problem. As already discussed, the predilection to biofilms as well as the immunosuppressed state in the immediate vicinity is further escalated by the presence of a fracture and instability. This is a different problem than the typical situation with joint replacements which will be discussed later – these implants can usually be removed with full functionality to the limb if the fracture integrity is somehow reestablished. Nevertheless, the same premise remains – an infection cannot be eradicated while infected hardware remains present.[208] Nevertheless, many orthopedic trauma surgeons believe that stability is more important than infection for ultimate fracture healing, and several studies, largely based on laboratory animal protocols,[209] support that hypothesis. As such, standard protocol usually dictates irrigation and debridement to minimize the bacterial load, suppressive antibiotics, with or without hardware exchange.[210] Reamed intramedullary nailing is usually the preferred method of fixation in long bone diaphyseal open fractures, even though external fixators are sometimes used for damage control.[211] Delayed conversion from external fixator to intramedullary nailing has been associated with increased risk of infection.[207] Nevertheless, Rightmire *et al.* report a rate of only 68% of infected complications with retained hardware after an open reduction and internal fixation progressing to union, with as many as 32% of cases requiring additional procedures. Even then, 38% of healed fractures required hardware removal for persistent infection, and another 21% developed a hardware associated infection later. Long-term suppressive antibiotics for more than 6 weeks after irrigation, improve the outcomes, but often fail in view of antibiotic resistance and resilient species. Based on DNA analysis, as many as 42% of fracture callus specimens show bacterial presence, with actual bacteria isolated from 14% of healing fractures.[212]

Such results remain unacceptable, and extensive work is underway to minimize those rates. This work has been used in civil fracture management, but becomes even more important in the battlefield setting, where military high energy gunshot wounds are automatically grade III. Even though fixation is the ultimate goal of management, the presence of the implant as a medium for bacterial survival is the unifying factor between trauma, spine, or arthroplasty.

6.609.5. Classification Schemes for Implant Infection

Attention to the timing of initial clinical presentation prompted a method of classifying periprosthetic infections as either early acute or late chronic.[213,214] This classification is based on several prospective and retrospective studies and introducing a couple of additional groups based on etiology and diagnosis.[139,215,216] Even though not complete, the

Figure 2 Open fractures. Gustilo *et al*. introduced an open fracture classification based largely on soft tissue injury. Type I fractures usually result from bone fragment disrupting the skin integrity, but the wounds are small and clearn, and the fracture is treated as close for all intense purposes (Top left: distal radius fracture with small overlying skin lac likely from small fragment penetration). Type II fractures have large skin wounds putting the patient at higher risk for contamination and subsequent infection (Top right: open ankle fracture with relatively clean wound). Type III fractures usually involve large soft tissue injuries and contamination. The differentiation between a IIIA and IIIB is dependent on the ability to close the wound and the requirement for skin graft/flaps (Bottom left: tibia and fibula fracture with large soft tissue defect over the anterior tibia). Type IIIC fractures are independent of soft tissue coverage but include vascular injury (Bottom right: ankle fracture dislocation with associated posterior tibial artery injury and absent pulses distally).

classification allows for a more pragmatic approach to diagnosis and subsequent treatment. Type I infections are identified as those clearly diagnosed by positive intraoperative culture obtained during revision surgery initially performed for aseptic loosening. Type II infections are acute, initiating within 4 weeks after implantation, associated with contamination during surgery, and presenting classical symptoms of fever, inflammation, and fluid/pus. Furthermore, type II can be separated into superficial (a) or deep (b) depending on the extension through the joint capsule. Type III infections are considered acute hematogenous in etiology due to the rapid deterioration of a previously normal joint. Onset usually starts later than 4 weeks with extension through the joint capsule. Finally, type IV infections are usually late, chronic infections that occur more than 4 weeks after primary implantation with sinus, induration, and joint involvement. Several of the groupings are relatively difficult to separate and do not hold validity in the current standard of practice. For example, classification as hematogenous infection may be difficult, as the presentation switches from acute to chronic depending on the duration of symptoms.[217,218] Later adaptations to this ranking system have changed the timing to define the breakdown between early and late infection at 6 weeks.[179] Furthermore, most of these classifications are overly simplistic and do not account for newer developments in the field of periprosthetic infection, including better understanding of biofilm biology, issues of drug resistance, and emerging challenges in diagnostic modalities. However, a discrete stratification of the patient population into groups provides a good scheme for developing a consistent strategy and standardizing the approach to periprosthetic infections.

6.609.6. Management of Periprosthetic Infection

The complexities associated with correct diagnosis is only the harbinger of the difficulties associated with successful treatment. Revision surgery is often indicated, although prosthesis retention with antibiotic therapy is a viable alternative in uncomplicated cases where acute presentation is within 4 weeks of initial surgery. Typically, the treatment of periprosthetic infection involves surgery with implant retrieval, extensive debridement and excision of contaminated tissue, one- or two-stage reimplantation, aggressive antibiotic therapy, and follow-up.[67,128,216,219–221] Long-term antibiotic suppression, arthrodesis, resection arthroplasty, and amputation are reserved for the extremely difficult case where other alternatives fail.

Currently, antibiotics are the only available noninvasive method for combating an active infection and are always used regardless of the chosen strategies.[222,223] However, once infection is established, common antibiotic combinations have limited effect.[188] Therefore, maximum impact is achieved only by prophylactic use of antibiotics before or during primary arthroplasty thereby allowing more stringent sterility measures. Perioperative antibiotics are now the standard and predosing is called for in patients with associated comorbidities. However, the antibiotics selection is often not the drug with best activity against adherent bacteria in biofilms.[128,224] The choice is complicated as, due to the involvement of biofilms in implant infections, common susceptibility tests are not good predictors of biofilm antibiotic efficacy.[225–227] Rifampin is the only antibiotic with well-documented activity against adherent biofilms; however, used alone, it induces resistance in as little as 24 h.[228,229] Rifampin in combination with fusidic acid showed 55% success against MRSA[230,231] and thus could be a more suitable choice. Another good choice is the quinolone antibiotics due to their capability to penetrate biofilms and equilibrate across the bacterial population. Both ciprofloxacin and ofloxacin are often used to treat bone or joint infections[128,134,231]; levofloxacin is even more effective, but data on efficacy in bone are still limited. When used after surgical debridement, ciprofloxacin in combination with rifampin produced a 100% cure rate in one study; only a 58% cure rate was measured with ciprofloxacin monotherapy.[82] Rifampin can also be combined with trimethoprim-sulfamethoxazole, minocycline, and linezolid, even though efficacy data are limited at this time.[87,88,128] The increasing risk of resistance development constantly requires strategy reevaluation and demands new drugs for the treatment of orthopedic infections. Linezolid, daptomycin, and tigecycline are three relatively new but promising drugs being currently explored for treatment of periprosthetic infections, albeit patient data are still insufficient for pertinent recommendations.

During the management of infection, both the identity and susceptibility of the infectious organisms should be determined soon after empiric therapy is initiated. Despite availability of new super-drugs, a basic algorithm suggests use of vancomycin for gram-positive organisms in acute or chronic infections, while cephazolin and gentamycin are recommended for hematogenous contamination.[137] Furthermore, third of fourth-generation cephalosporin alone or in combination with vancomycin are recommended for gram-negative and mixed flora.[137] Clindamycin or a combination of ampicillin with sulbactam are efficient against anaerobes.[228,229] Treatment should be continued for a minimum of 4–6 weeks, which also coincides with the typical period of revascularization.[139,228,229] At the same time, drug rotation is crucial in minimizing resistance,[232] so a varying antibiotic algorithm is favored rather than the constant prescription of a single drug like vancomycin. Such a strategy may decrease the risk of resistance by decreasing the selective pressure of a single drug.[233] Interestingly, recent hypothesis on antibiotic resistance actually recommend early prophylactic use despite the perceived unnecessary treatment. Such prophylactic strategy may prevent advanced infection and therefore prevent excessive late use of antibiotics, ultimately decreasing the total antibiotic pressure on the bacteria in our environment. Despite improved antibiotic strategies in the face of emerging resistance, periprosthetic infection often requires revision surgery.

6.609.6.1. Surgical Approaches

When everything else fails or the associated risks are too high, surgery has shown the best results at treating and ultimately eradicating the associated infection. Surgical intervention allows direct removal of the biofilm, further excision of contaminated tissue, and washing with antibiotic solutions in high local concentrations. During the early postoperative days, superficial infection without joint capsule involvement can be managed with soft tissue resection and debridement,

which allows implant salvage. Antibiotic-laden cement beads containing tobramycin or vancomycin are often used within the wound for up to 2 weeks.[216] Such cement beads maintain a high local antibiotic concentration inhibitory to bacterial growth while allowing the immune system to eliminate persisters. Intravenous antibiotics are continued for a duration of 4–6 weeks. This approach can yield very good results, with eradication reported in 26–71% of patients.[139,234] Delay in treatment, however, converts the early acute infection to a chronic status, with surgery and aggressive management necessary if symptoms persist for more than 2 weeks.[234]

Implant removal is always involved in more severe infections where the joint capsule is involved or symptoms have a late chronic presentation. Depending on the severity of infection, risk factors, and the surgeon's ability to cleanly excise the surrounding tissue, a one-stage or two-stage revision is performed. If the infection is (1) relatively mild, without sinus tracts or induration, and (2) the cultured organisms show simple flora susceptible to typical antibiotics, which is rare nowadays, then a one-stage procedure is possible with relatively good success.[179,215,235] The rate of reinfection after one-stage procedures varies from 8 to over 12%, allowing over 80% survival of the implant.[179,236] One-stage procedures are less involved and provide faster recuperation for the patient. Despite that, with the high risk and costs of reinfection, and the very limited indications for a one-stage procedure, two-stage exchange revision is currently the standard for many physicians in the United States.[179] After removal of the infected prosthesis with extensive debridement and soft tissue excision, an antibiotic cement spacer is used to help eradicate the remaining bacteria. A second surgery is used to remove the spacer and implant a new joint prosthesis. The specific timing for the procedures is not clearly defined and ranges from 3 to 6 months.[237–239] The system is very complex as biofilms are difficult to eradicate, so intraoperative aspiration and culture is recommended during the extraction of the spacer.[240] Comparison studies of two-stage versus one-stage procedures suggest an advantage to the two-stage revision with reinfection rates of 3–6%, even though another study documented up to 22% infection with delayed surgery.[179,241–243]

Despite improved treatment, the rate of infection is higher after revision surgery than primary joint arthroplasty. Such a conclusion emphasizes the critical role of a successful primary surgery, with maximum precautions taken to eliminate infection. The consequences of an aggressive infection are further amplified by additional complications associated with revision surgery. Extensive bone loss can take place, which precludes additional revisions, leaving no choice but arthrodesis or even amputation. However, considering that two-stage procedures are the management step just before amputation, antibiotic laden cements are currently considered the gold standard for local antibiotic delivery in cases of periprosthetic infection.[244]

6.609.6.2. Antibiotic-Laden Bone Cements

Antibiotics are crucial, along with surgical intervention, for the ultimate eradication of infection. However, given intravenously, antibiotics have poor diffusion to the implanted joint, especially when the environment is complicated by the associated injury, hematoma, and loss of vascular supply after surgery.[229] Therefore, antibiotics are often needed in concentrations many times higher than their MIC in order to be efficient against biofilm formation.[177] Such antibiotic concentrations, though, are impossible to maintain systemically due to toxicity and clearance issues. A carrier mechanism is necessary to bypass the systemic route and locally provide the drug in controlled, constant dosages. Such a carrier should be simple in design without additional complications and costs for either the patient or the surgeon.

Most experts agree that there is no ideal local delivery method for targeting antibiotics to the site of implant infection, even though bone cements now serve that role.[244–246] Originally used for stabilization and improved integration of the joint prosthesis, bone cements are being phased out by the popularity of cementless joint replacement.[247] However, materials like methyl-methacrylate and calcium-phosphate are quite pliable and easy to mix, mold, and otherwise manipulate, allowing them to be formed into spacers, intramedullary fixation nails, beads, and implant coatings.[248–252] Such applications for bone cements were investigated as early as the 1970s, with slow accumulation of data and clinical information in favor of clinical use.[253] The system is quite flexible and often allows mixing the antibiotic of choice right in the operating room. The form can be molded to the local anatomy with antibiotic concentrations adjusted for the individual patient infection and systemic clearance.[237]

Despite the initial success of antibiotic-laden bone cements and extensive applications and indications for their use, the FDA had not approved this local antibiotic delivery system until recently. The four forms of bone cement currently approved by the FDA include tobramycin SimplexP (Stryker Howmedica Osteonics, Mahwah, NJ), gentamycin Palacos® G (Biomet, Inc., Warsaw, IN), and gentamycin SmartSet GHV and MHV (DePuy Orthopaedics, Inc., Warsaw, IN). PROSTLAC with 1 g vancomycin and 3.6 g tobramycin (DePuy Orthopaedics, Inc., Warsaw, IN) is another system currently approved as a combination antibiotic therapy with reasonable gram-positive and gram-negative coverage. Industrialization of the process allows for reproducibility and standardization, eliminating inconsistent mixtures, and variations in texture or porosity. As a result, recent data from two-stage arthroplasty procedures further support use of antibiotic-laden bone cement as the best available management.

Unfortunately, while achieving supratherapeutic concentrations of antibiotic at the insertion site, antibiotic-laden cements are often associated with tissue toxicity due to the initial high antibiotic elution profile.[254–256] Multiple studies have clearly documented inhibition of bone cell proliferation and maturation, leading to possible inhibition of bone healing and osseointegration.[257] Several cases have even reported systemic toxicity associated with vancomycin and tobramycin-laden bone cements due to acute renal failure.[258] Such complications are mainly due to the pharmacokinetics of bone cements, which are difficult to control. The delivery of antibiotics depends on concentration gradients, which often fluctuate with the immediate host environment. That environment is inherently unstable due to local trauma in surgery, patient to patient anatomical differences, fluid flow, and changes in physiological electrolytes. Current elution data show an immediate burst of antibiotics to very high levels

within the first 24 h after implantation, which is followed by rapid depletion and exhaustion of antibiotics in the first days.[256,259,260] In fact, the cement material itself is a great biomaterial for bacterial colonization and propagation of biofilms.[261,262] The subsequent drop to sub-MIC concentration of antibiotic induces an environment conductive to resistance development within surviving persisters.[263–265] In addition, the popular methyl-methacrylate cement is highly exothermic during the curing process which may inactivate temperature sensitive antibiotics like vancomycin. Furthermore, no matter how efficient the local delivery systems may be, they themselves produce additional pain and disability, requiring more bone loss, prolonged lack of mobility, and additional surgery to replace the biomechanically inappropriate spacer with a true joint replacement. Thus, while these cements have proven to be powerful tools against established infection, their complications limit their utility.

6.609.6.3. Self-Protective Implants

New advances in biomaterials and biotechnology are rapidly visible in medical designs and stimulate the science behind novel concepts like 'smart' implants.[6,261,266] New implant coatings and direct surface modifications interact with cell surface proteins like integrins to modulate cell survival, proliferation, differentiation, and signaling.[267–270] They take advantage of current biomolecular concepts in order to target specific cellular responses at the cell signaling level.[267] However, industrial production of these biomaterials and their subsequent introduction into mainstream medicine has been hampered by the complexity of proposed technologies. Using classical methods in chemistry and engineering, synthesis of such materials is difficult to control and practically impossible to reproduce with uniform consistency.[262] To overcome limitations in research and development, new directives explore self-assembly and autonomous organization of molecules based on entropy.[271,272] A fresh approach requires nanoscale designs and robotics.[262] Such systems borrow and apply concepts developed in nature over many evolutionary eons. As an example, complex arrangements in the quaternary structure of proteins or self-assembly of membranes require simple physical interactions with reproducible products. Such interactions are often reversible and, thus, allow extensive modulation depending on the interplay and balance of involved molecules. Therefore, such complexes can be further modified to respond to external cues, like the change in acid-base balance or temperature, resulting in 'smart' biomaterials that monitor their environment.[262] Despite the application of such technology to further improve osseointegration, very little is done in the area of infection prevention.[267]

Currently, only a few applications have targeted incorporation of antibiotics into surface coatings directly deposited onto the implant.[273–275] Most of these applications build on the information learned from antibiotic-laden bone cements and provide an initial protective barrier for infection.[276–278] Current protocols include poly-D,L-lactide, calcium phosphate, or carbonated hydroxyapatite antibiotic coatings. Other direct techniques attempt to physically modify the surface for antibiotic adsorption or simply dip the implant in antibiotic producing a transient coating.[80,278–280] The coating is a local delivery system that provides targeted release into the periimplant space and allows use of high antibiotic concentrations while minimizing the risk of systemic toxicity. Still, these surface coatings are not radically different from antibiotic-laden bone cements, and, thus, they are associated with the same problems that affect elution technologies in general. Specifically, the release of antibiotics from the surface coating depends on concentration gradients, resulting in the initial burst of antibiotic with sub-MIC delivery at later times. Newer methods have attempted to improve control by introducing various biopolymers like ceramics and bioglasses.[27,281–283] These novel materials use improved assembly chemistry to control pore size and tortuosity to allow programmed release of the antibiotic over longer periods of time. Despite that, the duration of release is still limited, leaving the implant susceptible to late infection and contamination through hematogenous spread. Simultaneously, it is important to consider that late infection is often the most common presentation, and it is inherently difficult to treat.[220,284,285] Therefore, although elution technologies provide an excellent local antibiotic delivery system and represent an excellent strategy for the immediate postoperative period, they cannot deal with the more complex aspects of late periprosthetic infections. Even with newer, improved surface coatings, the issue of periprosthetic infection remains largely unsolved.

6.609.7. The Future of Implant Design in Orthopedic Infection

Even though immediate postoperative strategies help decrease the rate of acute infection, the most dreadful complications are often associated with late infection. The successful prevention and eradication of periprosthetic infection requires a more permanent solution for implant protection. Such technology should directly integrate biological defenses in the implant design, making protection feasible for the life of the replacement prosthesis.[128,286,287] Furthermore, the antibiotic dose should be controlled, specific against target microorganisms, and devoid of toxicity in both the immediate and distant host environment. Recent scientific progress in biomolecular interactions and nanoscale engineering provides new inspiration for medical implant designs that may have the potential to deal with infection.[6,262] Biodegradable thermoplastic elastomers with changing shape, biological sensors, and electroactive polymers that replace muscles provide a vast background for further development and translation into orthopedic implants.[265,266,288] A true cooperation between biology, chemistry, biomaterial science, and engineering can produce an implant that will resist bacterial colonization and thus prevent the survival of persisters within resistant biofilms.

6.609.8. Nanomolecular Permanent Modification of Biomaterials

In fact, we have been working on such a system that incorporates antibiotics not as a coating, but rather as a nanoscale permanent modification of the implant surface that makes the implant resistant to bacterial colonization.[289] We have

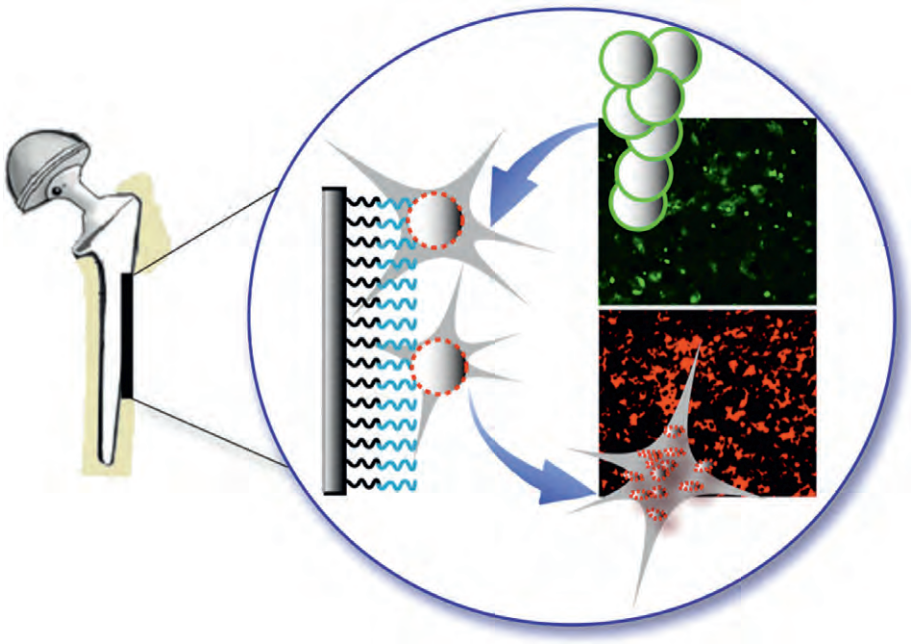

Figure 3 Smart implant. Antibiotic surfaces directly interact with their environment. Live bacteria coming in contact with the implant (SYTO® 9 green fluorescent nucleic stain) coming into contact with the surface die as a result of cell wall lysis (red fluorescent propidium iodide stain).

previously described the covalent attachment of antibiotics to the surface of titanium commonly used in surgical devices. We hypothesized that direct bonding of the antibiotics onto implant materials would provide a nanoscale stable surface that would prevent the aforementioned bacterial colonization and therefore prevent the progression of infection (Figure 3). We have, in multiple publications, presented the accomplishments of our group over the last 5 years in this regard.[176,290–292]

The chemistry was initially described for vancomycin but other antibiotics and biological compounds can be tethered using the same mechanism. In addition, the underlying surface is not limited to metallic materials but can easily be extended to silicone, plastic surfaces, synthetic vascular grafts, and potentially, ceramics, allowing extension of this technology for use in other medical fields such as plastics, vascular, cardiothoracic surgery, or general medicine. We have shown extensive antibiotic coverage on the surface and vancomycin remained present even after multiple challenges with very high bacterial counts. The antibiotic retained its bactericidal properties after linkage and showed potent and consistent activity when challenged with both *S. aureus* and *S. epidermidis*. Other currently available technologies attempt to prevent surface inhibition by including the antibiotic in an adsorbed or chemisorbed layer. The drug is then eluded from the material at variable kinetics dependent on concentration gradients, and may rapidly achieve levels that are toxic to the immediate bone environment.[257,293] The proposed antibiotic surface raises similar concerns due to the permanent nature of the modification, despite no perceived elution of antibiotics. Nevertheless, musculoskeletal cells showed normal colonization of the implant, indicating strong adherence and subsequent differentiation and maturation. Both osteoblastic and chondrocytic cell lines show normal morphology and metabolism capable of mineral or proteoglycan deposition respectively.

6.609.8.1. Feasibility of the Concept

A final test of feasibility involves testing in a mammalian system to simulate the clinical environment. The proposed vancomycin-modified rods inhibited microbial colonization of the surface, as observed by quantifying the adherent bacterial numbers. Furthermore, bone infection and the associated bone destruction was inhibited in the femora containing modified rods, while same implants supported normal fracture healing and bone repair. Interestingly, we have shown that both preoperative contamination of the implant during handling and the intraoperative contamination of the femoral canal can be effectively curtailed using the proposed implant. The material inhibits bacterial colonization at all stages in the clinical process. Furthermore, the vancomycin-modified implant showed such results under conditions that would typically lead to septicemia and shock in humans due to the high numbers of introduced bacteria.

These promising accomplishments continue to advocate for the potential use of antibiotic-modified implants in preventing and eradicating infection. The current data are far from complete but presents the necessary proof of principle that the technology is feasible and highly effective at controlling infection. The chemistry is simple and easy to reproduce, with the cost of reagents not exceeding $20 per synthesis. The antibiotic remains stable in the face of demanding environments and inhibits bacterial proliferation both *in vitro* and *in vivo*, while still allowing bone cell proliferation and adherence. In recent years, we have upscaled our technology to allow modification of plates, screws, and intramedullary nails used in clinical practice. The technology is currently being adapted for hip prosthesis to be used in canine and ovine models in order to closer approximate the human geometry. Additional animal experiments are in process in order to clarify the specific limits

of the surface with regard to bacterial dose, temporal survival *in vitro*, and osteointegration. We are encouraged by the early animal data and believe that this implant has great promise for use in clinical practice. In fact, the project anticipates the initiation of clinical trails in order to evaluate the efficacy of the proposed implant in its targeted application. With such exciting prospects, the current work has already set a pioneering template for a new generation of smart implants that use surface agents as a tool to control and alter the biomaterial–host interface. Such implants can truly shift the balance stated in Gristina's hypothesis,[162,170,294] allowing host cells to finally conquer the implant surface in defiance of quickly adapting infectious organism.

6.609.9. Conclusions

Joint replacement remains one of the most successful procedures in orthopedic surgery. There is a constantly rising demand for these procedures and, therefore, subsequent increase in the prevalence of complications. Despite immense progress in prosthesis design, periprosthetic infection remains one of the most common complications and one that has dreadful consequences that may lead to arthrodesis, amputation, and in rare cases, even death. The very nature of the implant and its propensity for bacterial colonization by small numbers of bacteria predisposes the implant to biofilm formation. Biofilms are resistant to available treatment strategies and, even when seemingly eradicated, leave behind persisting bacteria that are capable of reinitiating an infection long after the initial presentation. Furthermore, they complicate the diagnosis, with no clear-cut diagnostic assay or algorithm. Subjective decisions are usually required and they must take into account a panel of positive or negative tests and the clinical presentation. The inconsistent evaluation and variability in the present diagnostic algorithms make it difficult to standardize a diagnostic classification that would allow uniform management decisions. Revision surgery and antibiotics are quite successful, yet the risk of reinfection is more than tripled after such procedures. Even with successful treatment, the effort required to combat periprosthetic infections leads to more bone loss, excessive pain and disability, and immense cost for both the patient and the health care system at large. A new solution is needed to not only address the problem of infection by treating it, but prevent infection occurrence which would simultaneously improve all aspects of joint replacement. Smart implants and antimicrobial surfaces are the only answer that currently show reasonable success and that have immense potential. Perhaps, after more than a century of experimentation with joint replacements, the future is brighter than ever.

Glossary

Discogenic back pain Discogenic back pain is also known as lumbar disc pain. The most frequent symptoms of discogenic back pain are lower back pain and spasms.

Fretting corrosion Fretting corrosion refers to corrosion damage at the asperities of contact surfaces. This damage is induced under load and in the presence of repeated relative surface motion and wear.

Hemangiomas An abnormal proliferation of blood vessels that may occur in any vascularized tissue.

Laminectomy Spine surgery that removea the portion of the bone arch on the dorsal surface of a vertebra.

Osteopenia A condition in which bone mineral density is lower than normal, but not low enough to be classified as osteoporosis.

Pseudo elasticity A reversible response to an applied stress, caused by a phase transformation between the austenitic and martensitic phases of a crystal.

Vertebroplasty and kyphoplasty Medical spinal procedures in which a material is injected through a small hole in the skin (percutaneously) into a fractured vertebra and hardens; the goal of the procedure is to relieve the pain caused by osteoporotic compression fractures.

Abbreviations

AF Annulus fibrosus
GAG Glycosaminoglycan
IVD Intervertebral disc
NP Nucleus pulposus
PG Proteoglycan
TDA Total disc arthroplasty

6.610.1. Introduction

The spine has two main purposes: (1) it must provide a strong mobile central axis to support the skeleton and (2) it must also provide protection for the delicate nerves that travel from the brain to the periphery. A balance between stability and flexibility are essential to achieve this dual purpose. Aging, injury, disease, and genetic conditions can disrupt this balance resulting in back pain with more than 60% of the population experiencing back pain throughout a lifetime.[1] Low back pain alone accounts for 2% of all US physician office visits.[2] Pain can be generated in the spine from damage to several anatomical elements including the vertebral bodies, intervertebral discs (IVDs), facet joints, dura of the nerve roots, ligaments, facia, and muscles.[3] Stabilization of the spine has been the major focus of surgical interventions to alleviate back pain.[4]

Interventional techniques have evolved from the earliest use of metal screws and plates to correct scoliosis adapted from peripheral extremity repair in the late 1950s.[5] Internal fixation of the spine using pedical screws was first introduced in 1959 by Boucher in Canada.[6] In the 1960s, the advent of bony fusion techniques greatly increased the success of these procedures and currently, advancements are still being made on materials choice and structural design of spinal internal fixation devices.[7] The IVD has also been a major focus in spinal procedures with the first surgeries on disc protrusion reported in 1934 by Mixter and Barr.[6] Current techniques in treating discogenic back pain include removal of disc material and replacement with prosthetic devices[8]; however, advances in knowledge of the IVD ultrastructure have led to recent investigations into the repair of individual IVD components, that is, nucleus replacements[9] and annulus repair technologies (see **Chapter 6.613, Nucleus Replacement**).[10] Recent advances in minimally invasive surgery have also made a large impact on spine surgery and the potential for novel therapies.

Most notable is the development of the vertebroplasty and kyphoplasty procedures developed in the late 1980s for the percutaneous treatment of vertebral fractures (see **Chapter 6.611, Injectable Bone Cements for Spinal Column Augmentation: Materials for Kyphoplasty/Vertebroplasty**).[11–13] The development of materials for spinal procedures has been greatly influenced by advances in technology that permit the visualization of spinal structures, innovations of novel surgical procedures, and a better understanding of the biology and structure of the native tissue. Early materials were adapted from procedures designed for the repair of bones and joints in the extremities; however, as more is understood about the unique structure and mechanical needs of the spine, novel materials are being developed for use in spine specific procedures. Tissue engineering and drug delivery have also motivated the development of new materials with porous and regenerative surfaces. This chapter outlines the current materials utilized in the major surgical interventions (spinal fusion, total disc replacement, and annulus repair) and spine pathologies as well as the future direction of material development.

6.610.2. Anatomy and Physiology of the Spine

6.610.2.1. The Vertebral Column

The human vertebral column or spine functions to transfer loads and bending moments of the head, trunk, and any external loads to the pelvis, allows sufficient physiological movement and flexibility of the upper body, and protects the spinal cord from dangers due to motion and trauma.[14] It also serves as protection to other vital internal organs and as a base of attachment for upper-body ligaments, tendons, and muscles. These functions help explain its form and structure.

The spine consists of 24 individual vertebrae, the sacrum, and the coccyx, and spans from the skull to the pelvis. The vertebrae are stacked on top of each other and are grouped into five distinct regions – there are 7 cervical vertebrae, 12 thoracic, 5 lumbar, 5 fused sacral, and 3 fused vertebrae that make up the coccyx (**Figure 1**). From posterior perspective, the spine appears to be straight, but lateral view shows four normal curves that mechanically serve to give the spinal column increased flexibility and shock-absorption ability.

The vertebral body is the primary weight bearing area, and adjacent vertebrae are connected by an IVD (**Figure 2**). The vertebral foramen is the large hole in the center of the vertebra that is surrounded by lamina, forming the spinal canal. The spinal cord runs through this opening and is protected by it. The spinous process protrudes from the central posterior region of the vertebra and acts as a connection point for ligaments. There

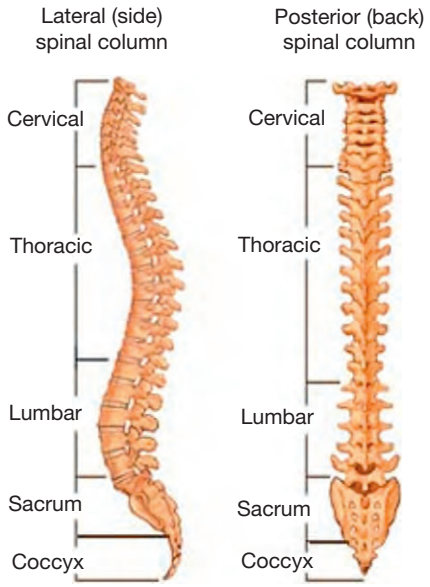

Figure 1 Regions of the human spine with respect to the vertebrae and corresponding intervertebral discs (http://healthbase.wordpress.com/2007/06/13/spinal-fusion-surgery/).

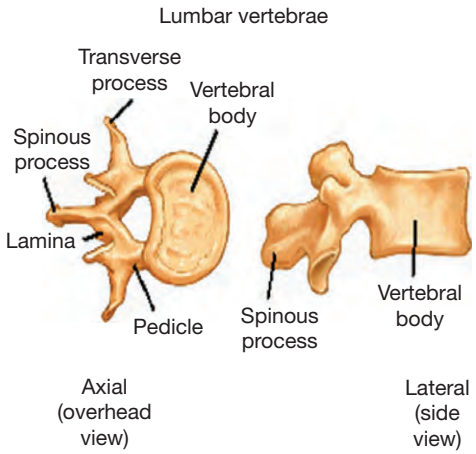

Figure 2 The lumbar vertebrae. Reproduced from Toida, T.; Kakinuma, N.; Toyoda, H.; Imanari, T. *Anal. Sci.* **1994**, *10*, 537–541.

are pairs of transverse processes which are orthogonal to the spinous process and provide attachment for the back muscles. There are also four facet joints on each vertebra that are found in pairs (one superior and one inferior), interlocking with adjacent vertebrae to provide stability to the spine. When osteoporosis occurs in the spine, vertebral collapse, or compression fractures, may occur (Figure 3.). Vertebral compression fractures may also be caused by hemangiomas, multiple myeloma, and osteolytic metastases.[15] Multiple fractures lead to a stooped or hunched posture, chronic pain, and loss of height.

6.610.2.2. The Intervertebral Disc

The IVD separates adjacent vertebrae and acts as a shock absorber, dissipating energy under loading. The disc is the largest avascular tissue in the human body requiring nutrients to enter and waste to be removed primarily through diffusion and fluid flow.[14] The disc structure is quite complex combining three distinct regions: the nucleus pulposus (NP), an inner gelatinous core; the annulus fibrosus (AF), a surrounding ordered fibrous structure; and the bony endplates that are partly cartilaginous and partly bony and serve as an interface between the disc and the vertebral bodies (Figure 4). The cellular content of the disc is very low, less than ~0.25% of tissue volume.[16] The extracellular disc matrix plays the main role in determining the mechanical properties of the disc.

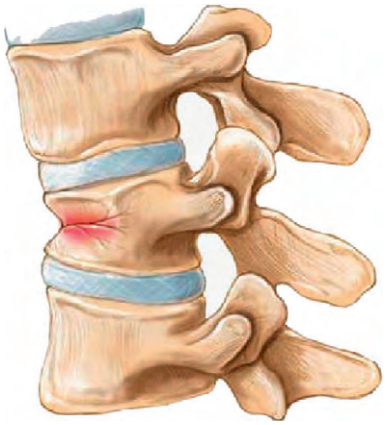

Figure 3 Vertebral compression fracture. Reproduced from Stryker-Interventional. 2008. Compression Fractures of the Spine. http://www.helpingbacks.com/spinalfractures.php.

6.610.2.3. The Nucleus Pulposus

The central NP region of the IVD is a gelatinous structure that is mostly water (77% of wet weight) but also contains a large constituent of proteoglycans (PGs) (14% of wet weight) which are composed of charged glycosaminoglycan (GAG) chains covalently attached to a protein core. Randomly organized collagen fibers are also present in the NP (about 4% of wet weight) and associate with the PGs to form a loose network.[17] Collagen fibers within the NP provide tensile strength while PGs create a large osmotic swelling pressure and draw water into the tissue (Figure 5). Charged groups on the GAG chains of the PGs carry with them mobile counter ions such as Na^+ which draw water into the tissue because of the osmotic imbalance generating a hydrostatic pressure within the NP.[18]

6.610.2.4. The Annulus Fibrosus

The AF of the IVD is a structure that serves to contain the gelatinous NP. The chemical composition of the AF comprises 65–90% wet weight of water, 50–70% dry weight of collagen, 10–20% dry weight of PGs, and noncollagenous proteins such as elastin.[19] The structure of the AF is laminate in nature, consisting of a minimum of 15 (posterior) and 25 (lateral) concentric layers. The layers are made up of type I collagen fibers which alternate in angles from 30° at the peripheral AF to 44° at the central AF with reference to the transverse plane of the disc (Figure 6). The concentric rings of the AF are referred to as lamellae, and the spaces between them as interlamellar septae.[19]

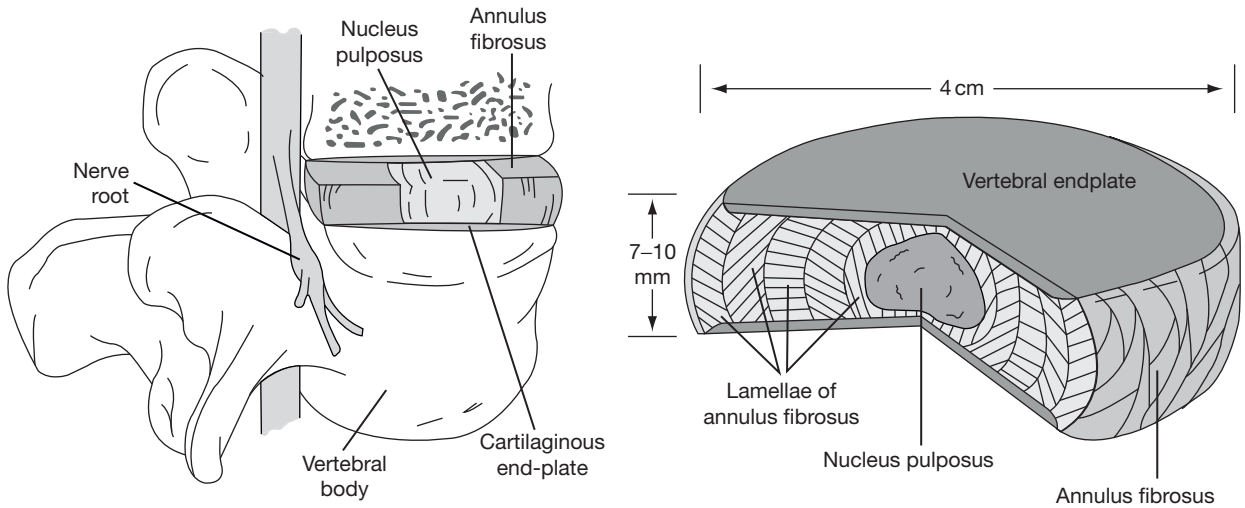

Figure 4 The intervertebral disc (IVD) location between adjacent vertebrae and the individual structures and average dimensions of the IVD. Reproduced from Raj, P. P.; Fipp, A. *Pain Practice* **2008**, *8*, 18.

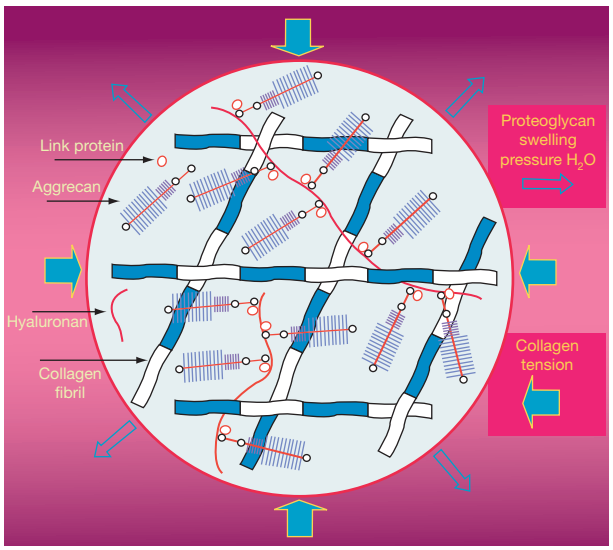

Figure 5 Constituents of the nucleus pulposus and subsequent development of hydrostatic pressure. Reproduced from Kiani, C.; Liwen, C.; Yao Jiong, W. U.; Yee, A. J.; Burton, B. Y. *Cell Res*. **2002**, *12*, 19–32.

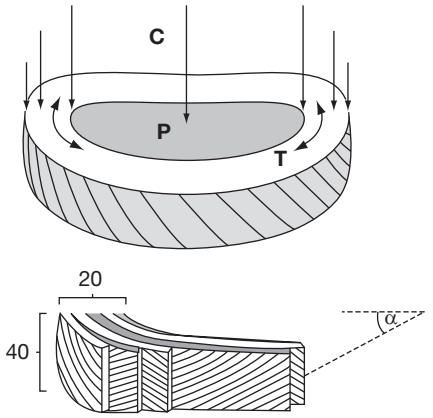

Figure 6 Load transfer in the intervertebral disc (IVD) and lamellar structure of the annulus fibrosus. When a compressive load (C) is placed on the IVD, a hydrostatic pressure (P) is generated in the NP and tensile stress (T) on the annulus. Lamella of the annulus has oblique collagen fibers in alternating directions. On average, there are 20 collagen lamellae in the annulus with approximately 40 collagen bundles per lamella. Reproduced from Adams, M.; Roughley, P. *Spine* **2006**, *31*, 2151.

Spinal compression generates a hydrostatic pressure in the NP that places the annulus into tension thereby resisting the applied load (Figure 6).[20] The AF has a very highly organized structure which results in complex anisotropic behavior with loading. The tensile, compressive, and shear properties of the AF differ in the axial, radial, and circumferential directions. The AF can be further divided into the inner and outer AF on the basis of the structural differences, the inner AF being subjected to higher hydrostatic pressures of the NP than the outer AF which is subject to tensile forces.

6.610.2.5. Intervertebral Disc Degeneration

The IVD of the spine is subject to degenerative changes induced by normal aging as well as injury, loading, or genetically induced accelerated disc degeneration.[21] The exact mechanism of IVD degeneration is not well understood; however, possible degenerative cascades have been proposed which lead to eventual changes in disc mechanical properties (Figure 7). Initial changes in the IVD are thought to be brought about by changes in the nutrient flow to and waste product flow out of the nucleus. Calcification of the cartilaginous endplates, the major route of nutrient supply to the disc, leads to harsh cellular environments, subsequently reducing matrix synthesis and increasing enzyme production further reducing PG and collagen content of the disc, in particular in the NP.[21,23,24] The loss of PGs in the NP has major effects on the load-bearing behavior of the disc, causing the osmotic pressure of the disc to fall and reducing the disc water content disrupting the NP's ability to behave hydrostatically under load. Loading can then

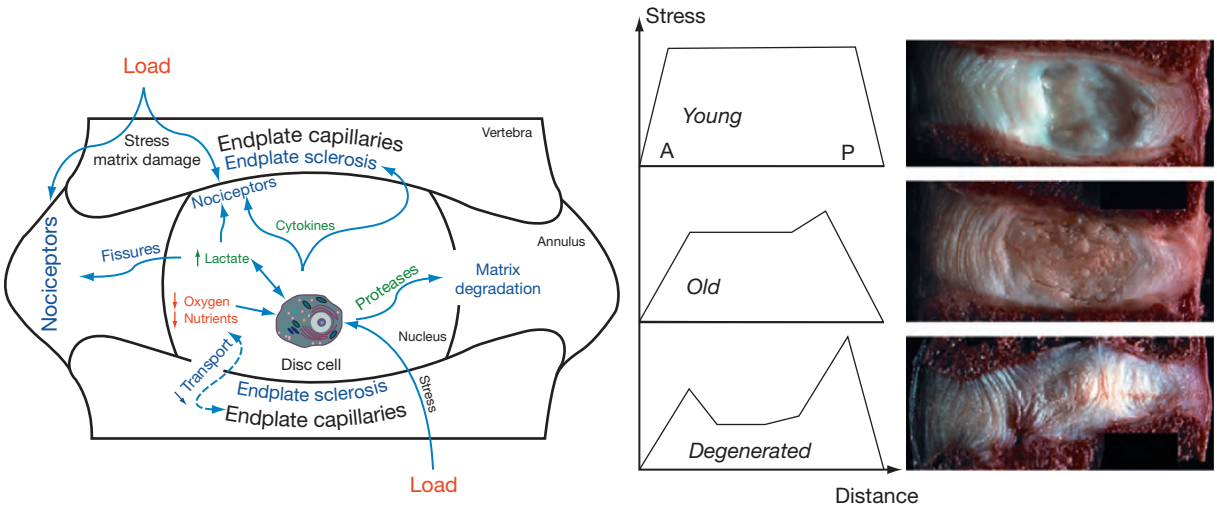

Figure 7 Cascade of events in intervertebral disc (IVD) degeneration[22] and changes in mechanical properties of the IVD with degeneration (Normal disc to degenerated disc from top to bottom). Reproduced from Adams, M. A.; Dolan, P.; McNally, D. S. *Matrix Biol*. **2009**, *28*, 384–389.

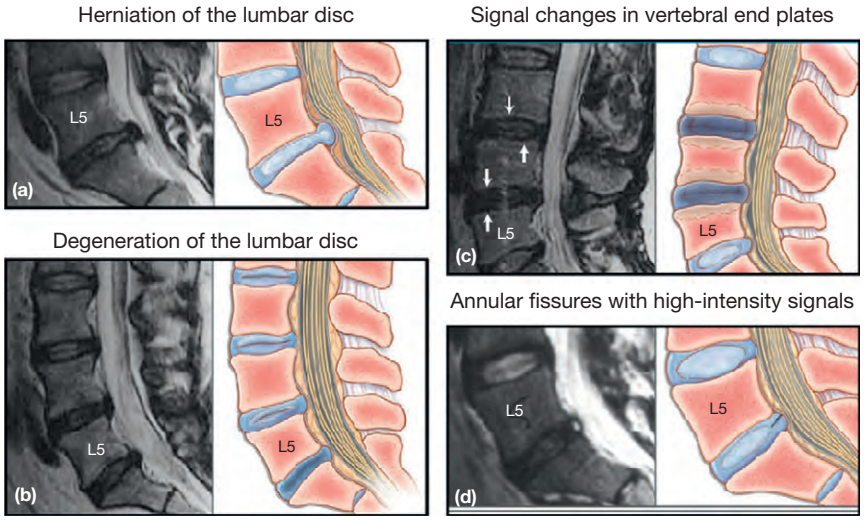

Figure 8 MRI and schematic images of intervertebral disc disruptions. (a) Herniation of the lumbar disc with extrusion of disc material found in 1–18% of asymptomatic subjects. (b) Degeneration of the lumbar disc increases with age and is found in 25–70% of asymptomatic subjects. (c) Signal changes in the vertebral endplates, found in 10% of asymptomatic subjects. (d) Disc with annular fissures seen in 14–33% of asymptomatic subjects. Despite high prevalence of these damage modes in healthy persons, these findings are often associated with serious back pain and are often treated with spinal fusion or disc replacement strategies. Adapted from Carragee, E. J. *N. Engl. J. Med*. **2005**, *352*, 1891–1898.

lead to inappropriate stress concentrations along the endplate and in the annulus with progressive changes as disc degeneration proceeds (Figure 7).

Changes in stress concentration can lead to damage of the AF as well as the endplates with stress concentrations being associated with discogenic pain.[17] Several manifestations of disc degeneration and damage can be visualized with MRI and are represented in Figure 8. Although these alterations in the IVD are prevalent in the asymptomatic population, disc disruptions have been associated with back pain and are targets for surgical interventions such as spinal fusion, total disc replacement, nucleus replacement, and annulus repair.[25]

6.610.3. Spinal Fusion

Spinal fusion and stabilization utilizes a wide range of devices such as screws, wires, artificial ligaments, and vertebral cages.[26] The instrumentation used in fusion surgery is designed to stabilize the spine during fusion and promote osseous fusion.[7] Material choice for these devices is therefore targeted toward the promotion of bone ingrowth, and immediate mechanical stabilization of the spine. Postoperative imaging and analysis of surgical success is also of importance in material choice for spinal fusion devices.[27] Early spinal fusion devices were based on metals commonly utilized in other orthopedic surgeries such as in hip implants.

Metals are still widely used in spine fusion implants today; however, advances have been made in implant design and material development in order to address the unique needs of the spine including maintenance of spine flexibility and to avoid the occurrence of adjacent area damage.

6.610.3.1. Metals for Spinal Cages and Interbody Spacers

The removal of the IVD in order to address discogenic back pain and disc herniation will lead to the loss of disc height and lead to spinal instability. Cage structures have been developed to assist in implanting allo- and autologous bone graft interbody spacers. These cages enhance stabilization of the spinal segment and prevent postoperative collapse.

The BAK™ interbody fusion system is a cage structure made of porous Ti–6Al–4V shell with a cavity for the placement of bone grafts (Figure 9).[28] This device is implanted centrally or bilaterally between the vertebral bodies.[28,29] The ends of this device are capped with ultrahigh molecular weight polyethylene (UHMWPE) plugs in order to contain the bone grafts and to minimize adhesion to surrounding nerves and blood vessels. The strength of the titanium material allows for the load bearing function of the spine and protection of the graft material while the implant design which incoroporates threading to stabilize the implant, and a hollow center to allow for bone delivery, achieves the other functions of this device. Metals, however, are subject to fatigue failure if the graft does not fuse; also the high modulus of metals can lead to stress shielding and eventual failure of the device to integrate into its surroundings.[26] See Table 1 for some common metals used in spine implants and their material properties.

Figure 9 The BAK cervical spinal fixation device. A threaded hollow titanium implant that allows bone grafts to be implanted within the shell to facilitate fusion. Ends are capped with UHMWPE to minimize adhesion. Reproduced from Martz, E. O.; Goel, V. K.; Pope, M. H.; Park, J. B. *J. Biomed. Mater. Res.* **1997**, *38*, 267–288.

Cobalt chrome has also been developed into a porous metal sponge for use in spinal surgery.[32] The porous structure was designed to match the structure of cancellous bone and the implant could be loaded axially up to 28.5 MPa. Problems arose, however, with metal ion release because of the high surface area imparted by the porous structure. Released metal ions may increase pain at the implant site and cause loosening of the implant and local bone resorption at the implant site.[33,34] Decreased pH levels at the implant site can be brought about by the inflammatory response and infection and may also have a deleterious effect on metallic implants causing fretting corrosion.[33,34]

6.610.3.2. Polymers and Composites for Fusion Cages

In order to address some of the drawbacks of metal fusion cages, composite materials have been developed and utilized in spinal cages. A cage made from a composite of poly ether ketone ether ketone ketone (PEKEKK) with pyrolytic carbon fibers interspersed within the polymer matrix was developed.[35] The material was molded to incorporate teeth located superiorly and inferiorly in order to resist expulsion (Figure 10). Material properties were modulated to better mimic those of bone in order to better support physiological loads as the graft material slowly integrates into the surgical site and in case the graft does not fuse. The cage was designed to have a Young's modulus of ~17 GPa, close to that of cortical bone.[35] This matched modulus decreases the likelihood of stress

shielding. An additional benefit of the nonmetallic implant is the ability to visualize the postoperative implant area because of the radiolucent property of the material.

Polyaryletherketones (PAEKs) are in the family of high temperature thermoplastic polymers and have been widely used for spinal cage implants after their introduction in the 1990s as an improvement over metal devices by Acromed (Cleveland, OH, now DePuy Spine, Raynham, MA).[36] PAEKs consist of an aromatic backbone molecular chain interconnected by ketone and ether functional groups. Specifically, poly (aryl-ether-ether-ketone), PEEK, and poly(aryl-ether-ketone-ether-ketone-ketone), PEKEKK, have been used in orthopedic and spinal implants. The chemical structure of PAEKs allows stability at high temperatures, exceeding 300 °C,[37] resistance to chemical and radiation damage,[38] compatibility with reinforcing agents such as glass and carbon fibers, and greater strength than even metals.[36] Mechanical and material properties for some PEEK formulations in comparison to other commonly used polymer materials are given in Table 2.[36] These materials are also radiolucent making them a good alternative to metallic spine biomaterials.

PEEK and PEKEKK were first used in the development of the Brantigan cage with 68% by weight carbon fiber reinforcement in a 2-year clinical trial beginning in 1989.[39] Clinical results were good with 100% interbody fusion identified. Interbody fusion could be identified because of the radiolucency of the PAEK materials which continued to be a major reason for the use of this material (Figure 11).[36,40]

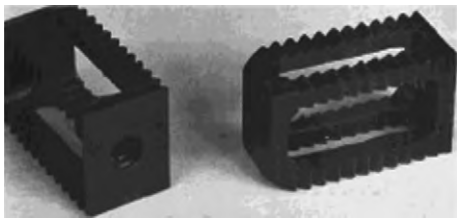

Figure 10 Carbon fiber composite cage made from Ultrapek. Reproduced from Martz, E. O.; Goel, V. K.; Pope, M. H.; Park, J. B. *J. Biomed. Mater. Res.* **1997**, *38*, 267–288.

In addition to carbon reinforced PEEK, neat PEEK is also utilized in the development of spinal cages and implants.[41–43] Studies have also been conducted to investigate the improvement of PEEK cages to incorporate accelerated fusion performance by adding bioactive materials such as hydroxylapatite or rhBMP-2.[41,43,44] Wear and fracture can be potential concerns with the use of PEEK as a load-bearing implant material; however, these concerns are not unique to PEEK. Although debris from wear has been noted in biopsies from carbon fiber PEEK cages, there has been no evidence of an inflammatory reaction making PAEK type materials promising in this application.[45] PEEK materials have also been investigated for other spine stabilization devices such as posterior dynamic stabilization devices[46] and total disc replacements.[36]

6.610.3.3. Wires, Tapes, and Cables in Spinal Fusion

Fusion of single or multiple spinal segments is also accomplished through the use of wires, tapes, and cables to secure adjacent bone segments. The most commonly used wire material is 316L stainless steel (Table 1).[26] Stainless steel is relatively strong, ductile, and relatively inexpensive. Stainless steel 316L is especially preferred because of its resistance to corrosion as a result of low carbon content (0.03% maximum) which prevents sensitization of the stainless steel. Nevertheless, even stainless steel 316L is susceptible to localized corrosion associated with a loss of the protective chromium oxide surface layer.[47] A concern in the use of metal wires for fixation is the possibility of neurological damage as well as concerns that the wire may cut through the bone if the bone is soft, which is especially the case in children.[26] As an alternative, polymer tapes have been introduced such as nylon and woven strands of polyethylene (Mersiline) for use in procedures on scoliotic children[48,49]

Table 2 Typical average physical properties of PEEK and CFR-PEEK structural composite biomaterials, compared with UHMWPE and polymethyl methacrylate (PMMA)

Property (ISO)	*Selected lavibio PEEK biomaterials (OPTIMALTI)*			*UHMWPE*	*PMMA*

Testing conducted at 23 °C.

6.610.3.4. Pedicle Screws, Plates, Bands, and Rods for Fusion and Dynamic Stabilization

Screws, plates, and rods are often used to augment spinal fusion. Screws placed in the pedicles or vertebral bodies act as anchor points for bands, rods and plates working together to restore spinal stability. The screw–bone interface is especially influential in the success of fixations. Surface treatments of metal implants of stainless steel[50] or titanium[51] have been utilized to increase fatigue life of the implants and promote better integration. Stainless steel fatigue strength is enhanced by the implantation of nitrogen ions by inducing the formation of extremely hard nitrides at the surface of the material while maintaining the bulk properties of the material.[26] Titanium can be modified by the introduction of bioactive titanate layers of, for example, sodium titanate, calcium titanate, or titanium oxide which induce apatite formation on the implant surfaces and have been demonstrated to enhance osteoinductivity as well as osteoconductivity for improved implant integration.[51]

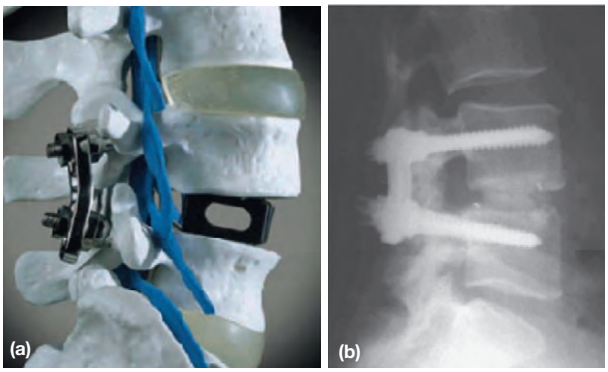

Figure 11 (a) Brantigan spine fusion cage and (b) lateral radiograph of a Brantigan cage with a solid fusion. (Note that the Brantigan cage has tantalum microspheres for visualization on radiographs.) Reproduced from Kurtz, S. M.; Devine, J. N. *Biomaterials* **2007**, *28*, 4845–4869.

Dynamic stabilization may be an alternative to fusion in some patients and may provide an improvement over fusion by altering load bearing and controlling abnormal motion while maintaining some flexibility. Dynamic stabilization devices incorporate a flexible ligament like component or other spring or mobile joint to allow motion in the spine while controlling movement such as flexion and extension. The diverse functionality of these devices often requires the use of both flexible polymeric materials and more rigid materials such as metals (Table 3).[7]

6.610.3.5. Bioresorbable Materials for Spinal Fusion Implants

Another key element in the successful stabilization of the spine in fusion surgeries is the restoration of the normal curvature of the spine. If the material system is too rigid, it becomes difficult to bend and twist to provide the appropriate curvature.

Table 3 Dynamic stabilization devices

Category and trade name	*Key features*
Pedicle screws and artificial ligaments	
Dynesys (Dynamic Neutralization System for the Spine); Zimmer Spine, Warsaw, Ind (18)	Semirigid artificial ligament system composed of titanium alloy pedicle screws and polycarbonaturethane spacers connected by polyster cords (artificial ligaments) that are placed under tension
Graf ligament; Surgicraft, Redditch, England (19)	Nonelastic polyester ligament looped around pedicle screws and placed under tension to prevent rotation while allowing some flexion; if tension is too high, hyperlordosis, foraminal narrowing, and nerve root impingement may result
IsoBar; Scient'x USA, Maitland, FL	Includes a mobile joint within metal rods
M-Brace; Applied Spine Technologies, New Haven, Conn	Implanted by using a minimally invasive technique
Stabilimax NZ; Applied Spine Technologies	Utilizes a dual spring mechanism
Dynamic Soft Stabilization System (20)	Elliptical metal coil connecting adjacent pedicle screws
Inter-spinour process decompression system	
Wallis ligament; Abbott Spine, Austin, Tex (21)	Interspinous process distraction device composed of a spacer held between spinous processes with Dacron tape
X STOP; St Francis Medical Technologies, Concord, NH (22)	Titanium device in two pieces, placed between adjacent spinous processes to hold spine in flexion; can be inserted by using a minimally invasive approach with a local anesthetic and is thus useful in elderly patients with degenerative spinal stenosis
Diam; Medtronic So famor Danek, Memphis, Tenn	H-shaped silicone device held in place by a mesh band and suture
Coflex; Paradigm Spine, New York, NY Posterior element replacement systems	U-shaped device that controls flexion and extension
Total Facet Arthroplasty System; Archus Orthopedics, Redmond, Wash	Consists of a sphere that slides along a curved plate anchored by pegs passing into the vertebral body
Total Posterior System; Impliant, Princeton, NJ	Posterior elements are removed and a plastic device is implanted and anchored with devices similar to pedicle screws

Note: Some of the devices listed may not yet have been approved by the FDA for clinical use.

Inducing an abnormal curvature may lead to stress induced osteopenia of the vertebral bodies and spinal degeneration in adjacent spinal levels.[26] This is, however, in contrast to the needs of a rigid system in order to promote the solid fusion process. Therefore, the use of a system whose rigidity decreases with time is desirable. Bioresorbable materials provide promise for such a system. Bioresorbable cages have stiffnesses comparable to those of bone, are radiolucent, and resorb over time.[52] These cages provide the additional benefits of eliminating risks associated with permanent implants such as implant removal on revision surgery. In addition, degradation of the polymer may allow for the incorporation of a drug release system into the implanted device.

The most commonly used biodegradable materials are polyesters derived from poly(α-hydroxy acids) such as poly (lactic acid) (PLA) and poly(glycolic acid) (PGA), and their isomers and copolymers. The chemical backbones of these materials are hydrolytically unstable, and the chains will degrade when placed in aqueous environments such as the body. PLA and PLGA degrade to lactic acid and glycolic acid respectively and are natural, biocompatible metabolic compounds. The strength and degradation rate of these polymers can be modified by the fabrication of copolymer systems. PGA degrades within months and is therefore used only in small amounts in copolymer systems, while PLA is more widely used in spinal implants. Chemical and physical properties of some commonly used PLA and PLA isomers are summarized in Table 4.

The polymer degradation kinetics and mechanical properties can be influenced by the polymer system utilized; however, the implant design and geometry itself has a large influence on the rates and types of degradation experienced by the implant. PLA devices degrade faster when they are less porous, less permeable, and have a bulkier design and wall thicknesses.[52] Sterilization of the implant can also have drastic effects on the physical and mechanical properties of the polymer. Many conventional sterilization techniques such as steam sterilization can cause melting of the polymer system and therefore cannot be utilized. Ionizing radiation is an alternative sterilization technique; however, this technique can also induce damage in the polymers causing changes in biocompatibility and biomechanical characteristics. Treatment with ethylene oxide or plasma sterilization provides better alternatives and shows limited effect on molecular weight and tensile strength of PLA-based materials.[53,54] Biocompatibility of PLA and related polymers has generally been demonstrated to be good with the absence of significant toxicity.[52] A local reduction in pH imparted by the degradation products, however, may be responsible for some adverse tissue reactions such as osteolysis and bone resorption around the implant.[55]

Table 4 Chemical and physical characteristics of PLLA and PLDLLA

	PLLA (literature)	*PLLA (own use)*	*70/30 PLDLLA (literature)*	*70/30 PLDLLA (own use)*

Bioresorbable PLA plates have performed well in comparison to titanium plates in controlled clinical studies. In an original study by Nabhan *et al.*, bioresorbable plates made of L-lactic and D,L-lactic acid in the ratio of 80:20 in the INION S-1 Biodegradable Anterior Cervical Fusion System were investigated in a prospective randomized controlled study with 40 patients.[56] The bioresorbable plates in this study were designed to hydrolyze over the course of 2 years. Plates maintained 90% of their initial strength after 6 months, then continued to decrease slowly to 70% after 9 months, and continued to absorb after 2 years. The fusion incidence and rates of fusion were found to be comparable to those of titanium plates but with several added benefits associated with the use of a biodegradable polymer. Advantages of the PLA plates included the radiolucency of the plates which allowed visualization of the graft material giving reassurance that the plates had not migrated. The plates were also somewhat flexible and were able to be bent to match the vertebral contours of the patients. Gradual resportion of the plates may allow the fusion to gradually assume the role of structural support and enhance fusion rates while reducing stress shielding.[56]

6.610.4. Total Disc Arthroplasty

The first mode of treatment proposed for the treatment of the majority of patients who suffer from disc degeneration is nonoperative care. On the basis of carefully considered guidelines, surgical interventions are recommended in the event that conservative remedies do not address the clinical needs of the patient. Arthrodesis or spinal fusion is the traditionally accepted surgical intervention technique advocated in cases of isolated disc degeneration in the cervical or lumbar spine. The procedure involves the removal of a motion segment through the use of bone grafts and sometimes through internal fixation. Indications for the procedure are instability of a motion segment caused by traumatic injury or degeneration.[57] A successful fusion procedure eliminates motion that causes pain and offers the ability to restore intervertebral height and alignment.[58]

However, spinal fusion has its limitations, some of which include the following[41]:

- No significant improvement seen in the success rate of fusion procedures despite the advances made in terms of surgical techniques and instruments;
- Morbidities associated with bone graft harvests during the procedure;
- Accelerated adjacent level disc degeneration;

- Long postoperative recuperation times;
- Increased costs of fusion procedures.

Disc arthroplasty is a surgical procedure that has been getting a lot of attention in the spine community. The procedure aims to potentially eliminate a painful disc while preserving/restoring motion.[58] The goals of arthroplasty include successful pain relief and functional recovery, acceptable levels of morbidity associated with the procedure (equal to or less than those seen in fusion), shorter postoperative recuperation times, and easily implantable surgical techniques.[41] The biomechanical objectives of disc arthroplasty are the restoration of disc function to relieve abnormal stress or strain caused by degeneration. More importantly, it is essential that the procedure does not cause any detrimental biomechanical effects on surrounding structures within the motion segment and on adjacent levels.[41]

6.610.4.1. Material Requirements

In order to understand the material requirements, it is necessary to understand the biomechanics of disc arthroplasty. The following are some of the biomechanical parameters that might be considered while designing a total disc replacement implant[59]:

- Restoration of mobility while avoiding segmental instability;
- Restoration of correct spinal alignment;
- Protection of adjacent structures from overloading and resultant accelerated degeneration;
- Stability and wear properties of the device.

The material requirements for a TDA prosthesis are discussed according to each component of the artificial disc to be designed, along with some examples where possible.

6.610.4.1.1. Implant endplate

The vertebral endplate is subject to repetitive physiological loads, and therefore, a material chosen for this component needs to be durable enough to withstand such types of loads. Other aspects to be considered include the reactivity of the material, its modulus of elasticity, ultimate tensile strength, imaging characteristics, ease of manufacture, and cost.[57] Commonly used materials for endplates are stainless steel, cobalt–chromium alloys, and titanium alloys.[58]

Stainless steel implants are inexpensive to fabricate, show relatively low corrosion, and have high moduli of elasticity. Cobalt chromium alloys have properties in between those of steel and titanium alloys. Depending on the alloy, processing of the end product can be tuned to a wide range of strengths and ductility, thus making these alloys versatile in their applicability as implants. However, such implants are more expensive to manufacture.[58] Currently used prostheses have endplates made out of these types of alloys.

Titanium alloys are attractive as implant materials owing to their high biocompatibility. They are also more corrosion resistant than the other two types of alloys. Further, they yield fewer debris particles as detected by imaging with magnetic resonance. Their mechanical properties are closer to those of cancellous bone, but they have higher susceptibility to wear debris generation. Pure titanium implants have not been studied clinically, but titanium coatings are being used currently.

6.610.4.1.2. Bone implant interface

Attachment of an implant to the endplate can be achieved through the use of screws, serrations, or fins. These structures help insert the device, prevent early displacement, and facilitate long term stability. Long term attachment of the device can be facilitated by the presence of microstructured features on the surface of the implant in order to encourage bony ingrowth. Other options for inducing bony ingrowth include titanium spraying or meshes, calcium sulfate coatings, and hydroxyapatite coatings.[58]

6.610.4.1.3. Bearing surfaces

Special attention is to be paid while selecting materials for the bearing surfaces of the implant. The bearing surface usually determines the long term stability of a well-fixed TDA implant. The articulation of these surfaces must allow low friction motion, resist permanent deformation, and show good wear resistance (see Chapter 6.614, Wear: Total Intervertebral Disc Prostheses).

Typically, surgical intervention to correct disc degeneration is performed on patients between the ages of 35 and 50 years. In order to reduce incidence of revision surgeries, the estimated life of a prosthesis is proposed to be over 40 years. Taking into consideration the number and amplitude of load cycles a lumbar disc experiences in a year, it can be assumed that the average adult bends 125 000 (extension and flexion movements) annually and takes about 2 million steps (gait cycles), the device is expected to endure roughly 85 million cycles of loading during its lifetime without significant degeneration.[60] It is recommended that the device be tested for a 100 million cycles of loading. This hypothesis is made after taking into account the implant's capacity to resist fatigue, and immunologic response to wear particles including their toxicity.

UHMWPE is used as a bearing material in several implants owing to its low creep properties. Even though polyethylene shows wear debris in its use with other joints, animal studies of metal-on-polyethylene disc implants have not shown significant evidence of wear particles.[61,62]

6.610.4.1.4. General material specifications

Metals are considered to be good candidates for a total disc replacement device owing to their inherent high fatigue strength. Also, metal alloys have been shown to possess good biocompatibility.[57] On the other hand, nonmetallic materials such as polymers and elastomers are also good candidates because of the similarities between their mechanical properties and those of native disc tissue. Over a short period of time, the lower elastic moduli of nonmetals help replicate disc behavior adequately. However, in terms of a long term device, such materials tend to pose a challenge to develop. Overall, the need of the hour is to develop materials that demonstrate both biomechanical applicability and biocompatibility while being user friendly in a surgical environment.[63]

In order to meet the needs for an artificial disc, combinations of both metallic and nonmetallic components have been researched. In most cases, these take the form of metal–polymer–metal sandwiches, wherein the metal portion is used to improve fixation using screws/spikes or porous coatings to promote tissue ingrowth. The polymer component of the fixed implant can provide the flexibility seen in native discs.[57]

6.610.4.2. Discontinued Artificial Discs

6.610.4.2.1. Acroflex

The Acroflex artificial disc was developed in the 1970s by Arthur Stefee. The device represents a leap in the concepts and design of artificial discs.[39,62] The design of the disc comprises two porous metal end plates coated with titanium and fused to a hyperplastic polymer disc which is made up of a hexane based polyolefin rubber.[62,64] The design of the device is such that the vertebral bone is intended to grow into the titanium plates to ensure long term fixation, while the polymer disc is intended for restoration of flexibility and motion to the functional spinal unit.[39]

The Acroflex device had significant biomechanical advantages. It helped in the preservation of disc height and allowed semiconstrained motion in all modes including compression.[58]

Over the years, there have been three generations of the Acroflex disc developed. Each generation of the device successfully passed the mechanical testing protocols to which they were subjected, only to fail in the short term when implanted in a series of limited human clinical trials.[10,39]

6.610.4.2.1.1. First generation

The first generation of Acroflex was composed of CoCr alloy and polyethylene as the polymeric core cemented together and implanted through an anterior approach.[39] The disc was tested in cadaveric spines; however, concerns were raised regarding the bone–cement interface, and the device idea was subsequently abandoned.[62]

A cementless design was developed in the 1980s using titanium end plates with a double layer of sintered 250 μm beads to enhance long term fixation. In this version of the disc, the polymeric core was made out of a polyolefin rubber known as Hexsyn, manufactured by Goodyear for fatigue resistant biomedical applications.[39]

The device was subjected to preliminary mechanical testing, and despite some incidences of local material failure, the tests were judged to be successful. The next step was animal testing; however, the company was never able to obtain permission to carry out animal studies. Instead, on the basis of *in vitro* studies to study biocompatibility, a decision was made to proceed to human trials directly.[39]

The device was implanted in six patients and follow-up studies were conducted. However, in 1990 the FDA raised concerns of the use of Hexsyn, which contained 2-mercaptobenzothiazole, a potential carcinogenic.[57] The disc was eventually removed from the market.

6.610.4.2.1.2. Second generation

There is very little information available in the literature about the second generation of the Acroflex device (**Figure 12**). In this iteration of the design, the polymeric core was composed of a silicone elastomer and clinical trials were performed in eight patients. Data for this generation of studies are not available because of the controversies surrounding the use of the silicone gel in breast implants. Class action lawsuits had been filed against the manufacturer of the silicone (Dow Corning), making the developers of the disc hesitate to publish their findings.[62]

6.610.4.2.1.3. Third generation

The third generation of the Acroflex disc once again used a hexane based polyolefin rubber core. The endplate design was modified to reduce the profile to facilitate easier implantation. The endplates were made from a Ti–6Al–4V ELI alloy, coated with porous beads made of pure Ti.[10] Mechanical testing was performed on the device and concluded to be satisfactory. Debris testing was not undertaken as the disc had no articulating surfaces.[65]

Animal studies conducted on 20 baboons showed significant evidence of osteointegration into the porous coating after 6 months. There was one case of failure and histological reaction because of the presence of wear particles in one animal.[66]

Pilot human trials were conducted with two groups of patients, with subtle design differences in the endplate of the device. Both sets of trials did not yield significant results to conclude the success of the device.[10,66]

Eventually, even after three decades of changes to the design and materials used in the Acroflex artificial disc, the device did not achieve significant clinical success. The design concept of using a one piece nonarticulating artificial disc is very attractive, as it would mimic natural disc function very well. However, this is hindered by the complex loading environment seen in the spine. The device was successful in terms of achieving rapid osteointegration. The biggest hurdle to the success of the Acroflex artificial disc though was the designers' inability to find a suitable polymeric core material to meet the required needs for an artificial disc.[62]

6.610.4.3. Currently Available Devices

6.610.4.3.1. Charitè artificial disc

The Charitè Artificial Disc (marketed by DePuy Spine), unlike the Acroflex was designed with the goal of replicating the kinematics of the disc as opposed to the motion. The device

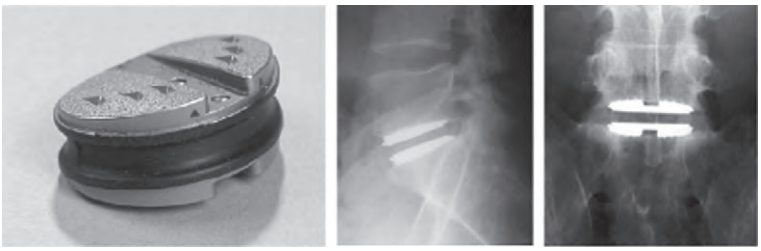

Figure 12 Second generation Acroflex implant with radiographic images post implantation. Reproduced from Melrose, J.; Smith, S. M.; Little, C. B.; Moore, R. J.; Vernon-Roberts, B.; Fraser, R. D. *Eur. Spine J.* **2008**, *17*, 1131–1148.

was designed by Kurt Shellnack M.D., and Karin Buttner-Janz M.D., Ph.D, who were affiliated at the time to the Charitè Center for Musculoskeletal Surgery at the University of Berlin.[67] The basic design of the device incorporates two metallic end plates made of cobalt-chromium alloy[57] which are attached to adjacent vertebral bodies, and articulate against a central polymeric core made up of UHMWPE.[67]

The UHMWPE core has two domed (convex) surfaces that help to articulate against the concave metallic endplates. The hypothesis is that in conditions of full flexion or tension, the core is free to translate or rotate when the polyethylene rim of the core contacts the metal rims of the endplates. The device is implanted through an anterior approach.[67] The device provides unconstrained motion during rotation, and semi constrained motion during flexion, extension, lateral bending, and translation, to some extent.[58]

The Charitè Aritficial disc has undergone four iterations in design since its inception and offers the largest and longest clinical trial of any existing artificial disc.[57,62] The rationale for choosing an UHMWPE core was because of the outstanding friction and fatigue properties of the material.

6.610.4.3.1.1. SB Charitè I and II

Only retrospective clinical data are available for the SB Charitè I and II, the first two generations of the device. The first two generations were made up of stainless steel endplates, which had protruding teeth for better fixation.[62] In the SB I disc, the end plates were circular and shaped like bottle caps, while in the SB II they were expanded by providing lateral wings to enhance contact with the vertebral end plates.[62] The SB I and II discs were implanted in 15 and 22 patients respectively and follow-up data obtained after a period of 17.5 years. Follow-up studies revealed a success rate of 87% (13/15) for the SB I disc, and 68% (15/22) for the SB II discs (**Figure 13**). The success was defined in terms of the absence of long term complications.[68]

The inventors performed mechanical testing on the devices and found that the height of the UHMWPE core was reduced by 10% during testing. They claimed that there was minimal wear and debris formation posttesting[67]; however, it has been seen that their claims are consistent with testing in a single direction, which produces far less wear particles than testing in multiple directions.

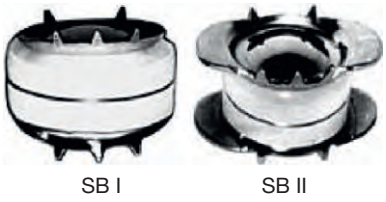

Figure 13 SB Charitè I and II.

6.610.4.3.1.2. SB Charitè III

Waldemar Link GmbH and Co. was the company that commercialized the Charitè artificial disc, resulting in the third generation SB Charitè III (**Figure 14**). Major changes were made to the endplate material, which was now constructed out of a proprietary CoCr alloy called VACUCAST (0.25% C, 28–20% Cr, 5.5–6.5% Mo, max 0.5% Ni, max. 0.5% Fe, 0.4–1% Si, 1% Mn, and the remaining 57.1–69% Co). The back of the alloy was 'satin' finished by corundum blasting, and the device was fitted with six sharp teeth to achieve fixation. The UHMWPE core design remained unchanged.[62]

There have been a number of clinical studies undertaken to document the performance of the SB Charitè III. In summary, most of these studies have demonstrated that the Charitè artificial disc has the potential to preserve motion and survive long term implantation in the body with good to excellent outcomes. However, cohort studies undertaken have shown variability in the complication and success rates of the device, which raises concerns regarding the repeatability and reproducibility of the procedure.

6.610.4.3.2. ProDisc

The ProDisc (Synthes Spine, Paoli, PA) also consists of metallic endplate with an UHMWPE core. Unlike the Charitè, the ProDisc is attached firmly to the inferior end plate through a locking mechanism. The convex surface of the polymer core articulates against the superior end plate. There have been two generations of the ProDisc, ProDisc I and II, but only the ProDisc II has been commercialized.[69]

The ProDisc has undergone the second largest clinical trial of any artificial disc after the Charitè. The ProDisc I had metallic endplates made of Ti alloy, whose back surfaces were plasma sprayed with a titanium coating to promote bone growth.[70] Follow-up reports for ProDisc I showed some procedure related complications. Minimal wear of the UHMWPE core was detected.[70]

Clinical studies on the ProDisc II have only been short term (17–31 months), with reports of positive outcomes. It is to be noted that the studies for ProDisc are more scientifically sound than the studies for the Chartité disc, which has only been retrospectively studied in Europe. Studies on the ProDisc

II however, are prospective and employ validated outcome measures such as the Oswestry Disability Index, which can be compared with alternative spine procedures (Figures 15 and 16).[62]

6.610.4.3.3. Maverick

The Maverick total disc replacement device was developed in 2001 by Medtronic Sofamor Danek (Figure 17). Initial prototypes were designed using alumina ceramic, but the commercially available device now features a two piece metal-on-metal design, which comprises superior and inferior endplates made of CoCr alloy. Bearing surfaces are made of CoCr alloy based on ultra low wear rates obtained in hip replacements. The endplates have been treated with hydroxyapatite to promote bone growth.[62]

Clinical trials of the Maverick disc began in 2002. Two-year follow-up results have been reported so far. Clinical success was reported in 75% of the patients. No revisions or device related complications were reported in this study. Mechanical testing on the disc showed good shock loading, and showed no mechanical damage after 10 million loading cycles. However, wear debris was produced, but the test methods were not published in the literature. On the basis of this, the life span of the device was predicted to be around 31.5 years *in vivo*, but this claim cannot be validated until further studies are conducted.[71,72]

To sum, the Maverick disc is a good alternative to metal-polymer-metal disc replacements that are currently available. Two-year follow-up studies and biomechanical testing have been reported. Metal-on-metal articulation produces less wear than metal-on-UHMWPE prostheses; however, it also produces metallic wear debris. This can be a cause for concern. Only further studies can tell if the Maverick disc will be clinically successful.

6.610.4.3.4. Flexicore

The Flexicore disc manufactured by Stryker Spine is the most constrained of lumbar discs and consists of four CoCr components: a superior and an inferior baseplate, a spherical head that attaches to the superior endplate, and a shield (Figure 18).[73]

The device is capable of supporting tensile loading because of the presence of the spherical head. It also contains mechanical stops in order to limit flexion/extension and lateral bending. The device endplates are coated with titanium plasma spray coating to promote bone growth. Mechanical testing has been conducted in tension, compression, and shear. The studies showed that the device is mechanically sound and has strength limits excessive to the load limits for the IVD. Wear testing showed that minimal or no wear damage was seen.[73]

The disc is undergoing a clinical trial at present, but the results are not expected for several years. The success of the Flexicore disc can only be determined when more clinical data become available.

6.610.4.4. Future Trends

The field of total disc replacement is a rapidly evolving area of new technologies and techniques, and great strides have been made in the development of spinal implants that are able to replicate and preserve motion in the IVD. The arena of total disc replacement has seen many leaps in terms of achieving short term benefits such as patient satisfaction and speed of recovery.

New implants are being designed, developed, and tested. The near future might hold answers regarding the long term benefits of using total disc replacements, especially the goal of reducing the incidence of adjacent segment degeneration. More comprehensive follow-up studies will reveal the future for these implants.

From a materials standpoint, there have been different design concepts explored. The use of all-metal implants and that of metal–polymer implants have been investigated. At this juncture, it is hard to say which system works better. Each type of design has its own inherent advantages and disadvantages; for example, the main issue with metal–polymer implants is the wear of the polymer core, which can cause early failure of the implant. The all metal implants show excellent wear resistance; however, the generation of wear debris is an issue of concern. The consequences of these wear particles and their corrosion solubility products are unknown at present. There might also be concerns regarding the maintenance of bony attachment with the degradation of bone tissue with age and osteoporosis with respect to these devices.

Nevertheless, the future holds a lot of promise for this field, and as more data are published on the available and developing implants, changes in design and materials can be conceptualized and implemented to meet the objective of achieving a successful implant that will meet all the needs of patients who require total disc replacement.

6.610.5. Annulus Repair

6.610.5.1. Procedure

The repair of the AF has seemed to be an intuitive idea for many researchers, but given the limitations posed by the current microscopic and endoscopic surgical techniques, this has not been attempted much. Advanced technologies are being developed to close annulus defects. These could also enhance the use of intradiscal prostheses which are contained by the AF. Efforts are also underway to develop devices that will support the annulus after a discectomy procedure.

6.610.5.2. Mechanical Role

The AF of the IVD is a structure that serves to contain the gelatinous central portion of the disc, the NP. The chemical composition of the AF comprises 65–90% water, 50–70% dry weight of collagen, 10–20% dry weight of PGs, and noncollagenous proteins such as elastin.[19]

The structure of the AF is laminate in nature, consisting of a minimum of 15 (posterior) and 25 (lateral) concentric layers. The layers are made up of type I collagen fibers which alternate in angles from 28° at the peripheral AF to 44° at the central AF with reference to the transverse plane of the disc. The concentric rings of the AF are referred to as lamellae, and the spaces between them as interlamellar septae.[19]

The AF has a very highly organized structure which results in complex anisotropic behavior. The tensile, compressive, and shear properties of the AF differ in the axial, radial, and circumferential directions. The AF can be further divided into the inner and outer AF on the basis of the structural differences, the inner AF being subjected to higher hydrostatic pressures of the NP than the outer AF which is subject to tensile forces.

Age related degradation of annulus tissue manifests in the form of annular tears and fissures, and can ultimately lead to

Figure 18 Components of the Flexicore artificial disc. Reproduced from Valdevit, A.; Errico, T. *Spine J.* **2004**, *4*, 276–288.

disc herniation.[74] Circumferential delamination and the formation of radial fissures can cause the extrusion of the NP material which is contained by the annulus.[13] This is referred to as disc herniation. Herniation can be defined as the localized displacement of disc material beyond the limits of the intervertebral disc space.[75] When this happens from the posterior region of the annulus, the release of chemical inflammatory signals can result in severe pain in the back.[13,76]

Degeneration of the annulus results in a transfer of load from the NP to the posterior portion of the annulus. To compensate for the added stress, the annulus tends to broaden, which often causes significant protrusion of the disc. This manifests in the form of circumferential disc bulging or focal herniation. Tissue remodeling in the posterior annulus is often accompanied by calcification and other changes that pose a challenge to the treatment of this issue.[77]

In the past, surgical intervention to reverse disc degeneration has focused on re-establishing disc height and geometry, while minimizing the flexibility of the disc. But recently, techniques that seek to retain or restore disc motion are being investigated in a bid to avoid the elimination of spinal segmental motion. Some of these include the replacement of the 'total disc' (i.e., the NP and a significant portion of the annulus) with a prosthetic implant. An alternative to this approach is to replace the NP while retaining a major part of the annulus.[78]

Studies have shown that an incision through the annulus can alter the mechanics of the involved disc. Hampton *et al.* showed that incisions made in the posterior annulus showed limited healing potential and the presence of a persistent defect could form a pathway for the leakage of nuclear fluid into surrounding perineural tissue.[76] This view was reinforced by other researchers who investigated annulotomy techniques in animal models. They found that a box type or window annulotomy technique produces a significantly weaker healing response than a slit or cruciate incision.[79,80]

On the basis of the results reported, it can be inferred that the AF has a limited capacity for regeneration after an annulotomy. On the basis of the type of annulotomy performed, the healing process leads to the formation of a thin layer of inferior fibrous tissue. The poor regenerative capacity may be due to the fact that the external repairs do not meet the needs of fiber recruitment to withstand the tensile forces applied to the annulus.[81,82] In order for the annulus to shift between axial loading and circumferential tension, it is necessary that the nucleus volume remains elastic, deformable, and contained. When the annulus suffers damage from an annulotomy or degradation, its ability to retain the nucleus is lowered.[19] In light of the above discussion, we can say that preservation of as much annular tissue as possible should be the goal during surgical interventions to treat disc degeneration.

6.610.5.3. Reported Treatment Methods

6.610.5.3.1. Suture techniques

There have been reports of closing annular defects with sutures after a microdiscectomy. The first instance of suture usage to close annular defects was reported by Yasargil in 1977, wherein he used 7-0 sutures to close a defect made to remove nucleus material. He reported that this method could help prevent adhesions in the annulus, but did not suggest any mechanism for the same. He tested his method on 105 patients, and recorded no reherniations, neurological impairment, or postoperative radiculopathy in them.[83]

Lehmann *et al.* have reported suture related techniques to close annular defects by using 4-0 sutures to close the flaps of the posterior longitudinal ligament, peridural membrane, and outer fibers of the annulus. In a study conducted in 152 patients, a larger percentage of patients who received sutures had less postsurgery pain compared to those who did not receive them; however, the result was not statistically significant. The investigators did not report on the incidence of reoperation or reherniation.[84]

Cauthen *et al.* have studied suturing of the annulus with a focus on reducing the rate of reoperations. He studied 254 patients and reported that there was a 21% chance of recurrent disc herniation when the patient did not receive sutures at 2 years. The use of one suture to perform microsurgical suturing showed a decreased recurrence rate of 10% while the use of more than one suture brought it down to as low as 5%.[85]

6.610.5.3.2. Sealant and bulking techniques

Biocompatible tissue adhesives have been used in many areas of the body containing soft tissue, for example, fascial hernias or cardiovascular procedures.[86,87] Such procedures, however, have not been extended to the AF because of the undesirable effects of adhesion that might occur with neural tissue in the vicinity. Instead, 'sealing' biomaterials, which are polymeric solutions that cure *in situ*, have been injected into the annulus.[88] In concept, these bulking hydrogels are intended to form a sealant which will take on the complex, irregular shape of the AF defect, and may bond strongly to the neighboring tissue around the defect. There have been no clinical reports of such a technique being applied to the annulus; instead, these types of biomaterials seem more applicable to nucleus replacement.[89,90]

6.610.5.4. Current Technologies

6.610.5.4.1. Xclose™ tissue repair system

The Xclose™ Tissue Repair System marketed by Anulex Technologies, Inc. is an FDA approved technology, and is recommended for reapproximation of soft tissue such as the AF after a discectomy procedure (**Figure 19**). The system consists of two tension band devices and one knot pusher. The device works by placing tension bands at the annulotomy site and securing them with tension bands.[78]

6.610.5.4.1.1. Material

All implanted components of the device are made up of polyethylene terephthalate.[78,91]

6.610.5.4.1.2. Procedure

All the components of the kit are provided in sterile conditions and preloaded on disposable delivery instruments. A tension band consists of a pair of nonabsorbable suture loops each of which is attached to a T-anchor. A third loop of suture with a pretied knot is then used to connect the two loops together, while facilitating the tightening of the tension band, which helps to draw the construct together and hence closes the defect in the tissue.[78]

Cadaveric experiments have been performed to study the use of the Xclose™ system. The results were presented at the annual

meeting of the Spine Arthroplasty Society in Berlin. The ability of the system to remain in place after cyclic loading of the repaired tissue was analyzed. A partial laminectomy was performed to make a posterior annular incision. A limited amount of nucleus was removed (~0.2 cm^3), and the incision was repaired using the Xclose™ system. Nine spinal units were tested in this study.[92]

Cyclic fatigue loading was performed, consisting of 20 K cycles of flexion–extension, 15 K cycles of lateral bending, and 5 K cycles of axial rotation. Calibrated digital macrophotography was used to assess the system's ability to keep the repaired tissue in place, and the knot slippage was measured to check for loosening of the suture knots.[78]

The study showed that all annulotomy defects remained closed and intact after 40 K cycles of loading. Post cyclic loading, the loosening in the system was minimal and knot slippage was measured to be 0.8 ± 0.7 mm. Also, the system did not migrate out of the annulus or pull out of the tissue.[92]

On the basis of the results of the study, we can infer that the Xclose™ system is a simple and effective method to close annular defects incurred during a discectomy. The materials used do not detrimentally affect the repaired tissue, and the system has shown stability upon cyclic loading. So far, the Xclose™ system has been implanted in over 6000 patients in the United States.[93]

The Xclose™ system is undergoing a Phase IV randomized clinical trial at present, but no clinical data are currently available. In 2009, the company also launched a Post Market Clinical study in which 750 patients from 34 facilities around the United States were enrolled.[93] On the basis of data from the clinical trials, more can be said about the materials that are used to construct the device and their role in the body post implantation. Until data from more long term studies *in vivo* are made available, the final understanding of this approach cannot be formulated.

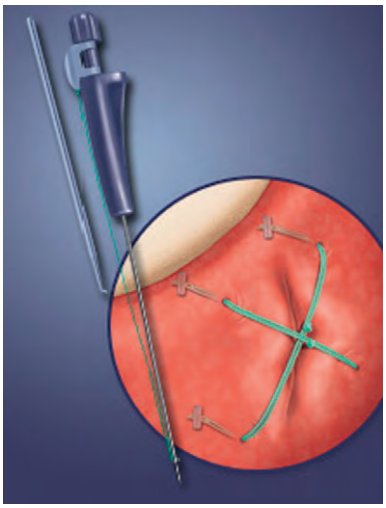

Figure 19 Schematic of the Xclose™ Tissue Repair System. Reproduced from http://www.anulex.com/anulex_technology/xclose.asp.

6.610.5.5. Barrier Technologies

6.610.5.5.1. Inclose™ surgical mesh system

The Inclose™ Surgical Mesh System is marketed by Anulex Technologies (Minnetonka, Minnesota) (**Figure 20**). The device is designed to act as a barrier and provide a scaffold for the repair of soft tissue such as the AF.[94] The surgical mesh implant is made up of a monofilament polymeric braid which is preloaded on a disposable delivery device.

6.610.5.5.1.1. Materials

The braided mesh is biocompatible, expandable, and composed of polyethylene terephthalate,[91] a commonly used polymer in medical devices.[75]

6.610.5.5.1.2. Procedure

The mesh is a low profile device which enables it to be inserted into the annulus in a minimally invasive manner. The device is inserted using a preloaded delivery device supplied with the kit. The system is secured in place using nonabsorbable surgical suture anchors.

The cylindrical device is mounted on a delivery instrument which allows it to extend in a circumferential direction to form a barrier by latching the cylinder ends together. The mesh device can be inserted into any tissue aperture, such as an annular defect, and once deployed into position, it can be tethered using sutures.[75]

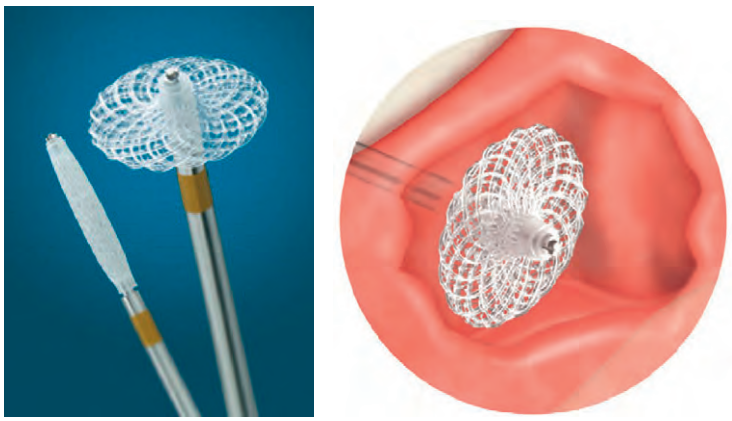

Figure 20 Inclose™ Surgical Mesh System and the configuration of the device post implantation (http://anulex.com/anulex_technology/inclose_us.asp).

6.610.5.5.1.3. Studies on the device

In vitro biomechanics studies were conducted using the device, and demonstrated that implantation of the Inclose™ system did not alter segmental spinal biomechanics. The study also showed that the implant position remained intact despite application of complex cyclic loading.[95] In theory, a stable spinal motion segment may be able to reduce risks of herniation in an adjacent disc by avoiding stress redistribution. Also, this study suggests that the repair of the annulus using such a device might indirectly avoid the need of nucleus material removal which is often a solution employed by surgeons to mitigate the effects of disc herniations.

Animal studies on intradiscal implants are faced with complications of downsizing the device in order to accommodate smaller tissue areas. In general, no animal models exist that can accurately represent the exact nature of disc space characteristics as seen in humans and correlate to human clinical use. Despite these limitations, animal models were designed to study the surgical implantation of the Inclose™ device and histological response to the PET mesh.

Peppelman *et al*. studied Inclose™ implantation in a Nubian goat model and showed that a lateral approach could be used to place the implant safely in the proximity of the annulus. When positioned and affixed properly, the implant remained intact over the course of 12 weeks, as seen using radiography. Also, the device was found to be incorporated histologically without any detrimental effects on the surrounding tissues.[96]

The device was studied after implantation in cadaveric and animal models. On the basis of a report submitted at the Spine Arthroplasty Society in Berlin in 2007, the studies demonstrated that the presence of wear particulates was minimal. Also, motion of the implant was negligible and it had no detrimental effects on spinal flexibility. Early findings showed that there were no recurrent herniations when the device was implanted.[97]

Early clinical use of the Inclose™ mesh device has shown promising results. Around 10 patients were implanted with the device after an endoscopic L4-L5 or L5-S1 discectomy. The implant was inserted with minimal disruption to the annulus, with access openings between 3 and 8 mm. There was inadequate length of follow up, because of which long term effects of the implant cannot be predicted yet. However, it was noted that the best technical results were obtained in patients with focal, protruded, and/or extruded disc herniations.[98]

6.610.5.5.2. Barricaid® prosthesis

The Barricaid® Prosthesis device is currently not clinically available in the United States. It is a device aimed at reconstruction of the annulus in the region of disc herniation. The Barricaid® implant works by forming a strong and flexible wall between the AF and NP, where it is implanted.

The salient features of the prosthesis include its ability to create a mechanical barrier that closes the annulus defect, while allowing more nucleus material to be retained in the disc. According to the manufacturers, the device can be implanted quickly, simply, and securely (Intrinsic Therapeutics).[104]

6.610.5.5.2.1. Material

The Barricaid® Prosthesis consists of a woven mesh made of polytetrafluoroethylene (PTFE) supported by a nitinol frame. The frame is made up of a nickel–titanium alloy base, which anchors the annulus and reinforces it while closing the defect.[104] The frame functions as a shape memory alloy, and exhibits pseudo elasticity (Intrinsic Therapeutics).

6.610.5.5.2.2. Procedure

The Barricaid® Prosthesis is implanted into the annulus through a small incision (5×10 mm defect) made on the posterior side, as part of a standard limited discectomy, just prior to wound closure (Intrinsic Therapeutics). The device covers a major portion of the medialateral distance in the posterior AF, and expands cephalad–caudad postinsertion.[75]

6.610.5.5.2.3. Studies on the device

In vitro biomechanical studies have been performed to evaluate the Barricaid® device, and they have demonstrated that the rate of recurrent herniations is decreased.[99] The ability of the device to withstand intradiscal pressure was demonstrated in a study by subjecting the device to complex applied loads, and measuring the intradiscal pressures.[100] The clinical use of the device was also tested, and the study demonstrated that compared to patients who were not implanted with the prosthesis, patients who received the device after a standard discectomy were seen to experience restoration in disc height lost because of the procedure.[101] However, the evaluation of the long term effects of the device in a clinical setting will require longer follow-up studies.

6.610.5.5.3. SpineJet XL®

The SpineJet HydroSurgery system is a novel technology that harnesses the power of water in medical applications such as surgery (**Figure 21**). The system comprises a controlled hair-thin supersonic stream of water that can be used as an effective cutting, ablation, and collection device. The advantage of such a system is that it has the power of laser technology and radiofrequency devices, but avoids the damage to tissue that such technologies cause.[102] The SpineJet XL is a percutaneous hydrodiscectomy device that can be used in the minimally invasive surgical intervention of intervertebral disc degeneration. The device aspirates tissue as it is being used, and can be used to remove cartilage and nucleus material.

The device is designed with four cutting surfaces. Annular thinning is accomplished using a windshield wiper motion to scrape the heel and toe of the device along the inner surface of the annulus. Lateral cutting sides are used to scrape cartilage off the endplates to increase the surface area for interbody lumbar fusion.[102]

The device is mainly used for the removal of NP, in order to perform spinal fusion. The system's use of cold fluid prevents thermal damage to tissue. The design of the device is such that it enables the removal of precise amounts of nucleus tissue without annular puncture or endplate damage.[102]

The device underwent a trial on 13 patients in 2008–2009.[103] Initial results suggested that percutaneous hydrodiscectomy could be a good alternative for the treatment of lumbar degenerative disc disease. However, more clinical data are required to properly assess the device before more widespread use.

6.610.5.6. Material Requirements

On the basis of the discussion of current materials/technologies, we can say that closure of an annulus defect using suture

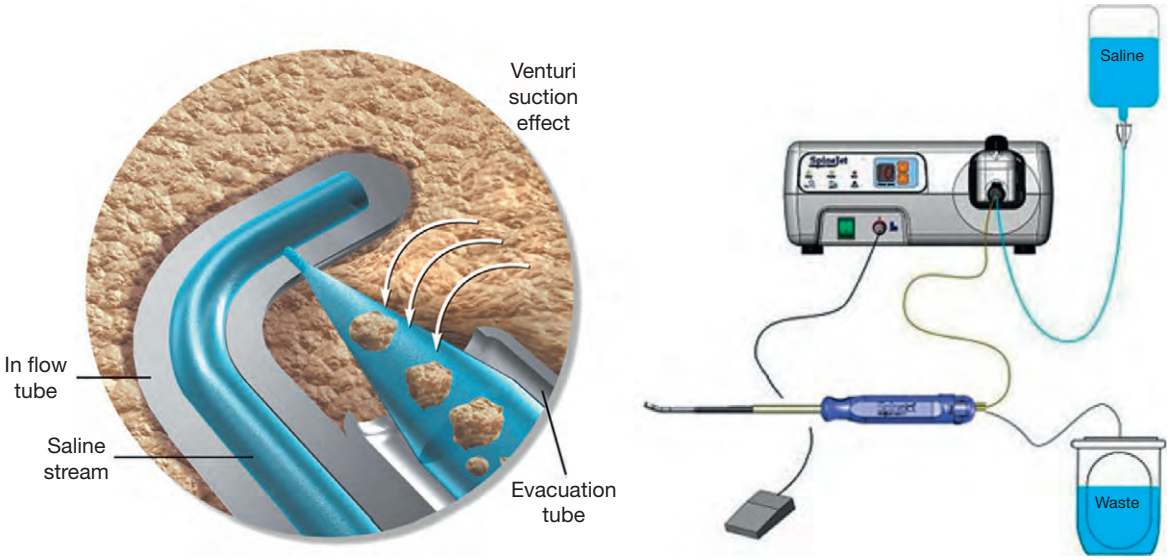

Figure 21 Schematic of the SpineJet XL hydrodiscectomy system and the complete setup.

approximations would require materials that are nonabsorbable, given the nature of an annular defect. With respect to the barrier type of technologies that have been developed so far, the material in question should be able to support the annulus appropriately on the basis of the biomechanical environments it is subject to, without the device getting damaged or causing damage to the annulus; that is, the material has to have mechanical properties matching those of the annulus. Any motion of the device due to functioning of the annulus should not generate any wear particles that might bring about adverse effects in the tissue. Further, considering that such types of techniques are limited by the method of implantation of the device, it is also required that the material in question has properties that enable molding it in a manner that facilitates easy and efficient implantation into the AF.

6.610.5.7. Future Trends

The field of annulus repair is still in its infancy, with data still being collected on implantation of devices that are currently available in the market. However, preserving the integrity of the annulus is an important consideration while repairing the intervertebral disc, as it is the only means of gaining access to the NP. On the basis of the discussion presented above, it is intuitive to try to preserve as much of the annulus as possible as the annulus is responsible for the mechanical properties of the disc. As more follow-up data become available, investigators can look to modifying the currently available technologies to refine their applicability, as well as lay the foundation for the design and development of newer devices that can be implanted minimally invasively, which will help retain the properties of the annulus while allowing access to the NP.

6.610.6. Concluding Remarks

Early spinal implants were based on metals because of the utility of metals in other orthopedic devices. The complex loading nature and function of the spine however necessitated the development of novel materials and techniques in surgical spine interventions. Composite materials and polymers have been utilized in spinal implants as an improvement over metals which do not have matching mechanical properties to the spinal anatomy and are subject to wear. A better understanding of spine anatomy, physiology, and pathophysiology has also led to the development of new materials with several materials being developed specifically for application in the spine. Failure of earlier devices has especially expanded the breadth of materials utilized in spinal interventions. Adjacent level disc degeneration with spinal fusion, expulsion of implant materials through surgical sites, and subsidence of implants into the endplates have driven the development of new surgical techniques and provided the impetus for the development of novel spine materials. This is especially illustrated by the development of *in situ* curing hydrogel and nonhydrogel nucleus replacements where materials were designed such that they could be delivered with minimal damage to the AF, a major way for nucleus replacement as well as the development of sealants for the AF itself. Another drive in materials for spine implants is the utilization of tissue engineering approaches. Tissue scaffolds that support nucleus and AF cell growth are under investigation; however, major limitations in nutrient supply to the implant after implantation must be addressed before tissue engineering approaches for the IVD can be realized.

VAS	Visual analog scale
VP	Vertebroplasty
Zn GPC	Zinc-based glass polyalkenoate cement

6.611.1. Introduction

In contemporary surgical practice, injectable bone cements are increasingly being used to treat a variety of pathological conditions of the spine including osteoporotic vertebral compression fractures, metastatic vertebral body lesions, and traumatic fractures. The principal goal of applying these injectable bone cements is to augment impaired bony structures in order to maintain or improve strength and stability of the spinal column. The first type of cement used in the spine,

PMMA (polymethyl methacrylate), was originally developed for completely different purposes in humans and used, for example, as the material for dental implants, ocular prosthetics, and later for implant fixation in artificial joints prosthetics. Currently, new injectable bone cements are designed specifically for application in the vertebral body. The clinical results obtained in the last decades by using PMMA bone cement in vertebroplasty (VP) and balloon kyphoplasty (KP) procedures have clearly established a demand for biomaterials better adapted to their function as vertebral body bone void filler. Many biomaterial research centers now focus on incorporating into new bone cements the features notably absent in PMMA, such as the properties for osseointegration, capability of remodeling, and mechanical characteristics better approximating that of cancellous bone.

This chapter aims to provide the reader with a brief introduction on the history of injectable bone cements for spinal column augmentation and discusses its currently accepted indications. Furthermore, an overview of frequently used injectable bone cements and their respective technical characteristics are described in detail followed by a summary of the clinical results obtained by this procedure. The clinical implications of cement leakage are discussed together with guidelines for bone cement handling to prevent this complication. A quick glance at possible future directions in the field of injectable bone cements for spinal column augmentation concludes this chapter.

6.611.2. History of Spinal Column Augmentation with Injectable Bone Cements and Currently Accepted Indications

6.611.2.1. History

The first published case of VP, a technique referring to the injection of bone cement into a vertebral body, dates back to 1987 when Frenchmen Galibert and Deramond treated a painful hemangioma, refractory to conservative medical treatment, by filling the intravertebral lesion with an injectable bone cement (PMMA) resulting in immediate and long-lasting relief of symptoms.[1] This paper is regarded as the index work on injectable bone cements for spinal column augmentation. However, the material used in this case had already been developed in 1928 and the process of polymerizing methyl methacrylate was invented as early as 1877 by Fittig and Paul. PMMA became commercially available in the year 1936 and is widely known to the public as an alternative to glass under the name plexiglas or perspex. The first clinical application of this material was in odontology where it was used to build dental implants. Following the observation by ophthalmologist Ridley during the Second World War that splinters of perspex from shattered aircraft cockpit canopies did not trigger an inflammation reaction in the eyes of wounded pilots, he made the material suitable for implantation in the form of artificial lenses, an operation he first conducted in 1949. Sir Charnley was among the first pioneers to use PMMA in orthopedic surgery to establish a bond between bone and implants in hip replacement surgery: a highly successful practice still in use today.[2]

Although the landmark paper by Galibert and Deramond, currently cited over 750 times, was followed by several other publications in French journals on this subject, VP as a new treatment for painful osteoporotic vertebral body fractures, did not gain momentum until the late 1990s when the first article in English was published by Jensen and coworkers.[3] Jacques Dion, a French Canadian and senior author of the article, became the pivotal link importing the French knowledge into North American medical practice. The year 1999 saw a large number of papers published on various topics related to VP including the expansion of indications to metastatic lesions; the first prospective trials; and the first descriptions of serious complications including infection, pulmonary embolism, and neurological deficits after extravasation of cement.[4–7] Around this time, the first critical notes on the (lack of) scientific evidence of the efficacy of injecting PMMA in the spinal column were also expressed.[8] Trout and Kallmes raised the question about whether VP caused incidental vertebral fractures but failed to reach strong conclusions due to insufficient quality of data available from the literature.[9] It has been estimated that over 1 million procedures have been performed worldwide.[10–12]

Meanwhile, in 2001 an alternative to VP, balloon KP, was described by Lieberman and coauthors.[13] In this technique, balloons were inserted in the vertebral body and inflated prior to injection of the cement. The potential benefits of this procedure consisted of improved restoration of vertebral body anatomy and a reduction in cement extravasation due to the creation of a cavity lined by higher density bone facilitating lower pressures needed to inject bone cement. Subsequent clinical studies have shown results comparable to VP with often lower rates of cement extravasation.[14]

Virtually all studies described above dealt with the treatment of painful osteoporotic vertebral compression fractures treated by injection of PMMA cement in the affected vertebral level. Notable exceptions published in the same timeframe were the studies by, among others, Nakano *et al*. in which painful osteoporotic vertebral compression fractures were treated by VP or balloon KP using calcium phosphate (CaP) cement instead of PMMA cement.[15–18] The rationale behind the use of CaP cement was the assumed superior biocompatibility, potentially leading to a more intimate bone–cement interface and subsequent remodeling of the biomaterial into bone by creeping substitution.[19]

In an attempt to combine the favorable characteristics of both PMMA (immediate stability) and CaP cement (superior osseointegration), some manufacturers have designed hybrid cements containing both materials.[20] To our best knowledge no clinical data on the performance of these hybrid cements is available from the literature and the application of these biomaterials must currently be regarded to be mostly in the experimental phase.[21]

Augmentation of the spinal column using either PMMA or CaP cement has, in combination with pedicle screw instrumentation, recently also become an adjunct to the surgical treatment of traumatic burst fractures of the spine. Proponents of this new indication for VP/balloon KP suggested this technique to be able to (partially) restore the anatomy of the intervertebral disk space thereby decreasing the chance for secondary deformity due to disk intrusion into the fractured vertebral body.[22]

6.611.2.2. Currently Accepted Indications

As can be concluded from the considerable media coverage and editorials that rapidly emerged following the publication of the first attempt at randomized controlled trials on VP and balloon KP in 2009, a debate is presently raging concerning the efficacy of augmenting the spinal column with injectable biomaterials for any of the indications stated above.[23–25] Notwithstanding the conflicting results gained from many studies conducted in the past two decades, augmentation of the spinal column with injectable biomaterials can presently be divided into the following main categories of indications for treatment:

1. painful osteoporotic vertebral compression fractures;
2. painful metastatic/malignant vertebral body lesions;
3. traumatic fractures.

6.611.2.2.1. Painful osteoporotic vertebral compression fractures

Most of the spinal augmentations with injectable bone cement are being performed due to painful osteoporotic vertebral compression fractures refractory to conservative medical treatment which mainly consists of bed rest and analgesics.[26] The natural history of these types of fractures is frequently benign with progressive resolution of symptoms 6–12 months after the onset of pain regardless of index treatment. It is the immediate and dramatic reduction of pain, typically within 24 h, giving VP or balloon KP the edge over nonoperative treatment strategies in the first 3 months of treatment.[27] Currently, the principal hypothesis explaining the beneficial effect of injecting bone cement into osteoporotic vertebral compression fracture holds that cement injected in the vertebral body stabilizes the fracture and the subsequent decrease in residual motion leads to a reduction of perceived pain.[28] Supporting this hypothesis, it has been demonstrated by many studies that painful vertebral bodies showing edema on magnetic resonance images, indicating unhealed vertebral body fractures, respond better to VP or balloon KP.[29] To prevent cement extravasation, the amount of bone cement injected has steadily decreased in the last decade without affecting the high success rates. It can be argued as to whether everdecreasing volumes of bone cement injected can still adequately stabilize a vertebral body fracture, in which case the 'stabilizing hypothesis' may ultimately prove to be incorrect. Alternative hypotheses claim the exothermic and polymerizing effects of curing PMMA to result in thermal and chemical destruction of nociceptors, respectively. These two hypotheses have been refuted by *in vivo* animal experiments showing little or no tissue necrosis or inflammatory response, after injection of PMMA cement.[19,30–32] Furthermore, by using CaP cement as bone void filler for osteoporotic vertebral compression fractures, Nakano *et al.*[18] demonstrated that this isothermic, nonpolymerizing biomaterial leads to identical results compared to PMMA cement when injected in the spinal column.

6.611.2.2.2. Painful metastatic/malignant vertebral body lesions

The first lesion to be treated by VP was a painful hemangioma. Many other pathologic lesions including metastatic spinal tumors and multiple myeloma have subsequently been shown to respond favorably to the injection of bone cements provided the pedicles and laminae were not affected and compression of the spinal cord was not present.[33] Spinal pain due to metastatic or hematological disease may be caused by a variety of factors and it has been suggested that they include (imminent) pathological fractures, chemical mediators, increased pressure within the bone, microfractures, overstretched periosteum, and compression of neural structures such as the spinal cord and roots.[34,35] Similar to the group of osteoporotic vertebral compression fractures, the exact mechanism by which augmentation of the spine with injectable bone cements achieves its beneficial effect in metastatic/malignant spinal disease has not been elucidated. It is possible that stabilization of the vertebral body after VP or balloon KP also underlies the relief of pain for this indication.[33] Deducing from the observation that tumor recurrence was rare in vertebral bodies treated with cement injection, some authors have suggested that PMMA has some antitumor properties. These properties could include cytotoxicity, hyperthermia, and local induction of ischemia. In a recently published review, Chi and Gokaslan[33] recommend VP or balloon KP in properly selected patients with painful pathologic fractures to be performed as early as possible. Furthermore, they speculate that newer more elastic biomaterials than those currently used may lower the risk for adjacent level collapse and reduce complication rates.

6.611.2.2.3. Traumatic fractures

Oner *et al.*[36] suggested that recurrent kyphosis after surgical treatment of traumatic thoracolumbar fractures resulted from improperly reduced endplate fractures. It was shown that intervertebral disks adjacent to the fractured segment could intrude through fractured endplates into the burst vertebral body thereby causing spinal deformity.[37] Hypothesizing that proper reduction of the endplates and subsequent augmentation of the vertebral body with bone cement could largely prevent this deformity, a technique was developed and subsequently tested to reduce fractured endplates in traumatic thoracolumbar burst fractures by pedicle screw fixation and balloon-assisted endplate reduction.[22] After optimal endplate reduction was achieved, the balloons were removed and the intravertebral void was filled with CaP cement. The choice for this filler material was based on the expected average age of patients with traumatic spine fractures, which is significantly lower (mean age ~35–40 years) compared to that of patients with osteoporotic vertebral compression fractures.[38]

6.611.3. Overview of Frequently Used Injectable Bone Cements for Spinal Augmentation

The biomaterials used for spinal column augmententation by VP or balloon KP require several characteristics including injectability, biocompatibility, and mechanical stability.[21] In selecting the biomaterial, a treating physician considers many parameters: patient condition, patient age, fracture configuration, selection of surgical technique, characteristics of the biomaterial, and environment of implantation site. In the next sections, the characteristics of the cements frequently used in, or with potential use for, VP and balloon KP are discussed.

6.611.3.1. Acrylate Cements

Virtually all cements commercially available for augmentation of the spinal column are based on PMMA, the synthetic polymer of methyl methacrylate. The monomer methyl methacrylate is an organic compound with the formula $CH_2=C(CH_3)CO_2CH_3$ (Figure 1(a) and 1(b)) which can be produced by several manufacturing routes. Fittig and Paul, two German physicists, were the first to invent, in 1877, the polymerization reaction leading to PMMA $(C_5O_2H_8)_n$ (Figure 2).

PMMA is a transparent material with a density of 1180 g l^{-1} and has good resistance against mechanical impact.[21] The melting and boiling temperatures are 130 °C (403 K) and 200 °C (473 K), respectively, while the material autoignites at 460 °C (733 K). The polymerization reaction of methyl methacrylate to form PMMA is initiated by benzoyl peroxide, while *N*,*N*-dimethyl-*p*-toluidine (DmpT) is used as a radical-forming activator. Before the bone cement can be injected in the spinal column, its ingredients, a powder (containing polymethyl powder, benzoyl peroxide, and often an opaque material such as barium sulfate to improve radiological visibility) and a liquid (methyl methacrylate and DmpT), must be mixed. In the ensuing process, benzoyl peroxide and DmpT react to produce benzoyl radicals which are highly reactive and readily bind to the C=C bond of methyl methacrylate. The radical-enhanced methyl methacrylate molecule subsequently starts the polymerization process by reacting with nearby nonradical methyl methacrylate molecules. The resulting (methyl methacrylate)$_n$ molecule retains its radical characteristics and continuous addition of new methyl methacrylate molecules leads to the formation of increasingly large chains of PMMA. The addition of each methyl methacrylate molecule to the developing chain is an exothermic process and can lead to temperatures of up to 100 °C (373 K) in the core of the polymerizing cement when the maximum number of reactions per time unit is reached.[39] As methyl methacrylate molecules eventually become rare in the increasingly viscous cement and radicals start to react with each other, self-extinguishing their reactivity, the chain-forming process decelerates and the chemical reaction peters out. The process from mixing the components to finalization of the polymerization reaction can be described in four functional phases:

1. mixing phase,
2. initial propagation phase,
3. injection phase,
4. curing phase.

6.611.3.1.1. Mixing phase

In this phase the components of the bone cement are combined and mixed into a low viscosity fluid; radicals form to start the polymerization process.

6.611.3.1.2. Initial propagation phase

During initial propagation, the number and length of (methyl methacrylate)$_n$ chains increase rapidly. The viscosity of the cement, although increasing, is still too low for safe injection.

6.611.3.1.3. Injection phase

Many polymer chains have now been formed resulting in a substantial increase in cohesion and simultaneously decreased adhesion within the bone cement. To assess whether the bone cement has entered the injection phase, many physicians probe or test the material qualitatively in what is sometimes, frivolously, called the 'toothpaste test' or 'spaghetti test' as the viscosities of these familiar products accurately resemble the ideal constitution for injection of bone cement into the spinal column.

6.611.3.1.4. Curing phase

The cement is not injectable anymore and now starts to radiate the heat generated by the exothermic polymerization reaction. Although the cement may appear fully hardened, the polymerization process is not complete for another 24 h.

The duration of each phase is highly variable and depends mainly on the temperature of the premixed bone cement components and ambient temperature of the operating theater or radiological suite.[40–42] This variability in duration of the various phases of the polymerizing cement poses a problem for physicians since it directly affects the time window available for safe injection.[43] It has been noted by many authors that a change of only a few degrees in ambient or cement component temperature may lead to substantial deviations in the duration of the injection phase.[44] Several *in vitro* studies have verified these observations and currently devices are being deployed to intraoperatively probe cement viscosity in real-time.[45]

Concerns have been expressed regarding the increased risk for adjacent level fractures after spinal augmentation with PMMA cement in osteoporotic vertebral compression fractures.[46] Although no study has proven that the occurrence of adjacent level fractures is directly related to a change of the mechanical and elastic characteristics of the spinal column after augmentation (as opposed to the natural history of an already weakened spine where the presence of one vertebral compression fracture is highly predictive for subsequent fractures) many clinical studies have, nonetheless, reported the phenomenon to occur frequently.[47] Moreover, *in vitro* studies assessing the stiffness (Young's modulus) of human cadaveric

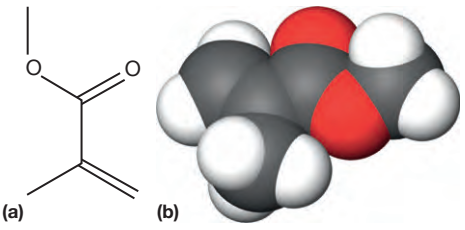

Figure 1 (a) Molecular structure of methyl methacrylate and (b) three-dimensional representation of methyl methacrylate.

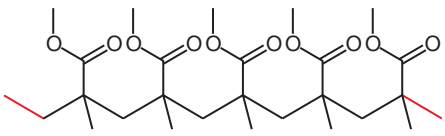

Figure 2 Molecular structure of polymethyl methacrylate.

vertebral specimens after VP or balloon KP using PMMA cement have demonstrated significant increases in stiffness after treatment compared to untreated control specimens.[48] The stiffness of PMMA cement has been shown in earlier biomechanical experiments to range somewhere between cortical and cancellous bone.[48] As a consequence, it has been hypothesized that the increase in stiffness resulting from cement augmentation may contribute to the failure of adjacent levels. Presently, some institutions are in the process of designing and testing PMMA cements with altered biomechanical properties to better approximate the compliancy of cancellous bone found in osteoporotic vertebral bodies, with the aim of reducing the adjacent level fracture rate.[49] Boger and coauthors added *N*-methyl-pyrrolidone to regular PMMA cement and found a significant decrease in Young's modulus, yield strength, and polymerization temperature while the handling time of the cement (i.e., injection phase) was increased by 200%.[50] It was suggested that this type of cement was promising, showing compliancy closer to cancellous bone, while simultaneously exhibiting favorable handling and thermal characteristics compared to unmodified PMMA cement. Other methods to reduce the stiffness of PMMA have been investigated and include increasing cement porosity by addition of ingredients such as hydrogels or oligomers.[51]

Alternative acrylic cement compositions, such as dimethacrylate-based cements, have been designed showing favorable biomechanical and biocompatible properties compared to regular PMMA cements.[52] Currently, most of these biomaterials continue to be studied in a meticulous way. Recent data suggest that the principles underlying their formulation may lead to enhanced clinical performance.[53]

6.611.3.2. CaP Cements

When performing spinal column augmentation with injectable bone cements, several material characteristics including injectability and moldability are required. Heini *et al.* compiled the requirements for materials in VP and KP (KP). This was later elaborated upon by Lewis.[21,54] These requirements can be subdivided into those intrinsically belonging to the material and the desired performance of the material and technique involved. CaP cements satisfy some of the requirements and this category of biomaterials is being considered useful for application in the spinal column. CaP materials have already been used for a long time in dentistry and maxillofacial surgery, but only recently in the field of spinal surgery.[55]

CaP cements are obtained by mixing a solid phase with a liquid phase, producing a paste that can be injected. Depending on the interaction between the solid and liquid phase and the particle distribution of the CaP powder used, there will be a variability in moldability and pressure filtering effect, the latter phenomenon referring to the undesired separation of the solid and liquid components when put under pressure, thereby greatly influencing injectability of the material.[56,57] For application in VP or balloon KP, CaP cement is preferentially tailored to mimic the viscous behavior of PMMA during injection, since this is considered the reference, without displaying the pressure filtering effect.[58] **Table 1** lists the CaP that can be found in several CaP cement compositions.

Table 1 Calcium phosphates that may be used in the solid phase of a calcium phosphate cement

Name	*Formula*	*Ca/P*
Monocalcium phosphate monohydrated	$Ca(H_2PO_4)_2 \cdot H_2O$	0.50
Monocalcium phosphate anhydrous	$Ca(H_2PO_4)_2$	0.50
Dicalcium phosphate dihydrate	$CaHPO_4 \cdot 2H_2O$	1.00
Dicalcium phosphate anhydrous	$CaHPO_4$	1.00
Octacalcium phosphate	$Ca_8H_2(PO_4)_6 \cdot 5H_2O$	1.33
α-Tricalcium phosphate	$Ca_3(PO_4)_2$	1.50
β-Tricalcium phosphate	$Ca_3(PO_4)_2$	1.50
Hydroxyapatite	$Ca_{10}(PO_4)_6(OH)_2$	1.67
Fluoroapatite	$Ca_{10}(PO_4)_6F_2$	1.67
Tetracalcium phosphate (TTCP)	$Ca_4(PO_4)_2O$	2.00

CaP cement holds distinct advantages over PMMA cement by having the potential to undergo resorption while also displaying osteoconductive properties. In recent *in vitro* studies the effect of CaP cements on vertebral body repair has been investigated.[59] Two types of calcium-based materials, namely CaPs and calcium sulfates (CaSs), are used in spinal applications (see also **Table 2**). CaS cements are sometimes considered not to have osteoconductive properties and, due to their fast dissolution characteristics, achieving adequate mechanical support in the spinal column is found to be more difficult.[60] In either case, CaP and CaS cements have demonstrated a superior biocompatibility profile *in vitro* compared to PMMA cements.[61] CaP cements are considered suitable scaffolds for bone substitution since they affect cellular function by virtue of their composition that is similar to the mineral phase of the bone.[62,63] CaP allows adhesion and differentiation of osteoblasts while CaP cements are injectable and can be molded to the defect they have to fill. CaP cements exhibit plasticity during their working period allowing the material to occupy the defect well in which they are injected.[64,65] In addition, by using different CaP powders, the dissolution/degradation and resorption behavior of CaP cements can be tailored. CaP cements are intended to be used as temporary scaffolds and the initial contact between cement and surrounding bone tissue is considered a key factor for the osseointegration and bone formation at the implantation site.[66] CaP cements are required to present a resorption behavior in synchrony with the bone formation.[67] CaP cements can be classified into four categories depending on the role and condition of the CaP solid and liquid components.[68,69] Among these, hydraulic cements are the most commonly used and usually the term cement refers to this category. Depending on the end solubility product, these CaP cements can be classified into two types: brushite or apatite cements.[58,70] Brushite cements contain less favorable mechanical properties but show faster biodegradability when compared to apatite cements.[71] Apatite CaP cements have been studied since the early 1970s and by the 1990s started to make inroads into reconstructive surgery.[72] When mixing CaP powder with the liquid phase, it will create a partial dissolution of the CaP, causing the creation of a paste with the liquid phase supersaturated with calcium and phosphorus ions, which then will reprecipitate, producing crystal growth and entanglement

Table 2 Commercially available cements for spine surgery

Cement type	*Product name (Company)*

providing the initial mechanical properties for the CaP cement. During this phase the CaP cement will be moldable. For CaP cement, solutions of 1–4 wt% Na_2HPO_4 are commonly used as the liquid phase.[69,73] The degree of supersaturation, pH and temperature of the mixture will dictate the endproduct, which can be resorbed and remodeled *in vivo*. Contrary to acrylic cements, CaP cements have the advantage that the setting phase is an isothermic process reducing the risk of thermal damage to surrounding tissues.[21,59] The phase formed after the reprecipitation of the CaP will dictate the resorption properties of the CaP cement.[74] Each phase presents a different solubility behavior.[75]

The injectability and mechanical properties of CaP cements can be changed by modifying the liquid-to-powder ratio, the type of liquid component or the use of a pore generator without affecting the final obtained CaP phase.[57,76,77] Porosity is found among the requirements for cements used in VP and balloon KP. After injection, CaP cements present a certain degree of microporosity depending on the dissolution–reprecipitation process which is related to the liquid-to-powder ratio used.[73] If the CaP cement is used by itself, comprising only the microporosity, it will take years for the material to degrade since it will do it by a layer-by-layer mechanism, even if it possesses the good chemical characteristics.[55] To increase the degradation between the material and the surrounding tissue, an increase in microporosity and/or the incorporation of a macroporous network could be used. This can be achieved by using various techniques.[78,79] However, it is important to remember that the mechanical properties of the CaP cement will come mainly from two sides, first from the dissolution–reprecipitation mechanism and further crystallization which creates the microporosity of the material and second from the contribution of additives or pore generators which will influence the macroporosity.

CaP cements can withstand compression forces of around 50 MPa after full crystallization which is within the ranges of human bone.[71,80] It has been reported that CaP cement loaded with particles, acting as pore generators or drug-delivery systems, can reduce compression values by 80% compared to cements not loaded with particles.[71,77] If particles are used for pore generator or drug delivery purposes, the mechanical properties will be dependent on the size, amount, and distribution of the particles in the cement, as well as their compositions.[55,71] An agglomeration of these particles should be avoided to not drastically reduce the mechanical properties of the cement.[81] The drug-delivery systems can be used to enhance the biological behavior and activity of CaP cement. Several studies have reported the use of growth factors and proteins in combination with this CaP cement.[82–85]

Surgical interventions of the spine are typically carried out under radiological guidance; therefore the material used must be radiopaque.[59] In contrast to acrylic cements, CaP cements are radiopaque once injected and fully crystallized. However, this action may take 1 day or more days depending upon the characteristics of the cement used. Improving the contrast characteristics of these cements in its early stage is important if CaP cements are aimed to be used in minimal invasive surgery. Tracking the material during the intervention is of high importance in order to avoid leakage of the material that may increase the risk of injuries or adverse effects.[86] Some common contrasting agents used are barium, iodine, tantalum, and tungsten.[87] Although this approach is relatively new for CaP cement, some groups have already explored this field.[88]

6.611.3.3. Composite Cements (Hybrid Acrylic/CaP Cements)

The goal of adding CaP additives to acrylic cements is to establish a compromise between the desired mechanical and biological properties.[89–91] These composite cements may be able to reduce stiffness, polymerization temperature, and potential monomer toxicity of PMMA while strengthening the bone–cement interface by creating a chemical bonding and changing the encapsulation of the acrylic cement to a direct contact with bone.[90,92,93] This type of cement has been developed quite recently and the interaction between the components is currently under research.[89,91] From the possible CaP candidates, hydroxyapatite (HA) has been most investigated due to the closest similarity of this material to the mineral phase of bone and its high stability.[94,95] However, there are also studies directing attention to other CaPs.[89,96] Bioactive glass has also been studied.[97] All these studies aim to provide a better characterization and understanding of the physical, chemical, mechanical, and biological behaviors of composite materials. It has been proven that the inclusion of CaP additives in the acrylic matrix does not modify the properties of the CaP. CaPs maintain their ability to promote bone ingrowth while the monomer concentration of the acrylic cements stays

stable.[96] When considering composites, understanding the properties related to the interaction between the phases will be essential to better understand the composite material, overall. In the case of the acrylic composites, this interaction will affect setting times, temperature, and mechanical properties. Table 3 shows the factors affecting the acrylate–CaP composites. The setting time of these composites will be affected mainly by the amount of CaP added while the exact type of CaP will only have a minor effect.[89,96] While PMMA by itself can reach temperatures up to 100 °C (373 K), the addition of CaP can reduce it to room temperature.[89,92,96] The addition of CaP will interfere with the polymerization of the acrylic cement and can therefore act as a heat absorber.[89] The mechanical behavior will be a complex interaction between the shape of the additive, and its dissolution and transformation properties as well as its distribution within the sample, amount within the sample, and the anisotropy created.[98] CaP particles may act as stress concentration factors or fracture energy absorbers, hence affecting the mechanical properties in several ways.[91] Some authors reported that the addition of CaP does not change the mechanical properties significantly, while others report an improvement or even a decrease in these properties.[90,95,96] These differences may be related to the type and size of the CaP and their bonding to the acrylic matrix. Standard ISO 5833 indicates that acrylic cements must present a minimum compressive, tensile, and bending strength of 70, 30, and 50 MPa, respectively.

Concerning porosity, acrylic cements by themselves have low porosity.[91,96,99] When the CaP is added, an important factor is the porosity and interconnectivity between the CaP particles. If particles are embedded in the acrylic matrix without contact to surrounding tissue, the properties of the CaP, and the reason for including them, will not be utilized. Here the CaP particle size and amount included will play a significant role, as it happens when loading a CPC with particles for pore generator or drug-delivery systems.[92,96] It has been demonstrated that including HA particles causes a void increment.[91] Therefore, CaP additives *per se* will have an effect on the pore size in the cement also. This effect will be related to the additive content and its wettability toward the acrylic material.[96] CaP materials are hydrophilic, so they are partially covered by the liquid monomer that later will polymerize with the powder polymer embedding the CaP into the acrylic matrix but without a strong interface.[89,95] Treated and untreated CaP additives (silinazed) have proven to have a different interaction with the acrylic matrix and influence the mechanical behavior of the composites.[95] However, these treatments may modify the hydrophobicity of the CaP additives, which could affect their biological properties. Thermal treatments affect the surface properties of CaP.[70] This approach could be used to increase the interaction of the CaP with the liquid monomer without affecting the biological properties of the CaP. Another approach that has been studied to modify the mechanical properties of this type of cement is the creation of a porous acrylic cement by preparing the PMMA with a biodegradable gel.[100,101] In this last approach, if combined with the loading of CaP particles, the structure will be affected on the mechanical properties due to the porous network and type, size, and amount of the particles included.[50,89] Acrylic cements with lower modulus are attractive since they allow better stress distribution in the filled vertebral body, thus potentially reducing the risk of fractures on the vertebrae adjacent to the operated sites.[102] In the case of using radiopaque agents for tracking the material during the surgical intervention, composite cements show a higher degree of complexity since the cement will be a three-phase composite system; hence the interaction of each component will not be one-to-one but one-to-two. Although studied to some extent by some groups the characterization of these three-phase systems is an area that needs to be researched further in order to fully validate the use of these composites.[91]

6.611.3.4. Miscellaneous Cements

Acknowledging the several drawbacks found in commonly used biomaterials for spinal augmentation (i.e., PMMA and CaP cement) consisting of difficult handling characteristics, thermal issues, potential for toxic reactions, mismatched Young's modulus, and limited mechanical strength, researchers have recently started to focus on entirely different materials to be used for this application.[21,103] Boyd and coauthors suggested aluminum-free, zinc-based glass polyalkenoate cements (Zn-GPC) to be a suitable alternative for use in VP.[104] In their recent work, comparing polymerization temperature, strength, Young's modulus, and biocompatibility of this cement formulation with three commercially available bone cements (two PMMA cements and one composed of resins and glass ceramic particles) it was found that, although setting times precluded clinical use in the current composition, thermal behavior of the new material was benign, its stiffness exhibited values similar to cancellous bone while biocompatibility was superior. The authors suggested Zn-GPC to be a suitable candidate material for further development as bone cement once the setting parameters were optimized. In recent studies by Perry *et al.*[105] two new biomaterials, polypropylene fumarate cement and CaS cement, were tested as alternatives for PMMA cement in a model for human cadaveric osteoporotic vertebral compression fractures treated by balloon KP. The authors concluded from their biomechanical tests, showing similar mechanical properties to PMMA, that both polypropylene fumarate and CaS were potential new candidates for this application. In 2004 Zhao and coworkers reported on the properties of a strontium-containing HA cement with surface treatment using methyl methacrylate to be used for VP and found favorable biomechanical results.[106] Other promising cement compositions include glass–ceramic-based cements.[52,107] The studies described in this section cover just a small selection of several biomaterials currently under study, but it can be expected that many more new biomaterials will be designed, tested and eventually qualify for clinical investigation in the near future. The prospect of the availability of biomaterials better adapted to

the needs of both the treating physicians, in terms of superior handling profiles, and patients, in terms of improved safety, efficacy, and biocompatibility, is encouraging.

6.611.4. Clinical Results of Spinal Column Augmentation with Injectable Bone Cements

6.611.4.1. Osteoporotic Vertebral Compression Fractures

In 1994 Gangi and coauthors described one of the first, small-scale, series of patients treated for various indications including osteoporotic vertebral body collapse and spinal metastasis treated with VP using PMMA cement.[108] They noted immediate relief of pain and absence of further vertebral body compression during follow-up in all. Jensen *et al.*[3] published a series of 47 spinal levels treated in 29 patients suffering from osteoporotic vertebral compression fracture and found relief of pain immediately after treatment. Identical results were reported by Martin and coworkers in their series of 68 levels treated in 40 patients with 80% of the patients experiencing substantially improved symptoms.[5] According to the authors, failures were related to insufficient pretreatment, clinical evaluation, and excessive injection of PMMA. In 2003 a prospective controlled trial was published by Diamond and coauthors, describing VP as a safe technique resulting in prompt relief of pain when compared to conservative medical treatment.[109] The same year a review was published, in which it was emphasized that this technique should be reserved for carefully selected patients who do not respond to conservative treatment.[110] In 2006, a review of the treatment of osteoporotic vertebral compression fractures by VP summarized 15 studies (11 prospective, 3 retrospective, and 1 controlled trial) containing a total of 1136 procedures in 793 patients.[111] The visual analog scale (VAS) for pain, a validated pain measuring tool, ranging from 0 to 10, with 0 meaning no pain and 10 the worst pain imaginable, improved from a mean of 7.8 to 3.1. The rate of complications ranged between 0.4% and 75.6%, and was frequently related to cement extravasation and included major adverse events. It was concluded that long-term, properly controlled trials were required to address the lack of sound scientific and clinical understanding of this technique. Hochmuth and coauthors performed yet another review on VP, describing the results from 30 studies and 2086 patients and, again, concluded that although spinal augmentation with PMMA cement seemed to dramatically improve symptoms in patients with osteoporotic vertebral compression fractures, randomized controlled trials were needed to confirm the efficacy of the procedure.[112]

In 2006 Bouza and coworkers published a review of the literature on balloon KP presenting the pooled clinical data of 26 previously published articles.[113] It was found that, although the methodological quality of the papers on which their review was based was generally low, balloon KP for the treatment of painful vertebral compression fractures led to significant improvements in pain intensity, vertebral height, sagittal alignment, functional capacity, and quality of life. The authors concluded the review suggesting that balloon KP was safe and effective. Hulme and coworkers, in their review of 69 articles published in the literature on the outcome of VP and balloon KP, refuted this claim, stating that definite proof of safety and efficacy of both procedures could not be obtained without comparative, blinded, randomized trials.[114] Taylor and coauthors found, in contrast again, Level III evidence to support balloon KP and VP as effective therapies in the management of patients with symptomatic osteoporotic vertebral compression fractures refractory to conventional medical therapy.[14] Moreover, balloon KP was suggested to offer a better profile with respect to adverse events than VP.

The first randomized controlled trial on this subject was the FREE trial published in the *Lancet* in 2009 describing the efficacy and safety of balloon KP compared with nonsurgical care for the treatment of osteoporotic vertebral compression fractures, metastatic spinal lesions, and multiple myeloma.[115] In this trial a total of 300 patients were enrolled and randomly assigned to receive balloon KP with PMMA cement or optimal nonsurgical care. A total of 266 patients completed the 1-month follow-up and a significant difference in SF-36 PCS was found between the two groups favoring the surgical intervention group. At 12 months, 38 out of 115 patients in the balloon KP group and 24 out of 95 in the nonoperative group had new or worsening vertebral fractures. It was concluded that balloon KP with PMMA cement was an effective and safe technique for patients with acute vertebral fractures. In the same year two studies were published in one issue of the *New England Journal of Medicine*.[10,11] These papers generally received a critical reception.[23,25] In the paper by Buchbinder and coauthors, a randomized, double-blind, placebo-controlled trial was performed to study the efficacy of VP using PMMA cement for the treatment of painful osteoporotic vertebral compression fractures in 78 patients. In this study patients were randomly assigned to receive regular VP or a sham operation in which the needle used to inject cement was not advanced in the vertebral body but rested upon the lamina but cement was not injected. During follow-up, the authors found no significant difference in perceived pain between the groups at any time-point while incidental vertebral fractures occurred in both groups (three in the VP group and four in the placebo group). The authors concluded that VP had no beneficial effect when compared to the sham procedure used. The study by Kallmes included a total of 131 patients who were assigned to undergo VP with PMMA cement ($n = 68$) or infiltration of the skin and periosteum with the possibility to crossover from either group at 1-month posttreatment. After 1 month no difference was found in disability scores or pain rating. At 3 months a significantly higher rate of crossover was found in patients from the control group than in the VP group. No incidental fractures were reported for any of the groups. The authors concluded that improvements in the VP study group were similar to improvements in the control group. Both studies have been criticized by virtue of a number of limitations: the low percentage of cases included from the total number of patients eligible; the improvement in pain after receiving treatment being unusually small for both the treatment and control arm, indicating that patients might have undergone inadequate or suboptimal VP procedures; the insufficient statistical power; the potential bias in patient selection; the inclusion of patients possibly not indicated for the treatment; and the sham not being a proper control.[23,25]

Studies describing the clinical results following VP using CaP cement to treat painful osteoporotic vertebral compression fractures are relatively rare.

Nakano and coauthors were, to our best knowledge, the first to describe the treatment of 65 osteoporotic vertebral compression fractures with VP using CaP cement.[18,116] Their results were indistinguishable from studies describing similar cohorts of patients treated with VP based on PMMA cement. Hillmeier and coauthors reported on the treatment of 102 patients with 192 osteoporotic vertebral compression fractures treated by balloon KP with PMMA cement in 138 cases and with CaP cement in 54 cases.[16] Again, the results were comparable for both groups and led to immediate, substantial, and long-term relief of pain in 89% of the patients. In 7% of all treated vertebral bodies cement leakage occurred, however, without clinical sequelae. Grafe *et al.*[15] performed a prospective comparative trial in which 20 patients received balloon KP with CaP cement and 20 patients with PMMA cement. After 3 years of follow-up, no differences were detected at any timepoint between the two groups. It was concluded that CaP cement was as effective as PMMA cement to achieve pain reduction and improvement of mobility in this category of patients. Furthermore, since CaP cement has the potential of being resorbed and replaced by new bone, they concluded this type of cement to be a promising alternative for PMMA cement especially in younger patients.

6.611.4.2. Metastatic/Malignant Vertebral Body Lesions

Metastatic vertebral body lesions and pathological fractures are exclusively being treated with VP or balloon KP in combination with PMMA cement. In 2003 Fourney and coworkers described the treatment of 97 vertebral levels in 56 patients with multiple myeloma ($n = 21$) or other primary malignancies ($n = 35$) by VP or balloon KP.[35] At a median follow-up length of 4.5 months, 84% of the patients noted marked or complete relief of pain while no patient was worse after treatment. Asymptomatic cement leakage was observed in six cases of VP; no cement leakage was observed in the KP group. The authors concluded that both procedures provided significant and durable pain relief in a high percentage of patients. In a recent review on cement injection for spinal metastases Heini and Pfäffli stated VP and balloon KP with PMMA cement to be extremely efficient procedures provided that treatment is restricted to osteolytic lesions in the presence of mechanically challenged bony structures. In a review of the literature, Bouza and coauthors reported on the pooled data of seven studies describing the clinical outcome of balloon KP with PMMA cement for the treatment of malignant spinal fractures and concluded, despite the limited methodological quality of the original studies, that balloon KP is a well-tolerated, relatively safe, and effective technique to provide early relief of pain and improved functional outcomes in this category of patients.[34]

6.611.4.3. Traumatic Fractures

Traumatic fractures of the spine are mostly seen in young and active individuals and bone void fillers used for vertebral body augmentation in this group of patients are likely to remain *in situ* for many decades and will be subjected to many load cycles.[117,118] Concerns on the detrimental long-term effects of acrylic cements in the spine, including short-term inflammation or thermal necrosis and long-term particle-induced osteolysis, have prompted researchers and clinicians to revert to alternative biomaterials. In 2005 Verlaan and coworkers reported on the application of CaP cement after pedicle screw fixation and balloon-assisted endplate reduction in a small series of 20 patients with traumatic thoracolumbar fractures.[119] It was found that the procedure was relatively undemanding for patients, a significant restoration of the vertebral body anatomy was achieved, and major complications were not observed except for an adjacent level fracture in one patient necessitating a secondary surgical intervention. All patients underwent elective removal of their pedicle instrumentation between 12 and 18 months posttrauma as part of the study protocol. At a minimum of 6 years follow-up it was found that recurrence of kyphosis had not occurred. Similar studies were published by Korovessis *et al.*[120] and Marco and Kushwaha,[121] respectively. In the series by Korovessis and coauthors, a total of 23 patients with thoracolumbar burst fractures underwent pedicle screw instrumentation followed by balloon KP with CaP cement and it was concluded after a minimum of 2 years follow-up that the technique provided excellent immediate reduction of posttraumatic kyphosis, provided significant spinal canal clearance, and restored vertebral body height of the fractured level. Marco and coauthors described a series of 38 patients with unstable thoracolumbar burst fractures with and without associated neurological deficits treated with short-segment pedicle screw fixation followed by transpedicular balloon-assisted endplate reduction and injection of CaP cement. It was concluded that the procedure led to maintained or improved neurological function in all patients with preexistent neurological deficits and a low rate of instrumentation failure or loss of correction. Maestretti and coauthors reported on a series of patients with traumatic thoracolumbar fractures treated with standalone (i.e., without pedicle screw fixation) balloon KP using CaP cement.[122] Although the clinical results were good, it was noted that CaP cement had distinctive biomechanical disadvantages compared to PMMA cement sometimes leading to loss of fracture correction and unpredictable resorption behavior. Currently, Blattert *et al.*[123] recommend against standalone treatment of traumatic thoracolumbar fractures by VP or balloon KP.

To our knowledge, only one article has been published on the treatment of traumatic thoracolumbar fractures treated by pedicle screw fixation and VP using PMMA cement.[124] In this work, Cho and coworkers report on a series of 70 patients of which 20 underwent VP additional to pedicle screw fixation and 50 underwent regular pedicle screw fixation.[124] The authors concluded from their work that reinforcement of the anterior column with VP using PMMA cement may achieve and maintain kyphosis correction and decrease instrument failure rate.

6.611.5. Complications in Spinal Column Augmentation

Within 2 years after the widespread use of VP with PMMA bone cement, the first descriptions of serious complications occurred. Two independent cases of symptomatic pulmonary embolism resulted from extravasation of bone cement into the pulmonary circulation.[6,7] Shortly after, it was found that the incidence of asymptomatic pulmonary embolism could

be as high as 87.9% and was predominantly related to an excessive volume of cement injected.[125,126] It is a currently accepted notion that during VP or balloon KP, leakage of cement into the surrounding soft tissue, venous circulation, or pulmonary system often goes unnoticed by both the physician and the patient. Complications arising from VP or balloon KP can be divided into categories of minor and major severity.[12] Minor complications include wound hematoma, superficial infection, rib fracture due to patient manipulation, needle malpositioning, and asymptomatic cement extravasation. These minor complications are responsible for an estimated 95–98% of all adverse events. Major complications include symptomatic pulmonary embolism, cement infection, symptomatic spinal cord or root compression, myocardial infarction, and death. Many studies have reported cement emboli to be present in the pulmonary circulation after augmentation of the spinal column by VP or balloon KP. In a recent meta-analysis of the literature, Lee *et al.*[12] reported on a total of 3078 cases of cement leakage found in 4097 patients treated with VP using PMMA leading to an unusually high leakage percentage of 75%. Symptomatic leakage of cement was, however, found in only 1.5% of cases reported. The number of asymptomatic versus symptomatic cement leakage after treatment with balloon KP was found to be 14% and 0.06%, respectively. The review by McGirt and coauthors confirmed these results and, moreover, reported neurological decline to occur in less than 1% of cases treated by VP and balloon KP.[127] These results raise the question as to why cement leakage is apparently tolerated so well by the majority of patients. It is currently, for example, not known what factors are involved or necessary for pulmonary embolism to become symptomatic after cement leakage has occurred. Patient-related factors, such as decreased pulmonary capacity and heart failure, may lead to a predilection for symptomatic pulmonary embolism but do not explain the actual occurrence since these highly prevalent conditions may be present in the asymptomatic group as well. Many reviews of the pertinent literature have, however, shown almost all complications, both of minor and major severity, to be related to leakage of bone cement. Two groups of factors have been identified to potentially influence the risk of adverse events following VP or balloon KP.

Factors increasing the risk of cement leakage are

1. fracture type,
2. duration of symptoms,
3. instruments/instrument positioning/spinal anatomy,
4. viscosity of cement injected,
5. volume of cement injected.

Factors not increasing the risk of cement leakage are

6. mechanical/thrombogenic/thermal properties of cement,
7. general patient health characteristics.

6.611.5.1. Fracture Type

Osteoporotic vertebral compression fractures are associated with less cement extravasation than malignant spinal lesions, which in turn are less prone to cement leakage than traumatic fractures.[128] The explanation for the differences may be found in the varying degree of fracture comminution, cortical disruption, and surrounding soft tissue damage for these three categories.[129] It is hypothesized that postural reduction and subsequent ligamentotaxis may decrease the risk of cement extravasation due to minimization of fracture gaps and (partial) restoration of the vertebral anatomy thereby facilitating unimpeded cement flow.[29]

6.611.5.2. Duration of Symptoms

It has been suggested that the duration of symptoms influences both clinical outcome and incidence of cement extravasation in osteoporotic vertebral compression fractures. It is generally accepted that the optimal window for treatment ranges approximately between 6 and 12 weeks after the onset of symptoms. Performing spinal augmentation at an earlier stage is, considering the generally benign nature of these lesions showing full resolution in the majority of patients, considered overtreatment while after 3 months the effect of postural reduction is diminished. The optimal timing of intervention for metastatic spinal disease or traumatic fractures by VP or balloon KP is unknown but, considering the natural history of the lesions in this category of patients, is rather on acute or emergency basis than elective.[121]

6.611.5.3. Instruments/Instrument Positioning/Spinal Anatomy

In order to minimize the resistance of bone cement to flow, short, large-diameter cement delivering needles are recommended, regardless of the type of biomaterial used. Assuming laminar flow of a liquid with a given viscosity through a tube, the following equation can be applied (nonalgebraic version of Poiseuille's law):

$$\text{Flow} = \text{Pressure}^{*}\text{diameter}^{4}/\text{viscosity}^{*}\text{length}$$

Assuming a limitation of the pressure that can be generated by human force using a manually operated syringe and assuming a lower threshold of viscosity needed for safe injection of the biomaterial in the vertebral body, shortening the length of the needle while increasing its diameter will increase flow. Since the increase in flow is proportional to needle diameter by the fourth power, it is clear that using large-bore needles optimally facilitates injection of higher viscosity cement. The topic of cement viscosity and flow in relation to cement extravasation is described in more detail elsewhere in this chapter. The optimal positioning of the needle(s) is considered to be close to the midline in the anterior third of the vertebral body. Deviating from this position may lead to uneven distribution of cement and increased risk for cement extravasation due to the proximity of venous structures (anterior vertebral venous plexus; intraspinal extradural venous plexus).[130] Unipedicular, bipedicular, or extrapedicular procedures are currently being performed for both VP and balloon KP and are showing identical results.[131] It can be argued that the utilization of the unipedicular approach would decrease the chance of instrument malposition by 50%. However, controlled clinical trials showing this theoretical advantage to lead to better clinical results and less cement extravasation or complications have

not been performed. Variations in patient anatomy, most notably small-diameter or aberrant pedicles, can lead to difficulties in proper access to the vertebral body and may, in case of pedicle wall fracture, increase the risk of false routes and subsequent leakage of cement.

6.611.5.4. Viscosity of Cement Injected

The viscosity of the bone cement injected in the spinal column is of utmost importance to achieve even flow and controlled distribution of the biomaterial in the vertebral cancellous bone. However, during polymerization of PMMA cement (or formation of HA crystals during setting in the case of calcium phophate cements), the viscosity increases slowly but exponentially with time from the moment of mixing the components until the fully cured state.[132] The interval in which bone cement can safely be injected is often called the working time or injection phase and is dependent on

- the initial ratio of ingredients (monomer-to-polymer in PMMA cement and ratio of liquid-to-CaP in CaP cement);[40,133]
- the presence of additives in PMMA cement or alternative solutions for CaP cement;[134,135]
- the temperature of the components before mixing;[136]
- the mixing process itself;[132]
- the temperature of the environment ('room temperature') during polymerization/setting;[136]
- considering the significant variations in working time under apparently identical circumstances: miscellaneous yet unidentified factors.[45]

By trial and error, clinicians have found, rather unscientifically, that the optimal viscosity for safe injection resembles that of toothpaste or spaghetti; cement of lower viscosity (before the injection phase) led to frequent extravasation while cement displaying higher viscosity (after the injection phase) substantially reduced injectability.[137] Baroud and coauthors quantified this observation using cements of different viscosities in an *in vitro* model of VP.[138] It was demonstrated that the highest viscosity cement stabilized flow and prevented extravasation but was no longer injectable using human force. An experimental study by Loeffel and coauthors, published in 2008, assessed distribution of PMMA cement in the vertebral body as a function of cement viscosity, bone porosity, and injection speed.[139] Their main conclusion was that viscosity was the key factor to reduce cement extravasation and should be adapted to each patient individually according to the degree of osteoporosis present. It was advised to use high-viscosity cement combined with high injecting speed to safely augment the vertebral body. The experimental work by Krebs and coworkers, investigating bone marrow fat embolism in an *in vivo* VP model, however, suggests that increasing cement viscosity and injection speed could lead to different, yet no less harmless, adverse events.[140,141]

6.611.5.5. Volume of Cement Injected

In the first decade following the invention of VP, near-complete filling of a vertebral body with bone cement was considered necessary for good clinical outcome. However, soon it was realized that smaller amounts of cement injected led to identical good results while substantially decreasing the occurrence of adverse events related to cement extravasation. Injection of 3–4 ml bone cement in the thoracic spine and of 4–6 ml cement in the lumbar spine is presently recommended by many authors and this practice has, thus far, been shown to yield the optimal compromise between clinical outcome and adverse events related to cement leakage.[142] No data are yet available on the efficacy and safety of spinal augmentation using even less cement.

6.611.5.6. Mechanical/Thrombogenic/Thermal Properties of Cement

Limited data are available on whether the contribution of bone cement to the development of pulmonary embolism after extravasation is by direct mechanical blockage of pulmonary vessels or by promotion of thromboembolic processes downstream. In multiple *in vitro* studies conducted by Cenni *et al.* it was demonstrated that several acrylic cements, when tested for hemolytic activity, antithrombotic properties, and the plasmatic phase of coagulation, did not seem to influence these parameters.[143–145] Further work by the same group showed that, in general, products released from acrylic cements were not able to elicit a specific immune or endothelial response.[146] The lack of thrombogenic activity in PMMA cement was confirmed by the work of Blinc and coauthors, adding that liquid components of this type of cement inhibited platelet aggegration and plasma clotting *in vitro*.[147] Concluding from these studies it seems plausible that mechanical blocking of the pulmonary circulation by cement particles, as opposed to chemical induction of thrombogenesis, is responsible for the development of pulmonary embolism when using PMMA cement. Large cement particle size (>2 mmr) in combination with preexistent risk factors for symptomatic pulmonary embolism can be hypothesized to constitute the key etiological factors for the occurrence of this complication.[86]

With respect to CaP cements and the occurrence of pulmonary embolism, two experimental *in vivo* studies have been conducted to test the hypothesis that extravasation of CaP cement into the venous circulation may result in uncontrolled activation of the coagulation cascade.[148,149] In the study by Bernards *et al.*,[148] CaP was injected directly into the venous system of 21 pigs to investigate any cardiopulmonary insults. An overall mortality of 13 out of 21 pigs was observed following a profound increase in pulmonary artery pressure and subsequent drop in left atrial and systemic blood pressure after cement injection. On autopsy, massive thromboemboli were found in the arterial pulmonary circulation and right ventricle. The authors hypothesized that semiliquid, curing CaP cement may have acted as a powerful scaffold for blood clot formation. Furthermore, it was suggested that the release of significant amounts of calcium in the circulation, being an important cofactor in the coagulation cascade, may have further stimulated the coagulation process.

The occurrence of neurological deterioration after leakage of cement into the spinal canal or neural foramina has been suggested to result from mechanical compression of neural structures (i.e., spinal cord, cauda equina, or neural roots)

or thermal damage. Currently, the damage by mechanical compression of neural structures, resulting from cement extravasation after VP or balloon KP, is undisputed and warrants immediate surgical decompression.[150] Patients in any of the three indication categories presenting with neurological deficits are not considered good candidates for spinal augmentation with injectable bone cements without additional surgical decompressive measures, since leakage of cement into the spinal canal may further compromise neurological function.

The often suggested possibility that local heat, produced during the exothermic polymerization of PMMA, may cause neural tissue damage has received considerable attention in recent *in vitro* and *in vivo* studies.[30,32,151] Several experimental investigations have demonstrated conductive and convective mechanisms by the circulation and flow of cerebrospinal fluid to effectively dispose of the excessive thermal energy generated by the curing cement. The heat effect of large quantities of polymerizing PMMA cement located in the spinal canal, however, was not studied and may still pose a considerable threat to neural tissue integrity. CaP cements set isothermically and concerns about thermal damage therefore do not apply.

6.611.5.7. General Patient Health Characteristics

Health hazards that are generally prevalent in the frail and elderly include hypertension, osteoporosis, diabetes mellitus, coronary artery disease, heart failure, coagulation disorders, and chronic obstructive pulmonary disease. These are obvious patient-related factors associated with an increased complication risk for virtually any surgical treatment and may account for, at least, some of the complications occurring after spinal augmentation including both minor and major events such as rib fracture, infection, hematoma, pulmonary embolism, and myocardial infarction.[12]

6.611.6. Future Directions and Conclusions

The number of articles published in basic scientific and clinical journals on injectable bone cements for spinal column augmentation has expanded immensely in the last decade. Despite all this work, no generally accepted explanations have emerged as to why augmenting the vertebral body leads, in general, to such good clinical results; whether adjacent fractures occur more frequently after augmentation of the spine; why cement leakage sometimes, but certainly not always, leads to serious complications. Acknowledging the logistic (study enrollment) and ethical (sham operations) difficulties in conducting randomized controlled trials to find an effect of VP or balloon KP, investigators could focus on well-controlled dose-dependent studies. In these studies the minimal amount of cement needed for adequate pain reduction could be established which could serve as a basis to support or refute the fracture stabilization theory and find the optimum balance between treatment effect and complication rate.

If augmentation of the spinal column indeed leads to pain reduction, by stabilization or other means, the next step would be to identify the key factors that determine success or failure. Considering the exceedingly large number of procedures of VP and balloon KP performed each year, establishing a registry (similar to the large total hip/knee replacement databases in worldwide use today) may help clinicians identify factors leading to the occurrence of adjacent level fractures and symptomatic pulmonary embolism, for example. Such analyses are generally useful for suggesting better performing biomaterial characteristics. It is a tempting concept that the biomechanical and biological properties of an ideal bone cement more closely match the individual patient requirements. Factors such as cement stiffness and capacity for osseointegration may be adapted to unique individual characteristics including easily quantifiable variables such as gender, age, and bone mineral density and further including more qualitative concepts such as activities of daily life, workload, risk of major intraoperative complications, and life expectancy. As the medical community is slowly gaining a better understanding of the specific needs for patients with spinal lesions, it is possible that, in time, more individualized vertebral bone void fillers may become available.

The last two decades have brought us promising new minimal invasive techniques and biomaterials to augment the spinal column of patients who otherwise would be confined to long-term immobilization and analgesics or subjected to major surgery. By virtue of sheer need, these techniques and biomaterials were introduced and became widely accepted. Well-controlled studies addressing safety and efficacy were not routinely performed. Continued progress in this exciting field should depend on rigorous scientific and clinical studies.

Glossary

Alginate The chemical compound sodium alginate is the sodium salt of alginic acid. Its empirical formula is $NaC_6H_7O_6$. It is a linear copolymer with homopolymeric blocks of (1–4)-linked β-D-mannuronate and its C_5 epimer α-L-guluronate residues, which are covalently linked together in different sequences or blocks. Sodium alginate is a 'gold-standard' for three-dimensional culture of disc cells from the nucleus pulposus (NP) and has been proposed for NP replacement.

Atelocollagen This the solubilized collagen revealed from enzymatic removal of telopeptides by proteolytic enzymes such as pepsin. Telopeptides are nonhelical portions of the collagen that molecule are located at the N- and C-terminal ends (9∼26 residues).

Bone morphogenic proteins (BMPs) A family of growth factors involved in the bone morphogenesis. BMPs interact with specific receptors on the cell surface, referred to as bone morphogenetic protein receptors (BMPRs). Signal transduction through BMPRs results in the mobilization of members of the SMAD family of proteins. The signaling pathways involving BMPs, BMPRs, and SMADs are important in the development of the heart, central nervous system, and cartilage, as well as postnatal bone development.

Discogenic phenotype A cell phenotype, which differs from the chondrogenic phenotype by the ratio of hualoronic acid to total collagen, which has been described to be about 29:1 according to Mwale *et al.*[1] The phenotype is furthermore distinguished from the chondrocyte phenotype by transcriptomics as shown recently by Minogue *et al.*[2]

Growth and differentiation factor-5 (GDF-5) It is a growth factor of the BMP family and is assumed to induce discogenic pathway on mesenchymal stem cells.

Mesenchymal stem cells Multipotent stromal cells that can be differentiated into different cell phenotypes of the mesenchyme such as bone, chondrocytes, adipocytes, and myocytes. These cells have anti-inflammatory action and active potential to migrate (known as homing) to the site of injury.

Nucleotomy Surgical removal of the native nucleus pulposus tissue.

PEG PEG, PEO, or POE refers to an oligomer or polymer of ethylene oxide. PEGs are prepared by polymerization of ethylene oxide and are commercially available over a wide range of molecular weights from 300 to

$10\,000\,000\ g\,mol^{-1}$. PEGs hydrogels have been used for disc regeneration.
POM Poly(1,8)-octanediol malate. It is a malic acid-based polyester, which is formed by polycondensation.
SMAD The SMAD proteins are homologs of both the *Drosophila* protein, *mothers* against *decapentaplegic* (MAD), and the *Caenorhabditis elegans* protein SMA. The name is a combination of the two.

6.612.1. Overview of Intervertebral Repair: Current Strategies

6.612.1.1. Introduction

The healthy spine is indeed the 'backbone' of our society. Healthy discs function as essential load-absorbers between all vertebrae, allowing bending, flexion, and torsion of the spine. As the global population ages, the incidence of intervertebral disc (IVD) degeneration and low back pain (LBP) increases. The occurrence of LBP has been associated in many cases with degenerative disc disease (DDD).[3,4] Given that disc degeneration is a cell-mediated response to progressive structural failure, new treatments that normalize disc cell homeostasis and restore full disc function are required. Here, we review recent studies that aimed to regenerate the IVD with comprehensive biomaterials.

6.612.1.2. Normal Disc Structure and Function: Disc Cells, Extracellular Matrix, Nutrition

The IVDs lie between the vertebral bodies and link them together. The height of all discs makes up about a third of the spine.[5–7] The IVD is a complex structure mainly composed macroscopically of two different tissues, the fibrous tissue, annulus fibrosus, (AF) and in the center the nucleus pulposus (NP); the AF is anchored to the cartilaginous endplates of the vertebral bodies and keeps the NP in position. The IVD is avascular, and there are, thus, steep gradients in the concentration of nutrients and metabolites from the blood supply at the disc's margins to the cells in the center of the disc.[5,8–10] Even in normal healthy animal discs, low oxygen and high lactic acid concentrations (and thus acidic pH levels) compared to the levels of blood plasma have been recorded. Thus, the 'niche' for disc-like cells of the NP is marked by low oxygen concentration, high lactic acid concentrations, and relatively high hydrostatic pressures.[11,12] A nonpathophysiological disc acts as a shock-absorbing organ and provides motion for the spine and maintains disc height; thus, the distance between two adjacent vertebral bodies is kept in a certain tolerance range. With a closer look, there are in fact four different tissue types, that is, from the outside to the inside: (1) the outer AF, a ring of highly oriented, densely packed collagen fibril lamellae, (2) the fibrocartilaginous inner AF, (3) the transition zone, a thin zone between the inner AF and the central NP, and (4) the vertebral endplates, initially comprising hyaline cartilage of which the cells resemble chondrocytes found in other hyaline cartilage.[13,14]

6.612.1.3. Aging and Degeneration: Pathophysiology, Effect on Function and Pain, Repair Capacity

There are two processes that change the mechanical properties of the extracellular structure of the IVD. The first is ageing and the second is genetic preposition, known as degenerative disc disease (DDD).[13,15–26] As we age, the disc undergoes major apparent structural rearrangements that become macroscopically evident from the color change to brown and an apparent water loss in the NP.[27] Also the NP becomes very fibrous in nature and the disc loses water content as seen on magnet resonance imaging (MRI).[21,22,28] One major biological change is the cell death of disc cells at a relatively early stage of our lifetime. It is hypothesized limiting nutrition overlaid over aging is a genetically predisposed IVD degeneration. This has been described as DDD. The evidence comes from twin studies, which demonstrate a high heritability for DDD (70%).[29,30]

6.612.1.4. Current Treatment Options (Conservative, Fusion Surgery, Motion Preservation Techniques, and Devices)

LBP is limiting the daily activities of about 80% of people of our modern society at least once in the lifetime and there is increasing evidence that it is directly associated with DDD.[31,32] There are a variety of disc replacement strategies out in the market; however, fusion is still considered the 'gold' standard for all cases that lack an alternative treatment.[33,34]

Although fusion rates of ~90% are achieved, early complication rates of up to 31% have been registered.[35] Most of these complications are local hematomas or superficial infections; however, deep wound infection rates of 1.9–20% are also documented in the literature.[36,37] With regard to the long-term outcome, a high reoperation rate of 21.5% was found in an 11-year follow-up study for instrumented fusion of the lumbar spine. Two-thirds of these cases were related to implant complications or pseudoarthritis.[38] Unfortunately, spinal fusion alters the normal biomechanics of the spine, and the loss of motion at the fused levels is compensated by increased

motion at other nonfused segments. As a result, a significant amount of additional load is placed on the discs and facet joints at the nonfused levels. One commonly observed (and usually long term) consequence of fusing spinal motion segments and thus increasing the forces on the adjacent levels has been adjacent segment disease (ASD). As adjacent mobile segments proximal to the fusion degenerate over time, the initial good results following posterior spinal fusion often degrade. Radiographic evidence of ASD has been reported with a prevalence of more than 30%.[39,40] Reoperation rates due to ASD or transition syndrome lie between 20 and 27% over 2–15 years postoperatively. Mechanistic disc prostheses all have their major drawbacks and are far from being perfect in terms of range of motion and longevity. Some of the disc replacements may even lead to disc degeneration of adjacent vertebral bodies, spinal stenosis, or hypertrophic facet arthropathy.[41,42] Thus, in the clinics, there is an urgent need to understand the mechanisms that lead to disc degeneration. Moreover, there is a need to develop good model systems for the disc, such as organ cultures, to understand pathological mechanisms and to test clinical treatment scenarios.[43–46]

6.612.1.5. New Treatment Strategies in Research (Protein Injections, Gene Therapy, Cell Therapy)

Two regenerative approaches for the early degenerative lumbar IVD that are currently debated include (1) injection of growth factors[47–51] and (2) application of autologous stem cells[52–58] (**Figure 1**) (see **Chapter 6.615, Intervertebral Disc**).

On the side of growth factors, insulin-like growth factor-1,[78,79] basic fibroblast growth factor (bFGF),[80–81] and growth factors of the transforming growth factor-β (TGF-β) superfamily, mainly bone morphogenic protein (BMP) 2 and 4 and TGF-β1, have been investigated.[82–86] A relatively recently identified growth factor of the BMP family is growth and differentiation factor-5 (GDF-5).[87] GDF-5 plays a major role in skeletal development and has been shown to promote proliferation and matrix synthesis of IVD cells. Gene expression of aggrecan and collagen type 2 of rat disc cells was significantly upregulated upon overexpression of rhGDF-5 by viral transfection, and also simply adding the substance to the media led to dose-dependent responses.[88,89] GDF-5 has also been identified as a potential candidate for restoring disc height in the rabbit degenerative model.[50] In fact, all of these growth factors seem to be able to reverse at least partially disc height loss as demonstrated for the annular stab rabbit degeneration model. The question remains whether growth factors would be successful for discs with larger dimensions and nutritional problems.[90]

Cytotherapy appears to be an extremely potential approach to regenerate the degenerating disc[91] (**Figure 1**). Autologous mesenchymal stem cells (MSCs) have intensively been investigated as promising candidates for regenerative medicine.[51,71,92–98] There are two major reasons for this; one is their multipotentiality to differentiate into different cell types of the mesenchyme, which promotes them as ideal candidates for regeneration of bone, cartilage, muscle, tendon, and potentially IVD tissue.[45,99,100] The second reason is that these cells can be relatively easily isolated from various tissues, such as the bone marrow or adipose tissue.[96,101–104]

The MSCs would be ideally supplied in a scaffold, which could be a kind of injectable hydrogel in the case of NP replacement.[105–109] Here, chitosan in combination with gelatin[110] or, alternatively, hyaluronan in combination of collagen type 2[60] could be very promising to differentiate stem cells toward the 'discogenic' phenotype. Atellocollagen type I was a successful

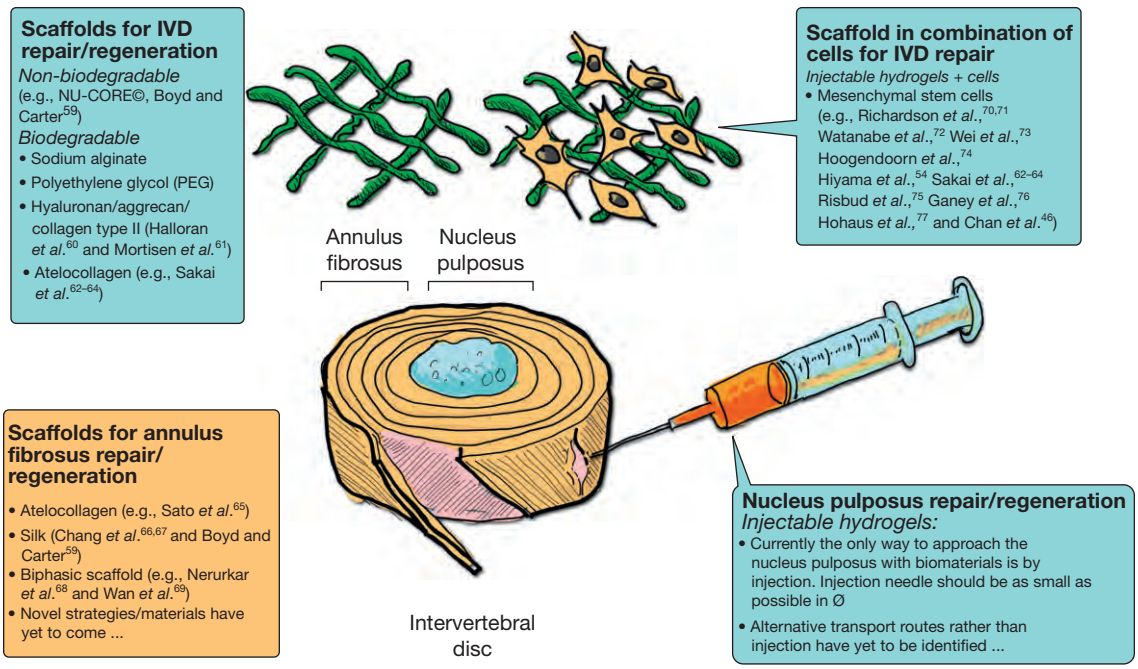

Figure 1 Overview of current regenerative approaches to rescue the intervertebrate disc from degeneration using a biomaterial scaffold with or without the injection of mesenchymal stem cells.

material to thrive stem cells toward discogenic phenotype or if NP cells are kept in hydrogels.[63,64] The definition of 'discogenic discs' to characterize differences between the phenotypes of NP cells and articular cartilage was completely lacking until recently. Some of these problems were addressed in recent comparative microarray studies to characterize the transcriptomes of the NP, the AF, and the articular chondrocyte phenotype in rat, dog, and human.[111–113] However, these recent studies also confirmed that the difference between the articular chondrocyte and the NP cell or a AF cell is only about a dozen genes, which show clear up or downregulation (in the order of >10 times difference). This finding, however, supports the old term of 'fibrocartilage,' which can be found in older text books on IVD tissue.

6.612.2. Repair of the NP

6.612.2.1. The Pathobiology of the NP

Developmentally, cells composing the NP are thought to originate from the notochord. At the beginning of the fourth week of embryonic period, somite undergoes a specialization to sclerotome, myotome, and dermatome (Table 1). Sclerotome becomes the future vertebrae. The mesenchymal tissue in the sclerotome forms a cylindrical column called perichordal tube that surrounds the notochord. Segmentation of the perichordial tube by aggregation of mesenchymal cells occurs to form dense perichordal discs. Then, chondrogenesis begins at the center of perichordal discs constricting the notochordal tissue passing through it, which eventually disappears in the vertebral bodies.[145,146] However, notochordal cells remain at the center which becomes the precursor of NP.[147] Classically, it has been documented that they are cells that contain large vacuoles interconnected with each other by gap junction to form cell clusters. However, in humans and several other species (e.g., chondrodystrophoid breed canines, cattle), these notochordal cells disappear earlier in life and chodrocyte-like mature NP cells from unknown origin take over. After the disappearance of notochordal NP cells remains chondrocyte-like cells of unknown origin, which produces more collagenous and less hydrated extracellular matrix (ECM) leading to aging or degeneration of the IVD and is often associated with LBP, spinal stenosis, and sciatica. Regarding the fact that species retaining notochordal NP cells for longer period of life rarely develops disc degeneration, understanding the molecular mechanism in the maintenance of notochordal and other NP cell populations may well provide key concepts to prevention of disc degeneration and regenerative strategies. It has been speculated that this morphological change in cells composing the NP is due to change in nutrition provided mostly by diffusion from the end plate. Hunter *et al.*[148] and Guehring *et al.*[149] have pointed out that notochordal cells are more metabolically active and more susceptible to nutrient deprivation compared to mature NP cells. They have also found that animal species with higher end plate porosity will retain the nucleus environment, which may prevent apoptosis of the notochordal cells.

6.612.2.2. Current Therapeutic Strategies

Treatment of disease resulting from disc degeneration includes surgical procedures, such as discectomy and spinal fusion; however, these procedures do not preserve the function of IVD. Moreover, they reduce the mobility of the associated spinal motion segment and increase the mechanical load and stresses on adjacent discs. Mobility preserving techniques using artificial disc and nucleus implants have been tested clinically to preserve mobility in cases of severely damaged discs (see **Chapter 6.614, Wear: Total Intervertebral Disc Prostheses**).

6.612.2.3. Candidate Biomaterials for Nucleus Repair

6.612.2.3.1. Polymers and biological molecules

There is an increasing demand for bioadsorbable polymers. One reason for this is that they can eliminate the potential for various implant-related complications resulting from stress shielding, corrosion, and release of wear debris. Polyglycolic acid (PGA) and poly-L-lactic acid are the two major bioabsorbable polymers. The former is metabolized to glycine

Table 1 Overview of biomaterials used for the repair of intervertebral disc, targeted for the nucleus pulposus (NP) and the annulus fibrosus (AF) or the entire disc (IVD)

(F) denotes classical approach to achieve intervertebrate body fusion, (B) denotes biological repair approach to repair or regenerate tissue parts.

in about 4–6 weeks, but the latter is to L-lactate and takes 6–12 months to degrade. Inflammatory tissue reaction is seen more in PGA than in poly-L-lactic acid. Polymer biomaterials have advantages over the others because of their ease and flexibility of manufacturing, relative low cost, and availability in a wide range of properties.

Current approach for IVD repair was proposed to apply injectable hydrogels. A hydrogel is a relatively broad term referring to a gel that has water dispersed in various types of polymer network. Owing to the polymer network difference, the mechanical and biologic properties for various hydrogels can be very different.

6.612.2.3.2. Biomaterials for tissue-engineering methods in cell-based nucleus repair

Alginate, agarose, collagen gel, collagen sponges, and fibrin gels were used previously to hold cells in three-dimensional (3D) culture systems. Besides using these materials as *in vitro* culture scaffolds, they are further expected to be useful as candidates for cell-carriers in cell transplantation therapy for IVD degeneration or cell-holding scaffolds in IVD tissue engineering. Autologous or allogenic disc cell transplantation has been reported from multiple research groups as a major approach in delaying the progression of degeneration by restoring lost cells. In delivering donor cells to the IVD, the selection of an adequate cell-carrier is important. The generation of disc-like tissue using various scaffolds and tissue-engineering techniques also possesses the potential of becoming a new strategy for regenerating the nucleus (see **Chapter 6.613, Nucleus Replacement**).

6.612.2.4. Overview of Nucleus Repair and Regeneration

Nucleus replacement devices can be classified to either injectable or preformed implants. Injectable, *in situ* curing materials can be divided into uncontained or contained devices. Uncontained are adhesive hydrogels (e.g., NuCore or BioDisc) and nonadhesive nonhydrogels (e.g., Sinux). Contained devices are hydrogel (with no currently available device) or nonhydrogel devices (e.g., DASCOR, PNR, PDR). Preformed implants can be divided into nonarticulating or articulating implants. Nonarticulating implants are hydrogel (e.g., PDN-Solo, Hydraflex, NeuDisc, Aquarelle) or nonhydrogel (e.g., Newcleus, NeoDisc, Regain). Articulating implants can be divided based on whether they are made of same material of components (e.g., NUBAC) or different components.[139]

6.612.2.5. Biomaterials for Cell Scaffolds

Among various cell scaffolds such as alginate, agarose, collagen gel, collagen sponges, fibrin gels, PGA, and poly-L-lactic acid, not many have been broadly used clinically in other areas of human body.

Atelocollagen is a collagen gel that has an advantage in safety, as the antigenic telopeptide region has been removed by pepsin digestion and differential salt precipitation during purification. Atelocollagen is in liquid form at 41 °C, but gels after incubation at 37 °C. Atelocollagen composed of type I collagen purified from calf dermis is already in use by physicians for subcutaneous injection during cosmetic and plastic surgery. Atelocollagen can be obtained as collagen types I–IV, depending on the animal and organ from which it is purified. The results of a study culturing human NP cells in atelocollagen showed that it can provide 3D culture condition for human NP cells, as measured by cell proliferation and proteoglycan (PG) production and also generate NP like tissue *in vitro*. A similar combination of collagen type II hydrogel has been proposed which uses a combination of noncross-linked and enzymatically cross-linked, atelocollagen type II-based scaffolds containing varying concentrations of aggrecan and hyaluronan.[60,63,64] These authors found that cross-linking atelocollagen type II-based scaffolds did not cause any negative effects on cell viability or cell proliferation over a 7-day culture period. **Figure 2** shows the optical appearance of non-cell-seeded and cell-seeded scaffolds. They compared cross-linked and non-cross-linked collagen/aggrecan/hyaluran mixtures: collagen (C), collagen/hyaluronan (CH), mTGase cross-linked collagen/hyaluronan (xCH), collagen/aggrecan/hyaluronan (CAH), and mTGase cross-linked collagen/aggrecan/hyaluronan (xCAH) (**Figure 2**).

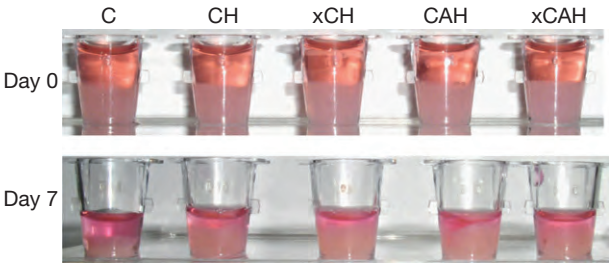

Figure 2 Acellular scaffolds (i.e., day 0) and nucleus pulposus cell-seeded scaffolds on culture day 7, on the top and bottom row, respectively. Progressing from left to right are the scaffold groups: collagen (C), collagen/hyaluronan (CH), mTGase cross-linked collagen/hyaluronan (xCH), collagen/aggrecan/hyaluronan (CAH), and mTGase cross-linked collagen/aggrecan/hyaluronan (xCAH). Reproduced from Halloran, D. O.; Grad, S.; Stoddart, M.; Dockery, P.; Alini, M.; Pandit, A. S. *Biomaterials* **2008**, *29*, 438–447, with permission from publisher.

6.612.2.6. Future Perspectives

Although many biomaterials have been tested in the laboratory or in the clinics, there has not been an ultimate solution for repair of the NP that lasts forever. The big challenge is to determine the appropriate pathology for the indication of each device or technique. Furthermore, since most of the nucleus replacement devices owe their function in intact AF, the repair/regeneration of the annulus remains a great consideration. Current strategies are to develop hydrogels that are thermo-responsive, for example, those that are in a fluid state at room temperature but are in a coiled and gel-like state at physiological temperature of 37 °C.[61]

6.612.3. Repair for the AF

6.612.3.1. Development and Healthy Structure of the AF

The IVD is confined by the two cartilage endplates and is composed of two distinct structures, the NP and the surrounding AF.[150,151] Although the two cartilage endplates

offer anatomical limitation to the vertebral bodies, morphology along the plate is distinguished by a central articular-like cartilage under the NP and a peripheral fibrocartilage appropriately associated with the AF. During embryogenesis, the AF develops from the mesenchyme, whereas the NP is derived from the notochord.[152] The AF consists of water (65–90%), collagen (50–70% dry weight), PGs (10–20% dry weight), and noncollagenous proteins (e.g., elastin).[153] The IVD has been recently described as tough, composite biomaterial which acts as a viscoelastic weight-bearing cushion and is a major contributor to the spinal flexibility and mechanical stability properties of the spine.[150] The AF is a structure, which surrounds the hyalinic PG-rich NP. The function of the AF in the young to middle-aged discs is to counteract the hydrostatic pressure of the NP and to prevent leakage.[13,154]

The need to find more satisfying repair strategies for the AF has been recognized only relatively recently.[155,156] The AF as a major component of the disc has been shifted to the current research focus.[155,157] It has been recently noticed that injection of needles, as it is done in discography, into the IVD can be a major risk for the onset of disc degeneration.[158] Carragee and his colleagues found strong evidence for discographic-induced disc degeneration at 10 years postoperative follow-up.

6.612.3.2. Surgical Strategies to Rescue the AF

Commercially, there are two implants to close the AF available. It is the Inclose© and the Xclose©, which can be seen as modified sutures with anchors.[155] However, these approaches try to contain the NP but cannot maintain the biological AF structure for the long term or stop AF degeneration. Barricaid© is another commercially available implant used in adjunction to discectomies that fully bridges the defect in the AF. This product reinforces the complete posterior annulus and could therefore even prevent contralateral herniation.

6.612.3.3. Nonbiodegradable Materials

Under this category fall the metals, ceramics, and polymers. To our knowledge, there were no metals successfully tested for the reconstruction of the AF till date, which lies in the nature of this complex and viscoelastic tissue. Metals are to stiff to fit the biomechanical needs for AF replacement. As for the ceramics, a combination has been applied to the IVD repair.[12,159–167] However, only few were tried for AF repair. Thus, none of these studies tried to rescue the AF for the long term but aimed to achieve fusion in the first place. As for the polymers, there were PDLLA/bioactive glass composite foams lately investigated to check cell attachment and phenotype.[114,115,168] These findings provide preliminary evidence for the use of PDLLA/bioactive glass composite scaffolds as cell-carrier materials for future treatments of IVDs with damaged AF region.

6.612.3.4. Biodegradable: Resorbable Materials

6.612.3.4.1. Polymers

More recently biodegradable malic acid-based polyester (poly [1,8] octanediol malate) (POM) was tested as a scaffold for AF replacement using rat IVD cells.[69,169] The POM was synthesized by mixing malic acid and 1,8-octanediol in the appropriate ratios. Recently, other hyaluronan-derived polymers were tested in female pigs[170]: two hyaluronan-derived polymeric substitute materials, that is, HYAFF 120, an ester, and HYADD 3, an amide, were injected into the NP of the lumbar spine of female pigs in which a nucleotomy had also been performed.

Hegewald and his colleagues[171] tested an absorbable PGA biomaterial, which was lyophilized with hyaluronic acid (HA) in bovine, lumbar spinal units. Hydrogels are recently good candidates for intervertebral disk replacement for NP tissue. However, for the AF, the hydrogel approach seems too less stiff and the elasticity is not ideal. In contrast to the NP, any material trying to move with the torsional and compressive deformation of the annulus might fail. It is known that if AF cells are cultured in hydrogels, such as alginate or matrigel, these cells become like NP cells over time.[172] Nevertheless, Shao and Hunter[108] created a scaffold from wet-spinned lyophilized alginate/chitosan. They found the AF cells growing in clusters and spread along the alginate/chitosan fibres. The cells

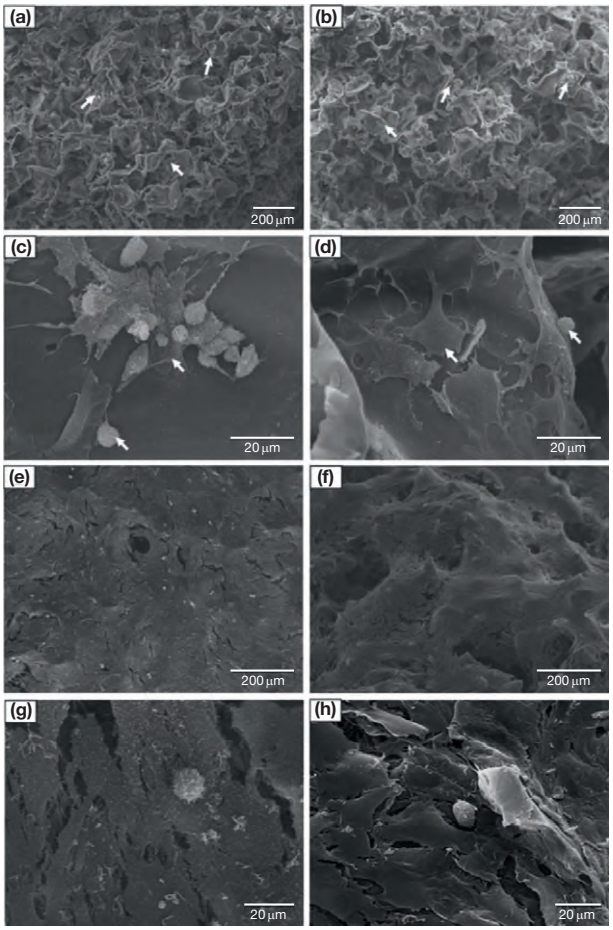

Figure 3 Scanning electron microscopy images of annulus fibrosus cells 24 h (a–d) or 14 days (e–h) after seeding onto nonmodified scaffolds (a, c or e, g) or modified scaffolds (b, d or f, h). Arrows indicate representative cells attached to porous silk scaffold. Reproduced from Chang, G.; Kim, H. J.; Kaplan, D.; Vunjak-Novakovic, G.; Kandel, R. A. *Eur. Spine J.* **2007**, *16*, 1848–1857, with permission from publisher.

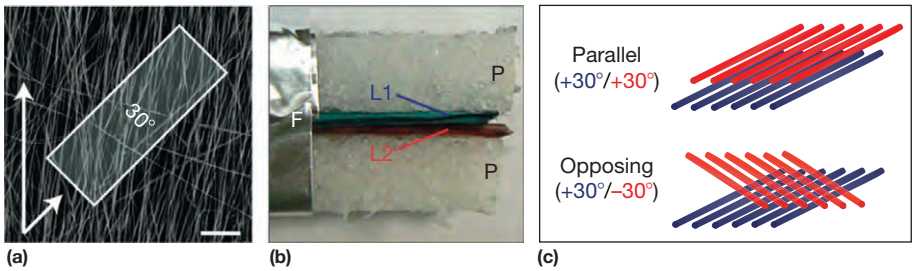

Figure 4 Fabrication of bilamellar tissue constructs. (a) Scaffolds were excised 30° from the prevailing fiber direction of electrospun nanofibrous mats to replicate the oblique collagen orientation within a single lamella of the annulus fibrosus. Scale bar: 25 μm. (b) At 0 weeks, mesenchymal stem cell-seeded scaffolds were formed into bilayers between pieces of porous polypropylene and wrapped with a foil sleeve. P, porous polypropylene; F, foil; L1/2, lamella 1/2. (c) Bilayers were oriented with either parallel (+30°/+30°) or opposing (+30°/−30°) fiber alignment relative to the long axis of the scaffold. Reproduced from Nerurkar, N. L.; Baker, B. M.; Sen, S.; Wible, E. E.; Elliott, D. M.; Mauck, R. L. *Nat. Mater.* **2009**, *8*, 986–992, with permission from the publishers.

expressed collagen I, II, and aggrecan. More elastic a biphasic scaffold to structurally and elastically simulate the AF tissue of the IVD was recently explored by Wan and his colleagues.[69] In this study, the outer phase of the scaffold was a ring-shaped demineralized bone matrix gelatin (BMG) extracted from cortical bone which mimics the type I collagen structure and ligamentous properties of outer AF. The inner phase of the scaffold was a bio-biomaterial poly(polycaprolactone triol malate) (PPCLM) orientated in concentric sheets and seeded with chondrocytes to recapitulate the inner layer of the AF, which is rich in type II collagen and PG.

6.612.3.4.2. Silk and other biomaterials

Silk has been proposed as a major biomaterial to be used as a suture or a tissue construct to close AF lesions and disc herniations.[59,67,173]

The chemical structure of silk is a polypeptide consisting of the amino acid Gly-Ser-Gly-Ala (Glycine-Sericine-Glycine-Alanine). In order to get a high medical grade silk of high biocompatibility and low allergenic reaction, the cocoons of the silk worm *Bombyx mori* (Lepidoptera: Bombycidae) are usually boiled for 30 min in low molar Na_2CO_3 solution and then rinsed with water to extract the contained Sericin, which has been identified to be a major allergen.[174] Sericin-free silk has been successfully applied in orthopedics for decades. Chang and his colleagues[66,67] investigated on different porosity of the silk scaffold for cell spreading and proliferation of AF cells. They also modified their scaffold by linking RGD peptides for better cell attachment. However, they did not find any significant difference in gene expression nor in cell spreading using this modification (Figure 3).

6.612.3.4.3. Collagen fiber scaffolds (electrospinning)

One of the major challenges, which is left for future tissue engineering of the AF, is not to dedifferentiate the cells in culture after *in vitro* culture. It is generally known that primary cells of NP or AF cells are cultured *in vitro* over longer passaging ($p > 6$) that these start to dedifferentiate.[175,176] The AF has a cell density of about 9×10^6 cells cm^{-3} in mature healthy subjects, this is about two times higher than that of the NP.[6,155,177,178]

Electrospun poly-ε-caprolactone has been studied by Nerurkar *et al.*[179] They report that cultured bovine AF cells became elongated over time and that these were aligned along the elongated cells aligned along the predominant fibers direction. Current approach is to electrospin the complex shape of the AF.[68] Figure 4 shows the principle how bilamellar tissue constructs can be formed from nano fibrous mats and how scaffolds are excised in a 30° angle from the prevailing fiber direction to replicate the collagen orientation within a single lamella of the AF.

6.612.3.5. Future Perspective: The Biological AF Replacement

Current approaches for a complete replacement of the IVD with a complete AF and NP seems difficult but may not be unachievable. Current *in vitro* approaches of tissue-engineered organs using stiffer materials such as tendon and AF could be successfully mimicked with biphasic biomaterials with high elastic modulus.[69,180] While 3D printing devices are emerging, which are able to print complex fixable shapes,[181–183] we might only be footsteps away to print a complete AF replacement polymer material along with mixed cells such as preconditioned MSCs.

6.613.1. Introduction

Low back pain is a widespread social and economic problem with 70–85% of people experiencing severe pain some time in their life.[1] When surveyed, one in four adults reports pain within the 3 months preceding the appraisal.[2] For employers, mechanical low back pain is the fourth most expensive medical cost and the most costly musculoskeletal disorder[3] as well as the single largest cause of absence from work.[4]

Disk herniation and changes associated with degenerative disk disease (DDD) are the common causes of low back pain. Herniation of some nucleus tissue past the annular fibers can impinge on nearby nerves causing pain as well as paralysis. If conservative treatment is unsuccessful, a discectomy is commonly performed. In a limited discectomy, the extruded nuclear material as well as a small amount of nucleus that is still within the annulus is removed. In a radical discectomy, the nucleus is completely removed. If insufficient tissue is removed, there is a risk that the remaining nucleus will herniate through the same annular defect; however, removal of the entire nucleus, as in a radical discectomy, may result in instability and acceleration of degeneration.

DDD is a gradually progressing disease characterized by several stages. Early degenerative changes are typically associated with the decreasing ability of proteoglycan within the nucleus to bind water. This affects the capacity of the nucleus pulposus to distribute the intradiscal pressure to the annulus fibrosus as a homogeneous pressure. The depressurized disk is unstable and exhibits excessive motion in the middle stages of this disease. This can cause pain via the motion itself, impingement of the surrounding nerves, or may be chemically mediated. Later stages of the disease involve boney growths connecting the upper and lower vertebrae, limiting or eliminating motion at the affected level. When low back pain of this nature does not respond to conservative treatment, surgical intervention may be unavoidable. Fusion is the most commonly applied treatment for painful unstable disks. It involves the removal of the disk and placement of stabilizing hardware. Bone is encouraged to grow between the vertebrae to eliminate motion simulating the later stages of DDD. The procedure is broadly successful in relieving pain but alters the biomechanics of the spine such that motion that previously occurred at the treated level is transferred to adjacent levels, increasing the stresses and possibly accelerating degeneration in these levels. There are no options following a failed fusion other than another attempt of fusion.

Another option to treat painful disks is total disk replacement (TDR) where the disk is completely removed and a mechanical joint is placed. Motion is retained and this may spare adjacent disks from the excessive loads associated with fusion. This very new procedure is currently only applicable to a small number of patients and does have other drawbacks. Of primary concern is the invasive nature of the surgery. In addition, the motion created in TDR is often very simple and lacks the hysteresis seen in healthy disks. This nonphysiological motion can produce excessive pressure on facet joints, particularly if the implant is not placed properly. The TDR is still evolving, as a result of which it probably still has a limited life span in contrast to other articulating implants, has the potential to subside into the adjacent vertebral bodies, and generates wear particles with the associated problems of biological responses and osteolysis.

Problems associated with discectomy, fusion, and TDR have prompted a focus toward the origins of the disease and treating or replacing the nucleus pulposus tissue with a synthetic material that, ideally, would restore the mechanical function of the nucleus. It would be inserted during the early stages of DDD. Intervention at the early stages of DDD has the potential to stop the degenerative changes in the spine in their tracks and postpone, if not eliminate, the need for more drastic surgeries such as fusion or TDR. The material could be implanted in a minimally invasive manner following complete discectomy or could be used as an adjunct to minimal discectomy where a portion of herniated disk is removed while a portion of the nucleus still within the annulus is removed and replaced by the synthetic material.

This chapter explore the biomechanics of the spine in terms of evaluation, the current standard protocols for treating painful disks, and nucleus replacement materials that are currently being studied for clinical use.

6.613.1.1. Intervertebral Disk

There are three primary components of the intervertebral disk: the nucleus pulposus, the annulus fibrosus, and the endplates of the vertebrae above and below. The nucleus pulposus is a hydrated mass of gelatinous tissue in the center of the disk. The annulus fibrosus is a complex, layered, isotropic ring of fibers that attaches circumferentially to the endplates. Fiber orientation between layers of the annulus alternate orientation by ~30°. The endplates are attached to the boney body of the vertebrae via thin layers of hyaline cartilage similar to articular

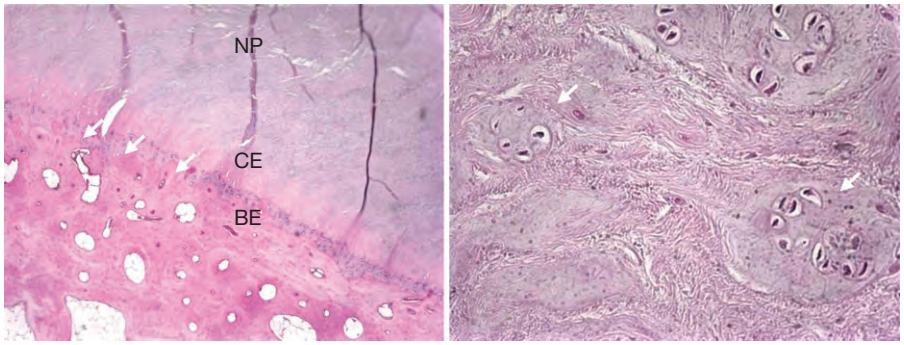

Figure 1 Left: 10× H&E stained section of the transition from nucleus to endplate. White arrows indicate row of densely packed chondrocytes. BE, boney endplate; CE, cartilagenous endplate; NP, nucleus pulposus. Right: 20× image of nucleus pulposus, arrows indicate chondrocytes.

cartilage. This layer is the cartilaginous endplate. Together the annulus and the endplates serve to contain the nucleus. In the healthy disk, an osmotic pressure gradient provides flow to the nucleus.

The intervertebral disk does not contain nervous tissue beyond the outer layers of the annulus fibrosus or the cartilaginous endplate of the vertebral body.[5,6] Blood supply to the vertebral bodies is provided by the precentral arteries which circumnavigate the body, venous return is provided via an external and internal plexus draining from the center of the vertebral body.[7] With no direct vascular supply, the intervertebral disk is the largest avascular component of the human body. The intervertebral disk relies entirely on diffusion for nutrition as well as elimination of waste products. Cells within the nucleus pulposus are sparse (Figure 1) and responsible for the maintenance of the extracellular matrix including proteoglycan.[8]

6.613.1.1.1. Microbiology of the intervertebral disk

Proteoglycans are mucopolysaccharides bound to protein, commonly found in connective tissues, and are plentiful in the nucleus. Proteoglycans are composed of glycosaminoglycans, which have strong water binding abilities. One example of a proteoglycan is aggrecan (Figure 2), which has an important physiochemical role in the maintenance of the hydration levels in articular cartilage with the ability to generate large osmotic pressures.[9] Due to their water binding ability, their spatial concentration correlates closely with water content of the disk.[10]

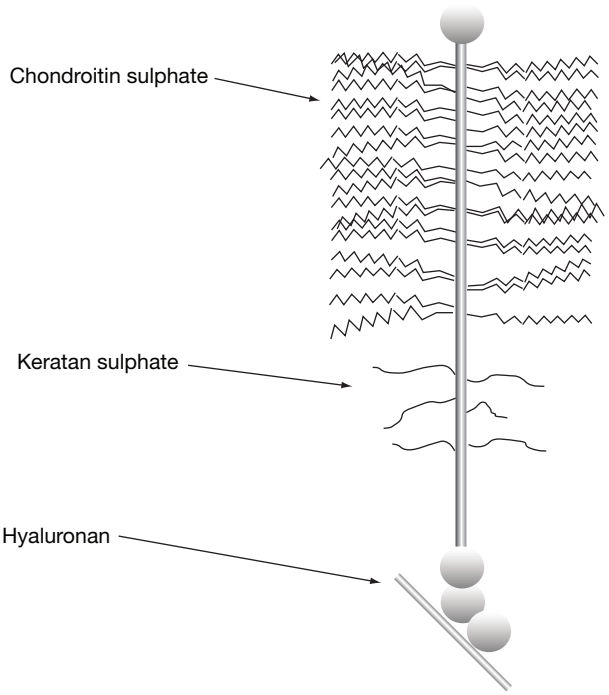

Figure 2 Structure of aggrecan.

6.613.1.2. Biomechanics

6.613.1.2.1. Principle planes/rotations

The intervertebral joints allow motion in 6 degrees of freedom. Translational motion is commonly described along the principal anatomical axes, in the sagittal, coronal, or transverse (axial) planes. Relative rotations between the vertebrae are described about three mutually perpendicular axes at the intersection of these planes (Figure 3). Flexion and extension of the spine occur around an axis perpendicular to the sagittal plane, left and right lateral bending occur around an axis perpendicular to the coronal plane, and left and right axial rotation occurs

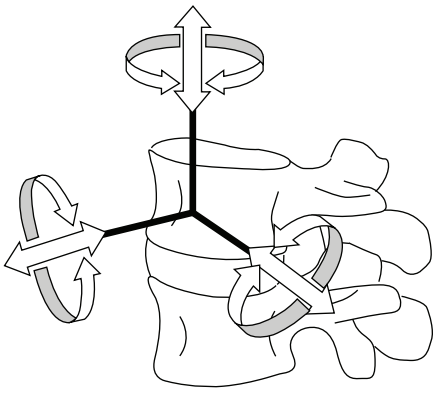

Figure 3 Mutually perpendicular axes for describing rotations and translations of vertebrae.

around an axis perpendicular to the transverse plane. These definitions can be applied to motions relative to the trunk but are more often applied relative to adjacent vertebrae.

6.613.1.2.2. Evaluation of spinal motion

Spinal motion in patients is commonly assessed in the clinical setting via simple range of motion (ROM) tests or radiographic imaging while passively or actively positioning the spine.[11] *In vitro* laboratory tests with cadaveric or animal spinal segments are used to more fully characterize the biomechanics of the spine.

Spinal motion testing can be carried out using either a stiffness protocol or a flexibility protocol. Ultimately, the best method depends on the goal of the test.[12–14] With an unconstrained flexibility protocol, a load is applied and the resulting motions are recorded; no center of rotation or motion path is prescribed. For a constrained stiffness protocol, a motion path or center of rotation is prescribed and forces are recorded. Many of the same values can be determined from either protocol and a load–displacement curve is created for both. Due to the difficulties of accurately reproducing the *in vivo* motion, a flexibility protocol is often employed.[15]

The application of pure moments for torsional tests eliminates off axis loads and allows a segment to determine its own center of rotation. The center of rotation changes throughout flexion and choosing a fixed center of rotation different to the center will affect results.[16] To carry out these tests, a motion segment, consisting of two vertebral bodies and the intervening disk, is mounted into a potting fixture, which is subsequently mounted into a testing machine (**Figure 4**).

These tests may be carried out with pulleys and weights;[17] however, computer controlled servo-hydraulic testing machines provide the ability to quickly change loads and allow the application of tightly controlled loading profiles. Biaxial testing machines may be fitted with special apparati[18] that allow pure moment application or more advanced systems may be employed that allow individual control of motion in all 6 degrees of freedom without adjusting the specimen.[19]

The result of this type of loading will produce a hysteresis curve. This can be divided into four segments as shown in **Figure 5** as loading+; loading from 0 to maximum torque, unloading+; from maximum torque to zero, loading−; the loading portion from 0 maximum negative torque, and unloading−; from maximum negative torque to zero.

Bending moments applied to the disk produce a stiffness curve that is nonlinear and steeper at higher loads than at lower ones. The overall angular rotation of the segment is known as the ROM. Stiffness is calculated from linear regions at the higher loads. The area of lower bending resistance is known as the neutral zone (NZ). There are variations on how this is calculated[18,20–23] but this is described qualitatively as a zone of laxity where a relatively small load will produce a large motion.

Axial load of the spine is shared between the facet joints and the intervertebral disk. Compressive loads directed through the vertebral body are transferred to the nucleus which distributes the force as a hydrostatic intradiscal pressure (**Figure 6**) across the inside of the annulus and the opposing endplate.[24,25]

Intradiscal pressures during activities of daily living have been shown to range between 0.1 MPa while lying prone to 2.3 MPa when lifting 20 kg weight with round, flexed back.[26] The nucleus is capable of opposing these pressures due to the previously mentioned ability to generate an osmotic pressure gradient. This pressure is essential for maintaining the stability of the spine.[27]

The thick collagen fiber bundles of the annulus fibrosus build gradually from the inner border with the nucleus. The organization of these bundles gradually builds as well, with the fibers arranged into individual concentric lamellae with alternating orientation of fibers.[28]

The integrity of this highly ordered and complex structured tissue is essential for maintaining the pressure on the nucleus pulposus.[29] Deformations of the annulus and nucleus are closely linked. The nucleus pulposus is relatively fluid and deforms toward the area of least compression.[30] Anterior rim lesions decrease the ability of the disk to resist bending and rotation. Concentric tears and radial tears have been shown to reduce the hysteresis response indicating an altered stress distribution.[31]

6.613.1.2.3. Viscoelastic properties

The balance between mechanical load and moisture content of the disk is dynamic. With prolonged compression, water is

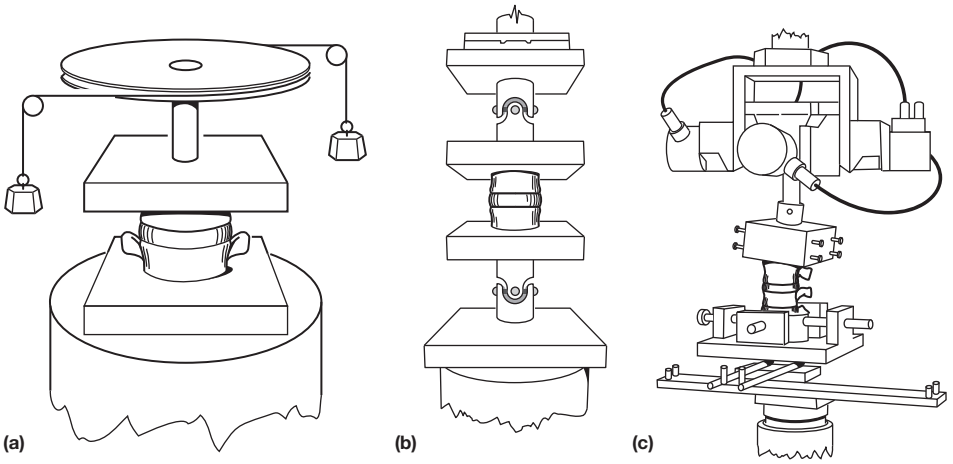

Figure 4 Examples (left to right) of pulley weighted system, system mounted in biaxial testing machine, system with full control of all degrees of freedom.

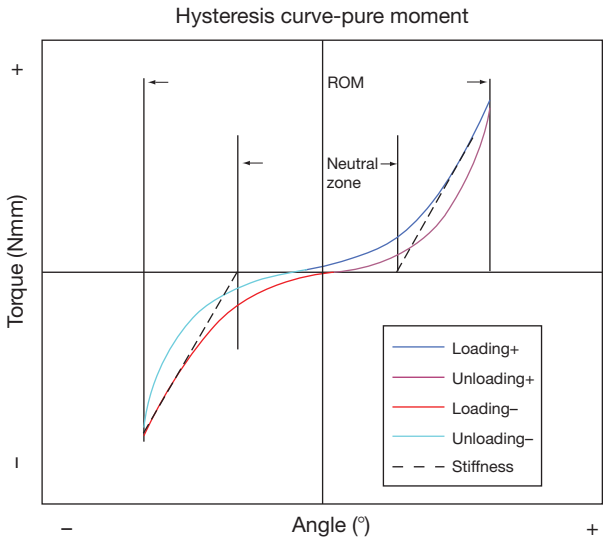

Figure 5 Typical hysteresis curve from torsional tests indicating commonly measured parameters of neutral zone, stiffness in the linear range of the loading curve and range of motion.

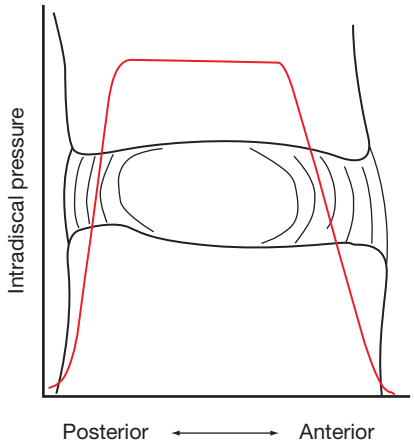

Figure 6 Pressure distribution across in the intervertebral disk.

driven out of the nucleus through the cartilaginous endplates and, to a lesser degree, the annulus fibrosus. This loss of fluid from the nucleus decreases intradiscal pressure requiring the annulus to bear more of the load.[32] *In vivo* the disks experience diurnal fluid transport during periods of sleep and waking by a volume of 1300 mm^3[33] corresponding to changes in disk height. Work by Iatridis *et al.*[34] quantified these properties in nucleus tissues, showing near fluid-like behavior under static loading with stress relaxation approaching zero, while dynamic modulus ranged from 7 to 20 kPa with loss angle ranging from 23 to 30°.

6.613.2. Ageing and Disk Injury

There are several conditions that may require intervention with respect to the intervertebral disk. Here, we will explore two of these: DDD and herniation.

6.613.2.1. Degenerative Disk Disease

DDD is characterized by many features that, given enough time, will play out naturally with aging. DDD is perhaps best described as an acceleration or exaggeration of these changes. From birth, the density of cells with notochordal origin in the intervertebral disk drops and approaches zero by ~6 years of age.[35]

Upon reaching skeletal maturity, the nucleus is populated by sparse chondrocyte-like cells with unknown origin. The disk at this point is completely avascular and completely reliant on diffusion and osmosis for obtaining nutrients and eliminating waste. This is a delicate system where the perimeter of the disk is important, and the rate of diffusion and osmosis is heavily influenced by mechanical loading.[36]

6.613.2.1.1. Causes of DDD

There are several risk factors for developing DDD. These include daily environmental factors such as driving vehicles with unsprung seats[37] and lifting very heavy objects,[38] especially in confined spaces.[39] There are also a number of morphological factors that affect the likelihood of developing DDD. Disks with low disk area in cross-section and large disk height are prone to larger motion, higher annular fiber stresses, and larger disk bulge, making them more likely to encroach on neural space.[40–42] Disks with concave endplates have a superior outcome, flat endplates do worse, and irregular endplates have the worst prognosis for DDD.[43,44] Several genetic factors have also been identified within certain populations[45–47] with hereditary effects explaining 47–66% of the degenerative changes.[48]

6.613.2.1.2. Morphologic changes

Following maturity of the disk, DDD is marked by specific morphological and microbiological changes. A healthy disk contains a moist nucleus pulposus, clear delineation between the annulus and vertebrae with rounded margins.

During the middle stages of DDD, the nucleus loses water content and becomes more fibrous.[49–51] Disk height decreases and the margins of the vertebrae above and below may develop osteophytes.[52,53] During more advanced stages, the nucleus will be considerably dehydrated with osteophytes (**Figure 7**) joining together, fusing the vertebral bodies around or through the intervertebral disk.[54]

6.613.2.1.3. Biomechanical changes

Accompanying the changes in the morphology of the disk are alterations in the motion of the spinal segments. Hypermobility has been seen in patients with back pain[55–57] as well as increased asymmetrical motion.[58,59]

A key cofactor of joint instability is the loss of intradiscal pressure, which accompanies DDD.[60] This loss of intradiscal pressure is due to the dehydration of the nucleus pulposus. The degenerate nucleus is less able to maintain its hydration resulting in increased NZ and ROM, and altered viscoelastic properties.[22,61–64]

The progression of DDD dictates that in the early and middle stages of degeneration, abnormal motion and motion in general are increased. In the later and final stages, the mobility decreases and may cease at the affected level completely.[65–67]

Figure 7 Sagittal radiograph of the lumbar spine, note increasing osteophytes from superior to inferior.

6.613.2.1.4. Microbiological changes

The loss of intradiscal pressure due to its dehydration is central to the degenerative process. The axial mechanics of the disk show a correlation between glycosaminoclycan content and decreased viscoelastic properties and increased NZ.[61] Lack of proteoglycan content decreases the ability of degenerated disks to maintain an osmotic pressure gradient.[64] Accompanying this are changes in the permeability of the boney endplates.[68]

6.613.2.1.5. Pain

Although pain is not invariably associated with DDD,[69] those patients who do experience pain often have a significantly decreased quality of life with local or radiating pain, increased analgesic intake and decreased mobility.[70] One cause of radiating pain in patients with DDD is impingement of nerve branches as they exit the spinal canal. This commonly affects the sciatic nerve and consequently is known as sciatica. In this condition, the decreased height of the disk and the associated changes in the facet joints lead to a smaller intervertebral foramen for the sciatic nerve to exit. Compression of this nerve presents as radiating leg pain with numbness, and possible weakness.[71] DDD may also cause to diffuse pain originating from the disk. The mechanism of this pain is not well understood although it may be chemically mediated.[72,73]

Segmental instability is also associated with lower back pain.[55] In the healthy spine, motion is kept within a pain free zone. It is believed that motion is increased to an extent that causes pain. If this motion is reduced back to the range of normal function, then pain is likely to be alleviated.[74]

6.613.2.2. Herniation

Although not necessarily a requisite for DDD, herniation of the nucleus pulposus beyond the confines of the annulus fibrosus is oftentimes associated with DDD and pain. Herniation may also serve as an injury that acts as an initiator for further degeneration of the disk, as many of the associated aspects such as morphology, microbiology, risk factors, etc., are similar.

6.613.2.2.1. Causes

As just stated, many of the risk factors for herniation are similar to those of DDD. The injury is usually caused by a high compressive or a high combination loading of the disk. Following from this, one of the risk factors is the lifting of heavy objects, with arms extended and while twisting.[75] Driving for extended periods is also associated with increased risk of herniation.[76,77] Disks with low area in cross-section and large disk height are prone to herniation.[78] Genetic factors also play a role.[79,80]

6.613.2.2.2. Morphological/radiographic/soft tissue changes

Herniations of the posterior annulus are the most common. In these cases, it is possible that herniated disk tissue can compress nerves exiting the intervertebral foramen causing weakness, tingling, or pain.

6.613.2.2.3. Changes in motion

An annular breach causes a loss of intradiscal pressure and similar biomechanical consequences to those of the dehydrated disk found in DDD. These include increased NZ and ROM and decreased viscoelastic properties.[22,61–64] Just as in DDD, the decreased intradiscal pressure and excessive motion increase the stresses on the annulus.[81,82] Over half of all herniations decrease in size over time with larger herniations more likely to regress than smaller ones.[83]

6.613.2.2.4. Microbiological changes

Failure of the annulus interferes with the normal diffusion in the disk similar to the way it does with endplate defects during DDD.[84,85] Herniated tissue is exposed to inflammatory mediators and becomes vascularized and may induce further vascularization toward the center of the disk.

6.613.2.2.5. Pain

The source of pain in herniated patients may be attributed to similar sources as those of DDD including those of chemical origin, mechanical overload, inflammatory mediators, or nerve effects,[86,87] but it is often associated with sciatica.[88]

6.613.3. Treatment Options

Treatment options for DDD include conservative treatment, discectomy, laminectomy, fusion, and TDR. Herniations are more commonly treated with less aggressive procedures, either conservatively or with discectomy. The treatment of nucleus replacement is at the horizon, but is not an established approach in the clinical armamentarium. The goal of all these procedures is to reduce or eliminate the source of the pain specific to each case. The treatments vary in invasiveness as well as the intended outcome and mechanism for relieving pain. They are chosen based on patients' symptoms, history, age, lifestyle, and the predicted outcome of the surgery.

6.613.3.1. Conservative Treatment

The current, initial treatment for both painful DDD and herniation is a conservative treatment involving initial rest followed by exercise to strengthen core spinal stabilization muscles. Nonsteroidal antiinflammatory drugs may be taken orally, and epidural, transforaminal, or interlaminar steroid injections may be prescribed for acute episodes of pain.[89–92] These treatments are aimed at decreasing inflammation but do not address the degeneration of the disk.

6.613.3.2. Discectomy

Discectomy is often the first course of surgical intervention for a herniated disk. Indications for discectomy are severe radiating pain which is unresponsive to conservative treatment for greater than 6 weeks, signs of neural deficit, and herniation as identified by discography or MR.[93,94]

6.613.3.2.1. Surgical procedure

Discectomy is the removal of the greater part, or a portion of the nucleus pulposus while leaving the majority of the annulus fibrosus intact. It can be performed as an open or an endoscopic procedure. A small window is made into the annulus and nucleus tissue is removed using a ronguer.[95]

6.613.3.2.2. Outcome

The outcome of the discectomy procedure is generally positive in terms of pain relief,[94,96,97] but this fades over time.[93,98] Patients show a high level of satisfaction and over 80% return to work rate although reoperation rates of around 15% are common.[98–101] However, revision discectomies have been shown to be just as effective at relieving pain and numbness.[97] Carragee *et al.*[102] have investigated the type of herniation and its effect on patient outcome. Annular competence as well as fragmentation of the herniated tissue was shown to be important for overall outcome.

6.613.3.2.3. Radical versus limited discectomy

One issue relating to the discectomy procedure is how much nucleus should be removed during the surgery (**Figure 8**). The radical removal of disk material decreases the possibility of reherniation by minimizing the chance that leftover disk material might become the source of another disk protrusion.[103,104] However, preserving as much disk material as possible shows better maintenance of hydration over the long term[105] and that radical discectomy is related to decreased disk height.[104,106]

6.613.3.3. Total Disk Arthroplasty

Implantation of a TDR involves the removal and replacement of the annulus fibrosus, nucleus pulposus, and generally the endplates of the adjacent vertebrae. A mechanical replacement is inserted into the void left by the disk. Implants marketed in the United States include the Charité III (Johnson & Johnson) constructed of cobalt chromium (CoCr) alloy endplates and a sliding PE insert and the ProDisc II (Synthes) composed of ultra high-molecular-weight polyethylene inlay sandwiched between upper and lower cobalt–chromium–molybdenum (CoCrMo) endplates.

As well as providing an earlier return to activities,[107,108] the major advantage of the TDR over fusion (discussed in following section) is the retention of motion at the affected level.[108–110] The retention of this motion requires less motion of the adjacent disk in comparison to fusion.[111] As mentioned previously, this excessive motion has been connected to degeneration at adjacent levels.[112] Total disk arthroplasty is still in an early phase of development and long-term studies to establish longevity and optimize design are lacking.[113–115]

6.613.3.3.1. Surgical technique

Implanting a disk replacement requires intensive surgery.[116,117] The implant is generally placed via an anterior approach, which requires the mobilization of the descending aorta and vena cava for L4–L5 and L3–L4 disk replacements. The endplates of the vertebral body are roughened or removed following the removal of the disk and the implant is placed.

Early[107,118] and midterm results are promising;[119] however, there are some drawbacks. The procedure is only applicable to a small portion of those with painful disks.[120] TDR also carries potential complications including damage to the genitourinary tract, injuries to the ganglia running along the anterior portion of the spine, and paralysis due to injuries to any of the nerves located along the anterior approach,[121] and vertebral split fractures.[122]

While these motion sparing implants have been shown to retain or even increase ROM quantity,[123,124] the quality is not necessarily retained.[125] This motion also generates wear particles, which have been associated with subsidence, migration, and adjacent fusion.[126–128]

6.613.3.4. Fusion

Intervertebral fusion involves surgery to induce a union between upper and lower vertebrae, thereby fusing the vertebrae. The goal of the surgery is to eliminate motion that may be causing pain. Spinal fusion is a well-established procedure that is applicable to a large portion of the patient population for a number of disorders.[129,130] Two common fusion techniques are posterolateral fusion and interbody fusion. Posterolateral fusion is achieved by placing bone graft between the transverse processes to eliminate motion between the posterior elements. Stabilizing hardware may also be used.

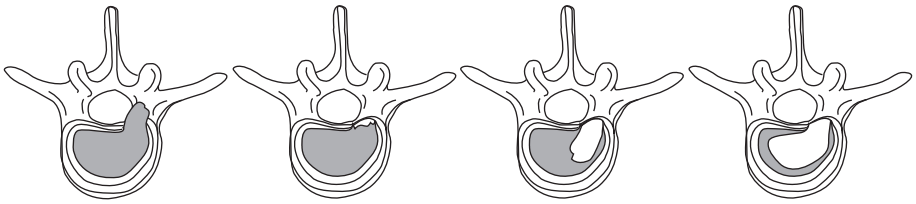

Figure 8 Nucleus present following (left to right): hernation, removal of herniated portion, limited discectomy, and aggressive discectomy.

Interbody fusion is achieved by placing graft between the vertebral bodies, often following discectomy. The objective is to form new bone between the vertebral bodies, through the endplates, and eliminate motion. Hardware generally used in this procedure may include fusion cages or pedicle screws, or bone graft alone may be used.[131]

Lumbar fusion has drawbacks, perhaps the most important being the extent to which it alters the biomechanics of the spine and, subsequently, the strains experienced in the surrounding tissues. Successful fusion results in either a significantly reduced amount of motion or no motion in the treated level. To maintain the overall ROM of the spine, the adjacent levels are required to compensate. This results in increased motion at these adjacent levels,[111,132] which induces increased stresses and intradiscal pressure,[132] which may, in turn, accelerate the degenerative process at these levels.

6.613.4. Nucleus Replacement

Replacing the nucleus pulposus has the potential to provide several benefits over traditional treatments. When compared to fusion, nucleus replacement has the advantages of being a minimally invasive procedure and retaining motion. In addition, there are few options after a failed fusion. However, if pain persists following nucleus replacement, TDR and fusion remain viable options for pain relief. Nucleus replacement most often uses the same surgical approach as discectomy, is generally no more invasive, and normally follows a discectomy. The retention of the endplates and annulus while replacing the nucleus with a material possessing viscoelastic properties similar to that of the healthy nucleus would be expected to reproduce more physiologic motion than TDR without the highly invasive anterior approach to the spinal column and the drawback of accumulating wear particles. In discectomy without nucleus replacement, there is no outward pressure applied to the endplates and inner annulus to place its fibers in tension. Without this pressure, the fibers bulge inward and are subjected to compressive forces between the endplates, and disk height is reduced.[106,133,134] With nucleus replacement, a discectomy would be performed to remove the ailing nucleus, and the nucleus replacement would be placed to restore disk height, avoiding further stenosis and associated pain generators. Ideally, this would decelerate the degenerative cascade and thereby postpone or prevent the need for more invasive interventions such as TDR and fusion.

Nucleus replacements require a patient to have largely intact and functioning annulus and endplates free from significant defects as well as healthy facet joints and greater than 5 mm disk height.[135] This excludes cases of advanced degeneration; significant loss of disk height may be difficult to restore. The ability to mimic the function of the intact nucleus is the ultimate goal of any nucleus replacement. An implanted material would need to resist expulsion through any fissure or injury, or through any incision or defect created during implantation. It would need to resist compressive forces between the vertebrae and be able to maintain properties through millions of cycles of loading/unloading produced through normal human activities of daily living.[134]

To date, several diverse designs have been conceived for nucleus replacement. They can be categorized into solid preformed implants, hydrogel preformed implants, externally inflated implants, and injectable implants.

6.613.4.1. Solid Preformed Implants

The first attempts at replacing the nucleus while maintaining the majority of the annulus were not entirely successful. In 1959 Harmon *et al.*[136] implanted spheres of a corrosion resistant alloy made of CoCrMo known as Vitallium®. This device was originally known as the Harmon sphere and was implanted after an open discectomy as a nucleus replacement but was eventually classified as a fusion device due to the spontaneous fusion occurring in some of its recipients.

A more extensive clinical evaluation was carried out by Fernstrom[137] and Reitz and Joubert[138] with respect to the use of metallic spheres as nucleus replacements. The Fernstrom ball was a simple stainless steel ball bearing, 16–10 mm in diameter, that was inserted through an annular incision following discectomy under local anesthetic. The device was implanted in over 100 patients, and although the results were acceptable, the significant difference in the mechanical properties of the native nucleus and stainless steel led to the subsidence of the ball into the vertebral body. Although the device was not successful, the concept of retaining the annulus and motion was explored. This, by itself, represented a meaningful advance.

The ball theme was modified by Gau *et al.*[139] who incorporated one or several balls which are hard, smooth, and non oxidizing into the design of a nucleus replacement (**Figure 9**). The balls were arranged into a cage in which they were freely movable. This design would likely limit the amount of subluxation into vertebral endplates but its size and shape would make it difficult to implant. Bryan *et al.*[140] created a unique shape and function in his peanut spectacle design. The device consisted of two peanut shaped shells containing resilient bodies.

Lawson *et al.* conceived two designs with anchorage to the inferior vertebrae. The first design was a flattened oval disk with convex surfaces (**Figure 10**). The bottom peg can be

cemented.[141] The second design had a separate keel of porous metal for fixation and was free to rotate about this keel.[142]

In an effort to completely fill the disk space following discectomy while limiting the damage to the annulus, Felt *et al.*[143] outlined a modular nucleus replacement (Figure 11). The unassembled pieces were inserted through the posterior annulus and interlocked *in situ*. The inner cores are to be constructed of polyvinyl alcohol (PVA) while the outer shell would be constructed of a polymeric material. Ferree *et al.*[144] also perceived modular designs (Figure 12) as well as several other concepts, one unique design[145] incorporated an annular or donut shape.

Recently, Kettler *et al.*[146] have studied implants consisting of knitted titanium filaments *in vitro* following discectomy. Biomechanical testing revealed that intact ROM was nearly restored after implantation. However, in axial rotation and extension, the ROM increased slightly with the implant. ROM in flexion decreased. Some of these changes in motion could be affected by the large annulotomy, spanning nearly two-thirds anterior aspect. Although there was no extrusion of the device, cyclic testing did cause increased ROM in all loading planes.

Biomet EBI scheduled an IDE study for the Regain Lumbar Artificial Disc (Figure 13), and preliminary testing in baboons has been completed.[147] The device is constructed of pyrolytic

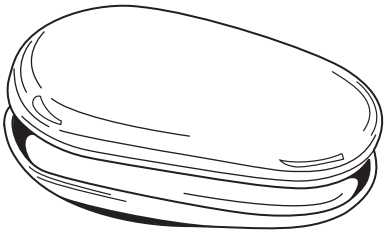

Figure 13 Depiction of regain lumbar nucleus replacement.

carbon, more detailed descriptions of carbon constructs can be found in **Chapter 1.107, Carbon and Diamond**; **Chapter 5.523, Carbon Nanotubes: Applications for *In Situ* Implant Sensors**; and **Chapter 3.330, Carbon Nanotube-Based Sensors: Overview**. The shape of the device has been carefully crafted so that it seats itself in a concave endplate while causing minimal subsidence. This makes patient selection based on endplate morphology an important factor for success of the implant. The 15–17 mm anterior incision required for insertion is likely to increase the likelihood of expulsion; however, this is offset by a shape designed to prevent migration. The device has been implanted in 10 patients and 3-month follow-up demonstrated increased disk height and decreased pain but no improvement in lumbar motion.[148]

6.613.4.2. Preformed Hydrogel Implants

Hydrogels are cross-linked macromolecular networks formed by hydrophilic polymers. As they are described in **Chapter 1.131, Superporous Hydrogels for Drug Delivery Systems**; **Chapter 1.132, Dynamic Hydrogels**; and **Chapter 3.329, Hydrogels in Biosensing Applications**, they will only be explained briefly with respect to nucleus replacement here. They are an attractive replacement material as they can be engineered to mimic the mechanical properties of the native nucleus, all while having a low level of immunogenicity. They have the ability to attract water and swell, thereby generating an osmotic pressure similar to what the native cells in the nucleus pulposus experience. Hydrogels are categorized as chemical or physical hydrogels, based on the type of bonding in the cross-links. Physical hydrogels are maintained by cohesion forces such as ionic bonding, hydrogen bonding, Van der Waals forces, and forces that arise during hydrophobic interactions. These can be produced by a number of methods including exposure to heating and cooling cycles.

Chemical, or permanent, bonds cannot be dissolved in water or solvents. This bond can be achieved by copolymerization of a monomer with a cross-linker, irradiation, free radical polymerization, thermal initiation, catalyzed initiation as well as other methods. The extensive control of cross-linking that can be achieved by chemical bonding is attractive. However, the toxic effects of residual monomers used for the hydrogel polymer synthesis are a potential drawback.[149]

Bao *et al.*[150] were among the first to use hydrogel as a substitute for nucleus replacement when proposing polyacrylonitrile hydrogels be implanted in a dehydrated state. Dehydration can decrease the implant size by more than half of its hydrated state. The isotropic swelling ability of the hydrogel permitted it to be inserted at a smaller size and to expand after insertion. In principle, this allowed a smaller annular defect to be created during the

procedure, and it provided the ability to generate a lifting pressure between the vertebrae after implantation.

After insertion, there is an annular defect and the path of least resistance will be in the direction of that defect. To counteract any possible extrusion effect, as well as annular bulging, the hydrogel may be preformed or otherwise constrained to promote expansion in the axial direction. Bao's design was intended for implantation in single or multiple preformed dehydrated pieces (Figure 14). A coiled design was later introduced to combat lateral bulging[151] while another version incorporated hydrogel pellets restrained by a woven bag.[152]

While the hydrophilic properties of hydrogels are initially appealing, the reversible nature of this water absorption may be a limitation. The implant is inserted in a tissue with limited fluid flow, which is in a diseased state, and in which water binding is compromised. Additionally, the deformational characteristics of hydrogels typically limit the ability to withstand bulging and expulsion.

One of the most used nucleus replacement to date has been the prosthetic disk nucleus (PDN) (RayMedica).[153–156] The PDN is a hydrogel core encased in a woven polyethylene jacket. The formed hydrogel pellet is a copolymer of polyacrylonitrile (nonhydrophylic) and polyacrylamide (hydrophilic) sustained by physical cross-links in a ratio that achieves a maximum of 80% water weight at full saturation. The hydrogel allows the implant to be dehydrated prior to implantation after which it regains hydration and increases disk height. The jacket limits the maximum expansion and radial bulge of the hydrogel. The device has been modified many times (Figure 15), reflecting the difficulty of optimizing this device with its underlying design principle. It was originally designed as a single implant then modified to include two, then the orientation was altered so that placement was lengthwise left to right rather than front to back, then a single, larger, and wedged implant was designed.[155,157–161]

Laboratory studies on motion segments have shown that following discectomy the PDN can restore compressive stiffness, viscoelasticity, disk height, and ROM *in vitro*.[162]

The PDN was first implanted in 1996, in Germany.[155,157] Results of early clinical trials showed a high rate of device migration.[153,156] Little data are available regarding longer term outcomes; however, a small series with follow up at 4 years showed subsidence in all cases although disk height and Oswestry scores remained improved for most patients, and none required surgical intervention.[163]

Patient selection now requires a minimum of 5 mm disk height, healthy endplates, and minimum diameter of the disk. The size of the implant requires an enlargement of the annulotomy formed to remove the nucleus. This is done by cutting an annular flap and suturing it back into position afterward.[154] The large annulotomy and the fact that the PDN does not fill the nucleus void completely are, however, significant drawbacks and have interfered with achieving a clinically effective device.

Replication Medical, Inc. developed NeuDisc.[164,165] NeuDisc produces controllable swelling of the hydrogel/fiber implant by internal restraint. The cylindrical implant also uses polyacrylomitrile hydrogel in a stacked design with layers of polyester fiber mesh interposed. The mesh restricts the radial bulge of the implant and therefore the outward bulge and pressure on the annulus. The implant is dehydrated and rolled for insertion (Figure 16) through the anterolateral annulus following discectomy and has successfully survived cyclic testing to 10 million cycles.[166,167] Clinical results are, as of yet, not available.

The axially directed lifting force is advantageous to increasing disk height but the incomplete filling of the nuclear space is nonphysiological and may lead to compression and inward bulging of annulus fibers.[168] In this context, it may be apparent that surgical placement is challenging.

Another company, Zimmer Spine developed NewCleus (Figure 17), a polycarbonate urethane elastomer with a spiral configuration.[169] The material absorbed up to 35% of its net weight in water once implanted. The spiral allows a small

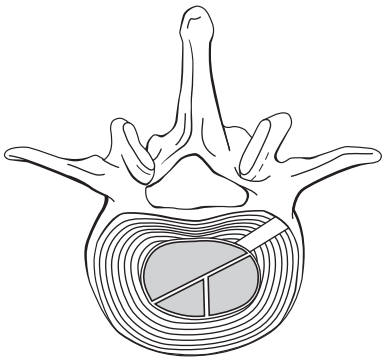

Figure 14 Interpretation of Bao's preformed hydrogel.

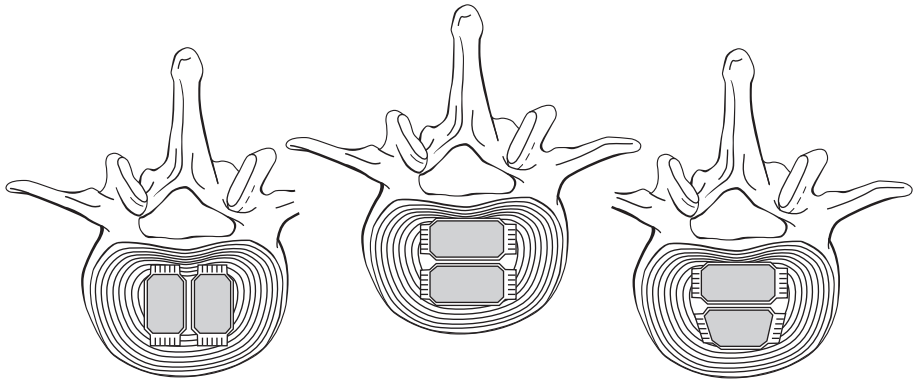

Figure 15 Different PDN designs and implanted positions.

incision relative to the size of the implant while having no fixed axis once implanted so that it does not need to be centrally located. Five patients have currently received the implant and, at 2 years, show improved postoperative pain and function with no signs of migration; however, there were some signs of changes in MRI signals in adjacent vertebrae potentially due to changes in loading.[135,169,170]

The Aquarelle hydrogel nucleus (Stryker Spine) is an unrestrained PVA bead (Figure 18) bound by physical cross-links.[171] It has been tested in two sizes; 0.1 and 0.3 cm^2 and is inserted through a 5 mm cannula using a lateral or posterior technique. Early tests in baboons revealed high extrusion rates, but no device related pathology at 2 years. The high extrusion rate of the implant may be due to the relatively high hydration at the time of implantation, requiring an annular defect similar to the implants size, as well as the rounded pill shape.

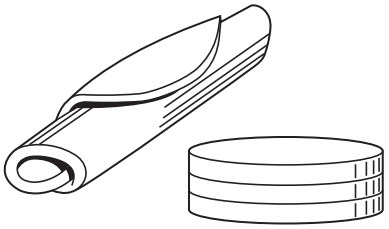

Figure 16 Depiction of NeuDisc rolled and dehydrated for implantation and in its hydrated state.

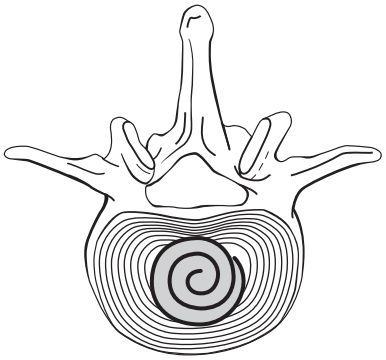

Figure 17 Diagram of implanted NewCleus.

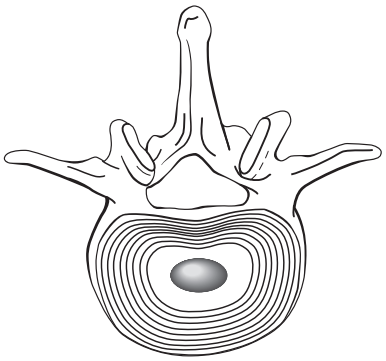

Figure 18 Diagram of implanted Aquarelle.

6.613.4.3. Externally Inflated Implants

Externally inflated implants require a smaller annular defect to insert than preformed implants while still achieving an inflated size that will prevent extrusion. The ability to be inflated decreases the need for the implant to generate a lifting force once implanted as they can be externally pressurized. Early designs that incorporate external filling include Froning's design[172] which used a plastic bladder implanted posterolaterally with anchorage to the endplates centrally, Krapiva's design[173] consisted of a flexible disk that was implanted in a hollow state and expanded *in situ* and then filled with a gel, and a variation of the coiled design by Baumgartner[174] which used a coiled elastic material with a central chamber that was filled with fluid (Figure 19).

More recently, Wardlaw *et al.*[175] has worked on a design similar to Froning's, with a woven outer or porous fabric bag containing hydrogel that allows the removal or addition of filler material after implantation. The outer bag is complex with several layers supporting transudative or ion transport. The outer surface would allow fibrous tissue ingrowth and water transport but not bone ingrowth.

The most current inflatable design is a continuation of the bag design (Figure 20)[176]; DASCOR® (Disc Dynamics, Inc.), which is an inflatable balloon delivered via a catheter and inflated with a polyurethane that is cured *in situ*. Following discectomy, the device is inserted and inflated to a desired level of vertebral distraction, the balloon is removed and another is placed which is filled with polyurethane activated with diisocyanate cross-linker that polymerizes in minutes (Figure 21).

Figure 19 Depiction of Baumgartner's inflatable device as it is implanted.

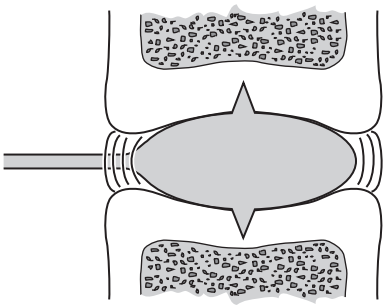

Figure 20 Variation of Bao's implantable design incorporating endplate spikes.

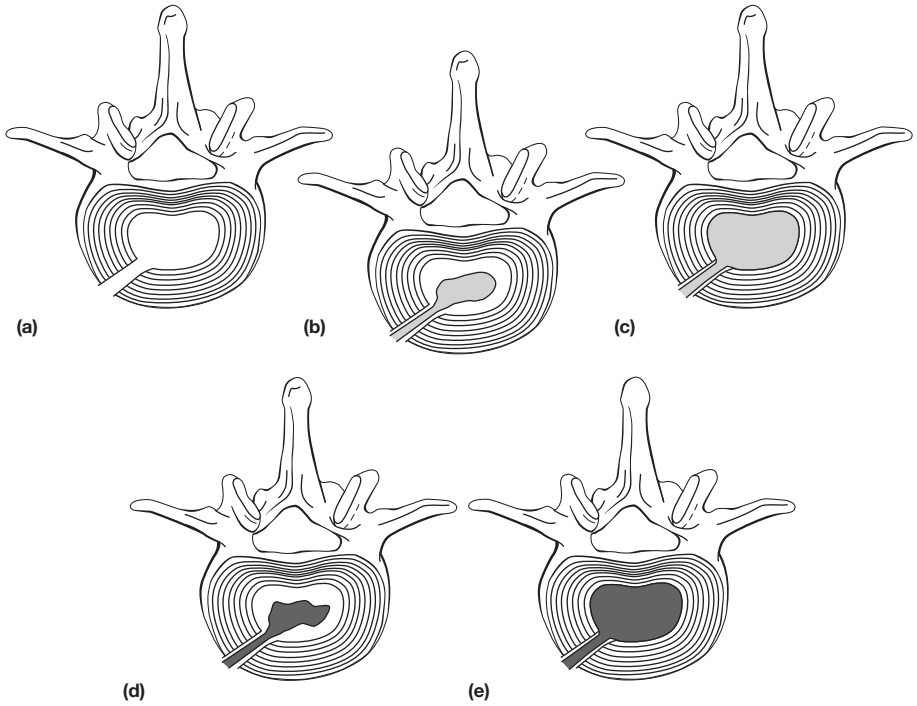

Figure 21 Implantation of the DASCOR device: (a) discectomy, (b) sizing/diagnostic catheter inserted, (c) balloon filled with contrast solution, (d) the final catheter inserted, and (e) mixed polymer injected, cured and the catheter is cut off.

Clinical studies with 2 years of follow up show decreased pain and increased function and maintenance of disk height.[177] Mechanical testing of cadaveric motion segments showed that the use of a cured polymer, restored mechanical properties better than the use of water.[178]

The use of an inflatable bag has the advantage of more completely filling the defect than preformed implants with a final shape that is unique to each patient. However, the constraining bag does not facilitate transport of nutrients, which may be a concern for the nutrition of residual disk tissue.

6.613.4.4. Injectable Implants

The first injected nucleus replacements were performed in 1956 by Cleveland *et al.*[179] injecting polymethylmethacrylate (PMMA) into the disk space following discectomy. PMMA is commonly used as bone cement in joint replacement arthroplasty. It is a relatively stiff polymer used to anchor the implants in the bone structure. This concept led to clinical results that were similar to fusion with arrested motion and pain. Yet, there was also some tissue damage arising from the exothermic reaction of the curing polymer.[180] Long-term (10–15 years) results were published and the procedure was less invasive than more traditional fusion although it had the same disadvantages as fusion.[181]

In 1962, Nachemson *et al.*[182] attempted to replace the nucleus with a more pliant material. In laboratory tests, vulcanizing silicone was injected into cadaveric disks after discectomy and showed some return to original properties. Unfortunately, after repeated testing, the rubber failed. The contribution from these studies is that these tests showed that the mechanics of the disk could be restored by replacing the nucleus tissue with a flexible material cured *in situ*.

In situ curing of an unconstrained nucleus replacement is an attractive idea, and the area is currently receiving a great deal of interest, particularly by using *in situ* setting hydrogels. By adjusting the ratio of PVA and polyvinyl pyrrolidone (PVP), hydrogels have shown the ability to return mechanical properties and height of the disk that are lost through denucleation.[183,184] Cloyd *et al.*[185] and Revell *et al.*[186] have shown that hydrogels based on hyaluronic acid (HA) have the ability to mimic modulus, Poisson's ratio, and stress relaxation properties of the nucleus. Leone *et al.*[187] have shown that hydrogels composed of modified polysaccharide cross-linked with diaminopropane also exhibit the thixotropic behavior of native nucleus tissue. This behavior was identified in the nucleus by Iatridis *et al.*[34,188] as the ability to behave as a liquid under certain mechanical conditions and as a solid under different conditions. Other researchers are working on adding clinically advantageous aspects such as radiopacity.[189,190]

The major advantage of using an injectable material is the small access required. The ability to inject through a small cannula or needle necessitates only a minute annular defect which will increase the maximum pressure that can be borne by the residual annulus.[191] Whereas the size of an inflated implant reduces the risk of extrusion, a material injected as a liquid and curing to a gel *in situ* has the ability to fully interdigitate with remaining tissue prior to curing. This intimate contact reduces the risk of extrusion and would theoretically function more like the intact nucleus.[184] There are several groups focusing on advancing these concepts. Patenting activity in this area is high with patents issued for injectable *in situ*

curing keratin hydrogels, hydrogels cross-linked by pH, temperature, exposure to moisture, for PVA/PVP combinations, and elastomers.[192–196] These materials are, however, still hydrogels, which will meet the same challenges as mentioned when describing the preformed hydrogels.

CryoLife, Inc. is developing an injectable hydrogel made from purified bovine albumin and glutaraldehyde called BioDisc. The material is injected following discectomy and eventually absorbs 63% liquid by volume. The unique makeup of the BioDisc allows covalent bonding to annular tissue. It is injected as a liquid and gels in 2 min with negligible exothermic reaction. Mechanical tests have shown restoration of disk height and stability in bovine specimens through 10 million cycles[197] and early results of a 10 patient trial have been positive for reduced pain and increased function.[198] One issue that may affect the results of the device is the toxicity of the activator agent, glutaraldehyde.[199,200]

Cohen *et al.*[201,202] have synthesized an injectable *in situ* nucleus replacement not based on hydrogel concepts. Viscoelastic behavior akin to that of the native nucleus is achieved using emulsion technology concepts. The DiscCell polymer emulsion cures in 5–7 min and is injected in a minimally invasive manner. Current work focused on establishing the biocompatibility of the material and the determination of the mechanical behavior under a range of physiologically relevant loading conditions. The material is radio-opaque making image guidance a useful tool to provide feedback on the amount of material injected and the placement of the material (**Figure 22**).

One can show that extended compressive loading will change the mechanics of the intervertebral disk *in vitro*; in fact, NZ and ROM are increased and disk height is lost. The injection of DiscCell, however, reverses these changes; that is, the disk height and NZ laxity are restored to conditions equal to or beyond the initial parameters.[203] These data support the notion to restore the biomechanics of disks in the middle stages of DDD and may obviate the need for discectomy completely.

SpineWave Inc. has developed an injectable nucleus device known as NuCore™. The protein polymer hydrogel is a copolymer of silk and elastin with one modified elastin block per mer for chemical cross-linking and two silk blocks and seven additional elastin blocks. The protein polymer is created through chemical DNA synthesis, produced by *Escherichia coli* through fermentation. The material is intended as a total or partial disk replacement, is mixed with hexamethylene diisocyanate cross-linker prior to injection, and cures *in situ* under pressure. The material has a working time of ~90 s, primary curing occurs in 5 min with full curing in 30 min. The hydrogel has the additional benefit of being adhesive to the residual disk tissue.[204]

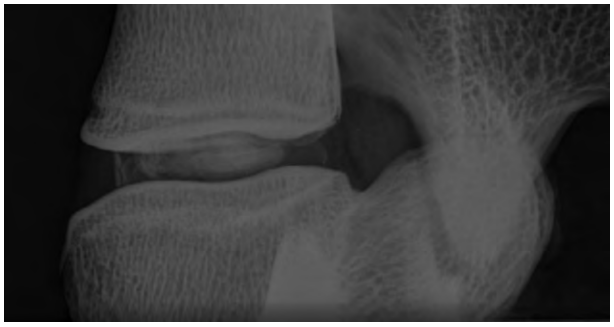

Figure 22 Sagittal radiograph of sheep disk with DiscCell implanted.

Pelletier *et al.*[205] have developed an ovine discectomy model to evaluate nucleus replacements involving the removal of the nucleus pulposus with a surgical shaver. This model has been employed with and without treatment with NuCore. At 52 weeks, results showed a high degree of biocompatibility and interdigitation with residual disk tissue, additionally treated levels showed decreased osteophyte formation in comparison to levels that received discectomy alone.

A 2 year follow-up on a pilot clinical trial[206] showed that treatment following discectomy and limited injection of synthetic material improved pain, function, and disability scores. Retention of disk height was superior when compared to published data on discectomy alone, showing the potential for nucleus replacement following discectomy to improve outcome over discectomy alone.

6.613.4.5. Scaffolds, Cells, Growth Factors, and Tissue Engineering Concepts

Several of the hydrogels described previously have been evaluated in terms of their ability to support cells from bone marrow and explanted intervertebral disk cells.[186,187,207,208] This provides the possibility of using the hydrogels as a scaffold for seeding the nucleus with cells capable of proliferation. Other materials have also been constructed as scaffolds for cells, Wilke *et al.*[209] evaluated a condensed collagen type I matrix but found that there was a significant problem with extrusion as the material did not cure, or increase in viscosity in any way after injection. Other scaffold materials have also been suggested including resorbable glycosaminoglycan molecules.[210]

Mizuno[211] harvested cells from sheep disks and constructed a scaffold of polyglycolic acid and polylactic acid, annulus fibrosus cells were pipette into the scaffold and allowed to attach for 1 day. Nucleus pulposus cells were suspended in alginate and injected into the center. The implants resembled disks histologically although this technology is far from clinical application. Work by Bron *et al.*[212] has shown the ability of dense collagen scaffolds to mimic the properties of the nucleus pulposus. While the collagen scaffold has lower energy dissipation, and gamma sterilization increased the shear moduli while decreasing swelling ability, the material has potential as a cell scaffold.

Various studies have addressed using growth factors to influence cell behavior in the intervertebral disk. Walsh *et al.*[213] have shown insulin-like growth factor-1 (IGF-1) to have some effect on the inner annular chondrocytes in degenerated disks and Gruber *et al.*[214] have shown IGF-1 to decreased apoptosis in low serum conditions. Many studies have looked into the effect of bone morphogenetic proteins (BMPs), important in the behavior of boney tissue, on intervertebral disk cells. The application of BMP-2 has been shown to increase chondrogenic phenotype, proteoglycan content, and aggrecan gene expression.[215–218] Similarly, BMP-7 has been shown to increase disk height, proteoglycan content

and metabolism, and production of collagen II.[219–221] Additionally, transforming growth factor-β (TGF-β) increases proteoglycan synthesis,[222] growth and differentiation factor-5 (GDF-5) stimulates aggrecan and collagen type II expression,[223,224] and matrix metalloproteinases (MMPs) influence proteoglycan content.[225]

Recent work by Hohaus *et al.*[226] used a canine model to demonstrate the possibility of implanting harvested autologous disk-derived chondrocytes into degenerated disks. Disk height was shown to correlate with the treatment. This has led to the use of adipose-derived stem cells as a source for chondrocyte-like cells. This work shows potential as a DDD therapy.

Sobajima *et al.*[227] have shown the ability of mesenchymal stem cells to survive as long as 24 weeks in a rabbit model. They pointed to limitations of attempting to implant the cells before a more complete understanding of the pathogenesis and pathophysiology of disk degeneration, the biochemical and physical signals needed to cause a stem cell to differentiate into a nucleus pulposus-like cell, and the specific mechanisms by which stem cells might exert beneficial stimulatory effects were known.

The results of these studies are promising, but the action of these therapies is not fully understood. This research is still at a very early stage and has many hurdles to pass. The factors have a sort lifespan with which to act and although they may utilize a natural signaling pathway, they do produce an unnatural influence. An increased proliferation of disk cells will use more resources in an already scarce environment. This may have a short-term benefit at a long-term cost. The initiator of degeneration is still unknown at this time. The degradation of the matrix of the nucleus pulposus and subsequent cell death may be a symptom and not the actual source of the problem. The source may be the inability to nourish the intervertebral cells due to changes in permeability and blood flow the endplates.

Simply increasing the population of cells in the nucleus may not be beneficial, as follows from the work by Kobayasi *et al.*[228] In this study, glycosaminoglycan accumulation was measured with cell populations at physiologic populations and at levels increased by a factor of 6. The result was an overall increase in glycosaminoglycan of 2–4% while the secretion per cell decreased by about 50%. In addition, apoptosis and cell death followed. Such data underscore current, inherent benefits for a synthetic approach to treat the nucleus pulposus. In fact, a nonliving nucleus replacement is not subject to apoptosis and does not require nourishment. Admittedly, wear and tear of a nonliving material would not be repaired, and changes in endplate condition may have an effect. Yet, the inherent ability to reconstitute function, this is mechanical function, at the time of placement represents a treatment advantage that cannot be matched by biological treatment concepts.

6.613.5. Considerations for Evaluating Nucleus Replacements *In Vitro* and *In Vivo*

Animal models can provide valuable information regarding local and systemic biocompatibility as well as potential functional performance of a nucleus replacement. The choice of the animal model is not trivial, as an inappropriate model may provide possibly confounding results. The model must be selected to address specific clinical questions and be technically feasible.

The evaluation of nucleus replacements prior to implantation, however, is vital to gain an understanding of the implant. ASTM is currently developing standard WK4863; *Standard Practice/Guide for the Mechanical Characterization of Lumbar Nucleus Devices*. This standard covers several mechanical tests to quantify static properties, creep behavior, ROM, and accelerated aging of nucleus replacements. The standard does not cover testing in biological tissues.

Testing with human cadaveric tissue or animal tissue can provide insight as to how a material behaves inside a loaded disk and how it affects the biomechanics of a motion segment. Spinal biomechanics, mechanical testing devices, and outcome measures have been covered previously; here, we explore some common considerations for testing of spinal segments in harvested tissues. The goal of *in vitro* studies is to gain information that can be related to *in vivo* tissue behavior, ideally by recreating *in vivo* conditions as closely as possible without sacrificing repeatability. Choosing boundary conditions and testing protocols that have temporal effects on a specimen may unduly affect the outcome of a laboratory study. The primary considerations include hydration of the disk, temperature, and effects induced by repeated testing.

6.613.5.1. *In Vitro* Evaluation of Nucleus Replacement Performance

6.613.5.1.1. Hydration/temperature

In life, the disk regularly exchanges over 1.2% of its volume in water during normal activities of daily living.[33] Nucleus tissue loses moisture in air, swells considerably in saline and is most stable when in a humid environment, such as a humidity chamber.[34] Common testing protocols include wrapping specimens in gauze or plastic wrap and moisturizing with saline, testing in a 37 °C saline bath, or in a humidity chamber. If the disk is placed in saline without preload, it swells by ~24% and remains static if wrapped in plastic and sprayed with saline.[33,229] The change is asymptotic and plateaus after ~7 h which corresponds to changes occurring in life.[33] These changes in hydration affect the biomechanical properties of the disk.[230,231]

Testing in air and moisturizing with sprayed saline provides a stable testing condition that will suffice for most tests.[19] The benefit of testing in a saline bath is that temperature can be more closely controlled to minimize artifact in measurements of biomechanics induced by the temperature dependent properties of spinal structures.[232,233] To offset the swelling of the nucleus, follower loads are often applied to provide a compressive load mimicking muscle forces.[234,235] When available, a humidity chamber provides a useful alternative to testing in a saline bath.[236,237]

6.613.5.1.2. Repeated testing

Specimens are commonly tested in sequence; intact, after discectomy, and after treatment with nucleus replacement. This is an efficient approach given that it allows for repeated measurements, and thus, that it enables to reduce the ultimate number of specimens needed. Unfortunately, it does not allow for randomization of treatment order. Allowing adequate recovery time between tests is important as work by

Johannessen *et al.*[238] and van der Veen *et al.*[239] have shown. When sheep disks were cycled through 10 000 400 N cycles, the mechanics of the disk were restored after 18 h; however, when pig disks were subjected to constant compressive loading for 15 min and allowed 30 min recovery, the mechanics were not restored.

In a very long-term study, repeated testing of spinal segments over 72 h, Wilke *et al.*[19] found steadily increasing ROM. This was shown to take place on a shorter time scale as well, with six repeated tests in three modes of bending over 6 h demonstrating steadily increasing ROM.[237] Testing of an additional specimen alongside treated specimens may help gauge the effects of a repeated testing protocol. An implant will have to overcome the effects of discectomy as well as tissue fatigue brought about by repeated tests.

6.613.5.2. *In Vivo* Studies: Animal Models

Few animals practice upright, bipedal walking as humans do. Nonhuman primates are capable of upright walking; however, upper limbs are often involved. Kangaroos often stand upright but their gait is distinctively different to the human gait; using all four limbs and tail at a slow gait, and two hind limbs in a hopping motion for high speed gait. Practical concerns regarding animal availability and caring facilities encourage the use of quadruped animals. One perceived disparity between the quadruped spine and the human spine is loading.

Quadrupeds do not stand upright and therefore gravity does not place the spine in constant axial load and the forces transferred due to vibration may be of a different nature. However, the loads placed on the lumbar spine are more complex than those generated by gravity alone, and surrounding musculature and ligaments generate loading which predominates axially.[240,241] Quadrupeds also show similar axial alignment of trabeculae within vertebral bodies[242] and signs of degeneration analogous to the human degenerative cascade.[243–245] Several animal models have served as models for the human spine and are applicable to *in vivo* evaluation of nucleus replacements (**Figure 23**).

6.613.5.2.1. Murine

The size of mice makes caring for them comparatively expedient, and the disks of both rats and mice have been shown to be scalable to the human, providing a useful model.[246] Lotz *et al.*[247,248] have shown the degenerative effects of mechanical loading on the mouse tail with a system of pins through the vertebral bodies. Similar devices exist for rats.[249] While these models are useful for investigating the degenerative cascade, these disks do not normally undergo significant compression or diurnal changes and they lack facet joints. Also, the mechanics of the tail do not correlate as well to a body weight adjusted human spine as lumbar levels.[250] The small size of the disk makes discectomy and implantation of a prosthetic nucleus difficult, thus they are less suitable for investigating nucleus replacements.

6.613.5.2.2. Leporine

Rabbits provide a medium-sized model for spinal devices. Grauer *et al.*[251] examined three-dimensional motion of the rabbit spine and have shown that is an acceptable model for representing the human spine although the NZ and ROM are somewhat greater than in the human. Degeneration may be induced mechanically,[252] via needle puncture,[253,254] or discectomy may be performed.[255]

The rabbit model has been extensively used to study the injection of cells into the intervertebral disk following aspiration of the nucleus pulposus.[227,256–259] Aspiration is commonly applied due to the difficulty of performing discectomy on the small disk, although traditional discectomy may be applied. Larson *et al.*[260] injected a hydrogel following discectomy with a micro-pituitary but few differences were noted between groups, likely influenced by a small sample size. Abbushi *et al.*[255] implanted a polyglycolic acid/hyaluronan scaffold following open discectomy and showed maintenance of disk height and improved MRI T1 signal compared to discectomy alone.

So *et al.*[261] has investigated a PVA hydrogel implant in the rabbit disk. This approach differed from previous models, as the implant was a sharpened rod that was inserted laterally through the disk and left proud following the removal of the transverse process and associated musculature. This procedure differed greatly from that which would be performed in the human. Despite this, the implant preserved disk height and delayed degenerative changes at 6 months.

6.613.5.2.3. Porcine

McLain *et al.*[262] compared the morphology of human and large animal L4 vertebrae finding the pig to be an acceptable match. Sheng *et al.*[263] evaluated the anatomy of several large animals and suggested that the thoracic and lumbar regions of the pig can be used as models for human. The intervertebral disk, although not as thick, is comparable if scaled by the size of adjacent vertebral bodies.[264]

Kaigle *et al.*[265] have shown that, in 50–60 kg 4-month-old pigs, an annular incision to the nucleus results in severe degeneration of the disk at 3-month follow up. Revell *et al.*[186] have utilized a porcine model to test two hyaluronan-derived polymeric substitutes that were injected after discectomy. Treated levels prevented fibrous tissue infiltration and endplate

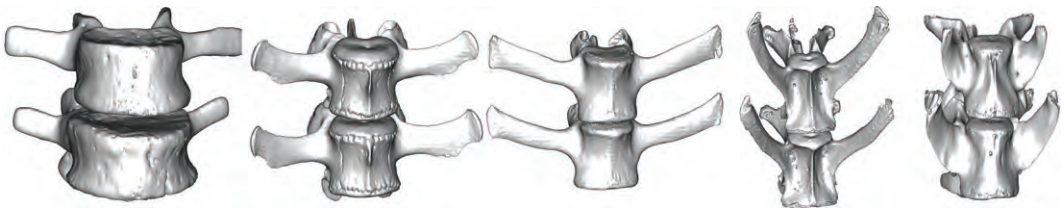

Figure 23 3D reconstructions of L3–L4 motion segments from computed tomography and micro computed tomography data, left to right: human, pig, sheep, rabbit, and rat. Images are not in the same scale.

disruption at 6 weeks. These pigs were 11 kg and were most likely immature. One difficulty in using immature pigs is that they quickly outgrow a normal human weight range.

Yingling *et al.*[266] advise that the porcine cervical spine shows similarities to the human in load and function and may serve as a substitute for the human lumbar spine. This model has been utilized by Drake *et al.*[267] to evaluate failure of motion segments but at present, has not been used for the evaluation of nucleus replacements.

Minipigs have also been used. The effects of nucleuotomy, nucleotomy with HA/sodium salt solution, chemonucleolysis with chymopapain, and annulus dissection on disk degeneration of minipigs have been described by Pfieffer *et al.*,[268] all of which could serve as prenucleus replacement models. Henriksson *et al.*[269] used 6-month-old 10–15 kg minipigs and transplanted mesenchymal stems cells after aspirating the nucleus. Cells were injected with and without a degradable amino acid based hydrogel carrier. Cells survived to the last 6-month time point.

6.613.5.2.4. Canine

The contributions of ligaments, posterior elements, and the intervertebral disk to the stability of a motion segment are similar between canines and humans. The torsional and axial mechanics are also similar but when normalized for scale, the canine properties are stiffer.[270] Ganey *et al.*[271] performed partial nucleotomy and injected HA, or HA and adipose-derived stem cells, finding the closest similarities in morphology between the intact and HA with cell treatment groups.

6.613.5.2.5. Bovine

The adult cow spine is difficult to relate to the adult human due to the fourfold increase in overall length. For this reason, and similarities in shape and structure, calf spines are often used.[272] They can be used on a limited basis as these similarities predominate in AR and LB, and facet joint orientation varies by as much as 107% at this level when compared to human.[273] Mean pedicle height is greater than for the human, as for most quadrupeds, but is an accepted model for the human lumbar spine.[263]

Wilke *et al.* have utilized this model to test a collagen matrix based scaffold nucleus replacement *in vitro*, demonstrating restored height and biomechanics following discectomy; however, extrusion was common.[209] More unique designs have also been tested in the calf model. Butterman *et al.*[274] used the calf spine, with posterior elements removed, in an investigational study to test a spring based, nonannulus sparing system, finding that spring stiffness was a primary determiniant of ROM in the reconstructed spine. Kettler *et al.*[146] have also used this model to test woven titanium filaments as a nucleus replacement, finding increased ROM in most directions. Yuksel *et al.*[197] treated denucleated calf motion segments with BioDisc which regained disk height and survived loading of 10 million cycles.

Calf spines are in a rapid phase of growth so *in vitro* tests are often more appropriate than *in vivo*. The cow tail has been suggested as a substitute due to similarities in microfibile organization,[275] ROM before scaling,[250] and intradiscal pressure under compressive load.[276] However, there are some limitations. The cow tail has differing creep characteristics,[250] and differences in cell phenotype and matrix contents,[277] as well as the limitations cited earlier for the rat spine. Currently this model has not been used to evaluate nucleus replacements.

6.613.5.2.6. Ovine

Wilke *et al.*[23,278] have studied the biomechanics and morphology of sheep and suggest that the sheep provides a useful model of the human spine, with qualitatively similar biomechanics. The vertebrae is taller and the disk height less, while facet joints and spinal canal are very similar to the human. The lumbar and thoracic regions show the closest match, and the lumbar spine is also useful for surgical training of discectomy for spinal surgeons.[279] The intervertebral disk itself has been shown to simulate the human in terms of construction and makeup,[280] with the proteoglycan content in the disk and endplate in sheep most closely matching that of human disks when compared to rats and cattle.[281] Easlyey *et al.*[282] evaluated the radiographic and biomechanical properties of the lumbar spine and found ROM and NZ as well as load sharing were in line with human published data.

Several models of degeneration have been applied to the sheep lumbar spine. Melrose *et al.*[283] found that nerve and blood vessel ingrowth is associated with proteoglycan depletion. Colloca *et al.*[62] performed stab incisions to the lateral annulus of sheep and identified a decreased viscoelastic response with time. This has also been shown to induce loss of disk height.[284] Fazzalari *et al.*[285] have used the sheep model to investigate the effect of annular tears on the biomechanics of the spine.

Meakin *et al.*[286] used the sheep disk to demonstrate the ability of a silicone rubber, uncured silicone and another elastic solid to reverse inward bulging of annulus fibers that occurs following nucleotomy. This is one of the principle functions of a nucleus replacement. An ideal Young's modulus was proposed for the implant near 3 MPa.

As described earlier, Pelletier *et al.*[287] used a surgical shaver to perform a nucleotomy on sheep lumbar disks and injected a hydrogel nucleus replacement. Results showed decreased osteophyte formation at 52 weeks when compared to discectomy alone.

6.613.5.2.7. Nonhuman primates

By virtue of their upright posture nonhuman primates are attractive as a model of the human spine. Baboons and macaque monkeys are well-established research models. Baboon lumbar spinal segments have similar compressive stiffness to the human, although glycosaminoglycan content differs. The macaque monkey represents one of the few naturally occurring examples of DDD. Nuckley *et al.* found that advanced degeneration was marked by osteophytes, loss of disk height, and changes in biomechanics that parallel the human progression of DDD in a study with animals of advanced age.[288]

Degeneration in baboons has been incited by injecting chondroitinase ABC to digest the nucleus resulting in bone marrow depletion and loss of disk height at 24 weeks,[289] but discectomy is more commonly applied.

Ledet *et al.*[290] examined the PDN in lumbar spine of three baboons. Two of these implants migrated and a revision was performed. It was found that there was a loss of disk height, endplate degeneration, subsidence, and sclerosis of adjacent

vertebrae. These complications were similar to those found in humans clinically, supporting the use of this model. Cook *et al.*[147] implanted six adult baboons with a solid preformed nucleus following discectomy finding no migration of the implant but some endplate changes. Allan *et al.*[171] implanted hydrogel beads in baboons following discectomy and although device related tissue responses were not present, extrusion occurred in one-third of cases. Cunningham *et al.*[291] implanted 14 mature baboons with DASCOR implants and found maintained motion but adjacent vertebral body changes in most levels at 12 months with no expulsion of implant.

6.613.5.2.8. Summary – animal models

Several animal models provide useful information regarding the performance of nucleus replacements. Smaller animal models may provide useful information regarding the biocompatibility of a material,[292] however relative size to the human disk is required to maintain the appropriate surgical procedure. The size of an annular defect relative to the overall disk size affects the recovery of the disk.[293] Smaller animals are also not suitable if residual tissue is present or the performance of the implant relies on diffusion. Smaller disks are at less of a disadvantage in terms of nutrition as distances are smaller and diffusion less of a challenge.[294] Although the scaled tissue properties of the disk are similar across species, the direct measures vary by orders of magnitude (**Figure 23**).[250]

While no animal model will perfectly substitute the human case, there are several models available that will aid in expanding the understanding of nucleus replacements. Nonhuman primates provide a good approximation; however, practical issues may preclude the use of these models. In this light, there are several useful quadrupedal models. The sheep and calf lumbar spines provide both accessible and acceptable surrogates to the human.[263]

While differences between discectomy alone, as well as the safety of nucleus replacements can be shown without preexisting pathology, the ideal animal model would apply nucleus replacement to treat a degenerative condition. There are few examples of naturally occurring DDD. The aged macaque, chondrodystrophoid dogs, and the sand rat represent a few. Present models of degeneration primarily use acute injury to accelerate degeneration. While this may increase repeatability and control over the extent of degeneration, it may not represent the diseased state. The exact initiator of degeneration is, as yet, not well understood and further progress in this regard will facilitate creating reproducible pathologies that more closely represent human DDD.

6.613.6. Summary

Nucleus replacement is the removal of the nucleus in the mid to early stages of DDD followed by replacement with a synthetic material. Replacement of the nucleus with a material possessing properties of a healthy nucleus would be expected to restore the biomechanics of the affected level, decelerate degenerative changes and relieve pain. If successful, nucleus replacement would postpone or preclude more drastic procedures, while still allowing them to be performed later if necessary.

Early attempts at nucleus replacement often resulted in fusion, but greater success followed from mimicking the properties of the healthy nucleus. Polymer technology has emerged as the means to achieve reliable nucleus replacement. Injectable polymers show promise due to the minimal disruption of the annulus and ability to interdigitate with remaining tissues making extrusion less likely. Although tissue engineering solutions with cells and growth factors can be added to the polymer concepts, there are, currently, inherent advantages to the synthetic route only, until further progress in cellular and biological treatments can address the imbalance with currently achievable functional outcomes.

Glossary

Degenerative disc disease (DDD) Degeneration of the intervertebral disc resulting in disc dehydration and shrinkage and a change in the biomechanical properties.

Facet joint The joints created by the articular processes of superior and inferior vertebrae. The facet joints are true synovial joints including a covering of cartilage and surrounded by synovium, also known as the zygopaphysial joints.

Functional spinal unit (FSU) The smallest component of motion in the spine, consisting of two vertebrae and the intervening intervertebral disc.

Intervertebral disc Soft tissue structure connecting adjacent vertebral bodies through a cartilage layer and consisting of a gel-like nucleus pulposus surrounded by collagen fiber bands.

Total disc replacement (TDR) Any replacement requiring complete (or near complete) removal of the natural intervertebral disc.

Trijoint complex The three joints providing articulation within each functional spinal unit. They are the two facet joints and the intervertebral disc.

Abbreviations

ALL	Anterior longitudinal ligament
AP	Anterior–posterior
AR	Axial rotation
ASTM	American Society for Testing and Materials
C1–C7	Cervical vertebrae 1–7
CFR-PEEK	Carbon fiber-reinforced PEEK
CoCrMo	Cobalt–chromium–molybdenum
COR	Center of rotation
DDD	Degenerative disc disease
DOF	Degree(s) of freedom
FDA	Food and Drug Administration (USA)
FE	Flexion–extension
FSU	Functional spinal unit
IAR	Instantaneous axis of rotation
IDE	Investigational device exemption
ISO	International Organisation for Standardisation
L1–L5	Lumbar vertebrae 1–5
LB	Lateral bending
LBP	Low back pain
NICE	National Institute for Clinical Excellence (UK)
PE	Polyethylene
PEEK	Polyaryletheretherketone
PEK	Polyaryletherketone
ROM	Range of motion
TDR	Total disc replacement
THR	Total hip replacement
TJR	Total joint replacement
TKR	Total knee replacement
UHMWPE	Ultrahigh-molecular-weight polyethylene
μCT	Microcomputer tomography

6.614.1. Introduction to Total Disc Prostheses

6.614.1.1. Back and Neck Pain

Back and/or neck pain affects 60–85% of individuals during their lifetime, in higher income countries.[1–3] In both conditions, 90% of individuals recover in a few weeks or months, while in ~5–10% cases, the pain develops into a chronically disabling disorder.[4,5]

Although back and neck pain are already a large social concern, their prevalence has seemingly increased in the post-war period, escalating even further in the past 2 decades.[6] One suggested reason for this is that jobs are becoming increasingly sedentary, and sitting for long hours is thought to exacerbate low back pain (LBP).[7] Conversely, these has also been a decrease in manual handling jobs, which has been suggested as another risk factor. Another school of thought suggests that the incidence of LBP itself has not increased but that a psychosomatic 'syndrome shift'[8] has occurred due to increased public awareness of LBP through media attention and government reports and increased reporting of symptoms due to dissatisfaction in daily life.[6]

Whether the increasing incidence is genuine or psychosomatic, the economic burden of back pain is substantial and increasing. The overall economic burden of back and neck pain includes health-care costs, out-of-work benefits, and production losses, estimated to be as high as $200 billion per year in the United States alone.[9] It is recommended that back and neck pain are first managed by structured exercise, manual therapy, or acupuncture, followed by pharmacological therapies and psychosocial management. Only when conservative methods have failed to provide relief, surgical referral is considered.

6.614.1.2. Degenerative Disc Disease and TDR

Back and neck pain have multifactorial etiologies, including systemic causes (such as malignancies and infection[10]), deformities (such as scoliosis and kyphosis), fractures (which may be a result of trauma or systemic disease such as osteoporosis), nerve root compression (which may be due to any of the preceding factors), muscle and ligament sprains, and degenerative disc disease (DDD).

DDD has been attributed to be a significant cause of chronic LBP,[11,12] even though a substantial proportion of healthy patients show evidence of some disc degeneration,[13] suggesting that DDD, in part, is just a natural progression of the aging process. Chronic neck pain is more commonly associated with mechanical injury of the disc, such as whiplash, after which degeneration is accelerated. The pain itself tends to arise from cervical radiculopathy, where the cervical nerve roots are compressed, or myelopathy, where the spinal cord is impeded by spinal stenosis, spondylolysis, or herniated disc, and as such, these are the indications for surgery, not the DDD.

For the past 25 years, the gold standard for the treatment of LBP from DDD and chronic neck pain has been spinal fusion (after conservative measures are exhausted), with an estimated 450 000 patients undergoing fusion procedures in the United States.[14] The aim of fusion surgery is to eliminate motion, thereby eliminating pain. Overall success rates for spinal fusion have varied widely from 32% to 99%,[15] and complications arise due to the suitability of graft materials, incidences of nonunion, and the technical difficulties of the procedure. In addition, it has been proposed that fusion of one joint may cause an acceleration of DDD at adjacent joints.[16–18]

In contrast to fusion, total disc replacement (TDR) aims at the preservation, rather than the elimination, of motion. The procedure involves excision of the disc (which itself may be causing pain), and it is thought that the restoration of near-normal biomechanics will reduce the risk of adjacent level disease.[12,19–21] TDRs have been used as implants in Europe for more than 20 years, yielding good short- to mid-term clinical results so far. Questions that arise regarding the long-term success of TDR focus primarily on the longevity of the device *in vivo*. In particular, there are concerns over wear of articulating devices in the spine, wear-induced osteolysis being the prime cause of late failure in other joint replacements.

6.614.2. Basic Anatomy and Biomechanics of the Spine

6.614.2.1. The Spine

The spine consists of a column of vertebrae, running from the base of the skull to the coccyx. These vertebrae are connected by the trijoint complexes, consisting of two facet joints and an intervertebral disc. In normal, healthy individuals, the spine is straight in the frontal plane, and consists of four curves in the sagittal plane. The cervical and lumbar regions are convex in the anterior, whereas the thoracic and sacral regions are convex in the posterior. It is thought that the cervical curve develops during infancy as we learn to support our heads, sit, and crawl, and the lumbar curve develops when we are learning to walk. The typical shape formed by these curves is thought to increase resistance to axial compression and enhance flexibility.[22] The spine has a number of biomechanical functions: protecting the spinal cord (and associated neural function), providing stability, facilitating mobility, and controlling the movement and coordination of the upper and lower extremities.[23]

The human spine consists of 33 vertebras, split into 5 regions: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused), and 3–4 coccyx (fused). Although all the vertebrae differ slightly in size and shape, they all share a common structure and features, with the exception of C1 and C2 (the Atlas and the Axis). A large block of bone, the vertebral body, lies at the anterior of the spine, from which the pedicles protrude to the posterior elements. The neural arch is formed by the laminae pars and the connections of the various processes: two transverse (right and left), four articular (superior and inferior: right and left), one spinous, two mamillary (right and left), and two accessory (right and left). The neural arch encloses the vertebral foramina, which are aligned to form the canal through which the spinal cord passes from the brain to the lumbar spine. Nerve roots extend from the spinal cord, passing through the intervertebral foramen created by the interlocking of the processes, to the rest of the body.

The vertebral body is the main weight-bearing component of the vertebra, having flat superior and inferior surfaces, and a core of trabecular bone. The vertebral body (and intervening discs) resists ~80% of the compressive load of the spine in the neutral position, the proportion decreasing with extension[24] and the load transferring to the posterior elements. The compressive strength of the lumbar vertebrae has been found by several authors to exceed 5000 N,[25] with L4 being able to exceed 8000 N.[26]

The pedicles are two pillars of bone projecting from the back of the vertebral body, connecting to the posterior elements. The posterior elements (processes) of the spine are all designed to provide stability and/or enable motion. The articular processes (of which there are four) are the only physical connections between each of the vertebrae, forming the facet joints. The spinous, transverse, accessory, and mamillary processes provide lever arms for effective muscle and ligament attachment. The laminae and pedicles connect the spinous processes to the vertebral body, allowing transmission of forces and so aiding stability and enabling motion of the vertebral body.

The subtle differences between the vertebrae are related to the differing loading demands placed on them, and so not surprisingly, vertebrae within the same region are more alike. The lumbar spine has larger vertebral bodies and larger articular processes, which enable better transference of the greater loads experienced at this level. The thoracic vertebrae are slightly smaller and have larger transverse processes that provide attachment for stabilizing muscles. The ribs also attach to the thoracic vertebrae, making the spine in this region more rigid, facilitating less movement and protecting the major organs. The spinous processes of the thoracic vertebrae are typically small, which reflects the limited flexion–extension of this region of the spine. The cervical vertebrae are smaller still, as they have much lower loads to support, only supporting the weight of the head and associated muscle action. The spinous and transverse processes are large so as to provide greater leverage for muscular attachments, which along with the less stable facet joints allow for the increased flexibility of the cervical spine.

The facet joints, otherwise known as the zygapophysial joints, are formed by the articulation of the articular processes. These joints are synovial, the surface of the facets covered by articular cartilage with synovial membranes and surrounded by a joint capsule. The purpose of the facet joints is to resist forward sliding and twisting of the vertebral bodies, preventing shear stresses being applied to the intervertebral discs. A significant amount of loading is apportioned to the facet joints, with estimates of the load borne from zero,[27] where the capsular ligaments are put under tension, to 45% of the compressive loading on the spine.[28] As such, they are subject to degeneration and are a possible source of back and neck pain.

The orientation of the facet joints varies throughout the spine and determines their mechanical importance at each level. The joints can be flat or curved, and oriented any way between 0 and 90° to the sagittal plane. Flat joints parallel to the sagittal plane resist rotation, whereas those perpendicular to it resist forward sliding. Those oriented between 0 and 90° to the sagittal plane will offer some resistance to both rotation and forward sliding. In curved joints, the degree of resistance depends on the proportion of surface area that is posterior facing, with 'C'-shaped joints offering more resistance than 'J'-shaped joints. In general, curved joints resist rotation, as they maximize the surface area contact between the joints.

The facet joints are of concern to TDR, as the motion of the disc is directly related to the facets. It is argued that unconstrained TDRs, such as the Charité (DePuy Spine, Raynham, MA), subject the facets (and posterior ligaments) to increased shear loads, as they have no inherent shear stability.[29,30] This increased loading may cause degeneration of the facet joints, leading to further instability and pain. The ProDisc (Synthes Spine Solutions, New York, NY) has been found to reduce facet joint loading when compared to the Charité,[31] although this study did not compare the two to normal physiological loads conditions. Conversely, unconstrained designs provide a physiological center of rotation (COR) and thus may prevent non-physiological loading of the facets[29,30] as well as transfer of the loading to other locations, such as the implant–bone interface, which may lead to implant loosening.[29] The nature of the effect of constraint with relation to facet joint degeneration is not yet clear,[32] but clinical studies have shown that facet joint degeneration is seen in more than 30% of TDR patients at 3-year follow-up, regardless of the choice of constraint[33] (see **Chapter 6.610, Trends in Materials for Spine Surgery**).

6.614.2.2. The Natural Disc and Associated Structures

Intervertebral discs are positioned between each of the non-fused vertebrae, facilitating motion between the vertebrae, supporting compressive loading, maintaining the height of the spinal column, and providing some flexibility and stability at the extremes of motion. The intervertebral disc is composed of three main parts: the nucleus pulposus, the annulus fibrosus, and the cartilaginous endplates.

The nucleus pulposus is the center of the disc and is composed of 70–90% water,[25] which is attracted to the nucleus by the presence of hydrophilic proteins known as proteoglycans. Collagen fibers are irregularly arranged throughout the nucleus, creating a firm, gel-like texture,[11] and mature cartilage cells known as chondrocytes exist in the voids between these fibers and the proteoglycans. The fluid, incompressible nature of the nucleus allows it to be deformed under pressure, and so allows transference of forces in all directions. It has the capacity to swell via the process of diffusion, which provides nutrients to the chondrocytes and also contributes to its compliance.

The annulus fibrosus forms the outer boundary of the disc, developing in concentric laminated bands around the nucleus. Collagen fibers are highly organized around the nucleus in lamellae, with the adjacent lamellae fibers oriented at 90° to each other. This structure allows the disc to resist tension in all directions,[24] which is particularly important at the extremes of motion.

The cartilaginous endplates provide attachment of the disc to the vertebral body. These endplates, which are ~1 mm thick, are composed of hyaline cartilage and fibrocartilage, similar to that seen in other articulating joints. This cartilage develops with age, with decreasing amounts of hyaline cartilage until it is virtually all fibrocartilage. These endplates attach directly to the inner annulus fibrosis, and so are strongly bound to the intervertebral disc, but are only weakly attached to the vertebral bodies. The outer annulus fibers anchor themselves directly to the vertebral body.

The intervertebral disc is often casually referred to as a shock absorber, but in order for this to be true, the disc must be able to dissipate energy. There are two possible mechanisms by which this can occur: elastic hysteresis during loading and unloading of the disc [34,35] and diffusion of water through the vertebral capillaries allowing transfer of heat energy.[11] Increases in loading rates reduce the ability of the disc to dissipate energy, thereby making it a less effective shock absorber, with high loading rates meaning that the disc has less time to 'recover.'

Although the intervertebral disc is capable of shock absorption, studies have shown that the contribution of the discs to shock absorption in the spine is minimal,[36] with the other soft tissue structures of the spine, particularly the muscles, being much more effective shock absorbers than the discs. However, the effect of replacing a minimal shock absorber with a completely rigid device has yet to be studied, but the development of elastomeric devices has originated from this concern.

6.614.2.3. The FSU and Spine Biomechanics

Consideration of 'healthy' spine biomechanics is important when defining parameters for any mechanical test. The loading and motion experienced by the lumbar spine have been much more complex to quantify than those in the hip and knee. The functional spinal unit (FSU) consists of two vertebrae and one intervertebral disc and is capable of six degrees of freedom (DOF).[25,37] A coordinate system has been adopted by both International Organisation for Standardisation (ISO) and American Society for Testing and Materials (ASTM) for spinal testing[37] where the *X*-, *Y*-, and *Z*-axes are defined in the anterior–posterior (AP), lateral, and superior–inferior directions, respectively. Lateral bending is described as rotation about *X*-axis, flexion/extension as rotation about *Y*-axis, and axial rotation as rotation about *Z*-axis.

The loads and motions vary significantly from FSU to FSU, with lumbar vertebrae experiencing higher loads but reduced motion compared to cervical vertebrae, but even within the same region, differences are significant. Idiosyncrasies are significant not only because the weight and activity levels of patients differ but also because vertebral recruitment patterns differ for any given motion.[38] Complexities also arise because motions are kinematically coupled, such as the coupling of translational motion and flexion–extension, and coupling of axial rotation and lateral bending.[39]

The spine is loaded not only by the head (in the case of the cervical) and upper body weight (in the case of the lumbar) but also by a complex group of muscles and ligaments that provide both stability and motion. The center of gravity of the upper torso lies anterior to the spine, and so these muscles and ligaments are in constant tension in order to retain an upright posture, and the muscles in the upper spine and neck must similarly support the head. As such, the spine is never fully unloaded, although it is partially unloaded in the prone position.

6.614.2.3.1. Cervical spine loading

The cervical spine experiences much smaller loading than the lumbar spine, supporting the weight of the head and associated musculature. These loads are usually up to three times the head weight, typically <200 N, but can reach up to 1200 N during everyday activities in which maximum muscle contraction occurs, for example, during contact sports or heavy lifting.[40]

6.614.2.3.2. Lumbar spine loading

Even in perceived inactivity such as standing and sitting, the lumbar spine experiences loads of between 1.5 and 2.0 times body weight.[41] Loading increases with increasing activity levels, so during level walking the compressive forces rise to more than three times the body weight in the lumbar spine.[42] Extremely high loads can be experienced during vigorous activity,[43] the extremes of motion,[43,44] and external load carriage[43,45–47] with loads in excess of five to six times the body weight.

6.614.2.3.3. Cervical spine motions

The motions in the cervical spine are on the whole much larger than those in the lumbar spine. Total ranges of motion for the cervical region are typically 120° flexion–extension, 80° lateral bending, and 140° axial rotation.[48] Maximum flexion–extension ranges between 15 and 25°, with lateral bending 5–12° and axial rotation 2–7°, except in the joint of the atlas/axis (C1–C2) where it is 40°.[25] The ranges of motion, observed in an *in vitro* study,[49] for C4–C5 and C5–C6, the most commonly operated cervical discs, are summarized in **Table 1**.

Table 1 Ranges of motion at C4–C5 and C5–C6

	Combined flexion/extension	*Total lateral bending*	*Total axial rotation*
C4–C5	7.3	5.4	3.6
C5–C6	10.1	4.6	2.8

Source: Goel, V. K.; Clark, C. R.; McGowan, S.; Goyal, S. *J. Biomech*. **1984**, *17*(5), 363–376.

6.614.2.3.4. Lumbar spine motions

The results of motion studies of the lumbar spine relative to the pelvis[42] show that peak flexion follows toe off, transferring to peak extension at heel strike. Lateral bending is directed toward the contralateral side and axial rotation toward the same side of heel contact. Increased cadence has been found to increase the magnitude of lateral bending, axial rotation, and flexion, but it decreases extension.[42] The above studies focus on the lumbar spine as a segment and so motion values are likely to be less than these figures suggest for a single FSU. Maximum flexion/extension angles have been found to be ~5°/3° at FSU L3/L4 and 4°/2° at L4/L5.[50] Another study has shown that although the maximum value of flexion/extension of an FSU for healthy patients *in vivo* was 6°, the average value was only 2.5°.[51]

6.614.2.3.5. Shear loads and motions

AP shear loads are important when considering TDR effects on the shear stability of the spine. Callaghan *et al.*[42] calculated the loads and moments experienced by the L4/L5 FSU during walking, finding that the lumbar spine underwent a significant anterior shear load during flexion–extension. Peak loading occurs at toe off, with a significant simultaneous anterior shear load of up to 200 N and a smaller lateral shear load directed toward the standing foot. Studies have shown that AP shear loads can be extremely large in cases of heavy lifting, approaching 1000 N.[45]

AP shear has also been measured in terms of the translation, with an anterior translation of 1.6 ± 0.3 mm and a posterior translation of 1.9 ± 0.3 mm in the cervical spine.[52] This translation is similar in the lumbar spine, with typical translations of 1–2.5 mm in both AP and lateral directions.[53,54]

6.614.2.3.6. Instantaneous axis of rotation

Another aspect important in the definition of motion of the spine, especially when referring to individual segments, is the instantaneous axis of rotation (IAR). This defines the point about which a body rotates in plane motion. The IAR can be summarized for all three rotations in the lumbar spine,[25] although changes at different levels of the spine and during motion.[29] The IARs alter significantly with DDD,[55,56] and one of the design criteria of TDR is to try to reproduce the IAR of the natural disc.

6.614.2.4. The Degenerated Disc and Associated Structures

Many studies have found decreased mobility of the spine with aging, but it is not clear whether this is due to degeneration, disease or as a result of decreasing activity.[25] Some degeneration appears to be part of the natural ageing process, and there are no definitive markers as to what constitutes disease.[24] Much of the literature has focused upon the disc as the primary cause of pain in the spine, whether this be due to the changes in the disc itself or the reduced ability of the disc to maintain normal biomechanics (possibly causing osteoarthritis in the facet joints) or the compression of veins and nerves because of changes in disc geometry.

With aging, the vertebral endplates become less porous and sclerotic, and inhibit the transfer of water and nutrients, resulting in metabolite accumulation and an increase in acidity. After the age of 30, there is a gradual change in the type and amount of proteoglycans within the disc nucleus.[57] This reduces the water content of the disc, meaning that it becomes dehydrated and shrinks, and reduces the effectiveness of the load transfer through the nucleus, increasing the load on the annulus.[58] This increased load can damage the annulus, resulting in radial fissures and tears, which may allow the disc nucleus to migrate through the tears, stimulating the sinuvertebral nerve and resulting in pain. If the nucleus transgresses completely through the annulus (disc herniation), it may compress a nerve root causing radicular pain that travels down the extremity in the distribution of that particular nerve, leading to chronic LBP associated with pain in the legs (Sciatica). Secondary to this, the nucleus, now being exposed, is recognized as 'foreign' by the body, inducing an inflammatory response.[59]

Another effect of the degenerating disc is that its loss of turgidity results in height loss and a narrowing of the neuroforamen, compressing nerve roots. This geometry change may also alter the biomechanics of the spine, compromising stability and increasing motion. The spinous processes adapt, resulting in hypertrophy, which can again narrow the vertebral foramen (spinal stenosis). An increasing amount of the compressive load must be taken by the facet joints, causing wear and inflammation. An impaired facet joint may no longer protect the disc from shear stress, and so disc degeneration is accelerated.

The spine is a cooperative system of elements, and degeneration of one component or at one level is closely followed by subsequent degenerations of components or at adjacent levels. It is therefore difficult to determine the initial cause of the degeneration, and so difficult to prevent entirely. Until this can be determined, treatments must exist to repair the spine once degeneration has begun.

6.614.3. TDR Surgery

6.614.3.1. Indications and Contraindications

Currently, TDR is still evolving, and clinical selection criteria for treatment are subject to ongoing discussion. TDR is typically recommended for the treatment of single-level symptomatic DDD in the lumbar spine for which fusion would be indicated in otherwise healthy, younger patients; it has extremely limited use for other spinal diseases, trauma, and deformities where instability is a problem (**Table 2**). Determining DDD is difficult as a significant number of asymptomatic patients have shown some evidence of DDD in radiographic examination.[13] Further, not all patients with established DDD can receive TDR due to the large number of contraindications to the technique. **Table 2** outlines the inclusion and exclusion criteria for the Charité disc Food and Drug Administration (FDA) trials; however, European clinical experience suggests broader applications of TDR. There

is no consensus as to whether patients with pathologies associated with DDD, such as facet joint osteoarthritis, spinal stenosis, and multisegmental pathology, should be accepted for TDR.[32] However, it has been reported that healthy facet joints and intact posterior musculature and ligaments are required for successful TDR.[60]

The indications are broader for cervical TDR, mainly because the surgical access is exactly the same as for TDR or fusion, and so it is not considered as risky as the procedure for lumbar TDR. However, complications may be deemed as more serious because of the closer proximity of the device to the spinal cord at this level, as well as the esophagus and the vessels serving the brain (Table 3).

TDR is generally indicated for patients younger than those typically seen for total hip replacement (THR), mean age 70 years, and total knee replacement (TKR), mean age 73 years.[61] The suggested age of TDR patients is between 18 and 60 years, optimally those under 50 years.[62] Elderly patients present further risk due to the prevalence of metabolic bone diseases, most commonly osteoporosis, which carry an increased likelihood of endplate subsidence and vertebral body fracture. The younger patients are likely to have a higher activity level than the majority of hip THR/TKR recipients, and live longer, placing increased demands on the endurance of the devices. In addition, failure of TDR is thought to be more serious than that of THR/TKR replacements, not only because of revision difficulties but also because of the proximity of the device to the neural network, and major organs and vessels.

Table 2 Inclusion and exclusion criteria for lumbar TDR

Inclusion criteria	*Exclusion criteria*
• Discogenic LBP with single-level DDD, proven by MRI or CT and/or discography • Age 18–60 years, optimally <50 • Minimum 6 months of unsuccessful conservative therapy • No signs of nerve root compression • The majority of the studies require preoperative Oswestry score of >40% and a VAS value of >40 mm	• Deformities • Tumors • Infection • Posttraumatic segments • Postoperative segments excluding postdiscectomy • Metabolic bone disease • Metal allergy • Pregnancy • Autoimmune disorders • Morbid obesity (BMI > 40)

Table 3 Inclusion and exclusion criteria for cervical TDR

Inclusion criteria	*Exclusion criteria*
• DDD with symptoms of radiculopathy and/or myelopathy, with or without neck pain • Compressive legion diagnosed by MRI, CT, or myelography • Age 18–65 years • Minimum 6 weeks of unsuccessful conservative therapy	• Ankylosing spondolytis, rheumatoid arthritis, ossification of PLL, or diffuse idiopathic skeletal hyperostosis • Insulin-requiring diabetes mellitus • Prior cervical spinal infection • Chronic steroid use • Morbid obesity (BMI > 40) • Pregnancy • Neck pain as the only symptom

6.614.3.2. Access/Surgical Techniques

The lumbar TDR procedure is most commonly performed with anterior access, having to pass the abdominal organs as well as major vessels to gain access to the disc space in the case of lumbar TDR, and the esophagus in the case of cervical TDR. Although the anterior approach involves close proximity to major organs, and dissection of the anterior longitudinal ligament (ALL), posterior spinal surgery would compromise the facet joints and further endanger the spinal cord. Lateral surgery is also an option[63,64] and means that both the posterior elements and the ALL can be preserved, but access is not possible at the lumbosacral joint.

The natural disc is partially or fully excised, and after appropriate sizing and preparatory work, the disc space is distracted. The metal endplates are positioned, along with the core (depending on the design), and then the disc space is retracted. The positioning and alignment of the disc is extremely important for the correct functioning of the device and for prevention of any adverse events such as dislocations (Figure 1).

The procedure itself presents its own surgical risks, regardless of the success of the actual device. Perioperatively, complications arise due to accidental damage to the greater vessels[65] and other factors consistent with any type of major surgery. Postoperative complications include spontaneous fusion,[66,67] persisting LBP,[65] vascular and neural complications,[30,65,68] infection,[65,69,70] and complications associated with damage to the presacral plexus such as retrograde ejaculation.[65,71]

6.614.3.3. Success

The clinical success of TDR is not well defined. Ultimately, the aim of TDR is elimination of pain while providing a normal, healthy range of motion (ROM). It also aims to reduce or eliminate increased incidence of adjacent level disease, without mechanical or design failure and be biocompatible, both in

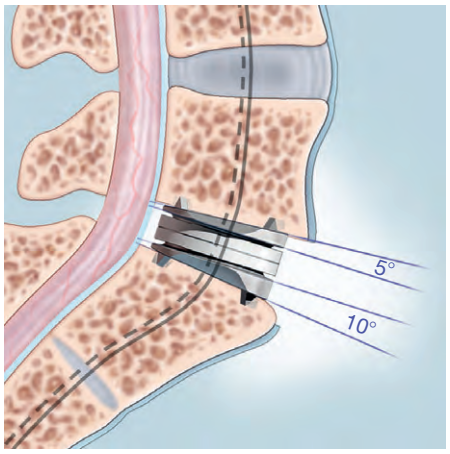

Figure 1 Placement of the total disc replacement within the disc space is of paramount importance for the biomechanical and clinical functioning of the device. Courtesy of DePuy International Ltd.

terms of base material reaction and secondary to any wear-related debris. If all of the preceding aims are achieved, the device will survive the remaining lifetime of the patient.

The clearest indicator of the success of a TDR is patient satisfaction, primarily with regard to pain relief and return to normal function. TDR has been shown to match the success of spinal fusion at least in terms of patient satisfaction. It has been shown to have advantages over fusion, including better and quicker back-to-work rates, presumably due to the increased mobility of the patient.

Investigational device exemption (IDE) trials have been performed for several TDRs, both lumbar (Table 4) and cervical (Table 5). The design of these trials was to prove equivalence to fusion, and as such, none can claim that the TDR is superior to fusion. However, all the TDRs that have undergone IDE trials have proven to be at least equivalent to their fusion counterpart and have often shown increased and more rapid back-to-work rates.

Good clinical outcomes increased from 63% in the beginning of the 1990s to 93% in 1997,[77] showing that improvement in surgical techniques and experience influence the outcome of surgery. High surgical volume has been associated with improved clinical outcomes for a number of clinical procedures including THR and TKR.[15] The Charité IDE study found that surgeons experienced in the technique reported a decrease in operative times, length of hospital stay, and rates of complications and neurological deterioration.[78,79]

6.614.3.4. Complications

Increased ROM has been evident in a number of studies in comparison to both fusion and preoperative states. Altered biomechanics have been shown to play a primary role in the development of accelerated DDD at adjacent levels.[25] Sixty-six percent of individuals implanted with the first-generation ProDisc device had ROM values within the range of 'normal' ROM, but did not restore the full ROM and was less successful than the Charité.[80] Twenty-four percent of patients had incidence of adjacent level degeneration, compared to 36% and 37% of patients reported for lumbar fusion.[17,18] Cadaveric studies have shown that the implanted Charité disc closely mimics the COR of the lumbar disc and it does not adversely affect the ROM at adjacent levels, whereas fusion results in a 'marked increase' in adjacent level motion.[81] Lumbar fusion patients have had a mean symptom-free period from adjacent segment degeneration of 13.1 years,[82] and so clearly long-term follow-up of TDR is needed to prove its worth against fusion.

Sagittal plane alignment has been associated with LBP and altered biomechanics for the past century.[83–85] It has been reported that correct lumbar lordosis increases spine strength (defined as the buckling load) by 34.4%[30] and that both hypo- and hyperlordosis are associated with LBP.[86] Altering the segmental angle of lordosis will alter the partitioning of the loading between the compressive axial component and the tangential shear component. Patients with decreased sacral inclination after lumbar fusion, defined as being $<35^{\circ}$, were found to have increased incidence of adjacent segment degeneration (from 8% to 47.8%).[17] Lumbar TDR restores lumbar and segmental lordosis closer to physiological values compared to fusion,[87] although it has been found that it decreases the lordosis at adjacent levels, which may cause loading alterations and degeneration.[86]

Facet joint degeneration is another concern if the biomechanics of the natural spine are altered. Fifty percent of patients treated with the Charité had progressive facet joint degeneration after 2 years,[88] and more than 30% of TDR patients have shown aggravated facet joint degeneration at the index level, with both the Charité and ProDisc.[33] Rousseau *et al.*[89] compared the effects of the ProDisc and the Charité on the facet joints, finding that the ProDisc decreased and the Charité increased the facet joint loading. Both cases result in alteration of the disc/facet load sharing, which explains why both discs are associated with facet degeneration. The surgical placement

of the disc has a large effect on the load sharing of the facet joints,[90] and this must be studied further in order to improve surgical outcomes.

Mechanical failure of TDR has been due to fracture of the polyethylene (PE) component,[91] dislocation of the PE component,[92] and subsidence of the metal endplates into the vertebral endplates.[67,93,94] Improved designs, careful patient selection, and advanced surgical techniques have gone on to see that these failures are extremely rare. Vertebral body fracture has been reported in a few cases,[95,96] although it is rare as metabolic bone diseases such as osteoporosis are a contraindication to TDR. There are suggestions for the use of vertebroplasty with TDR to allow patients with metabolic bone diseases to be considered for TDR.[97,98] It has been shown to decrease the risk of subsidence (compared to historical controls) with no adverse effects. Further study of the suitability of vertebroplasty with TDR surgery is needed to identify whether the inclusion criteria could be expanded for these cases (see **Chapter 6.603, Ultrahigh Molecular Weight Polyethylene Total Joint Implants**).

All materials currently used in TDR have a proven history of biocompatibility in other implants, and so in the short-term have yielded few problems. However, long-term biocompatibility of TDR has yet to be proven. TDR implantation is a relatively new procedure compared with other joint replacements, and so we have not had the chance to present significant numbers of late failure due to wear. However, in more recent years, a number of studies have demonstrated both the potential for osteolysis[99,100] and, more importantly, clinical cases of osteolysis with TDR,[101–103] occurring from as little as 8 years after implantation.[102] Failure due to wear is potentially more serious in the spine, with the close proximity to vital organs and neural networks in comparison to other joint replacement. Repeated invasive surgery needs to be avoided, and so the segment is often fused with the prostheses left in place. As a result of this, few explanted TDRs are available for study.

With the development of TDR matching the evolution of THR/TKR, many of the problems have been overcome. Improved designs, careful material selection, and advanced surgical techniques have removed many of the concerns regarding endplate subsidence, fatigue failure, and dislocations. The current focus in TDR is ensuring its capacity for long-term success, including further investigation of its effect on the facet joints (and possible subsequent degeneration) and the role of wear and wear debris-induced osteolysis. It is imperative that access to explanted components and tissues be made available, both at revision and postmortem, so that the long-term success of both unsuccessful and successful devices can be monitored.

6.614.3.5. Revision

TDR cases requiring revision are comparable in number with THR/TKR, but more numerate than spinal fusion (**Table 6**). Revision operations of TDR are difficult due to the limited amount of bone in the vertebrae to attach the implant, and so it is preferable to ensure the long-term success of these devices and eliminate the need for revision. In the lumbar spine, revisions tend to be performed using posterior fusion, fusing the TDR in place so as to avoid the invasive anterior approach for a second time, which is further complicated by the presence of scar tissue.

Table 6 Comparison of revision rates of TDR, fusion, THR, and TKR

Procedure	*Revision rate (%)*	*Study*
Lumbar TDR	11.2	Kurtz *et al.*[104]
Anterior lumbar fusion	5.8	Kurtz *et al.*[104]
Posterior lumbar fusion	7.4	Kurtz *et al.*[104]
Cervical TDR	8.8–12.1	Anderson *et al.*[105] and Phillips *et al.*[106]
Anterior cervical fusion	3.1–5.0	Anderson *et al.*[105] and Phillips *et al.*[106]
THR	13.9	Kurtz *et al.*[104]
TKR	7.7	Kurtz *et al.*[104]

6.614.4. TDR Design

6.614.4.1. History and Evolution

TDR describes any procedure that involves excision of the anatomical disc and its replacement with a device that restores natural motion to some extent. TDR has lagged behind replacements of the peripheral joints, mainly due to the complex biomechanics and the surgical challenges that replacement presents. Although the most common types are the articulating discs, they have also included 'spring and hinge' designs, fluid-filled chambers, and elastomeric discs.[11]

Several 'spring and hinge' devices, similar to the articulating designs in the attachment to the vertebral body by spikes,[107] have been patented by inventors, but the articulating surfaces are substituted with a collection of miniature springs or a hinge design[108,109] that has an element of 'springy' flexibility. These designs allow limited motion, as well as some compliance, but have never been used clinically.

Elastomeric discs, such as those made of silicone and polyurethane, were designed as it was thought that these could be mechanically, if not chemically, similar to the anatomical disc.[11] The Bryan disc (Medtronic Sofamor Danek, Memphis, TN) uses elastomeric material, a polyurethane membrane that surrounds an articulating core, which means that the quality of motion still relies on the articulating parts. Lumbar discs have been more difficult to develop because of the increased loading demands of the lumbar spine; yet in 2008, several designs began to appear for use in the lumbar spine, including the CAdisc-L (Ranier Technology, Cambridge, UK) and Physio-L (Nexgen Spine, Inc., Whippany, NJ). The manufacturers of these discs claim that they provide a more physiological kinetics, in that they replicate the viscoelastic nature of the natural disc, provide some shock absorbency, and show little wear. These discs are yet to be independently tested *in vitro* as well as *in vivo*, but they can have great potential if these claims are proven true.

6.614.4.2. Material Selection

The most successful lumbar TDRs to date are those articulating designs that have, in part, developed from the successes of THR/TKR. Material selection (**Table 7**) in TDR has closely followed the use of materials in other joint replacements. Metal–PE bearings were used in the first articulating TDR (Charité, ProDisc) and have remained the most implanted devices, particularly in the lumbar spine. Metal–metal bearing combinations followed shortly after, with supporting evidence that these bearings could reduce wear in THR. More recently, other materials have been

Table 7 Summary of TDR devices and materials

Device name	*Manufacturer*	*L*	*C*	*Materials*
Charité	Link/DePuy Spine	•		CoCrMo–UHMWPE

Theken eDsic	Theken Disc	•		Titanium endplates, elastomeric core

used including polyether–ether–ketone (PEEK) and one-piece elastomeric materials that are thought to significantly reduce wear or eliminate it completely (see **Chapter 6.601, Current and Projected Utilization of Total Joint Replacements**).

6.614.4.3. Constraint

Articulating TDRs are often referred to as constrained (also referred to as fixed-bearing), semiconstrained, or unconstrained devices (also referred to as mobile bearing). This terminology relates to the DOF that the devices can support. All current TDRs (**Table 8**) provide three DOF: flexion–extension, lateral bending, and axial rotation. Various TDRs provide an additional one to two DOF for AP displacement and lateral displacement, often being referred to as unconstrained or semiconstrained. Only the TDRs that provide a full six DOF, including axial compression, can be said to be fully unconstrained, and these are currently limited to the elastomeric designs.

Increasing constraint leads to a more stable design and has inherent shear stability that is thought to protect the facet joints. However, it may lead to underuse of the facet joint, which could subsequently lead to degeneration. Decrease in constraint leads to a more physiological motion, with a mobile COR, but little shear stability, which means that the facet joints may be overloaded, again leading to degeneration.

6.614.5. Evidence of TDR Wear

In the early use of TDR, radiographic measurements found no evidence that either PE wear[71] or osteolysis[80] had occurred after a mean follow-up of 8.7 years after ProDisc implantation and after a 10-year follow-up for the Charité disc.[110] However, more recently, with the increased number of implants exceeding short-term implantation, several studies have found that PE debris is accumulating around TDR in which the incidence of osteolysis has been reported.[103] Further *in vivo* monitoring of the wear process is essential in order to determine safe implantation times, increased risk factors, and additional complications resulting from the wear process.

Explanted components have shown evidence of wear. The volumetric wear of explants was studied using a microcomputer tomography (μCT) scanning technique.[111] The finding was an average height change of 0.2 mm over an average of 9.1 years, although this was a combination of wear and creep. Retrievals have also suffered from severe wear and even breakages of the PE cores,[112] although they have primarily been those early implants that were γ-sterilized in air. Study of explanted discs at postmortem would make it possible to ascertain whether these levels of wear are typical of well-functioning implants as well.

6.614.6. TDR Wear Simulation

6.614.6.1. ISO and ASTM Standards

The experience of THR/TKR wear studies and the biomechanical investigations of the spine have provided the basis for testing requirements as specified by both ISO 18192[113] and ASTM F 2423[114] for both the cervical (**Table 9**) and lumbar spine (**Table 10**). The loading profiles follow a sinusoidal pattern with the corresponding peaks clearly coincident with those seen in the work by Callaghan *et al.*[42] However, it is important to note that the Callaghan motion data are for a lumbar spinal

Table 9 ISO and ASTM input conditions for wear simulation of cervical TDR

Test profile	*ISO*		*ASTM*	
	Displacement control	*Load control*	*Displacement control*	*Load control*
Axial load	N/A	50–150 N (±3%)	N/A	100 N (±5%)
Flexion/extension	±7.5° (±0.5°)	N/A	±7.5° (±0.5°)	±2 Nm (±5%)
Lateral bending	±6° (±0.5°)	N/A	±6° (±0.5°)	±2 Nm (±5%)
Axial rotation	±4° (±0.5°)	N/A	±6° (±0.5°)	±4 Nm (±5%)

Table 10 ISO and ASTM input conditions for wear simulation of lumbar TDR

Test profile	*ISO*		*ASTM*	
	Displacement control	*Load control*	*Displacement control*	*Load control*
Axial load	N/A	600–2000 N (±3%)	N/A	1200 N (±5%)
Flexion/extension	6°/3° (±0.5°)	N/A	±7.5° (±0.5°)	±10 Nm (±5%)
Lateral bending	±2° (±0.5°)	N/A	±3° (±0.5°)	±10 Nm (±5%)
Axial rotation	±2° (±0.5°)	N/A	±6° (±0.5°)	±12 Nm (±5%)

segment, and not for an FSU, and so motion parameters may be exaggerated for simulator testing of a single FSU.

One crucial difference of the ASTM standard guide is that the suggested axial compressive load is static, which may lead to depletion of the lubricant between the bearing surfaces, and so resulting in unrealistically high wear rates.[114] Both standards state that displacement control be the preferred method of application for all three rotations, which ensures that the bearing is not displaced beyond its limits and so does not dislocate, and force control of the axial compressive load, which ensures that extreme contact forces are not generated. To date, there is no suggestion for the applications of AP or lateral shear loads, although these have been documented.[42,53] The application of AP shear loads in TKR wear simulation has been shown to affect wear performance, depending on implant type.[115] The same may be true in the spine, with additional shear loads altering the motion patterns and therefore cross-shear.

Both standards recommend a minimum of six active stations and one load-soak control station. The testing chambers should be isolated from each other such that the debris from each can be assessed independently and to prevent contamination from the surrounding environment. All stations are required to have control systems that maintain temperature at 37 °C, to a tolerance of ±2 °C[113] or ±3 °C.[114] Bovine serum lubricant is specified by both standards, although the protein concentration differs from $20\,g\,l^{-1}$ in the ASTM standard guide to $30\,g\,l^{-1}$ in the ISO 18192. The addition of antimicrobial agents is permitted to prevent degradation of the serum. These protein concentrations have been successfully used in THR/TKR simulator studies, and are considered analogous to the pseudosynovial fluid that is formed within the fibrous capsule that forms around these peripheral joint replacements.[116] However, the intervertebral discs are not synovial joints, and although it has been suggested that a similar fibrous capsule and pseudosynovial fluid are formed,[117] to date no *in vivo* studies have investigated the nature of this capsule. As such, the exact nature of the lubricant remains to be discovered.

6.614.6.2. Spine Wear Simulators

The increased use of TDR and the race for FDA approval for the US market has led to the development of wear testing standards and the development of commercial simulators based on these standards. There are currently five commercial simulator designs in use for TDR wear testing: Endolab Spine simulator (Rosenheim, Germany),[118] AMTI simulator (AMTI Boston, MA),[119] Bose Spinal disc fatigue/wear test instrument (Bose Corporation, Electroforce systems group, MN),[120] MTS Bionix[121] spine wear simulator (MTS systems corporation, MN), and ProSim 5DOF Spine Wear simulator (Simulation solutions, Manchester, UK).

Both the Endolab Spine simulator and the AMTI simulator incorporate four active DOF: flexion/extension, lateral bending, axial rotation, and axial compression, in accordance with ISO 18192[113] and ASTM F 2423.[114] The Bose and MTS Bionix simulators both claim to incorporate a full six DOF; however, the fifth and sixth DOF are only passive. The ProSim 5DOF Spine Wear simulator applies five active DOF, the fifth DOF being application of AP shear by either load or displacement (**Figure 2**). **Table 11** summarizes the ROM in each DOF for the five simulators discussed.

All the simulators are capable of producing the load motion profiles, with phase angles, as specified by the ISO 18192. Hydraulic actuators provide motions with a high degree of control and are used for four of the commercially available simulators. However, they are relatively high in cost and require effort to contain and maintain the fluid. Electromechanical actuators are used for all DOF in the ProSim 5DOF simulator and for one DOF in the AMTI simulator.

As well as the magnitude and phasing of the loads, the point at which the load is applied is likely to affect the wear pattern of TDR. The Endolab simulator applies the compressive force to the superior fixture, with all of the motions applied to the inferior fixture. The Bose, AMTI, MTS, and ProSim simulators apply the axial force and rotation to the inferior fixture, and the flexion–extension and lateral bending to the superior fixture. As TDR wear testing is still in its infancy, there is very little

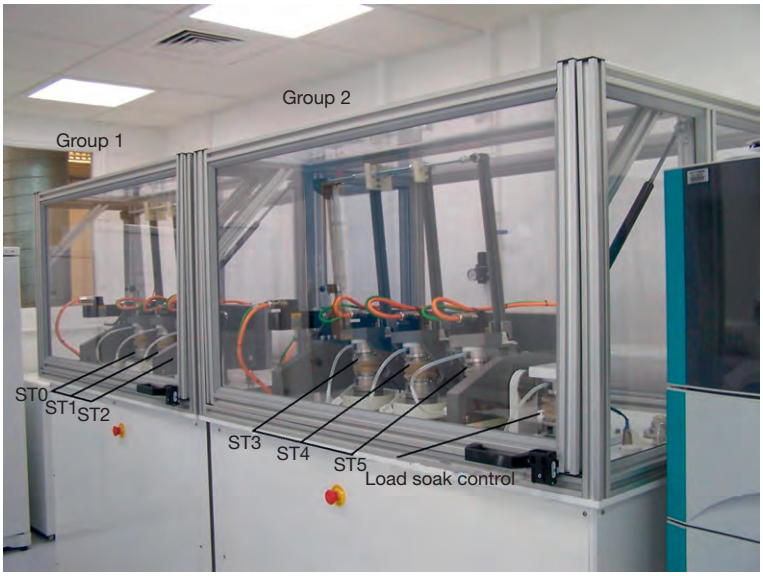

Figure 2 The ProSim Spine Wear Simulator, which comprises six wear and one load-soak station.

Table 11 Capabilities of spine wear simulators

	Endolab[118]	*AMTI*[119]	*Bose spinal*[120]	*MTS Bionix*[121]	*ProSim 5DOF*

validation to prove that the wear patterns produced by ISO 18192 (or any other loading profile) *in vitro* match those experienced *in vivo*.

Both ISO 18192 and ASTM F 2423 advise testing to be done over a minimum of 10MC (million-cycles), with analysis of test fluid and the core components over at least every 1MC. A definitive number of cycles experienced *in vivo* is as yet to be determined, but 10MC, incorporating a high safety factor, is suggested by ISO 18192 to exceed that required *in vivo*. In previous ISO standard hip studies, 1MC corresponds to the average number of steps per year, and the same could be considered for the spine. However, ASTM have approximated 125 000 significant motions within the spine per year,[114] and so 10MC would be equivalent to up to 80 years *in vivo*. Shorter test runs may be justified as wear in THR/TKR is accepted as steady state after the initial 'running in' period, and this has so far been the case for TDR.[99,122,123]

Measurement protocols currently consist of gravimetric and dimensional measurements, such as coordinate measurement. Other measurement methods to be considered are fluid displacement[124] and a relatively new dimensional method, μCT,[125] both of which have been used to measure wear of explants.

6.614.6.3. Wear Simulation Validation

To date, only a few attempts have been made to validate *in vitro* wear studies with explanted TDR. The ProDisc[126] and Charité[112] have both had *in vivo* and *in vitro* wear scars qualitatively examined, with the size of this attribute proving similar. However, key damage modes such as scratching and impingement were missing in the *in vitro* implants when compared to explants, suggesting that the simulator studies do not capture all *in vivo* conditions.

Height loss comparisons of *in vivo* and *in vitro* Charité suggest that 1MC of the ISO 18192 conditions equates to 5.6 years *in vivo* wear.[127] 1MC of ISO 18192 wear simulation in the lumbar spine (±95% confidence) has been shown to be equivalent to 0.5–1.5 years *in vivo* when comparing height loss alone.[128]

6.614.7. Wear of Metal–PE TDR

Independent four DOF wear tests of metal–PE TDR have shown wear rates to be 0.2–3 mg per MC in cervical implants and 10–20 mg per MC in lumbar devices (Table 12). These levels of wear represent up one-tenth of the wear seen in THR for the cervical case, but similar levels of wear are seen for the lumbar case in comparison to THR. These wear tests produce multidirectional motion on the surface of the PE.

Low cross-shear conditions, where the surface motion is reciprocating resulting in molecular orientation in the principal direction of motion, have been shown to reduce the wear rates in other joint replacements.[115,134] When only three DOF

[a]Reported in mm^3 per MC, converted to mg per MC using PE density of 940 kg m^{-3}.

conditions, or conditions that result in low cross-shear conditions, are used, reductions in the wear rate are seen, with wear at least halved (to 6 mg per MC) to <1 mg per MC (**Table 11**).

AP and lateral shear conditions for wear testing of TDR are not currently specified. However, tests incorporating an additional DOF, AP shear, did not produce any increase in wear rate for the ProDisc.[128] Similar tests of the Charité resulted in a substantial increase in the wear rate (a twofold increase).[128] Motion studies have shown that the addition of the fifth DOF had little effect on the ProDisc motion, but with the Charité, both bearing surfaces were engaged, and so the increase in wear rate appears logical.[135] This study shows that it is also important to consider the effects of device design when comparing wear rates.

Such input-related changes in wear rates indicate that clinically relevant input conditions are important so as to ensure that *in vitro* wear simulations are producing clinically relevant wear rates. The PE wear regimes relating to cross-shear and pressure dependency that are seen in TKR are also present in TDR designs, and so input conditions must include perturbations that consider these phenomenon, as well as classical wear theory.

Cross-linked PE has been used in THR for many years, and has consistently shown reductions in wear rates,[136] and as such is now commonly used. The radiation levels at which TDR PE is sterilized (2.5–4MRads) produce some mild cross-linking, but no intentionally cross-linked PE devices are currently available. In addition to possible reductions in wear rates, cross-linking can increase the brittleness of the PE, thereby leading to increased surface damage due to other processes such as fatigue.

Table 13 Summary of metal–metal wear rates published in the literature for cervical and lumbar discs

Lee *et al.*[138]	3DOF	Experimental design	6.2–15.8
Bushelow *et al.*[139]	4DOF	Maverick	4.91

6.614.8. Wear of Metal–Metal TDR

Published wear rates of metal–metal cervical TDR are 0.1–0.5 mm^3 per MC, similar to those seen in THR (**Table 13**). Despite the low reported wear rates in cervical TDR, independently published wear studies of metal–metal lumbar TDR have shown discouraging results following the use of metal–metal bearing combinations. Wear rates are within the same order of magnitude as those for metal–PE devices, up to 15 mm^3 per MC. The increased load in lumbar TDR may be increasing the wear in comparison to cervical TDR, with the material wear properties conforming to classical wear theory.[140] These large wear rates in comparison to THR and the damage modes seen suggest that preferential lubrication regimes do not occur in metal–metal TDR.[141] These studies show that current metal–metal TDR devices do not produce the wear characteristics that have made metal–metal THR so popular, and so metal–metal bearings may not be suitable for TDR, at least in the lumbar region. Metal–metal wear rates have been shown to be highly dependent on design,[142] and so improved bearing design may lead to improvements in wear rates.

6.614.9. Wear of Alternative Material TDR

The risk of osteolysis with PE bearings, the high wear rate of metal–metal TDR, and the concerns related to the use of noncompliant materials have led to the development of alternative bearing materials. These materials include elastomers, polyaryletheretherketone (PEEK), carbon-reinforced PEEK (CRF-PEEK), and polyaryletherketone (PEK) (**Table 14**).

Although elastomeric discs were developed to be biomechanically similar to natural discs, an added advantage was that the absence of articulating parts would ensure the absence of wear. However, some of the designs that use elastomeric materials involve articulation within the bearing (such as the Bryan), while others involve some rubbing of material (such as NeoDisc). The NeoDisc has been shown to have similar wear rates to other cervical TDR. One-piece elastomeric bearings will not produce wear debris due to articulation, but material loss is still possible due to other factors such as fatigue, erosion, or third-body damage. As such, the effects of these materials both in mass and particulate form must be studied.

PEEK has been shown to be a promising material for artificial joints in THR and TKR,[145,146] producing much lower wear

Table 14 Summary of alternative bearing wear rates published in the literature for TDR

Study	*Input conditions*	*Device*	*Mean wear rate*
Elastomer/ textile[143]	3DOF	NeoDisc	0.56 mm^3 per MC
PEEK-PEEK[144]	3DOF	NUNEC	0.34 mg per MC[a]
PEEK-PEEK[144]	4DOF	NUNEC	0.41 mg per MC[a]
PEEK-PEEK[128]	4DOF	Activ-C	1.4 ± 0.4 mg per MC
CFR-PEEK[128]	4DOF	Activ-C	0.02 ± 0.02 mg per MC
PEK-PEK[128]	4DOF	Activ-C	0.8 ± 0.1 mg per MC

[a]Reported in mm^3 per MC, converted to mg per MC using PEEK density of 1320 $kg\,m^{-3}$.

rates than PE. Tests on PEEK have not shown any decrease in wear rate for the cervical TDR when compared to metal–PE devices. PEK showed a small reduction (50%), but carbon fiber-reinforced PEEK (CFR-PEEK) showed a substantial reduction in wear rates.[128] Further research into alternative bearing materials is necessary in order to reduce wear rates further.

6.614.10. Biological Response to TDR Wear Debris

Although all of the materials used in TDR have a history of successful use in other implants, there is little information as to the effect of these materials in spinal tissues such as the dura and pia mater, and whether wear particles, in particular, could breach these and enter the spinal fluid. Such complications would denote a significant contraindication to any TDR procedure that is capable of producing wear particles (see **Chapter 6.606, Biological Effects of Wear Debris from Joint Arthroplasties**).

6.614.10.1. Biological Response to PE Debris in the Spine

The biological response to PE debris in total joint replacement (TJR) has been well documented and shows that osteolysis and implant loosening lead to late-stage failure in THR and TKR. As such, research on metal–PE bearings has focused on the reduction in wear rates, achieved by improvement in design and/or enhancement of the material properties of the PE by cross-linking. Some have suggested that the lack of a synovial capsule in the spine may be beneficial, in that the PE debris is not contained and so the levels of PE particles do not exceed the osteolytic threshold.

In vitro wear simulations have shown that TDR wear debris has osteolytic potential,[99,100] and evidence of increased osteolytic cytokinanes has been seen clinically as well as in *in vivo* studies,[102,147,148] indicating that an osteolytic response is at least possible, if not likely, within the tissue. Clinical cases of osteolysis around TDR are now beginning to emerge, as early as 8 years after implantation.[101–103]

6.614.10.2. Biological Response to Metal Debris in the Spine

Metal-on-metal implants have been used in THR as the wear rates are much lower than with conventional PE, and the particles have been shown to be less biologically active than PE particles. However, there are long-term concerns regarding the accumulation of metal ions in the body, including concerns associated with genotoxicity and carcinogenesis. The wear rates of metal-on-metal TDR have shown to be much greater than in THR, and so the resulting wear debris is likely to be more damaging.

Studies of titanium debris within spinal tissues have shown that an osteolytic response is also possible with metal–metal devices in the spine.[147,149] Other studies of metal debris have shown that the dura mater, subdural space, nerve roots, and spinal cord were free of reaction in an animal model.[150] Further studies of this type are necessary to ensure the safety of metallic debris around the spine.

6.614.11. Conclusions

Wear studies of TDR are still in their infancy compared with those for THR and TKR. Wear rates have been shown to be comparable, despite the smaller motions experienced by most TDRs, to THR/TKR. Recent studies have investigated the effect of different input conditions, material selection, and device design on wear rates. Biological studies have shown that particles have similar characteristics, and complications due to these particles are at least as serious, when compared to THR/TKR.

Further wear simulation is required to investigate the effects of device design, material selection, and input conditions on the wear behavior of TDR. Monitoring of the wear process *in vivo* is essential to patient safety and to the tracking of the progress of wear *in vivo* and its relation to future complications. Further, clinical validations are essential to determine the appropriateness of *in vitro* wear simulation. Finally, biological studies of wear particles and their effect on the spine must also be accelerated to determine the likelihood of severe complications such as neurological damage and carcinogenesis.

Glossary

Allograft Transplanted tissue from the same species but from different individual.
Autograft Transplanted tissue obtained from self.
Discogenic Originating from the intervertebral disc.
Fibrocartilage Tissue having both cartilaginous and fibrous tissue properties usually containing both collagen type I and proteoglycans in varying proportions.
Herniation Protrusion of nucleus pulposus tissue through disruptions in the annulus fibrosus.
Hydrogel Colloidal gel containing water as liquid constituent.
In situ Latin for 'in the place.'
Notochordal Originating from the notochord structure in embryos from which the spinal column develops.
Osteoconductive Having the ability to promote the ingrowth of bone.
Osteogenic Having the ability to deliver bone-forming cells.
Osteoinductive Having the ability to promote the differentiation of undefined cells into osteoprogenitor cells.
Osteolysis Resorption of bone in response to disease state.
Proteoglycan Heavily glycosylated glycoprotein with one or more covalently bound glycosaminoglycan chains.
Radiculopathy Disease of the spinal nerve root or nerves.
Spinal stenosis Narrowing of the spinal canal.

Abbreviations

AF	Annulus fibrosus
BMP	Bone morphogenic protein
ECM	Extracellular matrix
FDA	Food and drug administration
IVD	Intervertebral disc
MSC	Mesenchymal stem cells
NP	Nucleus pulposus
PCL	Polycaprolactone
PEG	Polyethylene glycol
PGA	Polyglycolic acid
PLA	Polylactic acid
PLLA	Poly-L-lactide
PMMA	Poly(methyl methacrylate)
rhBMP	Recombinant human bone morphogenic protein
SIS	Small intestine submucosa
TDR	Total disc replacement
TE-TDR	Tissue-engineered total disc replacement

6.615.1. Background

Intervertebral disc (IVD) degeneration is a leading cause of disability in the developed world, with ~65 million people in the United States alone suffering from prolonged back pain.[1] Although, a direct connection between pain and IVD degeneration is not always evident, the vast majority of chronic spine ailments involve some amount of disc degeneration. Moreover, by age 50, more than 85% of the population will have some evidence of this disease.

Degenerative disc disease can lead to a number of pathological conditions that can cause pain and discomfort. Due to the proximity of the IVD to the nerve roots, protruding disc material can impinge the local nerve roots causing radiculopathy.[2] In addition, peripheral sensitization and neoinnervation of the nerve fibers located in the outer lamellae of the annulus fibrosus (AF) and endplate can result in pain due to disc degeneration, and altered mechanical stimuli.[3] Furthermore, disc degeneration and herniation are associated with inflammation and immune response that can lead to neuritis and increased sensitivity in the nerves.[4] Finally, alterations in the AF and nucleus pulposus (NP) composition and structure lead to hypermobility in the spine that can result in greater inflammation and stimulation of the sensitized nerves. One of the difficulties of treating pain resulting from the IVD is the complex interactions between the inflammation, innervation, hypermobilitiy, and stenosis observed in IVD pathology. These interactions are currently an active area of investigation, as they are not fully understood to date.

The cost of treatment of degenerative disc diseases and its associated symptoms is estimated to be in excess of $50 billion per year in the United States. Due to the prominence of this disorder, a number of materials are currently being used for the treatment of degenerative disc disease (**Table 1**). Because the primary presentation of these disorders is pain, surgical treatments are primarily palliative, with less, if any, focus on restoring function to the diseased tissue.

6.615.1.1. Spinal Fusion

One of the most common surgical treatments is partial or complete discectomy, in which the IVD is removed in an attempt to eliminate the source of the pain, whether the pain is caused by the impingement of the nerve root or discogenic in origin. In the case of complete discectomy, the spine must be stabilized through the fusion of the vertebral bodies. This allows the pain-inducing disc to be removed, but results in the loss of mobility at the operated motion segment. As a result, it is necessary for the remaining motion segments to provide the required flexibility to the spine. In addition, it is essential to maintain the anatomy of the spine to protect the integrity of the intertwined nervous system. This includes the disc space height that was originally maintained by the IVD.

This is accomplished by implanting autologous bone grafts, cadaveric allografts, or bone graft substitutes in the disc space in combination with rods, screws, plates, or cages. The hardware is designed to provide stabilization to the spine while the grafts are implanted to promote bone formation between the vertebral bodies during fusion. An optimal material used for spinal fusion will have an osteoconductive scaffold that promotes the ingrowth of bone, osteogenic capabilities that provide cells to the fusion site, and osteoinductive factors that promote the differentiation of progenitor cells into osteoblast cells. The materials currently used all have at least one of these properties and multiple materials are being combined to maximize these properties in many cases.

6.615.1.1.1. Bone grafts

Bone grafts were the first material choice in promoting a fusion between the vertebral bodies.[5] They provide the exact material that is desired in the disc space and in the case of autografts are osteogenic, osteoconductive, and osteoinductive. As a result, the material could be harvested from the patient and implanted in the disc space to promote fusion between the vertebral bodies while maintaining the disc space height formally maintained by the IVD. The two types of bone grafts available are autografts and allografts.

Autografts are obtained from the patient's own bone and are usually obtained from the iliac crest of the pelvis. Autografts provide the highest likelihood of fusion due to the presence of bone, osteoblasts, and bone morphogenetic proteins (BMPs). However, autografts can result in donor site morbidity and chronic pain at the harvest site.[6,7] In contrast, allografts are obtained from a human source other than the patient. This bone is acquired from tissue banks and circumvents the issues of donor site pain and morbidity but introduce the possibility of disease transmission. When used alone, allografts tend to underperform autografts in producing a successful fusion.[8–11] This is likely due to the lack of osetogenic cells and minimal osteoinductive factors contained in the allograft despite its osteoconductive scaffold. The allografts cells are purposefully removed during processing to reduce the likelihood of an immune response caused by the foreign cells.

Table 1 Current treatments for degenerative disc disease

Treatment	*Physical therapy*	*Partial discectomy*	*Spinal fusion*	*Total disc replacement*	*Dynamic stabilization*	*IVD transplant*	*Tissue-based regeneration*
Disease severity	Mild–moderate	Moderate–severe	Severe	Severe	Moderate–severe	Severe	Mild–severe
Biomaterials	NA	NA	Autograft bone, allograft bone, demineralized bone, matrix, growth factors	Metal/polyethylene articulating joint	Metal/polyethylene screws, cords, spacers, flexible rods, flexible screws	Allograft IVD	Broad range of hydrogels, fibrous materials, and cells

Currently, in an attempt to increase the likelihood of fusion, adult stem cells are being investigated as a possible way to overcome the lack of living cells in allografts.[12]

6.615.1.1.2. Synthetic bone grafts

Autografts and allografts are both limited in supply since they require a donor and donor site. Synthetic bone grafts, on the other hand, could mimic the properties of bone and provide a material to promote fusion while circumventing the autograft/allograft cons of supply, donor site morbidity, donor site pain, and disease transmission. Bone has both an organic (collagen type I) and inorganic (hydroxyapatite) component. Synthetic bone grafts attempt to mimic the compositional content of the bone, usually the inorganic component, to provide a biodegradable osteoconductive scaffold to promote fusion. This involves producing calcium containing crystalline solids with porosity similar to that of bone that will promote bone ingrowth.

A number of synthetic materials designed to mimic the properties of bone, including various ceramics, are being investigated for use in fusion procedures. These materials are osteoconductive but, similar to allografts, do not contain cells. For this reason, they are often used in combination with autografts as bone graft extenders. The most commonly used materials are coralline hydroxyapatite, β-tricalcium phosphate, and calcium sulfate.[13–15] The use of these materials as an extender allows for less autograft material to be harvested, thus decreasing the risk of donor site morbidity and pain (see **Chapter 6.612, Biomaterials for Intervertebral Disc Regeneration**).

6.615.1.1.3. Demineralized bone matrix

While allografts and synthetic bone grafts provide an osteoconductive scaffold, they fail to provide substantial osteoinductive proteins to stimulate bone growth. The combination of both osteoconductive and osteoinductive properties similar to that found in autografts can further promote fusion beyond what an osteoconductive scaffold can produce alone.

Used as a bone graft extender, demineralized bone matrix is obtained by removing the mineralized component of allograft bone by acid extraction. The resulting matrix is predominantly type I collagen in addition to various growth factors including BMPs. As a result, demineralized bone matrix is both osteoconductive and osteoinductive. However, the mechanical stiffness of demineralized bone matrix are much lower than that of bone and must be used in combination with a material that can provide the necessary structural strength when implanted. For this reason, the material is used primarily as a bone graft extender to introduce the osteoconductive proteins into the disc space.

6.615.1.1.4. Growth factors and gene therapy

Both autografts and demineralized bone matrix have osteoinductive proteins and demonstrate the ability of these proteins to stimulate bone growth. As a result, it is advantageous to develop techniques that allow these osteoinductive proteins to be utilized for spinal fusion in combination with techniques other than autografts and demineralized bone matrix. In addition, recombinant production of growth factors enables greater control of the types and concentrations of growth factors delivered to the fusion site.

A number of growth factors including BMPs have been shown to be osteoinductive. As a result, the use of recombinant forms of these proteins has been combined with osteoconductive materials to be utilized in spinal fusion surgeries. Human trials have shown increased success over autografts when using either recombinant human bone morphogenic protein 2 (rhBMP-2) or rhBMP-7 in combination with a number of carrier matrices including collagen sponges, collagen type I powder, allograft bone, and ceramic granules.[16–20] Overall, this provides a technique that is both osteoconductive and osteoinductive without requiring autograft harvesting.

One of the drawbacks of rhBMPs is their soluble nature and high doses need to be inserted in the carrier matrix to be effective over a sustained period of time. As a result, the associated cost of this type of procedure is quite high. One possible solution is to utilize gene therapy to introduce the osteoinductive BMPs to the fusion site. Such a technique allows sustained production of the BMPs at the fusion site without having to insert large amounts of rhBMP into the carrier. Currently, a number of animal studies are being performed to test the efficacy of such strategies and investigate the safety concerns related to gene therapy[21–23] (see **Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**).

6.615.1.2. Motion Preservation

Despite the common use of spinal fusion for the treatment of various spinal complications, the procedure produces a number of deleterious consequences. First the fusion of the vertebral body results in a loss of motion at the fused site and often leads to adjacent-level degeneration thought to be caused by the altered mechanical loading at the adjacent levels.[24,25] For this reason, a number of devices have been designed to preserve the motion of the IVD at the operated level.

6.615.1.2.1. Total disc replacement

Similar to what is performed in the knee and hip, the first attempts to preserve motion as an alternative to fusing the vertebral bodies were total disc replacement (TDR) strategies. In this procedure, the entire disc is removed and replaced by an artificial joint containing an articulating surface designed to provide motion to the joint segment (**Figure 1**). The devices reaching clinical trial have contained either two metal alloy endplates with an ultra high molecular weight polyethylene articulating surface (Charité® and ProDisc®) or have a metal on metal design (Prestige®, Flexicore®, and Kineflex®). Currently, the Charité®, ProDisc®, and Prestige® have received food and drug administration (FDA) approval. Relatively short-term data indicates that these devices have been successful in reducing adjacent level degeneration[26,27]; however, it is unclear whether this will be true in the long term. Furthermore, it appears that these discs may suffer from polyethylene wear,[28,29] which could lead to osteolysis, dislodgement, and failure of the device. As a result, further investigation will need to be carried out to understand the long-term efficacy of the TDR strategy.

6.615.1.2.2. Dynamic stabilization

In addition to TDR, a new class of devices is currently being investigated for treatment of spinal disorders. These devices are designed to provide controlled motion at the disc level without

replacing the entire disc level. The devices attach to the posterior elements of the spine and are composed of some combination of screws, cords, spacers, flexible rods, and flexible screws. One example of such a system is the Dyneses® system, which has received FDA approval as an adjunct to spinal fusion surgeries but is not approved as a stand-alone device, although clinical trials are underway (Figure 2). The Dyneses® system is made of pedical screws, surgical polyurethane spacers, and polyethylene cords. This combination of parts is designed to maintain motion in a controlled manner that will decrease pain but allow motion similar to that of the healthy motion segment. Many similar devices can be imagined and quite a few are currently under investigation for the treatment of spinal disorders.[30,31]

6.615.1.2.3. IVD transplantation

In addition to using hardware to maintain motion and stability in the diseased spine, a novel technique of transplanting cadaveric IVDs is being investigated. The hypothesis behind this procedure is that the transplanted healthy native tissue will most accurately restore the complex function of the IVD to the spine while relieving the pain and circumventing the issues associated with using traditional metal/polyethylene materials. In this method, segments of the boney vertebral bodies are left on either end of the IVD in order to promote integration of the transplanted disc into the motion segment. The low vascularity of the IVD reduces the risk of tissue rejection and allows the procedure to be performed without immunosuppressant drugs.

IVD transplantation was originally investigated in canine[32–34] and primate[35,36] animal models and has now been tested in a small number of human patients.[37] Animal models showed that the transplanted discs were able to successfully integrate with the native tissue by 6 months and form functional motion segments after an initial period of hypermobility (2–4 months). However, despite forming functional motion segments, a loss of water and proteoglycans were observed in allografts from 6 to 24 months. In addition, nucleus cells had an irregular shape and mitochondrial swelling at 24 months. These findings indicate that the transplanted IVDs are capable of integrating and forming functional motion segments; however, they show signs of degeneration over time after implantation. Immune response was localized to the boney interfaces. Human trials in five patients have met with success as patients show no signs of significant pain at a 5-year follow-up. Radiologically, patients showed minimal disc height loss and a normal range of motion.

Overall, the animal models and early clinical results on IVD transplantation are promising. However, it will be important to carry out studies in a larger cohort of patients and investigate the long-term survival of the transplants. In addition, despite the apparent success of the procedure, IVD transplantation suffers from limited donor tissue, issues of size matching, and possible disease transmission. As a result, regenerative techniques are also being investigated for IVD tissue replacement.

Figure 1 Total disc replacement – Charité.

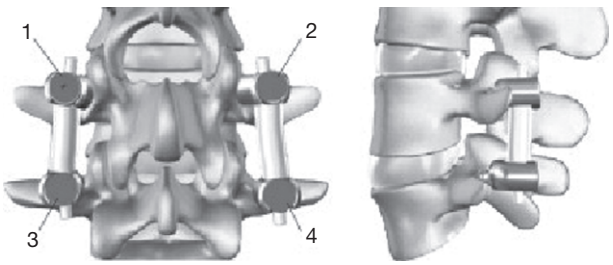

Figure 2 Dynamic stabilization – Dyneses system.

6.615.1.2.4. Regenerative medicine and tissue engineering approaches to motion preservation

Despite the development of TDR and dynamic stabilization devices, the long-term success that these devices will have in reducing adjacent segment degeneration remains unclear. While these devices are promising, it is likely that these devises will suffer from long-term failure modes (wear, fatigue, and loosening via osteolysis) similar to that of other traditional knee and hip polymer/metal implants. For these reasons, acellular and cellular tissue-based approaches that mimic the native IVD extracellular matrix (ECM) composition and architecture may be advantageous. The cellular component would allow the tissue to be remodeled and repaired over the life of the tissue while the ECM component could more accurately mimic the native IVD function than a metal–polymer implant. A tissue-based approach could create a treatment that could mimic this function, maintain mobility, and not suffer from the failure modes of wear, fatigue, and osteolysis. For this reason, the investigation of tissue-based approaches for the treatment of spinal disorders is actively being pursued (see Chapter 5.507, Tissue Engineering and Selection of Cells).

6.615.2. IVD Structure and Function

In order to understand the material design criteria involved in IVD repair, one must first be familiar with the complex structure and function of the native IVD. Grossly, the IVD is a composite tissue containing an outer AF, an inner NP, and the cartilage endplates.[38] Each of these regions is distinct in

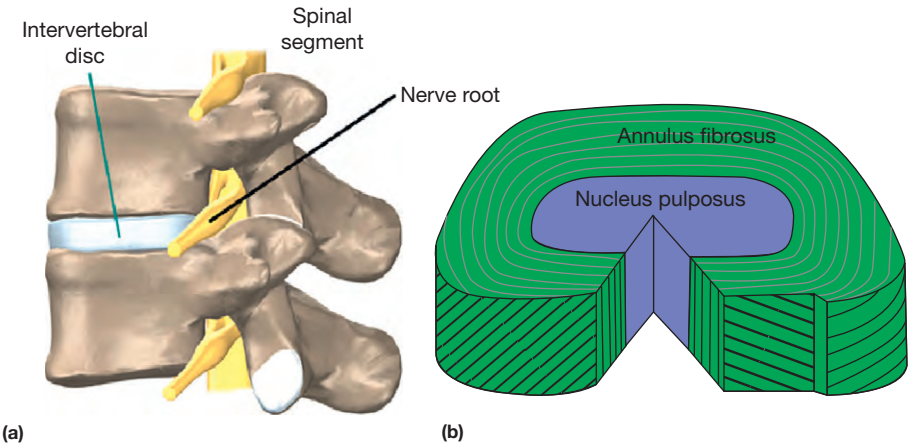

Figure 3 Intervertebral disc (IVD) structure. (a) IVD located in spine between vertebral bodies with the *cauda equina* (lumbar) or spinal cord (thoracic and cervical) running through the spinal canal posteriorly. Nerve roots exit from the spinal canal through the intervertebral foramen. (b) The IVD composed of the unorganized inner nucleus pulposus and outer highly organized annulus fibrosus. The annulus fibrosus is composed of lamellae and alternating collagen alignment (±28°) between each adjacent lamella.

composition, as well as organization, and work in concert to provide the mechanical function of the IVD (Figure 3).

The NP is an isotropic, unorganized, gelatinous material that is enclosed by the highly organized AF fibrocartilage on the side and the hyaline cartilage endplates on the top and bottom (Figure 3(b)). The encapsulation of the gelatinous NP by the AF allows the IVD to be both strong in compression while also withstanding complex tensile and shear forces in the AF region. Upon compression, the NP is pressurized as the AF resists the radial expansion of the NP. It is this pressurization that gives the IVD its high compressive stiffness.[39] In addition, during the bending and torsional movements of the spine, the complex collagen architecture of the AF bears the tensile loads.[40] It is this elegant function that one hopes to restore when selecting materials for IVD repair, and for this reason, it is advantageous to understand the material components and architecture that accomplish this naturally.

6.615.2.1. Extracellular Matrix

Overall, the key components of the IVD are water, collagens, proteoglycans, elastin, and cells with varying amounts and types located in the distinct IVD regions. The IVD is extremely hydrated with the AF and NP having a water content of ~65% and 80% of wet weight respectively.[41] In the AF, collagens make up 70% of the dry weight with 84% of that being collagen type I and 14% collagen type II at the outer AF.[42] In contrast, collagens only make up 20% of the dry weight of the NP with 80% of that being collagen type II. Proteoglycans follow the opposite trend with the percentage starting low in the AF and increasing until reaching 50% of the dry weight in the NP.[43]

Of these proteoglycans, the negatively charged large aggregating proteoglycans, aggrecan, and versican are found in the IVD with members of the small leucine-rich proteoglycan family (decorin, biglycan, lumican, and fibromodulin) also being present.[44,45] It is the negative charge of aggrecan that produces an affinity for water in the IVD via osmotic swelling and Donnan equilibrium. As a result, the high proteoglycan to collagen ratio produces the gelatinous nature of the NP and the low proteoglycan to collagen ratio and prevalence of type I collagen gives rise to the fibrous nature of the AF.

Finally, elastin is found in both the NP and AF.[46] The fibers are located predominately between the AF lamellae but are also found parallel to the collagen fibrils within the lamellae.

6.615.2.2. Organization

The degree of organization observed within the NP and AF is dramatically different. The NP has an unorganized collagen type II matrix dispersed within the proteoglycan-rich tissue. This unorganized state leads to the isotropic nature of the NP and its capacity for significant swelling when liberated from the surrounding AF. In contrast, the AF has a very organized collagen type I fiber structure. The AF is macroscopically segmented into lamellae surrounding the NP core. In each lamella, the collagen fibrils are highly aligned at an angle of ±28° to the transverse plane and this angle increases to 44° in the inner AF,[47,48] with the angle alternating in each successive lamella (Figure 3(b)). As a result, this organization leads to anisotropic mechanical properties and creates a tissue that is good at resisting the tensile loads observed in torsion and bending as well as withstanding the hoop stresses that occur during compression. Overall, this tissue produces a unique set of mechanical properties in compression, torsion, and bending that tissue-based approaches of repair will need to recreate to restore function to the diseased or injured IVD.

6.615.3. IVD Preservation, Repair, and Regeneration

By any measure, tissue-based IVD repair and tissue engineering is a relatively new field. Extracting broad trends from published data is quite challenging even with the small number of studies to date (~50 peer-reviewed manuscripts), since there is relatively little continuity in the cell types and materials used. The approaches can be broken down into NP, AF, and total disc repair.

6.615.3.1. Nuclear Replacement

The idea of nuclear replacement has received the most attention. This approach relies on the idea that replacing the herniated or diseased disc material will maintain or restore disc height and function to the spine. By replacing the NP, the disc height is restored and the AF fibers are placed back into tension, similar to that of a healthy disc. This type of intervention requires a healthy AF and, as a result, is a solution to an earlier stage of disease than used in spinal fusion and TDR. Currently, clinically available products are material based but research is being conducted on creating tissue-engineered material/cell solutions (Table 2) (see Chapter 6.613, Nucleus Replacement).

6.615.3.1.1. Acellular

Early attempts at nucleus replacement focused on acellular materials to restore disc height. The first attempt at nucleus replacement was conducted in 1955 by David Cleveland,[49] in which he replaced the NP after discectomy with methylmethacrylate. Aceular strategies continue to be investigated today and are at various stages of clinical evaluation. For a thorough analysis ofaceullar nuclear replacement, please see Chapter 6.613, Nucleus Replacement.

6.615.3.1.2. Cellular

Creating tissue-based strategies with a cellular component creates a tissue that can mature and repair over the life of the implant. As a result, this dramatically increases the theoretical limit for how long the treatment can be effective. The key to the successful development of a tissue-based strategy is in the proper selection of the material, cell source, and signaling. The NP has been a prime target for this type of therapy due to the isotropic unorganized structure of the tissue, which eliminates the need to worry about a complex tissue architecture during tissue development. Overall, the goal is to produce a tissue that is gelatinous in nature with high proteoglcyan content and type II collagen.

The choice of an animal source for IVD cells is challenging, as the time at which the cell population of the NP changes from notochordal to chondrocytic varies with species. Regardless of species chosen, it appears to be critical to ensure that cells are obtained from skeletally mature animals. To date, cells from seven species have been investigated for use in IVD regeneration, including murine,[50] lapine,[51] porcine,[52] ovine,[53,54] canine,[55] bovine,[55] and human.[56] It is highly likely that human cell sources will be required for clinical use; however, obtaining cells from the human IVD tissue may be difficult due to the diseased state of the tissue. As a result, the use of mesenchymal stem cells (MSCs) is being investigated. In fact, MSCs have been shown to take on a NP-like phenotype, both *in vitro* and after being injected into NP tissue[57,58] making them a suitable candidate for tissue-based NP replacement.

Disc degeneration results in decreased cell density in the NP and reduced cellular activity. As a result, one of the proposed treatments for NP degeneration is to simply inject cells into the NP without scaffolding material to promote *de novo* tissue formation in the NP of the degenerated disc. NP cells,[59] NP cells cocultured with MSCs,[60] MSCs,[61] chondrocytes,[62] and AF cells cocultured with MSCs[63] have all been investigated for NP injection. In general, cells were able to produce proteoglycan-rich matrix in the NP and delay degeneration in disc degeneration models. In a human trial, IVD cells were cultured and injected back into the NP after microdiscectomy surgery.[64] Patients receiving the treatment showed decreased pain at 2 years compared to those receiving no injection of cells after microdiscectomy. This data indicates that injecting cells into the NP may be able to delay degeneration in the IVD and be used as an adjunct to microdiscectomy to improve clinical outcomes.

While cell injection alone has shown potential to delay degeneration and promote *de novo* tissue formation, the use of a scaffolding material in concordance with the cells provides the additional ability to repressurize the NP by injecting the scaffold/cell material into the disc space. The isotropic gelatinous nature of the NP makes hydrogels a prime material candidate for NP tissue engineering. However, unlike acellular NP replacement, these materials must be deliverable in a noncytotoxic manner eliminating a number of hydrogels used in intradiscal implants. Wide ranges of scaffold materials have been used as substrates for cell culture. In general, NP cells have been cultured in hydrogels, with alginate[52–55] and gelatin[50] accounting for more than half of the studies published. Both materials appear to be well suited to maintaining NP cell phenotype and enabling proteoglycan synthesis, although significant accumulation of proteoglycan and collagen was not observed uniformly. Additional materials being utilized have been type II collagen,[65] hyaluranon composites,[66] calcium polyphosphate substrate,[67] type I atelocollagen,[61] and chitosan.[68]

While a large portion of this work has been done *in vitro*, a number of studies are available investigating the effectiveness of cell/material nuclear replacement *in vivo*. These studies have been conducted in degenerated animal lapine,[59] canine,[69] and murine[50] models. The results of the animal model *in vivo* studies have been promising, showing a delay in degeneration, restoration of disc height, and significant proteoglcyan-rich ECM. In addition to the animal studies, interim results of a human randomized trial have been reported. In this study,

Table 2 Nuclear replacement

	Acellular		*Cellular*	
	Intradiscal implants	*In situ* curable polymers	Cell only	Cell + scaffold
Goal	Restore/maintain disc height	Restore/maintain disc height, repressurize NP, minimally invasive	Restore/maintain disc height, repopulate lost cellularity to produce *de nove* tissue	Restore/maintain disc height, repressurize NP, repopulate lost cellularity to produce *de novo* tissue
Materials	Springs and hydrogels	Hydrogels, polyurethane, water/oil emulsion	Autologous disc cells, MSCs	Autologous disc cells, MSCs + hydrogels, type II collagen, hyaluronan composite, calcium polyphosphate, chitosan

autologous NP cells derived from therapeutic discectomy were cultured and delivered 12 weeks after discectomy in patients with chronic back pain.[70] Their data suggest MR imaging improvement consistent with increased proteoglycan matrix within the NP and a reduction in low back pain at 2 years when compared to controls. As a result, NP replacement may be a powerful adjunct to discectomy. However, it is important to note that this treatment must be conducted at an early enough stage that a functional AF is in place. Later stages of degeneration are unlikely to be treated by NP replacement alone.

6.615.3.2. Annular Repair

Due to the nature of disc herniation and the resulting disruption in the AF, it is necessary for the AF to be repaired to return proper mechanical function to the disc. In addition, the herniated region of the AF can allow the remaining NP or NP replacement to reherniate through the disruption. This can happen in up to 15% of patients after discectomy,[71–73] and unfortunately, the AF has a limited healing capacity and will only produce a thin biomechanically inferior tissue without intervention.[74] For this reason, it is a significant and relevant challenge to produce surgical treatments to repair the AF upon herniation (**Table 3**).

6.615.3.2.1. Acellular

The earliest attempts to repair the disrupted AF involved suturing the AF to provide both a barrier to reherniation and to promote healing. Unfortunately, few studies have been performed to study the effectiveness of suturing. In one of the few studies available, no significant increase in healing strength was observed as a result of direct annular repair.[75] In addition to suturing, a number of additional implants designed to close and act as barriers are being developed. These devices include sutures with anchors,[76] meshes,[77] and collagen poly(methyl methacrylate) (PMMA) injections.[78] However, currently there is little data to determine the effectiveness of these devices and they continue to suffer from the poor intrinsic healing of the AF, as they do not directly promote healing. For this reason, tissue-based approaches are also being investigated to promote a functional healing in the defect in addition to simply closing it.

6.615.3.2.2. Cellular

The goal of introducing cells into an annular defect is to promote the production of a functional tissue in the defect to both inhibit NP reherniation, as well as restore the mechanical properties of the AF. The creation of a functional engineered AF tissue is more difficult to produce than the NP due to its highly organized architecture and anisotropic mechanical properties. The tissue must not only contain the proper amounts of ECM, but they must also be organized properly to restore the mechanical function to the AF. The key organizational structures of importance are the high degree of alignment, the angle of alignment, and the alternating directions of alignment between lamellae. However, it must be noted that currently it is unknown as to what degree this organization needs to be recreated to successfully reduce the number of cases of reherniation and slow the progression of the disease state.

Cell selection for AF repair requires the selection of a cell that can produce a highly organized type I collagen ECM. The most likely candidates for use in AF repair strategies are the AF cells themselves or MSCs. However, once again autologous AF cells suffer from the diseased state of the tissue and diseased state of the resulting cells.[79] In addition, the availability of autologous AF cells varies greatly between patients and will likely require *in vitro* culture to expand to an adequate number of cells. These shortcomings may limit the effectiveness of these cells for clinical treatments. In comparison, MSC cells provide a more reliable cell source but are not without their own difficulties. Early work showed that MSCs differentiate into an NP-like phenotype and not an AF phenotype when cultured in hydrogels.[58,80] Nevertheless, the proper combination of scaffold and cell signaling that promotes an AF phenotype from MSCs may still be elucidated. In fact, more recent work has shown that when MSCs are placed on electrospun nanofibrous scaffolds the cells take up a more AF-like phenotype.[81,82] This may indicate scaffold selection as a key determiner of MSC phenotype and make proper material selection vital in producing a successful tissue-based approach to AF repair.

A number of scaffolds with a wide range of properties have been investigated for AF tissue engineering. Early work used scaffolds seeded with AF cells that lacked the structure necessary to promote collagen alignment and organization. These scaffolds included collagen type I/hyaluronan,[66] type I atellocollagen,[83] alginate,[51] type I collagen/glycosaminoglycan,[84] collagen sponges,[85] collagen gels,[85] fibrin gels,[85] polyglycolic acid/polylactic acid (PGA/PLA),[53] chitosan,[86] and electrospun poly-L-lactide (PLLA).[82] These constructs in general allowed for significant production of proteoglycans and collagen but the ECM development was still substantially lower than native values of ECM. In addition, no collagen organization was observed in these scaffolds.

Recently, focus has turned to culturing cells on scaffolds that promote tissue organization and alignment in the hope that an engineered AF tissue can be created that mimics the complex anisotropic function of the AF. This has been accomplished through the creation and use of aligned fibrous scaffolds. To date it has been achieved naturally with the use of small intestine submucosa (SIS),[87] with the self-assembly of contracted collagen gels,[88] and with the aligned electrospinning of polycaprolactone (PCL).[81] Each of these techniques has advantages and disadvantages for treating AF defects.

The SIS is obtained by processing small intestine to remove the mucosa layer. This results in a construct that contains oriented collagen fibers, proteoglycans, and trapped growth factors. This is ideal due to the similarity of the SIS ECM composition (aligned collagen and proteoglycans) and structure to the native AF. In addition, the trapped growth factors can be released and promote tissue development at the site of

Table 3 Annular repair

	Acellular	*Cellular*
Goal	Provide barrier to reherniation	Produce novel tissue in defect, provide barrier to reherniation
Materials	Anchored sutures, meshes, collagen PMMA injections	Autologous disc cells, MSCs + hydrogels, electospun nanofibrous scaffolds, chitosan, PGA/PLA, collagen sponges

implantation. SIS has been investigated for the repair of a number of tissues, including blood vessels, bladder defects, rotator cuffs, knee ligaments, and meniscus previously. The use of SIS for annular repair is relatively new but has shown promise in a sheep model by repairing AF defects and returning partial function to the IVD[89] (see **Chapter 5.524, Biomaterials for Replacement and Repair of the Meniscus and Annulus Fibrosus**).

Contracting collagen gels while controlling the boundary conditions has been shown to create aligned collagen fibrils and has been investigated for the repair of a number of tissues, including blood vessels, tendon, ligament, and cardiac tissue. The advantages of the technique are the production of aligned collagen architecture and aligned cells that are seeded throughout the tissue. However, contracted collagen gel tissues have notoriously week mechanical properties in contrast to the native AF. At early time points after implantation it may be difficult for an implanted collagen gel to withstand the mechanical loading imposed upon the aligned collagen gel. Conversely, the collagen nature of the scaffold may promote earlier integration of the tissue with the native AF and the high permeability of the collagen gel may promote the transport of nutrients into the developing tissue. This increased transport in the developing tissue may be especially important in the low nutrient environment present in the IVD and allow the tissue to mature into an integrated mechanically functional tissue after implantation.

Electrospinning allows scaffolds to be produced that have fibers of similar size to that of the collagen fibrils found in the AF. In addition, electrospinning can incorporate fiber alignment into the scaffold and has been used to create engineered tissues that contain lamellae with alternating $\pm 30^{\circ}$ fiber orientation.[81] These electrospun tissue structures developed tensile properties similar to that of native AF and showed promise for use in AF tissue engineering. However, the electrospinning process is not without its challenges. One of those challenges is the migration of cells into the electrospun scaffolds. Often, cells will fail to migrate to the center of the scaffold and will result in reduced tissue development at the center. Currently, a number of techniques are being studied to address these issues including the combination of composite electrospun materials that have differing degradation rates to encourage migration of cells into the scaffold.[90] In addition, a big question is how these organized fibrils will integrate with the endplate and vertebral bodies once implanted. Without integration and anchoring of the fiber structure, the fiber architecture will not be engaged and will fail to provide the mechanical function they are designed for. Further work is being conducted in the field to better understand how these electrospun scaffolds will integrate with the native tissue.

As can be seen, the amount of work done in the field of AF tissue engineering is limited and much of it has been *in vitro*. It will be important in the future direction of AF tissue engineering to understand how these strategies respond *in vivo* to the demands of AF defects. The major questions are centered on the ability of the repair strategies to confine the NP, the ability to restore pressurization capability to the IVD, and the ability to restore proper functioning to the AF in tension. Clearly, if these capabilities can be restored, it will have a profound effect on the treatment of disc herniation in the clinic.

6.615.3.3. Total Disc Replacement

A similarity exists between the IVD and a tire with the air of the tire being represented by the NP and the steel-belt reinforced rubber being represented by the AF. Furthermore, this similarity can be extended to the repair of the IVD as well. In certain situations, it will be advantageous to refill the air of the tire (nuclear replacement); in other situations, one may be able to patch a hole in the tire (AF repair), and finally, there are times when the entire tire must be replaced (TDR). It is the final situation, in which the herniation or degeneration of the AF is advanced enough that a sole NP or AF approach cannot be effective. It is for this reason that TDR is currently being investigated.

Artificial TDR has been recently introduced into clinical practice in the United States with the FDA approval of the previously discussed Charité device in 2004. The idea of a tissue-based composite disc was introduced with publication of the first tissue-engineered composite disc around the same time.[53] The idea that the entire IVD can be replaced by a tissue-engineered structure is an ambitious one due to the complex structure of the IVD; however, the early studies showed promising ECM and mechanical properties with a PLA/PGA/alginate composite. The major design criteria in developing a tissue-engineered total disc replacement (TE-TDR) are (1) designing a disc that can withstand the complex mechanical loading once implanted, (2) can recreate the mechanical function of the IVD, (3) can integrate with native tissues, and (4) can survive and develop in the nutrient-deprived disc space. These design criteria are complex and are even competing. The development of a mechanically stiff disc designed to withstand the complex loading will likely have low permeability properties and may make it difficult to get sufficient nutrient transport throughout the disc in the low nutrient disc environment. Conversely, a highly permeable disc that can provide better nutrient transport will be less stiff and may have trouble withstanding the mechanical loads. Currently, it is unknown what the proper balance of these competing properties will be in a successful TE-TDR.

To date, only four designs and five papers have been published on TE-TDRs. These TE-TDRs include an PGA/PLA (AF)/alginate (NP) composite,[53,54] an electrospun PLLA (AF)/hyaluronic acid (NP) composite,[82] a contracted collagen gel (AF)/alginate (NP) composite,[88] and an electrospun PCL (AF)/agarose (NP) composite.[91] The cell selection for these constructs has been either ovine IVD cells, bovine MSCs, or human MSCs. The material selection for each attempt has utilized a hydrogel for the NP, with a trend toward increasing hierarchical organization in the AF region (**Table 4**).

The first TE-TDR to be attempted was the PGA/PLA/alginate composite. The construct was seeded with ovine NP and AF cells in their respective regions of the disc. The alginate hydrogel provided an NP-like environment that maintained the rounded morphology of the NP cells once encapsulated. The AF region of PGA/PLA provided the gross morphology of the AF but contained none of the organization inherent in the native AF (**Figure 4(a)**). The scaffolds were implanted subcutaneously in the back of an athymic mouse for 4 months and produced proteoglycan composition similar to that of the native in the AF and NP. The constructs produced collagen to

Table 4 Tissue-engineered total disc replacement

near native levels in the AF but not in the NP where it developed 10% of the native values. The collagen produced was properly localized with increased collagen type I in the AF and type II in the NP. In addition, the compressive mechanical properties were similar to that of the native sheep IVD. Overall, these studies demonstrated the feasibility of developing a TE-TDR that mimicked the compositional and compressive properties of the native IVD. However, with the lack of organization and architecture in the AF, and the failure to test the discs in anything but compression, it is unclear if this design could mimic the torsional and bending properties of the native IVD (see **Chapter 5.509, Cell Encapsulation**).

The second attempt to produce a TE-TDR utilized electrospun PLLA and hyaluronic acid seeded with human MSCs. This technique was similar to the previous attempt in that it used an unaligned AF regional scaffold and a hydrogel NP scaffold. However, the use of electrospun PLLA allowed the fibers to be of similar diameter to the native collagen fibrils in the AF region. In addition, the hyaluronic acid was injected into the electropsun PLLA to pressurize the NP region within the scaffold and place the electrospun fibers in tension similar to that of the native AF. Furthermore, the use of human MSCs is significant due to the clinical relevance of the cell source and begins to investigate their effectiveness in a TE-TDR.

The constructs were cultured for 28 days *in vitro* and the AF cells organized into concentric layers resembling the concentric lamellae of the AF while the NP remained amorphous in structure. ECM proteoglycan deposition was most prevalent in the AF region with a less pronounced deposition in the NP. Collagen types I and II also had the highest concentration in the AF region with least present in the NP region. This poor tissue development in the NP was likely due to the decreased cell content in the NP region of the scaffold after construction. Overall, the electrospun PLLA showed promising results for the AF region and tissue development; however, no mechanical testing was performed on the tissue to investigate the mechanical function of such an implant and it will be necessary to overcome the poor cellular density in the NP in the future.

Unlike the first two TE-TDR designs, the contracted collagen gel/alginate construct was the first to introduce collagen alignment into the AF region (**Figure 4(b)**). The technique produced an alginate NP region seeded with ovine NP cells and a type I collagen gel region seeded with ovine AF cells surrounding the NP region. During culture, the cells contract the collagen fibril network around the alginate NP. As a result of the physical boundary of the NP, the collagen fibrils aligned circumferentially around the alginate NP. In addition, the AF cells were elongated and circumferentially aligned between the type I collagen fibrils similar to native AF cells and the NP cells took on a rounded morphology similar to the native NP. This technique provides a method of producing a TE-TDR that has an architecture and organization similar to that of the native IVD in the AF and NP region. However, despite the circumferential alignment of the collagen fibrils, the technique currently fails to capture the ±28° collagen alignment observed in the successive AF lamellae. In addition, no mechanical testing or ECM composition analysis was performed in this study.

The most recent TE-TDR combines the previous strategies to produce the most complex TE-TDR to date (**Figure 4(c)**). The technique uses electrospun PCL to produce aligned PCL fibers at ±30° angles in each successive lamella. Once again this is done around a hydrogel NP region, which in this case was agarose. The cells selected were bovine MSCs because of the clinical promise of MSCs. The idea is that the complex PCL fiber architecture will lead to organized collagen development with the same alignment of the original scaffolding.

After 6 weeks of culture, collagen and proteoglycan production was observed in both the AF and NP region. It was observed that both AF cells and collagen production were organized in the ±30° direction of the underlying PCL scaffold. Despite the deposition of ECM over culture time, values for proteoglycans were <32% of the native values in both the AF and NP and were 5% of the native values for collagen in the AF. The collagen values were similar between native and the TE-TDR in the NP. As can be seen, the technique of using aligned electrospun fibers does help promote collagen organization similar to the native AF. However, it will be important to investigate how to promote greater ECM development to native value levels in these scaffolds.

The development of these TE-TDR strategies has shown initial promise at promoting varying levels of ECM composition and organization similar to the native IVD. However, despite the trend toward increasing AF organization and the

focus on mechanical properties of these implants, it is currently unknown what is needed for the successful implementation of such a device in the native disc space. Less attention is given to other design parameters such as the permeability of these scaffolds, a property that might prove extremely important in the limited nutrient environment of the disc space. A better understanding of how these TE-TDRs react in the native disc environment will be necessary to recognize what the proper balance of scaffold properties is that will promote successful tissue development and proper spinal function. These implants will need to withstand the mechanical loading, survive and develop, and integrate with the native tissue once implanted.

Recent work has begun to address these *in situ* questions using the contracted collagen gel/alginate TE-TDR.[92] The TE-TDRs were implanted into the lumbar and tail disc space of the rat and cultured for up to 6 months. These studies demonstrated that despite the much lower modulus of the collagen/alginate TE-TDR at the time of implantation compared to the native disc, the tissue was able to maintain a majority of the disc height over 6 months (78%). In addition, the tissue saw extensive deposition of proteoglycans and collagen and had integrated with the vertebral bodies and endplates. Furthermore, when the engineered motion segment was tested mechanically, it demonstrated similar compressive properties to the native disc. These results were the first that showed a TE-TDR could successfully form a mechanically functional tissue when implanted into the disc space. These results are especially intriguing due to the relatively low mechanical strength of the TE-TDRs at implantation. It is possible that the coupled highly permeable nature of the collagen and alginate TE-TDR allowed sufficient nutrient transport that promoted the tissue development and integration in the disc space. It will be important as this field moves forward, for more work to be done in the native disc space to understand how the TE-TDR properties (modulus, permeability, cell type, ECM composition, AF fiber organization, etc.) affect *in situ* tissue formation (see **Chapter 6.614, Wear: Total Intervertebral Disc Prostheses**).

6.615.4. Future Challenges

The clinical need for new treatments to IVD injury and disease is driving the development of novel material- and tissue-based solutions. Many of these solutions are designed to treat IVD disease and injury at varying stages of disease progression. These range from posterior dynamic stabilization of the spine to tissue-based TDR. With the wide range of disease stages presenting in the clinic and variability among patients, it is likely that this broad spectrum of treatments will be needed.

The most immediate impact in disease treatment will be seen in non-tissue-based solutions. These include posterior dynamic stabilization, nuclear replacement, and novel TDR devices. These devices can provide improved performance in current clinical treatments while avoiding the more difficult FDA hurdles faced by cellular-based approaches. With the large range of possibilities in material design and solutions for dynamic stabilization, nuclear replacement, and TDR devices, one expects a large number of products to begin to hit the market and enter clinical trials. The biggest hurdles will be proving the effectiveness of the treatments at reducing disease progression and pain while determining the most effective devices among the large variable space of possible designs.

In contrast to acellular approaches, the regulatory path for tissue-based approaches is more complex. In addition, as cells are introduced and the complexities of the treatments increase, the cost of producing the technology will increase as well. However, despite the hurdles, the upside of developing tissue-based technologies is large. Tissue-based solutions provide the opportunity to restore complete function to the IVD and produce treatments with longer life spans. It will be necessary for continued investment into tissue-based solutions to bring these technologies into common practice. As the technologies become more common and better understood, the regulatory hurdles will also decrease.

One of the great challenges to tissue-based treatments to disease is the large variable space available in material and cell selection. One must contemplate material, formulation, concentration, cross-linking agent, material organization, cell type, cell source, culture length, media type, cell signaling, etc. The variable space can be so large, it can be difficult to investigate the entire variable space and narrow down to the best solutions. This can become even more clouded when animal model variables and selection are introduced into the equation. In addition, these variables are rarely independent of one another, making it very difficult to process and understand the data and results that are produced. As this field continues to advance, techniques will need to be developed to help process these large amounts of data and interactions between variables. One possible solution is neural network analysis, which has been used to process the large input and output variable space of chondrogenesis in elastin-like polypeptides.[93] Applying techniques like neural network analysis may allow ideal solutions and better understandings of how material properties and tissue development parameters interact. As a result, this may lead to better design criteria for creating complex tissue-based treatments to IVD disease.

Despite progress in research on tissue-based solutions of IVD repair, there are still a number of major unknowns. One of these unknown variables applicable to all the tissue-based approaches is the long-term survival and durability of the treatments. Despite evidence that new tissue can be developed that resembles the native tissue, it is unclear what will happen to this tissue over time, especially in a diseased environment. This is principally true for TE-TDR technologies that will require relatively large tissues to be supplied with nutrients during maturation and long-term survival. It may be difficult for tissues to survive and mature relying on diffusion of nutrients from the AF periphery and endplates. As a result, it will be critical to assess the tissue response and ability to survive once implanted. The ideal situation will be that the tissue can mature and last for the entirety of the patient's life; however, shorter tissue survival does not eliminate the usefulness of tissue-based approaches. The ability to extend and delay the need for spinal fusion or TDR treatments by even just 5–10 years could dramatically improve the patient's outcome and quality of life. Therefore, it will be important to understand the lifespan of these technologies and how they fit into the long-term care and outcome of the patient treatment.

In addition to the challenges facing all tissue-based approaches, TE-TDR has an additional specific challenge.

These tissues must deliver in a way that allows the tissue to mature and integrate with the native tissue while maintaining the stability of the spine. As a result of the removal of the native IVD, the time after implantation and before integration leaves the vertebral column compromised. This provides a situation that could result in deleterious consequences if the vertebral column is not stabilized. For this reason, it is likely that TE-TDR strategies need to be developed in concert with stabilization techniques. Some possible solutions would be to use resorbable plates similar to those being investigated for use during fusion surgeries[94] or using posterior dynamic stabilization devices as an adjunct. These techniques would give time for the tissue to develop and integrate and could even act to augment mechanical properties during tissue development. Whatever the solution, it will be important to answer these questions of stabilization as more TE-TDR studies move toward *in vivo* implementation.

Despite these challenges, as our research and understanding of IVD repair and regeneration moves forward, great strides can be made toward improving the lives of those suffering from IVD related disease. As the field moves forward, the biomaterials used will continue to expand, new ideas for treatment will arise, and unforeseen challenges will present themselves. However, great hope lies in the continued research and investigation of tissue and non-tissue-based solutions to IVD disease.

In the year 2000, worldwide, approximately 9 million people suffered from fractures.[1] There were several causes, ranging from high-energy trauma such as gunshot wounds, motor vehicle accidents, and contact sports to low-energy trauma such as falls from a standing height. Falls are the most common reasons for hospital admissions in the older age group and

account for 87% of fractures.[2] These fractures cause considerable financial, emotional, and psychological hardship – due to many factors such as pain, lack of mobility, lack of independence, and concomitant injuries. In addition, approximately 5–10% of fractures suffer complications such as mal- and nonunion. The goal of fracture treatment is to obtain fracture union, while restoring normal anatomy and function. Successful treatment of fractures depends on a thorough evaluation of the patient and formulation of a treatment plan tailored to their needs.

Generally, treatment of fracture is divided into nonoperative and operative management. Operative treatment is preferred in particular circumstances including open or displaced fractures and fractures involving weight-bearing bones, articular surfaces, or neurovascular structures. In the year 1990, approximately 3.6 million operations were performed in the United States to reduce and fix fractures.[3] The exact annual cost of these interventions is unknown. It is estimated that by the year 2050, the cost of treating osteoporosis-related fractures alone will be between $130 and $250 billion per year. Therefore, advances in fracture management that improve healing and reduce costs from complications, especially through the use of cutting edge implants, are important to society, both in terms of the human and financial costs.

In the setting of fractures, metallic alloys are commonly used to fabricate devices for both internal and external fixation. Internal fixation can be divided primarily into plate and screw fixation and intramedullary fixation. Understanding the link between the structure, material properties, and biological effects of fracture fixation devices in the context of fracture healing is essential to ensure safety and efficacy in clinical practice. Choosing appropriate biomaterials with correct balance between mechanical stability and preservation of an appropriate biological milieu is the key to obtain successful bone healing. This chapter discusses the fracture healing process and basic requirements of biomaterials used in fracture fixation devices. Common devices used in fracture fixation including plate and screw construct, intramedullary fixation, and external fixator are described in terms of their overall design and the application of their biomaterial properties in fracture fixation. Furthermore, we discuss synthetic bone graft substitutes that are being used as adjuvant biomaterials in fracture settings.

6.616.1. Fracture Healing

Fracture healing is a complex process that involves a unique, highly integrated sequence of events in which bone is restored to its original condition. Normal endochondral fracture repair proceeds along a continuum, with different overlapping stages beginning with inflammation and callus formation and ending with a remodeling phase. In the inflammatory phase of fracture healing, a hematoma is formed from the blood vessels ruptured by the injury. Inflammatory cells invade the hematoma and initiate degradation and removal of necrotic debris. A mixture of degranulating platelets, macrophages, leukocytes, histiocytes, and mast cells infiltrate the fractured area and amplify the initial inflammatory responses by elaborating additional proinflammatory cytokines and peptide signaling molecules that trigger and promote growth and repair, as well as begin to clean up necrotic debris.[4,5]

This cellular response is highly coordinated and involves a number of different cytokines and growth factors such as vascular endothelial growth factor (VEGF), tumor necrosis factor-α (TNF-α), bone morphogenetic proteins (BMPs), and interleukins-1 and -6. The reparative phase, which usually begins 4 or 5 days after injury, is characterized by the migration of mesenchymal stem cells, which subsequently differentiate into fibroblasts, chondroblasts, and osteoblasts, forming a soft tissue callus that is mostly cartilage. This soft tissue callus serves as a hypoxia-tolerant temporary scaffold for the formation of a bony callus that will replace it once vascular invasion occurs. As this process continues, multiple foci of cartilaginous formation merge to form a central plug. Proliferation of blood vessels within medullary spaces and periosteum helps direct the appropriate cells to fracture site and provides critical nutrients. Chondrocytes within the cartilaginous plug lead to hypertrophy and mineralize to become woven bone. At this stage, hard callus formation occurs, representing the penultimate stage of fracture healing. In the remodeling phase, woven bone is replaced by lamellar bone and the medullary canal is restored. The remodeling process at the fractured site begins during the middle of the reparative phase and continues long after the fracture has clinically healed. Although stages within the fracture healing process are somewhat distinctive from each other, these phases overlap one another making fracture healing a continuous process.

The capacity for bone to repair or regenerate after fracture is similar to the events that transpire during development in the growth plate: endochondral ossification and intramembranous ossification. Endochondral ossification is a process that results in healing primarily through cartilage formation, while intramembranous ossification occurs without a cartilage model. For intramembranous ossification, undifferentiated mesenchymal cells aggregate into layers. These cells differentiate into osteoblasts and deposit an organic matrix that mineralizes to form bone. This type of bone healing occurs without callus and resembles normal bone remodeling. The process of intramembranous bone healing is exceedingly slow and requires adequate stability until the fracture is healed. The process of fracture healing is closely related to the mechanical and biological environment at the fracture site including motion and oxygen tensions.[6] Motion or high strain (>2%) at the fracture site results in healing primarily through endochondral ossification, whereas stability or low strain (≤2%) promotes bone healing via intramembranous ossification.[7] Most fractures, however, heal through a combination of intramembranous and endochondral ossification.[8]

6.616.1.1. Biological Requirements for Fracture Healing

Numerous factors have been identified to play a major role in fracture healing. In addition to mechanical stability at the fracture site, there are vast requirements of biological factors for bone healing. These include skeletal progenitor cells, extracellular matrix, bone-forming cytokines, and intact vasculature. Understanding the cellular and molecular pathways that govern the process of fracture healing is important to determine the treatment options. In general, the biological methods of fracture repair can be categorized into three essential modalities: osteogenesis, osteoinduction, and osteoconduction. Osteogenesis is the formation of bone tissue by mesenchymal stem cells.[9] During fracture healing,

mesenchymal stem cells from surrounding tissues invade the fracture site, where they proliferate and differentiate into cartilage or bone. The recruitment and differentiation of mesenchymal stem cells into bone-forming cells at a fracture site are mediated by certain molecules or cytokines, such as insulin growth factors (IGFs), transforming growth factor-β (TGF-βs), and BMPs.[10] This molecular process that regulates recruitment and differentiation of the mesenchymal stem cells is called osteoinduction. Finally, osteoconductive materials serve as scaffolds upon which osteogenic and osteoinductive factors can function. These materials provide structural support for the ingrowth of perivascular soft tissue, osteoprogenitor cells, and microvasculature that supplies critical nutrients necessary for bone healing.[11] Some biological tissues such as the skeletal extracellular matrix provide two essential functions: osteoconduction and osteoinduction. Bone extracellular matrix serves not only as a scaffold, but also binds growth factors and cytokines that play critical roles in stem cell differentiation. Examples of osteoconductive biomaterials commonly used in fracture fixation include calcium phosphate cements (CPCs), hydroxyapatite, and tricalcium phosphate (TCP). Currently, these biomaterials are widely used as adjuvant devices for fracture fixation especially in the settings of poor bone quality such as in osteoporosis.

6.616.1.2. Mechanical Requirements for Fracture Healing

During the first stage of fracture healing, the method of immobilization determines the biological mechanism by which fracture healing will take place. In cases of fractures treated with rigid fixation (defined as fixation of a fracture that is permitted little deformation under load), where strain across the fracture site is less than 2% and the bone ends are aligned along their normal anatomic axis, intramembranous bone healing occurs.[158] The necrotic bone ends are invaded by neighboring osteons that subsequently bridge across the fracture ends in an accelerated type of bone remodeling. Examples of rigid fixation devices for fracture treatment include compression plating or interfragmentary compression screws. Stable fixation is defined as a fixation in which fracture fragments are kept within less than 10% strain during joint movement, thus allowing early painless mobilization. Where fractured bone fragments experience strain levels between 2% and 10%, endochondral bone healing occurs. There are several fixation techniques that employ stable fixation. These include casting, locking-plate fixation, intramedullary fixation, and external fixation. While the pioneers of internal fixation saw external callus formation as a sign of treatment failure in fracture healing, recent studies show that stable fixation and the endochondral bone healing are preferred.

6.616.2. Basic Requirements of Biomaterials for Fracture Fixation Device

The term biomaterials refers to all synthetic and natural materials that are used in clinical practice to replace, stabilize, or augment damaged tissue. To ensure the safety and functionality of the devices used in fracture fixation, orthopedic biomaterials must be biocompatible, resistant to corrosion, and have adequate mechanical strength.[8]

6.616.2.1. Biocompatibility

Biocompatibility is the ability of an implant material to function *in vivo* without eliciting detrimental local or systemic responses in the body.[8] Prior to their use in human fracture fixation, biomaterials undergo tissue and animal testing to determine their safety and efficacy. Biomaterials that elicit little or no host response such as cobalt–chromium metallic alloys can be thought of as inert materials. The importance of biocompatibility is demonstrated by the consequences of allergic reactions to nickel- and chromium-containing stainless steel implants. The biological rejection of an implant leads to an inflammatory response mediated by immune cells and can necessitate removal of the implant. Much of the research into new biomaterials is focused on improving biocompatibility of implants, avoiding unnecessary complications (see **Chapter 4.401, The Concept of Biocompatibility**; **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing**; and **Chapter 3.319, Characterization of Nanoparticles in Biological Environments**).

6.616.2.2. Corrosion Resistance

Corrosion is the oxidative deterioration of metals. As a metal corrodes, its mechanical properties weaken, compromising its function as a fixation device. Although orthopedic implants are subject to a variety of corrosive effects, galvanic corrosion is of particular concern. Galvanic corrosion is an electrochemical process in which one metal corrodes preferentially for another when both metals are in electrical contact and immersed in a conductive medium. This type of corrosion most often takes place at the interface between plates and the screws that secure it to the bone. The corrosion not only damages the surface of orthopedic implants creating surface defects that can act as stress risers but also releases corrosion products to the adjacent structures, resulting in damage to surrounding soft tissues and impaired healing. Therefore, biomaterials used in fracture fixation devices must be corrosion resistant even in the highly reactive environment of body fluids. For example, titanium alloy is corrosion resistant *in vivo* due to an electrically isolating protective layer that forms on its surface.

6.616.2.3. Mechanical Properties

Design of an effective fracture fixation device requires attention to shape, mechanical, and material properties. Mechanical properties of orthopedic implants depend on several factors including stress and strain, isotropic and anisotropic behavior, viscoelasticity, and wear resistance. A discussion of all aspects of mechanical properties of the fixation devices is beyond the scope of this chapter and the reader is referred to other resources devoted to this subject for more information.

As mentioned earlier, the concept of rigid versus stable fixation is critical for the selection of fracture fixation devices as well as biomaterials. In order to heal properly and maintain its normal strength, bone needs to be subjected to dynamic stresses. As stainless steel is significantly stiffer than bone (~10 times stiffer), using stainless steel in rigid fixation devices can alter fracture remodeling and decrease bone density,

leading to regional osteoporosis.[8] This phenomenon, known as stress shielding, occurs when a fractured bone is shielded from normal stresses by its more rigid implant, attenuating the normal mechanical stimuli necessary to heal and maintain normal strength.[12]

Implants used for the treatment of fractures must control the amount of strain as well as rotational motion at the fracture site to achieve bone union. The currently available fracture fixation devices can be classified on the basis of their function as load-bearing and load-sharing constructs. Load-bearing constructs such as plates reduce the strain on healing bone – over time, the reduced strain can lead to local bone resorption adjacent to the plate. This can prove to be hazardous upon removal of the implant, as foci of ostepenic bone can act as stress risers, and may refracture at this location.[3,13] For this reason, if possible, implants should be load sharing, subjecting the bone to an optimal amount of stress and strain during the healing process. In general, the majority of intramedullary constructs and external fixation are considered as load-sharing devices. The concept of load bearing and load sharing is important and remains an active area of inquiry in fracture implant biomaterials.[14]

6.616.3. Devices Used in Fracture Fixation

6.616.3.1. Plate and Screw Fixation

Screws were likely first used in fracture fixation in the late 1840s. The French surgeons Cucuel and Rigaud reported utilizing screws to reduce and fix both sternal and olecranon fractures. In these early cases, screws were primarily used to reduce the fracture fragments and wires were used to secure the reduction.[4] By the late 1880s, this had evolved to the first reported use of plate and screw fixation when the surgeon Hansmann of Hamburg used a plate and special screws to reduce and fix complicated fractures.[4] These original plates and screws were ordinary steel, and by the early 1900s, corrosion-resistant vanadium steel was utilized for both plates and screws.

In 1949, the surgeon Danis published his treatise on osteosynthesis (the process of mechanically bringing the ends of a fractured bone close together), and he was the first to describe the mechanism of bone healing in rigid plate fixation of fractures.[4] A year after publication, a young surgeon from Switzerland, Dr. Maurice Müller visited Dr. Danis. The visit served as a source of inspiration to Dr. Müller, who went on to assemble and form the internal fixation study group – *Arbeitsgemeinschaft für Osteosynthesefragen*, commonly known as AO – that would revolutionize modern internal fixation.

Plates are ideally used in situations where their biological and mechanical properties make them well suited to the requirements of fracture healing. This is typically true in periarticular or metaphyseal fractures; oblique, comminuted, or segmental fractures; fractures in flat or small bones; rapidly healing fractures; or fractures in patients who have suffered pulmonary trauma or have extensive soft tissue or anatomical contraindications to other fracture fixation methods.[15]

6.616.3.1.1. Design rationale

Plate and screw constructs have a range of designs related to their biomechanical and biological properties. Ultimately, plates are used to provide stability, limiting the amount of strain a fracture experiences while avoiding interference with the biological needs of the fracture. When used in the correct clinical situation and applied with skill, plates are extremely useful in the treatment of fractures.

Plates have evolved a great deal structurally, with a diverse range of structures, mechanical properties, and materials. Bridge plates are used to bridge between comminuted or segmental fractures, serving as a splint. Dynamic compression plates use friction generated by screws to compress the plate to the bone, acting as a conduit to transfer loads between the bone ends.[16] Limited contact-dynamic compression plates (LC-DCP), point contact fixation plates (PC-Fix), and locking compression plates (LCPs) serve the same purpose but with less bone–plate contact. In the case of LCPs, no contact exists between the bone and plate.[17] Buttress plates are used at the end of long bones in periarticular regions, preventing axial forces from distorting the initial reduction.[18] The common denominator to plates is that they must be designed to provide stability, limiting strain at the fracture site to less than 10% while limiting the biological insult that they cause.

Additional design goals of plates include attempting to spread and reduce the loads encountered by plate–screw constructs equally across the screws and hence to the bone. Several aspects of plate design affect functionality. Plate length is an important consideration that affects forces experienced by the screws.[3,19] Plate contact surface area is another important characteristic of plates – a smaller bone–plate contact surface area has less negative effects on bone growth, vascularity, and bone healing.[20] Plate shape and profile play a role in the anatomic reduction of a fracture as well as its interactions with the surrounding soft tissue. Plates and screws that protrude into moving structures such as tendons and neurovascular bundles can cause complications.[21] Plate screw hole configuration influences the type of screws a plate can accept and screw density which affect biomechanical behavior. Plates with combination screw holes can accept both locking and nonlocking screws.

Screws are an integral part of plate screw constructs, and there is an equally diverse range of types of screws, which is beyond the scope of this chapter. The impact of biomaterials used in screws is an area of active research, yet to date, physical design factors have had a greater impact on the performance of screws than the materials used. Screw inner diameter, thread pitch, and working length have been shown to affect variables such as yield strength, screw pullout strength, torque resistance, and fatigue strength more than the material composition of the screws.[22] Inner diameter is the diameter of the part of the screw that does not include the threads. Thread pitch is the distance between adjacent threads. Working length is the length of the screw that is in contact with bone.

Of prime importance are two types of screws – locking-head and non-locking-head screws. Non-locking-head screws are screws that can be inserted at any angle into the plate/bone, and require incorporation into the bone in order to maintain compressive forces at the bone–plate interface. Locking-head screws lock into the plate because of its matching threads. The screws are fixed perpendicular to the plate providing angular stability and allowing it to act biomechanically as a single beam construct which increases its strength and resistance to

breakage.[23] Locked-plate–screw constructs also do not need compression at the bone–plate interface, which avoids disruption of periosteal vascularization.[3] On the horizon are polyaxial locking screws that combine the locking-head screw with a swiveling threaded bushing that deforms upon tightening the screw, locking the bushing and screw in place at the chosen angle.[24] The ability to choose screw orientation, reap the biomechanical benefits of angular stability, and eliminate plate–bone contact is extremely promising.

6.616.3.1.2. Applications of biomaterials to plate and screw fixation

Plates and screws used for fixation of fractures have a number of challenges and complications that the design and composition affect. Plates and screws can lead to stress shielding, bone resorption and inhibition of bone formation, local irritation and inflammation, vascular compromise, and infection via a variety of mechanisms. Additionally, over time, plates can break prior to complete fracture healing. Research aimed at avoiding these complications is active in areas such as alloys, surface treatments, and coatings.

The vast majority of plates and screws are made of metallic materials such as stainless steel and titanium. Both materials are relatively biocompatible and while Disegi and Eschbach report that stainless steel possesses bulk mechanical properties such as high strength and stiffness, low weight, ease of handling and manufacture, and cost effectiveness making it practical to use, titanium shares all of these properties. Between the two, stainless steel offers greater stiffness and strength than titanium, although both lead to excellent union rates. While titanium and stainless steel can produce stress shielding, stainless steel has pronounced effects since it eliminates many of the dynamic loads that bone would otherwise experience, and needs in order to maintain its strength.

These concerns led to the development of titanium plates, which have a lower modulus of elasticity. This tends to attenuate the effects of stress shielding, although not completely eliminating them. Titanium plates were additionally found to have superior fixation strength, screw torque-out strength, and fewer loose screws when compared to stainless steel plates in animal fracture models.[25] Titanium screws were shown to have longer fatigue life than stainless steel screws, and both constructs were shown to result in bone of equal strength at the end of healing.[22] Additionally, titanium is better visualized on radiographic and computed tomography images. Other materials such as biodegradable plates made from biopolymers such as poly-L-lactic acid (PLA) and poly-glycolic acid (PGA) have been tested, although concerns over their inferior fatigue life, reduced torque strength, and rapid degradation have led to recommendations that they are used for only non-weight-bearing, rapidly healing fractures such as maxillofacial and carpal/metacarpal fractures. Further research and development is warranted however as biopolymer plates and screws hold theoretical advantages such as diminished stress shielding with gradual load transfer to bone, reduced need for hardware removal, increased biocompatibility, and radiolucency.[26] Ultimately, research into newer alloys such as magnesium–calcium hybrids and nitinol (nickel–titanium) promises to eliminate some of the problems of stress shielding found in metallic alloys. Magnesium–calcium and nitinol both have a modulus of elasticity that is very close to that of bone. Nitinol is superelastic with shape-memory properties that may be beneficial to fatigue life and strain minimization.[27] Magnesium calcium alloys may be osteoconductive, and the products of degradation are utilized by normal biochemical pathways.[28]

Stainless steel, although corrosion resistant, does corrode with time. The release of nickel and chromium ions into surrounding tissue can cause irritation, inflammation, local microvascular compromise, type IV allergic-type hypersensitivity reactions, and decreased resistance to infection.[29,30] These reactions have been shown to cause decreases in implant strength, osteoblast cellularity, and bone apposition as well as increases in bone resorption.[31] Additionally, there are several case reports of rare connective tissue neoplasms such as angiosarcoma, fibrosarcoma, and osteosarcoma arising adjacent to stainless steel plates.[32–34] While titanium is widely viewed as more biocompatible than stainless steel, with less corrosion, titanium particles have some inhibitory effects on osteoblast cytoskeletal function, impairing adhesion, proliferation, and viability, however less so than stainless steel.[35,36] Although biopolymers do not exhibit as many problems with biocompatibility as metals, they have been shown to lead to reactions such as osteolysis, synovitis, and sterile sinus tract and abscess formation.[10] Alloys such as magnesium–calcium can also exhibit rapid degradation,[28] leading to serious magnesium or calcium toxicity that can negatively affect cardiac functioning. These complications are uncommon, however, with the vast majority of patients experiencing few to no side effects. Nevertheless, additional research is underway aiming to improve the suitability of these promising materials for use in plate and screw fixation.

Closely related to biocompatibility is infection resistance. Infection is a serious, oftentimes grave complication of internal fixation and can lead to premature implant removal, nonunion, sepsis, and potentially death. Avoidance of infection, therefore, is of paramount concern that should extend from the operating room to the design and manufacture of internal fixation devices. While showing more resistance to infection than stainless steel, titanium implants are still susceptible to wound infections.[23,37–39]

Arising from these concerns, several common surface treatments are being developed to improve biocompatibility, osteoblast proliferation, and viability, and decrease susceptibility to bacterial adherence and colonization. Improvement of the surface wettability characteristics of stainless steel by CO_2 laser leads to improved cell proliferation regarding osteoblast adherence, spread, and rate of growth.[40] UV irradiation of titanium surfaces, also leading to increased wettability, did not alter human osteoblast adhesion or function, but did reduce bacterial adhesion.[41] Production of microroughened ultrafine-grain pure titanium through the use of equal channel angular pressing showed better osteoblast compatibility over other titanium implant materials.[42] Laser shock peening (LSP) of magnesium–calcium alloys improved the corrosion profile, considerably slowing its degradation, as well as producing a surface effect analogous to microroughening which is favorable for osteoblast adherence and growth.[28] Lastly, increasing surface porosity of stainless steel and inducing surface hydrophobicity in titanium sheets by treatment with butanol were found to attenuate inflammatory responses to the materials *ex vivo*.[43]

Several surface coatings that improve biocompatibility are currently being tested. Phosphate-ion incorporated micro-roughened titanium surfaces showed significant increases in cell attachment and growth, with higher torque removal forces, and increased osteoblastic gene expression compared to untreated surfaces.[44] Tantalum and hydroxyapatite and multi-walled carbon nanotube composite coatings of titanium and stainless steel can lead to better cell–implant interactions and higher living cell densities.[45,46] Coating of titanium alloys with zeolite – a microporous aluminosilicate that can sequester ionic species – can improve their already excellent biocompatibility by reducing the amount of cytotoxic aluminum and vanadium ions an implant can release into surrounding tissue.[47] Processing Ti–13Nb–13Zr alloys with a mixture of minimal essential medium and hydrogen peroxide leads to a porous layer of hydroxyapatite and amino acids that favor the growth of osteoblasts, acclerating osseointegration.[48] Several coatings using collagen have been shown to improve cell adhesion and viability.[14,49]

Another problem with plates is local compromise of circulation. In addition to loss of vasculature associated with implantation, local tissue reaction to plates can have inflammatory effects that can compromise local soft-tissue microcirculation and can lead to local necrosis and nonunion. Compared to stainless steel wear debris, titanium wear particles produce a modest and transient amount of inflammation, with no microcirculatory compromise.[50] Finally, electrocoating stainless steel with a bovine serum albumin derivative showed better biocompatibility in terms of local microvascular sequale, improving healing and incorporation.[51]

Surface coatings also play a role in the prevention of infections. Hydroxyapatite-coated screws show a greater resistance to *Staphylococcus epidermidis* adherence,[52] and chitosan-coated screws and plates have been shown to be bacteriostatic.[53] Silver, silicon polymer, and silicon or nitrogen doped diamond-like carbon (DLC) coatings on implants have reduced bacterial adhesion to components, and have shown efficacy against strains of *Staphylococcus aureus* and *Staphylococcus epidermidis*.[54–56] Hydrogel coatings containing the antibiotic ciprofloxacin are being developed to prevent implant-associated infections in titanium devices.[57] Finally, several coatings that elute drugs, biological factors, and minerals have been investigated with the goal of improving the biological response to growth. PTH- and bisphosphonate-coated stainless steel screws increased pullout strength and energy as well as fixation.[58,59] Plates that elute recombinant human BMP 2 were able to induce new bone formation and heal large segmental bone defects.[60–62] Lastly, strontium-eluting implants are capable of simultaneously stimulating bone formation and inhibiting bone resorption.[44,63]

6.616.3.1.3. Advantages of plate and screw fixation

Plates are particularly advantageous in complex periarticular and metaphyseal fractures where biological, anatomic, and mechanical factors that lead to successful healing favor their use. Fractures in these areas require precise anatomic reduction and heal via intramembranous bone healing. Additionally, the location of the fractures precludes the bony fragments from generating large lever arms and mechanical forces for the plate to counteract, which increases the plate's lifespan. Finally, the excellent blood supply to periarticular regions makes them more resilient in the face of potential vascular compromise.

Anatomic considerations can weigh heavily in deciding if plate osteosynthesis is indicated. It is beneficial in fractures in small or flat bones such as acetabular, facial, or hand fractures. In these cases, reconstruction plates can be contoured, intraoperatively to fit the fracture anatomy. Anatomic considerations also play a role in fractures that are commonly treated with intramedullary nailing, such as intertrochanteric femoral fractures. In this setting, the fracture can compromise areas that the intramedullary nail relies upon, causing that mode of fixation to become unreliable. In this situation, plate fixation may be useful.

Lastly in patients with head injuries, trauma-related medical conditions such as acute respiratory distress syndrome, or patients with extensive concomitant soft-tissue injury requiring vascular repair, or staged repair, plating is a viable option.[64] In this setting, the process of installing a plate can be less physiologically demanding than intramedullary nailing, and with newer techniques such as minimally invasive plate osteosynthesis, may have many of the same benefits.

6.616.3.1.4. Limitations of plate and screw fixation

There are several drawbacks to plate osteosynthesis. Certain types of fractures are more prone to difficulties when repaired with plates, including diaphyseal fractures, transverse fractures, and fractures in weight-bearing bones. Additionally, the process of implantation of plates and their local effects can be harmful as the surgical approach can require extensive soft-tissue stripping.

Simple, transverse fractures occurring in the diaphyseal areas are an example of fracture type and location that can exhibit difficulty in healing when fixed with plates. This is exaggerated in weight-bearing bones. In these cases, the biomechanical and anatomic factors that favored plate osteosynthesis in periarticular and comminuted or oblique fractures are no longer present. The fracture has long bone ends on either side, but has a short gap, which presents long lever arms, and because of the small gap makes the intraoperative design of low strain environments difficult. High strain in this situation can lead to bone resorption as the bone seeks a way to minimize strain – by increasing the distance between fragments, relative motion causes less strain, allowing healing – albeit by fibrous not bony tissue. Additionally, the mechanical factors at play in this situation maximize forces on the plates, leading to screw toggling, loosening, and ultimately plate breakage.

Additionally, in weight-bearing bones, the effect of stress shielding on bone integrity is amplified, as many plate constructs are load bearing. Stress shielding, leading to bone resorption and stress risers, is the mechanism implicated in early refracture after removal of plates.[13] As plates are placed alongside the bone, but not directly in line with the axial stresses, if stability is not provided, bone will be resorbed to limit the strain. In the setting of segmental defects, this resorption may lead to a nonunion. Stress shielding and nonunions are adverse effects of many plating techniques, and one that has prompted vigorous research. The use of newer metallic alloys and the improvement of biopolymer plates on the horizon may help to eliminate this concern.[65]

Finally, plate osteosynthesis can put nearby neurovascular and moving soft tissue structures at risk. As it is external to the bone, prominent features of the plate may irritate soft tissue.

In the forearm where plate osteosynthesis is the primary method of internal fixation, first-generation plates have been reported to cause tendon irritation and rupture, along with nerve compression.[21,66] The development of low-profile plates and coatings leading to less friction is a promising solution to this problem.

6.616.3.2. Intramedullary Fixation

The concept of intramedullary fixation was introduced in the late 1800s and proved early that it was capable of restoring length, axial rotational, angular alignment, and obtaining union. Intramedullary fixation of fractures is the process of introducing a metal rod (often referred to as a 'nail') into the medullary canal of a long bone. Bircher is credited with the first use in which attempts were made to secure fixation of a fracture using intramedullary ivory pegs.[67] Since that time, the design, technique, and indications for its use have drastically changed, and intramedullary fixation is now considered the standard of care for the treatment of most diaphyseal lower extremity fractures.[4] The distinct advantage to the use of intramedullary fixation is in its intricate design, which allows the nail to share the load with the bone and allow for the indirect reduction of the fracture without exposure of the fracture site. By doing this, it potentially reduces substantial operative time with minimal risk of infection or nonunion.[68]

Intramedullary fixation was initially indicated for fractures of the long bones in which instability of length, rotation, and angulation was of concern.[69] It is considered the gold standard in the surgical fixation of subtrochanteric as well as femoral shaft fractures. As time progressed, the spectrum of intramedullary fixation reached out to encompass a broad range of fractures. While the majority of the literature regarding intramedullary fixation involves fractures of the femur, its use for the correction of both the tibia and humerus has increased dramatically. For example, intramedullary fixation has become a popular treatment for displaced mid-diaphyseal tibial fractures with minimal comminution. As seen with intramedullary fixation for femoral fractures, those of the tibia experience the same benefits of reduced infection rate and early ambulation.[70,71] Although its popularity for the use in fracture of the lower extremities has increased, the role of intramedullary fixation in humeral shaft fractures remains controversial. Bhandari *et al.* performed a meta-analysis of three clinical trials in which intramedullary fixation was compared to plates in patients with humeral shaft fractures. The authors found that plate and screws construct reduced the need for reoperation as well as the prevalence of shoulder impingement. However, there were no differences in the rate of nonunion, radial nerve palsy, or infection.[72,73]

6.616.3.2.1. Design rationale

The healing properties of intramedullary fixation are rooted in its inherent strength and rigidity.[9] The prosthesis acts as an internal splint that aids in the fracture stability, load sharing, and scaffolding, in which the fracture is able to heal. They have a proven track record in providing relative stability with high union rates but low rates of hardware failure, loss of alignment, or infection. This makes intramedullary fixation of fractures a valuable alternative in the armamentarium afforded to orthopedic surgeons.

Intramedullary nails can be classified by anatomical and functional names such as centromedullary, condylocephalic, and cephalomedullary nails.[2] Centromedullary nails, such as those of Kuntscher and Sampson, enter the bone in line with the medullary canal. During the 1940s, Kuntscher introduced a nonlocking nail to be used in diaphyseal fractures of long bones.[74] The nail was made from inert metal, had the cross-section design of a clover leaf, and had a slit-like opening. This design allowed for elastic compression, strength, stiffness, and the ability of the nail to adapt to the canal.[75,76] Condylocephalic nails enter the bone in the condyles of the metaphysis and usually reach the opposite end of the metaphyseal–epiphyseal area. Examples of condylocephalic nails include Ender and Hackenthall pins. This type of intramedullary nail is commonly used in pediatric fractures.[77] Cephalomedullary nails have a centromedullary portion, but also permit fixation up into the femoral head. Zickel nail and Gamma nail are examples of this type.

Addition of interlocking fixation to the intramedullary nails allows a longer working length to the nail and thereby ability to resist both axial and rotational deformation of the fracture. Interlocking fixation is defined as dynamic or static. Dynamic fixation controls bending and rotational deformation but allows axial loading at the fracture site, while static fixation controls rotation, bending, and axial load. Dynamic fixation can be used in fractures that are considered to be axially stable.

6.616.3.2.2. The application of biomaterials in internal fixation

Intramedullary fixation has a biomechanical advantage over plate and screw construct due in part to the shorter distance to the center of the medullary canal. The shorter the distance in which the bending forces act, the lower the moment is on the device.[69] The key to the success of the intramedullary nail is its stiffness, rigidity, and strength.[76] Rigidity is defined from a load–deflection curve for a given structure. Load–deflection curve is divided into elastic and plastic regions. Elastic region represents the ability of the implant to retain its structure after a given load. Once loads exceed the proportional limit, a plastic deformation occurs and the structure of the biomaterials is permanently changed. The slope in the elastic region of this curve reflects the stiffness of the biomaterials. As the slope of the elastic portion of the curve (stiffness) increases, the given structure becomes more rigid. As stiffness decreases, so does the rigidity, and the structure becomes more flexible (plastic). The point at which elastic becomes plastic is known as the proportional limit. It is at this point, that once exceeded, permanent deformation of the device takes place.[76] An intramedullary nail that is loaded beyond the proportional limit can lead to complications such as non or malunited fractures and breaking or deformation of the implant itself. For this reason, the ideal intramedullary fixation device would have a high proportional limit to minimize the potential of these complications.

The biomechanics of the intramedullary implant have a more prominent role in healing than do the biomaterials. Nonetheless, the material of the implant does add to the biomechanical properties. The intramedullary implants most frequently used are made out of stainless steel or titanium. The biomechanical properties of each are different. Titanium

implants are more flexible and have a higher proportional limit than stainless steel. They have an inherent elasticity because of which they can be substantially over bent to maintain a curvature.[78] Stainless steel implants are stiffer and lead to greater fracture stability. Mahar *et al.* demonstrated that when compared to one another in biomechanical testing, titanium nails provide greater fracture stability than a stainless nail. The author postulated that it is due to increased contact of the titanium in the medullary canal as compared to its stainless steel counterpart. The characteristics of the titanium nail allow for the needed flexibility to mold to the naturally curved medullary canal of the femur.

The geometry incorporated into the design of the intramedullary nail is the basis of the implants ability to share the load. Calculating both the area and the moments of inertia enables the computation of bending and torsional forces through the cross-section of the device. The stiffest design (most rigid) is an implant that has the material distributed further away from the bending or torsional axis. This would lead to greater resistance to bending and torsional forces of the intramedullary nail.[9,76] While those with the highest rigidity are able to withstand the greatest forces, it turns out that it is not optimal for fracture healing. Intramedullary nails that have a good balance between rigidity and allowing some movement at the fracture margins have proven to show superior results regarding fracture union.[9]

Prior to the development of the locking intramedullary nail, all intramedullary devices were considered to be dynamic. Intramedullary fixations are determined to be dynamic in nature when only one end (the proximal portion) is locked, thereby allowing the distal fragment to move about the intramedullary device. Current models have predrilled screw holes at either end of the implant that allow for potential static or dynamic locking of the device. In doing so, the proximal and distal fragments of the fracture are potentially fixed in both length and rotation. When statically locked, the intramedullary nail prevents the contact between the two main fragments of the fracture. This allows for rotational control of the epiphyseal–metaphysial fragment.[68] Dynamization of the intramedullary nail can lead to fracture shortening and rotation of the fracture fragments. As the proximal end remains locked, the distal portion acts as a splint. For this reason, dynamic fixation is recommended if sufficient contact between the two main fracture fragments is present or for those fractures that have failed to show healing at 4–6 months after the surgery.[79] Fully threaded distal locking screws are preferred as they have a decreased chance of backing out, requiring additional surgery. While the use of one screw is often adequate, two screws are used in cases of infraisthmal fractures, severely comminuted femoral fractures, or for those patients who will not be compliant with weight-bearing instructions.[79]

6.616.3.2.3. Advantages of intramedullary fixation

The design of the intramedullary prosthesis reduces fracture fragment motion but does not completely eliminate it leading to bridging callus healing. This allows for endochondral healing as opposed to intramembranous healing that is seen in cases of rigid fixation. The presence of motion across the fracture site stimulates vascular invasion as well as increased thermal, mechanical, chemical, and local environmental factors which are all key elements in regulating fracture healing.[76] Intramedullary fixation is load sharing, allowing for minimal stress shielding. As a result, disuse osteoporosis is minimized by allowing the weight-bearing status of patients to be advanced at a quicker rate (once callus formation is confirmed via radiographs) than with plates and/or external fixation.

The procedure of introducing an intramedullary fixation is innately more advantageous than its plating counterpart. By being minimally invasive, the surgeon does not have to expose the fracture site, leaving the blood clot (and it healing properties) intact as well as any callus formation.[69] By not disturbing the fracture site or the hematoma that surrounds it, the copious amounts of natural healing cells in the area of the fracture lead to rapid healing with abundant callus. The act of reaming the medullary canal, to allow for the proper fit of the prosthesis, has an impact on blood flow. It was originally postulated that the reaming interrupts the local blood supply, but was later determined that it in fact may stimulate a periosteal reaction and increase blood supply to the bone.[80,81] In addition, the spillage of the reamings may fill into the fracture site allowing it to act as a natural bone graft. The design and mechanical properties of the nail allow for load sharing, which leads to an increased union rate, rate of healing, and early mobilization. This directly corresponds to a shortened time in the hospital, accrued hospital costs, and exposure to iatrogenic ailments.[82]

6.616.3.2.4. Limitations of intramedullary fixation

While complications are minimal, they are not obsolete. Heavy emphasis is placed on experience of the surgeon. In general, there is always risk of infection and in the case of intramedullary fixation, it has the potential to be problematic. The prosthesis allows easy passage of the organism(s) along the full length of the bone. This often necessitates the usage of intravenous antibiotics and in some cases the removal of the instrumentation. Therefore, it is relatively contraindicated in patients with bone infections. Many patients have also complained about local irritation in the area of the distal or interlocking screw(s). While it is encouraged to keep the hardware intact until the fracture is completely healed, many patients insist on having the screws removed to relieve the pain. The soft tissue irritation could be caused by the design of the screw head or the loosening of the screw as a result of poor purchase into the bone. On rare occasions, there are reported cases of intramedullary hardware that is either deformed and/or breaking, which would necessitate further surgical intervention (**Figure 1**).

Cases of compartment syndrome, malreduction, nonunion, and neurovascular injury have been documented in the use of tibial intramedullary nails. The most common reported adverse event of intramedullary fixation in the tibia is the inability to obtain an anatomical reduction of the fracture. This leads to a rotational malalignment, which is usually well tolerated by the patient.[83,84] With use in the setting of humeral shaft fractures, damages to the radial, axillary, musculocutaneous and median nerves, brachial artery, as well as the rotator cuff, are all possible.

6.616.3.3. External Fixation

Orthopedic surgeons use a variety of strategies to manage fractures of the long bones and pelvis. One particular approach, termed external fixation, involves the stabilization of a fracture

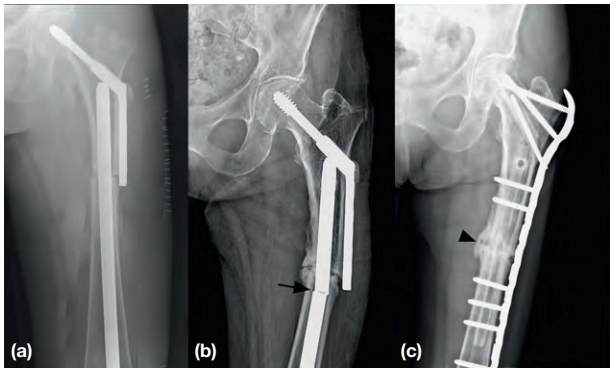

Figure 1 Radiographs demonstrating broken retrograde femoral nail. (a) Anteroposterior radiograph of the left femur showing proximal femoral shaft fracture at the tip of a dynamic hip screw fixation. Patient was treated with unlocked retrograde femoral nail. (b) 3-year post intramedullary fixation anteroposterior radiograph showing fracture of the intramedullary nail just distal to fracture site (arrow). (c) Revision surgery was performed with locking plate and intramedullary strut fibular allograft. This radiograph was taken 4 months after surgery and showed evidence of fracture healing (arrowhead).

site using a metal construct attached to the fracture fragments. The construct, called an external fixator, is primarily external to the skin but also enters the soft tissue envelope and interfaces directly with adjacent bone, maintaining its position to allow for fracture healing. The first modern use of external fixation dates back to the nineteenth century. Its originator is believed to be Joseph-François Malgaigne, a French surgeon who in 1843 used a percutaneous clamp to treat fractures of the patella.[85] In fact, his use of the device predated the development of plaster casts for fracture immobilization.[86] Since the time of Malgaigne, many developments in the design and composition of external fixators have been made and the use of this technique has become widespread within orthopedic surgery. Extensive research and development have brought about the use of external fixation for a wide variety of applications. These include limb lengthening, osteotomy, fusion, deformity correction, transportation of bone for defect reconstruction, and fracture fixation.[86] Among these procedures, the use of external fixation for fracture management remains its most common application.

6.616.3.3.1. Design rationale

While a countless number of configurations exist, all external fixators involve a pin or wire which penetrates skin and affixes to bone, a strut which is either bar-shaped or ring-shaped, and a connection between the two. Multiple iterations of this concept joined together comprise an external fixator. A pin is a metal portion of the construct which passes through the skin and soft tissue and into the bone. In Europe, pins are sometimes referred to as screws or nails. A full pin is one that penetrates the bone and soft tissue envelope on both sides of the extremity, connecting to the rest of the construct at both ends. These are sometimes termed through-and-through pins. A half-pin is a pin that only passes through soft tissue on one side of the extremity but engages both the near and far cortex of the bone in which it is placed. Full and half-pins are typically 2–6 mm in diameter.[86] A wire is a thinner version of a pin, usually less than 2 mm in diameter, which traverses bone and soft tissue and is attached to the rest of the construct on both sides of the limb. A wire is not nearly as stiff as a pin and is not inherently stable unless it is attached to the rest of the external fixator. A pin gripper is a component that attaches a pin or wire to the other portions of the construct. A bar is the element of the external fixator that connects the pin grippers to one another. A ring is similar to a bar and serves the same function, except that it is round, encircles the extremity, and runs perpendicular to the limb rather than parallel to it. A half-ring is also round and serves a function similar to that of a bar, but it does not completely encircle the extremity. Half-rings are used in parts of the body where a full ring could not practically incorporate the entire portion of the anatomy. This tends to be in more proximal portions of the extremities such as the upper thigh and the pelvis. An articulation is a component that connects one bar or ring to another.[4]

Several different configurations of external fixators exist (Figure 2). The choice of construct type depends on several factors, including the clinical scenario, location of the fracture site, and surgeon preference. A unilateral bar construct employs a bar connected to multiple pin grippers along with pins inserted into bone. This is considered the simplest design for external fixation. A bilateral bar external fixator contains a bar on both sides of the affected extremity, connected to full pins via pin grippers. These two bars are arranged in one spatial plane. A multiplanar construct uses pins or wires (connected to bars) oriented in two or more planes in order to increase overall stability of fractured bone. A ring external fixator employs circular bars oriented orthogonal to the affected extremity. Pins are then placed through the limb and connected on both ends to the ring fixator. Rings are then connected to one another by additional bars. This construct was developed and popularized by Russian orthopedic surgeons, including Ilizarov, whose name is often used to refer to the device.[87]

6.616.3.3.2. The application of biomaterials in external fixation

The goal of external fixation is to provide a stable construct that minimizes motion of fracture fragments in order to promote successful bone healing while avoiding infection. As such, orthopedic surgeons face a set of specific, well-characterized challenges in the application of this technique. The most common of these challenges include creating a strong, stabile construct to minimize gross motion at the fracture site, preventing loosening of pins from bone, and preventing infection at pin sites. Both the architectural design of the construct and the properties of biomaterials used in an external fixator play an important role in helping orthopedic surgeons address each of these challenges.

An external fixator must have sufficient stability such that it prevents gross motion about the fracture site that could disrupt the bony contact necessary for bone healing. Several geometric properties of the construct have a direct relationship to the rigidity of an external fixator. These include the number of pins used, the distance between each pin, the modulus of elasticity of each component, the number of distinct planes in which pins are placed, and most importantly pin diameter.[88] The distance between the bars of the external fixator and the involved limb has an inverse relationship to construct rigidity,

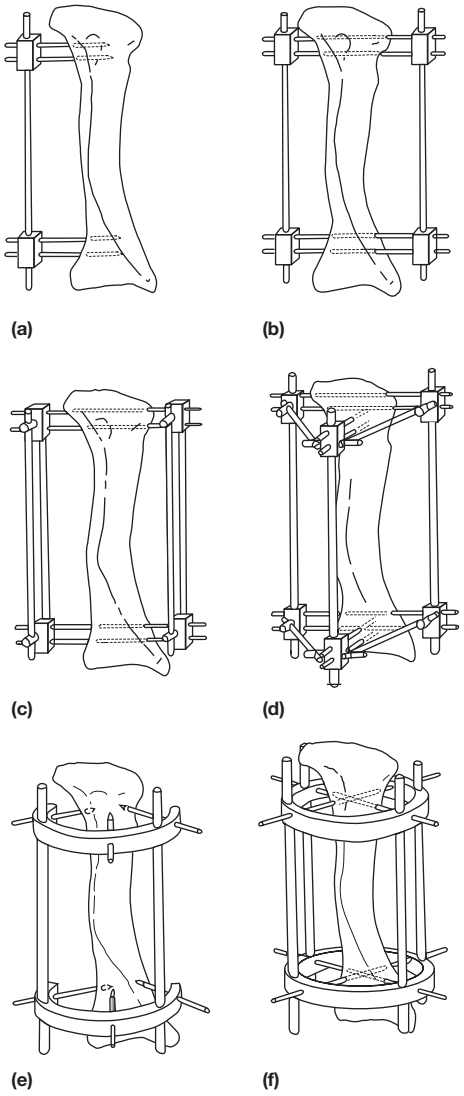

Figure 2 Basic configurations of external fixators: (a) unilateral bar, (b) bilateral bar, (c) quadrilateral multiplanar, (d) triangular multiplanar, (e) half ring, (f) full ring. Reproduced with permission from Stuart A. Green, MD (UC-Irvine).

that is, the closer the bar to the limb, the more rigid is the construct.[88,89] The type of pins used in external fixators has effects on construct rigidity. Stainless steel pins have a higher modulus of elasticity and are more fatigue resistant than titanium alloy pins, reducing the likelihood that they will fail.[86,90] The biomaterials used in bars and rings also affect the stability of external fixation. The stiffness of carbon fiber bars is approximately 15% greater than that of stainless steel tubes.[91] In addition, carbon fiber external fixator bars are radiolucent, meaning that they allow penetration by X-ray energy. This prevents them from obscuring the radiographs that are commonly used to assess fracture alignment in the external fixator during follow-up.

It should be noted that with respect to the overall structural integrity of the external fixator construct, there exists a tradeoff between rigid stabilization of the fracture site and stimulation of bone formation. Absolute rigidity of the construct ensures immobilization of fracture fragments so that movement does not compromise the constant bony contact that is essential for bone healing. However, an absolutely rigid external fixator will also shield the fracture site from compressive forces, detracting from stimulation of bone formation (stress shielding). To date, no data exist on the optimal ratio between absolute rigidity and flexibility that best allows for fracture healing in external fixation. In order to balance these opposing biomechanical principles, orthopedic surgeons rely on a feature of certain external fixators termed dynamization.[86] Dynamization refers to the process by which an external fixator acts to neutralize forces in the plane parallel to the fracture (often perpendicular to the extremity) while allowing for motion and compression in the axial direction, perpendicular to the fracture. Dynamization can be accomplished either by weight bearing on the extremity or by sequential adjustment of the pins of the external fixator to apply compression across the fracture site. Certain 'sliding' external fixators exist which allow pin gripper components to move along the bar to which they are attached, creating a dynamization.[92]

Loosening of the external fixators at the pin–bone interface presents a challenge because it can compromise the structural integrity of the fixator. Biomaterials play an important role in overcoming this obstacle. In particular, the coating of fixator pins with various materials has been investigated as a potential solution. As early as 1913, pins were coated with nickel and gold.[93–95] Since that time, many formulations of coatings have been investigated for their effect on pin loosening. Of all the different pin coatings in use today, hydroxyapatite has probably been the most widely studied. In both animals and humans, hydroxyapatite coating has been repeatedly shown to increase the strength of the interface between external fixation pin and bone, decreasing the likelihood of pin loosening.[96–98] Hydroxyapatite coating improves integration of bone with the metal implant by increasing bony ingrowth into the pin, hence increasing strength.[11,99] This property is of particular interest under the special circumstance in which patients with fractures in osteoporotic bone are treated with external fixation, as it is very difficult to prevent pin loosening in this patient population. Moroni and colleagues studied patients treated for wrist fractures with external fixation who were randomized to use either hydroxyapatite-coated pins or plain pins.[99] They found that the hydroxyapatite-coated pins demonstrated stronger pin–bone integration as measured by a statistically significant difference in the extraction torque necessary for removal. Moroni's findings suggest a unique role for hydroxyapatite in this clinical scenario. Both titanium and silver coatings have been investigated with regard to their potential to prevent pin loosening, but results have not been convincing enough to drive their use in clinical practice.[100–102] DLC, of considerable interest as a coating for prostheses, has gained attention for its potential to improve the pin–bone interface.[103,104] Early *in vitro* data suggest that the attachment of biological tissue to DLC-coated pins may be improved, but the coating has not been investigated in human trials for this purpose.[105]

Infection of external fixator pin sites, also termed pin sepsis, presents one of the considerable challenges in using this technique, occurring at a rate of up to 30%.[106] Pin sites are particularly vulnerable to infection because they provide a continuous

tract from the skin, which is universally colonized with many different types of bacteria. Pins made of different biomaterials have varying resistance to pin site infection. In comparison to stainless steel pins, titanium pins have better biocompatibility, better bony ingrowth, and have been shown in a randomized, prospective study to have lower rates of pin sepsis.[107] Of the coatings examined for this purpose, hydroxyapatite has been most extensively studied. Hydroxyapatite coatings have consistently been shown to be effective at decreasing rates of pin tract infection[98,108,109] and this may be related to its enhancement of osseointegration. Coating of external fixator pins with silver has also been investigated as a strategy for preventing pin sepsis. While silver coating was shown to be capable of preventing infection in animals and in human trials, concerns over leeching of silver into the blood precluded further consideration of its use for this purpose.[110,111] Antibiotic-based coatings, such as tobramycin-impregnated polymethylmethacrylate (PMMA) and combined minocycline/rifampin formulations, have been investigated in animal models and have shown efficacy in reducing pin site infection.[112,113] However, their utility in improving clinical outcomes in humans has not yet been demonstrated. As with pin loosening, the ability of DLC to prevent infection at pin sites has been studied and shown to be effective at reducing the number of bacterial colonies cultured from external fixation pins in an animal model.[105] These results have not yet been replicated in human subjects and so clinical use of this type of coating remains theoretical.

6.616.3.3.3. Advantages of external fixation

The application of external fixation has certain advantages. First, it allows for the rapid immobilization of a fracture in patients with significant soft tissue injury and damage to nearby arteries or nerves. In this setting, delicate repairs of these structures are carried out and require time to heal, during which the extremity must be immobilized. In addition, in cases with significant soft tissue damage, the soft tissue envelope may not be immediately amenable for open reduction of the fracture. If open surgery were to be undertaken in these cases, breakdown of the skin and soft tissues could cause internal hardware to be exposed. Exposure of internal hardware could lead to bacterial colonization of the implant and thus result in a serious infection of the limb. External fixation allows the surgeon to adequately immobilize the fracture during the time period necessary for the inflammation in the surrounding soft tissues to subside. External fixators are also advantageous in that they allow for constant adjustments to be made during the postoperative period in order to maximize bone healing. This may consist of moving fracture fragments into better alignment or even applying compressive forces across the fragment, as in dynamization.

There is currently newfound interest in expanding the traditional uses of external fixation, resulting, to some degree, from advances in biomaterials. Because of the advantages of external fixation, some surgeons believe that external fixation could play a role in the rescue of failure of internal fixation. This would be particularly useful in patients who are too sick to tolerate an extensive surgical procedure. In this scenario, external fixation could produce adequate fracture healing, albeit at the relatively minor cost of temporary inconvenience to the patient.

6.616.3.3.4. Limitations of external fixation

Limitations of external fixation include the significant skill level and training needed to place pins and create a stable construct. Development of this skill takes many years of training and is not widely possessed by nonresidency-trained orthopedic surgeons. External fixation is also difficult to employ across joints. Furthermore, external fixators require a high level of patient compliance in order to prevent compromise of the construct. Patients usually need to restrict their weight bearing on the affected extremity. If not kept clean, pin sites can quickly become infected. Some patients may find external fixators to be cumbersome and inconvenient.

6.616.3.4. Structural Augmentation

Over the past half-century, major advancements have been made in manufacturing fixation devices for the treatment of fractures. Despite these advancements, 5–10% of all annual fractures occurring in the United States show evidence of delayed or impaired healing,[114] emphasizing the need for methods of augmentation. The ability to provide stability at a fracture fixation site has significant effects on successful bone healing. Factors affecting fixation site stability include the patient's bone quality, initial extent of fracture displacement, and severity of fracture comminution.[115] As a result, several manufacturers have developed synthetic materials designed to stabilize comminuted bone fragments, facilitate load transfer in regions of metaphyseal fractures, and better secure internal fixation devices in the setting of poor bone quality.[115]

Although most fractures heal spontaneously, there are certain fractures in which structural augmentation has proven beneficial by reducing the risk of hardware-failure related impaction, facilitating early weight bearing, and improving overall clinical outcome.[116–120] Common examples of fractures requiring structural augmentation are those of the tibial plateau, vertebral bodies, and femoral intertrochanteric region. For example, unstable intertrochanteric fractures are routinely treated surgically with internal fixation using a fixed-angle sliding hip screw in an effort to facilitate early weight bearing; however, these devices are associated with mechanical failure rates as high as 16–23% with 76% of failure occurring due to collapse of the femoral neck-shaft angle into a varus position, causing extrusion or 'cut-out' of the hip screws from the femoral head.[121,122] In the past, an acrylic cement known as PMMA was routinely used for structural stabilization of the fixation construct, but this cement has failed to achieve wide clinical acceptance due to complications such as thermal necrosis, disturbance of healing, and difficulty of removal in the event of revision surgery.[123,124] Newer nonthermogenic ceramics have since been developed with capabilities of *in vivo* remodeling and replacement by host bone, while maintaining properties necessary for structural augmentation.[4,116] In this section, we discuss newer augmentation materials and their clinical applications: calcium phosphate ceramics, with subgroups of CPCs, hydroxyapatite, and TCP; glass ceramics; polymers; and composites.

6.616.3.4.1. Calcium phosphate ceramics

Calcium phosphate ceramics are highly oxidized mineral salts made into a polycrystalline structure by a process called sintering. Sintering fuses the compounds by heating to over 1000°C

Table 1 A comparison of mechanical properties between bone and selected ceramics[159–193]

	Examples of products	*Composition*	*Compressive strength (MPa)*	*Tensile strength (MPa)*	*Elastic modulus (GPa)*
Cancellous bone			5.5	3	1
Cortical bone			162	151	15
Calcium phosphate cement	Norian SRS	Carbonated hydroxyapatite (dahllite)	55	2.1	–
Coralline hydroxyapatite	ProOsteon	$Ca_5(PO_4)_3OH$	9.3	2.8	85
Glass	Bioglass	$Na_2O–CaO–SiO_2P_2O_5$	–	42	35
	AWGC	Apatite–wollastonite	–	215	118
Composite	Cortoss	Combeite reinforced Bis-GMA/Bis-EMA/ TEGDM A polymer resins	146	–	–
Polymer	Depuy 1, Palacos, Osteobond, Simplex P	PMMA	90	6.9	–

AWGC, apatite-wollastonite glass ceramic; Bis-EMA, bisphenol-a-ethoxy dimethacrylate; Bis-GMA, bisphenol-a-glycidyl dimethacrylate; Mpa, megapascal; GPa, gigapascal; PMMA, polymethylmethacrylate; TEGDMA, triethylene glycol dimethacrylate; –, no data available in the current literature.

Adapted from Gheduzzi, S.; Webb, J. J.; Miles, A. W. *J Mater. Sci. Mater. Med.* **2006**, *17*(5), 421–426; Moore, W. R.; Graves, S. E.; Brain, G. I. *ANZ J. Surg.* **2001**, *71*(6), 354–361.

and in the process, decreases the amount of unstable and weakly soluble calcium apatite in the scaffold.[4,125] Ceramics are generally considered to be chemically and biologically inert. Ceramics obtain these properties from the large heat of formation released during the sintering process; thus placing them in a very low energy and biocompatible state.[126] Ceramics are also generally known to be brittle and have poor tensile strength, limiting their use primarily to that of filling bone voids and restoring areas of bone loss resulting from fractures.[125] Nevertheless, calcium phosphate ceramics have proven useful in various orthopedic applications such as improving the mechanical holding strength of screws and conventional fixation devices.[115,125] These synthetic bone scaffolds have also been used as local delivery vehicles for growth factors, osteoprogenitor cells, and antibiotics.[4,127]

6.616.3.4.1.1. Calcium phosphate cements

Inorganic calcium and phosphate can be combined into an injectable paste to be delivered percutaneously into the cancellous bone of a fracture site in order to structurally augment bone healing.[128] Several injectable CPCs (Bone Source, Alpha-BSM, Biopex) are either in preclinical animal studies or human pilot studies, but none is as well established and documented in clinical use as Norian SRS (skeletal repair system; Norian Corp., Cupertino, CA).[129] It is a fast-setting cement that hardens within minutes *in vivo*, forming a carbonated mineral apatite known as dahllite.[4,125] Dahllite formation is 85–90% complete by 12 h with a composition and crystal morphology similar to that of mineralized bone.[128] It exhibits a higher maximum compressive strength and similar tensile strength as cancellous bone[128,130] (**Table 1**). Because of its crystalline structure, Norian SRS is resorbable over months and animal models have shown that it undergoes cell-mediated *in vivo* remodeling with replacement by host bone. Norian SRS is osteoconductive, but functions primarily in improving the mechanical stability of internal fixation devices in skeletal injuries, decreasing the time to full weight-bearing and total functional recovery.[4]

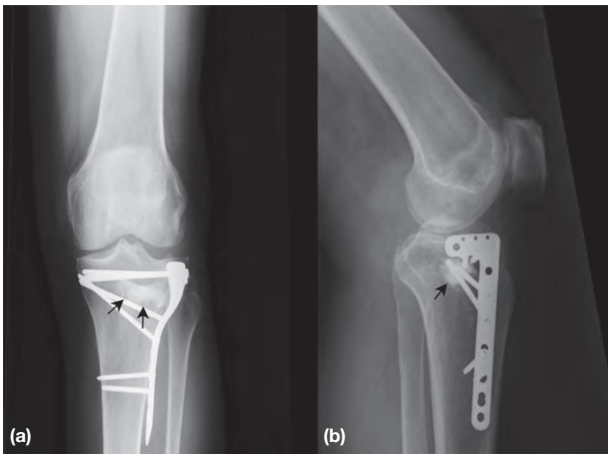

Figure 3 Radiographs demonstrating the application of calcium phosphate cement (Norian SRS). (a) An anteroposterior radiograph of the left knee showing the use of calcium phosphate bone cement (arrows) to fill the defect after tibial plateau fracture. (b) Bone cement can be used as an adjunct to increase the purchase of screws during fracture fixation (arrow). Courtesy of David L. Helfet, MD.

Unlike PMMA, Norian SRS is nonexothermic, eliminating the drawback of thermal necrosis.[119] As it is resorbable, it also eliminates the need for cement removal during revision surgery. The disadvantages of Norian SRS include its low tension and shear strength and an increased perioperative blood loss secondary to an increase in operating time.[115]

In regards to fracture healing in weight-bearing regions, CPCs have been applied as structural adjuncts in calcaneal, tibial plateau, and intertrochanteric fractures (**Figure 3**). Mattsson *et al.* augmented dynamic hip screw fixation of unstable intertrochanteric fractures by injecting approximately 20 ml of Norian SRS into the proximal femur using a curved needle. The goal of this approach was to achieve cement filling of the posteromedial gap with the intent of producing a mechanically

stable medial arch, which would provide load-sharing support between the bone and implant. At the 6-weeks postoperative period, patients in the augmented group had statistically significant lower global and pain scores, less pain after walking 50 ft, and better return of the activities of daily living. It is proposed that the more stable fixation in the augmented group reduced the pain of impaction during initial weight bearing, thus facilitating faster functional recovery. In the treatment of tibial plateau fractures, a similar void filling approach has been used along with only cancellous bone screws and temporary Kirschner wires to maintain reduction of the fracture. In this case, the cement was loaded and injected into the subchondral bone defect at the tibial plateau using a delivery gun. Results showed that patients treated with Norian SRS had less plateau depression at 1 year compared to patients treated with buttress-plating.[120] Additionally, Norian SRS has been suggested to permit early full weight bearing in the treatment of calcaneal fractures.[4] Callos (Skeletal Kinetics, Acumed LLC Hillboro, OR) is a next generation injectable CPC. It shares many of the same mechanical and biological properties as Norian SRS. It is non-exothermic, biocompatible, resorbable, and can be drilled and inserted with screws. Callos has superior tensile strength, flexural strength, and fracture toughness compared to Norian SRS.[131]

6.616.3.4.1.2. Hydroxyapatite

Crystalline hydroxyapatite is a slowly resorbing calcium phosphate ceramic that is very stable *in vivo* and has a resorbing rate of 5–15% per year.[132] The most relevant form of porous and highly crystalline hydroxyapatite currently in clinical use is manufactured by a simple hydrothermal exchange method, which converts weak calcium carbonate into mechanically superior hydroxyapatite. This crystalline hydroxyapatite is similar to human cancellous bone, exhibiting pore diameters in the range of 230–600 μm.[133] Several synthetic (Synatite, Cerapatite, permaOS, Orthoss) and biologic (Pro-Osteon, Endobon, Pyrost) hydroxyapatites are currently in clinical use. Of these, Pro-Osteon (Interpore, Irvine, CA) is the best known in regards to structural augmentation.[134–136] It is an effective osteoconductive material owing to its function as a matrix scaffold with an extensive interconnected pore system, which allows for bone ingrowth. The biocompatibility of Pro-Osteon and other coralline hydroxyapatites is demonstrated by a lack of local and systemic toxicity *in vivo* and its lack of eliciting a foreign body response.[137] A major disadvantage of this material is its lack of significant resorption, which prevents host bone replacement over time. Moreover, it also lacks osteoinductive properties, limiting its ability to facilitate new bone formation, and many investigators have reported problems of particle migration as a potential complication of using hydroxyapatites.[138]

The clinical applications of hydroxyapatite are mostly limited to serving as a bone graft substitute and coating of other biomaterials. For example, Healos (Depuy, Raynham, MA), is a highly porous and resorbable graft substitute composed of cross-linked type 1 bovine collagen coated with hydroxyapatite. This material can be soaked with concentrated bone marrow aspirate to deliver bone-forming stem cells to a localized area, thus enhancing bone healing.[139] In terms of fracture treatment in weight-bearing bone, Bucholz *et al.* examined the efficacy of ceramic hydroxyapatite in the treatment of split compression fractures of the tibial plateau in humans. After careful elevation of the depressed osteochondral fragments, the dimension of the cancellous defect was measured and an oversized block of coralline hydroxyapatite was approximately shaped to the dimensions of the defect. The newly shaped material was inserted into the void with insertion of additional variable-sized granules of Pro-Osteon. Standard interfragmentary screws and plates were used to stabilize the reduction. Functional knee joint assessments showed no difference between the Pro-Osteon group and control.[4] Similarly, Itokazu *et al.* have since conducted a study using Pro-Osteon for the augmentation of tibial plateau fractures with the exception of performing the procedure arthroscopically.[140]

6.616.3.4.1.3. Tricalcium phosphate

TCP, a fast-resorbing material, undergoes partial conversion to hydroxyapatite *in vivo*.[125] TCP is more porous than hydroxyapatite, thus giving it a faster resorbing rate, but rendering it weaker in compressive testing. TCP is found in two distinct crystalline configurations: α-TCP and β-TCP.[138] β-TCP is more stable and is a very biocompatible material. As TCP resorbs, new bone is formed simultaneously in the area previously occupied by the material. For this reason, TCP is ideally used in cases where resorption of implant material, with subsequent host bone replacement, is desired. Similar to hydroxyapatite, TCP is osteoconductive but not osteoinductive. Another disadvantage of TCP materials is that the parts that are converted to hydroxyapatite are slow to resorb, leaving unwanted fragments in place for years. TCP's unpredictable biodegradation profile has limited its clinical use. The effectiveness of ceramic TCP in treating fracture-related bony defects of the femur, tibia, and calcaneus has been studied with preliminary results indicating its viability as an alternative to cancellous bone grafts. It completely resorbs in 6–24 months, eliminates donor site morbidity, and exhibits an unlimited shelf-life in sterile vials.[141] The clinical applications of pure TCP ceramics such as Vitoss, β-Gran, OsteoPore TCP, and Ossaplast are limited. Composites, such as Graftys BCP, a porous biphasic (60% hydroxyapatite, 40% β-TCP) calcium phosphate ceramic, have wider clinical application in the extremities, spine, and pelvis because of their mechanical stability and ease of handling.[142] Graftys BCP is available as cones, wedges, cylinders, sticks, and granules.

6.616.3.4.2. Glass ceramics

Since the 1970s when Hench discovered Bioglass, several more glasses and glass ceramics have been found with similar ability to bind directly to living bone.[143] However, their weak mechanical properties have restricted their clinical applications to those of low load-bearing capacities. This material is bioactive in the sense that it binds bone by eliciting a response at the interface between material and tissue.[144] *In vitro* testing has shown that Bioglass undergoes a rapid multistage surface reaction, which forms a thin layer of biologically active hydroxy-carbonate apatite, the essential piece to its direct bond to bone.[145] Silicon-based glasses and glass ceramics currently in clinical use include Bioglass and apatite–wollastonite glass ceramics (AWGC), respectively. Bioglass (USBiomaterials, Alachua, FL) is made of SiO_2, Na_2O, CaO, and P_2O_5, while AWGC is composed of oxyapatite,

fluorapatite, and β-wollastonite. Bioactive glasses and bioactive glass ceramics mostly have the same composition, with the exception that P_2O_5 is slightly higher, and there is slightly less Na_2O in glass ceramics.[146] While both materials demonstrate good bonding with bone, AWGC is mechanically superior to Bioglass, thus allowing it to be used in stronger load-bearing applications such as vertebral prosthesis.[145] In granular form, Bioglass and AWGC can be used as bone filler for irregular shape defects. However, there are reports of difficulty in handling the granular forms and maintaining them within the defect. This has prompted a mixture of these materials with other products (i.e., glass–ceramic–fibrin mixture) to make them easier to handle and to facilitate retention within defects.

In clinical practice, the mechanical superiority of AWGC has allowed for its use in various load-bearing capacities such as in vertebral prosthesis, intervertebral disks, and iliac crest in dense bulk form. Dense and porous formulations of AWGC have also been applied as a bone spacer and filler in bulk or granular size.[147] Yamamuro *et al.* used AWGC as vertebral prosthetic replacement of thoracic and lumbar burst fractures.[148] He also applied it as prosthesis for the reconstruction of iliac crests that had undergone large autologous bone graft harvesting and were thus at risk for fracture. Due to its lack of mechanical strength, the clinical use of Bioglass has been limited to applications requiring low load-bearing capacities such as maxillofacial reconstruction and dental applications.[144]

6.616.3.4.3. Polymers

Of the multitude of biodegradable and resorbable organic compounds currently known, only a few possess the biocompatible and mechanical properties essential for use in internal fixation devices.[149] The most suitable and clinically relevant of these compounds are the self-reinforced polymers PLA, PGA, polydioxanone (PDS), and PLA–PGA copolymers. In clinical use, these polymers have been fabricated into mechanically stable implants such as pins, rods, screws, and plates for the purpose of fracture fixation. The emergence of resorbable polymeric implants stems from efforts to undo the long-term complications of metallic implants, which ultimately require surgical removal, exposing patients to potential surgical complications. These implants completely resorb, with subsequent host bone replacement.[149] Their function has been comparable with metallic fixation devices in regards to treatment outcomes and complication rate, making these polymers an attractive adjunct in treating weight-bearing fractures.[150] There are few technical difficulties associated with the use of polymers implants in fracture fixation, most notably the effort to prevent breakage of the implant as it is inserted into the fracture site. This may necessitate special instruments such as a torque screwdriver, drill-bits, and inserters of various sizes.[149] The major disadvantage of using polymers is a reported 7.9% rate of delayed noninfectious inflammatory tissue response requiring surgical drainage. Moreover, these polymer implants cost as much as fifteen times their metallic equivalent. In regards to weight-bearing application for fracture treatment, polymers are often combined with other biomaterials in order to form clinically relevant composites. An example of this is Plexur (Osteotech, Eatontown, NJ), a PLA–PGA copolymer scaffold that contains calcium, phosphate, and trace elements of matrix proteins. It is available in block, cylindrical, wedge, sheet, and granular form.[142] Plexur can be used as bone void filler or to improve purchase of implant materials such as screws.

6.616.3.4.4. Composites

Composite materials are composed of acrylic cements in combination with ceramics.[134] Similar to their constituents, they are biocompatible and bioactive and feature superior mechanical properties, which allows for diverse clinical applications.[129,135] A major advantage of using composites is that the combination of constituents allows it to demonstrate the superior mechanical properties of individual components, while each component can overcome the weaknesses of another. While there are many composites on the market, Cortoss (Orthovita, Malvern, PA) is one material that is well established in clinical use. It is a fast setting, low viscosity tetrapolymer reinforced with glass particles called combeite.[129,135] Similar to glass ceramics, it is available as injectable cement. Compared to PMMA, it has a lower curing temperature and features an optimal and constant viscosity, which minimizes the risk of leaking after placement. Its compressive strength of 211 MPa is over twice that of PMMA.[151]

Cortoss is undergoing clinical trial as a replacement for PMMA in vertebral augmentation, specifically percutaneous vertebroplasty and kyphoplasty.[129,135] It is also in preclinical testing as cement augmentation for proximal femoral fractures.[152] Cortoss serves as a good bone filler in these cases because it shares similar characteristics with human cortical bone. Similarly, Actifuse Synthetic Bone Graft (Apatech, Inc. Foxborough, MA), a silicate-substituted calcium phosphate composite, has also been used as bone void replacement after vertebral compression fracture and subsequent kyphoplasty.[153] Compared to traditional ceramics, silicon-substituted ceramics have shown an enhanced capacity for resorption and bone ingrowth in and around the implanted material.[154]

Fixation of osteoporotic fractures has always proven difficult due to poor bone quality. Cement augmentation of cannulated screws with side holes are currently in clinical use.[155] These screws allow bone cements (Norian SRS or Cortoss) to be injected through the cannula and into the cancellous bone surrounding the threads.[151,156,157] After the cement has hardened, the holding power of the screw is significantly increased. Because of its brittleness, Norian SRS has been known to easily crack, especially during screw insertion. However, drillable forms of Norian reinforced with copolymer fibers are also available. In the event that cannulated screws are not available, cement augmentation can still be achieved by injecting cement into the drill hole, followed by insertion of a standard screw prior to cement hardening.[156]

Glossary

Allografts Tissue harvested from one individual and implanted into another of the same species.

Amino acid motif A protein structural unit formed by a particular sequence of amino acids, often linked with a specific function.

Angiogenic factor Substance that contributes to the growth of new blood vessels.

Autograft Tissue from one site implanted in a second site in the same individual.

Bioreactor An apparatus or system that simulates a biological active environment.

Demineralized bone matrix (DBM) Bone that has been demineralized via acid extraction, leaving cell remnants, extracellular matrix, and a small amount of residual mineral.

Histomorphometrics The quantitative study of the organization and structure of a tissue.

Osseointegration The integration of the graft with the surrounding already existing bone.

Osteoconduction The ability of a material to serve as a scaffold on which osteoprogenitor cells in adjacent bone tissue can attach, migrate, proliferate, and synthesize and mineralize osteoid, resulting in new bone formation that is contiguous with existing bone.

Osteogenesis The events that cause bone tissue formation.

Osteoinduction The process by which materials or chemicals cause bone to form *de novo*, that is, unrelated to existing bone. The process involves recruitment of undifferentiated mesenchymal cells and their differentiation into cells of the osteochondral lineage. Osteoinduction is the result of osteogenesis.

Progenitor cells Cells that are committed to one or more lineages, but have not yet exhibited a differentiated phenotype. Osteochondroprogenitor cells are multipotent and may differentiate into chondrocytes or osteoblasts depending on their environment.

Retrovirus An RNA virus that contains reverse transcriptase, which allows it to transcribe RNA into DNA.

Xenograft Tissue from a donor of one species transplanted into a recipient/organism of another species, genus, or family.

6.617.1. Introduction

This chapter reviews current commercially available bone graft substitutes, future directions for bone tissue engineering, and how scientists use animal and *in vitro* models to assess bone graft effectiveness prior to clinical use. The history of bone tissue engineering is as long as humans have had bone injuries. Materials have included allografts, autografts, bone marrow, xenografts, processed bone, calcium phosphates, glass, synthetic polymers, and composites fabricated from among this eclectic group of component parts. Strategies have included *in vivo* recruitment of host cells, production of bone-like constructs *ex vivo*, and various forms of cell therapy. Many approaches work when used in small defects in otherwise healthy bone. The challenge for bone tissue engineering is to effect repair or regeneration of large defects in compromised patients.

6.617.2. Historical Overview

For years, scientists have worked with different materials to create bone graft substitutes that include three primary properties: osteoinduction, osteoconduction, and osteogenicity.[1] Osteoinduction refers to properties that stimulate undifferentiated cells to start differentiating into the bone-forming cell lineage, osteoblasts. In its simplest definition, osteoinductive materials cause bone to form in sites that would otherwise not form bone. Osteoconduction refers to properties that support migration and attachment of osteoblasts and osteoprogenitor cells, providing a substrate for bone ingrowth. An osteogenic material is one that supports new bone formation to a greater extent than would be expected by osteoconduction alone. Nonresorbable materials should result in osseointegration with the surrounding already existing bone. In contrast, resorbable materials should be replaced with bone, ideally as new bone formation occurs.

Autografts, grafts that are transplanted from one part of the body to another within the same individual, are considered to be the optimal material because they provide an osteoconductive surface and they contain osteoprogenitor cells that contribute to the osseointegration process.[2] Autografts are not osteoinductive as this property is defined earlier. Unlike osteoinductive materials, autografts are resorbed when implanted in nonorthotopic sites and new bone does not form.[3,4] Despite this, their osteogenic properties are sufficient in orthotopic sites to support osteogenesis in all but the most difficult cases. Autografts may require additional surgery, there may be loss of donor site sensitivity, quantity may be limited, and there may be pain and risk of infection.[1,5–7] Therefore, bone grafts alternatives started emerging including allografts (tissues/grafts from same species), xenografts (tissues/organs from different species), and synthetic and biological bone substitute materials not from donors.

Allografts are not as osteogenic as autografts but they do have several advantages over autografts. They can be used in large defect sites, there is no donor site morbidity, they are readily available, and they can be modified to be a composite bone graft. As allografts are derived from human donors, there is a risk of disease transmission, immunogenicity, and lack of uniformity in the products.[8,9] The most common allografts include frozen, freeze-dried, and demineralized bone. Most recently, the allograft concept has been extended to include bone that is minimally processed to remove immunogenic cells leaving a tissue that is enriched in progenitor cells.[10]

Demineralized bone matrix (DBM) is produced by acid extraction of human cortical bone leaving cell remnants, extracellular matrix (ECM), and a small amount of residual mineral.[11] DBM is osteoinductive due to the remaining growth factors after the acid extraction, in particular, bone morphogenic proteins (BMPs). When it is implanted in nonorthotopic connective tissues, DBM causes bone to form, satisfying the operative definition of osteoinductivity. Interestingly, BMPs are also present in nondemineralized allograft and autograft, but neither of these types of grafts are osteoinductive under the same experimental conditions as DBM. This suggests that factors other than simply the presence of BMPs play a role, including changes in matrix properties due to the acid extraction, removal of inhibitors, and differences in the initial biological response of peri-implant cells to the implanted materials.

Studies done with commercially available DBM and DBM combined with carriers have determined that there is variability in osteoinductivity between donor batches and tissue banks.[9,12–15] Currently, DBM is commercially available as dried powder, or in combination with gelatin, various hydrogels, lecithin, collagen, hyaluronic acid, bioglass, poly hydroxy acids, reverse copolymers, and calcium sulfate powder. DBM may be combined with carriers in the operating room or commercially to meet different clinical needs. Surgeons frequently premix DBM with autologous blood or autograft inside the operating room, to improve its biological activity and handling characteristics. They may also use it in combination with allograft to provide an osteoinductive stimulus. However, mixing DBM with different carriers can change its properties, in some cases causing particles to swell.

Ideal bone graft materials and substitutes should be osteoinductive, osteoconductive, biocompatible, bioresorbable, similar to bone structurally and mechanically, and must be cost-effective.[16] They should perform as well as autograft at least clinically. This goal may not always be met, but the bone graft material must accomplish the goal of supporting bone formation to a sufficient extent to restore function. There are now at least 200 forms of bone graft materials and substitutes that are approved for use in humans in the United States alone (**Table 1**). Because these materials often provide the scaffolding for bone tissue engineering, it is important to have an overview of their strengths and weaknesses. For the most part, the existing materials fit the tissue engineering concept of providing appropriate surfaces for the attachment, proliferation, and differentiation of osteoprogenitor cells into secretory osteoblasts. In the best of situations, they are osteogenic, recruiting cells in the osteoblast lineage to the site and enhancing their differentiation. A small subset is osteoinductive as well.

6.617.2.1. Ceramics and Glasses

Some of the ceramic-based bone substitutes clinically available are made of calcium phosphates, calcium sulfate, and bioactive

Table 1 Summary of typical bone graft substitutes that are commercially available – 2010

Company	*Commercially available product*	*Composition*	*Commercially available forms*	*Claimed mechanisms of action*	*Burdens of proof*	*FDA status*
AlloSource	AlloFuse™	Hear-sensitive copolymer with DBM	Injectable gel and putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Case reports • Animal studies • Cell culture	510(k) cleared • Bone graft extender • Bone void filler
Biomet Osteobiologics	BonePlast®	Calcium sulfate with or without HA/CC composite granules	Various volumes of power and setting solution	• Osteoconduction • Bioresorbable	• Case reports • Animal studies	510(k) cleared • Bone void filler
	BonePlast® Quick Set	Calcium sulfate	Quick setting paste	• Osteoconductive • Bioresorbable	• Case reports • Animal studies	510(k) cleared • Bone void filler
	InterGro®	DBM in a lecithin carrier	Paste, putty, and mix with HA/CC composite granules	• Ostoconduction • Bioresorbable • Osteoinduction	• Case reports • Animal studies • Every lot tested for osteoinduction	510(k) cleared • Bone graft extender • Bone void filler
	ProOsteon® 500R	Coralline-derived HA/CC composite	Granular or black	• Osteoconduction • Bioresorbable	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
	CONDUIT® TCP Granules	100% β-TCP	Granules	• Osteoconduction • Bioresorbable	• Case reports • Animal studies	510(k) cleared • Bone void filler
DePuy Spine	HEALOS® Bone Graft Replacement	Mineralized collagen matrix	Variety of strip sizes	• Osteoconduction • Creeping substitution • Osteogenesis when mixed with bone marrow aspirate	• Peer-reviewed, published human studies • Case reports • Animal studies	510(k) cleared • Bone void filler: must be used with autogenous bone marrow
Exactech	Optecure®	DBM suspended in a hydrogel carrier	Dry mix kit delivered with buffered saline	• Osteoconduction • Bioresorbable • Osteoinduction • Osteogenesis when mixed with autogenous bone graft	• Human studies • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft extender • Bone void filler
	Optecure® + CCC	DBM and CCC suspended in a hydrogel carrier	Dry mix kit delivered with buffered saline	• Osteoconduction • Bioresorbable • Osteoinduction • Osteogenesis when mixed with autogenous bone graft	• Human studies • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft extender • Bone void filler
	Optefil®	DBM suspended in gelatin carrier	Injectable bone paste-dry powder ready to be hydrated	• Osteoconduction • Bioresorbable • Osteoinduction • Osteogenesis when mixed with autogenous bone graft	• Human studies • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone void filler

(*Continued*)

Table 1 (Continued)

Company	*Commercially available product*	*Composition*	*Commercially available forms*	*Claimed mechanisms of action*	*Burdens of proof*	*FDA status*
	Opteform®	DBM and cortical cancellous chips suspended in gelatin carrier	Formable putty or dry powder ready to be hydrated	• Osteoconduction • Bioresorbable • Osteoinduction • Osteogenesis when mixed with autogenous bone graft	• Human studies • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone void filler
	OpteMx®	HA/TCP biphasic combination	Granules, sticks, rounded wedges, wedges and cylinders in several sizes	• Osteoconduction • Bioresorbable • Compressive strength of 400 psi • Osteogenesis and limited osteoinduction when mixed with bone marrow aspirate	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
Integra Orthobiologics/ (IsoTis OrthoBiologics)	Accell Connexus®	DBM, Accell bone matrix, reverse phase medium	Injectable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Every DBM lot tested for osteoinduction	510(k) cleared Extremities, pelvis • Bone void filler extremities, pelvis, spine • Bone graft extender
	Accell Evo3™	DBM, Accell bone matrix, reverse phase medium	Injectable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Animal studies • Every DBM lot tested for osteoinduction	510(k) cleared Extremities, pelvis • Bone void filler extremities, pelvis, spine • Bone graft extender
	Accell TBM®	DBM, Accell bone matrix	Various sized strips	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Every DBM lot tested for osteoinduction	510(k) cleared Extremities, pelvis • Bone void filler extremities, pelvis, spine • Bone graft extender
	DynaGraft II	DBM, reverse phase medium	Injectable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Every DBM lot tested for osteoinduction	510(k) cleared
	OrthoBlast II	DBM, cancellous bone, reverse phase medium	Injectable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Every DBM lot tested for osteoinduction	510(k) cleared Extremities, pelvis • Bone void filler extremities, pelvis, spine Bone graft extender
	Integra Mozaik™	80% highly purified β-TCP/20% highly purified type-1 collagen	Strip and putty	• Osteoconduction • Bioresorbable	• Human studies • Case reports • Animal studies	510(k) cleared Extremities, pelvis Bone void filler

Life Net Health	IC Graft Chamber®	DBM particles and cancellous chips	Lyophilized and packaged in various sizes within a delivery chamber	• Osteoconduction • Bioresorbable • Osteoinduction • Designed to be used with blood, PRP, or bone marrow to enhance DBM activity	• Animal studies • Case reports	• Regulated under CFR 1270 and 1271 as a human tissue and 510(k) cleared
	Optium DBM®	DBM combined with glycerol carrier	Formable putty (bone fibers) and injectable gel (bone particles)	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
Medtronic Spinal & Biologics	INFUSE® Bone Graft	rhBMP-2 protein on an absorbable collagen sponge	Multiple kit sizes	• Bioresorbable carrier • Osteoinduction • Chemotaxis of stem cells; indirect osteogenesis	• Human studies (level I and level III data) • Case reports • Animal studies	• PMA approved for fusion with spinal cage • PMA approved for open tibia fractures with IM nail
	MasterGraft® Granules	Biphasic calcium phosphate (15% HA/85% β-TCP)	Granules	• Osteoconduction • Bioresorbable	• Animal studies • Case reports	510(k) cleared • Bone void filler
	MasterGraft® Matrix	Biphasic calcium phosphate and collagen	Compression-resistant block	• Osteoconduction • Bioresorbable	• Animal studies • Case reports	510(k) cleared • Bone void filler: must be used with autogenous bone marrow
Medtronic Spinal & Biologics	MasterGraft® Putty	Biphasic calcium phosphate and collagen	Moldable putty	• Osteoconduction • Bioresorbable	• Animal studies	510(k) cleared • Bone graft extender: must be used with autograft • Bone void filler: must be used with autogenous bone marrow and/or autograft and/or sterile water
	MasterGraft® Strip	Biphasic calcium phosphate (15% HA and 85% β-TCP) and collagen	Compression-resistant strip	• Osteoconduction • Bioresorbable	• Animal studies	510(k) cleared • Bone void filler: must be used with autogenous bone marrow
	Osteofil®DBM	DBM in porcine gelatin	Injectable paste and moldable strips	• Osteoconduction • Bioresorbable • Osteoinduction	• Animal studies • Case reports	510(k) cleared • Bone void filler
	Progenix™ Plus	DBM in type-1 bovine collagen and sodium alginate	Putty with demineralized cortical bone chips	• Osteoconduction • Bioresorbable • Osteoinduction	• Animal studies • Case reports	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	Progenix™ Putty	DBM in type-1 bovine collagen and sodium alginate	Ready-to-use injectable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Animal studies • Case reports	510(k) cleared Extremities, pelvis • Bone graft substitute • Bone void filler spine • Bone graft extender: must be used with autograft bone
MTF/Orthofix	Trinity Evolution™	Viable cellular bone matrix	Multiple volumes available	• Osteogenesis • Osteoconduction	• Animal studies • Case reports	• Regulated under CFR 1270 and 1271 as a human tissue

Table 1 (Continued)

Company	*Commercially available product*	*Composition*	*Commercially available forms*	*Claimed mechanisms of action*	*Burdens of proof*	*FDA status*
MTF/Synthes	DBX®	DBM in sodium hyaluronate carrier	Paste, putty, mix, and strip	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies	510(k) cleared • Bone graft extender • Bone void filler
NovaBone/MTF	NovaBone®	Bioactive silicate	Particulate, putty, and morsels	• Osteoconduction • Bioresorbable • Osteostimulation	• Published human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
Orthovita	Vitoss®	100% β-TCP and 80% β-TCP/ 20% collagen and 70% β-TCP/ 20% collagen/10% bioactive glass	Putty, strip, flow, morsels, and shapes	• Osteoconduction • Bioresorbable • Bioactive/ osteostimulation • Osteogenesis and osteoinduction when mixed with bone marrow aspirate	• Published human studies (levels I and III) • Case reports • Animal studies	510(k) cleared • Bone void filler
Osteotech	GRAFTON® A-Flex®	DBM fiber technology	Round flexible sheet	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	GRAFTON® Crunch®	DBM fibers with demineralized cortical cubes	Packable graft	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	CRAFTON® Flex®	DBM fiber technology	Various sizes of flexible sheets	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler

	GRAFTON® Gel	DBM in a syringe	MIS and percutaneous injectable graft	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	GRAFTON® Matrix PLF	DBM fiber technology	Single and double troughs	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	GRAFTON® Matrix Scoliosis Strips	DBM fiber technology	Various sizes of strips	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	GRAFTON® Orthoblend Large Defect	DBM fibers with crushed cancellous chips	Packable graft	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
	GRAFTON® Orthoblend small defect	DBM fibers with larger cancellous chips	Packable moldable graft	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
Osteotech	GRAFTON Plus® Paste	DBM in a syringe	Injectable MIS graft, resists irrigation	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler

Company	*Commercially available product*	*Composition*	*Commercially available forms*	*Claimed mechanisms of action*	*Burdens of proof*	*FDA status*
	GRAFTON® Putty	DBM fiber technology	Packable moldable graft	• Osteoconduction • Osteoinduction • Incorporation/complete remodeling • Osteogenesis when mixed with bone marrow aspirate or autogenous bone graft	• Peer-reviewed published human studies (including levels I–II prospective studies) • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone graft substitute • Bone graft extender • Bone void filler
Regeneration Technologies	BioSet™	DBM combined with natural gelatin carrier	Injectable paste, injectable putty, strips and blocks with cortical cancellous chips	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Every lot tested *in vivo* for osteoinduction	510(k) cleared • Bone void filler
Smith & Nephew	VIAGRAF	DBM combined with glucerol	Putty, paste, gel, crunch, and flex	• Osteoconduction • Bioresorbable • Osteoinduction	• Animal studies	510(k) cleared • Bone void filler
Stryker Biotech	OP-1® Implant	rhBMP-7 with type-1 bone collagen	Lyophilized powder reconstituted with saline to form wet sand-like consistency	• Bioresorbable scaffold • Osteoinduction	• Human studies (level I data) • Case reports • Animal studies	• HDF approval for long bone nonunions
	OP-1® Putty	rgBMP-7 with type-1 bone collagen plus carboxymethylcellulose (putty additive)	Lyophilized powder reconstituted with saline to form wet sand-lime consistency	• Bioresorbable scaffold • Osteoinduction	• Human studies (level I data) • Case reports • Animal studies	• HDF approval for revision posterolateral lumbar fusion
Synthes	Calceon® 6	Calcium sulfate	Pellets	• Osteoconduction • Bioresorbable	• Animal studies	510(k) cleared
	chronOS®	β-TCP	Granules, blocks, and wedges	• Osteoconduction • Bioresorbable	• Animal studies	510(k) cleared • Bone void filler
	Norian® SRS®	Calcium phosphate	Injectable paste	• Osteoconduction • Bioresorbable	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
	Norian® SRS® Fast Set Putty	Calcium phosphate	Moldable putty	• Osteoconduction • Bioresorbable	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
Wright Medical Technology	ALLOMATRIX®	DBM with/without CBM in surgical grade calcium sulfate powder	Various volumes of injectable/formable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Cell culture	510(k) cleared • Bone void filler
	ALLOMATRIX® RCS	DBM with CACIPLEX™ technology in surgical grade calcium sulfate powder	Various volumes of formable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Animal studies	510(k) cleared • Bone void filler

	ALLOPURE™	Sterile femoral/tibial allograft	12 mm Evans wedge 6 mm Cotton wedge	• Osteoconduction	• Mechanical testing	• 100% derived from allograft tissue • Regulated under 21 CFR parts 1270 and 1271 as a human tissue
	CANCELLO-PURE® Wedges	Bovine bone	10 mm × 50 mm wedge 12 mm Evans wedge 6 mm Cotton wedge	• Osteoconduction	• Case reports • Animal studies	510(k) cleared • Bone void filler
	CELLPLEX®	β-TCP	Various sized granules	• Osteoconduction • Bioresorbable	• Case reports • Animal studies	510(k) cleared • Bone void filler
	IGNITE®	DBM in surgical grade calcium sulfate powder to be mixed with bone marrow aspirate	Percutaneous graft for problem fractures	• Osteoconduction • Bioresorbable • Osteoinduction	• Human studies • Case reports • Animal studies • Cell culture	510(k) cleared • Bone void filler
	MIIG® X3	High-strength surgical grade calcium sulfate	Minimally invasive injectable graft for compression fractures	• Osteoconduction • Bioresorbable	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
	OSTEOSET®	Surgical grade calcium sulfate	Various sized pellets	• Osteoconduction • Bioresorbable	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
	PRO-DENSE® Injectable Regenerative Graft	75% calcium sulfate and 25% calcium phosphate	Procedure kits, various volumes of injectable paste	• Osteoconduction • Bioresorbable • Dense bone regeneration	• Human studies • Case reports • Animal studies	510(k) cleared • Bone void filler
	PRO-STIM™ Injectable Inductive Graft	50% calcium sulfate, 10% calcium phosphate, and 40% DBM by weight	Procedure kits, various volumes of injectable paste/formable putty	• Osteoconduction • Bioresorbable • Osteoinduction	• Case reports • Animal studies	510(k) cleared • Resorbable calcium salt bone void filler device
Zimmer	CopiOs® Bone Void Filler	Dibasic calcium phosphate and type-1 collagen	Sponge and paste	• Osteoconduction • Accelerated healing versus autograft • Bioresorbable • Osteogenesis and osteoinduction when mixed with bone marrow aspirate	• Case reports • Animal studies	510(k) cleared • Bone void filler: must be used with autologous blood products like blood or bone marrow
	CopiOs® Cancellous Bone Graft	Bovine bone	Cancellous chips, cancellous cubes, and cortico-cancellous wedges	• Osteoconduction	• Case reports • Animal studies	510(k) cleared • Bone void filler
	Puros® DBM	Allograft DBM putty (putty with chips includes allograft chips from the same donor)	Putty and putty with chips	• Osteoconduction • Bioresorbable • Osteoinduction	• Every lot tested in an *in vivo* rat assay for osteoinductive potential demonstrating bone formation in an ectopic model	• 100% derived from allograft tissue • Regulated under 21 CFR parts 1270 and 1271 as a human tissue

glass. The idea of using ceramics as a material for bone grafts derived from the fact that bone mineral is a carbonate-substituted form of calcium hydroxyapatite (HA). Today, various forms of HA are used as bone graft substitutes. In some instances, they are derived from biological sources, including coral and bovine bone. In other cases, they are produced synthetically, resulting in materials that vary in calcium and phosphate content, the presence of other ions such as magnesium, fluoride, nickel and silica, and crystallinity, all of which can impact dissolution rates *in vivo*. Ceramics or glasses cannot be used for mechanical load-bearing applications because of their brittle nature. However, because their elastic modulus is similar to bone, they serve as coatings in composite grafts and as defect fillers where there is sufficient existing bone to carry the load or where other mechanical devices provide stability to the grafted site.

6.617.2.1.1. Calcium phosphates

Calcium phosphate materials are osteoconductive and are well integrated with surrounding bone.[17–19] Recently, there have been reports that some formulations of calcium phosphate materials are osteoinductive, based on the observation that bone can be found within the implant when particles are placed in muscle tissues.[20,21] A proposed mechanism in which calcium phosphates induce bone formation in a non-osseous environment is the adsorption of osteogenic molecules such as BMP-2 onto its surface, initiating bone formation. Differences in osteoinductivity were shown to be dependent on the location/proximity to the osteogenic environment.[20] The debate over whether this phenomenon is true osteoinduction has not been resolved, but it does raise important considerations for bone tissue engineering. It may not be necessary to produce a perfect material that provides scaffolding, bioactive molecules, and cells to achieve bone regeneration. The same goal may be achievable through engineering microenvironments that optimize the body's own regenerative process.

Common calcium phosphates include tricalcium and biphasic phosphate, calcium phosphate cements, and HA (coral-based or synthetic). Tricalcium phosphate $Ca_3(PO_4)_2$ (TCP), unlike other HA sintered ceramics, is resorbable *in vivo*[22] after stimulation of bone formation. TCP has a Ca:P molar ratio of 1.5 and it is less crystalline than HA with a Ca:P ratio of 1.67. High temperatures increase crystallinity of TCP creating α- and β-TCPs.[23] α-TCP is more soluble than β-TCP, but studies have shown comparable rates of degradation.[24] These crystalline TCPs are available in blocks, granules, powder form, or in combination with collagen and carboxymethylcellulose carriers to form pastes. Biphasic calcium phosphate is a composite of HA and β-TCP. It is more rapidly degradable than HA alone. Biphasic calcium phosphates in combination with HA and collagen are commercially available in granules, sticks, wedges, and cylinders and are used in posterior lumbar fusion mixed with autograft.[25]

Coralline HAs $Ca_{10}(PO_4)_6(OH)_2$ are derived from marine coral. The replamineform process is used to convert calcium carbonate found in natural mineral corals into calcium HA.[26] Modifications to the conversion process give commercial manufacturers the opportunity to control resorption rates and have more predictable products.[27] The final hybrid product will have a HA layer, which is resorbed slowly, and a carbonate core that once exposed, is resorbed rapidly allowing bone substitution.[11] The thickness of the HA layer will control the resorption rates. Synthetic HA differs from natural bone mineral in that it is more homogeneous in composition, has larger crystals, and crystals are more uniform. In general, synthetic HA degrades more slowly compared to the duration of the bone formation and remodeling process, raising concerns about the mechanical properties of the new bone at the treatment site. Synthetic HA is commercially available in dried powder, blocks, and in combination with collagen and cancellous bone chips, among other carriers.

Calcium phosphates that are enriched in carbonate to more closely approximate bone mineral[28,29] have also been developed as has silicated HA.[30] Whether these materials will prove more clinically useful as bone graft substitutes than other forms of calcium phosphate is not yet known.

6.617.2.1.2. Calcium sulfate

Calcium sulfate ($CaSO_4$), also known as plaster of Paris, is an osteoconductive crystalline substance used for bone void fillers and for cranial defects. Reports of *in vivo* use of calcium sulfate include deposition of cancellous host bone while the graft substance is resorbed.[31] Calcium sulfate is not suitable for structural support clinical applications due to its rapid biodegradability. Clinically, it is used in forms of pellets alone or in combination with other substances. Interestingly, as calcium sulfate dissolves, it acidifies the local environment resulting in antimicrobial action. Some of the calcium precipitates with local phosphate ions as HA, creating a microscaffold for osteoconduction within the defect.[32]

6.617.2.1.3. Bioactive glass

Bioactive glasses are considered highly reactive surfaces formed by melt or sol–gel techniques. Bioactive glass forms a hydroxycarbonated apatite layer when immersed in biological fluid, which enhances protein adsorption to the surface of the implant and integration with surrounding bone.[33,34] The rate of ion release from the bioglass surface is determined by the Ca:P ratio, composition, and microstructure. The initial reaction of some bioactive glasses with biological fluids causes local pH to increase[34]; some studies propose that this is beneficial to cell activity and HA production.[35] Clinically, the 45S5 form of bioglass has been used for bone defects, in restorative dentistry, and in craniofacial surgery. *In vitro* assays comparing osteoblast response to different bioglass formulations indicate that the phosphate content is an important variable.[36] Lower phosphate content, typical of the 45S5 bioglass that is used clinically, supports cell attachment and osteoblastic differentiation, whereas other forms of bioglass are less effective. Bioactive glass is currently available in sintered porous bulk or particulate form.

6.617.2.1.4. Physical parameters of ceramics and bioactive glasses

Bone's physical properties are important to its overall physiology. Because the early bone graft substitutes were not resorbable, the question of how the implants would be incorporated during the osseointegration process was critical to the overall success of the material. The goal was to produce a composite of graft and healthy new bone that would share the mechanical

load at the defect site. To do this required a pore size sufficiently large to permit ingrowth of blood vessels, ultimately surrounded by remodeled lamellar bone. A dogma was established that this meant a minimal pore size of 300 μm. The pore size consideration was taken into account not only when constructing ceramic blocks, but also when determining the size of spaces between particulate bone graft materials. More recent studies using biodegradable polymers indicate that pore size is not as critical a parameter if the material will stabilize clot formation and facilitate inward migration of osteoprogenitor cells and endothelial cells as it degrades.[37]
